CHAPTER 26

Urgent Syndromes at the End of Life

Quinten Robertson and Kelli Gershon

Key Points

- Numerous urgent syndromes can occur in the course of advanced disease, seriously affecting quality of life.
- Urgent syndromes include superior vena cava obstruction, pleural effusion, hemoptysis, spinal cord compression, hypercalcemia, and pathological fractures.
- Astute assessment and management skills are crucial to diminish distress and suffering for patients and their loved ones.

Introduction

End of life is a fragile and significant time, and palliative care can diminish distress and suffering for both the patient and the family. This chapter will discuss the following syndromes that may occur urgently at end of life: superior vena cava obstruction (SVCO), pleural effusion (PE), hemoptysis, spinal cord compression (SCC), hypercalcemia, and pathological fractures.

Superior Vena Cava Obstruction

Case Study: A Patient with Superior Vena Cava Obstruction

Mr. J, a 57-year-old man, went to the Emergency Department 1 week ago with shortness of breath and was subsequently diagnosed with non–small cell lung cancer. Before his first oncologist appointment, his wife noticed that his shortness of breath was increasing and his face was swelling. She called the new oncologist, who advised that Mr. J report to the nearest hospital.

Description

SVCO is defined as obstructed blood flow through the superior vena cava (mechanical), which is part of the venous system responsible for draining the upper extremities and head into the right atrium (see Box 26.1). The severity depends on the cause of the obstruction, which generally develops gradually, but can be emergent when SVCO occurs.[1]

Salsali and Cliffton found an SVCO incidence of 4.2% in 4,960 participating cancer patients, who are at highest risk for the illness.[2] Eighty percent of all tumors and infections that induce SVCO occur in the right thoracic region, and SVCO occurs in 5–10% of patients with infectious damage to a tissue or organ in this region. The most harmful form of SVCO occurs in people aged 40–60 years, with greater risk among males because of their higher rates of smoking-related lung cancer. Benign cases occur in individuals aged 30–40 years, but there are no gender-based differences in frequency. Because incidence of lung cancer and lymphoma differ according to race, the distribution of SVCO within the population depends on the prevalence of SVCO-inducing cancers in these communities.[3]

Pathophysiology

Tumor infiltration and thrombosis formation are the primary causes of SVCO. Compression of the superior vena cava (SVC) can result from intrinsic or extrinsic causes.[4] As a growing tumor occupies thoracic space, pressure inside the SVC increases from 2–8 mm Hg to 20–30 mm Hg, and facial swelling and enlargement of the neck and chest wall become visible. In response to SVC malfunction, the body uses collateral veins located in the thoracic, esophageal, and paraspinal regions—such as the inferior vena cava and the azygos veins—and the patient may experience difficulty breathing or eating. When the collateral veins cannot accommodate the excess pressure, the frequency of the symptoms increases and the patient may die.[5]

Signs and Symptoms

Signs and symptoms of SVCO depend on the acuity and degree of obstruction. The most notable symptoms are swelling of the nose, face, neck, and chest wall, especially in the morning hours after the patient has been recumbent. The swelling gradually subsides, but may remain visible in prolonged cases. Dyspnea—especially when sleeping—hoarseness, constant coughing, lethargy, and head fullness are symptoms of SVCO that may lead to exhaustion. Other clinical signs include facial swelling and abnormally rapid breathing when lying down or bending forward.[6]

Diagnostic Procedures

Physical examination is adequate to diagnose SVCO; however, diagnostic imaging is preferred to provide a more subtle assessment of the patient's condition. Initially, chest radiography is performed to reveal any inflammation or added mass in the right thoracic region, which could be the first sign of SVCO.[3] Computed tomography (CT) scan can reveal the exact location

Box 26.1 Symptoms of Superior Vena Cava Obstruction

- The primary causes of superior vena cava obstruction (SVCO) are lung cancer, lymphomas, thrombus, and stenosis secondary to venous lines.
- Facial and neck swelling commonly present with episodes of shortness of breath.
- Chest x-ray and computed tomography (CT) are used to identify the extent of obstruction, damage, and assist in the development of a treatment plan for SVCO.
- The SVCS grading system and management algorithm are available to guide clinical decisions.

of the blockage, whether it is the result of a thrombosis or tumor, and the extent of cavity damage to determine whether thoracic surgery is necessary.[7]

Magnetic resonance imaging (MRI), often preferred for cancer patients with contrast allergies or renal failure, can show damaged tissue in greater detail and offer different views of the infected area while allowing direct visualization of blood flow to assess pressure inside the SVC. Venography, the most conclusive SVCO diagnostic tool, reveals the full extent of vena cava occlusion and is necessary during preparation for corrective surgery.[8] Contrast venography is the most reliable technique for diagnosis of malignant SVCO; however, if the primary collateral vein—the inferior vena cava—malfunctions due to pressure or tumor necrosis and progresses to venous compression, a radionuclide technetium-99m venography is the preferred alternative.[9]

Treatment

SVC Stenting

SVCO may require endovascular treatments depending on the extent and urgency of the illness. For example, ultrasound-accelerated thrombolysis together with angioplasty and stenting of the SVC can remove a partial or complete obstruction.[10] Venography is essential during stent placement to determine the necessary length and number of stents to open the obstruction.[11] Stent placement has reportedly produced acceptable outcomes in the management of SVCO.[12] A minor complication associated with endovascular intervention is hematoma at the entry site; major complications may include stent migration, bleeding, and pericardial tamponade.[11]

Thrombolytic Therapies

When a thrombus is identified as the cause of mechanical SVCO, thrombolytic therapies are preferred for medical management. The patient may present with acute symptoms of SVCO, warranting delivery of thrombolytic agents via catheter to remove the thrombus.[11] Thrombolytic therapy should be initiated within 2–5 days of the initial symptoms for optimal outcomes and may not be effective if initiated after the 10th day.[11] Tissue plasminogen activator (tPA) is the most commonly used thrombolytic medication.

Drug Therapy

Though lacking evidence-based research to support their effectiveness, short-term administration of anti-inflammatory steroids such as dexamethasone have been used to treat SVCO.[13]

Box 26.2 Superior Vena Cava Obstruction Four-Part Grading System

- Grade: 0–5
- Category: Asymptomatic to Fatal
- Estimated incidence: 10% to <1%
- Definition: Absence of symptoms to death

Source: James BY, Wilson LD, Detterbeck FC. Superior vena cava syndrome—a proposed classification system and algorithm for management. *J Thoracic Oncol*. 2008;3(8):811–4.

Diuretics may also be used despite lack of evidence supporting their effectiveness.[13]

Medical Management

Physicians first work to identify the cause of SVCO, which is most often related to cancer or chronic illness. The care team then works to reduce the symptoms[14]; for example, elevating the patient's head may diminish facial swelling. In SVCO resulting from cancers such as non–small cell lung cancer (NSCLC), the histology of the primary malignant condition is then determined. Radiation therapy may be used when a tumor is the cause of the obstruction. According to Nickloes, chemotherapy is an alternative to radiation therapy for patients with chemotherapy-sensitive tumors.[3]

The increased predominance of SVCO caused by chronic diseases has prompted development of new treatment methods. Endovascular treatment that is effective but less invasive has since become the preferred method for managing SVCO patients in palliative care.[15] The superior vena cava syndrome algorithm developed by Yu, Wilson, and Detterbeck is a useful tool to guide clinical decision-making in the medical management of SVCO patients.[16]

Nursing Management

Nurses should employ palliative techniques to relieve pain and offer comfort to SVCO patients in tandem with medical management. Nursing assessment using the SVCO grading system is essential to identify clinical manifestations of SVCO (see Box 26.2).

It is vital for nurses to build relationships with the patient and their family to reduce stress and improve the patient's functional status. Nurses should also clarify the goals of treatment to ensure they are consistent with the patient's wishes. In addition, nurses should assess the patient's unique coping needs and provide necessary support, ensuring regular therapy tailored for each patient.[17]

Pleural Effusion

Case Study: A Patient with Pleural Effusion

Mr. S, a 39-year-old geologist who worked as an executive with a large oil and gas company, was diagnosed with stage III Hodgkin's lymphoma approximately 4 months ago. He started chemotherapy treatment and completed a positron emission tomography (PET) scan 2 weeks later. While at work last week, he noticed that he was having trouble breathing. The shortness of breath was mild at first, but gradually intensified until he began to sleep in a recliner because he was unable to lay flat at night. Eventually, the shortness of breath became so severe that Mr. S went to the emergency room, where medical personnel detected decreased breath sounds and a chest x-ray confirmed a large PE on the left side.

Description

PE occurs when too much fluid collects in the pleural space. It is commonly known as "water on the lungs" and is characterized by shortness of breath, chest pain, gastric discomfort, and cough. There are two types of pleural effusion: transudative and exudative. A *transudate* is a clear fluid similar to blood serum that forms when the forces that normally produce and remove pleural fluid at the same rate are out of balance, primarily in patients with heart failure. An *exudate* is cloudy fluid containing cells and large amounts of protein that results from disease in the pleura itself. For example, malignancy of the pleura frequently results in malignant PE.[18]

Epidemiology

Parapneumonic disease is the most common cause of PE, followed by malignancy. More than 175,000 individuals in the United States are affected by malignant PE,[19] most commonly secondary to lung cancer. Approximately 15% of lung cancer patients have malignant PE at diagnosis, but 50% of patients with disseminated lung cancer ultimately develop the condition. Breast cancer is the second most frequent cause of malignant PE; however, it is rare among presenting patients but generally occurs with progressive disease. Hematological malignances (lymphomas and leukemia) are the third most frequent cause of malignant PE.[20] The condition, which is generally associated with widespread disease, has a poor clinical prognosis—particularly in patients with malignancy.[21] Most patients with malignant PE are appropriate candidates for hospice care.

Pathophysiology

Each lung is covered with a serous membrane called the *pleura*, forming a closed cavity between the pleura and the lung surface. The normal pleural space contains approximately 10 mL of fluid, representing a balance between (1) hydrostatic and oncotic forces in the visceral and parietal pleural capillaries and (2) persistent sulcal lymphatic drainage. Osmotic and hydrostatic pressures act to maintain equilibrium between absorption and production of fluid in the pleural space. When this equilibrium is disturbed, fluid can accumulate in the pleural cavity.[22]

Pulmonary effusion is attributed to altered permeability of the pleural membranes caused by multiple conditions including inflammation, malignancy, and pulmonary embolism. In patients with malignancies, it is not uncommon to have multiple simultaneous causes of PE. Hypoalbuminemia can reduce intravascular oncotic pressure and increased capillary permeability, or vascular disruption can result from trauma, malignancy, inflammation, infection, or pulmonary infarction.[22]

Signs and Symptoms

Dyspnea, which may develop suddenly or gradually depending upon on how rapidly the fluid accumulates, is the most common symptom of PE and often results in increased anxiety. If the effusion is free-flowing, dyspnea will become more severe while the patient is fully prone; however, shortness of breath will remain constant regardless of the patient's position if the effusion is loculated. A large effusion will cause sudden and severe shortness of breath, whereas onset is more gradual with a small and slowly developing effusion. Patients may experience pleural pain, an intense pain in the chest area that is sometimes confused with cardiac pain.

The patient's inability to expand the lung leads initially to reports of exertional dyspnea. As the effusion volume increases, resting dyspnea, orthopnea, and tachypnea develop. The patient may describe a dry, nonproductive cough and a heaviness or aching pain—often described as dull or pleuritic—in the chest. Physical examination commonly reveals increased respiratory rate and use of accessory muscles for breathing. Auscultation indicates decreased breath sounds on the affected side, and percussion shows dullness in the affected lung field. A large effusion may cause tracheal deviation and mediastinal shift to the affected side.

Diagnostic Procedures

Chest X-ray

Standard anteroposterior and lateral chest radiography remain the most important techniques for initial diagnosis of PE. A fluid volume of 200 mL will be evident on a anteroposterior film, and costophrenic angle blunting can be seen on a lateral film at an accumulation of only 50 mL.[23] A chest x-ray will reveal whether the fluid is free flowing versus loculated, which will determine the preferred treatment plan.

Ultrasound

Ultrasonography can accurately detect even small amounts of PE, as characterized by an echo-free space between the visceral and parietal pleura. Ultrasonography is used to confirm a diagnosis of loculated PE and in marking a site for thoracentesis.[23]

Computed Tomography Scanning

CT scanning produces cross-sectional images that are useful for evaluation of complex cases where routine radiography or ultrasonography cannot provide a conclusive assessment. CT scanning can show pleural or lung masses, adenopathy, pulmonary abnormalities such as infiltrates or atelectasis, or distant disease.

Thoracentesis

Thoracentesis is indicated for all patients with more than a minimal PE (i.e., >1 cm in height on lateral decubitus radiography, ultrasonography, or CT scanning) of unknown origin. In some cases, once evidence of the effusion has been established and obvious nonmalignant causes have been ruled out, thoracentesis may be helpful in confirming the diagnosis.[23] Sonographic guidance can prevent problems associated with performing "blind" thoracentesis.

Treatment

Medical management of malignant PE depends on multiple factors, including the history of the primary tumor, prior patient history and response to therapy, extent of disease and overall medical condition, goals of care, and severity of symptom distress. It is important to evaluate the underlying cause of the PE and determine whether it can be treated to prevent further accumulation of fluid. This treatment might include systemic therapy (e.g., chemotherapy, antibiotics), hormonal therapy, or radiation therapy. Symptomatic management includes the use of opioids to manage pain and dyspnea, as well as anxiolytics to control concomitant anxiety. The most common treatments for PE include (1) observation to see how it responds to treatment of the underlying disease, (2) thoracentesis, (3) pleurodesis, (4) indwelling pleura catheter placement, and (5) palliation of symptoms.[24]

Thoracentesis

Thoracentesis has been shown to relieve dyspnea associated with large PEs. Although thoracentesis may produce rapid relief of symptoms, fluid reaccumulates quickly—usually within 3–4 days—and within 30 days in 97% of patients.[25] When fluid reaccumulates, it must be decided whether the risks of repeated thoracentesis outweigh the benefit. Risks include empyema, pneumothorax, unexpandable lung from inadequate drainage and/or loculated fluid, and possible increasing tissue malnutrition from the removal of the protein-rich effusion fluid. If the risks outweigh the benefit, alternative treatments including pleurodesis, pleurectomy, or indwelling catheter must be considered.

Pleurodesis

Pleurodesis is not recommended in patients who have a life expectancy of less than 3 months.[26] Palliative treatment, especially for those with a life expectancy of months rather than weeks, is best accomplished by thoracentesis or pleural catheter placement. The goal of pleurodesis is to drain the pleural cavity completely, expand the lung fully, and instill a chemical agent into the pleural cavity. With a large effusion, only 1,000–1,500 mL should be drained initially to avoid reexpansion pulmonary edema from rapid draining of large volumes, as in some cases large hydropneumothorax has resulted from rapid evacuation of large PE fluid volumes.[21]

After placement, the chest tube is connected to a closed-drainage device. To prevent reexpansion pulmonary edema, water-seal drainage and intermittent tube clamping should be used to allow fluid to drain slowly. Complications of chest tube placement include bleeding and development of pneumothorax, which results from rapid fluid removal in patients with an underlying noncompliant lung. The procedure causes pain and requires aggressive pain management with opioids and possible sedation.

The purpose of pleurodesis is to administer agents that cause inflammation and subsequent fibrosis into the pleural cavity to produce long-term adhesion of the visceral and parietal pleural surfaces to prevent reaccumulation of pleural fluid. Sclerosing agents or chemical irritants used to treat malignant PE include talc, tetracycline, minocycline, doxycycline, silver nitrate, bleomycin, cisplatin, recombinant adenoviral human p53, and human tumor necrosis factor (see Table 26.1).[27–29]

Table 26.1 Agents used to treat malignant plural effusion

Agent	Characteristics
Talc	Trilayered, magnesium sheet silicate Most effective and most commonly used
Minocycline and Doxycycline	Tetracycline derivatives Less effective than talc
Silver nitrate	Tetracycline derivatives Equal effectiveness to talc
Bleomycin	Less commonly used because of systemic toxicity and cost
Cisplatin	Widely used in patients with lung cancer
Recombinant adenoviral human p53 (rAD-p53)	Higher short-term response rate and fewer side effects than cisplatin Less effective but fewer side effects than talc

Pleurectomy

Pleurectomy, a surgical stripping of the parietal pleura, is a possible treatment for malignant pleura effusion, but this surgery lacks evidence as treatment in comparison to pluerodesis.[21] Video-assisted thoracoscopy (VATS) and pleurectomy have been performed successfully, but this intervention is generally inappropriate for the palliative care patient at end of life.

Indwelling Pleural Catheters

Patients with symptomatic, unilateral effusions who have a reasonable performance status may benefit from indwelling pleural catheters, which can be placed under local anesthesia. It has been suggested that tunneled pleural catheters may provide better long-term drainage and symptom control of malignant PE.[21] The tunneled catheter is a small-bore tube attached to a gravity drainage bag or vacuum drainage. Most patients and families can be taught to drain the effusion effectively with few side effects. Rare complications include tumor seeding, obstruction, infection, cellulitis of the tract site, and pain during drainage. This treatment offers the potential for better quality of life (QOL) and reduction of overall health care costs.[30]

Nursing Management

Nursing management includes symptom control, education, and communication regarding goals of care. Symptoms most commonly associated with PE are dyspnea, pain, and anxiety, which are treated aggressively with medications, education, and nonpharmacological techniques. Nurses should educate patients and their families about each procedure, including its purpose, how it is carried out, how pain will be addressed, home care techniques, and possible side effects or complications. A variety of nonpharmacological techniques can be used to relieve dyspnea and pain, including comfortably positioning the patient, using relaxation techniques, and providing oxygenation as appropriate.

Education is a large component of the nursing role in managing patients with PE, including instruction on treatment options and on self-management of interventions. For example, if the patient has a tunnelled catheter the family must recognize the importance of monitoring drainage volume to detect possible spontaneous pleurodesis, which can be identified through increased drainage output over time. Because PE and its associated symptoms are distressing to patients and family members, nurses should encourage open communication about their distress, concerns about advancing disease, and goals of care.

Hemoptysis

Case Study: A Patient with Hemoptysis

Ms. C, a 60-year-old retired waitress, was diagnosed with small-cell lung cancer 3 months ago. Initially hesitant to pursue treatment, she consulted with her family and decided to seek chemotherapy and radiation therapy. While at the clinic for treatment, Ms. C told the oncology nurse that she was concerned because she had been coughing up blood 3–4 days per week for about 2 weeks.

Hemoptysis, or expectoration of blood, can present in a broad range of conditions and manifestations.[31] The blood can range from small streaks in the sputum from the lungs to a larger volume of blood without any sputum. Hemoptysis can also result from bleeding outside the lungs and the airways.[31] Blood-tinged sputum mixed with blood suggests lung disease; *pseudohemoptysis* is coughing up blood that does not originate from the lungs.[32]

Epidemiology

According to research by the American College of Chest Physicians involving patients hospitalized for various diseases, lung cancer was the leading cause of hemoptysis at 40.6%. Bronchitis, tuberculosis, and pneumonia are the other significant causes of hemoptysis at 25%, 17%, and 10% respectively.[33]

Blood volume loss from hemoptysis can be minimal to massive or even life-threatening. While literature is inconsistent regarding volumes of massive hemoptysis, studies identify different volume thresholds ranging from 100 to 1,000 mL over a 24-hour period. Because of this inconsistency, it is recommended to measure blood loss on admission.[34] Mortality risk among patients with massive hemoptysis is greater than 80% without a timely intervention.[34]

Pathophysiology

The pulmonary and bronchial arteries are the two systems of blood supply in the lungs. The pulmonary artery facilitates gas exchange at low pressure, while the bronchial arteries are part of the systemic blood circulation at much higher pressure. The high pressure is partly responsible for the bronchial arteries being the primary source of hemoptysis, although nonbronchial arteries also contribute to the condition. When an infection such as bronchitis increases pulmonary circulation, the increased pressure results in bursting of the thin walls, causing overflow of blood into the alveoli and bronchi leading to hemoptysis. Similarly, chronic illnesses such as lung cancer can cause blood overflow when a growing tumor or the spread of malignant cells promotes the growth of fragile collateral vessels or the remodeling of other arteries. Lung cancer patients account for 7–10% of hemoptysis cases.[35] The blood vessels are thin-walled and prone to bursting from the slightest provocation, such as an acute case of vomiting. The bronchial arteries account for 90% of bleeding instances, while the pulmonary artery causes only 5% of cases.[36] The remaining episodes result from the nonbronchial systemic arteries. When blood overflows, it searches for an opening, which accounts for blood in the sputum when coughing or when vomiting.

Diagnostic Procedure

The source of the bleeding causing the hemoptysis must be quickly identified. A medical history and physical examination are completed to collect subjective and objective information that will assist in differentiating whether the patient has hemoptysis, hematemesis, or pseudohemoptysis. Diagnostic testing begins with a lateral chest x-ray; however, x-rays can offer insufficient information and a chest multiple detector CT (MDCT) may be ordered for patients with blood-streaked sputum and chronic illness such as lung cancer.[37] The MDCT locates the source of the bleeding and indicates the exact presence, number, origin, and trajectory of the bronchial and pulmonary arteries that may be the source of bleeding. The MDCT can detect 70–88% of cases resulting from bronchial artery overflow and 62–97% of the nonbronchial arteries that cause bleeding.[35] The MDCT may be followed by a diagnostic bronchoscopy, which is carried out during active hemoptysis or within 24–48 hours after cessation and can detect the source of bleeding in 73–93% of cases.[35]

Signs and Symptoms

The signs and symptoms of hemoptysis are specific to the area of possible involvement. It is difficult to predict the severity and course of hemoptysis,[32] therefore careful assessment is key. Cardiac signs and symptoms include tachycardia, heart murmur, chest pains, and fixed split S2. Respiratory signs and symptoms include tachypnea, voice hoarseness, wheezing, pursed lip breathing, decreased lung sounds, and shortness of breath.[38] The patient may also present with fever, cachexia, or nausea.

Differential diagnoses are formulated based on assessment findings. For example, findings for bronchogenic tumors may include night sweats, weight loss, and history of heavy smoking. Findings significant to pneumonia are fever, productive cough, decreased breath sounds, and pleuritic chest pain.[38] Because the causes for hemoptysis can be unclear, a thorough and accurate assessment is essential to identify the cause and location of the bleeding.

Management

There are two types of hemoptysis: nonmassive and massive. Common goals for the management of either type are to (1) identify the origin of bleeding, (2) stop the bleeding, (3) treat the underlying cause, and (4) prevent aspiration in patients with massive hemoptysis.[38]

Nonmassive Hemoptysis

The treatment plan for patients with nonmassive hemoptysis is focused on the cause of the bleeding and the blood volume loss over 24 hours. The blood volume should be scant or minimal, as this suggests a self-limiting cause such as pneumonia. This patient will require a standard chest x-ray for diagnosis confirmation and is considered low risk. Treatment is managed in the outpatient setting and involves a normal follow-up appointment. Some patients' hemoptysis may be high risk and require an outpatient CT. Nursing management of nonmassive hemoptysis includes establishing patient trust, education, and emotional support.

Massive Hemoptysis

Medical management for the patient with massive hemoptysis begins with airway protection and establishment of hemodynamic stability. Any acquired coagulopathies such as thrombocytopenia, disseminated intravascular coagulation, or drug-induced platelet dysfunctions are then identified and treated.[34] Hemoptysis has proved to be a difficult and uncertain symptom to manage, but recent technological advances and newer and better techniques (see Table 26.2)—such as bronchial artery embolization—have facilitated more effective symptom management.[33]

Nursing Management

The patient with massive hemoptysis, which can result in death if not resolved immediately, requires emergent management. Nursing management begins with a respiratory assessment to identify patients at risk for a compromised airway or aspiration.[33] Vital signs are monitored for significant hemodynamic changes because massive blood loss can lead to sudden cardiovascular instability. This situation can be frightening for the patient as well as the family, therefore the nurse should provide emotional support if needed. When hemoptysis occurs at end of life in people with cancer, aggressive therapies such as endoscopy, embolization, or surgery are used depending on the patient's condition, the likelihood of success based on the diagnosis, and the patient's goals of care.[35]

Table 26.2 Common treatments for hemoptysis

Procedure	Characteristics
Bronchial artery embolization (BAE)	Preferred due to its effectiveness and reduced invasiveness Stabilizes pressure and reduces risk of bleeding
Endoscopic treatment	Used to locate and identify the cause of bleeding in the lungs Airway patency is paramount and requires preparation for emergent interventions
Cold saline lavage	Used to control bleeding and improve visualization during a bronchoscopy Effectiveness has not been established
Endobronchial stents	Used to treat stenosis or obstruction of the bronchus Palliative treatment for respiratory distress
Laser photocoagulation (Nd: Yag laser)	Used to decrease hemoptysis in patients with central airway tumors Several lasers of different wavelengths available
Pulmonary isolation	Used to prevent blood from severe hemoptysis from entering unaffected lung Accomplished by selective endo-bronchial intubation (SEI) or placement of a bronchial blocker
Selective endobronchial intubation	Placement of an endotracheal tube opposite the bleeding site Must not occlude the wrong side in the bronchus
Bronchial blocker	Placed through an endotracheal tube to isolate bleeding site Can be repositioned as needed to explore other possible bleeding sites

Spinal Cord Compression

Case Study: A Patient with Spinal Cord Compression

Mrs. S is a 54-year-old woman who was diagnosed with breast cancer 3 years ago and was treated with a resection followed by radiation therapy. On a recent visit with her oncologist, she complained of significant back pain and said that she can't enjoy her grandkids anymore. Mrs. S thought her back was giving out, but was informed 2 months ago that cancer was found in her spine.

Description

SCC is a medical emergency in which the spinal cord is compressed as a result of pressure, for example from a bone fragment or tumor. SCC can occur anywhere between the cervical and the lumbar regions as a result of wear and tear on the vertebrae, spinal tumor, injury to the spine, bone disease, or infection.[39] The condition occurs in 5–10% of patients with advanced cancer. Rates of occurrence for different cancers are breast malignancies (5.5%), prostate cancer (7.2%), myeloma (7.9%) and nasopharynx (6.5%).[40] This condition qualifies as an end-of-life (EOL) manifestation because of its incidence in patients with terminal illness.

Pathophysiology

The pathophysiology of SCC includes injury as a result of trauma, infection, or inflammatory disease; however, tumors are the primary cause. At the point of epidural intrusion, venous flow in the spine is affected and the patient may experience sharp irregular pains during activities like walking. As the spread of malignant cells infiltrates the white and gray matter, and, depending on the level of the terminal illness, the patient experiences tissue death.[40] When the malignancy enters the bony structures of the vertebrae, the cells spread to the bones that support the arms and patients often experience difficulties walking and maintaining a straight posture. The pelvis, femur, ribs, humerus, and the skull are systematically destroyed, significantly impacting motor abilities and causing loss of bowel, bladder, and sexual function, followed by paralysis.[41]

Diagnostic Procedures

Diagnostic imaging used to identify spinal cord injuries includes spinal x-ray (usually insufficiently sensitive), CT scan, and gadolinium-enhanced MRI, which is the gold standard for its specificity and sensitivity.[41] MRI of the complete spine is useful because tumors are found at multiple sites along the spine in one-third of patients.[42]

Signs and Symptoms

Symptoms of SCC depend on the affected region of the spinal cord; however, back pain is the first sign of the condition in most cases.[43] The pain worsens with specific activities such as coughing, sneezing, or straining while toileting and can lead to difficulties during walking. Other non–pain-related symptoms include loss of bladder control, weak limbs, erection problems, and changes to body sensations.

Signs of SCC occur in four stages starting with pain and weakness and ending with ataxia and sensory loss. Back and neck pain, the earliest and lowest level symptoms, are the most common signs of SCC. Ataxia and loss of sensation are the highest level symptoms and are a critical EOL manifestation. Patients with ataxia have abnormal gait and nervous system dysfunction such that the person cannot coordinate body movements.[44] During ataxia, the patient cannot receive any treatment, and nurses manage the condition by providing hospice care. In the final stage of the illness before death, symptoms worsen and compression blocks nerve impulses, leading to paralysis and complete loss of sensation.[44] Hospice management of SCC symptoms at end of life depends on the patient's pain level and the stage of the condition.[45]

Metastatic SCC (MSCC) warrants intervention as early as possible. These signs and symptoms of MSCC would trigger a referral within 24 hours: (1) pain in the thoracic area, (2) spinal pain aggravated by straining, (3) localized spinal tenderness, and (4) nocturnal pain preventing sleep.[46] Emergent signs and symptoms that warrant an immediate referral in oncology patients are (1) loss of coordination, (2) bladder or bowel dysfunction, and (3) limb weakness and inability to walk.[46]

Medical and Nursing Management

Patients with SCC require consistent pain and neurological assessments to manage pain effectively and prevent additional neurological deficits that could diminish QOL. Important aspects of medical management topics for the SCC patient are analgesia, corticosteroids, radiation therapy, and decompression surgery.

Analgesia

The SCC patient will at some point experience discomfort and back pain as the spinal cord becomes more compressed.[42] Consequently, continuous pain assessment and management are essential. Several modalities can be used to effectively manage pain, including opioid and nonopioid analgesics and nonpharmacologic techniques. For cases of severe pain in patients with spinal tumors, opioids are the first-line medications to effectively manage pain.[47] When opioids are prescribed, the patient should be placed on a bowel regimen to prevent constipation and prevent any additional triggers of pain by straining. If pain is decreased and managed, opioids should be titrated accordingly.

Corticosteroids

Corticosteroids are essential to reducing edema at the compressed site in patients with SCC, and particularly in patients with MSCC, so that optimal radiation therapy can be applied at the tumor site.[42] As the edema around the spinal cord is reduced, compression pain may decrease and neurological function may improve.[47] Corticosteroids have adverse effects that must be monitored during steroid therapy, including weight gain, fluid retention, increased appetite, and facial puffiness.

Radiation Therapy

Radiation therapy is used to decrease the size of a tumor that is compressing the spinal cord, especially in cases of radiosensitive tumors.[42] Radiation treatment is guided by tumor size, spine stability, and the degree of symptoms related to the spinal cord compression.[41] Radiation therapy may be for palliative reasons if the patient has 6 months or less to live, but the National Institute of Health and Care (NICE) recommends single fraction radiation therapy.[48] Patients receiving radiation therapy may encounter side effects specific to the site of therapy, but general symptoms include fatigue, alopecia, nausea, and pain.

Decompression Surgery

Spinal surgery is required to remove a tumor compressing the spinal cord. Spinal surgery for patients with SCC would be the optimal choice if there is spinal instability, but spinal tumor patients with a prognosis of 2–3 months will receive palliative radiation therapy in lieu of surgery.[41]

In the management of SCC, regular exercise strengthens body muscles and keeps the spine flexible. Furthermore, maintaining proper body posture when standing, sitting, and sleeping maintains the natural body and spinal curve to avoid strain. In addition, a reasonable body mass index reduces extra pressure on the spine and minimizes the risk of spinal damage. The administration of body mechanics such as exercise routines, massages, and hot showers can be used to reduce back pains.

Hypercalcemia

Case Study: A Patient with Hypercalcemia

Mr. C is a 54-year-old tree cutter recently diagnosed with metastatic lung cancer. He was in good health until approximately 6 weeks ago when he noticed shortness of breath and fatigue. His primary care doctor treated him for bronchitis, but his doctor ordered a chest x-ray when he did not respond to treatment. The chest X-ray showed a lung mass with enlarged mediastinal lymph nodes. Diagnosis was confirmed by outpatient biopsy and an oncology appointment was scheduled. Unfortunately, he was admitted to a local emergency room with altered mental status and lethargy before his appointment and was found to have hypercalcemia with ionized calcium.

Description

Hypercalcemia is an excessive amount of ionized calcium in the blood. Patients with a corrected serum calcium level less than 12 mg/dL are considered to have mild hypercalcemia, those with serum calcium levels of 12–14 mg/dL are classified as having moderate hypercalcemia, and those with a calcium level greater than 14 mg/dL are classified as severe.

It is most frequently associated with multiple myelomas and breast cancers, but is also observed in patients with squamous cell carcinomas of the head and neck, lung, kidney, and cervix. It is much less common in patients with prostate cancer, small-cell lung cancer, and gastric/large bowel tumors.[49] Incidence ranges from 30% to 40% in breast cancer patients with bone metastases, 20% to 40% in patients with multiple myeloma, 12.5% to 35% in those with squamous cell lung carcinomas, and 2.9% to 25% in patients with head and neck malignancies.[49]

Primary hyperparathyroidism and cancer account for around 90% of hypercalcemia cases. Primary hyperparathyroidism occurs in around 25 people per 100,000 in the general population. Most episodes of malignancy-associated hypercalcemia occur in patients with advanced disease and typically result in a poor prognosis with 30-day mortality in up to 50% of patients.[50]

Pathophysiology

Hypercalcemia in malignant disease is primarily due to increased mobilization of calcium from bone, although increased renal tubular calcium resorption is also a factor. The most common cause (80%) is humoral hypercalcemia of malignancy (HHM). Parathyroid hormone-related protein (PTHrp) released into systemic circulation by cancer cells is the primary mediator. PTHrP shares significant N-terminal homology with parathyroid hormone (PTH) and stimulates osteoclastic bone resorption and renal tubal calcium reabsorption. In addition to hypercalcemia, PTHrP is important in other aspects of cancer biology including susceptibility and tumor behavior.[51] Twenty percent of cases are due to local osteolytic hypercalcemia (LOH) associated with multiple myeloma and metastatic cancers with large bone burden (e.g., breast, lung). Calcium is mobilized by osteoclasts activated by paracrine products.[52] Both HHM and LOH involve proliferation and activation of osteoclasts that resorb bone and generate hypercalcemia. Activation of vitamin D (seen with lymphomas) and secretion of native PTH are less common causes of hypercalcemia.

The kidneys normally adapt to disturbances in calcium homeostasis. However, in the presence of malignancy, patients may experience treatment or disease-related side effects including vomiting, mucositis, anorexia, dysphagia, and fever—all of which can lead to volume depletion. This imbalance signals the kidneys to resorb sodium to correct extracellular volume depletion. Calcium and sodium resorption is closely linked in the body; when sodium is resorbed, calcium follows. As calcium ions are resorbed in the kidney, the tubules lose their ability to concentrate urine, leading to high-output polyuria and further dehydration. Poor renal perfusion reduces glomerular filtration and compromises excretion of calcium, leading to a further increase of calcium in the blood and eventual renal failure.

High calcium level can significantly alter a patient's mental status, which in turn can greatly affect the patient's ability to drink fluids. Cellular dehydration and resulting hypotension are exacerbated by decreased proximal renal tubule reabsorption of sodium, magnesium, and potassium. Bone loss due to immobilization, lack of physical exercise, inappropriate use of thiazide diuretics, poor diet, and general physiological wasting will also increase the amount of free calcium ions in the circulation, further increasing calcium levels.

Symptoms of hypercalcemia are easily overlooked as they are insidious and nonspecific. Symptoms, their severity, and how quickly they appear vary from patient to patient. Mild symptoms of hypercalcemia include fatigue/lethargy, mental dullness, weakness, anorexia, increased thirst, polyuria, and constipation. Severe symptoms include drowsiness, delirium, nausea, vomiting, confusion, dehydration, and coma.[49] The most common symptoms are gastrointestinal, including nausea, vomiting, anorexia, constipation, and, in extreme cases, ileus. Polyuria and polydipsia are associated with hypercalcemia due to impaired renal tubular concentration.[52] Bone pain can be caused by cancer, but may also be a symptom of hypercalcemia. Rare symptoms include bradycardia and shortening of the QTc interval, wide T waves, cardiac arrhythmias, and prolonged PR interval.[49]

Because the symptoms of hypercalcemia can mimic both side effects of cancer treatment and progression of the disease, a thorough assessment is essential to the diagnosis and treatment of hypercalcemia. Many symptoms of hypercalcemia cause the patient to become increasingly dehydrated, which increases the hypercalcemia and creates a spiraling effect.

Ionized calcium concentration is the most important laboratory test in the diagnosis of hypercalcemia and the most accurate indicator of the blood calcium level, although the correlation between total serum calcium level and ionized calcium is fair at best. When ionized calcium cannot be used as a diagnostic tool, total serum calcium value may be used but must be corrected for serum albumin.[53] The formula is:

$$\text{Corrected Total Ca}^{2+}\text{mg/dL} = \text{Total measured calcium (mg/dL)} + 0.8\ (4\text{-measured albumin [g/dL]})$$

Treatment

Regardless of the overall goals of care, the active treatment goal for hypercalcemia is to alleviate distressing symptoms. Trial of therapy is warranted in all patients with symptomatic hypercalcemia, if the treatment will not exacerbate their existing symptoms. Hypercalcemia is reversed by replenishing depleted intravascular volume, promoting diuresis of calcium, shutting down osteoclast activity in the bone, inhibiting renal tubular reabsorption of calcium, and promoting patient mobilization to the greatest extent possible.[54] Table 26.3 lists commonly used treatments for hypercalcemia.

Hydration is the first step in effective treatment. Although restoration of fluid volume will aid in diluting the serum calcium concentration, its primary purpose is to increase calcium excretion. Electrolytes and other laboratory values are closely monitored including serum calcium (ionized or corrected), potassium, magnesium, other electrolytes, albumin, and bicarbonate levels. Renal function tests, including blood urea nitrogen (BUN) and creatinine, are also monitored, and dialysis may be considered in rare cases. In most patients, cardiac effects of hypercalcemia are minimal and outcomes are not usually affected, so cardiac monitoring is unnecessary.

Table 26.3 Common Treatments For Hypercalcemia In Palliative Care

Treatment	Mechanism of action
Hydration with IV fluids	Increase urinary calcium excretion & improve kidney function
Bisphosphonates (pamidronate and zoledronate most frequently)	Inhibit osteoclast activity
Denosumab	Monoclonal antibody leading to inhibition of osteoclast differentiation and bone resorption
Calcitonin	Inhibits calcium resorption
Dialysis	Dialyze excess calcium out

Bisphosphonate Therapy

After fluid administration, the first-line treatment option for malignant hypercalcemia is intravenous bisphosphonate therapy, an effective therapy for a number of cancers.[55] Bisphosphonates have a high affinity for the mineral component of bone, which allows them to reach very high skeletal concentrations.[53] Three bisphosphonates are currently available in intravenous form (bioavailability 1–2%), but only pamidronate and zoledronate are approved by the US Food and Drug Administration (FDA) for the treatment of malignancy-associated hypercalcemia.

Pamidronate has been the most frequently used bisphosphonate, but zoledronate is becoming more widely used in the outpatient setting due to its much more rapid infusion time. Pamidronate is usually given as 90 mg intravenously over 2 hours and has a response rate of 33.3% within 4 days, 63.6% within 7 days, and complete response within 18 days. Zoledronate is usually administered as 4 mg intravenously over 15 minutes and has a 45.3% response rate by day 4, an 82.6% response rate by day 7, and a complete response within 32 days.[54] Pamidronate and zoledronate can cause renal toxicity, making evaluation and continued monitoring of kidney function essential before and during administration. Some clinicians may opt to use pamidronate in lower doses over longer durations for renal patients. Bisphosphonates can cause osteonecrosis of the jaw, especially in patients with myeloma who have been treated with pamidronate and zoledronate over a long period of time and those with dental problems.[56] Since hypercalcemia tends to recur, pamidronate or zoledronate must be administered approximately every 4 weeks.

Immediate side effects of pamidronate therapy include low-grade fever appearing within 48 hours of treatment and redness, induration, and swelling at the catheter site. Hypomagnesemia and hypocalcemia may also occur. Rapid administration of intravenous bisphosphonates can cause significant pain and should be avoided. Subcutaneous administration of clodronate has been found to be an efficient treatment for malignant hypercalcemia[56] and may be particularly useful in hospital, home, and hospice settings. This approach reduces patient discomfort and decreases costs associated with transportation and intravenous administration in the hospital environment.

It is important to evaluate the entire clinical picture when choosing a bisphosphonate. Hydration is crucial before using this medication. Careful assessment of the severity of hypercalcemia, fluid volume status, renal function, and disease status should guide which type of bisphosphonate is used. Another consideration is the significantly lower cost of pamidronate compared with zoledronate (average wholesale price of $104 vs. $713, respectively).[48] However, pamidronate may result in longer hospitalizations, resulting in a similar overall cost of treatment.

Calcitonin

Calcitonin inhibits calcium resorption and can rapidly restore normal calcium, often within 2–4 hours of administration; however, it is much less effective than pamidronate. Its role in managing hypercalcemia is limited to short-term use of 2–3 days. Side effects are usually mild and may include nausea and vomiting, skin rashes, and flushing. Calcitonin can be an alternative treatment in patients with kidney failure for whom pamidronate and zoledronate are contraindicated.[56]

Denosumab

Denosumab is a monoclonal antibody that may also be a treatment option for patients with hypercalcemia of malignancy. Limited research suggests that this medication could benefit patients who cannot receive bisphosphates because of renal failure.[57] Denosumab was approved by the FDA in late 2014 for treatment of malignancy-associated hypercalcemia refractory to bisphosphonates based on an open-label, single-arm study of patients diagnosed with malignancy-associated hypercalcemia who were unresponsive to bisphosphonate therapy.[58] However, monoclonal antibodies are extremely costly and logistics often make them a less than ideal treatment option for emergency management of malignant hypercalcemia.

Dialysis

Removal of calcium by hemodialysis against a low-calcium dialysate bath and continuous renal replacement therapy using citrate as an anticoagulant and a calcium chelator has been reported.[52]

Nursing Management

Hypercalcemia can cause distressing symptoms including bone pain, agitation and confusion, severe constipation, and delirium. Treatment can reduce pain and other symptoms, improve QOL, and reduce hospitalizations. At end of life, promotion of comfort and symptom management are the primary goals of palliative nursing care. If hypercalcemia cannot be reversed or if the patient decides that the burden of interventions is greater than the benefit, the patient should be offered the option to discontinue treatment.

Hypercalcemia is a life-threatening condition that frequently occurs in end-stage cancer patients. Nurses must be well-versed in the treatment options for hypercalcemia and be able to clearly explain the advantages and disadvantages of each treatment to assist patients and their families in making educated choices. Because hypercalcemia is very symptomatic, it is also important for the nurse to review the symptom management plan with the patient and family. If the patient and/or family decide to withdraw or withhold treatment for hypercalcemia, it is the nurse's responsibility to support them in their decision. Ongoing education is essential to support the patient and family, as the patient will eventually die from untreated hypercalcemia.

Bone Metastasis and Pathological Fractures

Case Study: A Patient with Pathological Fracture

Ms. W. is a 61-year-old woman who had been receiving treatment for multiple myeloma; however, her treatment was put on hold when her insurance was terminated. Although she was working with the palliative care social worker to re-establish her insurance, she was temporarily without systemic treatment. While sweeping her patio, Mrs. W. had a sudden onset of severe pain in her upper left arm. After talking with the palliative care team by phone, she was instructed to report to the outpatient clinic. On arrival, she described severe pain in her upper arm with swelling, bruising, and loss of function.

Description

A pathologic fracture is a bone fracture resulting from weakness of the bone structure caused by disease. This process is most commonly due to osteoporosis, but may also be caused by other pathologies such as cancer, infection (such as osteomyelitis), inherited bone disorders, or a bone cyst.

Epidemiology

Metastatic disease is the most common bone malignancy, with prostate, breast, lung, kidney and thyroid cancer accounting for 80% of skeletal metastases.[59] The most common sites of bone metastases are the spine, pelvis, ribs, skull, and proximal femur.[59] It has been reported that 9–29% of patients who suffer from bone metastases develop pathological fractures,[60] most commonly in the long bones, although the spine is the most common site of skeletal metastases.

There is a 3-year survival rate of patients with bone metastases and pathological fractures as compared to those without pathological fractures (19% vs. 35%).[60] The most commonly reported survival rates across all patients are in the range of only 30–40% at 1 year. Median time from fracture to death across all patients was only 3.3 months, although the actual times were affected by the type of cancer and Eastern Cooperative Oncology Group (ECOG) score. Breast cancers had the best outcomes, with median survival time of 6.3 months, prostate cancer had a median survival time of 4.5 months, and lung cancer fared the worst with a median time of only 2.4 months from fracture to death.[60]

Pathophysiology

Once in the marrow, metastatic cancer cells take advantage of normal marrow physiology to survive away from the primary tumor.[61] Bone marrow is a unique environment that houses both cells of hematopoietic lineage and cells responsible for bone remodeling (osteoblasts and osteoclasts). These disseminated tumor cells (DTCs) also actively influence bone remodeling to create a favorable environment for further recruitment and better survival of DTCs within the marrow.[62] Subsequently, DTCs become dormant and eventually regrow.

Pain is usually the first sign of bone metastasis and is usually worse at night and may improve with movement. As the bone metastasis progresses, the pain becomes more severe and worsens with activity. Continued weakening of the bone because of the metastasis could eventually lead to a pathological fracture. Signs of pathological fracture are sudden onset of pain in the affected area, in addition to possible swelling, bruising, and loss of function.

Pathological spinal fractures usually cause severe pain or progressive neurological deficits; hence, prevention of pathological fractures is a primary goal in the management of spinal metastasis. However, diagnosis of spinal metastasis is frequently delayed because the onset of symptoms often results from neural tumor invasion or development of pathological fracture, which is initial manifestation of spinal metastasis in many cases.[63] Hypercalcemia may also result from bone metastasis, causing symptoms that include constipation, nausea, loss of appetite, extreme thirst, fatigue, weakness, sleepiness, and confusion. The high calcium also causes more urine output, leading to dehydration.

Diagnostic Procedures

Bone metastases are sometimes diagnosed when the patient seeks care because of pain or other symptoms. They are also sometimes found during the initial cancer workup or during follow-up imaging to determine response to treatment. In either case, bone metastases are usually found on an x-ray, a bone scan, a CT scan, an MRI, or a PET scan.

In osteolytic or lytic metastases, the cancer cells dissolve the bone making part of it less dense. If the cancer has destroyed enough of the bone, these changes look like a darker hole in the gray-white bone seen on an x-ray. Osteoblastic or blastic metastases cause an area of the bone to look denser or sclerotic, which appears on x-rays as spots that are whiter than the bone around them. Bone metastases often have both lytic and blastic features.

Occasionally, a blood and/or urine test will be ordered to evaluate for the presence of substances that indicate bone metastasis. A blood test, for example, may reveal high calcium and/or elevated alkaline phosphate. Several substances can be released into the urine when bone is damaged, such as N-telopeptide. Bone metastasis is confirmed through biopsy, frequently guided by CT scan.

Treatment

The goals of treatment for bone metastasis and pathological fractures are to relieve pain and restore function without causing further decline in QOL. Management options for skeletal metastases vary with bone type, anatomical location, and loading condition.[59] Treatments include radiation therapy, systemic treatment, embolization, electrochemotherapy, radiofrequency ablation (RFA), and high-intensity focused ultrasound (HIFU).[59] Treatment of pathological fractures involves surgery and splinting or immobilization.

Bone Metastasis Treatment

Palliative radiation. Palliative radiation therapy can reduce pain in 60% of patients, with about 25% of patients achieving complete response.[63] Palliative radiation therapy can be administered as conventional external-beam radiation or intravenous bone-seeking radiopharmaceuticals. The goals of palliative radiation therapy are to use a short treatment schedule to minimize the commitment of time for therapy and to achieve rapid symptomatic relief.[59] No significant difference in pain relief has been reported between single and multiple fractions of radiation therapy.[62] Palliative radiation is associated with few side effects, but an increase in bone pain called a "pain flare" occurs immediately after radiation therapy in 2–44% of cases.[63] Bone-seeking radiopharmaceuticals, such as radium-223 (^{223}Ra), selectively deliver ionized radiation to target areas of amplified osteoblastic activity.[64]

Systemic treatment. Palliative chemotherapy that is targeted to the treatment of a specific cancer can be used to treat bone metastasis; however, cancer metastasis remains poorly understood in terms of clinical outcome, pathology, and tissue specificity of different tumor types. The predilection of some cancers to target and proliferate in the bone is also unclear.

Palliative embolization. Embolization is useful for the treatment of metastatic bone disease as an adjunctive procedure to devascularize the tumor, reduce the size of the metastases, cause calcification of the margins of the tumor, and relieve pain. It is typically performed at 4- to 6-week intervals until symptoms improve or until the tumor's vascularity disappears, as indicated by angiography, MRI, or CT scan.[59] Embolization therapy does not appear to improve survival, but it may provide palliation and improve QOL. Previous studies have associated embolization with reduced pain and tumor volume lasting from 1 to 9 months.[59]

Radiofrequency ablation (RFA). RFA is a form of electrosurgery in which an alternating current of high-frequency radio waves passes from an electrode tip into human tissues and dissipates its energy as heat.[65] RFA has emerged as a safe, easy, and predictable technique for thermal ablation in the liver, kidney, heart, prostate, breast, brain, lung, lymph nodes, thyroid and parathyroid glands, nerve ganglia, and bone.[65] In the past two decades, use of RFA for the treatment of primary or metastatic bone disease has increased.

HIFU. HIFU has been described as a safe, completely noninvasive, and extracorporeal method to treat primary solid tumors and metastatic bone disease.[66] The treatment rapidly delivers the energy required to raise tissue temperature to a cytotoxic level so the tissue vasculature does not significantly affect the extent of cell lysis.[59] Although in its infancy, HIFU appears to be a safe, noninvasive, promising treatment approach for cancer patients with bone metastases.

Pathological Fracture Treatments

Because of the high mortality related to pathological fractures, the risk factors associated with metastatic bone disease remain poorly understood. This knowledge is necessary for the prevention, detection, and treatment of pathological fractures. Risk factors for pathological fractures in patients with bone metastasis include increasing pain, radiographic osteolytic appearance, lesion size (>25 cm), axial cortical involvement (>30 mm), and circumferential cortical involvement (>50%).[67]

Surgical treatment is a good option for patients with metastatic or impending pathological fractures and solitary metastatic lesions. Treatment must be tailored individually, considering the estimated life expectancy and general condition of each patient. The treatment goals are to reduce pain and restore function for the duration of the expected life span. A population-based study of patients with femoral metastasis showed that patients who received prophylactic stabilization of metastatic bone disease had better survival outcomes than those who received surgical interventions post fracture.[68]

Conclusion

The urgent syndromes presented in this chapter are discussed to educate, empower, and equip current and future palliative care nurses. Because many of these topics are emergent in nature, the palliative care nurse must be prepared to provide optimal patient care specific to the disease and to educate patients and family members. EOL care is all about maintaining hope and dignity even when urgent syndromes affect the patient.

CHAPTER 27

Sedation for Refractory Symptoms

Chandana Banerjee and Bonnie Freeman

Key Points

- Palliative sedation or continuous deep sedation is used during the final days to hours of life to control symptoms such as pain and restlessness, refractory to aggressive palliative treatment.
- Palliative sedation differs from euthanasia in that the medical provider's goal is to relieve refractory symptoms, not to end the patient's life.
- Palliative sedation requires expertise, collaborative decision-making and support, knowledge of ethical and legal issues, ability to understand the dynamics of suffering, informed consent, and a compassionate and therapeutic presence.
- Palliative sedation varies by provider and is an individualized end-of-life care option that focuses on the relief of a patient's unique refractory symptoms by dosing to effect. There is no maximum dose, and there is no one universal treatment plan.
- Palliative sedation effectively addresses the basic ethical principles of dignity, autonomy, fidelity, beneficence, and nonmaleficence.

Introduction

To fully understand the important role palliative sedation can play in the control of intractable pain and suffering for a dying patient, one must understand how the body shuts down during the dying process, the legal precedence for the use of palliative sedation, the specific goals of palliative sedation, and the patient's right to define what he or she perceives as suffering. It is also important for the healthcare professional to examine his or her own cultural, religious, and personal beliefs and how they may affect the ability to care for a patient undergoing palliative sedation.[1–9]

The Dying Process

During the dying process the body struggles to make the most effective use of available oxygen.[10] Its main focus becomes the preservation of cardiac, pulmonary, and cerebral function. All other systems experience a marked reduction in perfusion and function.[10,11]

- *The gastrointestinal system* undergoes a severe reduction in peristalsis, progressing to the loss of the ability to swallow. This contributes to a normal loss of appetite. Any food or fluid provided can result in vomiting, aspiration, abdominal distention, and pain. The loss of appetite and ability to eat may not be well accepted by a society that embraces food as a form of love and comfort. The fear of starving a loved one to death can result in the use of continuous tube feedings and forced feedings that can hasten death. The feedings may cause the patient to expend precious energy and create the likelihood of aspiration.[10,11]
- *The nervous system* is deeply affected by circulating toxins and waste products from progressively failing organs such as the kidney and liver. These toxins are particularly irritating to the cells of the brain and can result in confusion, agitation, and delirium. This is also heightened by the natural dehydration and hypoperfusion that occurs as part of the dying process. The dying will sleep more in an effort to conserve energy and will be less responsive as a result of reduced cerebral perfusion and cellular death. They will not be interactive with family and friends, and cognitive function will become progressively more impaired. Involuntary body functions such as breathing, will become more dependent upon the involuntary stimulus of the brainstem.[10,11]
- *The respiratory system* undergoes a dramatic change as the brainstem takes over involuntary function. Respirations become agonal and irregular, as the lungs continue to struggle to pull in oxygen. Blood pressure is insufficient to effectively maintain the required pressure gradient for oxygen transport, and fluid begins to accumulate in the lungs, causing the congestive "death rattle." Suctioning does not reduce these secretions; it only deprives the dying patient of more oxygen. High-dose supplemental oxygen will only prolong the dying process.[10,11]
- *The circulatory system* attempts to adjust to a continued drop in blood pressure, resultant loss of oxygen, and the loss of circulating protein. Colloidal osmotic pressure cannot be maintained, so fluids introduced into circulation have only a short time to influence blood pressure and cellular perfusion before they seep into surrounding tissues and ultimately accumulate in the lungs. Increasing intravenous fluids can result in massive pulmonary edema and cause a patient to die more quickly. The heart begins to fail as its energy needs cannot be met to continue to beat effectively. As cells die, there is an increased release of potassium and irregular heart rhythms worsen until finally the heart can only quiver, no blood can circulate, respirations cease, and brain cells continue to die.[10,11]

Legal Precedence for the Use of Palliative Sedation

The concept and use of palliative sedation or continuous deep sedation has evolved over the past 25 years and is no longer called terminal sedation, a term first coined by Enck in 1991. By 2010, the term "palliative sedation" was used consistently when describing the monitored administration of medications to induce sedation in an effort to control refractory and unendurable symptoms near the end of life.[2]

"Palliative sedation is not only a legal act; it is grounded in basic ethical precepts including dignity, autonomy, fidelity, beneficence, nonmaleficence, and the principal of double effect."[2 (p. 397)]

- *Dignity* involves an individual's right to be perceived as worthy of honor and respect. This personal desire involves the ethical concept of autonomy; individuals fear the loss of control over their bodies in the dying process, and this loss of control equates to the loss of dignity.
- *Autonomy*, also referred to as self-determination, is a core belief in the United States and is based on the principle of respect. It addresses the right of an individual to decide a course of action based on his or her personal goals and values.
- *Fidelity* is the commitment of healthcare professionals to keep our promises to patients and family members and not to abandon them and their needs, especially during the dying process.
- *Beneficence* involves doing good and caring for patients in a way that they would want. This typically is reflected in the management of their refractory symptoms.
- *Nonmaleficence* is the standard of not causing harm through omission of care or not following a patient's request that could result in a loss of their dignity, diminish their autonomy, result in abandonment, or ignore their care wishes.
- *Principle of double effect* acknowledges that there can be both good and bad consequences to an action, but the action is undertaken with the hope (ethical/moral) or intent that the good consequence will occur.[2] "Potentially causing complication or hastening death is not the means or the intent of the action so the use of palliative sedation is morally permissible."[2 (p. 397)]

The intent of palliative sedation is to control symptoms, not hasten death.[2,3] "Intent," was identified by the US Supreme Court as one of the dominant factors required to be proved when trying to establish a standard for euthanasia.[12,13]

In 1997, the US Supreme Court ruled unanimously that "there is no constitutional right to physician-assisted suicide" but, palliative sedation is "intended for symptom relief and not assisted suicide, and is appropriate in the aggressive practice of palliative care."[12,14,15] The American Nurses Association and the Oncology Nursing Society have position papers opposed to physician-assisted suicide.[16,17] Although neither of the position papers addresses the exact issue of palliative sedation, both support the risk of hastening death through treatments aimed at alleviating suffering or controlling symptoms as ethically and legally acceptable. The Hospice and Palliative Nurses Association has also issued a position paper in support of palliative sedation.[18] The use of palliative sedation to address existential suffering remains controversial.[19]

The use of palliative sedation requires three basic elements: (1) a need for relief of intractable symptoms, (2) death is estimated within days to hours, and (3) there is a need to involve medications to reduce awareness.[4] The concept of *proportionality* is another legal precedent used to justify the amount of medication required to reduce awareness. The patient's consciousness is lowered just enough to relieve refractory suffering.[9,20] Proportionality is also a factor referenced when attempting to clearly separate palliative sedation from euthanasia. The intent of palliative sedation is to allow the patient to die comfortably and peacefully at a pace set by their body.[8]

The benefits of palliative sedation should be stressed over the concerns of accelerating the dying process.[9] Refractory symptoms such as pain, delirium, and existential suffering can be controlled, and concerns over the loss of communication, starvation, dehydration, and fears of euthanasia must be weighed against the comfort benefits obtained from deep sedation and the fact that many of the disadvantages identified with the use of palliative sedation occur naturally during the dying process.[8,9]

An informed consent should be obtained prior to the use of palliative sedation. Ideally, informed consent should be obtained from the terminally ill patient.[2,3,8,9] Often, informed consent is obtained from the family, next of kin, or someone with a durable power of attorney who is designated as able to make decisions for the patient. Advance directives, extensive education, and planning are helpful strategies to prepare patients and their families for end of life, and these can greatly assist with the promotion of a peaceful death.[9]

The Goal of Palliative Sedation

The goal of palliative sedation is to provide a medically induced level of unresponsiveness for relief of refractory suffering during the actively dying process.[21,22] Palliative sedation is not intended to accelerate the dying process. Patients and their families should discuss its use as refractory symptoms are identified.[23,24] A plan to use palliative sedation should be instituted as part of a natural dying process to assist in the promotion of a comfortable, compassionate, and peaceful death.[2]

Impact of a Care Provider's Personal, Cultural, and Religious Beliefs

It is essential that the healthcare provider is aware of his or her personal views and biases regarding palliative sedation.[21,26] If the provider has a spiritual or personal objection, removal from direct patient care should be accommodated. Often the healthcare provider can become more comfortable if the purpose and implementation of palliative sedation is explained. There will continue to be objections for its use, but the requests of the dying patient and their family must take precedence. A semi-structured interview-based qualitative research study conducted by DeVries and Plaskota[25] exploring the ethical dilemmas faced by seven hospice nurses when administering palliative sedation to patients with terminal cancer concluded: "Hospice nurses need to be confident, competent, and well supported within the expert palliative care team when faced with making decisions about the use of palliative sedation."[(p. 155)]

The Patient's Right to Define Suffering

Suffering at the end of life may involve physical, psychological, social, or spiritual distress. In most situations, multidisciplinary palliative interventions can effectively comfort, but in some instances, suffering becomes refractory and intolerable.[2,3] Existential suffering (sometimes referred to as *terminal anguish*) is a more ethically challenging reason for the use of palliative sedation, but it has an important impact on quality end-of-life care.[19] The ability to empathize, to understand the need for hope and optimism and the desire of an individual to have meaning for his or her suffering are often poorly understood concepts by the healthcare professional and can cloud the importance of relieving personal and spiritual suffering.

Case Study: Existential Suffering

Edward was an example of a patient experiencing existential suffering. He was a 38-year-old man who had been fiercely independent all his life. He developed metastatic rectal cancer and now required help with all of his ADLs. This was intolerable to him, especially when he required help after his frequent episodes of incontinence. His pain was controlled with opioids, but he began to have terror attacks when he required any assistance. He begged his primary team to sedate him as his strength further declined, and he was finally placed on a continuous midazolam infusion. He died peacefully 3 days later. Was palliative sedation necessary for this man? By his standards, and the emotional suffering he was enduring, it was. The healthcare staff had difficulty sedating him even though his condition met the three basic elements for palliative sedation: (1) a need for relief of intractable symptoms, (2) death was estimated within days to hours, and (3) there was a need to involve medications to reduce awareness.[4] Several nurses declined to care for him after palliative sedation was initiated.

The use of palliative sedation for existential suffering remains challenging from ethical, personal, and professional standpoints. There should always be the option for healthcare staff to request that they not be involved if they hold strong beliefs against the providing of palliative sedation. An important concept to consider is that the goal should always be to provide quality end-of-life care as the patient defines it. For Edward, palliative sedation was the right choice for him.[12,19,20]

Medications Routinely Used for Palliative Sedation

Bodnar[7] surveyed 381 physicians regularly caring for hospice/palliative care patients and noted that 84% had moderate to no experience with palliative sedation, and only 88% had participated in palliative sedation in the past 5 years. The option to provide palliative sedation does not occur often, and its implementation can vary greatly by provider. There are varying definitions of the process, and no one standardized procedure exists.[7] Drugs most commonly used for palliative sedation include benzodiazepines, barbiturates, and propofol.[7] Additional agents such as opioids and psychotropic drugs like haloperidol and opioids are incorrectly given for their secondary sedating effects. "In end-of-life-care, medications indicated and used to address specific symptoms with a subsequent reduction in the level of consciousness to a varying degree as a side effect should not be used for sedation."[7(p. 17)] Haloperidol is the gold standard for delirium therapy and agitation. Opioids are designed to address pain and respiratory distress. Haloperidol is unreliable for complete sedation, and it is possible for some patients to have no response to it at all for delirium.

In addition to the use of medications not specific to providing sedation, actual levels of sedation can vary. Proportional sedation is recommended as a guideline. It requires that sedation be provided only to the point of symptom relief. In most areas of the United States, palliative sedation is considered deep continuous sedation as the patient is rendered unresponsive.[7,26,28] In other areas of the world, palliative sedation can take two distinct forms: one where the goal is to preserve alertness as much as possible, and the other is to sedate to unconsciousness because the patient's intractable symptoms are so profound.[7] In-depth discussions should be held with the patient and family to confirm their wishes for the level of sedation. In most instances, palliative sedation is not discussed until symptoms are too severe and intractable, so deep sedation is typically the standard of practice.

Bodnar noted that the most recommended agents used for palliative sedation are midazolam, lorazepam, diazepam, phenobarbital, and propofol (see Table 27.1).[7]

Midazolam is the most commonly used of the recommended palliative sedation-producing drugs.[7,28] It has a rapid onset of 60 seconds, a peak effect in 2–5 minutes, a half-life of 1–3 hours, and a duration of action of slightly less than 2 hours. There is a ceiling effect for central nervous depression found with all benzodiazepines. This can result in midazolam being ineffective over time. In cases where rapid sedation is required, midazolam can be given in 5–10 mg intravenous doses every 5 minutes to a maximum of 20 mg. Dosing beyond 20 mg has little to no efficacy, and another agent will be needed.

Since duration of effect is an important consideration for effective midazolam use, continuous infusions should always start with a bolus, and rates can be adjusted every 1–2 hours with additional boluses.[7]

Lorazepam is a favored benzodiazepine for prolonged palliative sedation cases anticipated to extend for greater than 24–48 hours because it begins to retain more than half of its effect after 4 hours of sustained sedation. It is a commonly administered drug, so nurses are more comfortable with its use. Lorazepam requires 20–30 minutes to reach full effect, and initially, all effects will wear off in 1–2 hours unless prolonged sedation is delivered.[7,21,29]

Diazepam, is a much older and fast-acting benzodiazepine. Its rapid peak onset of 2–5 minutes makes it a valuable resource when rapid sedation is required. Its duration of effect is half that of midazolam, but the need for large volumes of fluid to dilute, its tendency to precipitate out of solution, and its cumulative effect resulting in a long half-life has caused diazepam to become unsuitable for long-term and continuous sedation. Its use in palliative sedation is primarily as a supplemental agent.[7]

Phenobarbital can be given subcutaneously, like midazolam, although this is not an approved route by the manufacturer. The ability to give this drug subcutaneously makes it a valuable resource for sedation in both the hospital and hospice settings. Phenobarbital is stronger than midazolam and is often used when midazolam has proved ineffective, yet it is not a first-line agent used for palliative sedation because it was originally designed to treat intracranial hypertension and status epilepticus. It has a more extensive accumulation effect with repeated administration and with the use of a continuous infusion that can result in a half-life of 53–120 hours. Dosing in a hospice setting is 200 mg every 30 minutes, followed by intravenous boluses of 260–1250 mg every 8 hours or a continuous infusion of 30–160 mg/hr.[7]

Propofol is slowly gaining popularity as an option for use in palliative sedation. It was specifically designed for sedation and anesthesia. It has no central nervous system depression ceiling effect, a rapid onset and peak effect, a short half-life, and a duration of

Table 27.1 Medications used for palliative/continuous deep sedation

Medication	Effect	Peak effect	Bolus	Infusion	Considerations
Midazolam	1 min	2–5 min bolus 50–60 min infusion	2–5 mg q5min max of 20 mg	1–20 mg/hr titrate q1hr + bolus dose 0.7–10 mg/hr	Short half-life, give IV or SQ, central nervous system ceiling, variable effect
Lorazepam	5 min	30 min	4 mg q4h repeat q30min if no other agents available	20–40 mg 250 mL 1 mg/hr after 4 mg bolus, max 7–10 mg/hr	Prolonged time to peak effect, best for prolonged sedation. Peak effect lasts 4 hours
Diazepam	1 min	2–5 min	5–10 mg q5min max of 30 mg	5 mg in 100 mL will be stable for 24 hours	Very rapid onset to peak effect, best for deep sedation. Need large dilution for IV precipitates
Phenobarbital	5 min	30 min	200 mg q30min min effective dose ~100 mg	None Give 10% of loading dose q12h	Often effective with midazolam failure. Long half-life, accumulation. Difficult to titrate
Propofol	30 sec	90 sec	0.5–1 mg/kg, may repeat ½ of loading dose	1 mg/kg/hr or 15 mcg/kg/min titrate 5–10 mcg/kg/min q20min	High risk of side effect with large loading dose given rapidly CNS depression ceiling Always effective in sufficient doses

effectiveness of 2–6 minutes. There are only a few published studies on its use for an estimated 4% of all palliative sedations provided in the United States. Dosages for propofol are significantly smaller for palliative sedation than those required for anesthesia. Yet propofol is not a first choice for many healthcare providers due to policies that prevent its administration in unmonitored areas, requirement for its use to occur only with the failure of other sedating agents, and the lack of experience with the drug.

Palliative Sedation Nursing Care

The bedside nurse is an essential part of the palliative sedation team. Each physician will differ with his or her titrating criteria, but the goal for the provider is to keep the dying patient as comfortable as possible and allow the patient's body to shut down naturally without suffering. Sedation usually includes a continuous opioid infusion and the use of a benzodiazepine. Sedation is proportional in that the amount of sedation is in proportion to the patient's body requirements to be kept deeply and continuously sedated. The bedside nurse may need to stay in close communication with the prescribing physician, nurse practitioner, or physician's assistant for more specific directions or concerns.[30]

Family members become distressed if they feel their loved one is suffering, so the nurse should have orders available to him or her to address these concerns. Education and a continued presence are often required. Grieving friends and families of loved ones may not absorb information provided only once, so the bedside nurse should be prepared to re-explain all teaching as necessary. There will be a need to reinforce to friends and family members that palliative sedation is not intended to speed up the dying process, nor is it causing additional suffering because their loved one can no longer eat or drink. The normal course the body takes in shutting down during the dying process should be emphasized, as discussed in an earlier section of this chapter. The dying have a natural loss of appetite, thirst, and desire to communicate. Often the loss of these associated interactions is difficult for grieving families, and they will require frequent reassurance.[31,32]

General care for a patient undergoing palliative sedation becomes much like any other dying patient's care. The sedation has simply allowed them to be less restless and have their intractable symptoms controlled.[30]

> One family member stated that once he was sedated, they were actually able to spend a lot of quality time together. They played music that they played at their wedding, and he was so much more peaceful. She laid on the bed with him, and she slept in the room. And because he was in this state rather than the aggressive one, they were able to spend a few days of some quality time together without his last day of his life being agitated and aggressive. . . . He was settled and peaceful.[9(p. 153)]

Conclusion

Many nurses and healthcare professionals remain uncomfortable with palliative sedation. Often, this discomfort can be attributed to a lack of understanding of the ethics that guide the providing of palliative sedation and what transpires in the normal dying process. Patients with intractable symptoms that cause them to suffer on any level as they die need their symptoms to be addressed. Palliative sedation does not speed up the dying process, and it is not a form of slow euthanasia. Healthcare providers may not all agree about how to define a "good death," but there is a general understanding about what constitutes a "bad death." Palliative sedation is a reasonable and ethical option for patients with refractory and intolerable symptoms and suffering at end of life, and for many it is essential for a compassionate and peaceful death.

CHAPTER 28

Complementary and Integrative Therapies in Palliative Care

Mary-Anne Meyer and Melinda Ring

Key Points

- Patients with chronic illness frequently use integrative medicine to help address symptoms and improve quality of life.
- Evidence of efficacy of specific therapies for common concerns such chronic pain, mood issues, and gastrointestinal symptoms is growing.
- The nursing profession plays a critical role in guiding patients and families in the safe and appropriate use of integrative medicine for palliative care.

Integrative Medicine and Palliative Care: The Critical Role of Nurses

Integrative medicine aims to provide whole-person care with a focus on healing and health rather than curing and disease, and thus it is inherently aligned with palliative care. Incorporating the broader toolbox of therapeutic practices, a social-spiritual emphasis, and a compassionate partnership between provider and patient (and family/support persons) can be of benefit at any time from diagnosis to end-of-life care. Earlier adoption is encouraged to allow for greater potential benefits. For many patients and families, beyond the actual relief of symptoms and management or reversal of disease processes, active engagement in an integrative approach provides a sense of empowerment over their disease; this paradigm shift can be healing in and of itself. Nurses on the front-line of caring for patients with chronic debilitating symptoms and end-of life care are ideally positioned to help patients understand their options and facilitate access to safe and appropriate resources. The nursing profession additionally has deep roots in the philosophical approach to holistic, relationship-centered healing. This chapter serves as an introduction to frequently encountered terminology, complementary and integrative medicine (CIM) practices, and current evidence for common concerns addressed via an integrative palliative care approach.

Current Prevalence of Complementary and Integrative Therapies in Palliative Care

In the United States, approximately 38% of adults (about 4 in 10) and approximately 12% of children (about 1 in 9) are using some form of CIM.[1] Previous studies have shown that individuals opt to use CIM to improve health and well-being, to relieve symptoms associated with chronic diseases, or to manage side effects of conventional medicine.[2] Palliation of chronic pain and management of symptoms and side effects related to oncology care are among the top conditions for which patients report using CIM.[3,4]

In response to growing awareness in the medical community, integrative medicine services are increasingly available in academic and community health centers. The Academic Consortium for Integrative Medicine and Health membership increased from 9 North American academic institutions in 1999 to 69 in 2017.[5] The US military health system has been an early adopter of the use of integrative strategies for their stakeholders, especially in relation to its benefits for managing pain. In 2010, the Department of the Army Pain Management Task Force published its report with the recommendation for a comprehensive pain management strategy focused on an interdisciplinary, holistic, multimodal, patient-centered approach.[6] A survey of 14 Department of Defense medical treatment facilities found that 100% of the 14 facilities offered IM services, with 92% offering six or more modalities.[7] The research literature also documents a growing number of integrative oncology programs; at least 29 dedicated CIM oncology programs were noted, with many more integrative centers offering care to cancer populations.[8]

Hospice programs have also incorporated CIM options, with prevalence increasing over recent decades. In surveys from the early 2000s, 60–70% of responding hospice organizations offered CIM therapies.[9,10] The most common services were massage therapy (83%), music therapy (50%), therapeutic touch (49%), pet therapy (48%), guided imagery (45%), Reiki (36%), aromatherapy (30%), harp music (23%), reflexology (20%), art therapy (20%), hypnotherapy (4%), yoga (3%), acupuncture (1%), and humor therapy (1%).[9] A recent survey of 108 Illinois-based organizations listed on the National Hospice and Palliative Care Organization website found that 90.3% of the responding organizations offered some type of CIM.[11] The top five most frequently offered options in this report were pet therapy (64.5%), music therapy (61.3%), massage therapy (54.8%), art therapy (29.0%), and energy therapies (25.8%). However, even in hospices and palliative care programs that offer these services, they are accessed by less than 25% of eligible patients.[10] Profit orientation and the number of patients served by hospices have been identified as significantly related to the probability that hospices will offer CIM.[12] Not-for-profit hospices were approximately four times more likely to offer CIM than for-profit hospices, and for every 100 patients served by the hospices, the odds of offering CIM increased by 13%. Constraints to providing and use of these services include lack of funding, lack of staff time, lack of qualified therapists, inadequate knowledge about these services, and patient and staff resistance to the services.[9] Preliminary research outcome data on CIM programs have been favorable, and Demmer and Sauer found that patients who received complementary therapies were more satisfied with their hospice services.[13,14]

Patients may seek integrative medicine on their own or be referred by members of their healthcare team. A National Institute of Health (NIH)-funded study found that referrals to integrative medicine inpatient services at a tertiary hospital were often driven by nurses and mid-level providers.[15] In this survey, physicians and administrators indicated that nurses were better able to assess a need for CIM services, initiate discussions about them, and consequently recommend them to patients. In contrast, a survey about physician attitudes toward and knowledge about CIM reported that 76% had never referred a patient to a CIM practitioner, although 44% stated that they would refer a patient if a practitioner were available at their institution.[16] An online survey of professional members of the German Society for Palliative Care confirmed the stronger interest among nurses: among the 365 respondents (9.8% of all members), 85% of the physicians and 99% of the nurses claimed to be interested in CIM.[17] Combined, these findings highlight the important role of nurses in guiding patients to ensure safe and appropriate utilization of CIM services and therefore educating themselves on potential benefits versus risks for commonly seen conditions. The remainder of this article aims to provide an introduction for nurses to integrative health, with resources for additional learning and reference.

Terminology

It is helpful to have shared definitions when describing holistic system approaches to healthcare and the individual healing traditions and practices. The following basic terms are recommended by the National Institute for Health's National Center for Complementary and Integrative Health (NCCIH)[18]:

- *Complementary health approaches*: Practices and products of non-mainstream origin
- *Integrative health*: Incorporating complementary approaches into mainstream health care

A broader definition of integrative medicine as promoted by the Osher Collaborative, an international group of six academic centers funded by the Bernard Osher Foundation to study, teach, and practice integrative medicine follows.[19]

Integrative medicine:

- Reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of appropriate therapeutic approaches, healthcare professionals, and professions to achieve optimal health and healing.
- Applies rigorous scientific research methods to evaluate physiological and therapeutic mechanisms, efficacy, and use of approaches in society as they affect health, resiliency, and well-being.
- Educates practitioners, public, and policy to appreciate and address the full range of physical, emotional, mental, social, spiritual, and environmental influences that affect health.

Other descriptors of approaches to patient care that overlap with integrative medicine:

- *Alternative medicine* refers to the much less common occurrence of a non-mainstream practice being used in place of conventional medicine.
- *Functional medicine*, according to the Institute for Functional Medicine, determines how and why illness occurs and restores health by addressing the root causes of disease for each individual. It requires a "detailed understanding of each patient's genetic, biochemical, and lifestyle factors and leverages that data to direct personalized treatment plans that lead to improved patient outcomes."[20]
- *Holistic medicine*, according to the American Holistic Health Association "is the art and science of healing that addresses the whole person—body, mind, and spirit. The practice of holistic medicine integrates conventional and alternative therapies to prevent and treat disease, and most importantly, to promote optimal health."[21]
- *Lifestyle medicine*, per the American College of Lifestyle Medicine, "involves the use of evidence-based lifestyle therapeutic approaches, such as a predominantly whole food, plant-based diet, exercise, sleep, stress management, alcohol moderation and tobacco cessation, and other non-drug modalities, to prevent, treat, and, oftentimes, reverse the lifestyle-related, chronic disease that's all too prevalent."[22]

Complementary Health Approaches

There is overlap in the practice and proposed mechanism of different complementary health approaches; therefore, the NCCIH currently suggests considering them within two major subgroups: natural products or mind-body practices.[18]

Natural products include a diverse group of substances that includes vitamins, minerals, and probiotics, as well as compounds from diverse sources. Many natural products are produced from marine organisms, bacteria, fungi, and plants, herbs and botanicals.[23] Natural products can include complex extracts from whole plants or isolated compounds. In traditional herbalism, whole-plant extracts are often used due to purported positive synergistic interactions, while a more Westernized approach seeks to isolate the active compound.[24,25] According to the 2012 National Health Interview Survey (NHIS), 17.7% of American adults had used a dietary supplement (not including vitamins and minerals) in the past year, making them the most popular form of complementary approaches in the survey.[2]

Mind-body practices include a large set of techniques ranging from meditation, yoga, and tai chi to acupuncture, massage, and chiropractic manipulation. These practices are often taught or provided by a trained teacher or practitioner, though self-use is also common.

A third category of *whole healing traditions* incorporates many aspects of both natural products and mind-body approaches. Examples of these include Ayurvedic medicine (the traditional medicine of India), traditional Chinese medicine, naturopathy, and traditional healers.

Applications in Palliative Care

Conventional medicine excels at treating emergency situations, acute conditions such as infection, and problems requiring a surgical intervention. However, many chronic conditions are not fully amenable to treatment with conventional medicine approaches, or the side effects and risks significantly impair a patient's quality of life (QOL). In these cases, an integrative strategy can often provide important relief. Here, we focus on three categories of frequently encountered issues with examples of current research behind potential therapeutic options: (1) chronic pain, (2) fatigue and mood disorders, and (3) gastrointestinal conditions.

Case Study: Integrative Medicine

Aurelia was a 55-year-old woman with a recent diagnosis of Stage 1B hormone-receptor-positive breast cancer who presented with insomnia, fatigue, and joint stiffness. She was diagnosed after an abnormal finding on her routine mammogram and subsequently underwent a lumpectomy with axillary node dissection, chemotherapy, and radiation therapy. She was started on the aromatase inhibitor letrozole 1 month ago. Prior to being diagnosed, her health history was unremarkable other than being overweight (body mass index 29). She had significant personal stressors in her life including the death of her father during cancer treatment and the end of her marriage of 20 years last year. She reported trouble both falling asleep and staying asleep. She was prescribed many medications but preferred to take nonpharmaceuticals. She presented to the integrative medicine team for "holistic treatment."

Integrative Medicine Plan and Response

The initial integrative medicine consult consisted of an in-depth discussion of Aurelia's view of her illness, goals for her health, and understanding of her current social, spiritual, emotional, and environmental aspects of well-being.

Psycho-social-spiritual: In discussion, it became clear that, in many ways, Aurelia had been compartmentalizing her feelings in order to focus on the demands of her healthcare during treatment. She noted a feeling of tightness or heaviness in her chest that she associates with her emotional and physical fatigue. She noted never having time to grieve the loss of her father due to her own illness, and additionally didn't fully process the grief of the loss of her marriage, and now the loss of her health as the one thing she saw as intact in her life. Her cardiac evaluation was normal, and she did work with a therapist in cognitive behavioral therapy (CBT) weekly for the past year.

Recommendation: The grief and emotional stressors were not the sole cause of fatigue, but could be significant contributors. Aurelia found CBT helpful as a support but didn't feel like it helped her fully process her emotions. Energy therapy with Reiki was suggested, with a discussion about how traumas sometimes benefit from a therapy that works at a different level and can help move "stuck" emotions and support healing. She was additionally taught a brief Loving Kindness Meditation (LKM), to send loving emotions to herself and to troubling situations. Aurelia had been exploring essential oils and chakra/energy readings, so this approach was very appealing to her. She saw an experienced Reiki practitioner at the Osher Center weekly for 8 weeks and did the LKM meditation twice daily. At her follow-up visit she noted that, in her first few treatments, she had deep releases where she was sobbing on the massage table. She said after this early session that she felt a bit drained, but also cleansed. At the end of 2 months, she noted no longer feeling any chest tightness; she felt lighter, and while she still struggled with feelings of loss they were more manageable. Her sleep was improved and more restorative. She planned to continue Reiki sessions monthly, continue the meditation practice, and still see her therapist twice monthly as she created her vision for what came next.

Musculoskeletal: The joint aching was clearly associated temporally with starting the aromatase inhibitor. She noted this was a barrier to her being physically active, as she knew the importance of both physical activity and weight management for reducing the risk of breast cancer recurrence. She was considering stopping the medication unless the symptoms could be controlled.

Recommendation: The data on acupuncture for her situation were reviewed with Aurelia. She had received acupuncture during her chemotherapy sessions in the infusion suites by Osher center acupuncturists, and she felt they helped minimize her symptoms. Given her positive experience, she was interested in exploring this option. She began acupuncture sessions in the Osher Center, and was also given Traditional Chinese Medicine (TCM) herbs based on her TCM diagnosis. At the 2-month follow-up she noted some improvement in the symptoms starting at the fourth session. Given the positive trend, she planned to continue to see if she could have complete resolution.

Prevention: Aurelia had already received basic nutrition and physical activity counseling through the Cancer Survivorship program. She was making positive changes but sought additional counseling and wondered if she should be taking any dietary supplements. A full dietary and physical activity history was taken, and while she had been making some positive changes, her prior diet was low in vegetables, fruits, and fibers and had daily added sugars and refined carbohydrates. Lab tests revealed vitamin D deficiency and low essential fatty acids. Vitamin D supplements and fish oil were recommended, along with a shift toward a whole-food plant-based diet. Given her prior sedentary lifestyle and joint discomfort, she started an exercise regimen that included longer daily walks at a higher intensity and twice-weekly restorative yoga classes. At 2-month follow-up she had lost 5 pounds and was ready to increase her program, so 30 minutes of high-intensity interval training was added twice a week.

Chronic Pain

Pain is a complex phenomenon involving physical, emotional, social, and spiritual aspects that all must be addressed. Depression, anxiety, and spiritual distress can all increase the perception of pain intensity, and addressing these components can reduce the need for pain medication.[26] A comprehensive review of all effective integrative and complementary therapies for these concerns is impossible given the enormous diversity in this area. This chapter will share some of the most current data on mind-body approaches (e.g., movement, relaxation therapies, music, aromatherapy, massage, and acupuncture), and then review common dietary supplements for symptom management in serious illness or at end of life. Many modalities are quite effective for a number of symptoms in palliative care and have been studied in different populations.

Mind-Body Approaches for Pain

Physical Activity

Patients with cancer are often discouraged from engaging in exercise during cancer treatment, but the positive effects of continuing exercise on QOL, weakness, fatigue, and mood are documented in a number of studies.[27] A 10-year longitudinal study of post-treatment breast cancer patients showed that pain was significantly reduced in patients who maintained regular physical activity and an ideal body weight, as opposed to those women who had a weight gain of more than 5%, who were obese or overweight, and had a sedentary lifestyle.[26]

Massage Therapy

Massage therapy encompasses many different styles, but in patients with advanced chronic illness, gentler forms such as Swedish massage may be better tolerated. In a meta-analysis of studies involving massage for adult oncological patients receiving palliative care, 4 of 6 studies showed a statistically significant reduction in pain.[28] Other studies looking at the lasting benefits of massage on pain were less favorable, showing that the immediate benefits of massage seem to be higher than the longer term effects. Qualitative data from studies have also shown that interventions such as massage therapy seem to be effective if the patient is treated with empathy and if a relationship between the massage therapist and the patient had been formed beforehand.[29]

Aromatherapy

Aromatherapy—the therapeutic use of essential oils—is an increasingly popular option for use by nurses in inpatient and palliative care settings. The aromatic organic compounds are typically applied in one of three ways: (1) inhalation; (2) topically during baths, massage, or on a compress; or (3) through oral ingestion. A 2016 meta-analysis of 12 studies examined the use of aromatherapy for pain management.[30] It concluded that there was a significant positive effect of aromatherapy compared to controls (placebo or treatments as usual) in reducing pain reported on a visual analog scale, with stronger correlations found in nociceptive and acute pain versus inflammatory and chronic pain. Lavender was the most commonly studied essential oil, with others being orange, eucalyptus, clary sage, chamomile, rose, ginger, rosemary, peppermint, and lemongrass. Applications included hand massage, localized massage, acupressure, sitz baths, and vaporized, and the populations included children, pregnant women, and patients with chronic pain or in hospice. Many patients and healthcare providers are attracted to aromatherapy because of its low cost and minimal side effects.[31]

Acupuncture

Acupuncture involves the insertion of fine sterile disposable needles into specific body points along energy pathways known as *meridians* to address imbalances and thereby alleviate symptoms and prevent or treat disease. Traditional Chinese acupuncture is based on the health concept of Qi ("chee") or vital life force energy. Many studies and systematic reviews have been done but are generally not considered to be of sufficient quality to reach conclusions. However, a 2012 analysis of acupuncture for pain showed improved pain relief in patients who received acupuncture for back or neck pain, osteoarthritis, or chronic headache.[32] A 2016 meta-analysis of 20 randomized clinical trials (n = 892) reported that acupuncture alone was not superior to pharmacotherapy for cancer-related pain; but, of significance is that combination therapy may be more effective, resulting in quicker pain relief, longer pain remission, and improved QOL.[33] At the Sao Paulo Cancer Institute, 183 patients were enrolled in an acupuncture study that showed significant reductions in cancer pain, chemotoxicity, lumbar pain, and chronic postoperative pain.[34] Individual studies on acupuncture or electroacupuncture for aromatase inhibitor-related arthralgias suggest reduced pain and stiffness in treatment groups versus placebo or sham acupuncture, though these results did not achieve significance in a meta-analysis.[35] In 2016, the National Cancer Institute held a symposium on Acupuncture for Symptom Management in Oncology with a call to action for additional research.[36]

Music/Music Therapy

Simple music that is relaxing can be provided by anyone—typically healthcare staff—in what has been termed "music medicine." In contrast, in "music therapy" patients work with a trained music therapist in a therapeutic relationship where music (prerecorded, live, and/or interactive) is individualized based on a professional assessment.[37] The interventions in this review are generally classified as either *music medicine* or *music therapy*. In music medicine interventions, patients listen to prerecorded music that is administered by healthcare staff and preselected by study investigators, who may or may not have any formal training in music therapy.[7,8] Because there are a wide variety of modalities of music therapy, it has been difficult to perform reviews that give strong recommendations. Music can raise endorphin levels in the brain and lower adrenaline levels.[38] Music therapy has been studied in intensive care unit settings: Zimbardo and Gerrig found that 30 minutes of classical music therapy equaled the relaxation effects of 10 mg of diazepam.[39] Two recent studies in inpatient palliative care units suggest music therapy in this setting is feasible, well-received, and associated with promotion of relaxation and well-being.[40,41]

Mindfulness

Mindfulness-based stress reduction (MBSR) is an 8-week program of teaching moment-to-moment awareness of mind-body interactions through practices such as meditation, Hatha yoga, breath awareness, and body scan meditation. A meta-analysis review of studies using MBSR was significantly correlated with reductions in the anxiety, chronic pain, stress, and depression often found in patients at the end of life.[42]

Guided Imagery

Guided imagery has been shown to reduce anxiety, pain, and stress and to promote relaxation in some small trials.[43] Through guided imagery techniques, patients can learn to control functions normally controlled by the autonomic nervous system such as heart rate, blood pressure, respiratory rate, and body temperature. Through guided imagery, the patient can create an image of pain and then transform it into something less powerful and frightening.

Natural Products for Pain

Polypharmacy with nutritional supplements is to be avoided, similar to polypharmacy with medications, as these can increase the burden on the patient and caregiver without significant benefit as well as increase risk of interactions. In most cases of patients imminently dying, almost all nutritional supplements can be discontinued except for those giving specific symptom relief.[44] Supplements and herbs often utilized in pain management include turmeric, capsaicin, arnica, polyunsaturated fatty acids, vitamin D, and medical cannabis.

Curcuma longa (turmeric) has a growing body of evidence for the treatment of pain associated with osteoarthritis. This is likely related to the laboratory evidence showing that curcumin functions as a selective cyclooxygenase-2 (COX-2) inhibitor. A head-to-head clinical trial of curcumin supplementation in comparison with ibuprofen in the treatment of knee osteoarthritis demonstrated a similar treatment effect of each medication, with less gastrointestinal adverse events associated with curcumin.[45]

Capsaicin has been used topically for pain. Numerous studies have shown safety and modest efficacy of low-concentration formulations. A single 60-minute application in patients with neuropathic pain produced effective pain relief for up to 12 weeks. Topical capsaicin acts in the skin to attenuate cutaneous hypersensitivity and reduce pain by a process best described as "defunctionalization" of nociceptor fibers.[46] Over-the-counter (OTC) strength capsaicin (.025% to .075%) has been available for a long time, and studies did not show benefit beyond placebo.[47] More recently an 8% capsaicin patch has been used with more positive results.[48] A single patch applied for 30–90 minutes showed significant relief in the treatment of postherpetic neuralgia. The patch is difficult to tolerate as it causes a severe burning sensation and must be premedicated with topical lidocaine and even oxycodone. Capsaicin has also been studied in other conditions. Although enrolling only small numbers, the work done by Bhaskar and colleagues in cancer-associated neuropathic pain showed that almost 71% of patients in this subgroup had 90% pain relief.[49]

Arnica gel is an OTC product that has promising benefit. In 2013, a Cochrane Database Systematic Review concluded that "arnica gel probably improves symptoms as effectively as a gel containing nonsteroidal anti-inflammatory drug. . . . Comfrey extract gel probably improves pain, and Capsicum extract gel probably will not improve pain or function at the doses examined in this review. Further high quality, fully powered studies are required to confirm the trends of effectiveness identified in studies so far."[50]

It is thought that *omega-3 fatty acid* supplementation may have an anti-inflammatory effect.[51] Ramsden and colleagues performed a randomized controlled trial (RCT) examining the impact of omega-3 fatty acid supplementation for the treatment of chronic headaches. There was a significant reduction in the measures of headache intensity pain, in addition to increased markers of antinociceptive lipid mediators.[52]

There have been significant efforts examining the role of *vitamin D* in pain processing that involve complex pathophysiologic pathways. Earlier studies have demonstrated that high rates of hypovitaminosis D are prevalent in subjects with fibromyalgia and chronic pain. Several review studies have concluded that, although there seems to be a trend toward vitamin D supplementation and decreased pain, there is a need for further RCTs.[53] Considering that much time in hospice and palliative care is spent indoors and away from the best source of vitamin D, the sun, this is a worthy consideration.

Cannabis can potentially help alleviate neuropathic pain. Cannabinoid receptors are located in the central and peripheral nervous system (CB1) and the immune system (CB2). Numerous studies have shown safety and efficacy for central and peripheral neuropathic pain, rheumatoid arthritis, and cancer pain.[54] Studies in chemotherapy-induced peripheral neuropathy have shown that the activation of CB1 and CB2 receptors suppresses the development of vincristine-induced peripheral neuropathy in rats.[55] Nabiximols is an oromucosal spray of a formulated extract of the *Cannabis sativa* plant that contains the principal cannabinoids delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) in a 1:1 ratio. It is available in Canada and Europe for treatment of peripheral neuropathy. Studies in the United States were not found to be clinically significant but showed promise, and further study is warranted.[56]

THC has been shown to enhance the analgesic effect of narcotics. Abrams et al. performed a small study that showed significant decreases in overall pain scores after the addition of vaporized cannabis.[57] More study is needed, but this combination may lead to lower doses of opioid treatment with fewer side effects. Cannabis has been shown to be safe (no one has ever died from an overdose) and not likely to cause dependence (thought to be equally addictive as caffeine).[58]

Although CBD and THC are the most popular known cannabinoids, other cannabinoids within the whole plant also have significant therapeutic properties, including cannabigerol (antitumor), cannabichromene (analgesic, anti-inflammatory, and antibiotic), and tetrahydrocannabivarin (although psychoactive, contains antidiabetic and anti-obesity properties). CBD alone (the nonpsychoactive cannabinoid) has been shown to reduce nausea, pain, and inhibit cancer growth on its own. Because CBD can be derived from hemp and not the cannabis plant itself, individuals in states that do not license medical marijuana who wish to try this option may have access to hemp-derived CBD products.[59]

Mood and Sleep

Mind Body Approaches for Mood and Sleep

Physical Activity: Yoga

A meta-analysis of 13 randomized, controlled trials of yoga in cancer survivors documented significant reductions in distress, anxiety, and depression; moderate reductions in fatigue; moderate increases in social and emotional function and QOL; and a small increase in functional well-being.[27]

Aromatherapy

An RCT of 15 days of inhaled lavender essential oil in 60 patients in an intensive care unit showed statistically significant increased quality of sleep and reduced level of anxiety in patients with coronary artery disease based on the Pittsburgh Sleep Quality Index (PSQI) and the Beck Anxiety Inventory (BAI) scale.[60] Another RCT compared a 4-week trial of blended essential oil (*Lavendula angustifolia, Salvia sclarea*, and *Origanum majoranava*) versus lavender essential oil versus acupressure massage versus placebo in 132 career women.[61] All treatment groups showed significant improvements in PSQI and Short Form 36 Health Survey (QOL) ($p < 0.05$), with the greatest benefit in the blended essential oil treatment group.

A meta-analysis of mindfulness-based therapy suggests it is moderately effective for improving anxiety and mood symptoms from pre- to post-treatment in an overall sample totaling 1,140 participants in 39 studies.[62] Importantly, these effects were maintained over follow-up and were found in populations including those with cancer, generalized anxiety, and chronic pain disorders. Mindfulness-based therapies have also been developed to support caregivers of palliative care patients, with promising improvements in mental distress and life satisfaction.[63]

Energy Medicine

Biofield therapies are based on the premise that each person has an endogenous biofield, which affects physiologic processes.[64] Biofield or energy therapies are purported to improve the balance of the biofield through the practitioner's gentle laying on of hands, placement of hands within the biofield, or distance-based healing.

Healing Touch (HT) is a biofield therapy endorsed by the American Holistic Nurses Association and the Canadian Holistic Nurses Association.[65] HT has the most standardized training, with an independent certification after completing five levels of training. A pilot study of HT found it to have positive effects on stress, fatigue, pain, and mood of patients with cancer.[66]

Reiki is a system of natural healing considered an energy medicine practice. Reiki is administered by the gentle laying of hands on top of or above a clothed individual so the Reiki practitioner can act as a conduit for energy to flow to needed areas in the recipient. One small study showed benefit in well-being, relaxation, pain relief, sleep quality, and reduced anxiety.[67] More study is needed as most RCTs have yielded inconclusive results.

Therapeutic Touch is another energy therapy based on the restoration of balance using a technique in which the hands are used to direct energy for healing purposes, usually without any direct physical contact. A Therapeutic Touch Program was introduced to a geriatric palliative care unit with treatments provided by volunteer Therapeutic Touch Practitioners.[68] A retrospective chart review suggests that implementation is feasible and appears to be safe and well-tolerated, with patients achieving a state of relaxation or sleep after treatment.

Acupuncture

Several RCTs and meta-analyses support acupuncture as both a beneficial monotherapy and as adjunct treatment, though others did not find evidence of efficacy.[69] The Canadian Network for Mood and Anxiety Treatments 2016 Clinical Guidelines for the Management of Adults with Major Depressive Disorder (MDD) rate acupuncture as a third-line treatment for patients with MDD.[69] Two systematic reviews and meta-analyses of auricular acupuncture and acupuncture with moxibustion for primary insomnia had positive results; however, the findings are limited by studies of poor methodological quality, insufficient sample size, and possible publication bias.[70,71]

Hypnosis

Hypnosis creates a state of "focused awareness and attention" during which the patient can be taught to undertake diversional thinking from unpleasant somatic experiences such as pain. One small study showed a select group of patients noted decreased anxiety and increased relaxation as a result of hypnosis.[72]

Natural Products for Mood and Sleep

Supplements and herbs commonly used for mood and sleep include S-adenosyl-L-methionine (SAMe), St. John's Wort, hydroxytryptophan (5HTP), and valerian.

SAMe

SAMe is a chemical found naturally in the body. SAMe is made in the body from methionine, an amino acid found in many proteins. It is known to help many of our cells function normally.[73] A meta-analysis of studies using SAMe in the treatment of depression showed favorable results.[74] SAMe also shows promise as an anti-inflammatory supplement used for pain relief in fibromyalgia.[75]

St. John's Wort

St. John's wort is a herb that is commonly used to treat depression. Many studies show that St. John's wort works as well as traditional antidepressants for the treatment of mild to moderate depression with fewer side effects. However, St. John's wort can react poorly with many medications and other supplements so drug–herb interactions should be checked before using.[76]

5HTP

5HTP is a serotonin precursor used to treat depression, fibromyalgia, migraines, insomnia, and tension headaches. While there is evidence that precursor loading may be of therapeutic value, particularly for the serotonin precursors 5-HTP and tryptophan, more studies of suitable design and size are needed for more conclusive results.[77]

Valerian Root

Valerian root is used primarily for insomnia, dyssomnia, and for anxiety-associated restlessness and sleeping disorders. It has also been used for many other conditions, but studies for these conditions are only preliminary in nature. A meta-analysis of 16 studies suggests that valerian might improve sleep quality without producing side effects.[78]

Melatonin

One well-known supplement used for sleep is melatonin. Orally, melatonin is used for jet lag, insomnia, shift-work disorder, circadian rhythm disorders in the blind, sleep–wake cycle disturbances, and nicotine and benzodiazepine withdrawal. Additionally, there are many studies using melatonin in combination with chemotherapeutic agents to promote cancer regression.[79]

Gastrointestinal Symptoms

Mind-Body Approaches for Gastrointestinal Symptoms

Acupuncture

The benefit of acupuncture for nausea and vomiting has been generally accepted for many years; the NIH Consensus Statement of 1997 supported acupuncture for adult postoperative and chemotherapy-related nausea and vomiting.[80] One point, the PC6 point (located 2½ to 3 fingerbreadths from the wrist crease up the arm), has the most convincing evidence, leading to FDA-approved wrist devices to provide acupressure at the PC6 point.[81–83] Acupuncture or acupressure that includes the PC6 point is a reasonable consideration for patients with persistent nausea and vomiting.

Hypnosis

Hypnosis is a psychotherapeutic technique performed by a trained clinician who uses therapeutic suggestions to produce changes in perception, cognition, affect, mood, behavior, and sensation that are mutually acceptable to the patient and provider.[84] Advanced practice nurses can receive training in hypnosis and can explore options through the Society for Clinical and Experimental Hypnosis and the American Society of Clinical Hypnosis. Hypnosis is a safe option for managing anticipatory nausea and vomiting for patients receiving chemotherapy. Patients can also be taught or can use audio versions of scripts for self-treatment.[85]

Progressive Muscle Relaxation and Guided Imagery

Progressive muscle relaxation (PMR) is a technique of alternately tensing and relaxing muscle groups in sequence throughout the body. Patients can do this on their own, but often will use a prerecorded script to guide the process. Guided imagery is often added to PMR to enhance mental visualization. The 2016 updated Multinational Association of Supportive Care in Cancer (MASCC)/European Society for Medical Oncology (ESMO) consensus recommendations for anticipatory nausea and vomiting in children and adults receiving chemotherapy confirmed their prior recommendation of progressive muscle relaxation training as a valuable therapy.[86]

Natural Products for Gastrointestinal Symptoms

Supplements and herbs specific for gastrointestinal concerns include glutamine, ginger, magnesium, and calendula.

L-Glutamine

L-glutamine is an amino acid found in high levels in the body. Although glutamine is traditionally classified as a nonessential amino acid, it is essential for maintaining intestinal function, especially during times of severe stress. L-glutamine is used for many conditions including diarrhea, HIV wasting, chemotherapy-induced mucositis, and for protection of immune and gut barrier function in people with esophageal cancer undergoing radiochemotherapy. Taking glutamine orally seems to enhance intestinal absorption of nutrients, decrease intestinal permeability, and increase weight gain in people with HIV/AIDS.[87] Research findings in chemotherapy-induced diarrhea have been inconsistent.[88,89]

Ginger

Ginger (*Zingiber officinale*) is a perennial plant grown in warmer climates. Its tuberous root is the source of the popular spice. Orally, ginger has been used for a host of conditions including motion sickness, diarrhea, dyspepsia, and anorexia, as well as nausea and vomiting. Topically, the fresh juice of ginger is used for treating thermal burns. The essential oil of ginger is used topically as an analgesic. Studies of ginger in treating antiretroviral-induced and chemotherapy-induced nausea and vomiting show promise.[90,91]

Magnesium

Magnesium is a mineral that is involved in more than 300 biochemical functions in the body. Most magnesium comes from dietary sources. There is some evidence that magnesium supplementation may enhance opioid-induced analgesia without increasing side effects and may also help with constipation.[92]

Calendula

Calendula (*C. officinalis*) is commonly known as pot marigold. Orally, it is used as an antispasmodic, to reduce fever, and for treating inflammation of the oral and pharyngeal mucosa. Clinically, Calendula mouthwash ameliorated the severity of radiotherapy-induced oral mucositis in patients with head and neck cancer.[93] As with most supplements, more study is needed.

Resources

Resources for Natural Products, Evidence, and Safety

It would likely be impossible to have knowledge about all herbs and supplements patients might be using, so it is helpful to have access to resources that could help in the understanding of indications for use, overall and comparative effectiveness, and potential side-effect profiles (Table 28.1).

Resources for Natural Products and Quality

In the United States, herbal medicines and dietary supplements are not subject to strict oversight by the FDA. In response to concerns about supplement quality, several third-party organizations now perform independent quality-control testing of actual products, providing information on whether supplements contain the stated ingredients and are free of contaminants. Consumer Lab, Natural Products Association, NSF International, and United States Pharmacopeia (USP) are several of the most prominent and commonly encountered organizations. Dietary supplements may have seals of approval from these organizations after successful testing. The website ConsumerLab.com is additionally an excellent resource available for a modest annual fee to help learn more about the supplements tested and recommended brands.

Resources for Deepening Knowledge about Integrative Medicine and Integrative Nursing

Learning about integrative nursing and health can be an enriching personal and professional experience. For many providers, it helps them reconnect to the reasons they pursued a career in healthcare in the first place. Learning can range from reading articles or online modules to conferences to degrees. Some examples of engaging courses are listed in Table 28.2.

Table 28.1 Resources: Natural products, evidence, and safety

Natural Medicines	https://naturalmedicines.therapeuticresearch.com/	Natural Medicines has several helpful point-of-care resources for the clinic setting including "Herb-Supplement Interaction," Medication Effectiveness," "Nutrient Depletion," and "Pregnancy-Lactation Checkers." The Clinical Management Series provides excellent diagnosis-based learning and monograph-based courses provide in-depth overviews of individual herbal medicines. Access to this resource is subscription-based: it is frequently included in hospital and health system libraries.
Memorial Sloan Kettering Cancer Center's About Herbs database	https://www.mskcc.org/cancer-care/diagnosis-treatment/symptom-management/integrative-medicine/herbs	A tool for the public as well as healthcare professionals with information on common herbs and other dietary supplements.

Table 28.2 Resources for deepening knowledge about integrative medicine and integrative nursing

Center for Spirituality & Healing: Integrative Nursing	https://www.csh.umn.edu/education/focus-areas/integrative-nursing	University of Minnesota offers the first Doctor of Nursing Practice (DNP) in Integrative Health and Healing and well as access to continuing education modules.
Center For Spirituality & Healing: Learning Modules	https://www.csh.umn.edu/education/online-modules-and-resources/learning-modules-healthcare-professionals	Online free modules offer an introduction to various topics in the field of complementary therapies. Each of the modules takes from 1 to 3.5 hours to complete and is organized into short sections. All modules feature content written by subject matter experts and reviewed by a faculty team from the schools of Nursing, Pharmacy and Medicine at the University of Minnesota.
American Holistic Nurses Association	http://www.ahna.org/	AHNA advocates for holistic nursing through continuing education, research, practice, networking, and advocacy.
Academy of Integrative Pain Management	https://integrativepainmanagement.site-ym.com/	AIPM mission: "To improve the lives of people with pain by advancing a person-centered, integrative model of pain care through evidence-guided education, credentialing, and advocacy that is now defined as 'best practice' in the National Pain Strategy published by NIH."
Osher Center for Integrative Medicine at Northwestern University	http://www.feinberg.northwestern.edu/sites/ocim/ http://ocim.nm.org/	The authors' location with websites highlighting clinical offerings, and an academic site with content for health professionals.
The Osher Collaborative for Integrative Medicine	https://www.oshercollaborative.org/	The Osher Collaborative for Integrative Medicine comprises an international group of six academic Centers at Harvard University, UCSF, Northwestern University, Vanderbilt University, University of Miami, and Karolinska Institute. The website provides links to resources from the programs.
National Center for Complementary and Integrative Health (NCCIH) is a National Institute of Health initiative	https://nccih.nih.gov/	NCCIH supports research and education in this evolving field. The website contains free online continuing medical education (CME), videocasts of the annual Distinguished Lecture Series, and databases for both clinical guidelines and systematic reviews.
Academic Consortium for Integrative Medicine & Health	https://www.imconsortium.org/	The mission of the Consortium is to advance integrative medicine and health through academic institutions and health systems. Many member institutions have clinical centers and education programs. Listings for members can be found on the site.
Academy of Integrative Health & Medicine	https://www.aihm.org/	An interprofessional association of integrative clinicians who embrace a person-centered, team-based approach to health care. AIHM provides transformational educational programs, connections to a global network, and resources and toolkits for our members.

Conclusion

CIM offers many more tools in the nurse's toolbox to deal with conditions and issues dealt with in palliative care. This chapter has only outlined in broad strokes some of the options available. Clinicians owe it to themselves and their patients to be aware, supportive, and even suggest some alternatives to conventional Western medicine. Embodying the principles of integrative nursing can bring connection and healing to the patient, the family, and, ultimately, to the caregiver.

CHAPTER 29

Withdrawal of Invasive Mechanical Ventilation

Margaret L. Campbell

Key Points

- Mechanical ventilation can be withheld or withdrawn.
- Respiratory distress can be anticipated, assessed, and treated during withdrawal of invasive mechanical ventilation.
- Death follows ventilation withdrawal along varying trajectories characteristic of the patient's illness severity and dependence on other life-sustaining interventions, such as vasopressors.

Case Study: A Patient on Mechanical Ventilation

George, a 43-year-old man, presented to the emergency department with difficulty breathing secondary to streptococcal pneumonia. He required intubation, invasive mechanical ventilation, and admission to the MICU. His long MICU course with refractory pneumonia was complicated by deep venous thrombosis, pulmonary embolus, and witnessed cardiac arrest. He sustained anoxic encephalopathy and remained ventilator dependent with a tracheostomy. After discussion of his poor prognosis, his family made a decision with the MICU team to forgo further aggressive life-sustaining measures and to withdraw mechanical ventilation. The family was given the opportunity to remain at the bedside or wait in a private area during the withdrawal process.

George was not able to respond to commands but did withdraw from painful stimuli. Thus, it was presumed that he could experience distress. Further, he was ventilator-dependent and at high risk for developing respiratory distress during spontaneous breathing. For these reasons, he was premedicated with morphine 4 mg as an intravenous bolus with 1 mg of lorazepam. A rapid terminal weaning was undertaken in which oxygen and ventilation were reduced in step-wise fashion until George was breathing spontaneously. During the step-wise weaning he was monitored with the Respiratory Distress Observation Scale (RDOS). At each step, he was remedicated with morphine 4 mg if the RDOS score indicated the presence of respiratory distress. He required two bolus doses of morphine during the weaning process.

The ventilator was turned off and a humidified room air trach collar was placed. A continuous morphine infusion at 50% of the total bolus doses was initiated to maintain respiratory comfort. George died 4 hours after ventilator withdrawal.

Benefits and Burdens of Mechanical Ventilation

Mechanical ventilation has been used for decades to support breathing when patients experienced acute or chronic respiratory failure. Mechanical ventilation is of benefit when the patient, for a number of reasons, cannot maintain normal ventilation as evidenced by increasing carbon dioxide and respiratory acidosis; to treat these conditions, invasive and noninvasive modalities are employed. Invasive mechanical ventilation is accomplished after the establishment of an artificial airway, such as an endotracheal tube or tracheostomy. Noninvasive mechanical ventilation is applied over the nose or nose and mouth via a tight-fitting face mask. Examples of noninvasive mechanical ventilation include continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP).

Invasive mechanical ventilation is employed after cardiopulmonary arrest, during general anesthesia, to treat respiratory failure that is not responsive to noninvasive ventilation, or for patients who are ventilator-dependent. Endotracheal intubation is used for periods of less than 2 weeks of ventilation; continued ventilation after 2 weeks is supported by tracheostomy. When respiratory failure occurs during an exacerbation of chronic pulmonary disease, noninvasive ventilation is often useful as a first response.[1] Patients with obstructive sleep apnea, chronic obstructive pulmonary disease (COPD), and amyotrophic lateral sclerosis (ALS) often use noninvasive ventilation at night or when breathing is difficult during the day.

Patients often experience discomfort during mechanical ventilation. With noninvasive modalities, the tight-fitting mask may produce generalized pressure-associated discomfort, feelings of suffocation, and pressure lesions on the bridge of the nose. Endotracheal intubation causes gagging, coughing, and drooling, and leaves the patient unable to verbalize because the tube passes through the vocal cords. In many cases of endotracheal intubation and some cases of noninvasive ventilation, the patient requires mechanical restraints or sedation to maintain the integrity of the life-saving treatment and to ensure ventilator synchrony.

Ventilator-dependent patients experience fewer burdens because they are routinely ventilated through a tracheostomy. Nonetheless, chronic ventilator dependence limits patient mobility and contributes to the development of immobility complications such as pressure ulcers, deep venous thrombosis, and pneumonia.

Ventilator withdrawal is considered as a treatment option when the treatment is more burdensome than beneficial, such as when the patient has a terminal illness or is unconscious or when the patient makes an informed, capable decision to cease treatment because her or his quality of life is poor. Ventilator withdrawal is conducted to allow a natural death free of tubes and machines.[2] In critical care units (adult, pediatric, and neonatal), ventilator withdrawal is usually undertaken because the patient is not expected to survive and/or to regain functional consciousness. Clinical standards, policies, and procedures about foregoing life-sustaining therapy, including mechanical ventilation, are in wide use and reflect broad agreement about the underlying principles regarding these decisions.[3]

Although withdrawal of ventilation occurs on a frequent basis across settings of care, there is little empiric evidence to guide the process. A review of the evidence to guide a ventilator withdrawal process demonstrated that small samples and largely retrospective chart reviews characterize the body of evidence about processes for ventilator withdrawal.[2] The cited research is not conclusive to make recommendations in all cases of ventilator withdrawal. However, a number of suggested processes may be useful in this clinical context, along with a team approach to the procedure and patient care to address anticipated symptoms.

Patients are ventilated because of respiratory failure and an inability to exchange respiratory gases without mechanical support. Dyspnea arises from increased inspiratory effort, hypercarbia, and/or hypoxemia; dyspnea is anticipated during and after ventilator withdrawal. Prevention and alleviation of dyspnea or respiratory distress becomes the focus of care during ventilator withdrawal. Some patients, if awake, may experience fear or anxiety before or during ventilator withdrawal, and this will require attention if present. Adult patients may experience barotrauma to the trachea from the pressure in the cuff, leading to laryngeal edema or spasm after extubation with development of post-extubation stridor.

Invasive Ventilator Withdrawal Processes

Advance Preparation

The Centers for Medicare and Medicaid Services has enacted guidelines for consistent processes around organ donation.[4] Hospital staff must notify their state Organ Procurement Organization (OPO) when decisions about ventilator withdrawal are being considered. The OPO will collaborate with the hospital staff to identify whether the patient is a donor candidate for donation after cardiac death and to seek consent from the next of kin. This evaluation by the OPO must be completed before ventilation is withdrawn. See Chapter 45 for more information regarding organ donation.

Timing to conduct the withdrawal process is generally negotiated with the patient's family and the healthcare team. This timing will depend on which team members will be present, including support personnel such as a chaplain. The time needs to be communicated to all clinical team members, and, ideally, the assigned nurse should have a reduced assignment to be able to spend one-on-one time with the patient and family.

Not all family members want to be present at the bedside during withdrawal. Another room nearby can be arranged with adequate seating, facial tissues, water, and access to a telephone. Religious observances or family-specific rituals need to be accommodated and completed before beginning the withdrawal process. Patient and/or family questions about what to expect can be addressed before beginning the process.[5] When ventilation is withdrawn from a small child, infant, or neonate, it is customary for a parent to hold the child on his or her lap during the process.

Neuromuscular blocking agents (NMBA), such as pancuronium or vecuronium, are being used with less frequency in the intensive care unit (ICU); when in use it is impossible to assess the patient's comfort. Thus, the NMBA should be discontinued with evidence of patient neuromuscular recovery before ventilator withdrawal is undertaken. In some cases, the duration of action of these agents is prolonged, such as when the patient has liver or renal failure and impaired clearance. Therefore, although controversial, withdrawal can proceed with careful attention to ensuring patient comfort if an unacceptable delay in withdrawing mechanical ventilation occurs because of protracted effects of NMBA.[6]

Measuring Distress

Dyspnea, also known as breathlessness, is a nociceptive phenomenon defined as "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social and environmental factors, and may induce secondary physiological and behavioral responses."[7] Dyspnea can be perceived and verified only by the person experiencing it. Many patients who are undergoing ventilator withdrawal are cognitively impaired or unconscious as a result of underlying neurological lesions or hemodynamic, metabolic, or respiratory dysfunction that produce cognitive impairment or unconsciousness. Respiratory distress is an observable (behavioral) corollary to dyspnea; the physical and emotional suffering that results from the experience of asphyxiation is characterized by behaviors that can be observed and measured.[8]

Most patients undergoing ventilator withdrawal will be unable to provide a self-report about any dyspnea experienced, particularly patients who are unconscious, severely cognitively impaired, or infants and neonates. Attempts to elicit a self-report should be made if the patient is conscious. Skill is required to detect nuances of behaviors, particularly when the patient is unable to validate the nurse's assessment. Initiation and escalation of sedatives and opioids should be guided by patient behaviors.

The RDOS is suitable for assessing the adult patient during the withdrawal of mechanical ventilation; reliability, validity, and intensity cut-points have been established.[8–10] This eight-variable categorical scale is the only known tool for assessing respiratory distress when the patient cannot self-report dyspnea, as typifies most patients undergoing ventilator withdrawal. Each variable is scored from 0–2 points and the points are summed. Scores range from 0 to 16: 0–2 = no distress, 3 signifies mild distress, 4–6 represents moderate distress, and scores of 7 or higher signify severe distress (Table 29.1). Infants and neonates often display nasal flaring, grunting at end-expiration, and sternal retraction.[11] Brain-dead patients by definition will not show distress, cough, gag, or breathe during or following ventilator withdrawal, and sedation or analgesia is not indicated.

Premedication for Anticipated Distress

As is the standard with pain management, opioids should be initiated to signs of distress and the advice to "start low and titrate slowly" is sage. For the opioid-naive adult, an initial intravenous

Table 29.1 Respiratory Distress Observation Scale

Variable	0 points	1 point	2 points	Total
Heart rate per minute	<90 beats	91–109 beats	≥110 beats	
Respiratory rate per minute	≤18 breaths	19–30 breaths	>30 breaths	
Restlessness: nonpurposeful movements	None	Occasional, slight movements	Frequent movements	
Accessory muscle use: rise in clavicle during inspiration	None	Slight rise	Pronounced rise	
Paradoxical breathing: abdomen moves in on inspiration	None		Present	
Grunting at end-expiration: guttural sound	None		Present	
Nasal flaring: involuntary movement of nares	None		Present	
Look of fear	None		Eyes wide open, facial muscles tense, brow furrowed, mouth open	
Total				

Copyright Margaret L. Campbell, PhD, RN.

bolus of 3–5 mg of morphine is recommended. Pediatric dosing is usually initiated at 0.05–0.1 mg/kg.[12] Anticipatory premedication is a sound practice if distress is already evident and if distress can be anticipated. There is no justification for medicating a brain-dead patient, and one could argue that the patient in a coma with only minimal brainstem function is also unlikely to experience distress. Doses that correspond to customary dosing for the treatment of dyspnea should guide dosing during ventilator withdrawal. Documentation of the signs of distress and rationale for dose escalation is important to ensure continuity across professional caregivers and to prevent overmedication and the appearance of hastening death. At the conclusion of the process, a continuous infusion may be initiated to maintain patient comfort; an infusion rate equivalent to 50% of the total amount of bolus medication is recommended. Thus, if the patient received three boluses of morphine at 5 mg (15 mg), the infusion would start at a rate of 7.5 mg/hr.

Weaning Method

Terminal extubation is characterized by ceasing ventilatory support and removing the endotracheal tube in one step. *Terminal weaning* is a process of stepwise, gradual reductions in oxygen and ventilation, terminating with placement of a t-piece or with extubation. In a pilot study, patients undergoing terminal extubation experienced more distress than patients with terminal weaning in an algorithmic, RDOS-guided approach.[13] Likewise, patients in the terminal extubation arm of a multisite comparison of extubation versus weaning were in more distress than those in the weaning arm.[14] Terminal extubation poses an abrupt change from supported ventilation to spontaneous ventilation in a fragile patient, likely contributing to the distress noted in these studies.

Rapid terminal weaning may afford the clinician the most control because it allows for careful, sequential adjustments to the ventilator with precise titration of medications to ensure patient comfort (Table 29.2).[13] Continuous patient monitoring with readily accessible opioids will afford the patient and family comfort regardless of method employed.

Extubation Considerations

Patients who are ventilator-dependent for 14 days or more are generally ventilated through a tracheostomy tube. After ventilator withdrawal, a tracheostomy collar with humidified room air or low-flow oxygen can be placed. Patients experiencing acute respiratory failure are ventilated through a nasal or oral endotracheal tube. Adult tubes have a cuff to maintain tube placement and occlude the trachea to prevent air leaking and loss of tidal volume; neonatal tubes are cuffless.

Removal of the endotracheal tube should be performed whenever possible because of patient comfort and the aesthetic appearance of the patient. However, in some cases airway compromise can be anticipated, such as when the patient has a swollen, protuberant tongue, or has no gag or cough reflexes. In cases of airway compromise, the disconcerting noises may be more distressing to the attendant family than the presence of the tube. Medication with dexamethasone may reduce airway edema permitting extubation when patients are at high risk for post-extubation laryngeal edema, but dosing would need to start 12 hours before withdrawal if the timing permits. A cuff-leak test entails measuring the volume of air loss when the endotracheal tube cuff is deflated prior to extubation. Air loss of less than 140 cc predicts post-extubation stridor.[15,16] Aerosolized racemic epinephrine is a useful intervention to reduce stridor after extubation.[16,17] Family counseling about usual noises that can be expected and that cause no distress should be done prior to extubation.[18]

Noninvasive Ventilator Withdrawal

Decisions to cease CPAP or BiPAP warrant a patient-centered approach similar to that used in the withdrawal of invasive mechanical ventilation. The number of process steps are fewer since there is no need to consider cuff-leak testing or extubation. Premedication for anticipated distress should be determined with the same criteria as with invasive mechanical ventilation. When the patient is comfortable, wean the FiO_2 by .20 every few minutes until room air level is reached (0.21). Turn off the pressure support and remove the mask. Medicate with morphine for reported dyspnea or displayed respiratory distress.

Ventilator Withdrawal at Home

Occasionally, a ventilator-dependent patient is cared for in the home or is transferred from hospital to home for ventilator withdrawal. The home setting for this procedure poses some significant

Table 29.2 Sample rapid wean

Process	Steps	Rationale
Planning	Cuff-leak testing	Affords prediction of post-extubation stridor.
Premedication: Patients able to experience distress (e.g., RASS +3 to −3)	Morphine 4 mg IV bolus	Morphine is effective for treating dyspnea. Comatose patients may not need premedication but should be monitored for distress development.
Weaning	1. Turn off PEEP 2. Wean FiO_2 by 0.2 every 1–2 minutes if no distress until FiO_2 = .21 (room air) 3. Change ventilator mode to SIMV at a rate of 10 with PSV at 5 cm. 4. Reduce SIMV rate by 2 breaths every 1–2 minutes if no distress until SIMV rate = 4. 5. Change ventilator mode to CPAP 0 PSV 5 cm 6. Turn off ventilator and remove from patient. 7. Extubate if cuff-leak test passed.	Step-wise weaning affords an opportunity to pause the process when distress develops. Patients are given the opportunity to "adjust" to each change rather than rapidly being changed from full ventilation to complete spontaneous breathing.
Assess distress	Measure RDOS at baseline and after every ventilator change.	Patients may develop respiratory distress anywhere along the trajectory from fully supported ventilation to spontaneous breathing.
Treat distress	Morphine 4 mg IV bolus whenever RDOS is ≥4.	RDOS 0–2 = no distress, 3 = mild distress.
Maintain comfort	Morphine infusion if patient needed medication during withdrawal and if predicted survival is more than minutes. Calculate the total morphine given during withdrawal as bolus doses. Begin infusion at a rate = 50% of total bolus doses. Titrate to maintain RDOS ≤3.	Patients may survive longer than minutes and can be triaged to a non-ICU bed. Nurse–patient ratios on non-ICU units do not afford frequent IV bolus dosing.
Treat stridor	Racemic epinephrine in 3 cc normal saline as an aerosol treatment. May need to be repeated ×1.	Opioids and benzodiazepines will not treat airway obstruction.

RASS, Richmond Agitation Severity Scale; PEEP, positive end-expiratory pressure; FiO_2, fraction of inspired air; SIMV, synchronized intermittent mandatory ventilation; CPAP, continuous positive airway pressure; RDOS, Respiratory Distress Observation Scale.

limitations if an intravenous access is not available, particularly if the patient is awake and aware. Awake, ventilator-dependent patients are at the highest risk of developing respiratory distress compared to patients with cognitive impairment or decreased consciousness. Respiratory distress can be treated with oral or subcutaneous morphine, however, the peak effect by these routes is longer than by the intravenous route, possibly posing a protracted interval for patient distress. An ideal home-based withdrawal should follow the same procedure as the ICU-based withdrawal with continuous nurse and respiratory therapist monitoring, immediate delivery of intravenous morphine to signs of respiratory distress, and the subsequent placement of a humidified trach collar after the ventilator is turned off. The intravenous access may be achieved by keeping the hospital line in place at discharge to afford use by the home care team. Alternatively, a peripheral line can be placed by the home care team.

A much slower weaning will need to be considered if an oral morphine is used. After each ventilator change, distress is measured. The weaning is paused when there is distress until the peak effect of morphine is achieved; this is as quick as 10 minutes intravenously and as long as 30 minutes by mouth. A terminal wean with an intravenous access generally occurs in 20–30 minutes, but a home-based withdrawal relying on oral or subcutaneous morphine may take a few hours.

Oxygen

A growing body of evidence suggests that oxygen is a useful palliative intervention to treat dyspnea when the patient is experiencing distress and is hypoxemic but offers no benefit when the patient has normal oxygenation.[19] Furthermore, when patients are near death and in no distress, oxygen is not necessary.[20] Thus, the patient can be cared for without oxygen following ventilator withdrawal unless there are signs of respiratory distress and hypoxemia. Nasal cannula is better tolerated than a face mask if oxygen is initiated.

Duration of Survival

Triage considerations after ventilator withdrawal may be guided by estimations of duration of survival. As expected, patients with the highest illness severity will die more quickly, particularly if they are also dependent on vasopressors or high levels of oxygen.[21,22]

Conclusion

Withdrawal of mechanical ventilation is a procedure that occurs with relative frequency. The benefits of this therapy, when initiated, is to replace failing lungs, extend life, and improve quality of life by relieving dyspnea associated with respiratory failure. When the burdens exceed the benefits, or when the patient is near death or unresponsive, decisions may be made to cease this therapy. Measures to palliate anticipated distress must be applied. A peaceful death after cessation of mechanical ventilation can be provided.

SECTION III

Psychosocial and Spiritual Support

CHAPTER 30

The Meaning of Hope in the Dying

Valerie T. Cotter and Anessa M. Foxwell

Key Points

- Hope is a key factor in coping with and finding meaning in the experience of life-threatening illness.
- People with life-threatening illness and their families do not invariably lose hope; in fact, hope can increase at the end of life.
- Nurses can implement evidence-based practices to foster and sustain hope for patients and families at the end of life.
- Nurses need to understand and respect individual variations in hope processes to provide sensitive, effective care to patients and their families at the end of life.

Introduction

Emily Dickinson said: "Hope is the thing with feathers, That perches in the soul, And sings the tune without the words, And never stops—at all."[1] Classic writings have contemplated hope, extolling it as a virtue and an energy that brings life and joy.[2–4] Fromm[2] called hope "a psychic commitment to life and growth."

Despite its positive connotations, hope is intimately bound with loss and suffering. As the French philosopher Gabriel Marcel[3] observed, "Hope is situated within the framework of the trial." It is this paradox that manifests itself so fully at the end of life. Indeed, the critical role that hope plays in human life takes on special meaning as death nears. The ability to hope often is challenged, and it can elude patients and families during terminal illness. Hope for a cure is almost certainly destroyed, and even a prolonged reprieve from death is unlikely. Many patients and families experience multiple losses as they continue an illness trajectory that is marked by increasing disability and pain.

Even when hope appears to be strong within the dying person or the family, it can be problematic if hopefulness is perceived to be based on unrealistic ideas about the future.[5] Tension grows within relationships as people become absorbed in a struggle between competing versions of reality. Important issues may be left unresolved as individuals continue to deny the reality of impending death.

Despite these somber realities and the inevitable suffering, many people do maintain hope as they die, and families recover and find hope even within the experience of loss. How can this be? Part of the reason lies in the nature of hope itself—its resiliency and capacity to coexist with suffering. As witnesses to suffering and hope, palliative care nurses must understand these complexities and be confident and sensitive in their efforts to address hope and hopelessness in the people for whom they care.

To assist palliative care nurses, this chapter explores the many dimensions of hope and identifies its possible influence on health and quality of life (QOL). Nursing assessment and strategies to foster hope are described. In addition, specific issues such as "unrealistic hopefulness" and cultural considerations in the expression and maintenance of hope are discussed. The goals of the chapter are to provide the reader with an understanding about this complex but vital phenomenon, to offer guidance in the clinical application of this concept to palliative nursing care, and to explore some of the controversies about hope that challenge clinicians.

Definitions and Dimensions of Hope

Hope is an important concept for many disciplines, including philosophy, theology, psychology, nursing, and medicine. A classic nursing theory of hope, developed by Karin Dufault,[6] is particularly notable in its comprehensiveness. Dufault described hope as "a multidimensional, dynamic life force characterized by a confident yet uncertain expectation of achieving a future good which, to the hoping person, is realistically possible and personally significant." Dufault also theorized that hope has two interrelated spheres: particularized and generalized. *Particularized hope* is centered and dependent on specific, valued goals or hope objects. An example is the hope of a terminally ill patient to live long enough to celebrate a particular holiday or event. In contrast, *generalized hope* is a broader, nonspecific sense of a more positive future that is not directly related to a particular goal or desire. Dufault likened this sphere to an umbrella that creates a diffuse, positive glow on life.

Dufault postulated six dimensions of hope: affective, spiritual, relational, cognitive, behavioral, and contextual. The affective dimension of hope encompasses a myriad of emotions. Of course, hope is accompanied by many positive feelings, including joy, confidence, strength, and excitement. The full experience of hope, however, also includes uncertainty, fear, anger, suffering, and, sometimes, despair.[7] The philosopher Gabriel Marcel, for example, argued that, in its fullest sense, hope could only follow an experience of suffering or trial.[3] Marcel's thesis is corroborated by the experiences described by people with cancer who see their disease as "a wake-up call" that has opened their eyes to a greater appreciation for life and an opportunity for self-growth—in other words, an event that has forced them to confront their mortality while also inspiring hope.[8] The spiritual dimension is a central component of hope.[8,9] Hopefulness is associated with spiritual well-being,[9,10] and qualitative studies have shown that spirituality and spiritual practices provide a context in which to define hope and articulate hope-fostering activities.[11,12] These activities include religious beliefs and rituals but extend to broader conceptualizations of spirituality that encompass meaning and purpose in life, self-transcendence, and connectedness with a deity or other life-force.[13,14] Although spirituality is almost always viewed as a hope-fostering influence, serious illness and suffering can challenge one's belief and trust in a benevolent deity or be viewed as punishment from God; either interpretation of suffering can result in hopelessness.[15]

Relationships with significant others are another important dimension of hope. Interconnectedness with others is cited as a source of hope in virtually every study, and physical and psychological isolation from others is a frequent threat to hope.[16,17] Hope levels are positively associated with social support.[18,19] In addition to family members and friends, nurses offer patients a unique and independent source of support for hope.[20,21] Harris et al.[16] reported that HIV peer-counseling relationships inspired hope in both the counseling recipients and their counselors. Despite being vital sources of hope, other people can threaten a patient's hope by distancing themselves from the patient, showing disrespect, discounting the patient's experiences, disclosing negative information, or withholding information.[20,22]

The cognitive dimension of hope encompasses many intellectual strategies, particularly those involving specific goals that require planning and effort to attain. Identifying goals can motivate and energize people, thereby increasing hope.[16,22] When identifying goals, people assess what they desire and value within a context of what is realistically possible.[23] They appraise the resources necessary to accomplish their goals against the resources that are available to them. They then take action to secure the resources or meet the goals, and they decide on a reasonable time frame in which to accomplish the goals.[24] Active involvement in one's situation and attainment of goals increases the sense of personal control and self-efficacy, which, in turn, increases hope.[23] If a person repeatedly fails to attain valued goals, hopelessness and negative emotions, such as anxiety, depression, or anger can result.[22]

The behavioral, goal-focused thoughts and activities that foster hope are similar to the problem-focused coping strategies originally described by Lazarus and Folkman.[25] This similarity is not surprising because hope is strongly associated with coping.[26] Hope has been identified as a foundation or mediator for successful coping, a method of coping, and an outcome of successful coping.[26,27] Many strategies that people use to maintain hope have been previously identified as coping methods, and models of maintaining hope overlap substantially with models of coping.[26] Strategies to maintain hope include problem-focused coping methods (e.g., setting goals, actively managing symptoms, getting one's affairs in order), emotion-focused strategies (e.g., using distraction techniques, appraising the illness in nonthreatening ways), and psychosocial processes (reminiscing, leaving a legacy, positive reappraisal, motivating processes).[26,28,29]

Contextual dimensions of hope are the life circumstances and abilities that influence hope—for example, physical health, financial stability, and functional and cognitive abilities. Common threats to hope include acute, chronic, and terminal illness; cognitive decline; fatigue; pain; and impaired functional status.[26,28] These factors, particularly physical illness and impairment, do not inevitably decrease hope if people are able to overcome the threat through cognitive, spiritual, relational, or other strategies.

Influence of Hope and Hopelessness on Adaptation to Illness

Hope influences health and adaptation to illness. Empirical evidence indicates that diminished hope is associated with poorer QOL,[27] persistence of suicidal ideation,[30] and higher incidence of suicide.[31] Hopelessness also increases the likelihood that people will consider physician-assisted death as an option for themselves.[32] Hopelessness is significant in the etiology and maintenance of depression.[31]

In addition to its influence on psychological states and behaviors, there is some evidence to suggest that hope affects physical states as well. Researchers have found associations between hopelessness and early markers of endothelial dysfunction, a precursor to atherosclerosis.[33] Rawdin and colleagues[34] reported that hope was associated with the psychosocial elements of the pain experience.

Variations in Hope among Different Populations

The preceding description of hope is derived from studies involving diverse populations, including children and older adults. In addition, research has been conducted in inpatient, outpatient, and community settings with well persons and those with a variety of chronic and life-threatening illnesses. The experiences of families also have been described. Over these diverse populations and settings, many core concepts have been identified that transcend specific groups. However, some subtle but important differences exist. For this reason, hopefulness in selected populations is addressed in the following sections.

Hope in Children and Their Parents

A few investigators have examined hope in children and their parents. Lotz and colleagues[35] studied pediatric advance care planning (ACP) in bereaved parents. The findings suggested that holding onto hope is important and should be directly addressed in ACP conversations in order to elicit realistic hopes and make meaningful plans.

Salmon and colleagues[36] explored how hope arose in interactions between oncologists and parents of children aged 1–12 years with acute lymphoblastic leukemia. The investigators found an interpersonal basis of hope (e.g., most parents linked their ability to hope to "having faith in" the oncologist and consistently valued oncologists' explicit positivity) and a psychological basis of hope (e.g., focusing on short-term events associated with treatment and avoiding information about the longer term).

In another study, van der Geest and colleagues[37] surveyed parents of children who died with cancer to evaluate relationships between parents' sources of coping and the impact of faith and hope for a cure on parents' long-term adjustment. Neither faith nor strengthening of faith were associated with less long-term traumatic grief or symptoms of depression, and remaining hopeful for a cure was not related to increased levels of traumatic grief or symptoms of depression.

Hope and Older Adults

Numerous studies have examined hope in ill and healthy older adults.[38–40] Findings from these studies suggest that certain hope-related themes and factors take on special significance for this age group. For example, in a recent metasynthesis of qualitative research, hope was described as an important psychological resource that helped older adults deal with chronic illness.[39] Older adults used two interrelated processes to help deal with their experience: (1) transcendence, a process of reaching inwardly and outwardly, and finding meaning and purpose; and (2) positive reappraisal, a recognition and acknowledgment that their situation had changed and they could see positive possibilities for the future. Although chronic illness that impairs physical functioning is linked with decreased hope, diagnosis of a life-threatening disease, such as cancer, is not associated with low levels of hope.[41] This finding may reflect an attitude among older adults that the QOL that remains matters more than the quantity.

Hirsch and colleagues[38] studied older adults recruited from primary care settings. They found that functional impairment was associated with increased depressive symptoms, and individuals with higher levels of hope experienced fewer depressive symptoms. Also, the ability to generate goals and resources to accomplish goals contributed to higher levels of hope.

Among younger European American adults, hope tends to be tied to being productive; personal and professional achievements figure prominently in one's ability to nurture and maintain hope. In contrast, older adults are more likely to focus on spirituality, relationships, leaving a legacy focused on others, finding meaning and purpose, and other factors that are not linked with accomplishment.[39] Hope-fostering activities include reminiscing, adjustment to transitions and losses, spirituality, and relationships with others.[29,39]

Hope from the Family Caregiver's Perspective

Family caregivers are an integral component in palliative care. Patients and families influence each other's hope, and nursing interventions must focus on both groups. Often, the physical and psychological demands placed on family caregivers are great, as are threats to hope.[12,28,42] Threats to hope in caregivers include isolation from support networks; questioning of one's spiritual beliefs; concurrent losses, including loss of significant others, health, and income; and inability to control the patient's symptoms. Kellas and colleagues[43] found that difficulties in communicating with healthcare providers, such as communicating misleading information or "false hope," prevented family caregivers' transition from particularized to generalized hope. Other studies found that hope played a significant role in family caregivers' perception of increased strain and overall QOL.[44,45]

Strategies to maintain hope in family caregivers are similar to those found in patients, with a few differences. Spending time with others in the support network is very important for caregivers. In addition, being able to reprioritize demands helps caregivers conserve much-needed energy. Toussaint and colleagues[46] found that the relationship between self-forgiveness and hope was twice the size for caregivers of patients with cancer, as compared to patients. Encouraging self-forgiveness may be important to promote hope and unburden self-blame.

Case Study: Mr. R, Hope in a Spiritual Person

At 68 years old, Mr. R presented to the hospital with progressive abdominal distention over 4 weeks. His past medical history included hypertension, type 2 diabetes, and depression. Imaging revealed large-volume ascites, omental caking, and peritoneal carcinomatosis. Over the course of the next month, he went through an army of diagnostic tests, all of which pointed to cancer, none of which revealed the primary source. During his hospitalization, his sister died and he was unable to attend the funeral due to weakness and continued need for frequent paracenteses. Mr. R's spirituality was central to his being. It was helping him cope with the death of his sister and his new illness. He was hoping to "live a normal life" after treatment. He defined "normal" as going to church, walking independently, and driving the church van to pick up fellow parishioners. Mr. R was also hoping for a cure. He told the palliative care nurse practitioner, "I have to remain positive. I have faith that if there is a cure, then I will be cured."

As Mr. R remained in the hospital, he continued to wait for a diagnosis. He struggled with the unknown and processed everything that was going on with his body. He wished he could go home for "just one day, to go to church on Sunday." When the oncologists began to favor lymphoma as a primary cancer, they began high-dose steroids. When his ascites persisted, they placed a peritoneal drain. The drain was the first visible sign of cancer for Mr. R. Clinically, he was worsening and the shape of his hope began to change. On a visit with the palliative care team, just 2 months after his symptoms began, he said the following:

> I know what I have to do. I want to be home and with my family. I fought the fight and I ran the race. Now I have to let the Lord have his way. Lord, let be what will be. Lord let me go, if that is your will. Whatever good I have left, let me do it wonderfully. Don't get me wrong, I'm scared of dying but I will find peace. There are many things that I have to say to people that I have not yet said. I wish that more people could know my heart . . .

As Mr. R's illness progressed, he began to hope for something new. At the beginning of his cancer journey, he hoped for normalcy and for a cure. Now he hoped for peace, to be with his family, to follow God's will, and to continue his generativity to others. Mr. R also hoped to go home with hospice care on a Saturday so he could buy a new suit and surprise everyone at church on Sunday.

Clearly, Mr. R expressed some complex abstract hopes for the time he had left; he also described tangible accomplishable hopes for the near future.

Hope in Terminally Ill Patients: Is Hope Compatible with Death?

Research demonstrates that many people are able to maintain hope during acute and chronic illness. Hope also can thrive during the terminal phase of an illness, despite the realization that no cure is possible. In qualitative and mixed-method studies, hope was maintained regardless of the severity of disease or the proximity to death.[10]

Although hope levels may not decrease, the nature of hope often is altered through the dying process. Other changes in hope at the end of life include an increased focus on relationships and trusting in others, as well as a desire to leave a legacy and to be well-remembered.[10,28] Spirituality also increases in importance for some patients during the terminal phases of illness.[28] People also adopt specific strategies to foster hope at the end of life.[10] Many of these approaches are summarized in Box 30.1.

Box 30.1 Sources of Hope/Hope-Fostering Strategies in Terminally Ill Adults

- Love of family and friends
- Spirituality/having faith
- Setting goals and maintaining independence
- Positive relationships with professional caregivers
- Humor
- Personal characteristics
- Uplifting memories

Although hope tends to change in people with terminal illness, maintaining a delicate balance between acceptance of death and hope for a cure often remains an important task up until the time of death, even when people acknowledge that cure is virtually impossible.[47,48] The dying person also needs to envision future moments of happiness, fulfillment, and connection.[10]

Case Study: A Patient Highlighting Cultural Differences

Mr. N was an 84-year-old active man who was working around his house one Wednesday morning when he began to have some slurred speech. His wife noticed his change in speech and wanted to call their sons. Mr. N insisted it would pass and agreed to rest on the couch. A few hours later, he began to experience right arm and leg numbness. His wife was alarmed and called her eldest son, who then called 911.

Mr. N was brought to the hospital and imaging confirmed a left internal carotid artery occlusion, believed to be cardioembolic. He underwent thrombectomy with a postoperative course complicated by encephalopathy and nonconvulsive status epilepticus. A week later, repeat imaging revealed new multifocal right acute ischemic infarcts.

Throughout the course of his hospital stay, Mr. N's wife and two adult sons were updated on his progress. Multiple family meetings were held where neurologists painted the picture of a poor prognosis. His son said, "I know that my father will never walk again, talk again, or eat again. I only hope that he can open his eyes again and recognize my mom's voice." Mr. N's son explained that his father had experienced many struggles in his life and they felt that he could recover, despite the odds.

Mr. N was born in China and lost his parents at the age of 9. He worked hard and immigrated to the United States in the 1980s with his wife. They made a life for themselves in Philadelphia. He became a licensed contractor, and they raised two sons. He was a stubborn man and overcame much adversity. His family said they would accept if he died naturally, but they struggled with actively withdrawing any form of life support when there was even a minor chance that he could wake up. Mr. N's family struggled with the sudden onset of his debility and hoped that he might retain the basic faculties of hearing and voice recognition.

Multicultural Views of Hope

Over the past three decades, understanding of the clinical phenomenon of hope has increased dramatically through theoretical discourse and empirical investigation. Although knowledge regarding the components, processes, and outcomes of hope has grown dramatically, progress in multicultural research on hope has been limited. The samples in many studies that examine hope or hopelessness are ethnically homogeneous,[34,49,50] or their ethnic composition is unknown.[24.44] The studies that do include ethnically diverse samples are small,[51,52] precluding any comparisons or generalization of findings.

Several excellent European studies have contributed greatly to the general understanding of hope.[24,36] However, many of these investigations use frameworks and instruments developed by US researchers whose work is founded on homogeneous samples. Moreover, it may be that hopefulness for Europeans is more similar to that of middle-class Americans than it is different.[28]

Farone and colleagues[53] examined the associations among locus of control, negative affect, hope, and self-reported health in 109 older Mexican American women with cancer. They found that hope and internal locus of control both showed significant associations with better health outcomes. Although these findings are similar to those for white, non-Hispanic samples, the authors cautioned that they were unable to explore the characteristics of control that may be unique to Latina populations. They recommended that future research include attribution of control based on religious beliefs and the concept of *fatalismo* (fatalism).

Despite the growing body of research in diverse samples, existing research may not adequately reflect the experience of hope for people from non-European cultures. Several known cultural differences could certainly limit the applicability of current conceptualizations of hope, especially within the palliative care context. Three issues that theoretically could have a major impact on multicultural views of hope are time orientation, truth-telling, and one's beliefs about control.

Time orientation is identified as a cultural phenomenon that varies among cultural groups. Some cultural groups, usually highly individualistic ones, are future-oriented. Within these groups, people prefer to look ahead, make short- and long-term plans, and organize their schedules to meet goals.[54] Because hope is defined as being future-oriented, with hopeful people more likely to identify and take action to meet goals, members of these future-oriented cultures may possibly appear more hopeful than people who are predominantly present-focused. On the other hand, people who are more focused on the present may be better able to sustain hope at the end of life, when the ability to create long-range goals is hindered by the uncertainty surrounding a terminal diagnosis. Additional research is needed to clarify these relationships.

The value for *truth-telling* in Western healthcare systems also may affect hope. Current ethical and legal standards require full disclosure of all relevant healthcare information to patients.[55] Informed consent and patient autonomy in medical decision-making, two eminent values in American healthcare, are impossible without this disclosure.[55] Although few would advocate lying to patients, truth-telling is not universally viewed as helpful or desirable.[56,57] In some cultures, it is believed that patients should be protected from burdensome information that could threaten hope. Truthful, but blunt, communication may also be seen as rude and disrespectful in some cultures, and the feeling of being devalued and disrespected has a negative impact on hope. In addition to the threats to hope that frank discussion is believed to engender, people who prefer non-disclosure of threatening information may be seen as attempting to cling to unrealistic hopes by refusing to listen to discouraging facts about their condition.

A third cultural concept that may affect hope is one's feeling of being in *control*. As described earlier, control is a core attribute in many conceptualizations of hope. Although control can be relinquished to others, including healthcare providers or a transcendent power, personal control often is central to the hoping process. In Euro-American cultures, applying one's will and energy to alter the course of an illness or to direct the dying process seems natural and desirable. Advance directives are one culturally sanctioned way in which members of these societies exert control over the dying process.[58] However, this desire for and belief in personal control is not a common feature in many other cultures. In cultures where death is viewed as part of the inherent harmony of living and dying, attempts to exert any influence over the dying process may seem unnatural or inappropriate.[58] People from diverse cultures who take a more passive role in their healthcare, or who do not espouse a desire to control their illness or the dying process, may be viewed as less hopeful than people who manifest a "fighting spirit" and active stance.

More research is needed to test theories of hope in multicultural groups, both to ensure the appropriate application of current conceptualizations to diverse cultural groups and to develop new theories that are relevant for these groups. Until this work is done, palliative care clinicians must be cautious in applying current hope theories and sensitive to the possible variations in diverse populations.

Models of Maintaining Hope for People with Life-Threatening Illnesses

Many investigators have identified factors that foster hope and strategies that enable people to sustain hope despite life-threatening or chronic illness. Although there is considerable concordance across these studies regarding many of the major themes, various models emphasize different styles and strategies that demonstrate the diversity in hope-fostering approaches.

As described previously, many people with terminal illness turn to activities and coping strategies that cultivate generalized hope rather than an emphasis on achievement and control. These strategies reflect a sense of peace and acceptance of death and center on "being" rather than "doing." These strategies are described in Box 30.1.

In contrast, Olsson and colleagues[28] found that patients preserved their hope using two goal-oriented or problem-solving processes: (1) maintaining life and (2) preparing for death. The patients tried to maintain life in several ways, by keeping up with their day-to-day tasks and hobbies; communicating with others about practical matters and emotional feelings; involving other people such as family, friends, or professionals; and actively searching elsewhere for something to give them hope. To prepare for death, patients took responsibility for planning their own funerals and other practical matters and arranged things so that family would have less of a burden. People use multiple strategies that allow them to confront and to avoid the negative aspects of illness and death. Although the strategies used to manage the threat of death often seem to predominate, these activities occur within a background of recognition and acknowledgment of the possibility of death. This process of negotiating between acknowledgment and management of these fears has been identified in other studies of people with life-threatening illnesses.[59]

Although some people continue to search for a cure after receiving a terminal diagnosis, hoping for a cure can coexist with awareness of death and engagement with life's activities.[29,47] Most people eventually accept their prognosis and mourn the loss of their original goals. At this point, they need to develop and pursue alternative goals that are possible in light of their diminished physical function, end-of-life symptoms, and loss of energy.

These different approaches for maintaining hope are important to describe and understand because they assist the palliative care nurse in designing effective strategies to foster hope. They increase clinicians' awareness regarding the various ways that people respond to chronic and terminal illness, and they guide clinicians in their interactions with patients and families to sustain hope. They also help palliative care providers understand difficult or troubling responses, such as unrealistic hopefulness.

The Issue of "Unrealistic" Hopefulness

Reality surveillance is a feature of many conceptualizations of hope. Often, clinicians, researchers, and theorists believe that mentally healthy people should choose and work toward realistic goals. In these frameworks, adhering to unrealistic hopes or denying reality is a sign of maladaptive cognitions that could lead to negative health outcomes.

Clinical examples of unrealistic hopes that cause consternation are numerous and diverse. For instance, one patient with advanced cancer might hope that his persistent severe sciatica is from exercise and overuse rather than spinal metastases. The nurse working with this patient may continually contradict his theory, asserting that his denial of the probable malignant cause of the pain will delay effective treatment. Another patient might insist that a new cure for her illness is imminent, causing distress for the nurse, who believes that the patient's unrealistic hopes will hinder acceptance of and preparation for death.

Despite these concerns, however, some investigators argue that the nurses' fears may be unfounded. This perspective is based on more recent studies that have led researchers to question the view that denial and unrealistic hopes are maladaptive. Instead, they argue that to believe these patients' professions of hope are unrealistic is to challenge or negate the legitimacy of the dominant depiction of the promise and potential cure provided by medical science.[60,61]

In addition to promoting positive outcomes, "unrealistic" hopes need to be assessed within the context of uncertainty. For instance, people frequently respond to dire prognostic news with the observation that they can always "beat the odds." Given that no one can predict the future with absolute certainty, it is impossible to predict which individuals with a 2% chance of remission or recovery will actually be cured. So, if a person hopes for something in the future that appears highly unlikely, can it be known for certain that it will not occur? Patients and families often need to focus on this uncertainty to sustain hope.[59] Research supports the idea that patients' and families' hopes and goals are effective coping strategies, even when the likelihood of obtaining them seems remote.[45]

Olsman and colleagues[60] conducted an interpretative synthesis of the literature showing that nurses and physicians could take three perspectives on hope of palliative care patients: (1) realistic perspective, (2) functional perspective, and (3) narrative perspective. Hope is viewed from a realistic perspective when hope is truthful and focused on adjusting hope to the truth. From a functional perspective, hope helps patients cope with treatments or face uncertainty. Nurses who take a narrative perspective focus on meaning that is valuable to patients. They also suggested that clinicians can take more than one perspective at the same time.

Assessing Hope

As in all nursing care, thorough assessment of physical and psychosocial factors must precede thoughtful planning and implementation of therapeutic strategies. Therefore, consistent and comprehensive evaluations of hope should be included in the palliative nursing assessment. Some conceptual elements of hope, such as those focusing on meaning and purpose in life, are included in a spiritual assessment. Rarely, however, are comprehensive guides to assessing hope included in standardized nursing assessment forms. In Table 30.1, examples of questions and probes can be used to assess hope.

Like pain, hope is a subjective experience, and assessment should focus on self-report. However, behavioral cues can also provide information regarding a person's state of hope or hopelessness. Hopelessness is a central feature of depression; therefore, behaviors such as social withdrawal, flat affect, alcohol and substance abuse, insomnia, and passivity may indicate hopelessness.

As discussed earlier, the patient's terminal illness affects the hope of family caregivers, who, in turn, influence the hope of the

Table 30.1 Guidelines for the clinical assessment of hope in palliative care

Interview question/probe	Rationale
Illness understanding	
1. What is your understanding of what's happened to you and the probable course of your illness?	Explore the person's perceptions of seriousness of his or her illness, and possible future
2. How hopeful are you right now, and how does your illness affect your sense of hope?	Determine the person's general sense of hope and the effect of the terminal illness on hope
Caregivers	
1. Who provides you with emotional, physical, and spiritual support?	Identify people that provide support and enhance hope
2. Who are you most likely to confide in when you have a problem or concern?	Identify others in whom the person has trust
3. What kinds of difficult experiences have you and your family/caregivers had to deal with in the past? How did everyone cope with those experiences?	Explore experiences of coping with stressful situations
4. What kinds of things do family, support people, and healthcare providers do that make you more hopeful? Less hopeful?	Identify specific behaviors that affect hope and recognize that other people can also decrease hope
Sources of meaning and purpose	
1. What gives you hope?	Identify relationships, beliefs, and activities that provide a sense of purpose and contribute positively to hope
2. What helps you make sense of your situation right now?	Identify the ways in which the person makes meaning of difficult situations
3. Do you have spiritual or religious practices or support people who help you? If yes, what are these practices or people?	Identify if and how spirituality acts as a source of hope
4. Has your illness caused you to question your spiritual beliefs? If yes, how?	Terminal illness can threaten the person's basic beliefs and test one's faith
5. How can we help you maintain these practices and personal connections with spiritual support people?	Identify ways in which clinicians and others can support spiritual practices that enhance hope
Quality of life	
1. How would you rate your overall quality of life (excellent, good, fair, or poor), and why?	Assess the person's perceptions and threats to quality of life
2. What do I need to know about you as a person to give you the best care possible?	Explore what is important to the person, and possible sources of hope
Coping with the illness	
1. How are you coping with this illness?	Gain insight into the ways the person is coping
2. Where do you find the strength to face your illness?	Explore the person's spiritual, religious, and existential values
3. How well are you able to cope with the symptoms of your illness? How do these symptoms affect your hope?	Uncontrolled end-of-life symptoms have been found to negatively influence hope
Sources of hope over time	
1. In the past, what or who has made you hopeful?	Identify sources of hope from the person's past that may continue to provide hope during the terminal phase
2. Right now who and what provides you with hope?	Identify current sources of hope
3. What do you hope for in the future?	Assess generalized and specific hopes for the future

Table 30.2 Descriptions of selected instruments to measure hope and hopelessness

Instrument name	Brief description
Beck Hopelessness Scale	20-item, true-false format Based on Stotland's definition of hopelessness: system of negative expectancies concerning oneself and one's future Developed to assess psychopathological levels of hopelessness; correlates highly with attempted and actual suicide
Herth Hope Index	12-item, 4-point Likert scale; total score is sum of all items; range of scores 12–48 Designed for healthy and ill populations Assesses three overlapping dimensions: (1) cognitive-temporal, (2) affective-behavioral, (3) affiliative-behavioral Spanish, Thai, Chinese, Swedish translations available
Hopefulness Scale for Adolescents (Hinds)	24-item visual analog scale Assesses the degree of the adolescent's positive future orientation Tested in several populations of adolescents; healthy, substance use disorders, emotional and mental health problems, cancer
Miller Hope Scale	40-item scale, 5-point Likert scale Assesses 10 elements: (1) mutuality/affiliation, (2) avoidance of absolutizing, (3) sense of the possible, (4) psychological well-being and coping, (5) achieving goals, (6) purpose and meaning in life, (7) reality surveillance–optimism, (8) mental and physical activation, (9) anticipation, (10) freedom Chinese, Swedish translations available
Snyder Hope Scale	12-item, 4-point Likert scale Based on Stotland's definition of hope; focus is on goals identification and achievement Tested in healthy adults, adults with psychiatric illness, children

patients. Therefore, the hope of the patient's family caregivers and other significant support people also should be assessed.

Over the past decades, researchers from several disciplines have developed instruments to measure hope and hopelessness. The theoretical and empirical literature documents the comprehensiveness and face validity of these tools. Advances in psychometric theory and methods have allowed the evaluation of multiple dimensions of validity and reliability. The development and use of well-designed and well-tested tools has contributed greatly to the science of hope. Although a thorough discussion of these measures is beyond the scope of this chapter, Table 30.2 provides a brief description of several widely used and tested instruments.

Nursing Interventions to Maintain Hope at End of Life

Clinicians, theorists, and researchers recognize that nurses play an important role in instilling, maintaining, and restoring hope in the people for whom they care. Researchers have identified many ways in which nurses assist patients and families to sustain hope in the face of life-threatening illness. Box 30.2 provides a summary of nursing interventions to instill hope. A brief perusal of this table

Box 30.2 Nursing Interventions to Foster Hope

Experiential Processes

- Prevent and manage end-of-life symptoms
- Use lightheartedness and humor appropriately
- Encourage the patient and family to transcend their current situation
- Encourage aesthetic experiences
- Encourage engagement in creative and joyous endeavors
- Suggest literature, movies, and art that are uplifting and highlight the joy in life
- Encourage reminiscing
- Assist patient and family to focus on present and past joys
- Share positive, hope-inspiring stories
- Support patient and family in positive self-talk

Spiritual/Transcendent Processes

- Facilitate participation in religious rituals and spiritual practices
- Make necessary referrals to clergy and other spiritual support people
- Assist the patient and family in finding meaning in the current situation
- Assist the patient/family to keep a journal
- Suggest literature, movies, and art that explore the meaning of suffering

Relational Processes

- Minimize patient and family isolation
- Establish and maintain an open relationship
- Affirm patients' and families' sense of self-worth
- Recognize and reinforce the reciprocal nature of hopefulness between patient and support system
- Provide time for relationships (especially important in institutional settings)
- Foster attachment ideation by assisting the patient to identify significant others and then to reflect on personal characteristics and experiences that endear the significant other to the patient
- Communicate one's own sense of hopefulness

Rational Thought Processes

- Assist patient and family to establish, obtain, and revise goals without imposing one's own agenda
- Assist in identifying available and needed resources to meet goals
- Assist in procuring needed resources; assist with breaking larger goals into smaller steps to increase feelings of success
- Provide accurate information regarding patient's condition and treatment in a skillful and sensitive manner
- Help patient and family identify past successes
- Increase patients' and families' sense of control when possible

reveals an important point about these strategies: for the most part, nursing care to maintain patients' and families' hope fundamentally is about providing excellent physical, psychosocial, and spiritual palliative care. There are few unique interventions to maintain hope, and yet there is much nurses can do. Because hope is inextricably connected to virtually all facets of the illness experience—including physical pain, coping, anxiety, and spirituality—improvement or deterioration in one area has repercussions in other areas. Attending to these relationships reminds clinicians that virtually every action they take can influence hope, negatively or positively.

Another vital observation about hope-inspiring strategies is that many approaches begin with the patient and family. The experience of hope is a personal one, defined and determined by the hoping person. Although others greatly influence that experience, ultimately the meanings and effects of words and actions are determined by the person experiencing hope or hopelessness. Many approaches used by people with life-threatening illness to maintain hope are strategies initiated with little influence from others. For example, some people pray; others distract themselves with television watching, conversation, or hobbies (i.e., knitting); and many patients use cognitive strategies, such as minimizing negative thoughts, identifying personal strengths, and focusing on the positive. For many patients and families, careful observation and active support of an individual's established strategies to maintain hope will be most successful.

Family caregivers and other support people should be included in these approaches. Ample evidence demonstrates that patients and people within their support systems reciprocally influence one another's hope. In addition, family and significant others are always incorporated into the palliative care plan and considered part of the unit of care. Maintenance of hope also is a goal after death, in that hope-restoring and -maintaining strategies must be an integral part of bereavement counseling.[62]

Specific Interventions

The framework for the following discussion encompasses the major themes found in the literature, and, although they are not mutually exclusive, they provide a useful organizing device. This section also includes a brief discussion of ways in which nurses need to explore and understand their own hopes and values in order to provide palliative care that fosters hope in others.

Experiential Process Interventions

The experiential process of hope involves the acknowledgment and acceptance of suffering while at the same time using the imagination to move beyond the suffering and find hope.[10] Included in these types of strategies are methods to decrease physical suffering and cognitive strategies aimed at managing the threat of the terminal illness.

Uncontrolled symptoms, such as pain, fatigue, dyspnea, and anxiety, cause suffering and challenge the hopefulness of patients and caregivers. Timely and adept symptom prevention and management is central to maintaining hope. In home-care settings, teaching patients and families the knowledge and skills to manage symptoms confidently and competently also is essential.

Other ways to help people find hope in suffering is to provide them a cognitive reprieve from their situation. One powerful strategy to achieve this temporary suspension is through humor. Humor helps put things in perspective and frees the self, at least momentarily, from the onerous burden of illness and suffering. Making light of a grim situation brings a sense of control over one's response to the situation, even when one has little influence over it. Of course, the use of humor with patients and families requires sensitivity as well as a sense of timing. The nurse should take cues from the patient and family, observe how they use humor to dispel stress, and let them take the lead in joking about threatening information and events. In general, humor should be focused on oneself or on events outside the immediate concerns of the patient and family.

Other ways to move people cognitively beyond their suffering is to assist them in identifying and enjoying that which is joyful in life. Engagement in aesthetic experiences, such as watching movies or listening to music that is uplifting, can enable people to transcend their suffering. Sharing one's own hope-inspiring stories also can help.

Another strategy is to support people in their own positive self-talk. Often people naturally cope with stress by comparing themselves with people they perceive to be less fortunate or by identifying attributes of personal strength that help them find hope.[63] For example, an elderly, married woman with advanced breast cancer may comment that, despite the seriousness of her disease, she feels luckier than another woman with the same disease who is younger or without social support. By comparing herself with less fortunate others, she can take solace in recognizing that "things could be worse." Similarly, a person can maintain hope by focusing on particular talents or previous accomplishments that indicate an ability to cope with illness. People may also cite their high level of motivation as a reason to feel hopeful about the future. Acknowledgment and validation of these attributes supports hope and affirms self-worth for patients and families.

Spiritual Process Interventions

Several specific strategies can foster hope while incorporating spirituality. These strategies include providing opportunities for the expression of spiritual beliefs and arranging for involvement in religious rituals and spiritual practices.

Assisting patients and families to explore and make meaning of their trials and suffering is another useful approach. Encouraging patients and families to keep a journal of thoughts and feelings can help people in this process. Suggesting books, films, or art that focuses on religious or existential understanding and transcendence of suffering is another effective way to help people make sense of illness and death.

Palliative care nurses also should assess for signs of spiritual distress and make appropriate referrals to spiritual care providers and other professionals with expertise in counseling during spiritual and existential crises.

Relational Process Interventions

To maximize hope, nurses should establish and maintain an open relationship with patients and members of their support network, taking the time to learn what their priorities and needs are and then addressing those needs in timely, effective ways. Demonstrating respect and interest and being available to listen and be with people—that is, affirming each person's worth—is essential.

Fostering and sustaining connectedness among the patient, family, and friends can be accomplished by providing time for uninterrupted interactions, which is especially important in institutional settings. Nurses can increase hope by enlisting help from others to help achieve goals. For example, recruiting friends or arranging for a volunteer to transport an ill person to purchase a gift for a grandchild can cultivate hope for everyone involved. It is important to help others realize how vital they are in sustaining a person's hope.

Rational Thought Process Interventions

The rational thought process is the dimension of hope that specifically focuses on goals, resources, personal control and self-efficacy, and action. Interventions related to this dimension include assisting patients and families in devising and attaining goals. Providing accurate and timely information about the patient's condition and treatment helps patients and families decide which goals are achievable. At times, gentle assistance with monitoring and acknowledging negative possibilities helps the patient and family to choose realistic goals. Helping to identify and procure the resources necessary to meet goals also is important.

Often, major goals need to be broken into smaller, shorter term achievements. For example, a patient with painful, metastatic lung cancer might want to attend a family event that is 2 weeks away. The successful achievement of this goal depends on many factors, including adequate pain control, transportation, and ability to transfer to and from a wheelchair. By breaking the larger goal into several smaller ones, the person is able to identify all the necessary steps and resources. Supporting patients and families to identify those areas of life and death in which they do have real influence can increase self-esteem and self-efficacy, thereby instilling hope. It also helps to review their previous successes in attaining important goals.

This domain also includes ways in which clinicians balance the need to communicate "bad news" while sustaining patients' and families' hope. The difficulties inherent in delivering negative information to patients and families does not release us from our duty to communicate openly and honestly; however, it does require that palliative care nurses and other clinicians communicate skillfully in ways that assist patients and families to sustain hope. There are many articles describing empirically derived methods for delivering bad news sensitively and communicating in ways that maintain hope.[52,64]

Programs to Enhance Hopefulness

In addition to discrete actions that individual nurses take to foster hope, several investigators have developed and tested programs to enhance hope in people with life-threatening illness.

Duggleby and colleagues[29] evaluated the effectiveness of the Living with Hope Program (LWHP), a brief intervention designed for older adults with advanced cancer receiving home-based palliative care services. Grounded in their earlier research,[21] the LWHP is a 1-week intervention consisting of a visit from a trained assistant, a copy of the film "Living with Hope," and a choice of one of three hope-focused activities. The investigators found that LWHP participants used four psychosocial processes (reminiscing, leaving a legacy, positive reappraisal, and motivating processes) while participating in the intervention that fostered hope.

Rustøen and colleagues[24] studied the effects of a professional-led group intervention on hope and psychological distress in a community-based sample of cancer patients. The intervention consisted of eight 2-hour sessions focused on belief in oneself and in one's ability, emotional reactions, relationships with others, active involvement, spiritual beliefs and values, and acknowledgment that there is a future. The results showed increased hope levels and decreased psychological distress immediately following the intervention; however, this was not sustained at the 3- and 12-month assessments. The investigators suggested that, like other cognitive-behavioral interventions, additional "booster sessions" would have been helpful.

Hall and colleagues[65] conducted a randomized controlled trial to assess the ability of dignity therapy to reduce distress in advanced cancer patients. The intervention was comprised of an interview with a therapist in which the patient discussed the most important aspects of their life and their legacy or advice to family and friends they most want to be remembered. The interview was tape-recorded, transcribed, and edited into a document, which the patient could share with family and friends. Levels of hope and self-reported benefits were higher in the intervention group at 1- and 4-week follow-up, as compared to the control group.

Ensuring the Self-Knowledge Necessary to Provide Palliative Care

Providing holistic palliative care requires a broad range of skills. Astute management of physical symptoms and a solid command of technical skills must be matched with an ability to provide psychosocial and spiritual care for patients and families at a time of great vulnerability. To nurture these latter skills, nurses should continually reflect on and evaluate their own hopes, beliefs, and biases and identify how these factors influence their care. In an intriguing study, investigators examined the relationship between nurses' hope and their comfort in caring for and communicating with dying children and their families. They found that, after controlling for the number of years in nursing, nurses' hope and hours of palliative care education both were significantly associated with comfort in caring for dying children and their families.[66] These findings underscore the importance of education and self-reflection in delivering compassionate, skilled palliative care. In providing high-quality care, nurses also should evaluate how they are affected by patients' and families' responses and strategies to maintain hope. For example, does it anger or frustrate the nurse that the patient seems to refuse to acknowledge that his or her disease is incurable? Is this anger communicated nonverbally or verbally to the patient or family? In addition to self-reflection, it is important for palliative care nurses to remain hopeful while working with dying patients by engaging in self-care activities.

Conclusion

Hope is central to the human experience of living and dying, and it is integrally entwined with spiritual and psychosocial well-being. Although terminal illness can challenge and even temporarily diminish hope, the dying process does not inevitably bring despair. The human spirit, manifesting its creativity and resiliency, can forge new and deeper hopes at the end of life. Palliative care nurses play important roles in supporting patients and families with this process by providing expert physical, psychosocial, and spiritual care. Sensitive, skillful attention to maintaining hope can enhance QOL and contribute significantly to a "good death" as defined by the patient and family. Fostering hope is a primary means by which palliative care nurses accompany patients and families on the journey through terminal illness.

CHAPTER 31

Bereavement

Inge B. Corless and Janice Bell Meisenhelder

Key Points

- "Bereavement" is the state of having experienced the death of a significant other.
- "Loss" is a generic term indicating the permanent absence of a current or future possession or relationship.
- "Mourning" encompasses the death rituals engaged in by the bereaved.
- "Grief" is an emotional response to loss.

Bereavement

With the pronouncement of death, those who have the closest blood or legal connections to the deceased are considered *bereaved* in a given society. Bereavement confers a special status on the individual, entailing both obligations and special rights. The obligations concern disposition of the body and any attendant ceremonies, as well as disposal of the worldly goods of the deceased unless indicated otherwise in a legal document such as a last will and testament. The rights include dispensation from worldly activities such as work and, to a lesser degree, family roles for variable periods of time. Bereavement entails loss, grief, and recovery, and associated processes.[2] Before an expanded discussion of bereavement is undertaken, it is important to distinguish the concept of bereavement from such related terms as "loss," "mourning," and "grief."

Loss

"Loss" is a generic term that signifies absence of an object, position, ability, or attribute. More recently, it also has been applied to the death of a person or pet. Absence or loss of the same entity has different implications depending on the strength of the relationship with the owner. For example, loss of a dog with which there was an indifferent relationship results in less emotional disruption for the owner than the loss of a dog that was cherished. The term often is applied to the death of an individual, and it is the bereaved person who experiences the loss. That is not to say that friends and colleagues don't also feel a sense of loss with the death of a cherished friend or colleague or even an admired political or entertainment figure. When a loss occurs, its meaning is determined by the person(s) who sustained the loss. The attributes of loss can be formulated as follows:

- Loss in this context signifies the permanent absence of a given relationship or possession.
- Each loss is valued differently and ranges from no or little value to great value.
- The meaning of the loss is determined primarily by the individual sustaining it.

This suggests that it is wiser not to make assumptions about loss, but to query further as to its meaning to the individual.

Mourning

Mourning has been described in various ways. Kagawa-Singer[3] described mourning as the social customs and cultural practices that follow a death. This definition captures the social construct of mourning practices and the obligation of the bereaved to engage in these practices, such as participation in the customary rituals appropriate to membership in a given group. These rituals and behaviors acknowledge that a loss has occurred for the individual and the group and that the individual and the group are adjusting their relationships so as to move forward without the presence of the deceased individual.

Mourning is also expressed in the symbolism entailed in funerals and burials. Burial grounds contain the expressions of what was considered appropriate in each time period for the memorialization of the deceased. These memorials may be above or below ground, in cemeteries or memorial parks, as part of individual graves or mausoleums, or be various permutations of these. The availability of space for burials influences the manner in which burials and memorials are constructed. Bachelor examines the various reasons for a visit to cemeteries by mourners, including to fulfill obligations, to help achieve independence from the deceased, and to seek solace.[4](p. 408)

Grief

Grief is the response to the loss of a person, pet, or object with which there was an emotional attachment. As Stroebe and Boerner[5] note, grief is a "normal, emotional reaction to the loss of a loved person and not a psychiatric disorder."(p. 576) Nonetheless, the process of grief has been studied and reformulated, phases identified, types proposed (anticipatory, complicated, disenfranchised), and expressions of grief described. Given that nurses work largely with individuals and families, but in some cases also with communities, several sections of this chapter focus on grief as it relates to these different entities.

The Process of Bereavement

Bereavement takes many forms. It is influenced significantly by culture. In Victorian times, bereaved women in the northeastern United States wore black for a year and used black-edged stationery, while men wore a black armband for a matter of days before resuming their regular activities. Bereavement is also guided by religious practice, the nature of the relationship with the deceased, the age of the deceased, and the manner of death. For example, the impact of the additional factor of refugee status for an émigré Muslim widow living in Denmark is reflected in the story of her experience.[6] This epitomizes the multiple factors that affect the bereavement experience. Changes have occurred in what is considered "appropriate" for those who are bereaved. The wearing of black by a widow ("widow's weeds") for the remainder of her life and the presumption that grief will be "resolved" within a year are no longer societal or professional expectations.

Routine bereavement care involving a check-in with the bereaved can be helpful in identifying people at risk for complicated grieving. Situations in which individuals are expected to "get on with it" may pose difficulties for those who are bereaved. Individuals who have demanding work responsibilities may not receive the support required as a result of the need to remain productive. For individuals who are unable to avail themselves of face-to-face support groups, whether for reasons of time, distance, or responsibilities, an Internet support group may be an option. Pector[7] provides a host of such online resources. Given that the best therapy is prevention, palliative care teams who identify caregivers at risk for bereavement maladjustment can intervene early to prevent long-term difficulties.

Aside from such proactive approaches for all bereaved persons, Sheldon[8] reported the following predisposing factors for a poor bereavement outcome: ambivalent or dependent relationship; multiple prior bereavements; previous mental illness, especially depression; and low self-esteem. Other predisposing factors for poor bereavement outcomes include sudden and unexpected death, untimely death of a young person, lack of preparation for the death, stigmatized deaths (e.g., AIDS, suicide, culpable death), sex of the bereaved person (e.g., elderly male widower), caring for the deceased person for more than 6 months, and inability to carry out valued religious rituals.[8]

A nationwide study in Denmark found that those bereaved by spousal suicide had higher risks of developing mental and physical disorders (cirrhosis; sleep disorders) than the general population.[9] Furthermore, there were higher risks of mental disorders, suicidal behaviors, and mortality compared with spouses bereaved by causes other than suicide. Boyle, Feng, and Raab[10] note that widowhood increases the risk of death regardless of the type of death of the spouse. They observe that the risk of mortality is increased 10–40% for the surviving spouse.

In addition to the professional caregiver's gut feeling that this relative will not do well, other predictive factors of poor outcomes include level of perceived social support, hardiness, lack of opportunities for new interests, and stress from other life crises, as well as dysfunctional behaviors and attitudes appearing early in the bereavement period, consumption of alcohol and drugs, smoking, and morbid guilt.[8,10] Other poor outcomes, in a study conducted in Ireland, included the patient dying in a hospital (when that was not their choice), a relative stopping work to care for the dying person, being a close relative, and lower socioeconomic status.[11] Those who remained employed and in cases where the dying person had no preference as to place of death experienced better bereavement outcomes.

Another consideration that has an impact on bereavement is the caregiving demand on the family. The contributions of family members to providing care at home include personal care, preparation of food and drink, illness-related care (symptom management, appointments), shopping, and other tasks. In a national study conducted of cancer caregivers, it was found that the mean number of hours per week spent in such activities was almost 95 hours with a median of 69.5 hours.[12] This time expenditure exceeds the 24.5 hours previously reported. These demands can place a significant strain on the family and may have an impact on the bereavement experience, depending on how the caregiving experience is viewed by the caregiver and the family. In another study of caregivers and bereavement, there was no difference with regard to gender as to caregiver demographic characteristics other than a difference between younger and older spousal caregivers.[13] Younger widows and widowers experienced greater unmet social needs and were less likely to be able to "move on" with their lives.

Wartime bereavement has its own set of challenges. With the death of a service member, the spouse and children contend not only with the grief attending to the death of a loved one but may also lose their military base or other housing provided to them as service member families. The wife or husband also loses his or her role as a military spouse.[1] The importance of practical support for the bereaved is underscored whether they are military or civilian.[1,14]

Mental distress prior to bereavement, such as depression and anxiety, as well as a high level of perceived burden with lack of support, was predictive of a poor bereavement outcome.[15] Knowledge of and alertness to such predisposing factors are useful for the provision of help, both lay and professional, early in the course of the bereavement and even prior to bereavement so as to prevent further debilitating events for caregivers. In addition to social support, healthcare policy, such as paid time off for family illness or a bereavement leave, can have a profound effect on the experience of bereavement as part of the context in which care is provided.[16]

Mourning

O'Gorman contrasted death rituals in England with those in Ireland. She recalled the "Protestant hushed respectfulness which had somehow infiltrated and taken over a Catholic community."[17](p. 1133) The body was taken from the home by the funeral director. Children continued with school and stayed with relatives; they were shielded from the death. By way of contrast, in an Irish wake, "The body, laid out by a member of the family in order to receive a 'special blessing,' would be in the parlour of a country house surrounded by flowers from the garden and lighted candles."(p. 1133) The children, along with the adult members of the family, viewed the corpse. "When visitors had paid their 'last respects' they would join the crowd in the kitchen, who would then spend all night recounting stories associated with the dead person."(p. 1133) O'Gorman noted the plentiful availability of alcohol and stated, "by the end of the night, to the uninitiated the event would appear to be more like a party than a melancholy event."(p. 1133) Although O'Gorman initially found this distasteful, she "now believes that rituals like the Irish wake celebrate death as a happy occasion and bestow grace upon those leaving life and upon a community of those who mourn them."(p. 1133)

The Irish wake, like the reception held in a church basement, hall, restaurant, or private home, serves not only for the expression of condolences but also as an opportunity to reinforce the connections of the community. Anyone familiar with such events knows that a variety of social and business arrangements are made by mourners both within and outside the immediate family. And although some gatherings are more reserved and others lustier, giving the deceased a good send-off ("good" being defined by the group) is central to each. The good send-off is part of the function of the funeral as a transitional rite—that is, as a means of atoning for the sins of the mortal being and as preparation for life in the afterworld. The value of the Irish wake, which in the United States may look more like the Protestant burial O'Gorman[17] describes, is the time spent together sharing stories and feelings.

In the United States, funeral services are held not only in religious establishments such as churches or synagogues, but also in funeral homes. These services, frequently under the aegis of a clergyperson, may also be conducted by a staff member of the funeral home. More recently, these services have also taken on the earmarks of a memorial service, accompanied by pictures of the deceased and the bereaved and remarks by selected close family members and friends of the deceased.

With the Irish wake as practiced in Ireland, one is not alone with one's feelings but in the company of others who are devoting the time to mourning (integration). This devotion of time to mourning is also found in the Jewish religion, where the bereaved "sit shiva," usually for 7 days.[18] In Judaism, the assumption is that the bereaved are to focus on their loss and the grieving of that loss. They are to pay no attention to worldly considerations. This period of time of exemption from customary roles may facilitate the process. Certainly, having a "minion," in which 10 men and women (10 men for Orthodox Jews) say prayers each evening, reinforces the reality of the death and the separation. For the Orthodox, the mourning period is 1 year.

A very different pattern of mourning is practiced by the Hopi of Arizona. The Hopi have a brief ceremony with the purpose of completing the funeral as quickly as possible so as to get back to customary activities.[19] The fear of death and the dead, and of spirits, induces distancing by the Hopi from nonliving phenomena. Stroebe and Stroebe[19] contrasted Shinto and Buddhist mourners in Japan with the Hopi. Both Shinto and Buddhist mourners practice ancestor worship; as a result, the bereaved can keep contact with the deceased, who become ancestors. Speaking to ancestors as well as offering food is accepted practice. In contrast to this Japanese practice, what occurs in the United States is that those bereaved who speak with a deceased person do so quietly, hiding the fact from others, believing others will consider it suspect or pathological. It is, however, a common occurrence. As mentioned previously, bringing food to the ancestor or (e.g., to celebrate the Day of the Dead) to the cemetery is part of the mourning practice in Hispanic and many other societies. These practices have many functions, including signifying respect for the deceased and providing a mechanism for the expression of feelings by the bereaved.

Practices, however, change with time, although one can often find the imprint of earlier rituals. The practice of saving a lock of hair or the footprint of a deceased newborn may have evolved from the practice in Victorian times of using hair for mourning brooches and lockets. Today, virtual or online memorials take the form of personal web pages in a study by Mitchell and colleagues, who suggest that "virtual memorials blur the boundaries between the living and the dead."[20(p. 426)] The authors posit, "Virtual memorials may even imply a kind of ethereal techno-presence whereby the ideal of heaven is being reconfigured as technologically mediated space/time: a digital set of pearly gates."[20(p. 428)] These mourning practices of virtual memorials provide continuing bonds with the deceased and offer a clue to the answer to the question posed for the last section of this chapter: When is it over? Before addressing this question, another needs to be raised and that is the question of support and an assessment of the type of support required. One such assessment is the Bereavement Common Assessment Framework.[21] This framework examines "Client and Family Factors, Caring and Death Experience, and Environmental Factors."[(p. 679)] As Blackburn and colleagues state:

> If palliative care services are to more fully address needs in bereavement, this necessitates a person-in-environment, individualized client-centered and holistic bereavement support program that encompasses experiences of the death, interpersonal and intra-psychic factors and situational and environmental factors.[21(p. 680)]

The Nature of Grief

Rubin and Schecter conceptualized bereavement-related grief into the two-track model of bereavement as a means of understanding and addressing the bereavement process and its outcome.[22] Track 1 addresses biopsychological functioning and is concerned with two questions: (1) "Where are the difficulties in biopsychological functioning?" (2) "Where are the strengths and growth manifest?" Track 2 examines the relationship to the deceased and focuses on two questions: (1) "What is the state of the desire to reconnect with the deceased affectively and cognitively?" (2) "What is the nature of the ongoing relationship to the deceased? Is the death story integrated?" In essence, bereavement involves adjusting to a world without the physical, psychological, and social presence of the deceased. Li and Chen used the dual-process model to examine social support as encompassing the emotional, instrumental and informational spheres.[23] Stroebe and Schut added the important concept of "overload" as it applies to "activities, events, experiences, and other stimuli."[24(p. 100)] What is important here is the inclusion of everyday life stressors as affecting both "loss oriented" and "restoration oriented" coping. Fasse and Zech (2016) also address the impact of everyday activities as an additional stressor.[25]

The death of a spouse/partner shortly after bereavement has been shown to be more likely to occur in elderly persons within the first 3 months after the death of their loved one.[26] Cardiovascular events are also more likely to occur, especially within the first 30 days following bereavement[27] but are manifested differently in people with cardiovascular disease (CVD). In women with CVD, bereavement was associated with decreased mortality as compared with married women, whereas widowed men with CVD experienced higher mortality than married men with CVD.[28] The researchers account for this in the elimination of the stress of caregiving for the wives. In addition, Stahl and colleagues found no "significant interaction between depressive symptoms and bereavement."[28(p. 702)]

The distinction between grief and depression in the bereaved is an important one. As Middleton and colleagues[29] concluded, "The bereaved can experience considerable pain and yet be coping adaptively, and they can fulfill many depressive criteria yet at the same time be experiencing phenomena that are not depressive in nature." Even in individuals with a history of "sadness or irritability" before bereavement, although they may have more intense expressions of grief, the rate of recovery is the same as for those without such a history.[30] Fried and colleagues (2015) assert that their analysis reveals the complexity of the relationship between bereavement and depression and conclude that bereavement most likely engenders loneliness.[31] Other authors are not as sanguine and caution that subsyndromal symptomatic depressions are "frequently seen complications of bereavement that may be chronic and often are associated with substantial morbidity."[32] For example, more intense grief with an increasing risk of depression was identified in the caregivers of middle-aged cancer patients.[33] Furthermore, in Korea, using a nationally representative sample, there was a relatively high prevalence of both anxiety (48%) and depressive symptoms (57.6%) in family caregivers, 2–6 months post bereavement.[34] Being the spouse, and the younger age of the deceased and the spouse were associated with increased risk of both anxiety and depression.[34] It should be noted that the first 6 months and especially the period from 1 to 6 months post bereavement are the most challenging for many bereaved individuals. The debates about the nature of depression and grief in bereavement have taken on new relevance given the publication of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5),[35] discussed later in this chapter.

Various theorists have developed a series of stages and phases of grief work. The most well-known to the general public are those stages formulated by Elizabeth Kübler-Ross. Proposed for those facing a death, these stages have also been applied to those experiencing a loss. Kübler-Ross[36] identified five stages: denial and isolation, anger, bargaining, depression, and acceptance. The commonality among all theorists of the stages of grief is that the individual moves through (1) notification and shock, (2) experience of the loss emotionally and cognitively, and (3) reintegration. Based on these stages, Corr and Doka[37] proposed the following tasks:

1. To share acknowledgment of the reality of death.
2. To share in the process of working through the pain of grief.
3. To reorganize the family system.
4. To restructure the family's relationship with the deceased and to reinvest in other relationships and life pursuits.

With regard to the last task, some dispute has arisen concerning the degree to which separation from the deceased must occur. Klass and colleagues[38] make the compelling argument that such bonds continue. They opine that "survivors hold the deceased in loving memory for long periods, often forever" and that maintaining an inner representation of the deceased is normal rather than abnormal. Winston's study of African American grandmothers demonstrates that they maintained strong bonds with the deceased.[39]

The second area of dissension is the expectation that intense grief must be resolved within 2 weeks. More will be said later in the chapter about the changes in the time frame for the so-called *bereavement exclusion* for a diagnosis of major depressive disorder.

A third area of discussion concerns whether the concept of recovery, or some other term, best connotes what occurs after coming to terms with a death and getting on with one's life.[40,41] It has been suggested that "recovery" is a term more appropriate to an illness and that death is a normal process of life. Balk,[42] however, argues for a term that incorporates the potential for transformative growth.

A fourth area of debate is the issue of the medicalization of the grief process. Given that death is a normal part of the cycle of living, grief, too, is considered a normal process. As shall be observed in the following sections of this chapter, grief, although considered normal, may also become "complicated." As such, interventions may be needed. A medical diagnosis provides legitimacy to those engaged in the treatment encounter, including funding for those who are engaged in providing treatment.

A fifth area of vigorous discussion concerns the efficacy of grief counseling. Larson and Hoyt[43] provide a compelling argument about the efficacy of grief counseling and that the negative view of grief counseling's value is unfounded. The question of continuing bonds and the length of the grief process are addressed again at the close of this chapter. Readers are invited to consider all of these questions in light of their own experiences and readings of the literature. In this next section, types of grief are examined.

Types of Grief

The types of grief examined in this section are not exhaustive of all types of grief, but rather encompass the major categories. Different terms such as "common grief" and "chronic grief" may be used for some of these same phenomena.

Anticipatory Grief

Anticipatory grief shares similarities with other forms of grief. The onset may be associated with the receipt of bad news. Anticipatory grief must be distinguished from the concept of *forewarning*. An example of forewarning is learning of a terminal diagnosis. Anticipatory grief is an unconscious process, whereas forewarning is a conscious process. With forewarning of a terminal diagnosis, the question is, "What if we do?" With a death, that question becomes, "What if we had done?" With the former question, there is the potential for hope; with the latter query, there may be guilt.

Even with forewarning, preparation for loss may not occur, given that this may be perceived as a betrayal of the terminally ill person. There also have been instances of family members unconsciously preparing for the death of an individual and going through the grieving process only to have that person recover to find no place in the lives of his or her loved ones. This is an example of anticipatory grief.

Whether forewarning of death is helpful is dependent on how the time is used. If it is used to make some preparation for role change, such as becoming familiar with the intricacies of the role the terminally ill person plays in the family (e.g., mastering a checking account or other financial responsibilities of the family), such time may be used to the benefit of all concerned. On the other hand, anticipatory grieving resulting in reinvestment of emotional energy before the death of the terminally ill person is detrimental to the relationship.

Family members and friends are "warned" when their loved one is diagnosed with certain disease entities such as cancer with metastases. If the primary problem is Alzheimer's disease, there may be a long decline in which, ultimately, familiar figures are no longer recognized. In either situation, the death of the ill person may be experienced both with sadness and with a sense of relief that the caregiving burden is no more. The price of that relief is that the patient is no more.

The sense of relief experienced by caregivers is often a source of guilt feelings about wishing the patient dead. It is important to clarify for the family member or significant other that feelings of relief in being freed of the caregiver burden are not equivalent to wishing someone dead. A woman who experienced relief from not having to care for her bulky husband was assisted to examine this distinction and, consequently, was able to grieve uncomplicated by feelings of guilt. For other individuals, the concern is about what one did or didn't do prior to their loved one's death or guilt about once again feeling happy even though they are now bereaved.[44] Furthermore, persons who have cared for a dying person may experience a sense of accomplishment, knowing that they have done everything they could for their loved one. Research results on what makes an individual resilient after spousal loss include continued participation in everyday activities and in social relationships and the expectation that the survivor would receive comfort when needed.[45] In the following section, anticipatory grief is contrasted with what is termed "uncomplicated grief."

Uncomplicated Grief

In uncomplicated grief, an individual in a normal emotional state experiences a loss that causes a reaction and an emotional low; subsequently, the individual begins to recover to his or her former state. This process of recovery is occasioned by brief periods of relapse, but not to the depths experienced previously. Ultimately, the individual moves to adjustment to the loss. Although this description simplifies the turmoil that may be experienced, discussion of expressions of grief later in this chapter capture the physical, psychological, behavioral, and social upset that characterizes even uncomplicated grief.

Niemeyer[46] offered a new perspective by focusing on meaning reconstruction. He developed a set of propositions to capture adaptation to loss:

1. Death as an event can validate or invalidate the constructions that form the basis on which we live, or it may stand as a novel experience for which we have no constructions.
2. Grief is a personal process, one that is idiosyncratic, intimate, and inextricable from our sense of who we are.
3. Grieving is something we do, not something that is done to us.
4. Grieving is the act of affirming or reconstructing a personal world of meaning that has been challenged by loss.
5. Feelings have functions and should be understood as signals of the state of our meaning-making efforts.
6. We construct and reconstruct our identities as survivors of loss in negotiations with others.

Niemeyer[46] viewed meaning reconstruction as the central process of grief. The inability to make meaning may lead to complications.

Complicated or Prolonged Grief

Complicated and prolonged grief are terms for a prolonged, intense response to bereavement.[47(p. 652)] Researchers have identified the diagnostic criteria for complicated grief disorder. These criteria include "the current experience (>1 year after a loss) of intensive, intrusive thoughts, pangs of severe emotion, distressing yearnings, feeling excessively alone and empty, excessively avoiding tasks reminiscent of the deceased, unusual sleep disturbances, and maladaptive levels of loss of interest in personal activities."[48]

Other researchers have underscored the need for the specification of complicated grief as a unique disorder and have developed an inventory of complicated grief to measure maladaptive symptoms of loss.[49] The Inventory of Complicated Grief is composed of 19 items with responses ranging from "Never" to "Rarely," "Sometimes," "Often," and "Always." Examples of items include, "I think about this person so much that it's hard for me to do the things I usually do"; "Ever since she (or he) died it is hard for me to trust people"; "I feel that it is unfair that I should live when this person died"; and "I feel lonely a great deal of the time ever since she (or he) died."[49] This inventory may be helpful to healthcare practitioners because it differentiates between complicated grief and depression.[48] Finally, it is the severity of symptomatology and the duration that distinguishes abnormal and complicated responses to bereavement.[50]

The Inventory of Complicated Grief was used by Ott[51] with 112 bereaved participants in a study in which those identified as experiencing complicated grief were compared with those who were not. Those with complicated grief both identified more life stressors and felt they had less social support than the other bereaved individuals in the study. Lack of preparation for the death of a loved one has also been associated with complicated grief and depression.[52] The perspective of complicated grief as a stress response syndrome has been explicated by Shear and colleagues.[53] It is important to observe that the characteristics of complicated grief have not been found to vary by race or by the violence of the loss.[54,55]

It should be noted that there is some concern among professionals that what is a normal process is being transformed into a medical condition by healthcare practitioners. Complicated grief, however, may require professional intervention.[43,56] Approaches to therapy have included cognitive-behavioral therapy, presented face-to-face as well as over the Internet, and supportive counseling.[56] Bearing this in mind, disenfranchised grief poses different but potentially related problems.

Disenfranchised Grief

Doka[57] defines disenfranchised grief as "grief that results when a person experiences a significant loss and that the resultant grief is not openly acknowledged, socially validated or publicly mourned. In short, although the individual is experiencing a grief reaction, there is no social recognition that the person has a right to grieve or a claim on social sympathy or support." Those who are grieving the loss of relationships that may not be publicly acknowledged—for example, with a mistress or with a family conceived outside a legally recognized union, or in some cases with stepfamilies, colleagues, or friends—are not accorded the deference and support usually afforded the bereaved. Furthermore, unsanctioned relationships may result in the exclusion of individuals not legitimated by blood or legal union. Individuals in relationships of long-standing who care for their partners throughout their last illness may find themselves barred both from the funeral and from the home that was shared. For some time, infection with HIV was hidden from the community, thereby depriving both the infected and their caregivers support. The AIDS quilt has done much to provide a public mourning ritual but has not alleviated the disenfranchised status of gay or lesbian partners. This response to stigmatization constrains the public display of mourning by the griever. In this situation, the griever is not recognized. The griever with intellectual disabilities may also not be recognized. McEvoy and colleagues[58] examined the degree to which the person with intellectual disabilities comprehends the finality, universality, and inevitability of death. They conclude that there is only a partial understanding of death by their sample of individuals with intellectual disabilities. It is worth noting that some of the responses given could easily have been uttered by those without such disabilities. Clute[59] found that bereaved people with intellectual disabilities often grieve alone and are disconnected, with little help for their grief. As with any bereaved person, the most helpful approach is an individualized one.

There are other instances in which a loss has not been legitimized. Loss resulting from miscarriage or abortion has only recently been recognized. In Japan, a "cemetery" is devoted to letters written by families each year telling miscarried or aborted children about the important events that occurred in the family that year and also expressing continued grief at their loss. Grieving in secret is a burden that makes the process more difficult to complete. Disenfranchised grief may also be a harbinger of unresolved grief.

Unresolved Grief

Unresolved grief is a failure to accomplish the necessary grief work. According to Rando, a variety of factors may give rise to unresolved grief, including guilt, loss of an extension of the self, reawakening of an old loss, multiple loss, inadequate ego development, and idiosyncratic resistance to mourning.[60] In addition to these psychological factors, such social factors as social negation of a loss, socially unspeakable loss, social isolation and/or geographic distance from social support, assumption of the role of the strong one, and uncertainty over the loss (e.g., a disappearance at sea) may be implicated in unresolved grief. By helping significant others express their feelings and complete their business before the death of a loved one, unresolved grief and the accompanying manifestations can be prevented to some extent.

Eakes and colleagues[61] questioned whether "closure" is a necessary outcome. They explored the concept of "chronic sorrow" in bereaved individuals who experienced episodic bouts of sadness related to specific incidents or significant dates. These authors suggested the fruitfulness of maintaining an open-ended model of grief. With this in mind, grief is always unresolved to some degree; this is not considered pathological but rather an acknowledgment of a death. This model is now known as the theory of chronic sorrow.[62]

Expressions of Grief

In some of the earlier sections of this chapter, various manifestations of grief were mentioned. It is important to note that what is considered appropriate in one group may be considered deviant or even pathological in another. It bears repeating that the manifestations of grief and bereavement are influenced by culture.[63]

The perception of expressions of grief is also framed by professionals. For example, intense grieving beyond 2 weeks is considered in need of psychiatric intervention in the DSM-5.[35] In previous versions of the manual, grief was considered an exclusion for a diagnosis of major depressive disorder if bereavement occurred within a year, and subsequently 2 months, and now, in the current edition of the manual, 2 weeks. This has been a source of considerable debate, with professionals in the field of death and dying decrying such as approach as ill-advised and inappropriate. To quote from a letter from these experts: "Death is a life-altering event, but grief is not a pathological condition."[64] That is not to say that there are no physical, cognitive, and emotional responses to the death of a loved one. Balk and colleagues state, "We are concerned that for reasons of economic profit and clinical efficiency, people will often be prematurely diagnosed with depression and put on medication, rather than offered person-to-person counseling. Clinicians report anecdotally that this practice already occurs."[65(p. 208)] Wakefield warns against pathologizing grief when he states that the "grief process is less a step-wise preset series of events that lead to full resolution of pain, as classically portrayed, and more an individually constructed compromise between a degree of pain that never fully resolves and the need to compartmentalize that pain to move on with one's life."[66(p. 509)] Wakefield concurs with Bowlby that "normal grief can be a very lengthy process."[66]

In Table 31.1, physical, cognitive, emotional, and behavioral symptoms of grief are presented. Table 31.1 is not exhaustive of all of the potential symptoms, but rather is illustrative of the expressions and manifestations of grief. What distinguishes so-called normal grief is that it is usually self-limited. Manifestations

Table 31.1 Manifestations of grief

Physical	Cognitive	Emotional	Behavioral
Headaches	Sense of depersonalization	Anger	Impaired work performance
Dizziness	Inability to concentrate	Guilt	Crying
Exhaustion	Sense of disbelief and confusion	Anxiety	Withdrawal
Muscular aches	Idealization of the deceased	Sense of helplessness	Avoiding reminders of the deceased
Sexual impotency	Search for meaning of life and death	Sadness	Seeking or carrying reminders of the deceased
Loss of appetite	Dreams of the deceased	Shock	
Insomnia	Preoccupation with image of deceased	Yearning	Overreactivity
Feelings of tightness or hollowness	Fleeting visual, tactile, olfactory, auditory hallucinatory experiences	Numbness	Changed relationships
Breathlessness		Self-blame	
Tremors		Relief	
Shakes			
Oversensitivity to noise

of grief at 1, 3, and 15 months after a death are not the same in intensity. The widows in the study by Kowalski and Bondmass,[67] while experiencing a decline in symptomatology, also continued experiencing symptoms for up to 5 years—the limit of the bereavement experience of the research participants. Studies such as this may change our perceptions about grief.

A Question of Support

How important is the contribution of formal support in addition to the support of the social network of family and friends? The following sections will explore answers to this question.

Formal Support

Who needs support? The data provided by Aoun and colleagues[68] suggest that 68% of men and 54% of women are at low risk and need for bereavement support; 30% of men and 38% of women are at moderate risk, and 2% of men and 8% of women are at high risk and need for support.

Many of the mourning practices noted previously provide support by the community to the bereaved (Table 31.2). Formal support in the Jewish tradition is exemplified by the practice of attending a minion for the deceased person. The minion expresses support for the living. It is formal in that it is prescribed behavior on the part of observant Jews and incorporates a prayer service.

Other examples of formal support include support groups such as the widow-to-widow program and the Compassionate Friends for families of deceased children. The assumption underlying the widow-to-widow program is that grief and mourning are not in and of themselves pathological and that laypersons can be helpful to one another. The widow-to-widow program provides a formal mechanism for sharing one's emotions and experience with individuals who have had a similar experience. The Widowed Persons Service offers support for men and women via self-help support groups and a variety of educational and social activities. The Compassionate Friends, also a self-help organization, seeks to help parents and siblings after the death of a child. Other support groups may or may not have the input of a professional to run the group. Being in such a group, one doesn't have to explain oneself. The other participants have "gone through something so close, it's quite scary."[69(p. 9)]

Table 31.2 Bereavement practices

Lay	Professional
1. Friendly visiting	1. Clergy visiting
2. Provision of meals	2. Clergy counseling
3. Informal support by previously bereaved	3. Nurse, MD, psychologist, social worker, psychiatrist, counseling
4. Lay support groups	4. Professionally-led support groups
5. Participation in cultural and religious rituals	5. Organization of memorial service by hospice and palliative care organizations
6. A friendly listener	6. A thoughtful listener
7. Involvement in a cause-related group	7. Referral to individuals with similar cause-related concerns
8. Exercise	8. Referral to a health club
9. Joining a new group	9. Referral to a bereavement program

Aoun et al.[70] underscore the importance of using social networks. For those bereaved by suicide, Shields and colleagues suggest psychoeducation.[71] The importance of support and acceptance in such cases cannot be underemphasized given the higher risks of developing a mental disorder.[9,72] The question is whether support is readily available to what some may consider a devalued death, such as one by suicide or substance misuse—in essence a voluntary death, a stigmatized death.[73] Bottomley, Burke, and Niemeyer found that social support was associated with "reduced emotional struggles" by the grievers in the sample.[74]

Formal programs for children's bereavement support include peer support programs and art therapy programs. Institutions with bereavement programs, whether for children or adults, often send cards at the time of a patient's death, on the birthday of the deceased, and at 3, 6, 12, and 24 months after the death. Pamphlets with information about grief, a bibliography of appropriate readings, and contact numbers of support groups are also helpful. Family bereavement programs have been found to lead to improved parenting, coping, and caregiver mental health. The provision of bereavement follow-up to parents who have experienced the loss of a child or a pregnancy loss is helpful to the parents and also has implications for the support of the nurses and others who deliver this service.[75]

Attention to staff bereavement support has been given by institutional trauma programs, in emergency departments, and in critical care departments.[76] Brosche[77] provides a description of a grief team within a healthcare system. Keene, Hutton, Hall, and Rushton[78] outline a format for bereavement debriefing. This attention to the grief of healthcare providers empowers those involved to express their grief rather than to suppress it. All of these programs, whether for healthcare providers or family and significant others, maintain contact with the bereaved so as to provide support and make referrals to pastoral care personnel and other professionals as needed.

A variety of approaches have been used in working with the bereaved. Indeed, the combination of "religious psychotherapy" and a cognitive-behavioral approach was observed to be helpful to highly religious bereaved persons.[79] Religious psychotherapy for a group of Malays who adhered to the religion of Islam consisted of discussion and reading of verses of the Koran and Hadith, the encouragement of prayers, and a total of 12–16 psychotherapy sessions.[79] Targeting the follow-up approach to the characteristics of the population eschews the notion that "one size fits all."

Another approach to the provision of support was explored by means of a questionnaire to those bereaved by the death of a relative. They used the information obtained to develop various resources including booklets, posters, and educational sessions to build community capacity to support bereaved individuals.[80]

The evaluation of palliative care by the relative of the deceased family member varied by the setting in which the death occurred, with the home rated most highly followed by hospices. Hospitals and residential settings for the elderly received lower ratings.[81] Hospitals are examining the role they can play in end-of-life (EOL) and bereavement care. Participation in research by bereaved family members of intensive care unit (ICU) patients was determined not only to be feasible but therapeutic.[82] The queries as to their experience and feelings made these family members feel cared for and addressed their need to express their feelings about the ICU experience. In further research, Kentish-Barnes and colleagues examined the impact of a condolence letter for bereaved family members who died in the ICU.[83] While such a letter was perceived as supportive by some, for others it reaffirmed the reality of the death of their family member. When bereavement care is offered, it is usually provided by nurses.[84] In Australia and New Zealand, nurses provide bereavement care in the ICU after a death there, including the removal of clinical paraphernalia, cleaning the patient and straightening the bed, and the use of special attractive bedding and flowers if available, as preparation for family members visiting their dead relative.[85] Bereavement care as part of acute care may compete with other clinical demands, making such support challenging.[86] However, where such support is present, it can be helpful; and obviously, where and when it is not, informal support becomes crucial.

A recent study investigated the impact of advance care planning for the families of dialysis patients.[87] Surrogate family decision-makers and terminally ill patients participated in an intervention that included information/education about the patient's illness as well as end-of-life care and the opportunity to express their feelings about the situation and the choices that needed to be made. The intervention helped participants understand the illness, strengthened relationships between patients and family surrogates, and helped surrogates feel prepared for and comfortable with the decision-making attendant to EOL care. Not everyone is privy to such beneficial interventions.

Support groups may be open-ended (i.e., without a set number of sessions), or they may be closed and limited to a particular set of individuals. Support groups with a set number of sessions have a beginning and end and are therefore more likely to be closed to new members until a new set of sessions begins. Open-ended groups have members who stay for varying lengths of time and may or may not have a topic for each session. Lev and McCorkle[88] cited the finding that short-term programs of 2–7 sessions, or meeting as needed, were the most effective.

Other formal support entails working with a therapist or other healthcare provider (bereavement counseling). The 6- to 8-week programs run by the Lifeline Community Care Group Brisbane for those who were bereaved as a result of a suicide helped to normalize the suicide bereavement experience.[69] Cloyes and colleagues[89] caution that the style of the interaction, whether directive or facilitative, has an impact on the opportunity for expression by the family caregiver. Arnold[89] suggests that the nurse should follow a process to assess the meaning of loss, the nature of the relationship, expressions and manifestations of grief, previous experience with grief, support systems, ability to maintain attachments, and progression of grief. Furthermore, Arnold underscored the importance of viewing grief as a healing process (Box 31.1). She gave the following example of a patient situation and two different approaches to diagnosis[90]:

> A newly widowed woman feels awkward about maintaining social relationships with a group of married couples with whom she had participated with her husband.

◆ Grief as a pathological diagnosis: social isolation.[90]

Bereavement support was demonstrated to have an impact on the grief of gay individuals and was found to be important for bereaved women living with HIV who were at an increased risk for psychiatric conditions and suicide.[91] The risk reduction effects of community bereavement support for HIV-positive individuals was demonstrated by a community support program in Ontario, Canada.[92] These outcomes have implications for the approaches nurses use with other bereaved clients.

Box 31.1 Assessment of Grief

The bereaved often are weary from caring for the deceased. During this period, they may not have looked after themselves. An assessment should include:

1. A general health checkup and assessment of somatic symptoms
2. A dental visit
3. An eye checkup as appropriate
4. Nutritional evaluation
5. Sleep assessment
6. Examination of ability to maintain work and family roles
7. Determination of whether there are major changes in presentation of self
8. Assessment of changes resulting from the death and the difficulties with these changes
9. Assessment of social networks

The healthcare worker needs to bear in mind that there is no magic formula for grieving. The key question is whether the bereaved is able to function effectively. Cues to the need for assistance include:

1. Clinical depression
2. Prolonged deep grief
3. Extreme grief reaction
4. Self-destructive behavior
5. Increased use of alcohol and/or drugs
6. Preoccupation with the deceased to the exclusion of others
7. Perceived lack of social support

In addition to conventional talking therapy, such techniques as letter writing, empty chair, guided imagery, and journal writing can be used (Table 31.3). In letter writing, the empty chair technique, and guided imagery, the bereaved are encouraged to express feelings about the past or about what life is like without the deceased. These techniques can be helpful as the "wish I had said" becomes said. A journal is also a vehicle for recording ongoing feelings of the lived experience of bereavement. A story-telling intervention also shows promise and will be investigated further.[93]

It must be emphasized that grief is not pathology. It is a normal process that is expressed in individual ways. The techniques in Table 31.3 may prove helpful to the individual who is experiencing guilt about things not said or done. This list is not exhaustive, merely illustrative.

Another part of bereavement counseling is the instillation or reemergence of hope. In her exposition of the concept "hope," Stephenson[94] noted the association made by Frankl[95] between hope and meaning. Stephenson stated, "Frankl equated hope with having found meaning in life, and lack of hope as [having] no meaning in life."[94] Meaning-making appears key to the emergence of hope, and hope has been associated with coping.

Table 31.3 Counseling interventions

1. Letter writing	The bereaved writes a letter to the deceased expressing the thoughts and feelings that may or may not have been expressed.
2. Empty chair	The bereaved sits across from an empty chair on which the deceased is imagined to be sitting. The bereaved is encouraged to express his or her feelings.
3. Empty chair with picture	A picture of the deceased is placed on the chair to facilitate the expressions of feelings by the bereaved.
4. Therapist assumes role of the deceased	In this intervention, the therapist helps the bereaved to explore his or her feelings toward the deceased by participating in a role play.
5. Guided imagery	This intervention demands a higher level of skill than, for example, letter writing. Guided imagery can be used to explore situations that require verbalization by the bereaved to achieve completion. Imagery can also be used to recreate situations of dissension with the goal of achieving greater understanding for the bereaved.
6. Journal writing	This technique provides an ongoing vehicle for exploring past situations and current feelings. It is a helpful intervention to many.
7. Drawing pictures	For the artistically and not so artistically inclined, drawing pictures and explaining their content is another vehicle for discussing feelings and concerns.
8. Analysis of role changes	Helping the bereaved obtain help with the changes secondary to the death, such as with balancing a checkbook or securing reliable help with various home needs; assists with some of the secondary losses with the death of a loved one.
9. Listening	The bereaved has the need to tell his or her story. Respectful listening and concern for the bereaved is a powerful intervention that is much appreciated.
10. Venting anger	The professional can suggest the following: ◆ Banging a pillow on the mattress. If combined with screaming, it is best to do with the windows closed and no one in the home. ◆ Screaming—at home or in a parked car in an isolated spot with the windows closed. ◆ Crying—at home, followed by a warm bath and cup of tea or warm milk.
11. Normality barometer	Assuring the bereaved that the distress experienced is normal is very helpful to the bereaved.

In hospice programs, healthcare providers encourage dying persons and their families to have hope for each day. This compression of one's vision to the here and now may also be useful for the person who is grieving the loss of a loved one. Hope for the future and a personal future may be a process that is predicated on hope for each day and having found meaning for the past.

Sikkema and colleagues[91] compared the effectiveness of individual and group approaches by evaluating individual psychotherapy and psychiatric services-on-demand with a support group format. The strategies employed in dealing with grief included establishing a sense of control and predictability, anger expression and management, resolution of guilt, promotion of self-mastery through empowerment, and development of new relationships. Those assigned to individual therapy may or may not have taken advantage of the option. It is proposed that future research examine three groups: those receiving individual counseling, those receiving group therapy, and those assigned no specific intervention but given information about various options for counseling and support in a pamphlet.

A therapist provides an approach for ongoing discussion of the loss that informal caregivers may be unable to provide. A support group of bereaved individuals, or periodic contact with an institutional bereavement service, may also prove useful. What is helpful depends on the individual and his or her needs and also on the informal support that is available. The receptivity of the individual to support, whether formal or informal, is a critical element in whether support rendered is perceived as helpful by the recipient.[96] The underutilization of support by at-risk family members speaks to the need to improve access to those at-risk.[97]

What is a "good death?" According to bereaved family caregivers, it has the following elements:

- *Social engagement*: maintaining relationships and connection to identity
- *Care provider (professional) characteristics and actions*: proactive and empathetic caring
- *Carer's (family) ability*: confidence in caring and understanding the carer's role in "professional caring"
- *Preparation and awareness*: accepting a terminal condition and death
- *Presentation of the patient at death*: control of the dying body
- After death support for protected grieving[98(pp. 837–839)]

Rediscovering the "I" after bereavement is one challenge for bereaved women caregivers. In addition to emotional and social support, the need for practical support for various tasks was also noted.[99,100] The practical support may more likely be secured through informal support.

Informal Support

Informal support occurs among family members and from close friends, neighbors, and colleagues. Listening to the story of the deceased's last days as well as sharing memories is one aspect of this support. The family also has influence on the experience of grief by its members through the shared meanings of the death of their loved one. Indeed, as Naef and colleagues found in their research, the family needs to find a way to make meaning of the death and weave it into their family narrative.[101]

Informal support that is perceived as supportive and helpful can assist the bereaved to come to terms with life after the death of the beloved. Strategies evaluated as being helpful included presence or "being there" indicating "the willingness to listen, and expressing care and concern, whereas the least positively evaluated strategies included giving advice and minimization of other's feelings."[102](p. 419) Whether the bereaved is isolated or is part of a family or social group is of tremendous import to the physical, psychological, and social welfare of the individual. Community in a psychosocial sense and a continuing role in the group are key factors in adjustment.

In societies where the widow has no role without her husband, she is figuratively if not literally disposed of in one way or another. It is for this reason that the woman who is the first in her group to experience widowhood has a much more difficult social experience than a woman who is in a social group where several women already have become widows. In the former, there is no reference group; in the latter there is.

The presence of family and friends takes on added significance after the initial weeks following the funeral. In those initial weeks, friendly visiting occurs with the provision of a variety of types of foods considered appropriate in the group so that the bereaved do not have to be concerned with such activities. The importance of continued support for household tasks, home maintenance, and other financial and legal issues cannot be stressed enough.[99] After the initial period, friendly visiting is likely to decrease, and bereaved individuals may find themselves alone or the objects of financial predators. Counsel by the healthcare provider or by family and friends not to make life-altering decisions (e.g., moving) at this time unless absolutely necessary continues to be valuable advice. On the other hand, the comment that "time makes it easier" is a half-truth that is not perceived as helpful by the bereaved.[103]

What is helpful to the bereaved is listening to music enjoyed by both the deceased and the bereaved[104] and the bereaved being listened to by an interested person. Having family members with whom to grieve has been shown to be significant for grief processing and may enhance family bonding.[103] Quinton disliked the term "counseling" in that it implies the availability of a person with good counsel to offer.[105] What Quinton considered important was "lots of listening to what the victim wants to off-load."(p. 32) She observed, "The turning point for me was realizing that I had a right to feel sad, and to grieve and to feel miserable for as long as I felt the need."[105](p. 32) By owning the grieving process, Quinton provided herself with the most important support for her recovery from a devastating experience—her mother's murder in a massacre by the Irish Republican Army in 1987. The lesson is applicable, however, to any bereaved person regardless of whether the death was traumatic or anticipated. Quinton's turning point is another clue to answering the question of the next section of this chapter: When is it over?

When Is It Over?

To use the colloquial phrase, it's not over until it's over. What does this mean? As long as life and memory persist, the deceased individual remains part of the consciousness of family and friends. When is the grieving over? Unfortunately, there is no easy answer, and the only reasonable response is "It depends." And grief work is never over, in the sense that there will be moments in years to come when an occasion or an object revives feelings of loss. The difference is that the pain is not the same acute pain as that experienced when the loss initially occurred. How one arrives at the point of accommodation is a process termed "letting go."

Letting Go

The term "letting go" refers to acknowledgment of the loss of future togetherness—physical, psychological, and social. There is no longer a "we," only an "I" or a "we" without the deceased. Family members speak of events such as the first time a flower or bush blooms, major holidays, birthdays, anniversaries, and special shared times. Corless[106] quoted Jacqueline Kennedy, who spoke about "last year" (meaning 1962–1963) as the last time that her husband, John Kennedy, experienced a specific occasion:

> On so many days—his birthday, an anniversary, watching his children running to the sea—I have thought, "but this day last year was his last to see that." He was so full of love and life on all those days. He seems so vulnerable now, when you think that each one was a last time.

Mrs. Kennedy also wrote about the process of accommodation, although she didn't call it that[106]:

> Soon the final day will come around again—as inexorably as it did last year. But expected this time. It will find some of us different people than we were a year ago. Learning to accept what was unthinkable when he was alive changes you.

Finally, she addressed an essential truth of bereavement:

> I don't think there is any consolation. What was lost cannot be replaced.[106]

Letting go encompasses recognizing the uniqueness of the individual. It also entails finding meaning in the relationship and experience. It does not require cutting oneself off from memories of the deceased. It does require accommodating to the loss and to the continuing bonds with the deceased.

Continuing Bonds

Klass and colleagues[37] contributed to the reformulation of thinking on the nature of accommodating to loss. Although theorists postulated that the grief process should be completed in 1 year (or less), with one's emotional energies once again invested in the living, the experience of the bereaved suggested otherwise. Bereaved persons visit the grave for periodic discussions with the deceased. They gaze at a picture and seek advice on various matters. They maintain the presence of the deceased in their lives in a variety of different ways—some shared and some solitary. Such behavior is not pathological.

It is a common expectation that teachers in the educational system will have an influence on their students. The students' progress may or may not have continuing contact with those educators. Given that assumption about education, how could we not expect to feel the continuing influence and memory of those informal teachers in our lives, our deceased family members and friends? Integration of those influences strengthens the individual at any point in his or her life.

A Turkish expression in the presence of death is, "May you live."[107] That indeed is the challenge of bereavement. In this next section, we explore in depth death before its time.

Untimely Death

Death that occurs before the anticipated end of life in old age is perceived as a tragic event with distinct characteristics. The most prominent of such untimely deaths is arguably the death of a child. This section will discuss the research findings on parental bereavement and the role of the nurse in addressing these specific needs.

Parental Grief: Characteristics

The two primary tasks facing grieving parents are (1) expressing their intense pain and raw emotions and (2) honoring their deceased child.

The extent of the longing for the child is impossible to imagine for those who have not experienced it and tortuous for those who do. Although such grieving has the same characteristics of all grief, the extent in both force and duration is far greater than most grieving of other losses. In this sense, parents are often misunderstood and judged as "not coping" by the continuation of grieving well past the first or second anniversaries of the child's death. Phrases such as "moving on" or "closure" are particularly unhelpful and inaccurate, since parents learn to live with their loss, not recover from it.[108,109]

One study of 503 parents (predominantly mothers) of deceased babies or stillborns found 51% suffering depression and 42% scored clinically on the Impact of Event Scale several years after the loss.[110] Older parents often feel disenfranchised since losing an adult son or daughter results in the same intense bereavement as the death of a young child but is rarely acknowledged as such by the community.[111] Bereaved parents globally agree that the pain of loss never leaves them but rather softens over many years, becoming a continual thread in the tapestry of their lives, one they have learned over time about which to keep silent in order to avoid judgment.[112]

Extreme grief results in physical symptoms as well as emotional ones. Parents commonly feel significant fatigue, insomnia, gastrointestinal distress, and anxiety. Loss stimulates a cortisol response and hormone imbalance, as well as immune dysfunction. Exacerbations of chronic illnesses and other stress symptoms are likely to occur in the first months or years following a significant loss.[109,113,114]

In addition to the profound longing for the deceased, other emotional and mental changes are also distressing for those experiencing untimely loss. All grief results in distraction, inability to concentrate, and forgetfulness.[115] Any hurt stimulates anger, but grieving parents commonly also feel guilt, shame, and self-blame.[116,117] Parents commonly regret past behaviors and interactions and often blame themselves for the loss, even irrationally.[112] Elderly parents commonly feel survivor's guilt for still being alive when their children are deceased.[111] Negative thoughts such as self-blame or anger toward others have been shown to predict depression and prolonged grief in parents.[118] Parents need to find a path toward forgiveness, both for themselves and for any others whom they may blame. Such forgiveness is associated with less grief and more posttraumatic growth, but may take many years.[109,119]

Continuing the bond with the deceased child is critically important to parents and strongly associated with effective coping.[120] Bereaved parents counsel one another to visit the grave, collect photos, keep possessions, talk to the child, and continue to honor the child in every way that comforts them.[111,121] Parents also use symbolic or ritual representations to continue the bond.[112] Parents now use Facebook or other social media to create memorials and honor their child.[119] High degrees of such activities and continuing the bond with the child is associated with higher posttraumatic growth in bereaved parents.[122]

For many parents, continuing the bond and honoring their child evolves into a form of giving. Many parents express their grief by helping others in some meaningful way and giving back to the community.[123] Such philanthropy is a way of making sense of the child's death, creating good from their pain.[124] Such giving eases the pain of loss and helps to provide meaning to the loss. Seeing some kind of good come from their loss is associated with lower grief intensity and length as well as lower depression.[125,126] For many parents, making meaning out of this tragedy comes in the form of spiritual or religious beliefs and practices.[121] Spiritual activities, such as reflection and relating to others, are associated with lower symptoms of grief, lower posttraumatic stress, and lower depression in mothers, while religious activities are associated with greater personal growth.[127] Posttraumatic growth is positively correlated with increased activities in helping behaviors, relating to others, spiritual change, and appreciation for life.[110,128] Parents report new perspectives and new priorities following the death of a child, as well as increased compassion, empathy, and sympathy for others.[108,125]

Family Dynamics in Grief

Parental grieving greatly impacts both the spouse and the remaining children, which compounds and augments each person's suffering.[129,130] Often the timing of the waves of grief differ, so one spouse may be in extreme pain while the other finally is able to think about something else and is savoring the small break from the constant sadness.[112] Some men and women may grieve differently.[131] Research suggests that men may be more likely to be work and task-oriented, expressing their pain with busyness, while women may cry, talk, and express their emotions outwardly while being very child-focused.[109,132] Several studies indicate that open communication between partners is key. Avoidance of talking about the loss with the partner is associated with higher levels of grief in both partners.[133] In contrast, high levels of communication about the stress of loss correlate with higher levels of posttraumatic growth.[122] Sharing emotions with each other and maintaining bonds with their child helps both the marriage relationship and each individual's level of grief. Parents who integrate the memory of their child into ongoing life appear to experience less suffering.[134]

Role of the Palliative Care Nurse with Parents

Death is the ultimate loss of control, and families feel a distressing helplessness watching their loved one's condition deteriorate. In order to cope with such extreme loss, family members commonly grab for control of any little detail that they are able to influence. Family demands and unreasonable requests of nurses are expressions of the family's cry for help. Near the end of their child's life, parents may continue to express hope for a positive outcome, even if they know such an event would be miraculous. Such hope is not denial, but rather loyalty. Families may feel they are betraying their loved one to give up on life prior to the very last breath.[114] Family members experience lower grief when they are allowed to participate in rituals and have increased control over

EOL activities.[135] For example, parents, especially, experience less extreme distress and lower depression when they are allowed to have unlimited time with their child's body as well as keeping the body at home for viewing.[136,137]

Nurses play a critical role in validating the family's feelings, showing respect and sensitivity for their needs and their religious traditions.[138,139] Family members expect nurses to show great empathy, listening to their feelings, comforting with touch, and offering practical help.[109] Families identify a caring relationship with the nurses as extremely important, longing for their compassion and support.[140,141]

At the end of life and immediately after death family members need and want guidance from the nursing staff. They need encouragement to take time to say good-bye, bathing, dressing, holding, and taking photos before and after death, if they wish.[142] Families are in a foreign environment in the hospital and too traumatized to even think about their own needs. Nurses' guidance and suggestions help spouses and parents to capture precious memories that will greatly sustain them in the future. Keepsakes, such as hand and foot prints or a lock of hair, should be provided for parents. When nurses help with such concrete direction, parents later report deep gratitude for the assistance.[143]

Family members may also need practical information at the time of death about making arrangements for their loved one.[123] People in deep grief are by definition compromised in their ability to problem-solve. They need information from an informed and sensitive social worker as to funeral, obituary, and other details. Parents of stillborn or very premature babies commonly see their child as equally worthy of all death rituals and all ways of honoring their child. Parents expect equal treatment and respect for their deceased premature fetus as with any child or family member.[141] Parents and spouses often benefit from connections with other parents and spouses who have experienced similar loss and also desire help finding such peer bereavement groups.[123,142] Bereaved mothers and fathers also hope nurses and other healthcare professionals will provide information to their family and friends on how to support bereaved parents.[112,114,140]

Bereaved family members often turn to social media sites for peer support and especially crave contact with other parents in similar situations, such as suicide survivors.[123,141,144] Such online groups allow them to identify with other families in grief, express their feelings in a "safe" environment, and honor their loved one with photos and memories.[145]

Bereaved parents long for contact with their child's nurse well beyond the immediate day of death. They want the nurses who were like family to them in their darkest hours to continue to support them during the funeral and the months following the loss, although these parents wait for the staff to initiate such contact.[140,146] Bereavement services provide important continuing care for families, who also value phone calls from the nurses whom they knew well.[147,148]

Most importantly, nurses give critical support by words of affirmation. Family members long to hear positive words about their deceased loved one, especially when experiencing the acute pain of loss, but also for all of their lives.[114] Specific, sincere, positive feedback to families on any topic, from their physical appearance to behaviors or decisions, provides enormous emotional support to bereaved families, like a tremendous hug.[114] Since self-esteem is challenged by the death of a loved one, mourners who can hold on to their self-worth report lower symptoms of posttraumatic stress and depression.[123] Receiving gestures of compassion and support, especially during the most vulnerable moments of grief, helps to encourage positive transformation and growth long term for bereaved families.[142] Research has demonstrated that positive experiences with nurses can impact grief intensity and the coping ability of bereaved families.[138,147,148]

CHAPTER 32

Supporting Families and Family Caregivers in Palliative Care

Kelli I. Stajduhar and J. Nicholas Dionne-Odom

Key Points

- When a family member is faced with a life-limiting illness, it affects both individual family members and the entire family.
- Family members who provide care—family caregivers—require support from nurses and the healthcare system to sustain them in their caregiving role. The health and well-being of the family caregiver is just as important as those of the patient.
- Family members look to nurses and other health professionals to provide quality care to the patient in palliative care but also expect nurses to meet their needs for information, emotional support, and assistance with care. For the vast majority of families and their members, contributing to the care of their loved one is important. Individualizing care for each family and its members is a key role for nurses who provide family-centered palliative care.

Introduction

When a family member is faced with a life-limiting illness, it affects the entire family. Anticipating the loss of a significant other not only causes disruptions to the family unit as a whole but can challenge individual family members to make sense of the impending loss. Many families show resilience and adaptation in the face of such stress, and these experiences have the potential to create a deeper sense of meaning and connection among family members.[1] At the same time, research suggests a significant percentage of family members—18–35%—experience some form of psychiatric morbidity,[2] and if family members are giving care—family caregiving—the physical and financial consequences can be substantial.[3]

Nurses working with people who are dying are in a primary position to provide support to family members and families as a whole. Family-centered care is an important part of nursing practice, and, in the context of palliative care, the family as the unit of care has been central since the inception of the modern hospice and palliative care movement. The World Health Organization states explicitly that palliative care should not only improve the quality of life (QOL) for patients but also for their families. A family's experience of having an ill member is best understood in the context of their relationships with each other, and this becomes even more so when a family member is ill and is requiring care.[4] Changing patterns of dependency, reciprocity, and the rewards and challenges that arise influence each family in different ways. As such, "palliative care is predominantly a family affair,"[4(p. 278)] experienced uniquely for each family and the individuals in it.

This chapter focuses on the family as the unit of care and also places emphasis on family caregivers in palliative care. Family members who provide care to a loved one make substantial contributions to the health and social care systems, with estimates suggesting that they provide 80% of all care.[5] Many families willingly assume the role of family caregiver for someone at the end of life, often doing so out of a sense of love, compassion, or feelings of obligations to care. Providing such support can result in positive changes in family members and personal growth,[6] but many families and family caregivers are not always fully aware of the cost to their physical, mental, and financial health.[7] Some family caregivers do not perceive themselves to be in need of support from healthcare professionals and the healthcare system, even when giving care and support to an ill member becomes overly burdensome.[8,9]

In recent years, family caregiving has become more of an issue for several reasons. Improvements in treatments to control the disease mean that end-of-life (EOL) caregiving often comes after a long period of chronic illness. Depending on the illness, the decline toward death is sometimes precipitous, allowing little time for the family and the caregiver to adapt and acquire the necessary knowledge to support the person dying and themselves.[10] Many family caregivers are now asked to perform procedures in the home (and sometimes in the hospital)[11] that were once the exclusive domain of nursing care.[12] Fewer children per family and a more mobile society mean that there are usually fewer family members to care for dying relatives.[13] And, since we are living longer with more comorbidity, caregiving is more complex; spouse caregivers are older and often have their own serious illnesses as well.[13]

As a basis for offering optimal support to families in palliative care, this chapter will discuss family-centered palliative care and the experience of family members in supporting their significant others. In addition to presenting research that will inform nursing interventions for families, this chapter will include what is involved in being a family caregiver and some of the challenges that family caregivers face. In keeping with a core focus in palliative care on QOL, important elements in promoting family caregiver QOL and the needs of caregivers will be outlined. Considerations in family caregiver assessment and how to support family caregivers in the home, the hospital, and in intensive care and perioperative settings will also be highlighted, as will the family's role in decision-making and advance care planning, including providing resources that nurses can use to promote family-centered palliative care.

Family-Centered Palliative Care

Recognizing the importance of a family focus necessitates clearly defining what is meant by "family" and "family caregiving." Most often, families in palliative care consist of patients, their spouses, and their children. But, in today's world of divorce, repartnering, remarriage, and cohabitation,[14–16] step-relatives must also enter into the family portrait. In other instances, people unrelated by blood or marriage (also referred to as families of origin and families of choice),[17,18] or families made up of lesbian, gay, bisexual, trans, and queer or questioning (LGBTQ) individuals mean that our traditional definitions of families in palliative care must necessarily be broad and diverse.[15] Census definitions of family have tended to focus on defining family as people living in one household, but we know that not all family members live together, and how family is defined can vary from country to country.[19]

For the purposes of this chapter, family is defined as a group of individuals inextricably linked in ways that are constantly interactive and mutually reinforcing. Family can mean direct blood relatives, relationships through an emotional commitment, or the group or person with whom an individual feels most connected.[17] In its broadest sense, family is defined as whoever the person says his or her family is, including relatives, partners, neighbors, and friends.[17] Family caregivers in this context are defined as individuals who provide unpaid care and/or support to a family member, friend, neighbor, or significant other who has a physical or mental disability, is chronically ill, or is frail, and, in particular, is diagnosed with a disease where the likelihood of death is high.[19]

Palliative care programs are based on the principle that the family is the unit of care. In practice, the family is often viewed as a group of individuals who are sometimes perceived to be helpful or to resist efforts to deliver care. Regardless of the family situation and composition in palliative care, nurses and other health professionals must strive to understand the meaning of the palliative experience to the family as a whole, as well as to its individual members.[20] Some of the best outcomes are achieved when appropriate interventions are directed toward family members both individually and as a group. [20,21] If quality care is to be provided, nurses need to understand how all family members perceive their experience, how the relationships fit together, and that a multitude of factors interact to make families what they are.[21]

In the past 10–15 years, research has gone beyond focusing on the needs of dying patients for comfort and palliation to addressing issues relevant to other family members. Much of this research has focused on the family's perceptions of their needs,[22,23] experiences and challenges faced,[13] adaptation and coping skills required for home care,[24,25] the supportiveness of nursing behaviors [26,27] or physician behaviors,[28] and satisfaction with care.[27] Though research used to focus primarily on families of patients with cancer, palliative care extends the focus to other life-limiting illnesses. Reports for other diagnostic populations, such as Parkinson's disease,[29,30] heart disease,[31] motor neurone disease,[32] lung disease,[28,33] kidney disease,[34,35] and neurodegenerative diseases[26,28] are becoming more available, as is research and clinical care focused on the care needs of people with dementia and their families.[36,37] Regardless of disease or condition, research makes it clear that family members look to nurses and other health professionals to provide quality care to the patient.[34] Family members expect health professionals to meet their needs for information, emotional support, and assistance with care.[27] Recent research suggests that one of the most effective ways to support families may be to help them be successful in their caregiving roles.[27] Providing care might not always be what family's desire,[38] but, for the vast majority of families and their members, contributing to the care of their significant other is important. Individualizing care for each family and its members is a key role for nurses who provide family-centered palliative care.

Understanding the Experiences of Families in Palliative Care

The Transition of Fading Away

When a family member is faced with a life-limiting illness, the impending death presents a challenge to the entire family. Family members must try to find new balance during the illness and after their significant other has died. One of the most comprehensive research programs directed toward understanding the experiences of families in palliative care evolved from nurses' concerns about how to provide family-centered palliative care.[39] As authors of the previous version of this chapter, Steele and Davies[40] noted that nurses in a regional cancer center constantly had to attend to the needs of not only patients but also patients' families, particularly as they moved back and forth between hospital and home. In searching the literature for guidelines about family-centered care, Davies and her colleagues found that many articles were about the needs of patients and family members, about levels of family members' satisfaction with care, and about family members' perceptions of nurses, but nothing really described the families' experiences as they coped with the terminal illness of a beloved family member. Their research program, studying families of patients with advanced cancer, and later, families with AIDS, Alzheimer's disease, cardiac disease, and families of children with progressive, life-threatening illness resulted in a conceptualization—the *transition of fading away*—as a basis for thinking about the experiences of families in palliative care.[39]

The transition of fading away is characterized by seven dimensions: redefining, burdening, struggling with paradox, contending with change, searching for meaning, living day by day, and preparing for death. The dimensions do not occur in linear fashion; rather, they are interrelated and inextricably linked to one another. While a common view is that transitions are initiated by changes, by the start of something new, Bridges[41] suggests that most transitions actually begin with endings. This is true for families in palliative care. As Davies et al. found, the transition of fading away begins with the ending of life as a person knows it. Family members come to realize that the ill family member is no longer living with a life-limiting illness but is now dying from it.

Despite the fact that family members have been told about the seriousness of the prognosis, often since the time of diagnosis, they experience the usual ups and downs associated with the illness trajectory; for many the "gut" realization that a patient's death is inevitable occurs suddenly: "It struck me hard—it hit me like a bolt. Dad is not going to get better!" The awareness is triggered when family members see, with "new eyes," a change in the patient's body or physical capacity, such as the patient's weight loss, extreme weakness, lack of mobility, or diminished mental capacity. Realizing that the patient will not recover, family members begin the transition of fading away. As one patient commented, "My body has shrunk so much—the other day, I tried on my favorite old blue dress and I could see then how much weight I have lost. I feel like a skeleton with skin! I am getting weaker. . . . I just can't eat much now, I don't want to. I can see that I am fading. . . . I am definitely fading away." To help further illustrate the transition of fading away, we use exemplars from our own clinical work and studies with families in palliative care.

Dimensions of the Transition of Fading Away

Redefining

Redefining involves a shift from "what used to be" to "what is now." It demands adjustment in how individuals see themselves and each other. Patients maintain their usual patterns for as long as possible, and then begin to implement feasible alternatives once they realize that their capacities are seriously changing. Shelly, a young woman diagnosed with metastatic colon cancer, redefined what she was capable of as her illness progressed. Once an avid tap dancer, she could no longer participate in dance competitions in her age group. As she became more fatigued, she gave up dancing altogether but was still able to help her dance group behind the scenes with costume changes and make up. As her illness progressed, she became an audience member, cheering on her dance company. One day, Shelly realized that even that required more energy than she had. She was able to maintain connections with her dance community even toward the very end of her life, but those connections changed and were redefined; her family kept her updated about the dance group, posted pictures in her bedroom of her "dance friends" and made arrangements for friends to visit when Shelly felt well enough. Another patient, Fred, owned a landscaping business, and, as his chronic obstructive pulmonary disease progressed and he became increasingly short of breath, he could no longer do the physical work required. Fred lamented that he loved being out in the garden, but as time went on, he took over book-keeping duties while his son took over the family business. Eventually, he could no longer do that as his health deteriorated.

Both Shelly and Fred, like other patients, accepted their limitations with much sadness and a sense of great loss. Their focus narrowed, and they began to pay attention to details of everyday life that they had previously ignored or overlooked. While Shelly wanted to maintain connections to her dance community, over time, that became more difficult and she set her sights on spending more time with family and her nieces and nephews. Both Shelly and Fred talked about feeling "the same on the inside," although they acknowledged the drastic changes in their physical appearance. Some patients, like Shelly, became more spiritual in their orientation to life and nature. Early in her illness, Shelly organized groups of friends to go to the ocean early in the morning for a "healing circle," where meditation, yoga, and prayer were practiced. When patients are able to redefine themselves as Shelly did, they made the best of their situation, differentiating what parts of them were still intact. While Fred could no longer continue working as a landscaper, he could still enjoy going into his own backyard and "puttering around" when he felt well enough. His son, Jeremy, even built a backyard gazebo where Fred took up bird watching; he replaced one joy in life with another as a way to continue to connect with the outdoors.

Patients who are unable to redefine themselves in this way often attempt to maintain their regular patterns despite the obvious changes in their capacity to do so. Sometimes patients end up frustrated, angry, and feeling worthless. These reactions distance them from others, resulting in the patient feeling alone and, at times, abandoned. Lisa, for example, worked in a law office as a paralegal. Even though her health was deteriorating, she was unable to recognize that she could no longer work to full capacity. The demands of her job were high, often with tight timelines and occasions when she had to work overtime. While her workplace and employer were respectful of her need to contribute and maintain her work identity, Lisa had difficulty giving up responsibility. As the work piled up, it became clear that she could no longer complete assigned duties. Her co-workers began helping Lisa with her work, often working overtime themselves. At first, they were happy to help, but, as the months went by and Lisa's health further deteriorated, some co-workers started to feel resentful. Lisa became increasingly frustrated with her inability to complete work on time and increasingly angry with her boss who she felt was too demanding. Eventually, Lisa was encouraged to take time off work, with pay, to enable her to look after herself. Her husband remarked that not being able to work was devastating to Lisa who had previously enjoyed her job and who still felt that she was able to work to full capacity. While Lisa continued to have a relationship with her co-workers once she left work, her husband remarked that it was awkward and strained at times. According to Lisa's husband Dan, her co-workers began visiting less and less, leaving Lisa feeling abandoned and misunderstood.

For the most part, we have found that spouses take the patient's physical changes in stride. They attribute the changes to the disease, not to the patient personally and, as a result, are able to empathize with the patient. Patients' redefining tends to focus on themselves, the changes in their physical status and intrapersonal aspects; spouses' redefining centers on their relationship with the patient. Spouses did their best to "continue on as normal," primarily for the sake of the patient. In doing so, they consider alternatives and reorganize their priorities.

Sometimes family members experience the "reciprocity of suffering" that results from the physical and emotional distress that is rooted in their anguish of dealing with the impending death of a loved one and in their attempt to fill new roles as family caregivers. It appears that the degree to which family members experience reciprocal suffering relates to how patients redefine themselves. When patients are able to redefine themselves, spouses have an easier time. Such patients accepted spouses' offers of support; patients and spouses were able to talk about the changes that were occurring. Spouses felt satisfied in the care that they provided. But when patients were less able to redefine, then spouses' offers of support were rejected or unappreciated. For example, Louis was the main trumpet player in a military band. He loved to perform, and when he could no longer keep up with band members, his wife Donna encouraged him to quit, telling Louis that it was unfair to his band members. Louis got angry with Donna, telling her that "you don't know anything, I'm fine." Louis continued to play with the band, having Donna drive him to twice-weekly performances. One night at a performance, Louis collapsed and was taken to the hospital. Donna was frustrated that her concerns had not been heard by Louis, and Louis in turn was upset that Donna did not understand his need to continue performing. Their relationship became strained as Louis struggled to redefine life after his cancer diagnosis, and Donna struggled to know how to best help Louis.

In such situations, spouses often avoid talking about or doing anything that will remind the patient of the changes he or she is experiencing but not acknowledging. This often causes strain in relationships. Rather than feeling satisfied with their care, spouses become frustrated and angry, although often they remain silent and simply "endure" the situation. The ill person contributes significantly to the caregiver's ability to cope. In their systematic review of factors that influence family caregiving of persons with advanced cancer, Li and Loke[42] found that the spousal relationship contributed significantly to the capacity of the spouse to adjust their caregiving role and expectations in order to provide care despite their experience of overwhelming emotional and physical strain. Caregivers drew strength from the dying person when the ill person accepted the impending death, had an understanding of the caregivers' needs, and had attitudes, values, and beliefs that sustained their caregiving.[43]

Adult children also redefine the ill family member; they redefine their ill parent from someone who was strong and competent to someone who is increasingly frail. When Jeremy took over his father's landscaping business, he expressed disbelief at watching his father's strong body wither away. He had always viewed his father as a "strong man," and it was difficult to see him in a weakened state. Jeremy felt vulnerable in ways he had not previously experienced. As Davies and colleagues report,[39] children perceive that the changes in their ill parent are the result of disease and not intentional. Younger children are particularly sensitive to keeping the situation private, claiming they want to protect the dignity of the patient, but they seemed to want to protect their own sense of propriety. For example, one young woman in her early twenties was "devastated" when her father's urinary bag dragged behind him as he left the living room where she and her friends were visiting. It was difficult for some young adults to accept such manifestations of their parent's illness. Adolescents in particular had a difficult time redefining the situation. They preferred to continue on as if nothing was wrong and to shield themselves against any information that would force them to see the situation realistically. This is consistent with more recent research with adolescents who have a dying family member.[44]

When a patient is able to redefine, children are also better able to accept that dying is a natural part of life. Often, children (and others) recommit to their own health when they have a family member who is dying, and the experience causes them to reflect on their own life and the changes that they want to make. Fred's son David, for example, was estranged from his own children as a result of a long history of substance use. Though he had been alcohol-free for 5 years, he had been afraid to reach out to his now teenage children. Fred and his wife had not spent much time with their grandchildren. When David realized that his father was dying, it prompted him to be in touch with his ex-wife, which resulted in a meeting with his children. Fred's illness, while challenging for the family, prompted David to reconnect with his children and allowed Fred the opportunity to spend time with his grandchildren before he died. In contrast, when a dying person is unable to redefine, it can also affect his or her adult children. Dealing with the patient's angry emotions sometimes makes the relationship difficult. Valerie and her mother had experienced conflict in their relationship when Valerie was growing up. When her mom was diagnosed with metastatic cancer and her health began to deteriorate, Valerie began spending more time with her mother than she had in the past, but her mother was not overly receptive. After her mother had died, Valerie expressed regrets and wished that her mother had been able to accept her offers of help. Valerie said that she had spent many hours in bereavement counseling trying to reconcile her feelings about the relationship with her mother, suggesting that her mother's inability to redefine their relationship had affected her personal life in profound ways. The work of Sherman[43] underscores the importance of relationships among and between family members in facilitating their coping with the situation of terminal illness.

Burdening

One of the most common feelings that people who are dying express is a desire to not be a burden to their family.[45] If patients see themselves as purposeless, dependent, and immobile, they have a greater sense of burdening their loved ones. The more realistically that patients redefine themselves as their capacities diminish, the more accurate they tend to be in their perceptions of burdening.[39] They acknowledge other family members' efforts, appreciate those efforts, and encourage family members to rest and take time to care for themselves. According to Steele and Davies,[40] patients who are less able to redefine themselves do not tend to see that they are a burden on other family members in any way. Frances, a retired nurse, retold the story of her husband Bernie and how he did not seem to realize that she needed a break. Frances explained that when Bernie became ill and was no longer able to attend their weekly bridge group, he insisted that she also stay home to be with him. Frances arranged to have home help for Bernie so that she could continue her weekly outing as she found it a great source of support. When Bernie refused the help, Frances felt she had no choice but to give up her weekly game. She commented that Bernie "just didn't seem to have a clue that I needed to get out. . . . It wasn't about him, it was just that I needed the break."

Most spouses acknowledge that providing care and support to a loved one is hard work, and it can be overwhelming. While some spouses do feel overburdened, most often spouses feel a deep desire to provide care to their loved one out of a sense of love and obligation.[9] Spouses often do not focus on their own difficulties and, in fact, often put their own needs aside. Stories of loneliness and helplessness often surface during the experience, but caring for a loved one can also bring couples closer together as they revisit their relationship and deepen their love and respect for one another. Spouses of patients who are able to redefine often feel proud of their caregiving efforts and appreciated for their contributions to their spouse's life and dying process. Spouses of patients who are not able to redefine can feel unappreciated, exhausted, and some have even confessed to "waiting for the patient to die."

Steele and Davies[40] suggest that children, too, experience burdening, but the source stems from the additional responsibilities of helping to care for a dying parent, superimposed on their work responsibilities, career development, and their own families. As a result, adult children of all ages feel a mixture of satisfaction and exhaustion. Debbie's mother was diagnosed with metastatic lung cancer just as she was graduating from university and starting a new job in another city. While Debbie was reluctant to move, her father encouraged her to do so, but, over time, Debbie began to feel the strain of living at a distance. As her mother's disease progressed, Debbie, an only child, would fly home on weekends to help her father but often felt pulled between her work responsibilities and her responsibilities to her family. Both of Debbie's parents were understanding and recognized that Debbie was doing all she could to support them; they appreciated her efforts and were thankful when she was home. Adult children are influenced by the ill parent's redefining—if the ill parent acknowledges their efforts, they are more likely to feel satisfaction. Children's sense of burdening is also influenced by the state of health of the well parent. If that parent is also ill or debilitated, the burden on children is compounded. Children who are able to prioritize their responsibilities while also attending to their own needs do tend to feel less burdened, according to Steele and Davies.[40] As such, nurses can play an important role in coaching adult children toward self-care and balance so that they do not feel burdened by the multiple responsibilities that they can incur when a parent is dying.

Struggling with Paradox

Struggling with paradox stems from the fact that the patient is both living and dying. For patients, the struggle focuses on wanting to believe they will survive and knowing that they will not. Steele and Davies[40] write that on "good days," patients felt optimistic about the outcome; on other days, they succumbed to the inevitability of their approaching demise. Often, patients did not want to "give up" but at the same time were "tired of fighting." They wanted to "continue on" for the sake of their families but also wanted "it to end soon" so their families could "get on with their lives." Patients coped by hoping for miracles, fighting for the sake of their families, and focusing on the good days. Rose, a young woman diagnosed with terminal cancer, rarely talked about dying. Although she had been a palliative care volunteer, had journeyed with many dying people, and was told what the eventual outcome of her diagnosis would be, she focused exclusively on her cancer treatment, on living, and praying for a cure. As her functional status changed, her mobility declined, and she developed pain, it was difficult for Rose to ignore that the disease was progressing. Some days she talked about being healed and on others she doubted that this would happen. It wasn't until 2 days before she died that Rose agreed to register with the palliative care program.

Spouses also struggle with paradox: they want to care for and spend time with the patient, and they also wanted a "normal" life. Frances desperately wanted to continue with her bridge playing for the social outing but also because the social support that the group provided helped her cope with caring for Bernie. Because Bernie feared being left alone, but would refuse help, Frances felt that she had to put her life on hold and soon became exhausted herself. Eventually, Frances decided to invite the bridge group to her home. Even though this created more work for her as she prepared for their arrival, and it was not the complete break that she desired, it did provide her with a welcome distraction and created some normalcy in her life. Steele and Davies[40] report that spouses who manage to find ways of tending to their own needs usually are less exhausted and report fewer health problems than spouses who neglect their own needs.

Children struggle with hanging on and letting go to a greater extent than their parents. They want to spend time with their ill parent and also to "get on with their own lives." Feeling the pressure of dual loyalties (to their parents and to their own young families), the demands of both compound the struggle that children face.

Contending with Change

Those facing terminal illness in a family member experience changes in every realm of daily life—relationships, roles, socialization, and work patterns. The focus of the changes differs among family members. Patients face changes in their relationships with everyone they know.[40] They realize that the greatest change of their life is under way and that life as they knew it will soon be gone. Patients tend to break down tasks into manageable pieces, and, increasingly, they focus inward. The greatest change that spouses faced was in their relationship with the patient. They cope by attempting to keep everything as normal as possible. Children contend with changes that are more all-encompassing; they cannot withdraw as their ill parent did, nor can they prioritize their lives to the degree that their well parent could.[40] They easily become exhausted. As Debbie explained, it was hard to fly home every weekend to help her mother and father. She had just started a new job in a new city, and she wanted to begin building her professional career but she felt "the pull" to be at home. She felt guilty for not being there to help her father with the everyday demands but also stressed at learning her new job and wanting to impress her employer. She contemplated moving home and quitting her job several times, but, in the end, continued to travel back and forth for several months, up until her mother died and she helped her father after her mother's death.

Searching for Meaning

Searching for meaning has to do with seeking answers to help in understanding the situation. Patients tend to journey inward, to reflect on spiritual aspects and deepen their most important connections. Spouses and others close to the dying person often look toward their own personal growth and reconciling issues from the past. Gail and Nancy had been close childhood friends. They spent most of their summers together up until they each got married and moved to different parts of the country. Over time, their relationship became distant but when Gail was diagnosed with bladder cancer, Nancy was the first person she called. Nancy visited Gail and her husband several times over the 2 years before she died. They reminisced about their childhood and young adult days and tried to understand why their friendship had diminished. They sought experiences that reminded them of their earlier times together—going to the beach, fishing, and staying at lakeside cottages. After Gail died, Nancy remarked that spending time with Gail had caused her to reflect and reevaluate her own life. The experience helped her "put things in perspective," and she described becoming less concerned about bolstering her career and more concerned about spending time with family and friends. Children also tend to reflect on and reevaluate aspects of their lives when a parent dies.[40] One son said that his father had worked hard his whole life trying to provide for his children as they were growing up. He often worked late, traveled for work, and missed family celebrations. While he was appreciative of his father's efforts, he vowed to make changes in his own life so that he could spend more time with his children.

Living Day to Day

Living day to day is characterized by a focus on the present, on the "here and now" and trying to make the most of a challenging situation. When patients are able to find meaning in their experiences, they are more able to take one day at a time and often experience less turmoil.[39] Catherine approached her cancer diagnosis pragmatically. She had always been organized, a strong planner, and, when diagnosed with cancer, decided to not dwell too much in "what could have been" but rather focused on "the here and now."

Once she could no longer work, she turned her attention to learning new skills that she could handle and that would keep her busy. She began knitting hats and blankets for her family, and, when she tired, she would put that aside and rest. She was not discouraged, but rather decided on adopting an attitude of living each day to the fullest that she could. Not all patients are able to live day to day. For patients who are unable to find meaning in their situations, they tend to focus on persevering through difficult times and "getting through it."[39]

Spouses who are able to find meaning in the situation were better able to live day to day. They cherished the time that they had with their partner and made the best of things. Fred's wife Betty even suggested that Fred's diagnosis meant that they could spend time in their own garden together after years of Fred landscaping the yards of others. Although they could no longer make their yearly trip to Arizona, Betty said she "didn't mind" as she wanted to make the best of the time that she and Fred had left. Other spouses simply endure the situation without paying much attention to philosophizing about the experience. Steele and Davies[40] comment that children often have difficulty concentrating on living day to day because they are unable to defer their obligations and therefore worry about what else needs to be done. Other children cope differently and are able to "live for the day."

Preparing for Death

In preparing for death, patients, spouses, and children come to terms with the practical aspects of dying. Patients often have their family's needs uppermost in their minds and work hard to teach or guide family members with regard to various tasks and activities that the patient will no longer be around to do. Bea spent many months teaching her husband Harold how to cook and do laundry as he had not been responsible for those tasks in their married life together. Even though it was hard for both of them, Bea was determined that Harold be prepared. Many patients are also committed to leaving legacies for their loved ones, not only as a means of being remembered but also as a way of comforting loved ones in their grief. Gail learning to knit blankets and hats for those she loved enabled her to leave something special behind. She also created multiple memory books for her friends and family.

Spouses tend to concentrate on meeting the patient's wishes. They attend to practical details and anticipate their future in practical ways. Children offer considerable help to their parents with legal and financial matters. They also prepare their own children for what is to come. A central aspect of preparing is reassuring the dying parent that they would take care of the surviving parent.[39] Children also prepare for the death by envisioning their future without their parent.

In summary, the transition of fading away and its related dimensions provide a comprehensive picture of the families' experience in palliative care, how life-limiting illness can affect the family as a whole and its individual members. This conceptualization provides nurses with guidance for interventions with families. Table 32.1 summarizes key strategies that nurses caring for families can use in their everyday practice to promote family-centered palliative care.

Family Caregiving in Palliative Care

The primary goal of palliative care is to improve the QOL and quality of death of dying people and their families through provision of excellent care. Families share most intimately the experience of living with and dying from a life-limiting illness. They are strongly affected, both positively and negatively. Many also wish to provide care, and, in these cases, nurses and other healthcare professionals play a key role in supporting them so that they do not endanger their own health.

Family caregiving in palliative care involves many things, but, at its core, family caregivers provide most of the physical and emotional care for the individual who is dying.[46,47] Family caregivers manage medications, symptoms, and other aspects of patient care,[48] and, as the person who is dying functionally declines and is less able to get out and socialize with others, family caregivers provide social support.[47,49] Providing the person who is dying with practical support for activities of daily living, such as bathing and eating, as well as other household tasks is a common role for family caregivers, including taking on new roles that were previously those of the person who is dying. Family caregivers act as the spokesperson, advocate, and proxy decision-maker for their significant other, and they assume primary responsibility for coordinating the care of the patient.[46,48] There are many challenges for family caregivers. For example:

- The physical demands of providing care can be extremely difficult for family caregivers.[50] Many family caregivers are older and have health concerns of their own, which can make caregiving particularly challenging.[13]
- Developing assessment and caregiving skills may be challenging for family caregivers. They often report that they do not feel prepared for their caregiving role, especially in regards to medication management.[51] Caregiving responsibilities and lack of feeling prepared result in a considerable amount of anxiety and fatigue in family caregivers.[52]
- Family caregivers who look for information to help them prepare for caregiving often feel overwhelmed by the complexity and amount of information needed to fulfill their caregiving role, adding to their stress.[53]
- Caregiving responsibilities, carrying out multiple roles, and often being unable to leave the patient alone result in significant disruptions in family caregivers' regular routines and restrictions on their time and ability to participate in social and health-related activities that they value.[49] Younger caregivers, women, and those who are a child of the person who is dying often find disruptions to their own schedules especially difficult,[54] likely due to the stress of competing demands from work and family life.[46,53]
- Family caregivers may also experience financial stressors associated with caring for a dying person at home.[55] Many family caregivers quit their job, lose work hours, or use special leave or holiday time in order to fulfill caregiving responsibilities.[56] Loss of income and out-of-pocket costs incurred for items such as prescription and over-the-counter medications, home care, and equipment and home modifications result in many family caregivers having some type of financial difficulty due to home-based caregiving.[56,57]

These challenges often leave family caregivers feeling burdened by the demands of care. The literature provides a comprehensive description of the multidimensional nature of the burden experienced by family caregivers. Caregiver burden, commonly experienced by spouses, has been described in terms of physical burden,

Table 32.1 Dimensions of fading away: nursing interventions for family members

Dimension	Nursing interventions
Redefining	Ensure effective symptom management, because this allows patients and family members to focus outside the illness. Appreciate that relinquishing old and comfortable views of themselves occurs over time and does not necessarily occur simultaneously with physical changes in the patient. Tailor interventions according to the various abilities of family members to assimilate the changes.
Contending with change	Reassure family members that a range of responses and coping strategies is to be expected within and among family members. Create an environment in which family members can explore and manage their own concerns and feelings. Encourage dialogue about family members' beliefs, feelings, hopes, fears, and dilemmas so they can determine their own course of action. Provide opportunities for patients to talk about the illness, the enforced changes in their lives, and the ways in which they have adapted; for spouses to talk about how changes in the patient affect their marital relationship; and for children to talk about their own feelings of vulnerability and the degree to which they want to be open or private about the situation. Recognize that families communicate in well-entrenched patterns and their ability to communicate openly and honestly differs. Normalize the experience of family members and explain that such feelings do not negate the positive feelings of concern and affection. Reinforce normal patterns of living for as long as possible and as appropriate. When patterns are no longer viable, consider adjustments or alternatives. Provide information so families can explore the available resources, their options, and the pros and cons of the various options. Provide information in writing as well as verbally. Focus on the patient's attributes that remain intact, and acknowledge that roles and responsibilities may be expressed differently. Consider adjustments or alternatives when former patterns are no longer feasible. Explain the wide-ranging nature of the changes that occur within the patient's immediate and extended family.
Searching for meaning	Help spouses consider how they might reorganize priorities and consider resources to help them do this. Appreciate that the search for meaning involves examination of the self, of relationships with other family members, and of spiritual aspects. Help children appreciate their parent from another perspective, such as in recalling favorite stories or identifying legacies left . Realize that talking about the current situation and their recollections of past illness and losses is part of making sense of the situation.
Burdening	Provide opportunities for patients to talk about fears and anxieties about dying and death, and to consider with whom to share their concerns. Encourage life reviews and reminiscing. Listen to the life stories that family members tell. Help patients stay involved for as long as possible as a way of sustaining self-esteem and a sense of control. Suggest approaches for self-examination such as journal writing, and approaches for facilitating interactions between family members such as writing letters. Assist family members to take on tasks appropriate to their comfort level and skill and share tasks among themselves.
Living day to day	Support family members' reassurances to patient that he or she is not a burden. Explain that when patients reaffirm family members for their efforts, this contributes to their feeling appreciated and lessens the potential for feeling burdened. Listen carefully for the subtle shifts in orientation to living with a dying relative and gauge family members' readiness for a new orientation. Ensure effective control of symptoms so that the patient can make the most of the time available. Assess the need for aids. Explain the importance of breaks for family members. Encourage others to take over for patients on a regular basis so family members can take a break. Without minimizing their losses and concerns, affirm their ability to appreciate and make the most of the time left. Acknowledge the reorganization of priorities and the considerable adjustment in family routines and extra demands placed on family members. Acknowledge the "work" of caring for all family members. Review resources that would free family members to spend more time with the patient.
Preparing for death	Assess your own comfort level in talking about the inevitability of death, describing the dying process, and helping families make plans for wills and funerals. Realize that family members will vary in their ability to assimilate the changes and that a range of reactions and coping strategies is normal. Provide information about the dying process.
Struggling with paradox	Discuss patients' preferences about the circumstances of their death. Encourage patients to discuss these issues with their family. Acknowledge how difficult such discussions can be. Appreciate that you, as a nurse, cannot completely alleviate the psychosocial-spiritual pain inherent in the family's struggle. Assess your own comfort level in working with people facing paradoxical situations and ambivalent feelings. Encourage patients to do important "last things," such as completing a project as a legacy for their family. Provide opportunities for family members to mourn the loss of their hopes and plans. Do not minimize these losses; help them modify their previous hopes and plans and consider new ones. Provide opportunities for spouses and children to express their concerns about their future without the patient. Provide them with opportunities to reminisce about their life together. Acknowledge that such remembrances will have a bittersweet quality. Listen to their expressions of ambivalence, and be prepared for the ups and downs of opinions.

Source: Davies et al. (1995).

which includes fatigue and physical exhaustion, sleeplessness, and deterioration of health.[50] Social burdens encompass limited time for self and social stress related to isolation.[46] Financial burdens, reported as the costs of caring for a person at the end of life, are substantial.[55] Despite the burdens and challenges reported by many family caregivers, research shows that many caregivers continue to want to provide palliative care even when the experience becomes burdensome and overwhelming for them.[58]

Family Caregiver Quality of Life

Family caregivers identify that they are better able to cope with their caregiving roles when their QOL concerns are addressed and their needs are attended to. Family caregivers are diverse, and what is important to QOL at an individual level will vary greatly from person to person and even for the same person over time. Research shows, however, that there are some commonalities in what family caregivers say is important to their QOL. Cohen and colleagues[59] identified seven dimensions that family caregivers identify as important to their QOL:

1. *The state of the family caregiver*: Physical well-being, mental health, being able to think clearly and think of something other than the patient's illness and a sense of feeling in control;
2. *Their family member's condition*: When the patient has a good day, the family caregiver also has a good day;
3. *Their environment*: When family caregivers believe that their significant other is in the best place, be that at home, at the hospital, or other facility, and having privacy when they want it;
4. *The family caregiver's outlook on life*: When life has meaning, when faith and spirituality is comforting, and when providing care to their significant other is rewarding;
5. *Healthcare*: The family caregiver is comfortable with the way that decisions are made for their family member and is satisfied with the care their family member receives and how they are both treated by the healthcare team;
6. *Relationships*: That they have a relationship with the person they are caring for and with other people that are important to them; and
7. *Financial concerns are addressed and not negatively affecting their life*.

Family caregiver QOL is associated with the extent to which family caregivers perceive that their and the patient's needs are met.[60] Family caregivers have many needs related to both their own well-being and that of the patient. It is important that they focus on meeting both types of need. If they focus only on meeting their needs related to caring for the patient and neglect to take care of themselves, then they are likely to become unable to continue providing care, either because they become ill themselves or become overwhelmed.[61,62] *Their own health and well-being is just as important as that of the patient.* Some common needs found in studies of family caregivers are summarized in Table 32.2. Though they may not apply to all family caregivers in palliative care, it is important that these needs are taken into consideration when conducting family caregiver assessment.

Family Caregiver Assessment in Palliative Care

In both practice and research, palliative care has had the majority of its focus centered on families affected by cancer.[1–3,5–7,12] Yet in the past several years, a number of organizational reports, research priority papers, organizational statements, and reviews of the literature have synthesized and catalogued the state of the science of family caregiving generally[13,15,17,65–68] and within the context of serious non-cancer illnesses, including dementia and Alzheimer's disease,[36,37] heart failure and stroke,[63,69–71] kidney disease,[34,35] lung disease/chronic obstructive pulmonary disease (COPD),[28,33] and pediatric serious illness.[72,73] There can be several differences in the caregiving experience that are attributed to these specific illnesses. These differences can include the duration and intensity of caregiving (e.g., cancer caregiving tends to be of relatively short duration but very intense),[7] the types of treatment decisions faced (e.g., heart failure caregivers often assist with decisions about mechanical circulatory support device placement or pacemaker deactivation[69]), and special challenges due to a care recipient's cognitive impairment (e.g., dementia caregivers dealing with their care recipient's deteriorating sense of self). Hence, palliative care nurses are encouraged to review these cited resources for their respective areas of practices.

Despite these and other differences in the caregiving experience that may be characteristic of specific serious illnesses, there are common elements of assessment that the palliative care nurse should consider. Family caregiver assessment is important because research has found that nurses tend to focus on the patient, tend not to undertake comprehensive screening of family caregivers, and may be reluctant to openly do so in the patient's presence.[74] Without having a comprehensive understanding of the support needs of family caregivers, nurses' capacity to provide assistance is limited. The following points summarize these elements and are based on published guidelines and other texts.[75]

- An initial comprehensive assessment should be initiated when a patient is first diagnosed with serious, potentially incurable illness, even if disease-modifying and curative therapies remain the focus of medical treatment.
- Caregiver assessment should be tailored to an institution's resources, setting, and culture and yet result in a plan of care that is determined collaboratively with the family and that has measurable objectives of success.
- The purpose of caregiving assessment should ideally include (but not be limited to): (1) identifying the primary caregiver and other family members who assist with caregiving tasks, (2) assessing caregivers' physical and psychological health, (3) understanding the demands that the patient's illness is likely to place on the family, and (4) determining the capacity of the family to meet these demands.
- Assessment might also include what caregivers understand about how their patient's illness and its progression may impact their lives in the future. What have they discussed with the patient concerning advance care planning? Have they talked about surrogate decision-making?
- The history of the caregiver–care recipient relationship can be a significant determinant of how family members cope with the caregiver role. Not all family members will take on a caregiving role willingly, and hence this should be assessed.
- Assessment findings should be used to provide caregivers with educational materials relevant to immediate priorities and expressed concerns and to link caregivers to existing resources and community services. Family carers with assessment findings indicating clinically significant physical or mental health changes due to caregiving should be referred to a specialized professional or service.

Table 32.2 The needs of family caregivers in palliative care

Maintaining a balance	
Family caregivers' own needs	**Needs to be able to provide care for the patient**
Physical Maintain physical health Strength to provide care Sleep Rest *Psychological* Cope with strong and difficult emotions Maintain mental health Manage anxiety Avoid depression Be supported emotionally Maintain self-esteem Recognition of their anticipatory grief *Cognitive* Maintain cognitive functioning Get a mental break from caregiving and the illness Have privacy *Existential/spiritual* Retain hope Feel in control Find meaning in their new situation Strength from spirituality/faith Feel reward from caregiving Prevent isolation *Social* Financial security Learn new roles Be helped with other roles Cultural needs/differences to be respected	*Information* Obtain and understand information about patient's condition Feel prepared to provide care *Healthcare* Healthcare team to be competent Healthcare team to be available Access to assistive devices Be comfortable with the way they are involved in decisions for the patient's care *Relationships* Appreciation of their caregiving Have a good and trusting relationship with the patient Have a good and trusting relationship with the healthcare team *Environment* Have modifications made to the home Have a safe environment *Psychological* Feel confidence in their caregiving ability/role *Taught how to and/or help with* Administer medications through numerous routes (i.e., injections, suppositories, oxygen masks, etc.) Move and position the patient Be able to safely toilet, feed, and transfer the patient from one position to another Monitor/assess Emotionally support patient Household tasks (they are increased) Coordinate and navigate care Organize Ask others for help Access available financial benefits Transport the patient and themselves if patient is not living at home Plan for death

Source: Stajduhar & Cohen, 2008.

- Caregivers should be reassessed at regular intervals, including any time there is an acute change in the care recipient's health status, a care recipient transition in living situation or care setting, and prior to major treatment decisions (e.g., heart transplant, continue or discontinue dialysis).
- Caregiver assessment should be driven by a conceptual framework.

Tools to assist in the assessment of family caregiver support needs exist in the literature.[76,77] One recent example is the Carer Support Needs Assessment Tool (CSNAT) developed by researchers in the United Kingdom.[26] The CSNAT consists of 14 questions and can be used by nurses as a screen to identify family caregivers' key support needs that require further assessment. The tool is designed both to help legitimize family caregiver needs for support to family caregivers themselves and to make such needs visible and explicit to nurses and other health professionals. It focuses on support domains that enable the family caregiver to care for the patient ("Do you need more support with . . . understanding your relative's illness? Managing your relative's symptoms, including providing medicines? Providing personal care for your relative?

Knowing who to contact if you are concerned about your relative? Equipment to help care for your relative? Talking with your relative about his or her illness? Knowing what to expect in the future when caring for your relative?") and on more direct support domains for family caregivers themselves (i.e., "Do you need more support with . . . Having time for yourself in the day? Your financial, legal, or work issues? Dealing with your feelings and worries? Looking after your own health (physical problems)? Your beliefs or spiritual concerns? Practical help in the home? Getting a break from caregiving overnight?"). In addition to the 14 questions assessing family caregivers' needs for support, the tool includes one optional additional question to capture anything that might not have been addressed.

Supporting Family Caregivers in Different Settings

While the majority of care that families provide is in the home, there are many different settings where family caregivers play a critical role. The following sections describe the roles that caregivers can play in different settings, and general guidance is provided for the palliative care nurse on how to best prepare and support family members in these different settings.

In the Home

For family members of patients with advanced illnesses, family members have been reported to provide support an average of 8 hours per day for community-dwelling relatives in the home.[78] The tasks that are performed include routine tasks such as meal preparation, housework and lawn maintenance, managerial and financial tasks, transportation, and care for other family members. While some of these routine tasks may have already been part of the family member's normal daily routine, others may have been formerly managed by the patient until he or she became too sick to assume these tasks. Other tasks involve medical/nursing and hands-on patient care. These tasks might include healthcare and medical appointment coordination, emotional and spiritual support, medication management and administration, wound and medical device care, symptom monitoring and management, assistance with instrumental and other activities of daily living, promotion of care recipient self-care (e.g., physical activity), and healthcare decision-making. A large survey conducted in the United States found that just 14% of family members had received some kind of training to perform these medical/nursing tasks.[7]

The fundamental challenge that the palliative care nurse can help families with as they care for relatives with serious illness in the home is how to balance the additional demands of caregiving, their paid work, family life, and their own needs. This can be facilitated by helping caregivers make lists of their tasks and responsibilities and identify which tasks are absolutely necessary to accomplish and maintain. The next step is to help the family member estimate how much time each task takes. The family member then has three options to accomplish these tasks: (1) do the task(s) themselves, (2) ask and organize help from other family members and friends, or (3) hire outside assistance. If the caregiver decides to do the task themselves, assess how competent they are in doing the task and encourage them to acquire additional training if needed. For employed caregivers, there may be opportunities for leave, both paid and unpaid. A second option is to rally the assistance of family and friends. It can be difficult for caregivers to ask for volunteer assistance, and so it should be emphasized to caregivers that most family members and friends appreciate the opportunity to be helpful. The palliative care nurse can help caregivers make a list of the family and friends who could offer assistance and urge them to ask for help with specific tasks. A third option for families with the financial means is to hire someone or an agency to assist with tasks in the home. Different ways to find services to meet specific needs include referrals through the patient's provider or social worker, contacting a hospital's patient services department, searching the Internet, and asking family, friends, and community groups for recommendations.

Another particular issue of family caregiving for the palliative care nurse to be aware of are the preferences and special considerations for caregivers providing in-home care at end of life. Deciding to provide home care for relatives at end of life can have a profound effect on family caregivers. Many caregivers believe that providing home care for their loved one is the only option. Some make uninformed decisions, giving little consideration to the implications of their decision. Such decisions are often made early in the patient's disease trajectory or when the patient is imminently dying and may be influenced by the unrealistic portrayal in the media about dying at home. The patient's needs and wishes often drive decisions, with caregivers paying little attention to their own needs. Negotiated decisions for home care typically occur if caregivers and patients are able to talk openly about dying and have done so throughout the disease trajectory. For some families, a home death can bring additional burdens, worries, and responsibilities, so it is important that open discussion be facilitated. Large variations exist in the provision of home-based palliative and EOL care, although the development of hospice home services has enabled increasing numbers of seriously ill patients to experience care at home. Indeed, dying at home has been cited as the preference of the majority of patients, and studies of QOL at end of life have shown home deaths to be associated with higher quality death and dying. However, dying at home can present special challenges for family members. Clinicians must recognize the emotional impact of providing palliative care at home and must be sensitive to the potentially overwhelming task that caring for a dying relative imposes on family members. Care should be provided within a team context so that families understand that they are not alone in supporting the care recipient at end of life in the home and have access to a range of services from the palliative and hospice care team when needed. Furthermore, clinicians must work with the dying patients, with family caregivers, and with each other as equal partners in the caregiving process. Importantly, ongoing attention should be paid to improving hospital EOL care so that families feel they have a meaningful alternative to home care.

In the Hospital

Family caregivers play critical roles when their care recipients with advanced illness are admitted as inpatients into the hospital. They function as the patient's primary advocate, often having a close relationship to the patient that affords them an enhanced understanding of the patient's interests and values. Family caregivers are often present with patients over their illness trajectories and across settings. Hence, they are prime historians and "experts" in the patient's past and ongoing treatments and will often be a co-spokesperson with the patient in their encounters with different healthcare professionals. Though typically relieved of providing medical and nursing tasks while patients are in the hospital, family caregivers will often continue to provide essential companionship and emotional and spiritual support to patients. When appropriate, families may also provide hands-on patient care assistance such as bathing, dressing, hygiene, and feeding. And, finally, caregivers play an essential role in the discharge and transition-of-care process. To ensure patients continue to receive high-quality care after leaving the hospital, it is critical that families are prepared to assume and coordinate duties that patients cannot do for themselves but are made necessary by their medical condition and functional status.

For palliative care nurses interacting with families in the hospital, there are a few general principles to offering support that promotes their resiliency in the face of what can be a very intimidating and stressful event for them. First and foremost and unless otherwise directed by the patient, include family caregivers in all discussions with the patient about their condition, treatments, and tests. Treat them as partners in the patient's care. Clinicians should be aware that their own attitudes about the involvement of families in the care of patients is critical; if families feel they are a "nuisance" to healthcare providers, they will often become less cooperative with and more resentful of the healthcare system (which may ultimately negatively impact the patient). Second, help orient caregivers to what the different roles are of the different healthcare professionals. Many families may never have heard of palliative care or may associate it with hospice care or death and dying. It is important to convey that palliative care is not terminal illness care but instead serious illness care that is focused on providing an extra layer of support by offering relief from symptoms, pain, and the stress of serious illness. Finally, encourage caregivers to keep a small notebook whenever they talk with a member of the palliative care team. Family members should be reassured that nothing is trivial. All questions are important, and all observations are valuable. They should be encouraged to say when they do not understand something and to ask for information to be repeated as necessary. Palliative care professionals can help by spelling words that family members do not understand or by jotting down explanations. They should reassure family members that asking for help is not a sign of failure, but rather a sign of good common sense. Following such simple guidelines helps keep families from feeling overwhelmed.

In the Intensive Care Unit

Many family caregivers will experience seeing their care recipients in the intensive care unit (ICU) where the most invasive and aggressive medical treatments are performed. What caregivers do in the ICU is similar to what they might be seen doing in the hospital setting, and yet there are differences of relevance for the palliative care clinician. Studies report that family members in the ICU can be under marked psychological duress due to seeing their critically ill relative unconscious and connected to machines, having limited visitation to the patient, witnessing invasive procedures, experiencing distressing uncertainty, and being physically exhausted.[79] Being under such duress can challenge the ability of family members to cognitively process information,[80] and yet they are often asked to speak on behalf of patients' interests, participate in family meetings, and perform as surrogate decision-makers. A palliative care priority in interacting with family members in the ICU is the delivery of honest, easily understandable, and timely information as poor communication has been reported by families as the most frequent complaint in the ICU.[81] Families need to have their emotions and feelings acknowledged by clinicians, to have reassurance that everything is being done to help the patient, and have as liberal access to the patient's bedside as is possible, and they most generally want to know the patient's prognosis.[82] Palliative care nurses interacting with families in the ICU should become familiar with resources that further elaborate best practices for ICU communication skills,[83] conducting family meetings,[84] delivering prognosis,[85] and dealing with family emotions.[86,87]

In the Perioperative Setting

Regardless of whether a patient's surgery is planned or emergent, the perioperative experience for family caregivers can be physically and psychologically exhausting and manifest a range of intense emotions, including uncertainty, fear, and anxiety.[88] A prospective cohort study by Juarez et al.[88] of family caregivers of patients undergoing palliative surgery identified a number of ways that nurses can support families. These included (1) identifying any physical or psychological limitations of family members caring for patients after discharge, (2) educating families on patient postoperative symptom management, (3) ascertaining the caregiver's prior experiences with supporting the patient, (4) initiating referral for suspected psychosocial issues (e.g., depression, financial strain) or spiritual needs, (5) discussing anticipated out-of-pocket costs, (6) communicating patient needs after discharge that will require assistance from the caregiver, and (7) discussing distance and access to care for return visits and urgent care. Prospectively addressing caregiver distress related to uncertainty may be helped by informing families as early as possible about exactly what to expect before, during, and after surgery.[89] Offering support to family members by palliative care-trained nurses may be especially important in situations where the surgery was unexpected or emergent; the surgery is potentially futile or inappropriate; if there are complicated family dynamics; if family members are functionally debilitated, burned out, distressed, or depressed; if there are actual or foreseen ethical dilemmas; if there is expected to be complicated postoperative home-care requiring intense symptom and medication management; and any time it would be unsurprising if the patient became deceased within a year despite surgery.[90]

The Caregiver's Role in Decision-Making and Advance Care Planning

The effects of serious illness on the day-to-day lives of patients and their families inevitably gives rise to new problems and challenges where choices have to be made about the best course of action. Some of these decisions are treatment-related, such as deciding about whether or not to pursue an investigational new chemotherapy or whether to pursue a heart transplant. Others are wellness-related, such as deciding to engage in an exercise program or to change one's diet to reduce symptoms. Other decisions have little to do with health per se, but are imposed upon patients and families by the serious illness, such as whether to hire outside help to assist in the home, whether to sell a business to pay for medical expenses, whether to relocate the patient to a different care setting (e.g., home to assisted living or patient's home or caregiver's home), and even whether to give away a pet because the patient has become too ill to care for it.

In all these decisions, family caregivers play two key roles. First, they act as decision partners with patients who still have the ability to make decisions for themselves. In some cases, patients even regard their family members and sometimes even community members (e.g., pastors) as co-decision-makers along with them. For decisions about medical treatments, studies have reported that family members often help patients comprehend their medical situation, prognosis, and treatment options; are key communicators

and coordinators with providers during office visits where treatment decisions are made; and trigger help-seeking decisions when symptoms worsen.[91] For both healthcare and non-healthcare decisions, family caregivers are information gatherers and holders who often seek out and gather information about available options and the pros and cons of a decision. This can give family caregivers a great deal of influence because they are able to selectively seek out and relay information that consciously or unconsciously favors their own values and preferences. Family caregivers are also the individuals most proximally impacted by the consequences of patient decisions and, in this sense, have a vested stake in the choice selected and the outcome incurred. Evidence suggests that patients themselves are sensitive to this and often weigh decisions about palliative care and life-sustaining treatments based on how much they feel they are burdening family caregivers with their healthcare decisions and care.[92,93]

The second key role that caregivers play in the decision-making of patients is as a surrogate decision-maker when patients become unable to make decisions for themselves, often at end of life. Whether care is provided in the hospital or by families in the home or at a distance, patients at the end of life may not be able to make decisions about their own care. Family members, therefore, are often asked to make those decisions on the patient's behalf according to ethical standards of *concordance*, which require that decisions approximate as closely as possible those choices the patient would have made if they had been able.[94] These decisions are often about (though not limited to) the withdrawal or withholding of life-sustaining treatments such as mechanical ventilation, dialysis, and vasopressor support. A few challenges have been noted for family members in this role, including that the role itself can be extraordinarily burdensome and is often associated with negative psychological aftereffects that may persist for months to years after the death of a patient.[95] These psychological aftereffects can include depression, anxiety, and guilt about whether or not the "right" decision was made. Surrogates have also been repeatedly shown to be poor predictors of patients' treatment preferences.[96]

Many of the difficulties encountered in surrogate decision-making are related to family members not knowing what the patient would want. The palliative care clinician is thus urged to involve family members and their patients as early as possible in advance care planning. *Advance care planning* is a process that allows the patient's preferences to be made known to the family and to healthcare professionals. It involves discussions between the patient and his or her family and friends, as well as written instructions in the event that a patient can no longer express his or her choices verbally. Advance care planning is best begun while family members are healthy, but, when someone is ill, then as early as possible in the illness experience and revisited as needed because preferences can change over time. However, even in the less than 30% of cases when an adult has an advance directive, it may be neither specific enough nor available when needed. Clinicians should ask if advance directives are available, and they might invite family discussion regardless of whether or not such directives are in place. It is important for clinicians to be familiar with a patient's advance directive and to advocate for the patient if needed.

Recognizing the family caregiver's involvement in decision-making is critical to helping patients achieve their goals and receive care that is reflective of their values. When family members are involved in the advance care planning and decision-making process, they are more likely to work toward helping the patient achieve their preferences. Clinicians should be available to families, offering anticipatory guidance and support through the caregiving experience. Healthcare professionals must assist family members as they traverse the maze of treatment and care decisions, ranging from whether to give particular "as needed" medications, or what food to make for the patient to eat, to whether or not to seek hospice care, to sign "do-not-resuscitate" documents, or to terminate treatment. It is critical that palliative care professionals continually engage with caregivers in forward planning, interpretation, and monitoring of the inevitable decline and dying process of the ill person to facilitate the feeling in caregivers that they are secure and supported in their physically and emotionally exhaustive work. Families need to know whom to call and when, and how to reach them. Table 32.3 provides information on various resources available for family caregivers; palliative care nurses can supplement this table with local resources and service agencies.

Conclusion

The primary goal of palliative care is to improve the QOL and quality of death of dying people and their families through provision of excellent care. Families share most intimately the experience of living with and dying from a terminal illness. They are strongly affected, both positively and negatively. Many also wish to provide care for their loved one, but they require support from nurses and others in the healthcare team to do so without being overburdened and endangering their own health and well-being. Nurses play a key role in helping families to navigate uncharted territory, in identifying the family's needs for support, and in assessing and personalizing a plan of care not only for the patient but for the family as a whole and its individual members. While not all families generate positive benefits from the experience of losing a loved one, many families and family caregivers derive significant meaning from the experience of supporting another in the palliative phases of care.

Acknowledgments

The authors are very grateful for the original work on this chapter completed by Betty Davies, PhD, and Rose Steele, RN, PhD. The contributions they have made to the field of palliative care nursing cannot be overstated.

CHAPTER 33

Planning for the Actual Death

Patricia Berry and Julie Griffie

Key Points

- The care of patients near death and their families and the care afterward is an important nursing function—arguably one of the most important things nurses do.
- At the end of life, there are no dress rehearsals; nurses and other healthcare professionals only have one chance to "get it right."
- Assessment and aggressive management of symptoms must remain a priority, especially as death approaches.
- As the person nears death, the goals of care inevitably change in rhythm with patient and family needs and wishes. The nurse is key in picking up the rhythm of the situation and considering the perspectives and needs of everyone involved, assuring the best experience possible for all.
- Care of the body after death, including normalizing and interpreting postmortem changes and honoring rituals and individual requests, is critically important in communicating to family members and close others that the person who died was indeed important and valued.

Introduction

Issues and needs at the time of death are exceedingly important and, at the same time, exceptionally personal. While the physiology of dying is often the same for most expected deaths, the psychological, spiritual, cultural, and family issues are as unique and varied as the patients and families themselves. As death nears, the goals of care must be discussed and appropriately redefined. Some treatments may be discontinued, and symptoms may intensify, subside, or even appear anew. Physiological changes as death approaches must also be defined, normalized, explained, and interpreted to the patient whenever possible, as well as to the patient's family, close others, and caregivers. The nurse occupies a key position in assisting patients' family members at the time of death by supporting and/or suggesting death rituals, caring for the body after death, and facilitating early grief work. In past literature, most of the focus on death and dying has been on the dying process in general, making the need for a chapter focused specifically on the actual death—and the time right before and after—even more important for a discussion on the role of the palliative nurse during this experience.

Terminally ill persons are cared for in a variety of settings, including home settings with hospice care or traditional home care, hospice residential facilities, nursing homes, assisted living facilities, hospitals, intensive care units, prisons, and group homes. Deaths in intensive care settings may present special challenges, such as restrictive visiting hours and lack of space and less privacy for families—shortcomings that can be addressed by thoughtful and creative nursing care. Likewise, death in a nursing home setting may also offer unique challenges. Regardless of the setting, anticipating and managing pain and symptoms can minimize distress and maximize quality of life. Families can be supported in a way that optimizes use of valuable time and lessens distress during the bereavement period. Health professionals only have one chance to "get it right"—to do the right thing at the time rather than trying to go back and correct something when caring for dying persons and their families as death nears. This is especially true during the final hours before death. In other words, there is no dress rehearsal for the time surrounding death; anticipation of common symptoms and careful, thoughtful, and extensive planning ensures the least stressful and best possible outcome for all involved.

The patient's family is especially important as death nears. Family members may become full- or part-time caregivers; daughters and sons may find themselves in a position to "parent" their parents; and family issues, long forgotten or ignored, may surface. Although "family" is often thought of in traditional terms, a family may take on several forms and configurations. For the purposes of this chapter, the definition of family recognizes that many patients have nontraditional families and may be cared for by a large extended entity, such as a church community, a group of supportive friends, or the staff of a healthcare facility. Family is defined broadly to include not only persons bound by biology or legal ties but also those whom the patient defines or who define themselves as "close others" or who function for the patient as a family member would, including the provision of nurturance, intimacy, and economic, social, and psychological support in times of need; support in illness (including dealing with those outside the family); and companionship.

The occurrence of symptoms at end of life is temporal in nature; that is, there is a constellation of symptoms common throughout the course of end-stage disease and symptoms that appear during the period immediately preceding death, most often 2–3 days prior. As death nears, symptoms can escalate and new ones appear. While there is much known about the assessment and management of symptoms near death, most research demonstrates that many people experience a death with symptoms not well controlled.[1] In a systematic review of signs of impending death and symptoms in the last 2 weeks of life, a total of 43 symptoms were identified, with dyspnea (56.7%), pain (52.4%), noisy breathing/respiratory congestion (51.4%), and confusion (50.1%) as the most common.[2] Within a few days of death, many patients experience a higher frequency of noisy and moist breathing, urinary incontinence and retention, restlessness, agitation, delirium, and nausea and vomiting.[1–4] Symptoms that occur with less frequency include sweating and myoclonus, with myoclonus sometimes occurring as a reversible toxic effect of opioids, most notably morphine, especially in older adults and those with renal impairment.[2,3,5] In most studies, symptoms requiring maximum diligence in assessment, prevention, and aggressive treatment during the final day or two before death are respiratory tract secretions/moist breathing, pain, dyspnea, and agitated delirium, which is very common.[2–4] For some patients, the path of dying is characterized by progressive sleepiness leading to coma and death. For others, the pathway to death is marked by increasing symptoms, including restlessness, confusion, hallucinations, sometimes seizure activity, and then coma and death.[6,7] Assessment and intervention is focused on identifying those persons who are on the more difficult pathway and aggressively treating their symptoms to assure a peaceful death. Persons with cognitive impairment and the inability to self-report or communicate require specific attention to symptoms, especially as death nears. In any case, the nurse plays a key role in assessing and anticipating symptoms, acting promptly to assure, if at all possible, that symptoms are aggressively prevented and managed before they become severe. The nurse also has an important role in educating family members and other caregivers about the assessment, treatment, and ongoing evaluation of these symptoms.

Regardless of individual patient and family needs, attitudes, and "unfinished business," the nurse's professional approach and demeanor at the time near death is crucial and worthy of close attention. Patients experience total and profound dependency at this stage of their illness. Families are often called on to assume total caregiving duties, often disrupting their own responsibilities for home, children, and career. Although there may be similarities, patients and families experience this time through the unique lens of their own perspective and form their own unique meanings.

Some authors suggest theories and guidelines to help support the nurse in establishing and maintaining meaningful, helpful, and therapeutic relationships with patients or clients and their families. One example is Carl Rogers's theory of helping relationships, in which he proposed that the characteristics of a helping relationship are empathy, unconditional positive regard, and genuineness.[8] These characteristics, defined later as part of the nurse's approach to patients and families, are essential in facilitating care at the end of life. To this may be added "attention to detail," as this additional characteristic is widely accepted as essential for individualized, patient- and family-centered, quality palliative care.[9] Readers are urged to consider the following characteristics as they reflect on their own practice because they can serve as a powerful foundation for facilitating and providing supportive relationships:

- *Empathy*: The ability to put oneself in the other person's place, trying to understand the patient or client from his or her own frame of reference; it also requires the deliberate setting aside of one's own frame of reference and bias.
- *Unconditional positive regard*: A warm feeling toward others, with a nonjudgmental acceptance of all they reveal themselves to be; the ability to convey a sense of respect and esteem at a time and place in which it is particularly important to do so.
- *Genuineness*: The ability to convey trustworthiness and openness that is real rather than a professional facade; also the ability to admit that one has limitations, makes mistakes, and does not have all the answers.
- *Attention to detail*: The learned and practiced ability to think critically about a situation and not make assumptions. The nurse, for example, discusses challenging patient and family concerns with colleagues and other members of the interdisciplinary team. The nurse considers every "what if" before making a decision and, in particular, before making any judgment. Finally, the nurse is constantly aware of how his or her actions, attitudes, and words may be interpreted—or misinterpreted—by others.

The events and interactions—positive as well as negative—that occur at the bedside of a dying person set the tone for the patient's care and form lasting memories for family members. The time of death and the care received by both the individual who has died and the family members who are present are predominant aspects of the survivors' memories of this momentous event. Approaching patients and families with a genuine openness characterized by empathy and positive regard eases the way in making this difficult time meaningful, individualized, and deeply profound.

This chapter discusses some key issues surrounding the death itself, including advance planning and the evolving and ever-changing choices and goals of care, the changing focus of care as death nears, common signs and symptoms of nearing death and their management, and care of the patient and family at time of death. It concludes with two case examples illustrating the chapter's content.

Advance Planning: Evolving Choices and Goals of Care

Healthcare choices related to wellness are generally viewed as clear-cut or easy. We have an infection, we seek treatment, and the problem resolves. Throughout most of the life span, medical treatment choices are obvious. As wellness moves along the healthcare continuum to illness, choices become less clear, and the consequences of choices have a significantly greater impact.

Many end-of-life (EOL) illnesses manifest with well-known and well-documented natural courses. Providing the patient and family with information on the natural course of the disease at appropriate intervals is a critical function of healthcare providers such as nurses. Providing an opening for discussion, such as, "Would you like to talk about the future?" "Do you have any concerns that I can help you address?" or "It seems you are not as active as you were before," may allow a much-needed discussion of fears and concerns about impending death. Family members may request information that patients do not wish to know at certain points in time. With the patient's permission, discussions with the family may occur in the patient's absence. Family members may also need coaching to initiate EOL discussions with the patient. EOL goal-setting is greatly enhanced when the patient is aware of the support of family.

EOL care issues should always be discussed with patients and family members. The patient who is capable of participating in and making decisions is always the acknowledged decision-maker. The involvement of family ensures maximal consensus for patient support as decisions are actually implemented. Decisions for patients who lack decision-making capacity should be made by a consensus approach, using a family conference methodology. If documents such as a durable power of attorney for healthcare or a living will are available, they can be used as a guide for examining wishes that influence decision-making and goal-setting. The decision-maker, usually the person named as healthcare power of attorney (HCPOA), or the patient's primary family members, should be clearly identified. This approach is also useful with patients who are able to make their own decisions and, of course, should always include the patient as a participant.

To facilitate decision-making, convening a family conference that involves the decision-makers (decisional patient, family members, and the HCPOA), the patient's physician or provider, nurse, chaplain, and social worker is ideal. A history of how the patient's healthcare status evolved from diagnosis to the present is reviewed. The family is presented with the natural course of the disease. Choices on how care may proceed, including prognostic estimations and the benefits and burdens of treatments, are reviewed. Guidance or support for those choices is provided based on existing data and clinical experience with the particular disease in relation to the current status of the patient. If no consensus for the needed decisions occurs, decision-making is postponed. Third-party support by a trusted individual or consultant may then be enlisted. Decisions by patients and families a cross the spectrum of care range from continuing treatment for the actual disease, such as undergoing chemotherapy or renal dialysis or utilization of medications, to initiating cardiopulmonary resuscitation (CPR). The healthcare provider may work with the patient and family, making care decisions for specific treatments and timing treatment discontinuance within a clear and logical framework. A goal-setting discussion may determine a patient's personal preferences for care, such as:

- Treatment and enrollment in any clinical studies for which the patient is eligible.
- Treatment as long as statistically there is a greater than 50% chance of response.
- Full treatment as long as the patient is ambulatory and able to come to the clinic or office.
- Treatment only of "fixable" conditions such as infections or blood glucose levels.
- Treatment only for controlling symptomatic aspects of disease.

Once a goals of care framework has been established with the patient, the appropriateness of interventions such as CPR, renal dialysis, or intravenous antibiotics is clear. For instance, if the patient states a desire for renal dialysis as long as transportation to the clinic is possible without the use of an ambulance, the endpoint of dialysis treatment is quite clear. At this point, the futility of CPR would also be apparent. Allowing a patient to determine when the treatment is a burden that is unjustified by his or her value system, and communicating this determination to family and caregivers, is a pivotal point in management of the patient's care. There are multiple guidelines and formats for conducting and/or participating in a family conference and the role of the nurse. Box 33.1 suggests one format for an effective and comprehensive family conference.

Box 33.1 Moderating an End-of-Life Family Conference

I. *Why*: Clarify goals in your own mind. For example, what is the purpose of the meeting, who is attending? Gather members of the healthcare team prior to the meeting to assure that everyone is clear on their role and the goals of the conference.

II. *Where*: Provide comfort, privacy, circular seating.

III. *Who*: Include legal decision-maker/healthcare power of attorney; family members; social support; key healthcare professionals, patient if capable to participate.

IV. *How*:

  A. Introduction
    1. Introduce self and others.
    2. Review meeting goals: Review provider-intended goals, elicit patient/family-intended goals, and then negotiate a plan to proceed
    3. Establish ground rules: Each person will have a chance to ask questions and express views; no interruptions; identify legal decision-maker, and describe importance of supportive decision-making.
    4. If new to patient/family, spend some time getting to know the family and the patient as people.

  B. Determine what the patient/family knows and understands.

  C. Review medical status.
    1. Review current status, plan, and prognosis.
    2. Ask each family member in turn for any questions about current status, plan, and prognosis.
    3. Defer discussion of decision until the next step.
    4. Respond to emotions.

  D. Family discussion with decisional patient:
    1. Ask patient, "What decision(s) are you considering?"
    2. Ask each family member, "Do you have questions or concerns about the treatment plan? How can you support the patient?"

  E. Family discussion with nondecisional patient:
    1. Ask each family member in turn, "What do you believe the patient would choose if he (or she) could speak for himself (or herself)?"
    2. Ask each family member, "What do you think should be done?"
    3. Leave room to let family discuss alone.
    4. If there is consensus, go to V; if no consensus, go to F.

  F. When there is no consensus:
    1. Restate goal: "What would the patient say if he or she could speak?"
    2. Use time as ally: Schedule a follow-up conference the next day.

(*continued*)

Box 33.1 Continued

3. Try further discussion: "What values is your decision based on? How will the decision affect you and other family members?"
4. Identify legal decision-maker.
5. Identify resources: minister/priest; other physicians; ethics committee.

V. *Wrap-up*:
  - A. Summarize consensus, decisions, and plan.
  - B. Caution against unexpected outcomes.
  - C. Identify family spokesperson for ongoing communication.
  - D. Document in the chart who was present, what decisions were made, follow-up plan.
  - E. Approach discontinuation of treatment as an interdisciplinary team, not just as a nursing function.
  - F. Continuity: Maintain contact with family and medical team; schedule follow-up meetings as needed.

VI. *Family dynamics and decisions*:
  - A. Family structure: Respect the family hierarchy whenever possible.
  - B. Established patterns of family interaction will continue.
  - C. Unresolved conflicts between family members may be evident.
  - D. Past problems with authority figures, doctors, and hospitals affect the process; ask specifically about bad experiences in the past.
  - E. Family grieving and decision-making may include:
    1. Denial: False hopes, misunderstanding of the situation.
    2. Guilt: Fear of letting go, including regrets.
    3. Depression: Passivity and inability to decide; or anger and irritability.

Changing the Focus of Care as Death Nears

As death nears, the rhythm of care changes; visiting hours in an institutional setting are relaxed; the routines of care, for example, taking vital signs, tracking intake and output, and daily weights seem less important; and treatments automatically associated with caring for any patient are considered in the context of benefit and burden. Here we focus on some of these routines and treatments, recognizing that the nurse again plays a key role in explaining and normalizing the shifts in the rhythm of care to the patient and family. The nurse also plays an important role in advocating on behalf of the patient, relaying and advocating for the goals of care to colleagues, and assuring that the care delivered is consistent with the goals and preferences of the patient and/or family.

Vital Signs

As nurses, we derive a good deal of security in performing the ritual of measuring vital signs, one of the hallmarks of nursing care. When death is approaching, we need to question the rationale for measuring and recording vital signs. Are interventions going to change if it is discovered that the patient has experienced a drop in blood pressure? If the plan of care no longer involves intervening in changes in blood pressure and pulse rate, the measurements should cease. The time spent taking vital signs can then be redirected to assessment of patient comfort and provision of family support. Changes in respiratory rate are visually noted and do not require routine monitoring of rates, unless symptom management issues develop that could be more accurately assessed by measurement of vital signs. If the patient appears uncomfortable, the measurement of body temperature using a noninvasive route should continue on a regular basis until death. This allows for the detection and management of fever, a frequent symptom that can cause distress and may require management.

Fever often suggests infection. As death approaches, goal-setting should include a discussion of the benefits and burdens of treating an infection. Indications for treatment of infection are based on the degree of distress and patient discomfort.[11] Pharmacological management of fever includes antipyretics, including acetaminophen, and nonsteroidal anti-inflammatory drugs. In some cases, treatment of an infection with an antibiotic may increase patient comfort. Ice packs, alcohol baths, and cooling blankets should be used cautiously because they often cause more distress than the fever itself.[11]

Fever may also suggest dehydration. As with the management of fever, interventions are guided by the degree of distress and patient discomfort. The appropriateness of beginning medically administered hydration for the treatment of fever is based on individual patient assessment, the estimated prognosis, and the goals of care.

Finally, fever may suggest that death is imminent as many people develop a *central fever*; that is, they are cool to the touch but have an increased temperature. In this case, as with all interventions as death nears, treat for patient comfort.

Cardiopulmonary Resuscitation

Patients and family members may need to discuss, if they have not already, the issue of the futility of CPR when death is expected from a terminal illness. Developed in the 1960s as a method of restarting the heart in the event of sudden, unexpected clinical death, CPR was originally intended for circumstances in which death was unexpected or accidental. It is not indicated in certain situations, such as cases of terminal irreversible illness where death is not unexpected; resuscitation in these circumstances may represent an active violation of a person's wish to die on their own terms.

Over the years, predictors of the success of CPR have become apparent, along with the predictors of the burden of CPR. In general, a poor outcome of CPR is predicted in patients with advanced terminal illnesses, patients with dementia, and patients with poor functional status who depend on others for meeting their basic care needs. Poor outcomes or physical problems resulting from CPR include fractured ribs, punctured lung, brain damage if anoxia has occurred for too long, and permanent unconsciousness or persistent vegetative state.[12–13]

Medically Administered Fluids

The issue of medically administered or "artificial" hydration is emotional for many patients and families because of the role that giving and consuming fluids plays in many cultures. When patients are not able to take fluids, concerns may surface among caregivers. A decision must be reached regarding the appropriate use of fluids within the context of the patient's framework of goals. Beginning medically administered hydration is a relatively easy task, but the decision to stop is generally much more problematic given its emotional implications. However, the emotional response attached to withdrawing a treatment adds a world of difference to the decision to suspend. It is therefore much less burdensome to not begin treatment, if this decision is acceptable in light of the specific patient circumstances.[14]

Most patients and families are aware that, without fluids, death will occur quickly. The literature suggests that fluids should not be routinely administered to dying patients, nor automatically withheld from them. Instead, the decision should be based on careful, individual assessment. Zerwekh,[15] in a classic article, suggested consideration of the following questions when the choice to initiate or continue hydration is evaluated. These questions remain relevant today to this important issue:

- Is the patient's well-being enhanced by the overall effect of hydration?
- Which current symptoms are being relieved by medically administered hydration?
- Are other EOL symptoms being aggravated by the fluids?
- Does hydration improve the patient's level of consciousness? If so, is this within the patient's goals and wishes for EOL care?
- Does hydration appear to prolong the patient's survival? If so, is this within the patient's goals and wishes for EOL care?
- What is the effect of the infusion technology on the patient's well-being, mobility, and ability to interact and be with family?
- What is the burden of the infusion technology on the family in terms of caregiver stress or finance? Is it justified by benefit to the patient?

A systematic review from 2014 found insufficient evidence to support the use of medically administrated fluids near the end of life but did note some evidence of hydration reducing sedation and myoclonus.[16] In any case, the uniqueness of the individual situation, the goals of care, the benefits and burdens of the proposed treatment, and the comfort of the patient must always be considered.[17]

Terminal dehydration refers to the process in which the dying patient's condition naturally results in a decrease in fluid intake. A gradual withdrawal from activities of daily living may occur as symptoms such as dysphagia, nausea, and fatigue become more obvious. Families commonly ask whether the patient will be thirsty as fluid intake decreases. Hydration has the potential to cause fluid accumulation, resulting in distressful symptoms such as edema, ascites, nausea and vomiting, and pulmonary congestion.[16]

There is no evidence that rehydration actually prolongs life.[16] Healthcare providers need to assist patients and family members to refocus on the natural course of the disease and the notion that the patient's death will be caused by the disease, not by dehydration, which is a natural occurrence in advanced illness and dying. Nurses may then assist families in dealing with symptoms caused by dehydration.

Dry mouth, a consistently reported distressing symptom of dehydration, can be relieved with sips of beverages, ice chips, or hard candies. Another simple comfort measure for dry mouth is spraying normal saline into the mouth with a spray bottle or atomizer. (Normal saline is made by mixing 1 teaspoon of table salt in a quart of water.) Meticulous mouth care must be administered to keep the patient's mouth clean. Family members can be instructed to anticipate this need. The nurse can facilitate this care by ensuring that the necessary provisions are on hand to assist the patient.

Medications

Medications unrelated to the terminal diagnosis are generally continued as long as their administration is not burdensome. When swallowing tablets or capsules becomes too difficult, the medication may be offered in a liquid or other form if available, considering patient and family comfort. Continuing medications, however, may be seen by some patients and families as a way of normalizing daily activities and therefore should be supported. Considerable tact, kindness, and knowledge of the patient and family are needed in assisting them to make decisions about discontinuing medications.

Medications that do not contribute to daily comfort should be evaluated on an individual basis for possible discontinuance. Medications such as antihypertensives, replacement hormones, vitamin supplements, iron preparations, hypoglycemics, long-term antibiotics, antiarrhythmics, and laxatives, unless they are essential to patient comfort, can and should be discontinued unless doing so would cause symptoms or discomfort. Accordingly, special consideration should be given to the use of diuretics with patients with end-stage heart disease and corticosteroids in patients with neuropathic pain or for the treatment of increased intracranial pressure. While there are no specific guidelines governing this practice, the control or prevention of distressing symptoms should be the guiding principle in the use of medications, especially in the final days of life.[18]

Cardiovascular Implantable Electronic Devices

Cardiovascular implantable electronic devices (CIEDs) are used to prevent cardiac arrest due to ventricular tachycardia or ventricular fibrillation. Patients with CIEDs who are dying of another terminal condition or are withdrawn from antiarrhythmic medications may choose to have the defibrillator deactivated, or turned off, so that there will be no interference from the device at the time of death. If the patient has a CIED, it is critical to confirm its deactivation if that is in keeping with the goals of care. Screening for a CIED in out-of-institution care settings, like hospices, because of the high likelihood of preventable adverse events is critical.[19] The interprofessional guideline, *HRS Expert Consensus Statement on the Management of Cardiovascular Implantable Electronic Devices (CIEDs) in Patients Nearing End of Life or Requesting Withdrawal of Therapy,* provides detailed guidance on the ethical, legal, and practical aspects of CIED deactivation.[20]

Renal Dialysis

Renal dialysis is a life-sustaining treatment, and, as death approaches, it is important to recognize and agree on its limitations. Discontinuation of dialysis should be considered in the following cases:

- Patients with acute, concurrent illness, who, if they survive, will be burdened with a great deal of disability as defined by the patient and family.

- Patients with progressive and untreatable disease or disability.
- Patients with dementia or severe neurological deficit.

There is general agreement that dialysis should not be used to prolong the dying process. The time between discontinuing dialysis and death varies widely, from a matter of hours or days (for patients with acute illnesses, such as those described earlier) to days or a week or longer if some residual renal function remains. While there are clinical practice guidelines and continuing interest in palliative care in end-stage renal disease, opening a discussion about the burden of treatment is a delicate task.[21–24] There may be competing opinions among the patient, family, and even staff about the tolerability or intolerability of continuing treatment. The nurse who sees the patient and family on a regular basis may be the most logical person to recognize the discrete changes in status. Gently validating these observations may open a much-needed discussion regarding the goals of care.

The discussions and decisions surrounding discontinuation or modification of treatment are never easy. Phrases such as, "There is nothing more that can be done" or "We have tried everything" have no place in EOL discussions with patients and families. Always reassure the patient and family members—and be prepared to follow through—that you will stand by them and do all you can to provide help and comfort. This is essential to ensure that palliative care is not interpreted as abandonment.

In addition to addressing concerns the patient and family may have as death nears, the nurse should explore and confirm wishes and preferences for after the patient dies. For example, have funeral arrangements been discussed? Have any decisions been made? Has a funeral provider been selected? Are there any special considerations for eye, tissue, or body donation? The nurse has a pivotal role in encouraging family members to carefully select a funeral provider and to gather information as they would any other provider (for example, a long-term care facility, a healthcare provider). Urge the family, if the choice is not certain, to take the time to call and visit funeral providers before taking advice from others and making a final decision. This is a critical nursing function regardless of the setting of care and the place of anticipated death.

Common Signs and Symptoms of Imminent Death and Their Management

There usually are predictable sets of processes that occur during the final stages of a terminal illness due to gradual hypoxia, respiratory acidosis, metabolic consequences of renal failure, and the signs and symptoms of hypoxic brain function.[1,7] These processes account for the signs and symptoms of imminent death and can assist the nurse in helping the family plan for the actual death.

The following signs and symptoms provide cues that death is only days away[1,7,25]:

- Profound weakness (patient is usually bedbound and requires assistance with all or most care)
- Gaunt and pale physical appearance (most common in persons with cancer if corticosteroids have not been used as treatment)
- Drowsiness and/or a reduction in awareness, insight, and perception (often with extended periods of drowsiness, extreme difficulty in concentrating, severely limited attention span, inability to cooperate with caregivers, disorientation to time and place, or semicomatose state)
- Increasing lack of interest in food and fluid with diminished intake (only able to take sips of fluids)
- Increasing difficulty in swallowing oral medications

During the final days, these signs and symptoms become more pronounced, and, as oxygen concentrations drop, new symptoms also appear. Measurement of oxygen concentration in the dying person is not advocated because it may add discomfort and does not alter the course of care. However, knowledge of the signs and symptoms associated with decreasing oxygen concentrations can assist the nurse in guiding the family as death nears.[25] As oxygen saturation drops below 80%, signs and symptoms related to hypoxia appear. As the dying process proceeds, special issues related to normalizing the dying process for the family, symptom control, and patient and family support present themselves. Table 33.1 summarizes the physiological process of dying and suggests interventions for both patients and families.

As the imminently dying person takes in less fluid, third-spaced fluids, clinically manifested as peripheral edema, ascites, or pleural effusions, may be reabsorbed. Breathing may become easier, and there may be less discomfort from tissue distention. Accordingly, as the person experiences dehydration, swelling is often reduced around tumor masses. Patients may experience transient improvements in comfort, including increased mental status and decreased pain. The family, in this case, needs a careful and compassionate explanation regarding these temporary improvements and encouragement to make the most of this short but potentially meaningful time. There are multiple patient and family educational tools that are widely available to assist families in interpreting the signs and symptoms of approaching death. However, as with all aspects of palliative care, consideration of the individual perspective and associated relationships of the patient or family member, the underlying disease course trajectory, anticipated symptoms, and the setting of care is essential for optimal care at all stages of illness, but especially during the final days and hours.

Care at the Time of Death, Death Rituals, and Facilitating Early Grieving

At the time of death, the nurse has a unique opportunity to provide information helpful in making decisions about organ and body donation and autopsy. In addition, the nurse can support the family's choice of death rituals, gently care for the body, assist in funeral planning, and facilitate the early process of grieving. Family members' needs change around the time of death, just as the goals of care change. During this important time, plans are reviewed and perhaps refined. Special issues affecting the time of death, such as cultural influences, decisions regarding organ or body donation, and the need for autopsy, are also reviewed.

Under US federal law, if death occurs in a hospital setting, staff must approach the family decision-maker regarding the possibility of organ donation.[26] Although approaching family at this time may seem onerous, the opportunity to assist another is often comforting. Some hospital-based palliative care programs include information about organ donation in their admission or bereavement information. Readers are urged to review their own organizations' policies and procedures.

In any case, it is important to clarify specifically with family members what their desires and needs are at the time of death. Do they wish to be present? Do they know of others who wish to now

Table 33.1 Symptoms in the normal progression of dying and suggested interventions

Symptoms	**Suggested interventions**
Early-stage sensation	
Perception	Interpret the signs and symptoms to the patient (when appropriate) and family as part of the normal dying process; for example, assure them the patient's "seeing" and even talking to persons who have died is normal and often expected.
Impairment in the ability to grasp ideas and reason; periods of alertness along with periods of disorientation and restlessness are also noted.	Urge family members to look for metaphors for death in speech and conversation (e.g., talk of a long journey, needing maps or tickets, or in preparing for a trip in other ways) and use these metaphors as a departure point for conversation with the patient.
	Urge family to take advantage of the patient's periods of lucidity to talk with patient and ensure nothing is left unsaid.
	Encourage family members to touch and speak slowly and gently to the patient without being patronizing.
	Maximize safety; for example, use bedrails and schedule people to sit with the patient.
Some loss of visual acuity	Keep sensory stimulation to a minimum, including light, sounds, and visual stimulation; reading to a patient who has enjoyed reading in the past may provide comfort.
Increased sensitivity to bright lights while other senses, except hearing, are dulled	Urge the family to be mindful of what they say "over" the patient because hearing remains present; also continue to urge family to say what they wish not to be left unsaid.
Cardiorespiratory	
Increased pulse and respiratory rate	Normalize the observed changes by interpreting the signs and symptoms as part of the normal dying process and ensuring the patient's comfort.
Agonal respirations or sounds of gasping for air without apparent discomfort	Again, normalize the observed changes by interpreting the signs and symptoms as part of the normal dying process and ensuring the patient's comfort; assess and treat respiratory distress as appropriate
Apnea, periodic, or Cheyne-Stokes respirations	Assess and treat respiratory distress as appropriate.
Inability to cough or clear secretions efficiently, resulting in gurgling or congested breathing (sometimes referred to as the "death rattle")	Assess use and need for parenteral fluids, tube feedings, or hydration. (It is generally appropriate to either discontinue or greatly decrease these at this point in time.)
	Reposition the patient in a side-lying position with the head of the bed elevated.
	Suctioning is rarely needed, but when appropriate, suction should be gentle and only at the level of the mouth, throat, and nasal pharynx.
	Administer anticholinergic drugs (transdermal scopolamine, hyoscyamine) as appropriate, recognizing and discussing with the family that they will not decrease already existing secretions.
Renal/urinary	
Decreasing urinary output, sometimes urinary incontinence or retention	Insert catheter and/or use absorbent padding.
	Carefully assess for urinary retention because restlessness can be a related symptom.
Musculoskeletal	
Gradual loss of the ability to move, beginning with the legs, then progressing.	Reposition every few hours as appropriate.
	Anticipate needs such as sips of fluids, oral care, changing of bed pads and linens, and so on.
Late-stage sensation	
Perception	
Unconsciousness	Interpret the patient's unconsciousness to the family as part of the normal dying process.
Eyes remain half-open, blink reflex is absent; sense of hearing remains intact and may slowly decrease	
	Provide for total care, including incontinence of urine and stool.
	Encourage family members to speak slowly and gently to the patient, with the assurance that hearing remains intact.
Cardiorespiratory	
Heart rate may double, strength of contractions decrease; rhythm becomes irregular	Interpret these changes to family members as part of the normal dying process.

(*continued*)

Table 33.1 Continued

Symptoms	Suggested interventions
Patient feels cool to the touch and becomes diaphoretic	Frequent linen changes and sponge baths may enhance comfort.
Cyanosis is noted in the tip of the nose, nail beds, and knees; extremities may become mottled (progressive mottling indicates death within a few days); absence of a palpable radial pulse may indicate death within hours.	
Renal/urinary	
A precipitous drop in urinary output	Interpret to the family the drop in urinary output as a normal sign that death is near, usually 24–72 hours away.
Carefully assess for urinary retention; restlessness can be a related symptom.	

say a final goodbye? Have they said everything they wish to say to the person who is dying? Do they have any regrets? Are they concerned about anything? Do they wish something could be different? Every person in a family has different and unique needs that, unless explored, can go unmet. Family members recall the time before the death and immediately afterward with great acuity and detail.

Although an expected death can be anticipated with some degree of certainty, the exact time of death is often not predictable. Death often occurs when no healthcare professionals are present. Often, dying people seem to determine the time of their own death—for example, waiting for someone to arrive, for a date or event to pass, or even for family members to leave—even if the leave-taking is brief. For this reason, it is crucial to ask family members who wish to be present at the time of death whether they have thought about the possibility they will not be there. This opens an essential discussion regarding the time of death and its unpredictability. Gently reminding family members of that possibility can assist them in preparing for any eventuality.

Determining that Death Has Occurred

Death often occurs when health professionals are not present at the bedside or in the home. Regardless of the site of death, a plan must be in place for who will be contacted, how the death pronouncement will be handled, and how the body will be removed. This is especially important for deaths that occur outside a healthcare institution.

Death pronouncement procedures vary from state to state and sometimes from county to county within a state. In some states, nurses can pronounce death; in others, they cannot. In inpatient settings, the organization's policy and procedures are followed. In hospice home care, generally the nurse makes a home visit; assesses the lack of vital signs; contacts the physician, who verbally agrees to sign the death certificate; and then contacts the funeral home or mortuary. Local customs, the ability of a healthcare agency to ensure the safety of a nurse during the home visit, and provision for "do-not-resuscitate" orders outside a hospital setting, among other factors, account for wide variability in the practices and procedures surrounding pronouncement of death in the home. Although practices vary widely, the police or coroner may need to be called if the circumstances of the death were unusual, were associated with trauma (regardless of the cause of the death), or occurred within 24 hours of a hospital admission.

The practice of actual death pronouncement varies widely and is not often taught in medical school or residencies. The customary procedure is to first identify the patient, then note the following:

- General appearance of the body
- Lack of reaction to verbal or tactile stimuli
- Lack of pupillary light reflex (pupils will be fixed and dilated)
- Absent breathing and lung sounds
- Absent carotid and apical pulses (in some situations, listening for an apical pulse for a full minute is advisable)

Documentation of the death is equally important and should be thorough and clear. The following guidelines are customary:

- Record the patient's name and time of call.
- Record who was present at the time of death and at the time of the pronouncement.
- Record detailed findings of the physical examination.
- Record the date and time of death pronouncement (either pronouncement by the nurse or the time at which the physician either assessed the patient or was notified).
- Note who else was notified and when—for example, additional family members, attending physician, or other staff members.
- Record whether the coroner was notified, rationale, and outcome, if known.
- Note special plans for disposition and outcome (e.g., organ or body donation, autopsy, special care related to cultural or religious traditions).

Care of the Body after Death

The care of the patient does not end with the death, but rather continues during the immediate postmortem period as the body is prepared for transport into the care of the funeral provider. Regardless of the site of death, therefore, care of the patient's body is an important nursing function. In gently caring for the body, the nurse can continue to communicate care and concern for the patient and family members and model behaviors that may be helpful as the family members continue their important grief work. Caring for the body after death also calls for an understanding of the physiological changes that occur. By understanding these changes, the nurse can interpret and dispel any myths and explain these changes to the family members, thereby assisting the family in making their own personal decisions about the time immediately following death and funeral plans. In the section below and in Table 33.2, we incorporate principles of general funeral practice with information received in conversations with multiple funeral directors.

A classic article regarding postmortem care emphasized that, although postmortem care may be a ritualized nursing procedure, the scientific rationale for the procedure rests on the basics of the physiological changes that occur after death.[27] These changes occur at a regular rate depending on the temperature of the body at the time of death, the size of the body, the extent of infection (if any), the position of the body, and the temperature of the air. The three important physiological changes—*rigor mortis*, *algor mortis*, and *postmortem decomposition*—are discussed along with the relevant nursing implications in Table 33.2.

Care of and respect for the body after death by nursing staff should clearly communicate to the family that the person who died was indeed important and valued. Often, caring for the body after death provides the needed link between family members and the reality of the death, recognizing that everyone present at the time of death and soon after will have a different experience and a different sense of loss. Many institutions no longer require nursing staff to care for patients after death or perform postmortem care. Furthermore, there are very few professional resources related to postmortem care. Those available are outdated and do not reflect knowledge of postmortem changes.[27–31] Research is also limited and either focuses on legal procedures and physical preparation of the body or standardizing care including involving family members.[32–33] Postmortem care, especially in the hospice and palliative care setting, is clearly more than attention to the legal imperatives and physical care. A kind, gentle approach and meticulous attention to detail grounded in knowledge of the physiology of dying and death is imperative. Rituals that family members and others present find comforting should be encouraged. Rituals are practices within a social context that facilitate and provide ways to understand and cope with the contradictory and complex nature of human existence. They provide a means to express and contain strong emotions, ease feelings of anxiety and impotence, and provide structure in times of chaos and disorder. It is the family's needs

Table 33.2 Normal postmortem physiological changes and their implications for nursing and care of the body after death

Change	Underlying mechanisms	Nursing implications
Rigor mortis	Approximately 2–6 hours after death, adenosine triphosphate (ATP) ceases to be synthesized due to the depletion of glycogen stores. Because ATP is necessary for muscle fiber relaxation, the lack of ATP results in an exaggerated contraction of the muscle fibers that eventually immobilizes the joints. Rigor begins in the involuntary muscles (heart, gastrointestinal tract, bladder, arteries) and progresses to the muscles of the eyelids, head and neck, trunk, and lower limbs. After approximately 96 hours, however, muscle chemical activity totally ceases, rigor passes and the muscles will become pliable again. Persons with large muscle mass (e.g., body builders) are prone to more pronounced rigor mortis. Conversely, frail elderly persons and persons who have been bed bound for long periods are less subject to rigor mortis. In this case, muscle chemical activity ceases and rigor passes within 24–96 hours.	The guiding principle is to understand that rigor mortis is a natural and temporary postmortem change and immediate positioning of the decedent does not impact the appearance of the body long term. After death, position the person in as relaxed and peaceful a manner as is possible. For example, gently close the eyes if possible, position the person with the head and shoulders on pillows, and fold the hands. Due to the wide variation of circumstances of the death and the person, there are times when, regardless of position, the jaw will remain open. There is no need, however to mechanically manipulate it or use a towel or small pillow to keep it closed. If rigor mortis does occur, it can often be "massaged out" by the funeral director. Finally, by understanding this physiology, the nurse can also reassure the family about the myth that, due to rigor mortis, muscles can suddenly contract and the body can appear to move. The nurse can also reassure the family that the funeral director is expert in managing and interpreting these normal postmortem changes.
Algor mortis	After the circulation ceases and the hypothalamus stops functioning, internal body temperature drops by approximately 1°C or 1.8°F per hour until it reaches room temperature. As the body cools, skin loses its natural elasticity. If a high fever was present at death, the changes in body temperature are more pronounced and the person may appear to "sweat" after death. Body cooling may also take several more hours.	The nurse can prepare family members for the coolness of the skin to touch or the increased moisture by explaining the changes that happen after death. Also note to the family that their own body heat will transfer from them to the decedent and the place where they touch will feel warm. The nurse may also suggest kissing the person on their hair instead of their skin. The skin, due to loss of elasticity, becomes fragile and easily torn. Do not remove dressings, bandages, and/or tape after the death. If a dressing needs to be applied after death, it is best to secure them using either a circular bandage or paper tape. Remove oxygen masks and nasal prongs; if an endotracheal tube is present facilitate its removal. Handle the body gently as well, being sure to not place traction on the skin.
Postmortem decomposition or "livor mortis"	Discoloration and softening of the body are caused largely by the breakdown of red blood cells and the resultant release of hemoglobin that stains the vessel walls and surrounding tissue. This staining appears as a mottling, bruising, or both in the dependent parts of the body as well as parts of the body where the skin has been punctured (e.g., intravenous or chest tube sites). Often this discoloration becomes extensive in a very short time. In cardiac-related deaths, the face often appears red or purple in color regardless of the positioning at or after death.	As the decedent is handled (e.g., while bathing and dressing), the nurse informs the family member about this normal change that occurs after death. Discoloration is more pronounced in the areas of the body that are dependent. Positioning the person on his or her back and not on either side is critical. Using pillows to assure the person stays on his or her back is encouraged to minimize visual discoloration. Prop the body up with pillows under the head and shoulders or raise the head of the bed at least 30 degrees. Remove heavy blankets and cover the person with a light blanket or sheet.

and desires that direct this activity—not the nurse's. The nurse's role is to facilitate and support these rituals and to assure that families have sufficient time to complete them. There are, again, no rules that govern the appropriateness of rituals; rituals are comforting and serve to begin the process of healing and acceptance.

To facilitate the grieving process, it is often helpful to create a pleasant, peaceful, and comfortable environment for family members who wish to spend time with the body, according to their desires and cultural or religious traditions. The nurse should consider engaging family members in after-death care and ritual by inviting them to either comb the hair or wash the person's hands and face, or more if they are comfortable. Parents can be encouraged to hold and cuddle their baby or child. Including siblings or other involved children in rituals, traditions, and other EOL care activities according to their developmental level is also essential. During this time, family members should be invited to talk about their family member who has died and encouraged to reminisce—valuable rituals that can help them begin to work through their grief.

The family should be encouraged to touch, hold, and kiss the person's body, as they feel comfortable. Some may wish to clip and save a lock of hair as a keepsake. The nurse may offer to dress the person's body in something other than a hospital gown or other nightclothes. Babies may be wrapped snugly in a blanket. Many families choose to dress the body in a favorite article of clothing before removal by the funeral home. It should be noted that, at times, when a body is being turned, air escapes from the lungs, producing a sighing or gasping sound. Informing family members of this possibility is wise. Again, modeling gentle and careful handling of the body can communicate care and concern on the part of the nurse and facilitate grieving and the creation of positive and long-lasting memories.

It is best to leave tubes, drains, and other devices for the funeral director to remove as special chemicals may be needed to treat the site. Mortuaries also have the facilities to dispose of any medical waste. Placing a waterproof pad, diaper, or adult incontinence brief on the patient often prevents soiling and odor as the patient's body is moved and the rectal and urinary bladder sphincters relax. Packing of the rectum and vagina is unnecessary because not allowing these areas to drain increases the rate of bacterial proliferation that naturally occurs.

Occasionally families, especially in the home care setting, wish to keep the person's body at home, perhaps to wait for another family member to come from a distance and to ensure that everyone has adequate time with the deceased. The body can, in most cases, remain in the home for approximately 12–16 hours before further decomposition and odor production occur. If the family wishes to have the body remain in the home, the nurse can suggest to the family that they adjust the temperature in the immediate area to a comfortable but cooler level and remove heavy blankets or coverings. Be sure, however, to inform the funeral director that the family has chosen to keep the body at home until a designated time. Remember, reputable funeral directors are a reliable source of information regarding postdeath changes, local customs, cultural issues, and state laws

Care of the body after death is a significantly meaningful experience for nurses. In addition to mindfully providing support for the family, including preparing the body for viewing, many nurses regard care of the body as a sacred act, communicating dignity for the person who died and his/her family. Support of co-workers and management in providing after death care is critical and enhances job satisfaction and coping with the demands of caring for persons and their families/close others at the end of life.[34]

The care of patients and families near the time of death and afterward is an important nursing function—arguably one of the most important. As the following case studies are reviewed, consider how the nurse interceded in a positive manner, mindful of the changing tempo of care and the changing patient and family needs, desires, and perspectives.

Case Study: A Patient with Parkinson's Disease and Dementia

Bill, 88 years old, was a "tough bird." He was raised in the south during the Depression, served in the Army during World War II, and had a storied career in the aerospace industry. He lived with his 90-year-old wife of 65 years. Together, they were active in their church and community and had a close network of friends. They had two married daughters and grandchildren, who "were not close by."

Bill was diagnosed with Parkinson's disease at the age of 82. As the neurological symptoms progressed, Bill, on his own volition, sold his woodworking tools, and "let go" of his woodworking hobby. Life quickly became very frustrating and "depressing."

Goals and framework of care: Bill and his wife had bought funeral plots and planned their services when they were in their early 60s. His after-death plans were clear. Suddenly, he was obsessed with how life would be until he did die. His visits to his neurologist resulted in "he says I'm doing fine. Not to worry." His wife accompanied him on the visits and heard the same thing. Both Bill and his wife were seeking more answers about what the future would hold. However, they soon recognized that there simply were no answers. Their family stepped in to encourage them to travel as much as they could and continue to participate in community activities. Gradually, these activities became more and more difficult. Bill lost his motivation to leave the house. And he became increasingly angry. Episodes of paranoia became more and more frequent. His family physician suggested an antidepressant drug. Bill refused it, saying "He's trying to kill me."

Goals and framework of care, revised: Family members developed increasing concern for the safety of Bill's wife. Home hospice was asked to visit and evaluate the situation. With great discretion, the evaluation was competed, and Bill was determined eligible for acceptance into home hospice with a diagnosis of Failure to Thrive. Home care services were put in place, with key goals of establishing a relationship of trust with Bill. Bill's wife continued to handle the majority of his care, as he refused assistance from others, including their children. During one of the daughter's visits, Bill became angry and lashed out at her. Hospice staff encouraged the wife and mother to get Bill to take an additional dose of an antipsychotic drug that was in the home, but he refused. Instead, he picked up a skillet and threatened to harm his wife. Hospice personnel supported the family in calling 911. Bill was transported to the hospital and emergently detained.

Final care revision: Bill was sedated and transferred to an inpatient hospice unit. A computed tomography (CT) scan of his head was done to rule out any underlying diseases the team was unaware of. It showed no evidence of additional disease; rather, it was simply characteristic of advanced dementia findings. A family conference was held, and the goal of care was to use medications to prevent Bill from experiencing hallucinations and paranoia. If the side effect of this approach was sedation that prevented Bill from interacting with his environment, the family was in agreement that this was the best symptom management possible. Bill died peacefully, 8 days later. His funeral proceeded, honoring his long established wishes.

Case Study: A Patient with Lymphoma

Jane, 66 years old, was diagnosed with lymphoma at the age of 51. She was successfully treated and remained disease-free for 15 years. During the 15 years of remission, her husband died suddenly of cardiac arrest. Her three sons all married, and she had become a grandmother five times. She sold her home, retired, and moved to a senior citizen apartment complex. The recurrence of the lymphoma happened shortly after her move to the apartment and presented as a bowel obstruction, requiring surgery.

Goals and framework of care: Recovery from the surgery required Jane to be transferred to a rehab facility with the goal being to build physical ability to accomplish activities of daily living (ADLs) and live independently in her apartment. Her children and grandchildren were available to assist her as needed upon her return to her apartment. She would begin chemotherapy as soon as she was discharged from the rehab center. Jane and her family were optimistic that she could respond to second-line treatment and have a good quality of life again, even though they doubted that it would be another 15 years. Jane was clear: she wanted “at least 10 more years” and would fight for that.

After 5 weeks in the rehab center, Jane returned to her apartment. She was scheduled for chemotherapy the following Monday. She and her children took the weekend to make a short day trip to visit family and her husband’s grave. She was able to have a serious conversation about her wishes. And it was clearly, “I’m going to fight this.”

Goals and framework of care, revised: During her weekend trip, Jane developed abdominal pain and vomiting. On the way home, the family brought Jane to the emergency room where the staff confirmed Jane’s fears: the bowel obstruction had recurred. She was admitted, and although the obstruction did not require surgery, the decision to start chemotherapy was placed on hold. Instead, it was decided to try radiation of the area. After 3 days, she was transferred to an assisted living facility. As the pain from the obstruction was controlled, Jane once again told staff, “I’m ready to fight.” Jane and her family were offered a family conference, but refused. “I have no questions” was her response.

At the end of a week, Jane’s abdominal pain increased in intensity. Jane was rehospitalized for pain control. The attending physician “ordered” a family conference. Jane allowed nursing staff and social services to contact her three sons and facilitate the meeting.

Final care revision: A 90-minute family meeting took place with Jane, her three children, and four adult grandchildren in attendance. After a lengthy discussion, the physician explained how he was recommending pain control be achieved and that this was best done with hospice staff members skilled in pain management. Jane and her family asked for time to talk about this. The physician said he would be available for them the next morning. Later that evening, Jane asked the nurse caring for her to contact the physician if he was available. It happened that the physician was still in the hospital. He returned to Jane’s bedside, and Jane requested that she be admitted to a hospice program.

Jane was transferred to an inpatient hospice 24 hours later. She died peacefully, 72 hours later.

Conclusion

Assisting and walking alongside dying patients and their families, especially near and after death, is an honor and privilege. Nowhere else in the practice of nursing are our words, actions, and guidance more important. Caring for dying patients and their families is indeed the essence of nursing. Take this responsibility seriously, understanding that although it may be stressful and difficult at times, it comes with personal and professional satisfaction beyond measure. Your patients and families are the guides to this remarkable and momentous journey.

CHAPTER 34

Spiritual Screening, History, and Assessment

Elizabeth Johnston Taylor

Key Points

- A tiered approach to assessing a patient's spirituality often expects that the nurse or other trained volunteer or clinician first conducts an initial screening for spiritual problems or needs. Salient spiritual screening questions include: "How does your spirituality help you to live with your illness?" and "What can I/we do to support your spiritual beliefs and practices?"
- Numerous typologies identifying the dimensions of spirituality exist and provide guidance for what to address in a spiritual history or assessment.
- Spiritual history and assessment strategies include obtaining spiritual timelines, life stories, and pictorial depictions of spiritual experience, as well as asking simple questions.
- Although spirituality should be assessed near the time of admission to palliative care service, the process of assessment should be ongoing.
- Spiritual assessment data should be documented to at least some extent.

Spiritual Screening, History, and Assessment

To solve any problem, one must first assess what the problem is. Consequently, the nursing process dictates that the nurse begin care with an assessment of the patient's health needs. Although palliative nurses are accustomed to assessing patients' pain experiences, hydration status, and so forth, they less frequently participate in assessing patients' and family members' spirituality.

Because spirituality is an inherent and often extremely valued dimension for those who receive palliative nursing care, it is essential that palliative care nurses know how to assess spirituality. This chapter reviews models for spiritual screening, history-taking, and assessment; it also offers general guidelines on how to conduct these three tiers for assessing patient spirituality and discusses what the nurse ought to do with the obtained data. These topics are prefaced by arguments supporting the need for spiritual assessments and descriptions of what spirituality "looks like" among the terminally ill.

What Is Spirituality?

Numerous analyses of the concept of spirituality have identified key aspects of this ethereal and intangible phenomenon. Nursing conceptualizations of spirituality often include the following as aspects of spirituality: the need for purpose and meaning, forgiveness, love and relatedness, hope, creativity, and religious faith and its expression.[1] For example, Weathers, McCarthy, and Coffey recently concluded from a concept analysis of "what is spirituality" that it "is a way of being in the world in which a person feels a sense of connectedness to self, others, and/or a higher power or nature; a sense of meaning in life; and transcendence beyond self, everyday living, and suffering."[2(p. 93)]

Usually, spirituality is differentiated from religion—the organized, codified, and often institutionalized beliefs and practices that express one's spirituality.[3] To use a dated but nevertheless helpful metaphor: "Spirituality is more of a journey and religion may be the transport to help us in our journey."[4(p. 141)] Definitions of spirituality typically include transcendence—that is, spirituality explains persons' need to transcend the self, often manifested in recognition of an Ultimate Other, Sacred Source, Higher Power, Divinity, or God. Although these definitions allow for an open interpretation of what a person considers to be sacred or transcendent, they may be inappropriate for atheists, humanists, and those who do not accept a spiritual reality.

Indeed, a pluralistic definition of spirituality (however "elastic" and vague it is) is necessary for ethical practice, and hence a spiritual screening and history-taking process that is sensitive to a myriad of worldviews is essential—it is even appropriate for those who reject a spiritual reality.[5] The assessment methods introduced in this chapter are all influenced inherently by some conceptualization of spirituality. It is important to note, therefore, that the literature and methods for spiritual assessment presented in this chapter are from the United States and Europe, influenced most by Western Judeo-Christian traditions and peoples. Hence, they are most applicable to these people.

Why Is It Important for a Palliative Care Nurse to Assess Spirituality?

Spiritual awareness increases as one faces an imminent death.[6] Although some may experience spiritual distress, others may have a spiritual transformation or experience spiritual growth and health. For example, in a sample of persons with cancer, nearly one-quarter reported spiritual distress.[7,8] In a sample of 292 consecutive cancer patients receiving palliative care, however, 44% were identified as having spiritual pain—that is, "pain deep in your soul (being) that is not physical."[9] The average amount of spiritual pain among these patients was 4 (0 = best, 10 = worst). When assessing the prevalence of spiritual "needs" among New Yorkers receiving outpatient palliative care ($N = 727$), 79% reported at least one[10]; among 285 German cancer patients, 94% identified at least one need at least *a little*; the average number of needs was 8.6 (range = 0–19).[11] These observed variations in the frequency of spiritual distress or pain may be related to the variation in how the phenomenon was studied and among whom it was studied.

There is also mounting empirical evidence to indicate that spirituality moderates health-related quality of life (QOL) among persons with terminal illnesses.[12] Whether the terminally ill are persons with cancer, end-stage renal disease, or heart failure, there is evidence that spiritual well-being is also associated with coping and psychological adaptation.[13–16] Family caregivers of seriously ill patients also find comfort and strength from their spirituality that assists them in coping.[17,18] Religious beliefs and practices (e.g., prayer, beliefs that explain suffering or death) are also known to be valued and frequently used as helpful coping strategies among those who suffer and die from physical illness.[3] Indeed, it may be that spiritual distress and transformation occur concurrently; the distress may prompt the transformation.

Evidence from research suggests that attention to the spirituality of terminally ill patients and their caregivers is of utmost importance.[19] That is, if patients' spiritual resources assist them in coping, and if imminent death precipitates heightened spiritual awareness and concerns, and if patients view their spiritual health as most important to their QOL, then a spiritual assessment that initiates a process promoting spiritual well-being is vital to effective palliative care.

It is for reasons such as these that several organizations offer mandates for assessing and addressing spirituality among persons receiving palliative care. The National Consensus Project (NCP) and National Quality Forum included guidelines and preferred practices for supporting spirituality in palliative care.[20] The NCP guidelines (5.1) state: "Spiritual and existential dimensions are assessed and responded to based upon the best available evidence, which is skillfully and systematically applied." Similarly, the Hospice and Palliative Nurses Association's position paper on spiritual care affirms that spiritual care is "essential" to palliative care, and that this care "requires" assessment.[21] Likewise, The Joint Commission (TJC) stipulates that comfort and dignity be a priority for patients receiving end-of-life care in an approved facility, and that this includes spiritual care as well as other types of care[22]; although the TJC no longer discusses spiritual assessment specifically, it is assumed that assessment must precede such care. These mandates presumably cascade from the World Health Organization's definition of *palliative care* as holistic, including "early identification and impeccable assessment and treatment of spiritual [problems]."[23]

Why should palliative care nurses be involved in assessing patient spirituality? After all, chaplains and clergy are the spiritual care experts. Although chaplains are the trained experts in spiritual care, current thinking on this topic espouses that all members of a hospice team participate in spiritual caregiving. Indeed, findings from several studies suggest that this team approach to spiritual care is beneficial.[19] This position was advocated during a multidisciplinary consensus project that offered the following guidelines for spiritual care at the end of life:

- All patients should be screened for spiritual distress upon admission and a referral made if support is needed.
- Structured assessment tools are recommended to aid documentation and evaluation of care.
- All palliative care clinicians should be trained to recognize and report spiritual distress.
- All clinicians should be trained to perform a spiritual screening; more thorough assessments are to be completed by a certified chaplain.
- Screenings, histories, and assessments should be documented.
- Patients should be reassessed when there is a change in their condition.[24]

Not only do professional palliative care recommendations include nurses in the process of spiritual assessment, but also generic nursing ethics and professional standards support the nursing role in health-related spiritual and religious screening and history-taking.[3] Indeed, considering nurses' frontline position, coordination role, and intimacy with the concerns of patients; the holistic perspective on care; and their lack of association with a particular religion, nurses can be the ideal professionals for completing an initial spiritual screening or history-taking if they have some preparation for doing so.

However, nurses must recognize that they are not specialists in spiritual assessment and caregiving; they are generalists.[25] Most oncology and hospice nurses perceive that they do not receive adequate training in spiritual assessment and care. In fact, it is this lack of training, accompanied by role confusion, lack of time, and other factors that nurses often cite as barriers to completing spiritual assessments.[26,27] Therefore, when a nurse's screening or history indicates need for further sensitive assessment and specialized care, it is imperative that a referral to a spiritual care specialist (e.g., chaplain, clergy, patient's spiritual director) be made.

How Does Spirituality Manifest?

To understand how to assess spirituality, the palliative care nurse must know what to look for. What subjective and objective observations would indicate spiritual distress or well-being? Numerous descriptive studies have identified the spiritual needs of patients and their loved ones facing the end of life.[28] Whereas any listing of what spiritual issues might arise at the end of life would be incomplete, Puchalski and colleagues[24] provided a fairly comprehensive listing; these are illustrated in Table 34.1.

Although the terminology "spiritual need" may suggest a problem, spiritual needs can also be of a positive nature, as the final bullet in Table 34.1 illustrates. For example, patients can have a need to express their joy about sensing closeness to others or have a need to pursue activities that allow expression of creative impulses (e.g., artwork, music-making, writing). The following models for assessing spirituality will provide further understanding of how spirituality manifests.

Models for Assessing Spirituality

Healthcare professionals from multiple disciplines offer models for assessing spirituality. The most useful models from chaplaincy, medicine, social work, and nursing will be presented here. Although some assessment models have been published recently, many were developed since the 1990s, when the research about spiritual care began to proliferate. Although some were developed

Table 34.1 Spiritual issues at the end of life

Spiritual issues at the end of life	Examples
Lack of meaning and purpose	"Why do I have to suffer on the way to death? Why couldn't I just go to my death in my sleep?" (meaninglessness of suffering) "I feel like I never really did anything important in life, and now it's too late." (purposelessness)
Despair and hopelessness	"I just want to give up; it is not worth it anymore." (despair) Suicidal ideation (hopelessness)
Religious struggle	"Sometimes it is hard to believe there is a loving God upstairs that has my best interests in mind." "I used to believe. . . , but now how could It?"
Not being remembered	"Death is just so final; I know my friends will eventually move on and I'll have been like a blip on the monitor."
Guilt or shame	"I think my cancer is a punishment for something I did when I was young." (guilt) "I'm mortified that I'd get cancer in my private area." (shame)
Loss of dignity	"Look and smell this body! It's so embarrassing . . . it's not me anymore." "I'm such a burden now."
Lack of love, loneliness	"Everyone is so busy. . . . too busy to take care of me."
Anger at God/others	"Why would a loving God allow this to happen to me?" "Why did that corporation pollute the water where we lived for so long?"
Perceiving abandonment by God/others	"I feel like my prayers aren't being answered . . . where is God?" "The folks from church have stopped coming to visit; I guess I've been sick too long and they are tired of me."
Feeling out of control	"I'm ready to go . . . but it's not happening."
Need for reconciliation	Desire to be reunited with estranged family members
Grief from losses	Spiritual issues often accompany the various losses persons mourn when living with a terminal illness, such as the loss of independence, social roles and vocation, body image, and function.
Need for gratitude	"Now I have learned to appreciate the little things in life, and I'm just so happy for each new day that dawns." "I wish I didn't need to rely on others so much; but I am so thankful for how people do help me."

by clinicians caring for the terminally ill, others—easily adapted or used with those at the end of life—were developed for general use for those with an illness.

A two-tiered approach to spiritual assessment has been advocated.[3,29] That is, a brief assessment for screening purposes is conducted when a patient enters a healthcare institution. If the screening assessment generates an impression that there are spiritual needs and the patient desires support from healthcare team members, then spiritual care should be planned only after further information is collected. The second tier of assessment allows for focused, in-depth assessment so that patient-specific care can be delivered.

More recently, however, a three-pronged approach to assessing patient spirituality is accepted.[19,24] That is, the process of assessment of spirituality can potentially include:

- Spiritual screening
- Spiritual history-taking
- Spiritual assessment

These three approaches, as well as when they are appropriate, will be described next.

Spiritual Screening

One purpose of a spiritual screening is to determine if the patient presents with any spiritual distress and if they wish for the healthcare specialist or team to provide spiritual support. This screening can be conducted by anyone who has received training to do so.[7,24] Thus, a screening should involve only one or very few questions.

Several stand-alone screening questions have been developed and/or evaluated during research. These include:

- "Are you at peace?" This question was found to correlate highly with spiritual and emotional well-being in a large study of terminally ill patients.[30]
- "How important is spirituality or religion to you?" Research findings from 114 terminally ill persons found this single question about the importance of religion to be more discriminating than a question about frequency of attendance at religious services.[31]
- "[How much do you have] pain deep in your soul (being) that is not physical?" Fashioned after the Edmonton Symptom Distress Scale, this item is accompanied by response options from 0 (best) to 10 (worst) spiritual pain.[9]
- A global "overall spiritual well-being" item with response options on a 7-point scale from 1 (very poor) to 7 (excellent), as well as a don't know/can't answer option, was developed by the European Organization for Research and Treatment of Cancer (EORTC) for use in research and clinical practice.[32]
- "What is really important to you?" This is a spiritual screening item used by Fletcher in an Australian community-based palliative care service.[33] Designed for use within a multidisciplinary team, this item is the initial question of the Connecto model which aims to understand a patient's connections/disconnections

within/between self, others, creation, and mystery or that which is transcendent. Thus, the model guides clinicians to listen to the patient's response and indicate on a diagram how the "the self" is connected to:

- self (e.g., whether the patient is accepting, self-forgiving, possessing inner peace and self-knowledge, versus despairing, fearful, and suppressing feelings);
- others (e.g., sensing belonging and being valued, versus alienation, withdrawal, conflict);
- creation (e.g., appreciating, wondering, versus global loneliness, missing nature)
- Something Bigger (e.g., hope, meaning, awe, sacredness, versus doubt, inability to transcend the present); and
- religiosity (e.g., connection to a faith community versus loss of that connection or "backslidden").

These screening questions assess simply how important spirituality is to the patient or how much spiritual distress or well-being they experience. These questions do not determine the preferences of the patient with regard to receiving spiritual support, if spiritual needs exist. The following screening protocols, however, do.

- ◆ Physicians Lo and colleagues[34] proposed the following questions for use in palliative care settings: (a) Is faith/religion/spirituality important to you in this illness? Has faith been important to you at other times in your life? (b) Do you have someone to talk to about religious matters? Would you like to explore religious matters with someone?
- ◆ Chaplain Fitchett's research team has evaluated the Rush Spiritual Screening Protocol, what may be the most widely recognized approach.[7] It first asks patients how important spirituality or religiosity (S/R) is to them. Then, based on their response, the clinician follows up with (a) whether the patient perceives their spiritual support is adequate (for those who indicate S/R is important to some degree) or (b) whether the patient has previously found S/R supportive (for those who indicate S/R is not presently important). For those who indicate a deficiency in spiritual support or who indicate that S/R was previously important (and a life experience like the present illness triggered a change), the patient is referred to a chaplain. For a study to evaluate the accuracy of several one-item spiritual screening questions, Fitchett and colleagues rephrased this protocol as follows: "Does your religion/spirituality provide you all the comfort and strength you need from it right now?" Answer options included not applicable, and four options between not at all and a great deal.
- ◆ One tick box on the National Comprehensive Cancer Network's Distress Thermometer list of problems is "spiritual/religious concerns." The thermometer indicates responses can range from no distress to extreme distress.[35]

Although other screening questions have been offered by clinician scholars,[36] the preceding may be the most suited for inclusion in written intake assessment forms that patients complete upon admission to palliative care, given their quantitative or tick box response options. King and colleagues investigated the sensitivity of six spiritual screening questions (several of which are identified in the preceding list) and found none of them reached the desired 85% sensitivity they a priori determined was necessary.[37] Indeed, they observed the frequency of reported spiritual struggle ranged from 13% to 38% in this sample of 1,449 cancer survivors, depending on screening question. After additional analysis, they concluded that the most sensitive approach to screening should include the following two items: "Do you struggle with the loss of meaning and joy in your life?" and "Do you currently have what you would describe as spiritual or religious struggles?"

The spiritual screening questions can determine (with some, but not complete, accuracy) how important S/R is to a patient or family caregiver, whether there is spiritual distress, and/or whether they would appreciate support. A caveat is in order, however, regarding the role of non-chaplain clinicians inquiring whether spiritual support is desired. Some chaplains may not want clinicians to inquire if patients want a chaplain visit. They fear that if the nurse does it and receives a negative response, then they do not have permission to approach the patient. Indeed, there is evidence from a Swiss study that when a hospital chaplain asked a patient if spiritual support was desired, 86% agree; however, when nurses asked using a scripted question (i.e., "Do you want to have the visit of the chaplain of this hospital unit?"), only 37.5% agreed to have a chaplain visit.[38] Although this is only one study, it points to the importance of collaborating with chaplains in selecting a screening protocol.

Spiritual History-Taking

A spiritual history is also to be taken at the beginning of any relationship with palliative care; the reason is to obtain more details about the patient's spirituality and religiosity so that any care (physical, emotional, or spiritual) can be provided with sensitivity to this fundamental dimension. An expert panel recommended that the spiritual history be obtained by the primary care provider. In palliative care, it is typically the patient's primary nurse who is responsible for coordinating care and should complete this level of assessment.[24]

Several clinicians have devised models for use in spiritual history-taking. Several of these include apropos mnemonics. The most widely cited tool is Puchalski's Faith, Import, Community, Address (FICA) tool, which has been validated as feasible within a hospital palliative care service and among nursing students.[39,40] Whereas Maugens's[42] and Vermandere et al.'s[45,46] models were specifically designed for use in palliative care, the rest were generically designed but can be used just as well in palliative care.

The history-taking models in Table 34.2 are dependent on the clinician's verbally interviewing the patient. It is possible, however, that the initial screening and history-taking process can be accomplished using a standardized paper-and pencil questionnaire. There are dozens of instruments developed for measuring aspects of spirituality and/or religiosity for research purposes. Instruments for collecting clinically relevant data without undue burden, however, are few.

Table 34.3 presents questionnaires that are most likely to hold promise for palliative care patient spiritual history-taking. These questionnaires were selected for their brevity, validity, and/or clinical relevance. Whereas the SNAP[49] and HEALS[50] were created specifically for palliative care patient assessment and reflection, the others were designed for the generic patient or person.

This approach to spiritual assessment allows for identification and, possibly, measurement of how one spiritually believes, belongs, and behaves. In other words, using an instrument for

Table 34.2 Spiritual history models

Author/s	Components (mnemonic)	Illustrative questions
Anandarajah and Hight[41] HOPE model	H (sources of hope)	What or who is it that gives you hope?
	O (organized religion)	Are you a part of an organized faith group? What does this group do for you as a person?
	P (personal spirituality or spiritual practices)	What personal spiritual practices, like prayer or meditation, help you?
	E (effects on medical care and/or end-of-life issues)	Do you have any beliefs that may affect how the healthcare team cares for you?
Maugens[42] SPIRIT model	S (spiritual belief system)	What is your formal religious affiliation?
	P (personal spirituality)	Describe the beliefs and practices of your religion or spiritual system that you personally accept. What is the importance of your spirituality/religion in daily life?
	I (integration with a spiritual community)	Do you belong to any spiritual or religious group or community? What importance does this group have to you? Does or could this group provide help in dealing with health issues?
	R (ritualized practices and restrictions)	Are there specific elements of medical care that you forbid on the basis of religious/spiritual grounds?
	I (implications for medical care)	What aspects of your religion/spirituality would you like me to keep in mind as I care for you? Are there any barriers to our relationship based on religious or spiritual issues?
	T (terminal events planning)	As we plan for your care near the end of life, how does your faith impact on your decisions?
McEvoy's BELIEF model (for use in pediatric care)[43]	B (belief system)	What religious or spiritual beliefs, if any, do members of your family have?
	E (ethics or values)	What standards/values/rules for life does your family think important?
	L (lifestyle)	What spiritual habits or activities does your family commit to because of spiritual beliefs (e.g., any sacred times to observe or diet you keep)?
	I (involvement in spiritual community)	How connected to a faith community are you? Would you like us to help you reconnect with this group now?
	E (education)	Are you receiving any form of religious education? How can we help you keep up with it?
	F (near future events of spiritual significance for which to prepare the child)	Are there any upcoming religious ceremonies that you are getting ready for?
Puchalski[44] FICA model	F (faith)	Do you have a faith belief? What is it that gives your life meaning?
	I (import or Influence)	What importance does your faith have in your life? How does your faith belief influence your life?
	C (community)	Are you a member of a faith community? How does this support you?
	A (address)	How would you like for me to integrate or address these issues in your care?
Vermandere, et al.[45,46] "Ars Moriendi" model	Holding on vs letting go	What gives you strength in this situation? Who/what inspires you? Whom are you holding on to? Can you let go of life?
	Joyous vs forgetting	If you look back upon your life, what do you feel? Are there important things to discuss with anyone still?
	Knowing vs believing	What does death mean to you? Do you feel supported by any beliefs or faith?
	Oneself vs The Other	Are you leaving the world in the way that you want? Are you able to be yourself? Feel authentic?
	Doing vs underdoing	How are you holding up? Is there any way we can support you?

assessment purposes allows for the measurement of spirituality. This standardized measurement can allow comparison between time points in a patient's illness experience and between patients, to determine what may be "normal" or unusual. Caution in this regard, however, is urged.

When using a quantitative instrument for obtaining spiritual information from a patient, it is important to recognize the limitations of such a method. First, this type of tool should not "stand alone" in the process of spiritual assessment; rather, it can be the springboard for a more thorough assessment and deeper encounter with a patient, as appropriate. A quantitative tool should never replace human contact; rather, it should facilitate it. Second, there are potential negative implications of comparing how a patient "measures up" with others. Noting to what degree a patient is spiritually struggling or is intrinsically religious should not bring with it an evaluative judgment. Third, collecting spiritual distress or well-being information with a questionnaire can delude clinicians into thinking "that box is ticked." Instead, any written assessment process must be accompanied by face-to-face interaction that allows the patient to debrief about the process;

Table 34.3 Spiritual history-taking instruments

Instrument name	Instrument description	Illustrative items
Functional Assessment of Chronic Illness Therapy-Spiritual Well-being (FACIT-Sp)[47,48]	12-item instrument with 5-point response options ranging from "not at all" to "very much." Assesses both religious and existential/spiritual well-being (or faith and meaning, and possibly peace). Strong psychometric support; widely used for health-related research purposes.	"I feel peaceful." "I am able to reach down deep into myself for comfort."
Spiritual Needs Assessment for Patients (SNAP)[49]	Systematically developed and tested, and found to have good support for its validity and reliability. Measures psychosocial domain (5 items), spirituality (13 items), and religious needs (5 items). Response options range from 1, "not at all," to 4, "very much."	Resolving old disputes, hurts or resentments among family and friends Religious rituals such as chant, prayer, lighting candles or incense, anointing, or communion
Healing Experience in All Life Stressors (HEALS)[50]	48 items with response options from strongly disagree (1) to strongly agree (5). Tested in small sample, yet obtained internal consistency (Cronbach's alpha) of 0.94. Factor analysis indicated 5 subscales: religion, family, meanings placed on interaction with the world, intrapersonal, and psychological growth.	"My religious beliefs give me hope." "I have greater appreciation for my life." "I accept things that I cannot change." "I feel isolated."
Spiritual Needs Questionnaire[51]	19-item scale with 4-point responses measuring degree of agreement/disagreement. Developed in Germany, so wording may not be fitting for North American patients. Tested with cancer and chronically ill patients with pain. Cronbach's alpha observed was 0.93; factors analysis identified 4 subscales measuring religious needs (6 items), need for inner peace (5 items), existential/meaning (5 items), and actively given of oneself (3 items).	Read religious/spiritual books Dwell at a place of quietness and peace Talk to someone about the meaning of life Give away something from yourself
Daily Spiritual Experience (DSE)[52]	16-item scale with Likert-type response options measuring frequency of perception of the transcendent (e.g., God) in daily life. Developed and tested in culturally and religiously diverse samples. Has been used often in research; well-established validity.	"I am spiritually touched by the beauty of creation." "I feel a selfless caring for others." "I accept others even when they do things I think are wrong."
Duke Religion Index (DUREL)[53]	5-items that measure 3 concepts: organizational religiosity (1 item); non-organizational religiosity (1 item); and intrinsic religiosity (3 items). Only IR items can be summed, as other items measure different concepts. Frequently used in research; psychometrically well supported.	How often do you attend church or other religious meetings? [organizational religiosity] How often do you spend time in private religious activities, such as prayer, meditation, or Bible study? [nonorganizational religiosity] "My religious beliefs are what really lie behind my whole approach to life." [1 of 3 intrinsic religiosity items]
Spiritual/Religious Struggles Scale[54]	The RSSS includes six subscales (in 26 items) with 5-point response options that can be used alone or in concert. The six subscales measure supernatural (i.e., divine and demonic), interpersonal, and intrapersonal (moral, ultimate meaning, doubt) struggles. The RSSS was rigorously developed and evaluated.	"Questioned whether my life will really make any difference in the world." "Felt troubled by doubts or questions about religion or spirituality." "Felt as though God had abandoned me."
Attitudes Towards God Scale (ATGS-9)[55]	9-item scale with 4 items addressing anger and doubt, and 5 items measuring positive regard for God. Extensively tested among well persons.	To what extent do you currently: View God as unkind Feel loved by God
Spiritual Needs Inventory (SNI)[56,57]	17-items with Likert response options rating frequency in one column and whether the need was being met in another column. Items are introduced with: "In order to live your life fully, you need. . . ?" Measures 5 factors: religious needs, outlook needs, community needs, inspiration, and spiritual activities. Developed based on data from hospice patients; also validated among caregivers of hospice patients. Cronbach's alpha = 0.85.	Think happy thoughts Be with friends See smiles Be with family/friends Pray

this will also allow the clinician to gain the requisite rapport for further spiritual care.

Table 34.3 is not exhaustive. Consult existing systematic reviews of other instruments measuring spiritual needs or spiritual well-being for additional options. Consider the reviews provided by Monod and colleagues[58]; Lunder, Fulan, and Simonic[59]; and Seddigh.[60] Monod and colleagues observed that only 2 of the 35 scales measuring spirituality could have clinical usefulness. If spirituality is indeed a vital sign, as Lunder and colleagues posited, then careful consideration of how this vital essence of personhood can be screened and assessed by nurses is imperative.

Spiritual Assessment

If the screening or subsequent observation provides evidence that a spiritual need exists that might benefit from specialist-provided spiritual care, the nurse ought to make a referral to the chaplain or designated palliative care team member with expertise in spiritual care. It is the board-certified chaplain or specialist in spiritual care who then completes a spiritual assessment. The spiritual assessment is an in-depth exploration and evaluation of the patient's spiritual perspectives, concerns, and resources. A spiritual assessment is a grand tour assessment that covers multiple aspects of the patient's spirituality.[24]

Often, however, the palliative care patient or family member who has a warm and respectful relationship with their nurse will raise a spiritual/religious topic when only the nurse is available. Or they may not overtly raise the topic, yet give nonverbal or indirect evidence that there is a spiritual need. At such times, the nurse may need to complete a spiritual assessment to some degree.

When should clinicians assess spirituality further, probe more deeply? Hodge[29] suggested four criteria for determining whether to move on to a more comprehensive assessment:

- First, consider patient autonomy. The patient must give informed consent. A comprehensive assessment may drill into inner depths the patient does not wish to expose to a clinician.
- Second, consider the competency of the clinician with regard to discussing spiritual matters. Is the clinician culturally sensitive and aware of how a personal worldview might conflict with the patient's? Might the clinician suffer from religious countertransference and inappropriately relate to the patient from personal biases?
- Third, consider if the spiritual issue identified is relevant to the present healthcare situation. If not, it may not be in nurses' purview. For patients at the end of life, however, many past and diverse spiritual struggles can resurface; although these struggles may seem tangential to present caregiving, the patients may benefit from spiritual expertise that aids them in addressing these issues before death. (The nurse's curiosity or desire to evangelize the patient is never an ethical rationale for spiritual assessment.[3])
- Finally, consider the importance of spirituality to the patient. The extreme illustration of this would be if a patient states spirituality is personally irrelevant; then a comprehensive spiritual assessment would be inappropriate.

Observing these guidelines can prevent inappropriate and time-consuming assessment and care.

Although a comprehensive spiritual assessment may well be beneficial to many patients at the end of life, it is likely that few palliative care nurses are competent or able to conduct such an assessment. Fowler posited that a person's spiritual or religious experience is arranged in layers like an onion. The outer layers of public and semi-public spiritual belief and practice are an appropriate domain for the nurse negligibly trained in spiritual assessment and care, whereas the deeper, more intimate—and often pain-filled—inner layers are best assessed and addressed by spiritual care experts.[61]

With these cautionary caveats in mind, a few models for spiritual assessment are presented. These were developed by chaplains for chaplain use. They are extensive in their scope. By reviewing them, however, the nurse can increase his or her awareness of spiritual dimension and how to query and listen for them.

Possibly the first comprehensive spiritual assessment model was that developed by Pruyser,[62] the patriarch of modern chaplaincy. Pruyser's original model identified seven aspects; each of which may be viewed as a continuum. These aspects of spirituality included:

- Awareness of the holy or the lack thereof
- Sense of providence or the lack thereof
- Faith or the lack thereof
- A sense of grace or gratefulness, in contrast with a lack of appreciation and a sense of entitlement
- Repentance versus unrepentant stance toward others and the world
- Communion (or feeling part of a whole) or on the continuum toward sensing no connection with others or the world
- Sense of vocation (purpose) versus meaninglessness

Although this model is clearly influenced by a Christian worldview and may therefore be limited in its applicability, it offers a beautiful approach to thinking about spirituality comprehensively.

Fitchett,[63] a chaplain, developed the "7-by-7" model for spiritual assessment with a multidisciplinary group of health professionals. In addition to reviewing seven dimensions of a person (medical, psychological, psychosocial, family system, ethnic and cultural, societal issues, and spiritual dimensions), Fitchett advances seven spiritual dimensions to include in an assessment:

- Beliefs and meaning (i.e., mission, purpose, religious and nonreligious meaning in life)
- Vocation and consequences (what persons believe they should do, what their calling is)
- Experience (of the divine or demonic) and emotion (the tone emerging from one's spiritual experience)
- Courage and growth (the ability to encounter doubt and inner change)
- Ritual and practice (activities that make life meaningful)
- Community (involvement in any formal or informal community that shares spiritual beliefs and practices)
- Authority and guidance (exploring where or with whom one places trusts, seeks guidance)

This model likely offers chaplains and spiritual care experts the most comprehensive of all approaches to assessment.

LaRocca-Pitts[64] offered the FACT spiritual assessment model for chaplains. This model explores the following aspects of a patient's spirituality and religiosity: facts (or the patient's current situation), feelings, family and friends, faith, fun, finances, function (or role in society, family), fame/fortune (or impact on the world), future understanding (what they perceive is in their future). For each of these "F" aspects of life, the chaplain can assess its "A" (access or availability, or related anxiety), "C" (coping, or conflict or comfort related to it), and "T" (treatment, or an evaluation of treatment outcomes). This model may be broader in scope than others (e.g., includes examining how finances impact their spiritual state) yet can still be helpful to those in palliative care.

Shields's[65] Spiritual Assessment and Intervention Model (AIM) does not provide a catchy mnemonic, but instead a detailed philosophic and empirically derived description of how a chaplain can approach spiritual assessment and intervention. Spiritual AIM is based on three fundamental assumptions. First, it accepts the psychological theory (and subsequent supportive empirical evidence) of object relations; that is, it is within relationships that humans develop spiritually. It is our initial relationships that most influence how we view the divine and interpret spiritual experiences. For example, how a believer experiences his or her biological father influences how he or she views God. Thus, spiritual healing requires examining how and why a patient relates to others.

Second, Shields's[65] Spiritual AIM accepts and bases clinician–patient interaction on the ethic of reciprocity. That is, love of self is a concurrent experience with love of others and the divine (e.g., the Golden Rule). Third, Spiritual AIM accepts that there are three core spiritual needs among humans. These include the need (1) for meaning and direction, (2) for self-worth and belonging within a community, and (3) to love and be loved (e.g., be reconciled to those from whom one is estranged). Shields observed that when a person is in crisis, at least one of these spiritual needs manifests.

Other Spiritual Assessment Methods

Other approaches to spiritual assessment have been described in addition to the interview and questionnaire techniques. Life reviews can become, in essence, spiritual assessments. Life reviews are especially valuable for persons who are dying as they allow patients to make sense of and reconcile their life story. By doing a life review with a terminally ill patient, the nurse can assess many dimensions of spirituality (e.g., worldviews, commitments, missions, values) in a natural, noncontrived manner. Life reviews can be prompted by questions about the significant events, people, and challenges during the life span. A life review can also occur when inquiring about personal objects, pictures, or other memorabilia the patient wants to share. A meta-analysis of eight studies of the effectiveness of life reviews concluded that it improves QOL among terminally ill.[66]

Chochinov and various colleagues around the world have developed and tested *dignity therapy*, which basically allows persons at the end of life an opportunity to do a life review.[67] The semi-structured questions of dignity therapy include the following: "Tell me a little about your life history, particularly the parts you either remember most or think are most important? When did you feel most alive? Are there specific things that you would want your family to know about you? What are the most important roles you have played in life? What are your most important accomplishments? Are there particular things that you feel still need to be said? What are your hopes and dreams for your loved ones? What have you learned about life that you would want to pass along? Are there other things that you would like included?" The patient's responses to these questions, potentially asked by a trained volunteer, are recorded and transcribed into a permanent record that the patient helps to design and that can be left as a legacy for loved ones. Although dignity therapy is reminiscence therapy, these questions overlap with what could be included in a comprehensive spiritual assessment.

Hodge[68] identified several creative approaches to collecting information about client spirituality. As a social worker, Hodge is well aware that some patients are not verbal or are not comfortable expressing their spirituality in words. Thus, he explained more visual ways for a patient to describe his or her spiritual experiences. These methods for assessments include:

- *Spiritual life maps*, or a pictorial depiction of where the patient has been spiritually, where the patient is presently, and where the patient expects to go. It can be a simple pencil drawing on a large piece of paper; words and illustrations can be used to convey the spiritual story—the spiritual highs and lows, blessings and burdens, and so forth.
- *Spiritual genogram*, like a standard genogram, depicts the issues and influences over one to three generations. Sources of spiritual influence from certain relationships (including those external to the family) can be drawn. Words that identify key spiritual beliefs and practices that were transmitted via relationships and significant spiritual events that contribute to the patient's spiritual life can be noted around this spiritual family tree.
- *Spiritual ecomaps*, rather than focusing on past spiritual influences, direct the patient to consider present spiritual experiences. In particular, the patient can diagram (with self portrayed in the center) the relationship with God or transcendent other/value, rituals, faith community, and encounters with other spiritual entities.
- *Spiritual ecograms* allow the patient to diagram present perspectives on both family and spiritual relationships; it is a fusion of the spiritual genogram and ecomap.

Other strategies include having clients draw a spiritual timeline that includes significant books, experiences, events, and the like. Another unusual approach involves sentence completion. For example, a client may fill in the blank of sentences like "My relation to God . . ." or "What I would really like to be . . . ," or "When I feel overwhelmed. . . ." Having verbally oriented assessment strategies as well as these nonverbal methods provides clinicians with a "toolbox" for assessing spirituality, allowing the clinician to choose an approach that fits the patient's personality, circumstances, and purpose for assessment.[68]

Summary of Spiritual Screening, History-Taking, and Assessment Models

The preceding summaries of various models for spiritual assessment identify spiritual dimensions that may be included in a spiritual assessment. Many of the dimensions identified in one model are observed (often using different language) in other models. Except for Hodge's[68] diagrammatic methods, these assessment approaches generally require the professional to make observations while asking questions and listening for the patient's response. The vast majority of questions recommended for use in following such a model are open-ended. Several of the questions—indeed, the dimensions of spirituality—identified in this literature use "God language" or assume a patient will have belief in some transcendent divinity. All these models are developed by professionals who are influenced predominantly by Western, Judeo-Christian ways of thinking.

General Observations and Suggestions for Conducting a Spiritual Assessment

When to Assess

The spiritual assessment consensus project advocated that spiritual screening should be done at admission and whenever there is a change in patient status.[24] Furthermore, when the spiritual screening suggests potential for spiritual distress, a trained chaplain should be called for a more complete assessment within 24 hours. However, spiritual assessment should also be an ongoing process. The nurse does not complete a spiritual assessment simply by asking some questions about religion or spirituality during an intake interview. Instead, spiritual assessment should be ongoing throughout the nurse–patient relationship. A nurse tuned to know how spiritual health is manifested will be able to see and hear patient spirituality as it is embedded in and suffuses the everyday encounter.

Gaining Entrée

Spiritual needs are complex and often difficult to acknowledge and, more so, to describe with words. Furthermore, the patient may not yet feel comfortable divulging such intimate information to a nurse with whom rapport has not been established. Indeed, some patients may not want to share such inner, heart-touching experiences. Evidence indicates that the requisites patients want in clinicians who provide spiritual care are relational (e.g., "show me kindness and respect" and "get to know me first"); training in spiritual care or sharing similar beliefs as the patient is less important.[69]

Because spirituality and religiosity are sensitive and personal topics (as are most other topics nurses assess), it is polite for a nurse to preface a spiritual assessment with an acknowledgment of the sensitivity of the questions and an explanation for why such an assessment is necessary. For example, Maugens suggested this preface: "Many people have strong spiritual or religious beliefs that shape their lives, including their health and experiences with illness. If you are comfortable talking about this topic, would you please share any of your beliefs and practices that you might want me to know as your [nurse]?"[42(p. 12)] Such a preface undoubtedly will help both the patient and the clinician to feel at ease during the assessment.

Assessing Nonverbal Indicators of Spirituality

Although this discussion of spiritual assessment has thus far focused on how to frame a verbal question and allow a patient to verbalize a response, the nurse must remember that most communication occurs nonverbally. Hence, the nurse must assess the nonverbal communication and the environment of the patient.[3,70] Does the patient appear agitated or angry? What does the body language convey? What is the speed and tone of voice?

Assessment of the patient's environment can provide clues about spiritual state. Are there religious objects on the bedside table? Are there religious paintings or crucifixes on the walls? Are there get well cards or books with spiritual themes? Are there indicators that the patient has many friends and family providing love and a sense of community? Are the curtains closed and the bedspread pulled over the face? Many of the factors a palliative care nurse usually assesses will provide data for a spiritual assessment as well as the psychosocial assessment.

Language: Religious or Spiritual Words?

One barrier to spiritual assessment is the nurse's fear of offending a nonreligious patient by using religious language. However, when one remembers the nonreligious nature of spirituality, this barrier disappears. Patient spirituality can be discussed without God language or reference to religion. Also, using the terms "need" or "distress" immediately after "spiritual" could be denigrating for a patient. Especially with spirituality, patients may be upset when they hear others consider them to be in need. Nurses can easily avoid such jargon.

To know what language will not be offensive during the process of assessing spirituality, the nurse must remember two guidelines.[70] First, the nurse can begin with questions that are general and unrelated to religious assumptions. For example, "What is giving you the strength to cope with your illness now?" or "What spiritual beliefs and practices are important to you as you cope with your illness?" Second, the nurse must listen for the language of the patient and use the patient's language when formulating more specific follow-up questions. If a patient responds to a question with "My faith and prayers help me," then the nurse knows "faith" and "prayer" are words that will not offend this patient. If a patient states that the "Great Spirit guides," then the sensitive nurse will not respond with, "Tell me how Jesus is your guide."

Stewart reminds clinicians of how patients use spiritual language in colloquial ways.[71] For example, how often people say things like: "Thank God!" "OMG!" "Everything happens for a reason." "God willing. . . . ," or "I'm blessed." Such spiritual expression provides a potential prompt for exploration: "OMG?" "What do you think the reason is?" or "How are you blessed?" Such exploration not only can provide clinically relevant data, but also an opportunity for the patient to reflect on their inner experience.

Questions using nonreligious language are presented in Box 34.1. These questions will allow a nurse to broach the topic of spirituality without awkwardness. They likely will emerge in the natural course of a conversation, as a patient talks about the challenges of living with illness. Such questions can allow for continued assessment without use of one of the preceding formalized protocols.

Box 34.1 Nonreligious Spirituality Questions

You've gone through so much lately. Where do you get your inner strength and courage to keep going?

What is helping you to cope?

What comforts are most satisfying for you now?

As you think about your future, what worries you most?

Some people seem more to live while they are dying, while others seem to die while they are living. Which way is it for you? What makes it that way?

What kind of person do you see yourself as? (Note: Chaplains suggest that how one views self parallels how one views one's Creator or God.)

What do you see as the purpose for your life now, given your body isn't allowing you to do all you used to do?

What hopes and dreams do you have for your future? For your family?

What legacy would you like to leave? How can we make sure that happens?

As I've gotten to know you, I've noticed you speak often of (spiritual theme [e.g., betrayal, yearning for love]). How do you think (this theme) has influenced your life, or will influence your future? How happy with your life's theme are you?

Tell me about times during your life where faced a huge challenge. What got you through? Is that resource still available to you now?

Asking Questions

Because asking a patient questions is an integral part of most spiritual assessments—and an art,[72] it is good to remember some of the basics of formulating good questions. Asking closed-ended questions that allow for short factual or yes/no responses is helpful when a nurse truly has no time or ability for further assessment. Otherwise, to appreciate the uniqueness and complexity of an individual's spirituality, the nurse must focus on asking open-ended questions. The best open-ended questions begin with "How," "What," "When," "Who," or phrases like "Tell me about. . . ." Generally, questions beginning with "Why" are not helpful; they are often mixed with a sense of threat or challenge (e.g., "Why do you believe that?").[70]

Listening to the Answers

Although it is easy to focus on and worry about what to say during an assessment, the palliative care nurse must remember the importance of listening to the patient's responses.[72] Discussion of active listening is beyond the scope of this chapter, yet a few comments are in order. Remember that silence is appropriate when listening to a patient's spiritual and sacred story; silence has a role.[70] Remain neutral, nonjudgmental. View the patient as a fellow sojourner on the journey of life. Recognize that you are not the authority or savior for the patient expressing spiritual pain. Rather you are a companion, or a supporter if so privileged. Listen for more than words. Listen for metaphors, listen for a spiritual theme that keeps re-emerging throughout life stories, listen for where the patient places energy, listen for emotion in addition to cognitions.[70,72] The nurse will do well to listen to his or her own inner response. This response will mirror the feelings of the patient.[70]

Overcoming the Time Barrier

Healthcare professionals may believe that they do not have enough time to conduct a spiritual assessment. Indeed, Maugens[42] observed that completing his spiritual history with patients took about 10–15 minutes. Although this is much less time than Maugens and his colleagues expected it to take, it is still a considerable amount of time in today's healthcare context. One response to this time barrier is to remember that spiritual assessment is a process that develops as the nurse gains the trust of a patient. The nurse can accomplish the assessment during "chit chat." Furthermore, data for a spiritual assessment can be simultaneously collected with other assessments or during interventions (e.g., while bathing or completing bedtime care). And finally, it can be argued that nurses do not have time *not* to conduct a spiritual assessment, considering the fundamental and powerful nature of spirituality.

Overcoming Personal Barriers

Nurses can encounter personal barriers to conducting a spiritual assessment. These barriers can include feelings of embarrassment or insecurity about the topic or can result from projection of unresolved and painful personal spiritual doubts or struggles. Every nurse has a personal philosophy or worldview that influences his or her spiritual beliefs. These beliefs can color or bias the nurse's assessment techniques and interpretation. Hence, an accurate and sensitive spiritual assessment presumably correlates with the degree of the nurse's spiritual self-awareness.[73] Put another way, your ability to hear your own spiritual story is directly related to your ability to hear a patient's spiritual story.[70] Nurses can increase their comfort with the topic and their awareness of their spiritual self if they ask themselves variations of the questions they anticipate asking patients. For example, "What gives my life meaning and purpose?" "How do my spiritual beliefs influence the way I relate to my own death?" "How do I love myself and forgive myself?" Recognizing how one's spiritual beliefs motivate one's vocation as a nurse is also extremely helpful.

Concluding Cautions

Although the presented models and evidence supporting spiritual screening, history-taking, and assessment imply that it is an unproblematic and simple process, it would be naïve to leave this impression. Several experts suggest potential problems associated with spiritual assessment. These include:

- The process of taking spiritual assessment data to make a spiritual diagnosis pathologizes what may be a normal process of spiritual growth. Assessment tools often assume that spiritual well-being correlates with feeling good, that spiritual health and suffering cannot coexist. A more appropriate way to evaluate spirituality may be to ask how harmful one's spirituality is to self and others.[70]
- A "tick box" approach to spiritual assessment could freeze patient spirituality to the time when the assessment was completed; spiritual assessment would be considered complete and fail to continue in an ongoing manner.[72]
- A fairly prescribed assessment tool could have the unintended outcome of disempowering a patient. That is, the clinician controls (overpowers) the agenda by determining what spiritual matters are discussed. A tool used for assessment could end up limiting and controlling patient expression.
- A spiritual assessment to some degree will reflect the assumptions influencing the clinician (a major one being that spirituality is universal). Thus, a spiritual worldview will be imposed to some degree on a vulnerable patient. An ethical spiritual assessment is nonalienating, nondiscriminating, and engages and respects the patient. Indeed, extant standardized spiritual assessment tools generally have not been tested in many cultures, so it is unknown how culturally appropriate or sensitive they are.[59]

Thus, a spiritual assessment tool—if a tool is needed—should be able to generate helpful information for guiding patient care, encourage patient participation, be flexible and easy to use, take little clinician time, be nonintrusive, allow for a patient's unique story to be understood to some degree, and be simple and clear. A tall task? Perhaps. But important to strive toward.

Assessing Special Populations

Impaired Patients

Although verbal conversation is integral to a typical spiritual assessment, some terminally ill patients may not be able to speak, hear, or understand a verbal assessment. Patients who are unable to communicate verbally may feel unheard. In such situations, the nurse again must remember alternative sources of information. The nurse can consult with the family members and observe the patient's environment and nonverbal communications. Alternative methods for "conversing" can also be used. For patients who can write, paper-and-pencil questionnaires can be very helpful. Always be patient and be unafraid of the tears that can follow. Questions that demonstrate concern for their innermost well-being may release floodgates for tears.

A creative approach developed by a chaplain for use among patients who are ventilator-dependent involves showing them cartoon pictures labeled with a word that they can indicate as reflective of their answer.[74] That is, this "picture guide" has four sections that assesses the patient's religious affiliation (with symbols for each of the major faith traditions as well as one for nonreligious perspectives), feelings (with faces depicting 24 emotions), the spiritual pain rating scale (on a 1–10 continuum), and many options for spiritual interventions that a chaplain could provide (prayer, blessing, "sit with me," and options for reading from various religious scriptures and for facilitating various religious rituals). Berning and colleagues systematically evaluated this picture guide in an intensive care unit (ICU) setting and found those who completed this assessment experienced substantial decrease in their stress.[74]

For persons with dementia or other cognitive impairments, it is helpful to recognize communication can still occur on an emotional or physical level even if positive improvements to mental state are not observed. Their disjointed stories will still offer you a window onto their world. Even if you cannot sew the pieces together, trying will help you to remain curious and engaged.[70] A meta-synthesis of eight studies describing spirituality among persons with dementia provided evidence that spirituality and religiosity often provide these persons with a reminder of their identity and comfort, given that these feel familiar. Although this synthesis of evidence did not address spiritual assessment, it does suggest that spiritual and religious practices, symbols, and rituals are important to know if we are to provide care that is comforting and respectful.[75]

Children

Several strategies can be employed to assess the spirituality of children. The clinician must remember, however, that building trust and rapport with children is essential to completing a helpful spiritual assessment. Children are especially capable of ascertaining an adult's degree of authenticity. Children also are less likely to be offended by a question about religion. If a nurse creates a comfortable and nonjudgmental atmosphere in which a child can discuss spiritual topics, then the child will talk. Never underestimate the profoundness of a child's spiritual experience, especially a dying child's.

In addition to asking assessment questions verbally, the nurse can use play interviews, picture drawings, observations, and informal interviews.[76] The nurse may need to be more creative in formulating questions if the child's vocabulary is limited. For example, instead of asking the child about helpful religious rituals, the nurse may need to ask questions about what they do to get ready to sleep or what they do on weekends. When asking, "Does your mommy pray with you before you go to sleep?" or "What do you do on Sunday or Sabbath mornings?" the nurse can learn whether prayer or religious service attendance are a part of this child's life. An assessment question that Fosarelli found to be particularly helpful with 6- to 18-year-olds was: "If you could get God to answer one question, what one question would you ask God?" [76]

While assessing children, it is vital to consider their stage of cognitive and faith development.[76,77] Questions must be framed in age-appropriate language (e.g., a 4-year-old will likely not understand what "spiritual belief" means). Toddlers and preschoolers talk about their spirituality in very concrete terms, with an egocentric manner. School-aged and adolescent children should be addressed straightforwardly about how they see their illness. Inquiring about the cause of their illness is especially important, as many children view their illness and impending death as punishment.

As with adults, nonverbal communication and behaviors are also significant forms of information for a spiritual screening or assessment. Mueller[77] advises that extensive crying, withdrawal, and regressive or resistant behaviors are potential indicators of spiritual distress. Likewise, difficulty with eating or sleeping (nightmares) and somatic complaints can be reflective of an undergirding spiritual distress.

Family Caregivers

The spiritual distress of family caregivers is not unlike that of their beloved.[17,57,78] Given the provision of 24/7 physical care, the unrelenting uncertainty and anxiety, and the constellation of stressors family caregivers endure, it is not surprising they may feel angry at God, isolated from their faith community, challenged to have a meaningful outlook on life, prone to blaming and regret, and welcoming of faith-related practices that bring meaning, comfort, and forgiveness.[17,57,79,80] Indeed, in Delgado-Guay and colleagues' study, 58% of family carers surveyed reported some spiritual pain.[78]

Parents of Pediatric Palliative Care Patients

Understanding the family's spirituality is pivotal to understanding the child's. Structured interviews or unstructured conversations with parents and even older siblings will inform the healthcare team about the child's spirituality.[76] Although it is highly unlikely that a nurse will be completing a comprehensive spiritual assessment of a family, an awareness of this process can give the nurse a richer perspective with which to conduct a screening or history when it is appropriate. Furthermore, clinician inquiry about parental spiritual needs is associated with perception of spiritual support.[81] A small study of parents of children referred to a palliative care service (76% being mothers, and 19 of the 25 interviewed being religious) found that although a third would not want a clinician to ask them about their spiritual needs, they all would not be offended or uncomfortable with a question about their spirituality or religiosity from a team member.[81] Similarly, nearly half of parents of pediatric ICU patients ($N = 162$) reported that if their child was seriously ill they would want their physician to provide spiritual care; this was especially true for the parent who self-identified as religious.[82] It is important to note, however, that this study's findings also documented that parents were twice as likely to want a chaplain's spiritual support than a physician's.

Barnes and colleagues[83] suggested the following questions as guides for assessing how a family's spirituality affects illness experience:

- How does the family understand life's purpose and meaning?
- How do they explain illness and suffering?
- How do they view the person in the context of the body, mind, soul, spirit?
- How is the specific illness of the child explained?
- What treatments are necessary for the child?
- Who is the qualified person to address these treatments for the various parts of the child's healing?

- What is the outcome measurement that the family is using to measure successful treatment (good death)?

Family Caregivers of Adults Receiving Palliative Care

Similarly, knowing the spiritual or religious family context of an adult patient can also inform clinicians about a patient's faith context. Ferrell and Baird[84] offer a couple of family spiritual assessment questions that are specific to the caregiving role many family members often perform:

- We recognize that often family caregivers' spirituality may be similar to or very different from the patient's spirituality. Are there spiritual needs you have as a family caregiver?
- Many family caregivers tell us that while caring for a loved one is very difficult, caregiving can also be a very meaningful experience. What has it been like for you?[84(p. 257)]

These questions will likely be welcomed by the family caregiver who is engaged in providing much health-related care to a loved one. Asking such questions will acknowledge to this caregiver that his or her role is recognized and appreciated. It will also provide the family caregiver opportunity to express and reflect on their needs, which is a therapeutic experience.

Buck and McMillan took the Spiritual Needs Inventory (SNI) developed by Hermann for patients and tested its validity with 410 family caregivers of hospice patients.[57] This 17-item instrument assesses religious needs (e.g., for devotional practices and service attendance), outlook needs (e.g., "think happy thoughts," "be with friends," "see smiles"), and community needs (e.g., knowing about or being with family and friends) (see Table 34.3). The SNI offers a possible method for a standardized approach to family caregiver spiritual screening and assessment.

Assessing Diverse Spiritualities

Spiritual assessment methods must be flexible enough to obtain valid data from persons with diverse spiritual and religious backgrounds. Although the questions and assumptions presented in this chapter will be helpful for assessing most patients living in Western, Euro-American cultures, they may not be applicable for some patients who do not share these presuppositions. For example, some may believe it is wrong to discuss their inner spiritual turmoil as they face death and will refuse to fully engage in the process of spiritual assessment. For example, some Buddhists and Hindus may believe they must be in a peaceful state to be reincarnated to a better state; African American Christians may think it is sinful to express doubts or anger toward God.[85] Framing spiritual assessment in a positive tone may overcome this type of barrier (e.g., "Tell me about how you are at peace now"). Others may assume there is no spiritual reality and therefore decline any questions regarding their "spirituality." This barrier to assessment can be overcome with questions that are void of such language (e.g., "How is your courage?"; see Box 34.1).

For patients who are religious, it is important to remember that no two members of a religious community are exactly alike.[3] For example, one orthodoxly religious person may believe he should never consume any mind-altering drugs, such as morphine, while a less conservative member of the same denomination may understand that such drugs are a gracious gift from God. Although having a cursory understanding of the world's major religious traditions provides nurses with some framework for inquiry, remaining open to the variation of religious experience and expression is essential.

The Next Step: What To Do with a Spiritual Assessment

Interpreting the Data

Even a spiritual screening can generate a lot of information. This information must be processed to identify what, if any, spiritual need exists and to plan spiritual care. Several points can be considered while processing the data. These include:

- What patients tell you at first reflects not how well you have asked a good question; rather it shows how safe and respected the patient feels with you.
- Consider what incongruities exist. Do the affect, behavior, and communication (ABCs) line up?
- Consider the level of concreteness or abstractness in the patient's talk about spiritual matters. Healthy spirituality straddles these opposites.
- Consider how defensive or threatened the patient is by talk about spirituality. Did the patient change the topic? Give superficial answers? Become competitive? Analyze feelings?
- Keep in mind that crises (e.g., illness) expose the gaps in a patient's spiritual development. Did significant events earlier in life stunt the patient's spiritual growth?
- Remember that religion offers a lens for interpreting life. Likewise, when patients tell meaningful stories, legends, or passages from their holy scripture, they are telling you about themselves.
- Reflect on how helpful versus harmful a patient's spiritual beliefs and practices are. Do they create inner anxiety? Do they limit the patient from using other helpful coping strategies?[70]
- Although an in-depth analysis is beyond the scope of most palliative care nurses, having an awareness of the various ways to evaluate what a patient says will help the nurse begin to make sense of the data.

Documentation

Although assessments of physiological phenomenon are readily documented in patient charts, assessments and diagnoses of spiritual problems are less frequently documented. Indeed, a survey of outpatient healthcare professionals in a Christian healthcare organization (which included 217 nurses and other nonphysician clinicians), revealed 80% were of the opinion that the terminally ill should be screened for spiritual distress.[86] Although only 68% of this sample believed spiritual screening data should be documented, there are reasons why spiritual assessments and care should be documented to at least some degree. These reasons include (1) to facilitate the continuity of patient care among palliative care team members and (2) to document for the monitoring purposes of accrediting bodies, researchers, quality improvement teams, and others. Data collected during spiritual assessments are often very private, sensitive material; to document such may breach confidentiality and thus pose an ethical dilemma. As with other sensitive charted information, nurses must treat spiritual assessment data with much respect and observe applicable privacy codes.

Formats for documenting spiritual assessments and diagnoses can vary. Some institutions encourage staff to use Subjective, Objective, Assessment, Plan (SOAP) or similar formatting in progress notes shared by the multidisciplinary team. Others have developed quick and easy checklists for documenting spiritual and religious issues. Perhaps an assessment format that allows for both rapid documentation and optional narrative data is best. However, merely documenting one's religious affiliation and whether one desires a referral to a spiritual care specialist certainly does not adequately indicate a patient's spiritual status and need.

A few studies provide evidence about how clinicians document spiritual screening, history, or assessment findings. Whereas a couple of studies examine documentation of spirituality/religiosity in the ICU setting,[87,88] three studies provide indications about how frequently it occurs in palliative care settings.[89–91] The strongest evidence comes from Kamal et al.'s[89] multisite chart review (N = 1,989). They found that rates of documentation regarding spiritual concerns at the first palliative care visit varied significantly by whether the clinical setting was acute or non-acute. That is, in acute care settings, only 17% completed a spiritual history (e.g., 0% in emergency departments), whereas it occurred 47% of the time in non-acute setting (e.g., 70% in the home setting). Whereas the data in Kamal et al. were collected in the Southeastern United States, O'Reilly and colleagues[90] observed in an Irish tertiary setting palliative care service that spiritual screening documentation occurred only in 23% of patient records (although 91% of patient religious identity was documented). After an intervention that introduced a collection of palliative care assessment tools (including the FICA for assessing spirituality), these researchers brought the spirituality documentation completion rate up to 82%. In contrast, an audit of charts of patients never seen before in a New England outpatient palliative care clinic revealed that 80% of 142 charts included "emotional/spiritual" assessment information; however, only 13% recorded any recommendation related to these data. A chart review of 144 ICU patient records likewise observed that only about half had any spirituality data documented.[87] This documentation, however, rarely included a description of discussions clinicians had with patients about spiritual concerns. Indeed, another analysis of chaplain entries in ICU patient records concluded that they tended to use "coded" language (i.e., jargon other clinicians might not understand), provided description (rather than interpretation), and tended to be passive about follow-up plans for the patient.[88] In concert, these findings indicate that spirituality may be infrequently documented; however, institutional interventions can increase the rate of completion and documentation.[39,90,92]

Organizational Approaches to Supporting Spiritual Screenings and Histories

Evidence reviewed indicates that spiritual screening, histories, and assessment are often not completed and/or not documented. For example, although 89% of outpatient clinicians in the Christian healthcare organization previously cited were willing to conduct spiritual screenings (40% often or very often), only 11.5% did so often or more often.[86] When exploring the frequency of spiritual screening from a patient viewpoint, very few patients in an urban oncology outpatient clinic (N = 727) reported that clinicians had asked about their spiritual beliefs (17%) or needs (11%), and 23% responded that their spiritual needs were not being met.[10] Even though clinicians typically accept that persons with terminal illness should be assessed for spiritual needs, few act on this belief.[86] Clinicians may worry that spiritual screening and history-taking may be misinterpreted as religious proselytization, they may perceive that they lack time or skill, or they may believe it is not within their purview or feel discomfort with broaching the topic.[26,27]

Given this incongruity between the philosophy of palliative care that embraces the importance of spirituality and the delivery of care that evolves from spiritual screening, history-taking, or assessment, several healthcare organizations have implemented processes to correct for this discrepancy.[39,46,92,93] Two American quality improvement projects were designed to increase the documentation of palliative care patient spirituality.[39,92] Lamba and colleagues inserted a "SmartPhrase" in the electronic health record (EHR) to prompt palliative care clinicians to include certain aspects of an assessment.[92] This included a prompting for "psychological" symptoms that included spirituality-related concerns. Gomez-Castillo and team engaged stakeholders to identify barriers to completing the FICA history in their palliative care service. They next initiated an expectation that every new patient during 1 of the first 3 visits would be co-visited by a chaplain. Both initiatives led to significant increases; the FICA documentation increased from 49% to 72% (N = 79).[39]

Many healthcare systems have instituted a screening tool comprising a few screening questions that are embedded in the standardized admission assessment, typically electronically. The electronic medical record system is sometimes designed then to allow the clinician to not only insert patient responses to screening questions (sometimes requiring the nurse to translate a qualitative response into a yes/no tick box response), but also to submit a referral or add to a care plan if a spiritual need was identified. Skalla and Ferrell completed a pilot study of outpatients receiving cancer care (N = 29) to learn how feasible it would be for these patients to complete a spiritual assessment online.[93] Patients completed 49 items that included items from existing scales on a laptop. Whereas some patients did complete the questionnaires, 22 declined to participate. This observation underscores the need for spiritual screening that is brief and clinically relevant.

Conclusion

Spirituality is an elemental and pervading dimension for persons, especially for those receiving palliative care. Assessment of spirituality, whether in an initial screening, a history, or more complex assessment, is essential to effective and sensitive spiritual care. Indeed, spiritual assessment is the beginning of spiritual care. While the nurse questions a patient about spirituality, the nurse is simultaneously assisting the patient to reflect on the innermost and most important aspects of being human. The nurse is also indicating to the patient that grappling with spiritual issues is normal and valuable. The nurse also provides spiritual care during an assessment by being present and witnessing what is sacred for the patient.

CHAPTER 35

Spiritual Care Intervention

William Rosa

Key Points

- Spiritual care is an essential component of whole-person care, providing healing through authentic presence and the creation of a caring-healing, spiritually safe environment.
- Employing the skills to effectively identify and meet a patient's and family's spiritual care needs requires a clear intentionality, compassion, and the integration of multiple modalities that tend to the spirit through all ways of being, doing, and knowing.
- Holistic spiritual care allows the ones being cared for to feel fully self-expressed, address the source of their pain at spiritual-existential levels, and embrace their humanity in a way that frees them to explore meaning and purpose in their life.
- Love is the ultimate spiritual care intervention.

Introduction

"Spirituality is inextricable from the sacredness of nursing practice. Both are a search to know [the Sacred] through the continued healing of self and others. Both create a state in which we potentiate and are present to an experience of Oneness."[1(p. 24)]

The following definitions will be useful in reading this chapter on spiritual care interventions:

- *Spirituality*: "The essence of our being. It permeates our living in relationships and infuses our unfolding awareness of who we are, our purpose in being, and our inner resources. Spirituality is active and expressive. It shapes—and is shaped by—our life journey. Spirituality informs the way we live and experience life, . . . spirituality is expressed and experienced through living our connectedness with the Sacred Source, the self, others, and nature."[2(p. 135)]
- *Spiritual care*: "That care which recognizes and responds to the needs of the human spirit when faced with trauma, ill health or sadness and can include the need for meaning, for self-worth, to express oneself, for faith support, perhaps for rites or prayer or sacrament, or simply for a sensitive listener. Spiritual care begins with encouraging human contact in compassionate relationship, and moves in whatever direction need requires."[3(p. 6)]
- *Spiritual well-being*: The depth of a person's ability to find purpose and meaning; feel connected with self, others, the Sacred, and nature; balance the energy required for rest and recreation; and integrate opportunity for reflection on the journey.[2]
- *Religion*: "An organized system of beliefs regarding the cause, purpose, and nature of the universe that is shared by a group of people, and the practices, behaviors, worship, and ritual associated with that system."[2(p. 135)]

Case Study: A Patient Seeking Spiritual Comfort, Part I

Jacob is a 43-year-old man diagnosed 7 months ago with metastatic stage IV pancreatic cancer to his liver and bilateral lungs. "Jake," as he prefers to be called, has been married to his high school sweetheart, Anne, for the past 20 years. The couple had three children, daughter Pat (age 16), daughter Marcia (age 10), and son Paul (age 6). Jake's parents, Mary and Jake Sr. were both in their 70s and maintained a close relationship with their children and grandchildren. Jake had one younger and estranged brother, Mark. There was no additional family support except several close friends. Jake had been employed as a financial analyst for the past 12 years and was still working. Raised as a Catholic, he had strong aversions to organized religion, and his faith was "not important" to him. He did not appear to be at peace with his illness or his grim prognosis of 6 months to 1 year. Jake had no other significant medical or surgical history, had never smoked, and denied illicit drug or alcohol use. Jake's last dose of chemotherapy was 2 weeks ago, and now he has presented to the urgent care center of an acute care hospital for pain crisis and increased dyspnea on exertion for the past 48 hours prior to admission. The palliative care team has been consulted for assistance with pain and symptom management. The admitting nurse, Patrick, understood the importance of integrating spirituality and spiritual care into his assessment and plan.

Spirituality and Spiritual Care

Spirituality is one of the primary unifying forces of the human experience. It inextricably links us as human beings of the global village across cultures, continents, faith traditions, genders, socioeconomic differences, and the continuum of wellness–illness.[4] The spiritual journey is a vulnerable exploration of the mystery of life that yearns to seek meaning and purpose and to embrace both the light and shadow sides of one's nature. Tending to the spiritual needs of another is one of the most privileged responsibilities of nursing; a task rooted in compassion and love that elevates nursing's role in healing and alleviating suffering.

Spiritual care addresses the suffering inherent to the human experience.[5] This care seeks to mitigate the deeply painful consequences of loss (of autonomy, relationships, health, etc.), hopelessness and/or isolation, recognizing one's mortality, or feeling unseen, unheard, unacknowledged, or voiceless.[6] In order to deliver and sustain ethically sound spiritual care, the nurse must learn to integrate personal beliefs regarding spirituality with the professional responsibility of service and a focus on patient and family needs.[7] This is a substantial request for it asks the nurse to forge increased self-awareness and equanimity in his or her professional relationships, surrender judgments, and commit to healing the other with respect for that person's subjective beliefs, practices, questions, uncertainties, worries, joys, sadness, and perspectives on life, living, dying, and death.

Spiritual care is not a linear action item, but rather a circular, iterative process that emerges and evolves through relationship-building: a dance between continual assessment and intervention, reassessment, and the delivery of additional interventions.[8] The very practice of spiritual assessment is, in fact, an intervention—it is a time of "being with," asking the more challenging questions about the mystery of life, and bearing witness to the human experience of making meaning and finding purpose. Box 35.1 provides a list of spiritual care questions that provide a starting point for guiding the encounter.[9] Not all questions must be asked, as the answers given will guide next steps. The human spirit is dynamic and ever-changing, and the care provided must flow with the spiritual currents of another's tide. While the palliative care nurse plays an influential role in spiritual care, it is vital to know when to consult the experts. There are certain questions, found in Box 35.2, that, when asked by a patient or family, suggest the need for a chaplain referral.[9] Spiritual care requires as much attention as the physical, psychological, and social domains of care,[5] and when this dimension is nurtured in integrity, it continually influences the nurse's ways of being, doing, and knowing in this sacred and privileged work.[8]

Box 35.1 Spiritual Care Questions from Nurse to Patient

- How is your spirit doing today?
- Are you scared?
- What are you most afraid of?
- What makes life worth living?
- Is there anything you haven't done that you need to do?
- What do you hope for?
- What is your deeper hope?
- Is there anything worse than death?
- What are you most proud of in your life?
- Do you have regrets?
- Do you need to forgive anyone?
- Do you need to ask forgiveness from anyone?
- What will your legacy be?
- What do you love most about your life?
- Are you at peace?

Source: Adapted from Reference 9.

Box 35.2 Questions/Statements by the Patient Requiring Chaplain Referral

- What have I done to deserve this?
- I pray but I'm still sick.
- I used to believe in God, but now I'm not so sure.
- I feel like all hope is gone.
- No one has ever accepted me because I'm different.
- How will my family get along without me?
- What did my life mean?
- What is there left to care about?
- No one understands.
- I'm scared.

Source: Adapted from Reference 9.

Holism, Theory, and Intentionality: Prerequisites for Spiritual Care

Spiritual care calls the nurse to fully engage with the human being at hand and to attend to the patient and family from a holistic stance. *Holistic nursing* is " all nursing practice that has healing the whole person as its goal and honors relationship-centered care and the interconnectedness of self, others, nature, and spirituality"; it seeks to optimize one's level of health and well-being, and it integrates caring-healing modalities, or what may be referred to as complementary and alternative medicine (CAM).[10(p. 3)] Integrative nursing principles include assumptions that human beings are whole systems, inseparable from their environments; human beings have the innate capacity for health and well-being; nature has healing and restorative properties; care is person-centered; practice is informed by evidence and a full range of therapeutic options based on need and context; and that care of both self and other are of tantamount importance.[11] Furthermore, a holistic lens requires nurses to employ all ways of knowing: personal, empirical, sociopolitical, ethical, aesthetic, and "not knowing"—being open to the emerging scenario without preconceptions or judgments.[10]

The annals of nursing theory offer myriad perspectives on the holistic design of spiritual care interventions. For example, Watson's Human Caring Science posits that the moral foundation of nursing lies in caring-healing relationships and the promotion and assurance of human dignity, first and foremost and at all costs.[12,13] Human Caring Science suggests that the physical form of the human being is really embodied spirit, and so, in caring for another, the nurse is in direct contact with the human spirit. In this worldview, *all* care is spiritual care. Table 35.1 provides the Caritas Processes, the ethical guideposts of Human Caring Science, accompanied by reflection questions for nurse self-development.[14] Reed's Theory of Self-Transcendence addresses the everyday practicality of spirituality that is accessible as the patient expands intrapersonally (greater awareness of personal values and beliefs), interpersonally (connection with others, nature, and environment), transpersonally (relation with extraordinary dimensions beyond the tangibles of the physical plane), and temporally (integration of past and future to give meaning to the present).[15] Parse's

Table 35.1 Caritas Processes with self-reflection questions

Ten Caritas Processes	Reflective Caritas Inventory for self-healing and development
1. Embrace altruistic values and practice loving kindness with self and others.	Have I set an intention of self-caring and self-kindness today? Have I centered myself with an act of self-love so that I might be restored?
2. Instill faith and hope and honor others.	Am I clear about what I have faith in? Have I reminded myself of the people, places, and spaces that give me hope?
3. Be sensitive to self and others by nurturing individual beliefs and practices.	Have I responded to my thoughts and feelings today with gentleness, knowing that my experience is unique and sacred?
4. Develop helping-trusting-caring relationships.	Have I empowered myself to release toxic relationships and embrace supportive connections in my life with truth and vulnerability? Just for today, can I trust myself to be there for me?
5. Promote and accept positive and negative feelings as you authentically listen to another's story.	Have I authentically accepted my own story? Do I fully embrace all aspects of who I am; the positive and the negative, the light and the dark?
6. Use creative scientific problem-solving methods for caring decision making.	Do I recognize how creative I am? Have I celebrated my "me-ness" in how I approach, interact with, and inspire this world around me?
7. Share teaching and learning that addresses the individual needs and comprehension styles.	Am I forthcoming about my needs at work and at home? Do I remain flexible and energized or easily tire with my old patterns of rigidity?
8. Create a healing environment for the physical and spiritual self which respects human dignity.	Have I physically or energetically touched my heart today? Have I connected with my own heartbeat; the same heartbeat shared by all of humanity? Have I admitted to myself that my healing starts within?
9. Assist with basic physical, emotional, and spiritual human needs.	Have I paused to attend to my own hunger? My anxiety? My worries? My frustrations? Do I recognize my individual needs as valid?
10. Open to mystery and allow miracles to enter.	Can I release the need to be certain, to explain, defend, protect, and define? Can I surrender to the moment and allow life to unfold as it will?

Source: Adapted from Reference 14.

Humanbecoming School of Thought suggests that health is a dynamic process that develops as humans choose the way they live and that nurses attend to the human experience as unique and unpredictable.[16] It is in this unfolding space of being and becoming referenced by Parse, which may be vulnerable or uncomfortable for the patient, that intelligent spiritual care becomes essential.

Intentionality is a cornerstone of spiritual care intervention. It can be defined as "holding the heartspace with compassion in our knowing, doing, and being while performing an action."[10(p. 24),17,18] Mindless behaviors enacted by the nurse may trigger biocidic (life destroying) repercussions, such as anger, despair, or a sense of decreased well-being.[13] However, mindful caring-healing engagement on behalf of the nurse may be biogenic (life-giving) for all involved and, ultimately, fosters spiritual freedom.[13] As the nurse co-creates with the patient an experience where such freedom is possible, one intention might be to ground nursing practice in an ethic of *evolving human-centered care*:

> compassionate and empathic care that responds, attends, and conforms to the human as a living, breathing, evolving experience; human as fluctuating phenomenological being of engagement; human as history, as story, and as narrative; human as presence, emergence, and possibility; human as fellow sojourner; human as caring-healing; and human as LOVE.[19(p. 336)]

In this way, compassion becomes the currency for the humanistic delivery of spiritual care.

Compassion in Action

Compassion can be defined as a "virtuous response that seeks to address the suffering and needs of a person through relational understanding and action."[20(p. 195)] It is quite possibly the single most sacred virtue in the history of humankind and the central common aspect of almost all faith traditions.[21] It is a vessel for the expression of the human spirit. The literature suggests that compassion, as well as its absence, yield significant consequences on those being cared for.[22,23] While compassionate behaviors help patients to trust their providers and attain increased feelings of satisfaction and emotional support,[24] further studies are needed to identify how best to train providers regarding compassion and create tools for the accurate measurement of compassionate care-related outcomes.[25–27]

Sinclair and colleagues[20] identified seven categorical elements of compassion with related themes identified by patients: (1) virtues (genuineness, love, openness, honesty, authenticity, care, understanding, etc.), (2) relational space (patient awareness, engaged caregiving), (3) virtuous response (knowing the person, person as priority, beneficence), (4) seeking to understand (seeking to understand the person and their needs), (5) relational communicating (awareness of demeanor, affect, behaviors, engagement), (6) attending to needs (compassion-related needs of body, mind, and spirit, taking action in a timely manner to alleviate suffering), and (7) patient-reported outcomes (alleviation of suffering, enhanced well-being, and perception of enhanced care).

Compassion in theory and in the face of significant clinical time constraints may often feel elusive or idealistic, but compassion in action is possible—an achievable moral imperative of nurse-delivered spiritual care.[9,28] Notable journalist Krista Tippett has identified component parts of compassion that make it tangible: the observable actions that bring it to life in the realm of human interaction.[29] These component parts—presence, generosity, forgiveness, empathy, kindness, mystery, beauty, and tenderness—serve as catalysts for spiritual expression and help metabolize the experience of compassion in human relationships.

Presence. The concept of *presence* can be defined as "the essential state or core of healing; approaching an individual in a way that respects and honors her or his essence; [being with rather than doing to]."[30(p. 55)] In order to be present and maintain a state of authentic presence, the nurse might consider cultivating a deeper level of self-inquiry and self-knowledge in order to release distractions and engage from a place of being centered and grounded.[31] Being intentional with one's presence is a cultivated and practiced skill that allows the nurse to work from a space of clarity by releasing limiting judgments, embracing personal fears about illness and death, and being fully available to the needs of the patient and family.[32]

Generosity. When providing spiritual care, generosity does not refer to the donation of material or financial resources, but rather being generous with one's context.[28] Each person generally creates a context or lens through which they see the world. When nurses engage in spiritual care intervention, they generously suspend their context in order to immerse in the context and worldview of another.[33] Contextual generosity ensures socially conscious care delivery. It requires time and attention to ensure spiritual care does not fulfill the nurse's agenda, but rather meets a patient and family where they are.

Forgiveness. The need to forgive or ask for forgiveness are tasks that often arise for patients experiencing serious illness or at end of life. One of the most challenging roles for palliative care providers is to facilitate forgiveness between patients and families.[34] The act of forgiveness may reflect a process and attitude rather than a formal reconciliation.[35] Patients may need to forgive themselves, their bodies, others, parents, children, siblings, employers, God, or the world in order to return to a sense of wholeness and well-being.[36] Providing space for forgiveness to occur is a nursing spiritual care intervention and an exercise of compassion.

Empathy. In order to truly meet a patient's needs, nurses must demonstrate increased sensitivity to another's views of the situation at each point along the encounter and articulate concern and empathy to improve communication.[37] Effective empathy requires attention, curiosity, and imagination; the acknowledgment of complex and shifting goals of care; and the willingness of a nurse to find out what has been misunderstood or misperceived within the relationship.[38] It is through empathic communication, both verbal and nonverbal, that the nurse may find a balance between validating the facts of a scenario and reframing and re-establishing hope.[39]

Kindness. Loving kindness is a foundational principle of all faith traditions and, in fact, it has been shown that many patients will accept a clinician's offer of prayer if that clinician demonstrates genuine kindness and respect.[40] Offering prayer is most appropriate for patients who have expressed a desire to pray with others and may be detrimental for patients who are nonreligious or do not share the same beliefs as the nurse. Whether in times of prayer, silence, or attending to clinical needs, kindness informs the quality of time spent in the nurse–patient relationship and serves as a reminder of the nurse's regard for the patient's well-being. Kindness as an act of compassion calls for sensitivity and patience and a self and system evaluation of *how* care is provided. Kindness is deeply related to beneficence, the ethical principle of "doing good," and evokes questions regarding social justice equity in health care and *how* care is rendered.[41] What does the doing of good mean without the demonstration of kindness?

Mystery. As discussed earlier, the realm of spirituality and spiritual care revolves around the mysteries of life and a desire to derive meaning. There is an inherent mystery to human existence: something in each human being—but also something between each human being—waiting to be unlocked and found and seen. Allowing what is mysterious in one's self to meet with and know the mystery in another is a courageous act that promotes compassionate relationships.[28] And in that moment of connection and vulnerability—something new is nurtured—an emerging relational mystery comes alive by being in partnership for the journey. Compassion cannot exist in an arena of deterministic thinking. In fact, its most substantial barriers are restrictions, such as agendas, pressure, and time limits, but being available to the mystery allows compassion to resonate and grow.

Beauty. Embracing beauty in a way that awakens compassion asks us to move beyond the empirics to simply become aware of the uniqueness of another in this moment. The practice of beauty and dropping into an aesthetic way of knowing connects human beings to the fragility of life. It is in this fragile place that compassion is given the natural playground to express itself; not from a place of outcomes-focused intervention, but from a simpler place—a place of being available to the beauty in the moment.

Tenderness. Kahlil Gibran wrote of "knowing love as the pain of knowing too much tenderness." In this way, tenderness becomes one's connection to love and an outward demonstration of love for both self and others. Tenderness brings all the other components of compassion together. Tenderness as a way of staying present, generous, forgiving, empathic, kind, and being open to the mystery and beauty emerging in the moment; tenderness as a way of being, doing, and knowing, and as a demonstration of the deepest regard for another's spirit.

Transpersonal Development and Transpersonal Nurse Coaching

There is an aspect of human consciousness that transcends the boundaries of the ego identity and is a part of something greater: the aspect of self that recognizes connection, unity, and oneness with all other beings, the larger environment, and with spirit—this is the *transpersonal.*[42] Scientists posit that all human beings are a part of one mind and one consciousness at a greater level beyond rational understanding.[43] Caring for the transpersonal domain of another's well-being gives the nurse direct access to their spirit for the purpose of returning to right relation. *Transpersonal development* suggests that every person has within his or her own deeper nature the resources required to be in harmony with life as it is and the capacity to open his or her personality and discover his or her unique and inherent healing capacities.[44] Fostering the discovery of transpersonal resources of peace, wisdom, purpose, and oneness in another aids them in moving through crisis and awakening to new healing possibilities.[45]

The holistic arena of professional nurse coaching trains providers to develop literacies in spiritual intelligence, which often arises from the practices of authentic presence and deep listening.[46,47] Transpersonal nurse coaching (TNC) is a specialty within professional nurse coaching that specifically aids patients in moving from fear to choice, opening their personality, and moving from separateness to oneness.[48] According to Schaub,[48] the basic principles of TNC include:

- A focus on pro-active health promotion, helping patients understand how to awaken to their deeper resources in difficult times.
- The nurse is not "fixing" or "suggesting," but rather aiding patients to awaken to what already exists within them.
- Awareness techniques provided are safe, effective, and proven and are applicable to all cultures and belief systems.
- The nurse assists patients to develop subjective meaning related to their experiences of inner peace, wisdom, life purpose, or oneness.

The tools of the transpersonal nurse coach include guiding patients through awareness practices, deep relaxation, techniques that help to release tension throughout the body, and quiet moments of reflection to help them identify and release personal triggers, unresolved feelings, spiritual pain, and body-mind-spirit disconnection.[44,45,48]

Modalities: One Spirit, Many Ways

Nurses may use a wide range of modalities to access the transpersonal domain and spiritual nature of another.[8] Table 35.2 shows various modalities for tending the human spirit in health and healing. Quinn suggests that, regardless of the origin or starting point, the entire body, mind, and spirit is affected each time a modality is applied.[8]

Learning modalities is an excellent opportunity for palliative care nurses to expand their knowledge. It is also a chance to consult and collaborate with experts in integrative medicine when available. Such modalities include energy healing—tending to the

Table 35.2 Modalities for tending the human spirit in health and healing

Approaches to tending the spirit through the individual, inner experience	***Approaches to tending to spirit through the body***
Spiritual practices from one's religion or as given by spiritual guides	Performing ritual practices of one's religious tradition or spiritual path
Meditation consistent with patient beliefs, experiences and desires, for example:	Mindful eating
	Mindful exercise/movement work
Simple breath meditation	Fasting
Zen	Yoga
Vipassana	Pranayama breathing
Contemplative practices, such as Centering Prayer	Walking meditation, including the Labyrinth
Spiritual reading and/or spiritual study	Sacred dance, including Dances of Universal Peace
Integral Inquiry practice with "Big Questions"	Listening to or making music
Cultivating deeper self-awareness	Singing/chanting/repeating mantras
Forgiveness practices	Emotional Freedom Technique
Prayer of all varieties, both active and listening	Tai Chi
Reflective journaling	Qi Gong
Imagery and visualization	Mindful cooking for self and loved ones
Writing/reading poetry	Viewing and/or making Art
Any inner activities that bring people closer to their spiritual ideal, by whatever name/language.	*Any physical activities that bring people closer to their spiritual ideal, by whatever name/language.*
Approaches to tending the spirit through the shared inner experience between/among people	***Approaches to tending to spirit through natural, social, cultural, and institutional environments***
Sitting in Sacred Space with nurse and allowing the questions to arise and be met	Seeking/using appropriate referrals
	Being in nature
Spiritual direction	Being with animals and pets
Group spiritual direction	Organized religious/spiritual services/celebrations
Pastoral care/counseling	Working for social change
Spiritually oriented therapy	Participating in group service activities and causes that feed the soul/spirit
Centering Prayer group	Gardening
Being with loving family/friends	Creating/utilizing Sacred Space
Support groups	Caring for the environment in meaningful ways
Ministry of availability – being willing to be fully present to others who are struggling	Loving-kindness practice in work and other outer, system settings
Seeking healing in broken relationships	*"Anything you do every day can open into the deepest spiritual place, which is freedom."*
Loving-kindness meditation practice	—Rumi
Any shared inner activities that bring people closer to their spiritual ideal, by whatever name/language

chakra system or subtle energy body (i.e., Reiki, healing touch)[49]; relaxation—shown to decrease pain and anxiety, improve immune system function, increase pain medication efficacy, and improve a sense of well-being (i.e., biofeedback, meditation, mindfulness, self-regulation)[50]; imagery—bridging connection between body, mind, and spirit (i.e., guided imagery, visualization)[51]; touch- and hand-mediated therapies—shown to decrease fear, anxiety, and feelings of loneliness or isolation (i.e., massage therapy, reflexology, therapeutic touch)[52]; creative expression—fostering acceptance of uncertainty and developing resilience (i.e., improvisation, narrative storytelling, laughter, song, dance, painting)[53]; and aromatherapy—the medicinal use of essential oils through olfaction or topical application to treat pain, infection, and alleviate intense emotions or spiritual distress (i.e., use of oils such as bergamot, true lavender, sweet basil, and sweet marjoram for spiritual distress).[32,54]

The Power of Ritual

Rituals, such as rites of passage, the use of religious or spiritual symbols, and precise, repetitive acts, have been used throughout time to garner personal or social identity, relieve anxiety, discover inherent cultural wisdom, and provide stability amid transition and change.[55] While rituals tend to invoke a religious context, there is a healing potential in the practice of everyday rituals, which may be particularly comforting to patients who have struggled with chronic disease, are confronting the symptoms and experiences of serious illness, or are entering the dying process.[9] The nurse–patient relationship is the quintessential opportunity for co-creating compassionate rituals, given the intimate and interpersonal dynamics of nursing care.[56] There are simpler rituals, such as being present and caring while bathing and dressing a patient, administering medications, or simply listening while the patient reminisces, which may enhance spiritual well-being. And there are the rituals of engagement and disengagement that may be more challenging, such as preparing to greet or leave a patient in spiritual distress at the beginning or ending of a shift or the grief rituals that nurses and interprofessional teams develop to pay respects to a patient who has died.[57] Praying with patients, or remaining fully available during their prayers, can be an empowering ritual symbolizing a communion with the Sacred and can be an expression of a relationship with the Sacred.[58] However, as mentioned earlier, this intervention should always be delivered in response to a patient's need or desire.

Conscious Dying: Holding Sacred Space at the End of Life

Conscious dying provides a guiding ethic for nurses to hold healing and sacred space for those at end of life in order to provide the highest quality and spiritually guided humanistic care. The framework of conscious dying is rooted in a caring science ontology[59] and recognizes the nurse as a primary healing instrument: a doula who births and guides the sacred passage of the dying one.[19] The Conscious Dying Principles and Practices (CDPs) are listed on the left of Table 35.3 with reflective questions for nurses listed on the right to assess the readiness of healthcare systems to create optimal healing environments at end of life.[60] The CDPs tend to the physical plane and open awareness regarding the spiritual dimension, laying the groundwork for a conscious dying experience. The Subtle Energy Realms (SERs) listed in Box 35.3 move the nurse from a space of doing toward deeper ways of being and knowing.[61] "Rather than principles, they are really stages or phases within the dying process that appear—or not—as the human being turns

Table 35.3 Conscious Dying Principles and Practices with self-reflection questions

Conscious Dying Principles and Practices	Reflective conscious dying inventory for systems healing and development
1. Increase beauty, pleasure, contentment.	Do systems provide space for beauty? Do I see patients having time to value and partake in pleasure?
2. Provide emotional and spiritual support.	Have we as a system attended to the spiritual needs of the patient today? Has the patient been emotionally seen, heard, and acknowledged today?
3. Initiate conversations about the dying process.	Are my colleagues and I comfortable talking about death and dying? Is the patient aware that death is a process?
4. Practice self-care to prevent burnout and compassion fatigue.	Are the connections clear between my own self-care and the care I provide for my patient? Can I co-identify with the vulnerability of my patient and gently attend to my own self-care needs?
5. Demystify the stages of the dying process.	Am I clear about the mental-emotional-spiritual stages of the dying process? Is the patient attended to throughout the spectrum? Is there a dissonance between my knowledge, system-wide protocols, and patient needs?
6. Acknowledge mysteries, miracles, and unexplained events.	Are systems willing to bear witness to the mystical? If yes, am I able to validate and share the patient's subjective experiences within this realm despite my personal discomfort?
7. Learn how to be with intense emotions.	Do systems "lean into" the difficult emotions? Can we guide providers to invest in and engage with the actual, moment-to-moment story of our patients and families?
8. Honor others' beliefs without them threatening your own.	Are systems able to release agendas selflessly to support the patient's beliefs with flexibility? How can we facilitate and empower individualism through compassionate advocacy and empathy?
9. Be a steward of conscious deaths.	Do we see systems pave the path for peaceful transitions of integrity? How can we humanize dying by creating an environment of dignity and adequate, anticipatory preparation?
10. Attend at bedside – no one dies alone.	Does the infrastructure of the systems allow for sustained human caring? How can we systematically prepare in meeting the undeniable need to bear witness?

Box 35.3 Subtle Energy Realms

1. Acknowledge mysteries.
2. Be open to miracles.
3. Acknowledge unexplainable events.
4. Be aware of nearing death portals.
5. Allow for the return of the ancestors.
6. Validate the presence of departed loved ones.
7. Honor the waiting in between.
8. Protect the time of crossing over.
9. Imagine breaking into light.

more inward toward the realm of spirit and invisibility . . . into the spiritual-energetic realms we cannot physically see. Naming these subtle energies is really naming the realms/phases that are inherent in the transition [toward death]."[19(p. 339)] This philosophy asks nurses to bear witness to another's suffering without interruption, surrender the need to fix or change what is happening, and to be in touch with one's own grief and suffering to be there for another in theirs.[9] Conscious dying asks the nurse as primary healing instrument to remain humble, curious, willing, reverent, and present to the unfolding of life and death, remembering that suffering is not always reflective of discomfort and may be a sign of the deeper processes of personal and spiritual growth.[62]

Case Study: A Patient Seeking Spiritual Comfort, Part II

Jake was admitted to the medical floor for pain and symptom management and observation. Jake reported improved pain and dyspnea control after medication administration. Patrick, his nurse, took a mindful breath, asked permission to sit at the foot of Jake's bed, and held the space for a shaken-up Jake. Jake shared that his disease had brought to the forefront all unresolved issues. He had recently had multiple calls with his estranged brother and taken accountability for past transgressions. Mark had forgiven him and they had found peace in each other.

Jake said to Patrick, "I am not a religious man. But I am scared for my wife and children. Will you pray with me?" Patrick replied, "I will sit here with you and share your prayers." Jake began to ask God for the protection of his family since he knew he would not be with them forever. Patrick, who had trained in Transpersonal Nurse Coaching, offered to lead Jake through a deep relaxation exercise, which he gratefully accepted. Patrick asked Jake to follow the inward and outward flow of his breath for a few moments, helped Jake to find and release tightly held tension in his back and shoulders, and then asked, "What is your hope?" Jake responded, "That I won't be in any pain." Patrick paused for a minute or two and then added, "What is your deeper hope?"[44(p. 110)] And Jake answered, "That I will be loved." Patrick finished by applying some true lavender oil to a cotton swab and encouraged Jake to take some deep breaths while holding it under his nose. As Jake opened his eyes, he thanked Patrick for being so kind and compassionate.

Jake declined over the next 3 days, eventually becoming verbally unresponsive. Patrick shared with the family that Jake's deepest hope was that he would know love in his final moments. He stood with them as they grieved in anticipation and remained fully available, choosing not to try and fix or change their suffering. Patrick ensured Jake's favorite music was playing softly, and he encouraged Jake's wife to put out pictures of the family to fill the room; he placed flowers by the bedside and covered Jake with his favorite blanket from home. As Jake mumbled or spoke to "people who aren't there," Patrick reminded the family that this was all natural. The Therapeutic Touch practitioner stopped by and taught the family how to comfort Jake through touch. The chaplain returned several times to pray with the family.

When Jake died a few hours later, Patrick was there to witness the pain of Jake's loved ones. His mother collapsed to the floor and Patrick lifted her, putting her in the bed so she could "hold her baby." Later, as Patrick cleaned and prepared the body, he placed his hand on Jake's heart and carried out his own grief ritual of saying good-bye. After a quiet, centering pause, Patrick leaned forward and whispered in Jake's ear, "You are deeply loved and never forgotten."

Love: The Final Word

It is rare to hear the term *love* used in healthcare today. But it continues to be the universal language of humanity; the surest way toward peace and the alleviation of suffering; the most enlightened tool in the healing of another. Goldin calls the "practice of nursing" the "practice of love of humanity."[63(p. 289)] Love is the moral/ethical foundation of nursing: the holy work of touching bodies and spirits and souls.[63] Researcher-storyteller Brené Brown writes,

> We cultivate love when we allow our most vulnerable and powerful selves to be deeply seen and known, and when we honor the spiritual connection that grows from that offering with trust, respect, kindness, and affection. Love is not something we give or get; it is something that we nurture and grow, a connection that can only be cultivated between two people when it exists within each one of them—we can only love others as much as we love ourselves.[64(p. 26)]

And that is the essence of spiritual care.

CHAPTER 36

Meaning in Illness

Tami Borneman and
Katherine Brown-Saltzman

Key Points

- Finding meaning in illness is an important issue when facing the end of life.
- The process of finding meaning in illness involves a journey through sometimes very difficult transitions.
- A terminal illness can greatly impact the patient–caregiver relationship.
- It is essential for nurses to experience their own journey in the dying process and bring with them an openness to be transformed by it.

Introduction

"In the driest whitest stretch of pain's infinite desert, I lost my sanity and found this rose."[1] Is it possible to adequately articulate and give definition to meaning in illness? Or is meaning in illness better described and understood through using symbolism and metaphors like the poem by Galal al Din Rumi?[1] To try to define that which is enigmatic and bordering on the ineffable seems almost sacrilegious. The unique journey of finding meaning in illness that is faced by patients and their families would seem to be diminished by a process that relegates the experience to the confining boundaries of language.

Is it that patients seek to find meaning in illness, or is it that they seek to find meaning in the life that is now left, in relationships, and in all that we value? Do patients seek to find meaning in illness itself as an isolated event or that which is beyond the illness, such as how to live out this newly imposed way of life? Terminal illness often forces one to reappraise the meaning and purpose of life. If one allows space in life for the process of meaning in illness to unfold, one then moves from the superficial to the profound.

Terminal illness also compels one at some point to look directly at death, yet at times patients resist getting in touch with the feelings that arise. Everything in a person seeks life, hopes for life, and denies death. There is something very cold, very unmoving, and very disturbing about it all. Does the end of one's human existence on Earth need to be the sole metaphor for death?

Although end-of-life care has greatly improved, there is still much work to be done to provide the dying patient with personal, compassionate, and comprehensive care. It is not enough for nurses to solely rely on the nursing process. The patient's illness odyssey beckons the nurse to go beyond assessment, diagnosis, intervention, and evaluation to a place of vulnerability, in a way that allows for a shared connectedness unique to each patient–nurse relationship. Nurses need to be willing to use feelings appropriately as part of the therapeutic process. Separating oneself from touching and feeling for purposes of protection only creates more vulnerability because one's emotions are placed in isolation. Nurses can be a catalyst for helping the patient and family find meaning in the illness, and, in the process, they, too, can define or redefine their own meaning in life, illness, and death.

Meaning Defined

Johnston-Taylor[2] presents several definitions for *meaning* (Table 36.1). In the dictionary,[3] one finds *meaning* defined simply as "something that is conveyed or signified" or as "an interpreted goal, intent, or end." But it is the etymology of the word "mean" that helps nursing come to understand the potential for supporting patients in the process of finding meaning in their lives, even as they face death. "Mean" comes from the Old English *maenan*, "to tell of." One does not find meaning in a vacuum; it has everything to do with relationships, spirituality, and connectedness. While the process of finding meaning depends greatly on an inward journey, it also relies on the telling of that journey. This may involve language as in a narrative or in story-telling, but it may also be conveyed by the eyes, through the hands, or just in the way the body is held. Frankl[4] reminds us that the "will to meaning" is a basic drive for all of humanity and is unique to each individual. A life-threatening illness begs the question of meaning with a new sense of urgency and necessity.

Cassell[10(p. 67)] states that "all events are assigned meaning" by judging their significance and value. Meaning cannot be separated from the person's past; it requires the thought of future and ultimately influences perception of that future.[11] Finding meaning is not a stagnant process; it changes as each day unfolds. As one patient reflected on his diagnosis, "Even though I have this I am still a whole person. My thoughts are different, my ambitions are a little different because I want to spend as much time as I can with my grand-kids."[12] Coming face to face with one's mortality not only clarifies what is important but also focuses the poignancy of the loss on much that has been meaningful.

One's spirituality is often the key to transcending those losses and finding ways to maintain those connections, whether it is the belief that one's love, work, or creativity will remain after the physical separation or the belief that one's spirit goes on to an afterlife. *Meaning in life* concerns the individual's realm of life on Earth. It has to do with one's humanness, the temporal, relationships, and what one

Table 36.1 Definitions of meaning

Meaning	"Refers to sense, or coherence. . . . A search for meaning implies a search for coherence. 'Purpose' refers to intention, aim, function. . . . however, 'purpose' of life and 'meaning' of life are used interchangeably"[5] "A structure which relates purposes to expectations so as to organise actions. . . . Meaning . . . makes sense of actions by providing reasons for it."[6]
[Search for] meaning	"An effort to understand the event: why it happened and what impact it has had . . . [and] attempts to answer the question(s), What is the significance of the event? . . . What caused the event to happen? . . . [and] What does my life mean now?"[7] "An attempt to restore the sense that one's life [is] orderly and purposeful."[8]
Personal search for meaning	"The process by which a person seeks to interpret a life circumstance. The search involves questioning the personal significance of a life circumstance, in order to give the experience purpose and to place it in the context of a person's total life pattern. The basis of the process is the interaction between meaning in and of life and involves the reworking and redefining of past meaning while looking for meaning in a current life circumstance."[9]

has done in life to give it meaning.[13,14] *Meaning of life* has more to do with the existential, beyond one's earthly physical existence to an eternal, secure, and indelible God or spiritual plane. The existential realm of life provides a sense of security whereby one can integrate experiences.[13,14]

Spirituality has been defined as a search for meaning.[15,16] One of the Hebrew words for meaning is *biynah* (bee-naw), understanding, knowledge, meaning, and wisdom. It comes from the root word *biyn* (bene), which means to separate mentally or to distinguish.[17] How does one come to knowledge and understanding? Patients who are dying often describe a sense of isolation and loneliness. They frequently have endless hours available while at the same time experiencing a shortening of their life. It is here that the nurse has a pivotal role as the listener, for when the ruminations of the dying are given voice, there is an opportunity for meaning. Important life themes are shared, and the unanswerable questions are asked. As a stranger, the nurse develops intimacy and trust with the patient, and meaning takes hold.

Suffering creates one of the greatest challenges to uncovering meaning. For the dying patient, suffering comes in many forms: physical pain, unrelenting symptoms, spiritual distress, dependency, multiple losses, and anticipatory grieving. Even the benefits of medical treatments given to provide hope or palliation can sometimes be outweighed by side effects, inducing yet further suffering. The dictionary defines *suffering*: "The condition of one who suffers; the bearing a pain or distress."[3] But once again, it is the root word that helps to move one—the Latin *sufferer*, which comprises *sub*, "below," and *ferre*, "to carry." The weight and isolation of suffering now becomes more real at the visceral level. Cassell[10] reminds us that pain itself does not foreordain suffering; it is the meaning that is attributed to that pain that determines the suffering. In his clinical definition, Cassell states: "Suffering is a state of severe distress induced by the loss of the intactness of person, or by a threat that the person believes will result in the loss of his or her intactness."[10(p. 63)] Clinicians can further unnecessary suffering, as attested to in the research by Berglund et al., by making patients feel objectified or by providing fragmented care.[18] Suffering is an individual and private experience and will be greatly influenced by the personality and character of the person; for example, the patient who has needed control during times of wellness will find the out-of-control experience of illness as suffering.[10] In writing about cancer pain and its meaning, Ersek and Ferrell[19] provide a summary of hypotheses and theses from the literature (Table 36.2).

It is the duty of all who care for patients to alleviate suffering and not just treat the physical dimensions of the illness. This is no small task, as professionals must first be free from denial and the need to

Table 36.2 Summary of hypotheses and theses from the literature on meaning

Hypothesis/thesis	Authors
The search for meaning is a basic human need.	Frankl 1959[4]
Meaning is necessary for human fulfillment.	Steeves and Kahn 1987[20]
Finding meaning fosters positive coping and increased hopefulness.	Ersek 1991[21]; Steeves and Kahn 1987[20]; Taylor 1983[8]
One type of meaning-making activity in response to threatening events is to develop causal attributions.	Gotay 1983[22]; Haberman 1987[23]; Steeves and Kahn 1987[20]; Taylor 1983[8]; Chrisman and Haberman 1977[24]
Meaning-making can involve the search for a higher order.	Ersek 1991[21]; Ferrell et al. 1993[25]; Steeves and Kahn 1987[20]
Meaning-making often involves the use of social comparisons.	Ferrell et al. 1993[25]; Taylor 1983[8]; Ersek 1991[21]; Haberman 1987[23]
Meaning can be derived through construing benefits from a negative experience.	Ersek 1991[21]; Haberman 1987[23]; Taylor 1983[8]
Meaning sometimes focuses on illness as challenge, enemy, or punishment.	Barkwell 1991[26]; Ersek 1991[21]; Lipowski 1970[27]
Pain and suffering often prompt a search for meaning.	Frankl 1959[4]; Steeves and Kahn 1987[20]; Taylor 1983[8]
Uncontrolled pain or overwhelming suffering hinder the experience of meaning.	Steeves and Kahn 1987[20]
One goal of care is to promote patients' and caregivers' search for and experiences of meaning.	Ersek 1991[21]; Ferrell et al. 1993[25]; Steeves and Kahn 1987[20]; Haberman 1988[28]

self-protect to see the suffering of another. Then, they must be able to attend to it without trying to fix it or simplify it. The suffering needs to be witnessed; in the midst of suffering, presence and compassion become the balm and hope for its relief.

The Process of Finding Meaning in Illness

Nurses who have worked with terminally ill patients and their families have found that many themes arise as a patient seeks meaning. The title given to each theme is an attempt to represent observed transitions that many terminally ill patients seem to experience. Not all patients move through the transitions in the same order, and not all transitions occur for each patient. The themes shared in this section are the imposed transition, loss and confusion, dark night of the soul, randomness and absence of God, brokenness, and reappraisal. In experiencing some or all of these transitions, patients may find meaning in this difficult time of life.

The Imposed Transition

When one is told that he or she has a terminal illness, it can be like hearing the sound of prison doors slam shut. Life will never be the same. The sentence has been handed down, and there is no reversing the verdict. For many, terminal illness is a loss, and there is nothing that can be done to change the prognosis even though the final outcome may temporarily be delayed. For some patients, the essence of their being is shaken, and their soul is stricken with a panic unlike any other ever felt. For the first time, they may be faced with an "existential awareness of nonbeing."[29] For a brief moment, the silence is deafening, as if suspended between two worlds, the known and the unknown. As the patient "regains consciousness," so to speak, the pain and pandemonium of thoughts and emotions may begin to storm the floodgates of their faith, coping abilities, and internal fortitude, while simultaneously the word "terminal" reverberates in one's head. For many, there is no easy or quick transition into the acceptance of a terminal diagnosis. Although there are circumstances where patients, either because of being so burdened by illness or frailty, may welcome dying.

For many patients, facing the end of life provokes questions. The self-reflective questions include both the meaning *of* life and the meaning *in* life. Whether one embraces with greater fervor the people and values that collectively give one meaning in life or one views it as now lost, the loss and pain are real. Nothing can be done to prevent the inevitable. There is a sense of separation or disconnectedness in the sense that while one remains the same person, he or she also becomes permanently different from others. In a rhetorical sense, the meanings one gains in life from relationships and the material world serve to affirm one as a participant in these meanings.[29,30] When these meanings are threatened by a terminal diagnosis, people may fear the loss of who they are as functioning productive and relational human beings. The affirmations they received from their meanings in life are now at a standstill.

Case Study: A Patient Who Wishes to Leave a Legacy

Accepting of his prognosis and not afraid of dying, an 84-year-old retired carpenter was not yet ready to die. He absolutely adored his grandchildren and they gave him great meaning in life. Life was always better when they were around. He was presently on his third line of chemotherapy for lung cancer, hoping it would allow him more time. He wanted his grandchildren to remember him and to know how much they meant to him.[31] When asked about leaving a legacy, he had not thought about it but was very interested. Several ideas were discussed, and he decided to write letters to each grandchild. The letters contained the same short biography of his life followed by personalized stories for each one from their childhood into adulthood. He commented on their strengths and ended with words of encouragement for the future. Each grandchild received his or her letter upon his death.

In addition to questioning meaning *in* life, many facing the end of life also question the meaning *of* life. A life-threatening illness makes it difficult to maintain an illusion of immortality.[32] "What happens when I die?" "Is there really a God?" "Is it too late for reconciliation?" For those believing in life after death, the questions may focus on the uncertainty of eternal life or the possibility of this being a test of faith. No matter what the belief system, the existential questions are asked.[33] Many may reach out for a connection with God or something beyond one's self to obtain some sense of security and stability. Then, in this ability to transcend the situation, ironically, one may feel a sense of groundedness. Frankl[4] states, "It denotes the fact that being human always points, and is directed, to something or someone, other than oneself—be it a meaning to fulfill or another human being to encounter." There is a strong spiritual need to find meaning in this new senseless and chaotic world. Ellingsen et al. interviewed terminally ill patients and explored this concept of being in "transit" as being experienced by both time and space. The vulnerability of an incurable illness and the state of embodied suffering can be altered by the establishment of a safe environment (i.e., pain skillfully addressed), which in turn diminished the unpredictable aspects of the body's failure. This creation of predictability, safety, and also a sense of home allowed for a transition with a feeling of security and peacefulness.[34]

Loss and Confusion

One cancer patient stated, "Our lives are like big run-on sentences and when cancer occurs, it's like a period was placed at the end of the sentence. In reality, we all have a period at the end of the sentence, but we don't really pay attention to it."[35] With a terminal diagnosis, one may feel as if life is changed forever, for however long that life may be. Each day, life seems to change as one is forced to experience a new aspect of the loss.[36–38] There is a sense of immortality that pervades one's lust for life, and when made to look at one's mortality, it can be staggering. With all of the many losses, coupled with the fear of dying, one may feel confused from the infinite possibilities of the unknown. The panorama of suffering, at times, seems to be limitless.

For many, the pain of loss is as great as the pleasure derived from life.[39] Confusion is caused not only from one's world having been turned upside down; it is also caused by those who love us and care about us. It is not intentional; nevertheless, its impact is greatly felt. In trying to encourage or trying to help find meaning, friends and family may unintentionally minimize the loss and pain by comparing losses, by denying the freedom to be angry at God, or by immediately focusing on the time left to live. The hurting soul needs to feel the depth of the loss by whatever means it can. The pain from loss can be relentless.

Case Study: A Patient Confronting Mortality

A 46-year-old woman with advanced renal cancer stopped her treatment due to illness progression. Additional long-standing comorbidities had greatly limited her physical activities, exposing her to many losses over the years. She knew she was going to die and wanted to talk about it with her family. Thinking they were acting in her best interest, the family would not engage the patient on this topic believing that it would be too much of a burden. This was both frustrating and hurtful to her. What the family did not realize was that this refusal to engage imposed yet another loss for her. Their approach, as loving as they were trying to be, only served to remind her of her impending death.

In Tolstoy's *The Death of Ivan Ilyich*, one hears the agony of Ivan's similar experience, "This deception tortured him—their not wishing to admit what they all knew and what he knew, but wanting to lie to him concerning his terrible condition, and wishing and forcing him to participate in that lie. . . . And strangely enough, many times when they were going through their antics over him he had been within a hairbreadth of calling out to them: 'Stop lying! You know and I know that I am dying. Then at least stop lying about it!' But he had never had the spirit to do it."[40(p. 86)]

Dark Night of the Soul

There are patients who go through a period of the extraordinary work of the dark night of the soul. As difficult as this work is, it holds promise of transformation. The descent into darkness pervades every crack and crevice of one's being. One now exists in the place of Nowhere surrounded by nothingness that is void of texture and contour. One's signature is seemingly wiped away, taking with it the identification of a living soul.[39] Job states, "My days are swifter than a weaver's shuttle, and come to an end without hope . . . my soul is poured out within me; days of affliction have seized me. At night it pierces my bones within me, and my gnawing pains take no rest . . . ."[41] "One enters the abyss of emptiness—with the perverse twist that one is not empty of the tortured feeling of emptiness."[42] This is pain's infinite desert.

For some, darkness looms as one thinks about the past, full of people and things that provided meaning in life that will soon have to be given up. Darkness looms as one thinks about the future because death precludes holding on to all that is loved and valued. Darkness consumes one's mind and heart like fire consumes wood. It makes its way to the center with great fury, where it proceeds to take possession, leaving nothing but a smoldering heap of ashes and no hope of recovering any essence of life.[43]

Case Study: A Patient Struggling with Darkness

After several years free of ovarian cancer, a 33-year-old woman was informed that the cancer had recurred. Her first thoughts were of her three girls, ages 7, 9, and 12. She opted to go on a clinical trial, hoping to gain more time. After only 6 months, the cancer progressed. She became depressed and agonized over leaving her girls at such critical ages. She tormented herself thinking about whether she had done the right thing in pursuing the clinical trial. Her children would lose her anyway, what had she accomplished except time away from them? She experienced an inconsolable darkness and needed help. The nurse was present to her suffering, allowing her space to grieve. They worked together on a plan for the patient to focus on being a mother as well as preparing the girls for her death. The patient was able to move through the darkness and into meaning.

Although one might try, there are no answers—theological or otherwise—to the "whys" that engulf one's existence. Death moves from an "existential phenomenon to a personal reality."[44] For many, presuppositions about life fall away, and one is left emotionally naked. In the dark night of the soul, there is neither the physical, the emotional, nor the spiritual strength to help one's own fragility. The world becomes too big, and one's inner world is overwhelming.[39] The enigma of facing death strips order from one's life, creating fragmentation and leaving one with the awareness that life is no longer tenable. This is a time when patients are at risk for considering physician-assisted suicide and need careful assessment and support.

Randomness and the Absence of God

For many, the pronouncement of a terminal diagnosis may provoke inner turmoil and ruminating thoughts from dawn to dusk. Even in one's chaotic life, there was order. But order does not always prevail. A policeman is killed responding to a domestic violence call. A young man is struck and killed by lightning while in his home. Children are held hostage and abused by their parents. Hurricanes devastate cities, killing hundreds. There seems to be no reason. It would be different if negligence were involved. For example, if the young man was walking outside during a thunderstorm; although the loss is still quite devastating, a "logical" reason could be assigned to it. But randomness leaves us with no "logical" explanation.[42]

The word "random" comes from the Middle English word *radon*, which is derived from the Old French word *randon*, meaning violence and speed. The word connotes an impetuous and haphazard movement, lacking careful choice, aim, or purpose.[3] The feeling of vulnerability is overwhelming. In an effort to find shelter from this randomness, many may seek meaning and comfort from God or from something beyond one's self, but how does one know that God or something beyond one's self is not the cause of one's loss? One's trust may be shaken. Can one reconcile God's sovereignty with one's loss?[42] Can one stay connected to and continue to pull or gain strength and security from something beyond one's self that may be the originator of one's pain? There is a sense of abandonment by that which has been one's stronghold in life. Yet to cut one's self off from that stronghold out of anger would leave one in a state of total disconnection. A sense of connection is a vital emotion necessary for existence, no matter how short that existence may be. But facing death forbids one to keep one's existential questions and desires at a distance. Rather, it seems to propel one into a deeper search for meaning as the questions continue to echo in one's mind.

Brokenness

Does one come to a place of acceptance within brokenness? Is acceptance even attainable? Sometimes. Sometimes not. Coming to a place of acceptance is an individual experience for each person. In a wonderful analogy of acceptance, Kearney states, "Acceptance is not something an individual can choose at will. It is not like some light switch that can at will be flicked on or off. Deep emotional acceptance is like the settling of a cloud of silt in a troubled pool.

With time the silt rests on the bottom and the water is clear."[45 (p. 98)] Brokenness does, however, open the door to relinquishing the illusion of immortality. Brokenness allows the soul to cry and to shed tears of anguish. It elicits the existential question "Why?" once again, only this time not to gain answers but to find meaning.

Case Study: A Patient Finding Meaning

When younger, knitting had always been a way for this 67-year-old woman to relax. Over the years of raising children and volunteering with the local Rotary Club, she found that knitting went by the wayside. Diagnosed with advanced breast cancer 6 months ago, the woman's cancer continued to progress in spite of treatment. No longer able to ambulate even with a walker, she was confined to the hospital bed in her home. At first, she was angry at God, sad, and resentful of having to live this way. Reminiscing with her granddaughter during a recent visit, they talked about her knitting days. Inspired by her granddaughter's encouragement, she decided to start knitting again. This activity gave her peace as well as a purpose. Before she died, she had knitted an animal for each child in her granddaughter's first-grade class.

If we go back to the poem at the beginning of this chapter, it wasn't until "sanity" was lost that the rose was found. A gradual perception occurs, whereby one realizes that the way out is by no longer struggling.[45] When one comes to the end of one's self and the need to fight the inevitable that is death, space is given for meaning to unfold. It is not that one gives up the desire but that one relinquishes the need to emotionally turn the situation around and to have all questions answered. Sittser, a minister who experienced a sudden loss of several immediate family members, stated, "My experience taught me that loss reduces people to a state of almost total brokenness and vulnerability. I did not simply feel raw pain; I was raw pain."[42(p. 164)] Pain and loss are still profound, but in the midst of these heavy emotions there begins to be a glimmer of light. Like the flame of a candle, the light may wax and wane. It is enough to begin to silhouette those people and things that still can provide meaning.

Reappraisal

It is here where one begins to realize that something positive can come from even a terminal diagnosis and the losses it imposes.[46,47] The good that is gained does not mitigate the pain of loss but rather, it fosters hope—hope that is not contingent on healing but on reconciliation, on creating memories with loved ones, on making the most of every day, on loving and being loved.[48] It is a hope that transcends science and explanations and changes with the situation. It is not based on a particular outcome but, instead, focuses on the future, however long that may be. Despair undermines hope, but hope robs death of despair.[49]

Case Study: A Patient Finding Hope

After a 15-year remission, a male patient in his mid-40s diagnosed with a relapse of leukemia, required a bone marrow transplant. He spent a long time in the hospital, including 35 days in isolation. Once moved to a regular room and allowed to leave his room, he visited a young teenage girl down the hall who was struggling with treatment side effects and ready to give up. They became friends, and, when possible, he would sit with her during part of her treatment and they would talk or just be quiet. Through this personal interchange, they strengthened each other's hope.

Encountering a terminal diagnosis is complex and challenging. It will always have tragic aspects because it causes pain and loss to everyone involved.[50,51] But, at a time unique to each person facing death, a choice can be made as to whether one wants to become bitter and devalue the remaining time or value the time that is left as much as possible.

An important choice to be made during this time is whether to forgive or to be unforgiving—toward oneself, others, God, or one's stronghold of security in life.[52] Being unforgiving may breed bitterness and superficiality. As one faces the end of life, one needs both an existential connection and a connection with others. Being unforgiving can separate one from those connections, and it is only through forgiveness that the breach is healed. Forgiveness neither condones another's actions nor does it mean that this terminal diagnosis is fair. Rather, forgiveness is letting go of expectations that one somehow will be vindicated for the pain and loss. Whether by overt anger or by emotional withdrawal, in seeking to avoid vulnerability to further pain and loss, one only succeeds in making one's self more vulnerable. Now one has chosen a deeper separation that goes beyond facing the death of the physical body—that of the soul.[42] Vulnerability through forgiveness provides a means of healing and, when possible, reconciliation with others. It provides healing and reconciliation with one's God or one's stronghold of security. Forgiveness allows both physical and emotional energy to be used for creating and enjoying the time left for living.

Case Study: A Patient in Need of Forgiveness

A 28-year-old woman was admitted to the hospital with advanced colon cancer. She was single, a business woman, and close with her sister and father. During the intake, she stated that her mother was deceased. When offered standard supportive care, she refused social work and chaplaincy. She felt like she had everything under control even though she had been seen crying when she thought no one was watching. While in her room, a nurse was able to engage her in conversation. The nurse learned that the patient's mother was not dead, rather, she was a psychiatric patient who had left her, her younger sister, and their father when the girls were little. Her mother refused help for years and when she finally sought help, was noncompliant with appointments and medications. She called her daughters out of the blue, sometimes crying and other times not making any sense. The patient kept her mother out of her life and did not want her at the hospital. As far as she was concerned, her mother's actions were unforgiveable. Over time, through presence and gentle conversation, the nurse encouraged the patient to open up in an environment of emotional safety. This time a chaplaincy offer was accepted. One may not always be able to fix the pain of life's fractures or bring people to a place of forgiveness, but it is important not to underestimate what is happening in the moment.

There are many emotions and issues with which those facing death must contend. It is not an easy journey, and the process is wearing; nevertheless, the rose can be found.

Impact of the Terminal Illness on the Patient–Caregiver Relationship

Each person comes to new situations with unique life experiences and the meanings gained from them. It is no different when confronted with illness and the end of life. However, in this special episode of life, there are often no personal "reruns" from which to glean insight. Patient and family come together as novices, each helping the other through this unknown passage.[53] Because different roles and relationships exist, the impending loss will create different meanings for each person involved.

Facing the loss of someone you love is extremely difficult. For the family caregiver, the process of finding meaning is influenced by the one facing death. One example involved a wife's discussion with her terminally ill husband over several months regarding his outlook on life. As Christians, they knew death would take them to heaven, but she was curious as to what that meant to him and how he was handling the unknown. She felt strong in her own faith but also felt like she was giving lip service to it at times. He described life as having even more meaning in that, although he loved her very much and the life they had together, he could now "cherish" every moment of that time. He was sad knowing that he would eventually die from the cancer, but until that time came, he just wanted to enjoy life with her. She shared that while what he said seemed obvious when he said it, for some reason, this time it really spoke to her soul and she felt peace.

In another example, a female patient with renal cancer wanted to help her family create meaning as they went through the cancer journey with her. She bought each of her four adult children a photo scrapbook and asked them to spend a weekend with her but did not explain why. When they arrived, the patient had pictures, letters, drawings, and other memorabilia, ready for them to create their own meaningful memories. There were lots of tears and laughter. The patient died just 2 weeks later.

One final story. A 45-year-old woman was a heart transplant recipient 2 years before being diagnosed with stage IV lung cancer. Her shortness of breath had increased, which both frustrated and scared her. She was very active in community arts as well as in raising horses, and she already had cut back on the community arts. She was a strong woman who didn't want to need help, and she was supported by a loving husband of many years. She was depressed and refused any medication. She struggled greatly with anger and resentment at having had a life-saving heart transplant only to get cancer. Life was fast losing meaning for her. She received several lines of chemotherapy but each one worked only a short time before the cancer progressed. Her main goal now was to live long enough to see the foal that would be born soon. On her last visit to the hospital before starting hospice, a friend who had visited the farm encouraged her to stop and visit the foal that was born the day before in case she was unable to leave the house again. The husband and wife did just that. Seeing the foal meant the world to her, and she died peacefully at home several days later.

These actual patient stories were presented to exemplify how the patient's meaning in illness affects the meaning held or created by family members. Differing or divergent meanings can be detrimental in a relationship, or they can be used to strengthen it, thereby increasing the quality of time left together. That is not to imply that the patient is responsible for the meaning created by family members; rather, they are responsible for how one affects the other. Germino, Fife, and Funk[54] suggest that the goal is not merely arriving at a single meaning within the patient–family dyad but, rather, encouraging a sharing of individual meanings so that all can learn and relationships can be deepened and strengthened.

There are many issues that family caregivers face in caring for a loved one nearing the end of life.[55–57] There is one issue, however, that warrants more attention: the loss of dreams—the loss of dreams for a future with a loved one, in addition to the loss of the person him- or herself. It is the loss of the way one used to imagine life and how it would have been with that person. It is the loss of an emotional image of oneself and the abandonment of chosen plans for the future and what might have been.[58]

For a child and the surviving parent, those losses of dreams will be played out each time Mother's or Father's Day arrives and at important life-cycle events, such as graduations, weddings, or the birth of the first grandchild. As her mother lay dying, one child expressed that loss in the simple statement, "Mommy, you won't be here for my birthday!" The mother and child wept, holding and comforting each other. Nothing could change the loss, but the comfort of love would remain forever.

The loss of dreams is an internal process, spiritual for some, and seldom recognized by others as needing processing.[35,58–60] Nurses have a wonderful opportunity to verbally acknowledge the family caregivers' loss of dreams and to encourage them in their search to find meaning in the loss. The ability to transcend and connect to God or something greater than one's self helps the healing process.

Transcendence: Strength for the Journey that Lies Ahead

Transcendence is defined as lying beyond the ordinary range of perception; being above and independent of the material universe. The Latin root is *trans-*, "from or beyond," plus *scandere*, "to climb."[3] The images are many: the man in a pit climbing his way out one handhold at a time; the story of the Biblical figure Job as he endured one loss after another and yet found meaning; the climber who reaches the mountaintop, becoming closer to the heavens while still having the connection to the earth; or the dying patient who, in peace, is already seeing into another reality. The ability to transcend truly is a gift of the human spirit and often comes after a long struggle and out of suffering. It is often unclear which comes first—does meaning open the door for transcendence, or, quite the opposite, does the act of transcendence bring the meaning? More than likely, it is an intimate dance between the two, one fueling the other. In the Buddhist tradition, suffering and being are a totality, and integrating suffering in this light becomes an act of transcendence.[61]

Transcendence of suffering can also be accomplished by viewing it as reparation for sins while still living—preparing the way for eternity, as in the Islamic tradition. In other traditions, transcendence is often relationship-based, involving the connection to others and sometimes to a higher power.[4] For example, the Christian seeing Christ on the cross connects one to the relationship and endurance of God and the reality that suffering is a part of life. For others, it is finding meaning in relating to and caring for others. And for some, that relationship may be with the Earth, a sense of stewardship and leaving the environment a better place. It is rare that patients reach a state of transcendence and remain there through their dying. Instead, for most, it is a process in which there are moments when they reach a sense of expansion that supports them in facing death. The existential crisis does not rule because one can frame the relationship beyond death; for example, "I will remain in their hearts and memories forever, I will live on through my children, or my spirit will live beyond my limited physical state."

Nursing Interventions

If one returns to the root word of "meaning," *maenan*, or "to tell of," this concept can be the guide that directs the nurse toward interventions. Given the nature of this work, interventions may not be the true representation of what is needed. Intervention implies action—that the nurse has an answer, and she or he can direct the course of care by intervening. "Intervention" is defined as "To come, appear, or lie between two things. To come in or between so as to hinder or alter an action."[3] But finding meaning is process-oriented; while finely honed psychosocial skills and knowledge can be immensely helpful, there is no bag of tricks. One example would be of a chaplain who walks into the room and relies only on offering prayer to the patient, preventing any real discourse or relationship-building. The patient's personhood has been diminished, and, potentially, more harm than good has been done.

In revisiting *maenan* "to tell of," then, what is required of the professional who enters into the healing dimension of a patient's suffering and search for meaning?[62] Respect may be the starting point—respect for that individual's way of experiencing suffering and attempts of making sense of the illness. Second, allow for an environment and time for the telling.[63,64] Even as this is read, the sighs of frustration are heard, "We have no time!" If nursing fails at this, if nurses turn their backs on their intrinsic promise to alleviate suffering, then nursing can no longer exist. Instead, the nurse becomes simply the technician and the scheduler—the nurse becomes a part of the problem. She or he has violated the American Nurses Association's Code of Ethics for Nurses that asserts that they are obligated to address the alleviation of suffering and provide supportive care to the dying: "Optimal nursing care enables the patient to live with as much physical, emotional, social, and spiritual well-being as possible and reflects the patient's own values. Supportive care is particularly important at the end of life in order to prevent and alleviate the cascade of symptoms and suffering that are commonly associated with dying."[65(p. 1)]

If patients in the midst of suffering receive the message, nonverbally or directly, that there is no time, energy, or compassion, they will, in their vulnerability, withdraw or become more needy. When patients feel distrusted, objectified, and overlooked, they suffer at the hands of those who were to provide care.[18] Their alienation may become complete. On the other hand, if privacy and a moment of honor and focused attention are provided, this allows for the tears to spill or the anguish to be spoken. Then the alienation may be eliminated, and the opportunity for healing is begun.

The terminally ill are a vulnerable population. They die and do not complete patient satisfaction surveys; their grievances and their stories die with them. But any violation or neglect does not stop, for each nurse now holds that violation, as does society as a whole. The wound begets wounds, and the nurse sinks further into a guarded and unavailable approach, alienated. Without engagement or connection, the work holds few rewards, only endless days and demands. She or he has nothing left to give. The patient and family are ultimately abandoned. In the work of Kahn and Steeves,[66] one finds a model for the nurse's role in psychosocial processes and suffering. It represents the dynamic relationship of caring, acted out in caregiving as well as in the patient's coping, which transform each other.

For the nurse to provide this level of caregiving, he or she must understand the obstructions that may interfere. It is essential that the nurse undergo his or her own journey, visiting the intense emotions around the dying process and the act of witnessing suffering. A nurse can serve the suffering person best when she or he is willing to be transformed through the process of one's own grief as well as by the grief of others.[67]

In light of pervading technology, nurses need to be careful that technology does not enable them to avoid, even if inadvertently, being present with their patients.[68,69] Presence may, in fact, be the greatest gift to these patients and their families. Still, imagine charting or accounting for presence on an acuity system! Presence "transcends role obligations and acknowledges the vulnerable humanness of all . . . to be present means to unconceal, to be aware of tone of voice, eye contact, affect, and body language, to be in tune with the patient's messages."[67] Presence provides confirmation, nurturing, and compassion and is an essential transcendent act.

Touch becomes one of the tools of presence and is valued by the dying and their families.[70,71] It has also been shown to reduce anxiety, pain, and fatigue in adults as well as children.[72–74] Used with sensitivity and respect, touch can be as simple as the holding of the hand or as powerful as the holding of the whole person. Sometimes, because of agitation or pain, direct touch becomes intrusive; even then touch can be invoked, by the touching of a pillow or the sheet or the offering of a cold cloth.

Listening is more than the collection of data; it is therapeutic in providing space for the narrative to take place.[75–77] If a key aspect of meaning is to tell, then one might be led to believe that the spoken word would be imperative. However, over and over, it is silence that conveys the meaning of suffering, "a primitive form of existence that is without an effective voice and imprisoned in silence." Compassionate listeners in respect and presence silence their voice, open their heart, and share the stillness.[67,78] They use the most intuitive skills to carry the message. This may also be why other approaches that use symbols, metaphors, and the arts are the most potent in helping the patient communicate and make sense of meaning. The arts, whether writing, music, or visual arts, often help the patient not only gain new insight but also convey that meaning to others. There are many levels on which this is accomplished. Whether it is done passively through reading poetry, listening to music, or viewing paintings, or actively through creation, thoughts can be inspired, feelings moved, and the sense of connectedness and being understood can evolve.[63,69,79,80] What once was ubiquitous can now be seen outside of one's soul, as feelings become tangible. It can be relational because the act of creation can link one to the creator, or it can downplay the role of dependency, as the ill one now cares for others with a legacy of creational gifts.[79]

Meditation, mindfulness, and yoga are other acts of transcendence that can be extremely powerful for the dying.[63,81–85] Even those who have never experienced a meditational state can find that this new world in many ways links them to living and dying. The relaxation response from meditation or yoga allows the anxious patient to escape into a meditative state, experiencing an element of control while relinquishing control. Many patients describe it as a floating state, a time of great peace and calm. Some who have never had such an experience can find the first time frightening as the existential crisis, quelled so well by boundaries, is no longer confined. Most, given a trusting and safe teacher, will find that meditation will serve them well. The meditation can be in the form of prayer, guided imagery, breathing techniques, or mantras.

Prayer is well-documented in the literature[86–90]as having meaning for patients and families; not only does it connect one to God, but it also again becomes a relational connection to others. Knowing that one is prayed for not only by those close at hand but by strangers, communities, and those at a great distance can be deeply nurturing. Often forgotten is the role in which the patient can be empowered: that of praying for others. One patient prayed for her nurse and her nurse's healing, and, in so doing, the patient lost the sense of worthlessness and glowed with joy.

Leaving a legacy may be one of the most concrete ways for patients to find meaning in this last stage of their lives.[91–93] It most often requires the mastering of the existential challenges, in which patients know that death is at hand and choose to direct their course and what they leave behind. For some patients, that will mean going out as warriors, fighting until the end; for others, it will mean end-of-life planning that focuses on quality of life. Some patients will design their funerals, using rituals and readings that reveal their values and messages for others. Others will create videos, write letters, or distribute their wealth in meaningful ways. Dignity therapy, life review, and legacy documents are interventions being utilized successfully with the dying.[94,95] Blogging is a way to decrease a sense of isolation for patients as they record their experiences and also leaves a permanent imprint of their lives on the Internet.[96–100] It becomes a diary of the illness and has been shown to increase a sense of purpose and meaning as they share with others.[96,101–103] Vlogging (video blog) is another way for patients to share their cancer experiences as well as a means for leaving a legacy.[104,105] Parents who are leaving young children sometimes have the greatest difficulty with this aspect. On one hand, the feelings of horror at "abandoning" their children are so strong that they have great difficulty facing their death. Still, there is often a part of them that has this need to leave a legacy. The tug-of-war between these two willful emotions tends to leave only short windows of opportunity to prepare. The extreme can be observed in the mother who slowly pushed her teenage daughter away, using excuses for the distancing. It was only after a trusting relationship had been established with one of her nurses that helped her to see how this protective maneuver was, in fact, harming her daughter. The mother needed not only to see what she was doing but to see how her love would help her daughter and how others would be there for her and her husband in their pain and grief. With relief, the mother reconnected to her daughter, creating living memories and a lifetime protection of love.

Another courageous parent anticipating the missed birthdays, bought cards and wrote a note in each one, so that the child would be touched not only by the individual messages, but the knowledge that the parent found a way to be there for him with each new year. A mother wrote a note for her young daughter so that if she should ever marry, she would have a gift to be opened on her wedding day. The note described the mother's love, wisdom about marriage, and her daughter's specialness, already known through a mother's eyes. An elderly person may write or tape an autobiography or even record the family tree lest it be lost with the passing of a generation. The nurse can often be the one who inspires these acts, but it must always be done with great care, so as not to instill a sense of "should" or "must," which would add yet another burden.

Helping patients to reframe hope is another important intervention.[106–108] Dr. William Breitbart, chief of the Psychiatry Services at Memorial Sloan-Kettering Cancer Center in New York City, designed and conducted research on a meaning-centered psychotherapeutic intervention to help terminally ill patients with cancer maintain hope and meaning as they face the end of their lives.[5,109] This research was inspired by the works of Dr. Victor Frankl, a psychiatrist and Holocaust survivor. Cancer patients attended an 8-week, group-focused, standardized course of experiential exercises that addressed constructs of despair at the end of life, such as hopelessness, depression, loss of meaning, suicidal ideation, and desire for a hastened death. The study revealed that the patient's spiritual well-being and loss of meaning was more highly correlated to the components that made up despair at the end of life than either depression or hopelessness alone. As a result, if the patient could manipulate or reframe his or her sense of meaning and spiritual well-being, this would positively affect the foundational elements of despair at the end of life. When patients are able to do this, their hope may be sustained because they have been able to reframe the focus of their hope.

The Healthcare Professional

Although the healthcare professional can be educated about death and grieving, like the patient and family, it is in living out the experience that understanding is reached. It is a developmental process, and, given the demands of the work, the nurse is at great risk for turning away from her or his feelings. There is often little mentoring that accompanies the first deaths, let alone formal debriefing or counseling. How can it be that we leave such important learning to chance? And what about cumulative losses and the impact of the years of witnessing suffering? Healthcare needs healing rituals for all of its professionals to support and guide them in this work. Individual institutions can develop programs that address these needs.

At one institution, "Teas for the Soul" (sponsored by the Spiritual Care Department) provide respite in the workplace on a regular basis, as well as after difficult deaths or traumas. A cart with cookies and tea, as well as soft music, is provided as physical and emotional nurturance for the staff and to legitimize the need to come together in support. Another support is a renewal program, the "Circle of Caring." This retreat supports healthcare professionals from a variety of institutions in a weekend of self-care that integrates spirituality, the arts, and community-building. The element of suffering is a focal point for a small-group process that unburdens cumulative effects of the work and teaches skills and rituals for coping with the ongoing demands.

Perhaps one of the most challenging aspects of finding meaning for a nurse is when nonbeneficial treatment is continued and palliative care is forestalled. The nurse experiences not only the emotional burden of the normal emotions of caring for the dying, but now has the added weight and guilt of feeling that she or he is contributing to harming the patient. While efforts must be made to address the nonbeneficial treatment and refocus on appropriate goals of care, during that gap, it is essential that nurses and the entire healthcare team attend to the moral distress. Research has demonstrated that speaking up clearly makes a lasting impact on moral distress and yet often it is not addressed. The potential for elevation of the crescendo effect is significant, as is detaching from patients or even leaving the profession.[110–112] Ultimately, even if constrained by a lack of do-not-resuscitate orders or continued burdensome treatments, the nurse can focus her or his intentions on what she or he is able to do for the patient and family. Whether it is treating the patient with respect and tenderness or humanizing the experience through the simplest of acts (offering music, the reading of a poem, or comfort to those at the bedside), an awareness of the moral action of caring, so essential to nursing, will not only improve the care but the resiliency of the nurse.

Clearly, there is much that can be done to support nurses individually and to support organizations. There are many opportunities for assisting nurses in their own search for meaning and for enhancing the care of patients and families. When the nurse takes the time to find meaning in this work, she or he is finding a restorative practice that will protect him or her personally and professionally. "Searching for and reflecting on meaning becomes the wellspring that helps balance the draining aspects of caring work, and perhaps even more importantly, is a constant reminder of the richness of a life well lived."[113] Like the patient, she or he will need to choose this journey and find pathways that foster, challenge, and renew.

> As long as we can love each other,
> And remember the feeling of love we had,
> We can die without ever really going away.
> All the love you created is still there.
> All the memories are still there.
> You live on—in the hearts of everyone you have
> Touched and nurtured while you were here.
>

SECTION IV

Special Patient Populations

CHAPTER 37

Cultural Considerations in Palliative Care

Carrie Cormack, Polly Mazanec, and Joan T. Panke

Key Points

- Quality palliative care requires consideration of patient and family cultural values, practices, and beliefs.
- A multidimensional assessment of an individual's and family's culture is essential to providing quality palliative care.
- An individual's culture encompasses multiple components, including race, ethnicity, age, gender, socioeconomic status, differing abilities, sexual orientation, religion, and spirituality.
- Cultural self-awareness is necessary if nurses are to better understand their own values, practices, and beliefs and the impact these may have on the care of others.

Culture Defined

Culture is "the integrated pattern of human knowledge, belief, and behavior that depends upon the capacity for learning and transmitting knowledge to succeeding generations."[1] Shaped over time, these beliefs, traits, values, and lifestyle patterns are designed to ensure survival and well-being and to find a common purpose or meaning throughout life.[2]

Although culture is often mistakenly thought of as simply race and ethnicity, the definition of culture is multidimensional, encompassing such components as age, gender, languages, religion and spirituality, socioeconomic class, differing abilities, composition of family, and geographic environment.[3] Each cultural component plays a role in shaping individual responses throughout one's entire life span, from birth until time of death.[2,3]

A broad definition of culture recognizes that various *subcultures* exist within the dominant cultures. These subcultures may further affect individuals' experiences and responses in any given situation, including dealing with trauma or serious illness and end of life. It is essential that nurses consider the role that culture or subcultures may play in patient and family choice and decision-making during these more difficult times. The nurse must also be constantly aware that the culture of the healthcare system and the culture of the nursing profession, as well as his or her own personal beliefs, may shape the interactions with patients, families, and colleagues.

Culture as a Global Palliative Care Issue

Care of the seriously ill and dying is complex, with many of these individuals coping with multiple chronic illnesses, age-related syndromes and needs, complicated medication regimens aimed at ameliorating symptoms of disease, and often a limited social support and caregiver base to help with care. Globally, nurses need to acquire and maintain generalist palliative care nursing knowledge and skill to address the unique needs of individuals coping with serious illness and their families. Variations in global nursing education and workforce challenges exist, yet attention to the cultural aspects of care, regardless of where one lives, is necessary to providing compassionate and skilled nursing care across disease states. Discussion of all cultural variations is beyond the scope of this chapter; however, the authors encourage readers to consider how to apply key concepts to their specific global setting.[4]

Increasing Diversity in the United States

As the United States becomes increasingly diverse, the growing range of treasured beliefs, shared teachings, norms, customs, and languages challenges the nurse to understand and respond to a wide variety of perspectives. The total US population in 2016 was estimated to be 323.1 million.[5] Population statistics from the US Census Bureau illustrate that cultural diversity is increasing among the five most common pan-ethnic groups, which are federally defined as American Indian/Alaska Native, Asian/Pacific Islander, black or African American, Hispanic, and white (Table 37.1).[6]

Census projections suggest that, by 2060, the combined minority groups that currently make up 37% of the US population will constitute the majority (57%).[6] Globally, the population aged older than 60 is expected to more than double in the next several decades from 841 million in 2013 to more than 2 billion in 2050,[7] and the number of the "oldest old," the 85 and older age group, is expected to more than triple. This trend will present significant challenges to health systems and healthcare providers worldwide as they look to meeting the needs of older adults.[4]

With these changes in cultural diversity comes increasing diversity in the nursing workforce. Beliefs and attitudes about nursing's role and the status of the nurse may be underappreciated or not acknowledged in some parts of the world. Nurses must be aware of how their own cultural beliefs and norms shape their professional

Table 37.1 US ethnic group census estimates for 2017

White alone	76.9%
White alone, non-Hispanic or Latino	61.3%
Hispanic or Latino alone	17.8%
Black or African American alone	13.3%
Asian alone	5.7%
American Indian/Alaska Native alone	1.3%
Hawaiian and Other Pacific Islanders	0.2%

practice and differ from the beliefs and norms of the patients and families for whom they care.

Culture and Palliative Care Nursing

The essence of palliative nursing is to provide holistic supportive care for the patient and the family living with a serious or life-limiting illness. Palliative nursing strives to meet the physical, emotional, social, and spiritual needs of the patient and family across the disease trajectory.[8] To meet these needs, nurses must recognize the vital role that culture has on one's experience of living and dying. The beliefs, norms, and practices of an individual's cultural heritage guide one's behavioral responses, decision-making, and actions.[3] Culture shapes how an individual makes meaning out of illness, suffering, and death.[9] Nurses, along with other members of the interdisciplinary team, partner with the patient and family to ensure that patient and family values, beliefs, and practices guide the plan of care.[10]

The National Consensus Project (NCP) *Clinical Practice Guidelines for Quality Palliative Care*[11] define the core concepts and structures for quality palliative care delivery. The guidelines comprise eight domains with corresponding criteria that reflect the depth and breadth of the specialty. Cultural aspects of care constitute one of the eight domains, emphasizing the central role that culture plays in providing strength and meaning for patients and families facing serious illness.[11] Within this domain, two overarching guidelines define culture and outline cultural competencies for interdisciplinary team members (Box 37.1).

Culture is a source of resilience for patients and families and plays an important role in the provision of palliative care. It is the responsibility of all members of the palliative care program to strive for cultural and linguistic competence to ensure that appropriate and relevant services are provided to patients and families. The following case illustrates the challenges faced when caring for a patient and family with serious illness and importance of cultural considerations.

Box 37.1 *Clinical Practice Guidelines for Quality Palliative Care*: Cultural Aspects of Care

Guideline 6.1 The palliative care program serves each patient, family, and community in a culturally and linguistically appropriate manner.

Criteria:

- Definition of culture and cultural components
- Cultural identification of patient/family
- Assessment and documentation of cultural aspects of care
- The plan of care addresses the patient's and family's cultural concerns and needs
- Respect for the patient's/family's cultural perceptions, preferences, and practices
- Palliative care program staff communicate in a language and manner that the patient and family understand and take into account
    - Literacy;
    - Use of professional interpreter services and acceptable alternatives;
    - Written materials that facilitate patient/family understanding.
- Respects and accommodates dietary and ritual practices of patients/families
- Palliative care staff members identify and refer patients/families to community resources as appropriate.

Guideline 6.2 The palliative care program strives to enhance its cultural and linguistic competence.

Criteria:

- Definition of cultural competence.
- Valuing diversity in the work environment. Hiring practices of the palliative care program reflect the cultural and linguistic diversity of the community it serves.
- Palliative care staff cultivate cultural self-awareness and recognize how their own cultural values, beliefs, biases, and practices inform their perceptions of patients, families, and colleagues.
- Provision of education to help staff members increase their cross-cultural knowledge and skills and reduce health disparities.
- The palliative care program regularly evaluates and, if needed, modifies services, policies, and procedures to maximize its cultural and linguistic accessibility and responsiveness. Input from patients, families, and community stakeholders is integrated into this process.

Source: Adapted from National Consensus Project for Quality Palliative Care. *Clinical Practice Guidelines for Quality Palliative Care* 2013. www.nationalconsensusproject.org.

Case Study: Cultural Considerations of a Family

Cristina, a 17-year-old girl, had a long medical history of tuberous sclerosis, a complex, genetic condition that causes tumors in the brain and other vital organs. Cristina was nonambulatory, nonverbal, and fully dependent on others for all of her needs. She lived in a trailer with her father and mother. Her primary caretaker was her mother, Rosa, who was 39 years old. Rosa did not speak English. She came to the United States from Mexico at 24 years of age, in hopes of a better life and better medical care for herself and her daughter. Rosa also had tuberous sclerosis, although less severe, and complications included tumors in her lungs. Her disease had progressed over the past few years and she was dependent on oxygen and unable to lift Cristina independently. A lung transplant had been recommended for Rosa, but due to her immigration status she was ineligible for health insurance. Her only hope for curative medical treatment was to return to Mexico, but the logistics of getting there were too much for her to coordinate and she would have to leave her daughter behind. There was no extended family, her husband works 6 days a week in construction, and Rosa did not feel he would be able to care for Cristina independently.

This complex case addresses several areas requiring cultural consideration. Both mom and daughter have life-limiting conditions which require support and care. The complex factor of their limited access to care adds to the need for comprehensive assessment of the values, practices, beliefs, and goals of the family.

Questions to Consider in this Case

1. What cultural issues must be considered in this case, and how may these issues impact decision-making?
2. How may a palliative team be helpful to this family, and what resources may they access to assist with the cultural needs of this family?
3. What are some communication techniques that the nurse and other healthcare providers might use with this family?

Striving for Cultural Competence

All nurses should value the importance of being culturally sensitive and strive for cultural competence. This sensitivity and competence is especially vital for nurses working with patients with a life-limiting illness and their families.

Cultural competence refers to a dynamic, fluid, continuous process of awareness, knowledge, skill, interaction, and sensitivity.[12] While the term remains controversial, as some question whether true "cultural competence" can ever be achieved,[3] cultural competence remains an important outcome for nursing students[13] and essential for all nurses, as noted by nursing organizations worldwide.[14] Cultural competence is more comprehensive than *cultural sensitivity*, implying not only the ability to recognize and respect cultural differences but also to intervene appropriately and effectively.[15] According to Campinha-Bacote's model for enhancing cultural competence, there are five components essential in pursuing cultural competence: cultural awareness, cultural knowledge, cultural skill, cultural encounters, and cultural desire.[12]

Cultural Awareness

Integrating cultural considerations into palliative care requires, first and foremost, awareness of how one's own values, practices, and beliefs influence care. Cultural awareness begins with an examination of one's own heritage, family's practices, experiences, and religious or spiritual beliefs.[12] Cultural awareness challenges the nurse to look beyond his or her ethnocentric view of the world, asking the question, "How are my values, beliefs, and practices different from those of the patient and family?" rather than, "How is this patient and family different from me?" Exploring one's own beliefs by completing a personal self-assessment will raise an awareness of differences that have the potential to foster prejudice and discrimination and limit the effectiveness of care.[16] Often identifying more similarities than differences, the nurse and patient can recognize universal aspects of life, family, trust, love, hope, understanding, and caring, which will enhance the quality of care.

Cultural Knowledge

Acquiring knowledge about different cultural groups is the second component to striving for cultural competence, but knowledge alone is insufficient in providing culturally appropriate care.[12] Having in-depth knowledge of all cultural variations of health and illness beliefs, values, and norms is an impossible task. A suggested strategy is to identify the most common ethnic group/cultures living in the nurse's community and to integrate a basic understanding of norms and practices impacting issues likely to arise in palliative and end-of-life (EOL) situations.

It is important to be aware that knowledge gained of a particular group should serve only as a guide to understanding the unique cultural needs of the patient and family, which comes through individualized assessments. Relying solely on culturally specific knowledge to guide practice, rather than individual assessment, is incongruent with culturally competent care. Resources may also be helpful to assist the nurse in acquiring knowledge about specific groups including cultural guides, literature, and Web-based resources (examples listed in Box 37.2).[17]

Cultural Skill

Cultural skill is the third component of cultural competency.[12] Skills in cultural assessment, cross-cultural communication, cultural interpretation, and appropriate intervention can be learned. Multiple tools are available to assess cultural behavior and beliefs. For the new nurse, key assessment questions, applicable in the palliative care setting, may be helpful in guiding the assessment (Box 37.3). These questions, although useful to guide a discussion, should not replace patient and family interaction. Listening to the stories of heritage/family history and asking about their cherished practices and beliefs is an invaluable way to learn more about the patient and family and build a trusting relationship.

Cultural Encounters

The fourth component encompasses the concept of cultural encounters.[12] The more opportunities we have to engage with persons with differing values, practices, and beliefs, the more we learn about others and ourselves and the less likely we are to draw erroneous conclusions about each other. Active engagement with community leaders and use of learning tools such as case studies and role plays all help expose nurses to varied cultural experiences.[12] Increasing exposure to cultural encounters may also improve confidence in one's ability to meet the needs of diverse populations.[12]

Cultural Desire

The fifth and final component of Campinha-Bacote's model for cultural competence is cultural desire.[12] This is the interest and openness with which the nurse strives to understand patients and

Fast Fact & Concept #78; Cultural Aspects of Pain Management: https://www.mypcnow.org/blank-a8lpj

- This website contains many "fast facts" regarding palliative care. Number 78 addresses important cultural considerations and provides assessment questions when working with patients in pain.

Fast Fact & Concept # 216: Asking About Cultural Beliefs in Palliative Care: https://www.mypcnow.org/blank-g562

- This resource offers a framework for assessing patient and family cultural needs by taking a "cultural history."

Office of Minority Health: https://minorityhealth.hhs.gov/

- This website has training tools for developing cultural competency.

Transcultural Nursing Society: http://www.tcns.org

- The society (founded in 1974) serves as a forum to promote, advance, and disseminate transcultural nursing knowledge worldwide.

families and the communities from which they come. Cultural desire is motivation to "want to" engage in the process of cultural competence as opposed to being "forced to" participate in the process. The desire is genuine and authentic. Such experiences lend opportunities for the nurse to grow both personally and professionally.[12]

Some researchers suggest that the term "cultural humility" is more acceptable than cultural sensitivity or cultural competence when trying to provide culturally appropriate care.[2,12] They have suggested that multiple generations of blended families and intercultural marriages have made it nearly impossible to know all about the healthcare practices of particular communities. These social scientists and writers recommend that nurses strive to mindfully respect each patient/family member as unique individuals rather than the components of culture (ethnicity, religion/spirituality, place of residence, etc.) that might label them.[18,19] We believe that integrating the proposed model of cultural competence with cultural humility into clinical practice will strengthen nurses' ability to respect and support patient and family wishes in palliative care settings.

Box 37.3 Key Cultural Assessment Questions

Formal cultural assessments are available for the nurse to use (see resources in Box 37.2). Remember that a checklist does not always instill trust. Listed here are some suggestions for ascertaining key cultural preferences from both patients and family caregivers.

Basic Assessment Questions

- Tell me a little bit about yourself (e.g., your family, your mother, father, siblings, etc.).
- Where were you born and raised? (If an immigrant, "How long have you lived in this country?")
- What language would you prefer to speak?
- Is it easier to write things down, or do you have difficulty with reading and writing?
- To whom do you go for support (family friends, community, or religious or community leaders)?
- Is there anyone we should contact to come to be with you?
- I want to be sure I'm giving you all the information you need. What do you want to know about your condition? To whom should I speak about your care?
- Whom do you want to know about your condition?
- How are decisions about healthcare made in your family? Should I speak directly with you, or is there someone else with whom I should be discussing decisions?
- Addressed to patient or designated decision-maker: Tell me about your understanding of what has been happening up to this point. What does the illness mean to you?
- We want to work with you to be sure you are getting the best care possible and that we are meeting all your needs. Is there anything we should know about any customs or practices that are important to include in your care?
- Many people have shared that it is very important to include spirituality or religion in their care. Is this something that is important for you? Our chaplain can help contact anyone that you would like to be involved with your care.
- We want to make sure we respect how you prefer to be addressed, including how we should act. Is there anything we should avoid? Is it appropriate for you to have male and female caregivers?
- Are there any foods you would like or that you should avoid?
- Do you have any concerns about how to pay for care, medications, or other services?

Death Rituals and Practices

- Is there anything we should know about care of the body, about rituals, practices, or ceremonies that should be performed?
- What is your belief about what happens after death?
- Is there a way for us to plan for anything you might need, both at the time of death and afterward?
- Is there anything we should know about whether a man or a woman should be caring for the body after death?
- Should your family be involved in the care of the body?

Cultural Assessment

Conducting a Cultural Assessment

There are many tools available to help with cultural assessment. These tools include the components of culture discussed throughout this chapter. Completing a cultural assessment involves asking questions that enhance the development of a trusting relationship. When meeting the patient and family early in the disease trajectory, the palliative care nurse has the advantage of time to establish such a relationship. Unfortunately, this luxury of time is not always available. The nurse must develop the skill of presence and active listening as these are often more beneficial than a standardized tool. Checklists do not necessarily build trust and can be burdensome. Asking the patient and/or the family member about him- or herself and then listening to those narratives is powerful. Simple inquiries into patient and family practices and beliefs can assist the nurse in understanding needs and goals of care, and these stories often give clues that may trigger further questioning. Box 37.3 provides examples of trigger questions.

Components of Culture

Race

The commonly held misconception that "race" refers to biological and genetic differences and "ethnicity" refers to cultural variation is outmoded. Race exists not as a natural category but as a social construct.[20] Any discussion of race must include the harsh reality of racism issues and disparities that have plagued society and continue to exist even today. Recent studies have demonstrated the discrimination of persons of certain races regarding healthcare practices, treatment options, and hospice utilization.[21] When viewed in relation to specific races, morbidity and mortality statistics point to serious gaps in access to quality care. Racial disparities are still evident worldwide, even after adjustments for socioeconomic status and other access-related factors are taken into account.[22]

There is often an underlying mistrust of the healthcare system. Memories of the Tuskegee syphilis study and segregated hospitals remain with older African Americans.[23] The combination of mistrust and numerous other complex variables influence palliative care issues such as medical decision-making and advance care planning.[24] Compounding the situation is the fact that healthcare providers often do not recognize existing biases within systems or themselves.[25]

Researchers have tried to identify causal mechanisms for healthcare disparities in psychosocial, cultural, and spiritual palliative care; however, the work is sparse and limited by methodological flaws. Evans and Ume[26] recommend using a conceptual framework such as that used in the National Healthcare Disparities Report[27] to explore causal mechanisms, which include access to care, receipt of care, quality of care, and examination of barriers, usage, and costs of care and effectiveness, safety, timeliness, and patient centeredness.

Ethnicity

Ethnicity refers to "a group of people that share a common and distinctive racial, national, religious, linguistic, or cultural heritage."[27] The values, practices, and beliefs shared by members of the same ethnic group may influence behavior or response. Ethnicity has been identified as a significant predictor of EOL preferences and decision-making.[28] Currently, there are more than 100 ethnic groups and more than 500 American Indian Nations in the United States.[27]

Ethnicity has been shown to influence utilization of hospice and palliative care service. Ethnic minority groups are less likely to use hospice services when compared with non-Hispanic whites. Furthermore, there has been little increase in hospice utilization in Black, Hispanic, or Asian populations in recent years.[28] Researchers have demonstrated an understanding of disparities in quality EOL care among ethnicities but have not yet identified why this is happening.[29,30] Further study into the multiple factors influencing utilization of these services is needed.[31]

Although an individual may belong to a particular ethnic group, he or she may not identify strongly with that group.[3,32] Members of the same family from the same ethnic group may have very different ideas about what is acceptable practice concerning important palliative care concepts such as communication with healthcare professionals, medical decision-making, and EOL rituals. In multigenerational families, some members may hold to the traditional beliefs and practices of their ethnic community of origin. Other family members may have a bicultural orientation, moving between the family culture of origin to the host society, and others may have left their cultural roots and identify with the host society. For example, in the United States, second- and third-generation members of immigrant families may be more assimilated into Western culture than first-generation members. This can lead to cultural conflicts within families around sensitive palliative care concepts.

The assumption that an individual will respond in a certain way because he or she is a member of an ethnic group contributes to stereotyping. The nurse should assess each individual's beliefs and practices rather than assuming that he or she holds the beliefs of a particular group. Note that many studies have demonstrated that regardless of race or ethnicity, all persons share common needs at the end of life: being comfortable, being cared for, sustaining or healing relationships, having hope, and honoring spiritual beliefs.[3,8,19,32,33]

Age and Developmental Stage

Age has its own identity and culture.[3] Age cohorts are characterized by consumer behaviors, leisure activities, religious activities, education, and labor force participation.[34] Each group has its own beliefs, attitudes, and practices, which are influenced by their developmental stage and by the society in which they live. The impact of a life-limiting illness on persons of differing age groups is often influenced by the loss of developmental tasks associated with that age group.[3]

Infant/Toddler

Although in modern society we expect that children will outlive their parents, every year more than 50,000 children die from various causes including congenital malformations, traumas, and acquired illnesses.[34] While many of the principles of adult palliative care can be applied to children, caring for an infant or toddler with a life-limiting condition or at end of life brings new challenges to a nurse, which can be difficult to manage without experience or preparation.

Palliative care principles can be applied at time of diagnosis, which for some parents is during pregnancy. Compassionate care should be offered to the family during this time and discussions should be facilitated to allow parents options regarding care and treatment.[34] The National Association of Neonatal Nurses has a position statement outlining the values and recommendations for palliative care with newborns and their families.[35] These recommendations include advocating for family-centered care throughout the illness trajectory and following the death of a child because family members will continue to require support as they cope with their loss.

School-Aged Children

Just as children develop and change as they grow, offering palliative care to children as they emerge from infancy and toddlerhood into the school-aged years, requires another set of skills for the palliative care nurse. Depending on the developmental level of the child at the center of the care, the focus should be to assist the child to cope with the illness and offer support to the family. Typically developing children during the school-aged years have fears as well as vivid hopes and dreams, all which must be acknowledged during difficult times of illness. School-aged children strive for increased independence and autonomy and seek opportunity for control and responsibility,[36] traits often diminished by necessary medical procedures, clinical appointments, tests, and hospitalizations. Friends and a sense of belonging to groups of peers is important for this age group, and children with life-limiting illnesses are often excluded or forced into more solitary activities. This can be isolating and painful for the school-aged child, and recognition of this can help build trust between a patient and nurse. Family members also need support to consider the wishes of the child and help facilitate what may be important to them during this time.

Adolescence

Cultural considerations with adolescents coping with serious illness bring yet another set of concerns for caregivers. An increased sensitivity to their appearance[36] can be agonizing for teens going through bodily changes beyond their control. Peer groups and acceptance remains important, although adolescents strive to secure their own identities, including their own ethical and moral decisions. Adolescents should be involved in all decision-making regarding their care. Future goals and plans are often considered, and the impact that a serious illness may have on this trajectory can be distressing to both the teen and family. Providers must be sensitive to the self-preoccupation that teens have and the often critical self-image or low self-esteem that may be a factor during these difficult times. Spiritual development can be helpful and is often explored during this time. This may be an important implication for practice when caring for an adolescent with a life-limiting illness.[37]

Young and Middle-Aged Adulthood

Serious illness is less common in young and middle-aged adults than in older adults. The death-denying society of the United States does not expect young or middle-aged adults to have to face life-threatening illnesses or death. For young adults (aged 21–40) and middle-aged adults (aged 41–60), developmental tasks include finishing their education, starting and engaging in a work and career, finding a life partner, establishing a long-term relationship, and starting a family. A serious illness can interfere with being able to accomplish any or all of these tasks. Research has shown that patients with dependent children have more worry and anxiety over the uncertainty of the future and time away from family for treatment than those who do not have children at home.[38]

Older Adulthood

The world's population is aging. By 2050, it is estimated that the number of individuals aged 65 and older will increase from 8.5% in 2015 to approximately 16.7% of the population.[39] The population in the United States mirrors that of the global rise in the older adult population, with those over the age of 65 predicted to more than double their numbers listed in the 2010 Census.[40] As the population of young-old (60–69), middle-old (70–79), and very old (80 and older) adults rises, the importance of addressing the unique palliative care needs of the older adult becomes more evident.[41] Each group of older adults has specific developmental tasks that reflect cultural traditions and range from positive experiences (e.g., retirement, grandparenting) to losses associated with aging (e.g., loss of independence, death of those close to them, and physical and mental health changes).

Cultural considerations related to this aging population include the impact of serious illness on finances, home environment, caregiving needs and availability, medical decision-making abilities, management of complex medication regimens and comorbid conditions, availability of medications, and pain and symptom management disparities. Cognitive changes make decision-making and patient safety critical issues across the aging trajectory.

As the adult population lives longer, spousal caregivers, who may also be among the very old, often have their own medical issues that may impact their ability to provide care.[42] Research suggests that informal caregiving can have a negative impact on the health of the family caregiver, highlighting the need for intensive monitoring of both patient and family caregiver.[43]

Gender

Gender Considerations

Cultural norms have guided specific roles for men and women regarding illness and EOL care. For some families, gender determines roles in decision-making and caregiving.

It is culturally sensitive to be aware of family dominance patterns in decision-making and determine which family member or members hold that dominant role. In some families, decision-making may be the responsibility of the female head of the family, in others the male head of the family or eldest son. For example, those of Asian ethnicity who follow strict Confucian teaching believe that men have absolute authority and are responsible for family decision-making.[17] When caring for families who adhere to these norms, discussing prognosis and treatment with a female family member is likely to cause the patient and family distress and may result in significant clashes with the healthcare team and mistrust. It is critical to ask every person and family who should have the responsibility for decision-making and never assume how that family functions.[19]

In addition to decision-making, cultural expectations exist regarding the responsibilities of caregiving. In many families, women have traditionally been expected to take on the role of caregiver when someone in the family is facing a serious illness. This responsibility, in addition to responsibilities at work and for children, has been overwhelming for many women, affecting their physical and emotional well-being. Research has demonstrated that female caregivers tend to experience greater caregiver burden, anxiety, and depression than male caregivers.[44] Supportive interventions for family caregivers, regardless of gender, are an essential component of palliative care.[19,45]

Gender Identity

One of the most profound gender disparities in the delivery of quality palliative care involves providing quality palliative care to those who are lesbian, gay, bisexual, transgender, or queer/questioning (LGBTQ).[42] It is recommended that the best way to address these disparities is by providing LGBTQ-inclusive palliative care rather than conceptualizing LGBTQ people as a "special population" that is separate from all others.[46] Acquaviva[46] suggests that making subtle changes in the way palliative care is delivered will allow for inclusive, nonjudgmental hospice and palliative care for all persons.

First, it is essential to use language that is nonjudgmental. It is not appropriate to assume an individual's gender identity based on biologic sex. Sex refers to biology and physiology. Gender identity refers to "that person's internal sense of being a man or a woman. Gender expression, or gender presentation is the way a person outwardly expresses that internal sense."[47] When meeting a patient for the first time, it is important to ask questions that are person-centered. Examples of those opening questions are listed in Box 37.4.

There are some particular aspects of palliative care where the LGBTQ population may be at risk. Ethical and legal issues related to advance care planning, healthcare decision-making, disposition of the body after death, and property ownership are particularly important to address early in care. Waiting until the end of life to have these discussions may be too late. Nurses play a major role in educating patients and families about the importance of appointing and documenting a healthcare power of attorney, especially for unmarried LGBTQ persons and those who may be estranged from family members.

Risk for discrimination of LGBTQ older adults has been brought to the forefront recently.[48] A report on the issues facing the aging LGBTQ population has highlighted concerns about discrimination from nursing home staff and mistreatment by roommates and other residents.[49] Antidiscrimination policies and staff education need to be put in place across the United States.

It is important to note that transgender individuals may have some unique health needs that can influence disease and symptom management in palliative care. Some transgender persons have had medical or surgical interventions to help them achieve their gender identity,[46] and these interventions may have implications on morbidity and mortality. For example, cross-sex hormone therapy may have a negative effect on cardiovascular disease and diabetes in transgender men but may have important psychological benefits, thus requiring a benefit–burden conversation in palliative and EOL care. However, many healthcare professionals are not knowledgeable about the risks associated with medical or surgical interventions that should be monitored closely. Nurses should be aware of the benefits and burdens these individuals face across the life span in order to support them in treatment decision-making.

Box 37.4 Questions Regarding Gender for Establishing Trust and Respect

- What name do you use?
- What sex were you assigned at birth?
- What gender do you identify as now?
- What gender pronouns do you use?
- Whom do you consider to be your "family"?

Language

It is essential to determine the dominant language and dialect spoken and the literacy level of both the patient and the family. If there is a language barrier, a professionally trained interpreter of the appropriate language should be contacted. This may include the use of a computerized interpreter service that offers secured services under the Health Insurance Portability and Accountability Act (HIPAA). If such services are not available, other health providers, ideally those trained in palliative care, may serve as interpreters. Family members should only act as interpreters in emergency situations and only if they agree to do so, as family members placed in this role may feel uncomfortable should sensitive issues or questions arise.[3,11] Always determine what is culturally appropriate to disclose prior to discussion regardless of who is involved in the communication of medical information.[2] When using an interpreter, direct all verbal communication to the patient/family rather than the interpreter. Ongoing clarification that information is understood is critical.

Religion and Spirituality

Religion is the belief and practice of a faith tradition, a means of expressing spirituality. Spirituality, a much broader concept, is the life force that transcends our physical being and gives meaning and purpose.[50,51,52] Although religion and spirituality are complementary concepts, these terms are often mistakenly used interchangeably. It should be noted that an individual may be very spiritual but not practice a formal religion. In addition, those who identify themselves as belonging to a religion may not necessarily adhere to all the practices of that religion. As with ethnicity, it is important to determine how strongly the individual aligns with his or her identified faith and the significance of its practice rituals.

Chaplains, clergy from a patient's or family member's religious group—ideally their own community clergy—are key members of the interdisciplinary palliative care team. Those who turn to their faith-based communities for support may find the emotional, spiritual, and other tangible support they need when dealing with a life-limiting illness.[53] Keep in mind, however, that some individuals who are struggling with misconceptions of the tenets of their own faith may experience spiritual distress and need spiritual intervention from caring chaplains or spiritual care counselors. Also, be aware that many community clergy are not trained in EOL care and may need assistance from the palliative care team in order to support the patient's spiritual journey.

Spirituality is in the essence of every human being. It is what gives each person a sense of being, meaning, purpose, and direction.[53] It transcends the self to connect with others and with a higher power, independent of organized religion.[3,27,33,50] One's sense of spirituality is often the force that helps transcend loss and suffering.[31,50,54] Spiritual distress can cause pain and suffering if not identified and addressed. Assessing spiritual well-being and attending to spiritual needs, which may be very diverse, is essential to quality of life (QOL) for patients and families facing serious illness and confronting end of life. For more information on spirituality, see Chapters 34 and 35.

Socioeconomic Status

One's socioeconomic status, which is usually measured as a combination of education, occupation, and income, is an important aspect of one's cultural identity, affecting physical and mental health and playing an important role in palliative care. Inequities in health distribution and resource availability are increasing in the United States and globally.[55] Individuals who are socioeconomically disadvantaged, with lower educational achievement, poverty, and poor health, face unique challenges when seeking healthcare and health insurance[55] and may struggle to navigate the healthcare system and to find information and support.

Financial costs, including those for medications, medical tests, and treatments not covered by limited insurance plans, transportation, and childcare add additional burdens. Regardless of financial status, an estimated 25% of families are financially devastated by a serious terminal illness.[3] Patients experiencing disease progression, or in whom treatment side effects preclude the ability to work, are forced to confront profound losses: loss of work and income, loss of identity, and loss of a network of colleagues.

While an exhaustive review of the impact of socioeconomic status on health and health outcomes is beyond the scope of this chapter, we discuss some important aspects that the palliative care nurse should consider in the following paragraphs.

Health Literacy, Health Numeracy, and Financial Literacy

Individuals who are socioeconomically disadvantaged may experience additional difficulties when attempting to understand medical terms and basic body functions, and when interpreting statistics and evaluating risks and benefits.[56] While no universal definition exists, most definitions identify *health literacy* as the degree to which an individual can obtain, process, and understand basic health information in order to make decisions related to health.[57,58] Even individuals with good literacy skills can have low health literacy, health numeracy, or financial literacy.[56,58]

Health numeracy is related to health literacy, referring to the degree to which individuals have the capacity to obtain, interpret, and process quantitative information for health behavior and decision.[59] Health numeracy includes four functional categories: basic numeracy skills (identify numbers and comprehend data), computational skills (ability to count, quantify, compute, and use simple manipulation of numbers or figures), analytical skills (e.g., inference, estimation, and proportions), and statistical numeracy skills (e.g., analytical skills plus the ability to critically analyze information and research findings and weigh risks and benefits).[59]

Financial literacy refers to an individual's ability to use knowledge and skills to manage financial resources effectively for life-long financial well-being.[60] Individuals who lack the ability to consider health insurance options, calculate out-of-pocket expenses, and navigate other complex financial choices may have more difficulty in making important health decisions.[58,61] Globally, financial illiteracy is widespread.

Individuals facing serious illness need information in a format and language that is easily understood in order to make informed healthcare decisions.[62] For individuals who are socioeconomically disadvantaged, the challenges just described regarding health, numeracy, and financial literacy may be more significant. Nurses can assist patients and family by considering whether the information they receive reflects their socioeconomic status, age, cultural background, language, and literacy skills.

Place of Residence

Access to services is challenging for some individuals depending on their geographic location. For those living in rural areas, access to palliative care services is inadequate when compared to urban areas.[63] While access to and availability of specialty palliative care services has seen an increase in the past few years,[64,65] internationally, research suggests that lower socioeconomic status is associated with lower use of palliative care services.[66] Factors that affect poorer utilization include an inconsistent number of service providers in disadvantaged areas and increased travel time to specialist palliative care providers and facilities.[66] Hospice services are also lacking in rural counties, with discrepancies between needed and received hospice care.[67] Recent developments, including community support, academic partnerships, and telehealth initiatives, suggest that improvement in access for the seriously ill and dying may be feasible in the most remote areas.[68]

Homeless Individuals

The homeless face significant mortality, comorbid conditions, and high disease burden compared to age- and sex-matched peers.[69] The last global survey of homelessness was completed by the United Nations in 2005 and estimated that 100 million people were homeless and that more than 1 billion people lacked adequate housing in both industrialized and developing nations.[70] In the United States, it is estimated that at least 500,000 persons are homeless, and that nearly 1.5 million people use homeless shelters.[71]

Many of the health, numeracy, and financial literacy concerns mentioned earlier may be present for homeless individuals. Additionally, individuals may not have a trusted surrogate decision-maker and may be estranged from family members.[72] Despite significant barriers to advance care planning with this population, research indicates that homeless individuals have the desire to complete advance directives when given the opportunity.[71–73]

Homeless persons with serious illness may have greater social challenges, mortality at a younger age, higher prevalence of physical symptoms associated with psychosocial distress, mistrust of the healthcare community, and a higher occurrence of psychological symptoms than the general population.[69,71,73] Individuals also experience a higher incidence of substance use, severe mental illness, and infectious diseases (e.g., HIV/AIDS, hepatitis C).[73]

Despite calls for improved palliative resources and access to services, the homeless continue to have limited access to quality palliative care services.[74] Access to transportation, stigmatization by healthcare providers, prioritizing basic needs of food and shelter, and ineligibility for health insurance may delay a person from accessing healthcare or obtaining adequate follow-up.[73,75] Healthcare professional attitudes (perceived or real negative stereotyping) and lack of experience may also contribute to existing barriers.[75]

Suggestions to improve palliative and hospice services for homeless persons include building trust and relationships, increasing collaboration between professionals, increasing flexibility within health services, and providing training and support for professionals working with homeless people.[75] Several examples of programs offer hope for homeless individuals facing serious illness, including shelter-based and street-based palliative care programs,[76] programs aimed at increasing advance care planning in the homeless population,[72] and increased education for health providers. With an increase in community-based palliative care, some of the access issues may begin to lessen; however, continuing financial concerns and adequate shelter and caregiving needs will require ongoing research and efforts in both rural and urban settings.

Prisons

Globally, the number of seriously ill and dying persons in prisons is growing. Most current literature focuses on US prison hospice programs or on identifying barriers to quality palliative and EOL care in prisons.[77] Examples of successful practices include the use of inmate volunteers alongside interdisciplinary teams and prison staff training and partnerships with local hospice organizations. Barriers to improved palliative care in prisons include mistrust between staff and prisoners, safety concerns, concerns regarding the use and potential misuse of opioids and other medications used to ameliorate symptoms, ethical dilemmas based on custody versus care, staff and public apathy toward rights to healthcare for this population, and debate over the use of compassionate release.[77]

Immigration Status

Immigrant populations face both cultural and logistical challenges when faced with serious illness and dying due to language differences, potential health literacy deficiencies, variations in family decision-making and role responsibilities, insurance barriers, and the possibility of lack of financial or social resources.[78] It is important to consider whether there are true disparities rather than differences in patient/family care preferences, as well as to consider professional bias toward perceived cultural differences when approaching goals of care discussions and assessments.[79] Over time, acculturation may decrease true variations in preferences; however, completing an in-depth cultural assessment is necessary to determine individual norms and preferences.

The number of undocumented immigrants varies worldwide. It is estimated that there are approximately 11 million unauthorized immigrants in the United States in 2015,[80] many of whom are educationally and socioeconomically disadvantaged and living in rural areas without access to healthcare.[81] For undocumented immigrants, challenges to optimal healthcare include limited social support, geographic distance from family, language and cultural barriers, financial concerns, and fear of deportation. Most are not insured, and access relies on provisions for emergency medical treatment through the Emergency Medical Treatment and Labor Act (EMTALA) and safety net clinics.[81–83] Disparities in hospice access for unauthorized immigrants exist in areas where most hospice care is delivered by small, for-profit agencies.[84] Health insurance and healthcare access is limited. Undocumented individuals are excluded from federally funded insurance options (full Medicare and Medicaid). This lack of both insurance and access to needed health services negatively impacts patient and family care and support.

Disability Status

Individuals with physical disabilities or mental illness are at risk of receiving poorer quality healthcare. Those with differing abilities constitute a cultural group in themselves and often feel stigmatized. This discrimination is evident in cultures where the healthy are more valued than the physically, emotionally, or intellectually challenged.[3] If patients are unable to communicate their needs, then pain and symptom management and end-of-life wishes are often not addressed. Additionally, this vulnerable population's losses may not be recognized or acknowledged, putting individuals at risk for complicated grief. Taking time to determine an individual's goals of care—regardless of differing abilities—and identifying resources and support to improve QOL is essential.

Essential Cultural Concepts in Palliative Care

Culture impacts all aspects of palliative care. This section focuses on key palliative care issues and concepts that are heavily influenced by patient and family values, practices, and beliefs. Communication, medical decision-making, pain and symptom assessment and management, nutrition, and EOL rituals are presented.

Case Study: The Impact of Culture on Palliative Care

Mr. J was a 72- year-old African American man, diagnosed 3 months ago with stage IV non–small cell lung cancer, with metastases to the spine and brain. The palliative care team of a large academic medical center was called to offer a consult during a recent hospitalization for uncontrolled hip pain and dyspnea. He had received palliative radiation for his back pain and brain irradiation to his three metastatic lesions previously.

Since his diagnosis, he has been living with his daughter and her family (three children, ages 10, 14, and 17) in a small apartment in the inner city because he is unable to care for himself. He refused to take opioids for his hip pain and dyspnea, stating, "I don't want to become an addict like my brother." Mr. J's daughter did not want to have him living at her house taking opioids because her oldest daughter has been treated for addictive disease and, "I can't have those drugs in my house."

The oncology and palliative care team agreed that the patient had progression of his cancer, as evidenced by new bone metastases in his hips and new liver metastases. With his past medical history of type 2 diabetes, hypertension, and renal insufficiency, no further cancer treatment was recommended. The oncologist met with the patient and his daughter and recommended hospice care. Mr. J was furious that "they are giving up on me," and his daughter states that "they are only suggesting this because they don't want to take care of Medicaid patients like my father at this hospital."

Questions to Consider in this Case

1. What cultural considerations may have contributed to the challenges of pain and symptom management for Mr. J?
2. What cultural issues may have influenced Mr. J and his daughter in their mistrust of the healthcare system and his oncology care?
3. What communication strategies may have helped with the complexity of the patient's and daughter's fears and concerns?

Communication

Communication is the foundation for all encounters between nurses, patients, and family members.[85] When the nurse and the patient–family unit are from different cultural backgrounds, discussing news regarding serious illness or a poor prognosis can be challenging if the nurse is not aware of potential cultural conflicts. Communication disparities may lead to poorer outcomes and reduced patient and family satisfaction.[16,86] The establishment of a trusting relationship with the nurse, where the nurse seeks to understand the unique concerns of the patient and family, provides a foundation for all future communication and decision-making.[19]

Communication is an interactive, multidimensional process, often dictated by cultural norms, and it provides the mechanism for human interaction and connection. Given the complexities of communicating diagnosis, prognosis, and progression of a life-limiting disease, there is no "one size fits all" approach.[87] Cultural assessments, including cultural norms related to communication, should occur early in the initial assessment, and findings should be clearly documented and shared with all health providers involved in the care of the patient and family (Box 37.5).

Box 37.5 Culturally Competent Communication Skills and Best Practices for Palliative Care

1. *Foster respect.* Baseline assessment and documentation should include primary language/dialect. Determine need for professional interpreter services. Determine how individuals prefer to be addressed and who should be involved in giving/receiving medical information and participating in decision-making, especially in regards to treatment options for serious illness.
2. *Engage in person-centered conversations through active and reflective listening.* Reflective listening involves hearing, understanding, retaining, analyzing, and evaluating information. Get to know the patient as an individual with values, beliefs, and hopes for the future. During conversations, be aware of cultural implications of nonverbal communication. Is eye contact or touch acceptable during active listening or is it disrespectful?
3. *Provide presence.* This is the greatest gift nurses can give their patients and families. Listen to the stories, life goals achieved, and future goals. Pull up a chair for a few minutes and let the patient tell you what is important to him or her. Show empathy and compassion; be quiet/reflective during times of silence.
4. *Assess the patient's interpretation of what is important in life, what gives life meaning for them.* Understanding what is important to the individual and those closest to him or her will assist in individualizing the palliative care plan. Support the patient's strengths and encourage the patient to maintain hope. Life review can help identify what gives life meaning.
5. *Assess and address religious and spiritual preferences and concerns.* It is important to understand the role that a religious/faith community and spiritual beliefs and practice play in the patient's life. Consider including clergy and others that the individual/family identifies as key supports. Offer spiritual care (books, music, rituals, meditation, etc.) to enhance healing and peace.
6. *Demonstrate consideration of patient's privacy, decision-making strategies, and experience of loss and grief.* Early assessment of cultural issues related to beliefs about disclosure of diagnosis and decision-making preferences will ensure that care is given in ways that respect patient and family values. Observe for signs and symptoms of anticipatory or complicated grief and refer to appropriate interdisciplinary team members.
7. *Assess patient and family knowledge of disease trajectories, if culturally appropriate to discuss.* Assess and address distressing symptoms, side effects of treatment, and likely disease progression. Reaffirm goals of care and attempt the relief of symptoms and other concerns. Incorporate preferred healing practices and traditions. Discuss early access to hospice care to support goals as disease progresses.
8. *Anticipate times when communication will be difficult.* Dealing with serious illness is often stressful. Be proactive by anticipating situations when communication may be difficult (i.e., breaking bad news, holding family meetings, and helping patients and family members communicate last wishes at end of life). Utilize appropriate interdisciplinary team members to provide support to the patient and family during these difficult times.

Source: Adapted from Reference 34.

Providing presence and active listening are the most important communication techniques for the nurse to master. Elicit patient and family concerns, customs, norms, beliefs, and values, and take time to reflect back what is heard. Encourage patients and families to also reflect back what they have heard. Listening to words alone is not enough. Pay attention to nonverbal cues (e.g., gestures, posture, use or avoidance of eye contact). Nonverbal communication will give valuable information and insight into the emotional impact of what is being said and will help inform the clinician regarding how to behave as well. The reader is referred to the Communication in Palliative Care, Chapter 5 for further discussion on this subject.

Medical Decision-Making

Over the past 45 years in the United States, ethical and legal considerations of decision-making have focused on patient autonomy.[28,53] This focus replaced the more paternalistic approach—decision-making as solely the physician's responsibility—with an approach that emphasizes a model of shared responsibility with the patient's active involvement.[24] The Patient Self-Determination Act of 1991 sought to further clarify and to protect an individual's healthcare preferences with advance directives.[88] The principle of respect for patient autonomy points to a patient's right to participate in decisions about the care he or she receives. Associated with this is the right to be informed of diagnosis, prognosis, and the risks and benefits of treatment to make informed decisions. Inherent in the movement for patient autonomy is the underlying assumption that all patients want control over their healthcare decisions. Yet, in fact, for some individuals, patient autonomy may violate the very principles of dignity and integrity it proposes to uphold and may result in significant distress.[53]

This European-American model of patient autonomy has its origin in the current dominant culture, a predominantly white, middle-class perspective that does not consider diverse cultural perspectives.[3] In fact, in some cultures, patient autonomy may not be viewed as empowering but rather as isolating and burdensome for patients who are too sick to have to make difficult decisions.[53]

Emphasis on autonomy as the guiding principle assumes that the individual, rather than the family or other social group, is the appropriate decision-maker.[24] However, in many non–European-American cultures, the concept of interdependence among family and community members is valued more than individual autonomy.[28,53] Cultures that practice family-centered decision-making, such as the Korean American and Mexican American cultures, may prefer that the family, or perhaps a particular family member rather than the patient, receive and process information.[27,53] The traditional Chinese concept of "filial piety" requires that children, especially the eldest son, are obligated to respect, care for, and protect their parents.[17] Based on the values and beliefs of this culture, the son is obligated to protect the parent from the worry of a terminal prognosis.

Although full disclosure may not be appropriate, it is never appropriate to lie to the patient. If the patient does not wish to receive information and/or telling the patient violates the patient's and family's cultural norms, the healthcare provider may not be respecting the patient's right to autonomously decide not to receive the information. Some cultures believe that telling the patient he has a terminal illness strips away any and all hope, causes needless suffering, and may indeed hasten death.[34,53] For example, for those adhering to traditional Navajo values, imposing negative information, such as prognosis of a life-limiting illness, on the person who is ill is a dangerous violation of their values.[53]

The nurse must consider the harm that may occur when the health system or providers violate cultural beliefs and practices. Assessing and clarifying the patient's and family's perspectives, values, and practices may prevent a cultural conflict.[3,16] The nurse is in a key position to address these critical patient and family issues (see Box 37.3 for examples of questions to ask). By asking how decisions are made and whether the patient wishes to be involved in both being told information or participating in the decision-making process, nurses respect patient autonomy and honor individual beliefs and values.[16]

Pain and Symptom Assessment and Management

It is important to remember that the acknowledgment and expression of pain and symptoms is heavily influenced by culture. Assessment must be performed with a cultural lens. For some, even the word "pain" has a negative connotation and some patients may not answer the assessment questions when those terms are used. For example, in certain cultures, it is unacceptable for a male to report pain; admission of pain is a sign of weakness.[3] These individuals may respond more openly to questions about "discomforts," "something hurting you" or "aching," rather than pain.

The same is true when assessing for symptoms. For example, depression, a common symptom in palliative care, may not be able to be assessed simply using the standard assessment question, "Are you depressed?" Patients who are unable to admit depression due to stigma or other cultural considerations may be open to discussing feelings of "sadness" or "having no energy" or "no interest in things that usually bring joy." An association between the report of symptoms and symptom distress has been reported. Individuals from Asian-speaking communities in the United States have reported low symptom distress because of their fatalistic beliefs regarding acknowledging symptoms and their meaning. Sensitivity to the language used in assessment of pain and symptoms is essential for an accurate assessment.

Managing pain and symptoms may also be culturally challenging. If a patient and family has relied on remedies commonly used in their culture to manage symptoms, insisting on more Western-style medications/interventions is inappropriate and can result in a cultural clash and an ethical dilemma. It is important that the nurse work together with the patient and family and the team to identify safe, effective, and culturally respectful ways to address pain and symptoms associated with the serious illness.

Research has demonstrated that racial and ethnic differences continue to exist in pain assessment and pain management.[21] The unmet needs for good pain management in an African American population when compared to a Caucasian population at the time of a palliative care consult highlights this issue in the United States.[89] Western providers are reported to underestimate pain in 75% of African Americans and 64% of Hispanics experiencing pain.[90] It is important to be aware of these disparities in delivery of quality palliative care and work to ensure equal care for all.

Nutrition

One of the most central aspects of caring for each other in nearly every culture is feeding. Food and nutrition are essential human needs, and sharing food together is an essential social interaction for families and communities. When patients with serious illness no longer have the desire or ability to take food in, families often become distressed. Many mistakenly believe that providing food or fluids at the end of life will prolong survival.[91] Research has shown that the burdens associated with medically administered nutrition or hydration at end of life usually outweigh the benefits.[58] Families need to be educated about the burdens and taught ways to provide care other than making food or feeding. For example, teaching them how to do good oral care for the patient, keeping the mucous membranes and lips moist, will allow them to provide comfort and physical caregiving. Encouraging them to offer small bites of favorite foods for pleasure and tasting can be enjoyable for the patient and family. This is especially important when certain cultural foods are essential for QOL.[8,33,91]

End-of-Life Rituals

It is critical that the nurse explores what cultural rituals should be honored as death approaches, at the time of death, and immediately after death. These important rituals and practices should be known well in advance of the death, if possible. Rituals are important social aspects of care that can provide a means to express emotions, ease anxiety, and offer structure in times of distress.[92] However, if the patient and family are not given the opportunity to engage in valued rituals, needless suffering occurs and the grieving process may be complicated. Memories of the loved one's death will stay with the family forever.

Examples of rituals prior to death that may be offered include, among others, having a priest administer the Sacrament of the Sick to practicing Catholics. Those who are practicing Hindi may prefer to die at home, lying on the floor close to Mother Earth.[52] Every effort should be made to get the patient home and honor that valued practice. Immediately after death, for those adhering to the Muslim faith, the body should be placed facing Mecca or the East. This should be known ahead of time and honored immediately following death. In the Orthodox Jewish tradition, as well in other cultures, care of the body after death is gender-dependent.[17] Therefore, it is important after death that a female nurse not clean a male body if the family is adhering to Orthodox practices.

Rituals that are spiritual and nondenominational can be a tremendous support to families after the death of their loved one. A bathing and honoring ritual, developed by hospice nurses at Cottage Hospice in California, has been shown to be a meaningful way to respect the patient's body, honoring the person-centeredness of that individual and comforting the family.[93] This ritual can be offered by nurses in acute care, hospice or home care, and long-term care.

Finally, rituals that honor the work that professionals have done in caring for the deceased patient and family are extremely important to our profession. Taking a moment at the time of death to honor the person who has died as "somebody's mother, somebody's daughter, somebody's loved one" is essential to healthy grieving for the healthcare team. A ritual called "The Pause," performed after death in the emergency room or in the intensive care unit, is appropriate in all healthcare settings and important in preventing compassion fatigue in healthcare workers.[94]

Conclusion

Given the changing population of the United States, we as nurses must advocate for the integration of cultural considerations in providing comprehensive palliative care. It is imperative that each of us move beyond our own ethnocentric view of the world to appreciate and respect the similarities and differences in each other. We are challenged to embrace a better understanding of various perspectives. Striving for cultural competence first requires an awareness of how one's own cultural background impacts care. In addition, acquiring knowledge about cultures and developing skill in cultural assessment and communication are essential to improving palliative care for patients with life-limiting illnesses and their families. Most importantly, maintaining a sense of cultural humility, caring for each patient/family member as a unique human being with unique needs, and attending to those needs with dignity and respectfulness are the essence of providing culturally sensitive care.

This chapter encourages nurses to integrate cultural assessment and culturally appropriate interventions into palliative care. It is the hope of the authors that readers will enrich their practice by seeking new knowledge about different cultures through available resources and, most importantly, by respectfully interacting with the most valuable resources on cultural considerations we have—our patients and their families.

CHAPTER 38

Older Adult Patients in the Community

Carol O. Long

Key Points

- Caring for older adults with serious and life-limiting illness who reside in the community requires special considerations. Known as geriatric palliative nursing, a comprehensive, holistic, and person-centered approach incorporates physical, psychological, social, and spiritual care to enhance quality of life for older adults.
- Community-based palliative care for older adults refers to care of the person living within the environment in which they reside.
- Geriatric palliative nursing care encompasses targeted assessment and management strategies specific to older adults.
- Community-based palliative care of older adults includes general principles related to ethics and advocacy.

Introduction

Palliative care nursing for older adults continues to evolve, with expanded inquiry into all of the elements that support dignity, relief of suffering, and quality of life (QOL) along the trajectory of illness toward the end of life. Older adults will encounter increasing physical limitations and comorbidities and the potential for diminished cognitive ability. These progressive losses, that span ages 65 to 100, can be challenging for the patient and family. Nursing care of older adults in the community requires a unique set of assessment and management skills for the palliative care nurse. The purpose of this chapter is to provide an overview of the complexities of aging and the mechanisms necessary to allow individuals to age successfully until the end of life. The key tenets of palliative care nursing for patients residing in the community are described.

Aging in America

Older adults make up one of the fastest growing demographic groups in the United States. According to the US Census Bureau, there are approximately 47.8 million adults aged 65 years and older in the United States, an increase of more than 8 million since 2000.[1] To date, one in seven Americans (15% of the population) is an older adult.[2] Of those over the age of 65, the greatest projected increase is in the 85 and older segment, estimated to grow from 6.3 million to 14.6 million by 2040.[2] This age group is most likely to require long-term care or community-based nursing services due to increasing difficulty with activities of daily living (ADLs), many chronic conditions, and dementia. This group is expected to be 29.7% of the population in 2050.[3] Similarly, 21.8% of noninstitutionalized persons age 65 and older report that they are in fair or poor health.[4]

The United States is also becoming more diverse. In 2015, a record high number of 22% of older adults reported membership in one or more racial or ethnic populations. By 2050, minority populations are projected to increase from 14% to 22.7% of the older adult US population.[3] Educational attainment has improved over the past 20 years, with 85% of older adults completing high school.[2] Sources of financial income vary widely with most (84%) receiving Social Security payments in addition to income from other assets and pensions.[2] However, one in seven older adults (15%) experiences poverty.[5]

The average life expectancy in the United States in 2012 was more than 78 years compared to 50 years of age in the early 1900s.[6] Life expectancy continues to increase as people aged 65 and older can anticipate adding 19.4 years to their lifespan (20.6 years for females and 18 years for males). Women aged 65 and older (26.7 million) continue to outnumber older men (21.1 million), while older men (70%) are more likely to be married than older women (45%).[2]

As the average life expectancy has changed, so have the causes of death. The 10 leading causes of death in 2014 account for approximately 75% of all deaths for those 65 years and older (Box 38.1).[6,7]

Only 1.3 million adults live in residential care settings; thus, the majority of older adults live in the community, of which 13.6 million live alone.[2,8] *Community-based care* refers to care delivered in the environment in which a person lives, largely excluding residential skilled nursing care and acute care settings. Among older adults, 61% prefer to age in their own homes.[9] However, where older patients live may not be where they die. While there has been a shift toward more home-based palliative and hospice care for older adults, many still live out their remaining days and die in the hospital, emergency department, or intensive care unit.[10] To date, 84% of hospice patients are aged 65 and older.[11] Correspondingly, two out of every five Americans aged 65 and older have not completed any advance directive. Thus, the care that people would choose at the end of life may not be the care that they receive, and chronically ill older adults may receive expensive futile care.[12]

In summary, the 65 and older demographic sector is forecasted to increase as more than 10,000 people turn 65 each day.[13] The shift to an aging population and the inherent complexities in community-based healthcare are expected to continue until 2060. As such, palliative care nursing will increasingly shift its attention to the care provided to older adults and particularly those living in the community.

Box 38.1 Ten Leading Causes of Death

Diseases of the heart	25.5%
Malignant neoplasms	21.5%
Chronic lower respiratory diseases	6.5%
Cerebrovascular disease	5.9%
Alzheimer's disease	4.8%
Diabetes mellitus	2.8%
Accidents	2.5%
Influenza and pneumonia	2.3%
Nephritis, nephritic syndromes, and nephrosis	2.1%
Septicemia	1.5%
Other	24.5%

Case Study: A Community-Living Older Patient

"Isabel Menendez, age 68, was diagnosed with heart failure last year. On any given day, Mrs. Menendez, a proud Hispanic women and mother of six grown children, would have told you that her life had been blessed. Married for more than 40 years, she and her husband had lived in an Arizona rural community their entire lives. To her, home and family was everything. So was her local Catholic church, her neighbors, and afternoons watching *telenovelas*. Three years ago, her life changed after suffering an acute myocardial infarction while at the grocery store. After experiencing extensive cardiac damage, Mrs. Menendez became oxygen-dependent and took many medications that often made her drowsy. Adamant to stay at home, her family had pondered what could be done to promote her independence at a time of physical compromise. She was often sad and lamented that "my best days are behind me and I have nothing to look forward to." At her last cardiologist appointment, Mrs. Menendez reported increasing dyspnea, and she was admitted to the hospital. Her ejection fraction was 38%, and her prognosis was poor. She had yet to complete her advance directives. Two more times, she entered the hospital and was discharged to her home, a bit weaker and more dependent than ever before. While not yet terminal, the hospital team believed that a palliative care consult was necessary. With a desire to go home, a community-based palliative care team met with Mrs. Menendez and her husband to discuss how to best meet her goals of care while providing the symptom relief necessary to make her comfortable. Future discussions would include hospice care but, for now, the team contemplated what physical, psychological, social, and spiritual components needed to be addressed to support the QOL that Mrs. Menendez desired.

This case study illustrates episodic setbacks that punctuate the downhill trajectory experienced by Mrs. Menendez and others in their aging years. Most often, older adults want to remain at home during their final days. Expert nursing knowledge and skills are necessary to maintain a safe and caring community-based approach for older patients.

The Aging Adult

Aging is an evolving, complex biological process that begins at birth. The course of aging is influenced by a person's past experiences, the environment, family and home life, physical and mental health factors, culture, and the community in which a person resides. Being mindful of mind, body, and spirit interrelatedness, from wellness through illness and along the continuum of care, is the essence of nursing in the care of older adults. Geriatric palliative nursing care incorporates physical, psychological, social, and spiritual care for those who are seriously ill until the end of life. Highlighting the key aspects of aging illuminates the opportunities available for community-based palliative care nursing (Box 38.2).

Box 38.2 Indications for Geriatric Palliative Care

- Individuals with progressive complex healthcare needs
- Significant symptom distress
- Functional deficits
- Number and complexity of chronic, comorbid chronic conditions
- Prevalence of debilitating geriatric syndromes

Physical Well-Being

Age-Associated Changes and Chronic Conditions

Aging, independent of disease, is variable from one person to the next. Numerous age-associated physiological and anatomic changes occur across all organs and systems as a normal consequence of aging but are more pronounced for individuals age 85 and older.[14] Decreased or diminished cardiac reserve, vital capacity and forced expiratory volume, oxygen consumption, cerebral blood flow, muscle mass, bladder wall elasticity, and renal function, to name a few, are possible age-associated changes seen in older adults. Age-associated sensory changes include presbycusis, vision changes (e.g., decreased visual acuity, problems with night vision), and changes in taste and smell which may contribute to compromised safety or other living adjustments. In one study, olfactory impairment was associated with an increased risk of mortality in older adults.[15] Other changes may ultimately lead or predispose individuals to disease, advanced medical conditions, or geriatric syndromes.[14,16] As such, physiologic and functional age-associated changes must be differentiated from pathological conditions or diseases to guide interdisciplinary team (IDT) recommendations that address the patient and family goals of care.

Chronic Conditions

Older adults are likely to encounter multiple chronic conditions as they age, and the primary cause of death in adults aged 65 and older is chronic disease.[17] It is estimated that more than 50% of older adults have one or more chronic diseases.[18] The increasing effects of disability related to chronic illness may compromise independence and QOL. As expected, functional disability associated with chronic conditions increases with age. The overall cumulative effect may significantly impact the older adult's well-being, especially when facing a serious or terminal condition.

Increasing comorbid or multimorbid conditions in older patients are likely to lead to increasing risk of death.[19–21] Multimorbidity may lead to further physical and functional decline and contribute to increasing complexity of care for palliative care clinicians in community-based settings.

Geriatric Syndromes

The term *geriatric syndrome* is used to describe an array of clinical manifestations that do not fit a discrete disease or medical condition category.[22] Geriatric syndromes are common in older adults and are most often linked to functional decline, decompensation, and poor health outcomes. Dementia, depression, frailty without a known cause, urinary incontinence, pressure ulcers, thermodisregulation, self-abuse or neglect, failure to thrive, syncope, falls, sleep disorders, atypical presentations, and delirium are geriatric syndromes, to name a few.

There is no uniform consensus about the total number of geriatric syndromes nor is it known how many older adults are afflicted with these conditions. Over the life course, many older adults may experience multiple syndromes or ones that cascade and lead to additional syndromes. Patients who are more ill or frail, with dementia or delirium, impaired homeostasis, or low body mass index are more likely to face increased mortality compared to the average in other older adults; the ratio of risk of geriatric syndromes to mortality increases as one ages.[20,22] Accordingly, geriatric syndromes and their associated risks may lead to symptom distress that requires palliative care interventions and may be more difficult to detect within community-based or primary care settings (Box 38.3).

Box 38.3 A Geriatric Syndrome: Falls

The propensity for unintentional falls is considered a geriatric syndrome. Falls are a leading cause of injury in the community (e.g., fractures and traumatic brain injury) and fatal deaths in older adults.[23] While falls, in and of themselves, do not require palliative care or hospice, falls in conjunction with other geriatric syndromes, as in dementia (e.g., Alzheimer's disease) or delirium, and coupled with comorbid or multimorbid conditions may be indicative of a downward decline in older adults. Thus, palliative care should be considered. See *ConsultGeriRN.org* for a complete review of common geriatric syndromes and conditions in older adults; access the *TryThis* series with numerous tools and instruments to use in the care of older adults. https://consultgeri.org.

Functional Status

Over time, older adults are at risk for increasing disability and functional decline due to sudden or chronic medical or mental health conditions. In 2015, 35% of older adults living in the community indicated that there was some type of disability, such as difficulty related to ambulation (23%), hearing deficits (15%), cognitive impairment (9%), compromised self-care (8%), and vision difficulties (7%). However, the same percentage indicated that their health was excellent or very good, while 22% reported fair to poor health status.[1,2,4]

Additionally, 30% of older adults age 65 and older living at home report difficulty in performing one or more activities of daily living (ADLs) in addition to one or more instrumental activities of daily living (IADLs). Arthritis, cancer, hypertension, and diabetes are commonly reported diagnoses for people age 75 and older. In general, noninstitutionalized older people report significant difficulty in doing errands alone and report diminished cognitive ability necessary to concentrate, remember, or make decisions. This escalates as people age and is more common among women compared to men.[4] Thus, the assessment of IADLs and basic ADLs is necessary in community-based palliative nursing care.

Finally, aggressive pain and symptom management is a core component in palliative care nursing and is addressed elsewhere in this textbook. General assumptions that pain and other physical deficits are a normal consequence of aging need to be dispelled and evaluated for treatment and aggressive comfort management.

Psychological Well-Being

Mental Health and Cognition

The mental health of older adults is largely underassessed and underaddressed. This is often due to the public stigma of mental illness or lack of understanding by clinicians regarding the necessity of evaluating depressive disorders, which is the most prevalent mental health condition in people aged 65 and older. Older adults living in the community may go day to day with mental health needs unnoticed. Evidence shows that the presence of depressive disorders can adversely affect the course of treatment and patient outcomes for older adults who have chronic diseases.[24] Older adults with multiple chronic and mental health conditions, such as depression and anxiety, and with greater illness burden are at risk for compromised lower self-confidence.[25] There is no evidence that older adults experience age-associated cognitive changes as they age.[26] However, individuals with dementia require palliative care because these conditions are considered terminal. Evaluating the mental health and cognitive abilities of older adults is an important consideration in geriatric palliative nursing care within the community.

Loss and Grief

Older adults encounter numerous losses as they age. The progressive or sudden loss of physical independence due to a medical condition or cognitive ability or sensory functions (hearing and vision) may be a constant reminder of one's own morbidity and mortality. For some, the death of close friends and family members may lead to depression, isolation, and despair. Shrinking social networks due to deaths and other physical or social losses (e.g., reduced mobility, driving cessation, lack of transportation) may compromise QOL. The progression from independence to dependence on others or living alone and later living in a nursing care facility are major losses for older adults. Suffering emerges as the individual tries to find stability and the opportunity for growth amid loss and resulting grief. Balancing the opportunity to live life fully with multiple losses and grief becomes life's biggest challenge for older adults.[27] Vigorous assessment and attention to single and cumulative loss and grief is essential in community-based care for older adult patients.

Person-Centered Care and Communication

Person-centered care is an essential element in community-based care for older adults and the cornerstone of palliative care nursing. While not widely studied in palliative care yet, recent research about older adults with chronic conditions indicates that the person-centered approach (care that is holistic, empowering, respectful, individualized, and dignified while promoting self-determination and purposeful living) improves satisfaction and quality of care in older adults with chronic conditions.[28–30] What remains is the need to formalize a definition and operationalize the key attributes of person-centered care within a community-based setting for older adults.

As such, acquiring excellent communication skills is a core competency and necessary component of person-centered care. Epstein and Street's seminal work in patient-centered communication in cancer patients identified six core functions necessary to provide better health outcomes: (1) fostering healing relationships, (2) exchanging information, (3) making decisions, (4) responding to emotions, (5) enabling patient self-management, and (6) managing uncertainty.[31,32] Patient-centered communication leads to enhanced QOL, treatment adherence, and self-efficacy. The inclusion of family members is vital in all communication efforts.[33] Palliative care nurses can intervene with older adults and families to diminish suffering by being present during conversations with patients and families while advocating for, being supportive of, and preserving dignity.

Spiritual Well-Being

Spirituality is integral to the care of the whole person. Finding meaning in life and redefining beliefs and values may be pivotal concerns for adults as they age and encounter life-changing medical events. Most of the research on spirituality and aging has been related to religion and health outcomes, thus the entire spectrum of spirituality and aging remains largely untapped.[34] Learning more about a person's faith or religious affiliation and spirituality is a core component of palliative care nursing. Integrating spirituality into the plan of care is a necessity. Organizational programs within communities may augment services provided by the palliative care team.

Social Well-Being

Evolving Living Arrangements

Our communities today are faced with pressing social issues related to the safety and sustainability of older adults living at home. Older people live in a variety of community settings across rural and urban America, spanning from independent living to institutionally based care. Most older adults prefer to "age in place," meaning that they prefer to live at home until their death. However, as older people age, they are more likely to live in care facilities, such as nursing homes, or move in with family members. Others may live in assisted living facilities, congregate housing or shared homes, and a myriad of other housing options which may be considered part of the community-based network. The primary causes for institutional placement are related to increasing physical or cognitive changes that result in dependency upon trained care providers to meet self-care deficits. Even so, more than 12 million households are managed by adults aged 75 or older, many of whom face the day-to-day effort of ongoing maintenance and general upkeep while living on a limited or fixed income.[1] It is estimated that 29% of noninstitutionalized adults live alone, and almost half of older women (46%) live alone by age 75.[1] Over time though, obstacles to continuing independence and autonomy may pose challenges for older adults and even more so if their health declines.

The potential for an unsafe home environment is also very real, especially with multilevel homes or apartments and other factors that may pose challenges for older adults, such as poor lighting or kitchen or bathroom hazards. Others have transportation problems, thereby limiting access to community and health resources in a timely manner. Older adults may access other community-based resources, such as adult day care and either skilled or personal home health care. Palliative care may be provided at an outpatient or independent home setting, bridging across many healthcare settings. Hospice care is available during the terminal stages of the person's life, and this care is available at home, within an inpatient setting, or nursing care facility.

Finally, transitions in care and in living arrangements are likely to occur as the older adult encounters changing health conditions that may tax the capacity of the family, financially or otherwise, to provide needed care and support. Other factors facing communities today are those who are homeless, disenfranchised from their family members for a myriad of reasons, and the unfriended. With many older adults living alone, it is necessary to assure that personal connections to the larger social and spiritual/religious communities are evaluated and included in the plan of care. Linking palliative care services and resources along the continuum of care is a significant concern for older adults living in the community.[35] If an older adult patient has been hospitalized, impeccable discharge-planning from acute care with insight into the home and family situation is necessary.[33,35]

Family and Caregivers

Formal and informal caregiving is common in community-based care. Formal caregiving is generally personal care services provided by paid direct care workers and other home help support staff from local agencies. Payment for this care generally comes from out-of-pocket, long-term care insurance, or home- and community-based services for those who are eligible. In general, informal caregivers are family members who provide unpaid care in response to an illness or functional impairment in a chronically ill older adult, partner, friend, or neighbor that exceeds the level of care and support typical in family relationships.[36]

Informal family caregivers may encounter caregiver burden and stress, physical distress, and increased financial burden related to the breadth and depth of caregiving. Many individuals would be institutionalized if caregiving at home was not available. It is estimated that more than 17.7 million family members provide unpaid care for older adults in the home.[37,38] Most of the caregivers are women, and many are aged 50 or older; on average, older care recipients are 75 years of age or more. Generally, caregivers provide 21 hours of care per week.[37,38]

Family caregivers, most of whom are spouses or adult children, form the backbone of community-based caregiving for older adults.[8] Caregiving may range from intermittent to round-the-clock care for individuals who are dependent on others to meet their daily personal care needs, illness-related care, and other supportive care, such as advocacy and steady companionship. Family caregiving can be equally as challenging as it is rewarding. Palliative care nursing includes attention to family situations and the consideration of the family in concert with the goals of care.

Nursing Interventions: Geriatric Palliative Care Nursing Practice

Numerous opportunities exist for the IDT and nurses specifically to proactively include palliative care in their daily practice. The goal of geriatric palliative care along the continuum of care in the community is to promote QOL and specialized care for older adults with serious illness regardless of the home setting.

Case Study: A Community-Living Older Patient (continued)

Soon after her hospitalization for heart failure, Mrs. Menendez was admitted to a community-based palliative care program. A comprehensive geriatric assessment, completed in the hospital was soon updated and the patient-family goals of care were reviewed. *Cor pulmonale*, a geriatric syndrome, emerged as a new diagnosis, and soon Mrs. Menendez's appetite diminished. Her medications were reviewed and distressing symptoms assessed. Upon consultation with Mrs. Menendez and her entire family, plans were put in motion to assure safe living conditions at home. Her bed was moved from the upstairs loft to the first floor. She was now close to the kitchen so that she could eat whenever and whatever she desired. Mrs. Menendez's social worker arranged for church members to bring in local homemade food during the week for Mr. and Mrs. Menendez, and they often stayed to chat for several hours. The palliative care team never visited in the afternoon so that Mrs. Menendez could continue to watch her favorite *telenovelas*. Family members pitched in to clean the house and maintain the yard. She now received Holy Communion on Sundays at home, which was arranged by the parish nurse and pastoral care team. Symptoms were well-managed, and she was now on morphine for dyspnea and an oxygen concentrator as needed. Her advance directives were completed in the hospital, and she desired to die at home, surrounded by family members. Mrs. Menendez's condition deteriorated, and she was admitted to hospice. Weekly patient–family and staff meetings were held to ensure that Mrs. Menendez's goals of care were being met. Soon after, Mrs. Menendez died peacefully at home, with all family members present.

Mrs. Menendez's case study illustrates key principles about geriatric palliative nursing care in the community and are illuminated in Box 38.4. Note that this overview does not take into account the substantive contributions of each IDT member, contributions that are critical in the home care environment. Additional considerations related to advocacy of older adult patients are provided.

Box 38.4 Summary of Geriatric Palliative Nursing Care in the Community

1. *Apply the principles of patient- (person-) and family-centered care.*
    a. A person-centered nursing approach embraces the whole person. Come to know the person as they are and craft a care plan to meet the patient–family goals of care that are realistic and measurable.
    b. Meeting basic needs is primary for all patients. Comprehensive care is necessary to support older adults in the community who require palliative care. Managing day-to-day physical and emotional needs can be taxing. A holistic palliative care approach in older adults includes attention to adequate and appropriate housing and living conditions, safety in all aspects of care (e.g., safe housing, daily life, medications), adequate food and nutrition, rest and sleep measures, the treatment of pain and discomfort, the management of functional decline, and maintaining cognitive reserve.
    c. Actively engage the older adult and significant others or family in education about their health and illnesses.
2. *Promote QOL and general well-being.*
    a. Physical assessment and management needs to be tailored to parameters for older adults.
        i. A comprehensive geriatric assessment (CGA) is necessary to distinguish age-related changes or differences related to disease pathology or medical conditions that may require intervention. The CGA is a multidisciplinary physical assessment and medical history approach that uses evidence-based tools and practice guidelines to capture the impact and needs related to medical condition(s), functional needs, and social and economic impact on the individual and constitutes a baseline assessment for care planning and future comparison.[39] Integrate palliative care assessment tools into the evaluation process.[40]
        ii. Recognize and differentiate normal age-associated changes from disease, geriatric syndromes, and atypical presentations. Monitor for increasing functional dependence in instrumental and general activities of daily living. Note the interrelatedness of medical conditions for complex palliative care management. Use the CGA and other symptom assessment tools to differentiate. Reduce harm and enhance efficacy by reviewing the medication profile routinely.
        iii. Monitor for the insidious predictors of emerging geriatric syndromes. Often obscure in the community, these conditions may increase risk and an accelerated decline. Note that the number, severity, and complexity of multimorbid conditions, geriatric syndromes, cognitive decline, and functional deficits require expert geriatric palliative nursing care.
        iv. Regularly anticipate and assess for distressing pain and symptoms using evidence-based tools for older adults. Dispel common myths of aging, such as pain is a normal consequence of aging.
    b. Continuous evaluation of mental health is necessary for older adults.
        i. Provide needed psychological support through the palliative care IDT or community resources.
        ii. Screen for depression and other psychological conditions as warranted using tools validated for older adults.
        iii. For people living alone, assess for loneliness and isolation that may affect safety and overall QOL. Work with IDT members to remediate and enhance social connections.
        iv. Identify and screen for loss and grief.
        v. Engage in positive communication skills.[28–30] Provide emotional support, therapeutic presence, and expert listening skills. Always instill hope.
    c. Assess and address spiritual needs and ways to enhance growth and fulfillment.
        i. Within the community context, learn about local formal religious organizations and social service agencies that may be faith-based and could be integrated into palliative care planning.

(*continued*)

Box 38.4 Continued

- ii. Collect information about community entities that can augment spiritual well-being, such as for breast cancer, grief, Alcoholics Anonymous, and caregiver support groups.
- iii. Identify congregational health ministries or parish nurses in the local community that interface services with palliative care teams.
- iv. Identify ways for the older adult to engage in creative or expressive arts, music, story-telling, and spiritual reminiscence.

3. Advocate for older adults.
   - a. Patient and family values and wishes guide the plan of care. Continuously ascertain individual and family preferences that may evolve over time. Identify cultural and spiritual backgrounds and values that can strengthen the care plan and support the older adult and family members.
   - b. Advance care planning is an expectation in palliative care.[41] Facilitate the documentation of advance directives and revisit frequently as the patient's condition changes.
     - i. Identifying terminal decline and prognostication can be problematic, but supporting the older adult patient along uncertain trajectories is imperative.
     - ii. Utilize ethical principles when discussing treatment complexity and feasibility when making clinical management decisions. Frame clinical management decisions within the context of risks, benefits, burdens, and prognosis related to life expectancy and QOL.[18]
     - iii. Elicit and attend to patient preferences in medical decision-making. Normalize advance care planning by assuring the older adult that preferences that are made known can and will be honored.
     - iv. Ascertain the dying preferences of the older adult patient should institutionalization emerge as a possibility. Discuss hospice early during care-planning.
   - c. Payment for services and healthcare may not be well understood. The patient and family may experience financial burden. Explore financial well-being and provide education and access to resources when indicated.
   - d. Identify and integrate community resources into the plan of care.
     - i. Facilitate the coordination of community services and referral networks.
     - ii. Navigating the complex fragmented health system can be overwhelming. Prepare for transitions and connect with community resources for needed or supplemental care at home.
     - iii. Ascertain formal and informal caregiving networks and supportive care services to enable the older adult to remain at home, should this be the goal. This may include housecleaning, home modification, transportation services, and more.
     - iv. Engage the palliative care IDT along the trajectory of the illness. Incorporate clinicians, support personnel, and others within the local and religious or social service community to augment the care plan.
     - v. Assess caregiver stress and burden and provide access to additional services as needed.[42] Promote positive communication, hope, and support.[43]
   - e. Complete a home evaluation assessment and ascertain ways to enhance safety (e.g., monitor fall risk). Assure that basic care needs are being met (e.g., food, clothing, housing). Secure community resources to meet identified needs (e.g., home-delivered meals programs, senior outreach services, home modification programs).

Conclusion

Aging is often not welcomed in today's society. Seen as a time of increasing disability, uncertainty, and numerous challenges, the trajectory of decline can be stressful and troubling for older adults and clinicians alike. However, it is does not have to be that way. Armed with knowledge and a skills set that is contextualized to meet the physical, psychological, social, and spiritual care needs of older adults, geriatric palliative care nursing can enhance and support the needs of older adults and their families. Community-based palliative care incorporates caring for the individual and the family within the context of where the person lives while fostering the principles of patient-centered care and advocacy. With this perspective, the possibilities of geriatric palliative care nursing in the community are endless.

CHAPTER 39

Poor, Homeless, and Underserved Populations

Caroline Olney, Sarah Stroe, and Anne Hughes

Key Points

- Poor people are at risk for a poor quality of living and a poor quality of dying.
- People whose lives have been filled with physical and emotional deprivation may be suspicious of efforts to engage them in "shared" decision-making to limit therapy, regardless of the therapy's burdens and limited benefits.
- Many persons who are poor have multimorbidities and other marginalizing social characteristics.
- Poor people's interactions with the healthcare system are frequently marked by rejection, shame, and discontinuity of care.

Introduction

Poverty is inextricably linked to increased morbidity, premature mortality, and limited access to both preventive healthcare and ongoing medical care. Beyond the medical outcomes of poverty, the personal and social costs are substantial and often invisible. People who are poor constitute a *vulnerable population*, a term used in community health to describe social groups at greater risk for adverse health outcomes. The root causes of this vulnerability typically are low socioeconomic status (SES) and a lack of access to resources.[1] Vulnerable populations by definition are underserved by the healthcare system in terms of access to and quality of healthcare. Underserved communities for palliative care include not just the poor and those without adequate health insurance but also the unbefriended elderly, non–English-speaking persons, the mentally ill, those with dementia, the developmentally delayed, nursing home residents, and those persons with limited health literacy.[2] When individuals or groups are denied what is regarded as standard-of-care interventions, moral questions about social justice must be asked.

The Institute of Medicine's report evaluating racial and ethnic disparities in healthcare failed to address the role of poverty in disparities.[3] However, the role of poverty in contributing to inequalities, independent of race and ethnicity, is difficult to decipher because class and race are often closely intertwined.[4,5] Some believe poverty may be most responsible for disparities in healthcare.[5] In a systematic review of social determinants of death in the United States, the researchers concluded that low education, poverty (at both the individual and community levels), racial segregation, limited social support, and income inequality were as likely causes of death as pathophysiological and behavioral causes.[6] In other words, being poor is as important a cause of mortality as are pathophysiological and behavioral explanations.

Although much has been written about the state of end-of-life (EOL) care in the United States, until recently not much has been said about those in our society who live at its margins, such as the urban poor.[7–16] Lewis (2011) conducted a systematic review of the barriers to accessing quality palliative care among the poor. Compared with those receiving palliative care who were not economically disadvantaged, the poor had less access to specialty care (often because of transportation), received fewer home visits and hospice services if they lived in high-crime areas, and were at higher risk of dying in institutions. Additionally, because of limited health literacy, more of the economically disadvantaged received more aggressive medical interventions, had fewer discussions clarifying goals of care, and were challenged negotiating complex care delivery systems.[17]

To be poor and to have a progressive, life-threatening illness presents more challenges than either one of these conditions alone. As Taipale elegantly notes, "Poverty means the opportunities and choices most basic to human development are denied."[18(p.54)] Consider the following questions: What type of death would a person hope for when that person doesn't have a home or lives in a room without a phone, a toilet, or kitchen? What are the meanings of life-threatening illness and death when premature death is an all-too-common part of life? What matters at the end of life if most of your life has been spent trying to survive day to day? These questions, in part, introduce us to the worlds of the poor who are confronting a life-threatening illness. Physical, psychological, and spiritual deprivation are not all that poor people contend with—deprivation also harms the moral self and the ability both to act and to live autonomously.[19]

The purpose of this chapter is to consider those characteristics of the poor as an underserved population that place them at risk when seriously ill and when palliative care is indicated.[4] In particular, this chapter looks at a subset of the poor who are homeless or marginally housed and how this affects both access to and quality of care at the end of life. This chapter focuses on persons whose "membership" in this group is more long term and not the result of an identifiable global economic crisis; similarly, this chapter does not address the experiences of persons living in extreme poverty in resource-limited countries around the globe.

The experience of being poor is not singular, nor it is universal; poor persons are as diverse a population as those who are not. Case studies are used to illustrate the concepts discussed and to demonstrate the need for more research to guide practice. The cases described were modified to disguise identifying characteristics; the cases are reflective of the authors' clinical practice in an urban area that is greatly impacted by homelessness.[20] Therefore, these cases are not generalizable to all the poor or all the homeless. Poverty is only one social determinant that affects health status and access to resources. Persons with many vulnerabilities (e.g., being poor and a member of a minority community, elderly, or having other medical problems) are at the greatest risk for adverse outcomes at the end of life.[21]

Epidemiology of Poverty in the United States

In 2016, more than 40.6 million Americans (12.7% of the population) were poor.[22] The poverty line established by the federal government is based on annual household income. In 2017, a single adult younger than 65 years of age was considered poor if his or her income was less than $12,060, and a family of four (with one adult and three children under age 18 years) was considered poor if their annual income was less than $24,600.[22] Most experts believe the federal definition of poverty underestimates the true prevalence of poverty in the United States. For example, the poverty line (annual household income) does not capture cost-of-living differences across the country nor out-of-pocket medical costs. Table 39.1 lists states in which the poverty level exceeded the national average in 2016.[23]

Table 39.1 States whose poverty rates exceeded the national average in 2016

State	Rate of poverty (%)
Mississippi	20.8
Louisiana	20.2
New Mexico	19.8
District of Columbia	18.6
Kentucky	18.5
West Virginia	17.9
Arkansas	17.2
Alabama	17.1
Arizona	16.4
Oklahoma	16.3
Georgia	16.0
Tennessee	15.8
Texas	15.6
North Carolina	15.4
South Carolina	15.3
Michigan	15.0
New York	14.7
Florida	14.7
Ohio	14.6
California	14.3
Idaho	14.4
Indiana	14.1

Source: From Reference 24.

The poverty rate has slowly been decreasing since 2014 from a rate of 14.8% to 12.7%; it is now approximately the same as just prior to the recession of 2008 (in 2007, the poverty rate was 12.5%).[24] High poverty rates continue due to continued high unemployment rates and the decreasing value of and access to public assistance; these issues are compounded by the increasing cost of healthcare, domestic abuse, mental illness, and drug addiction.[25]

Those living in poverty in the United States disproportionately include persons of color, children, foreign-born individuals, and single-parent families. African Americans have the highest rates of poverty in the United States (22.0%), followed by Hispanics (19.4%), Asians (10.1%), and non-Hispanic white (8.8%), according to the US Census Bureau Report for 2016.[24] Children have greater rates of poverty than young and middle-aged adults and the elderly. Approximately 42.1% of children under 18 years old living in a female-headed household were poor compared with 8.4% of children living with two married parents.[24]

Although poverty is not confined to urban areas, as evident in Table 39.1, which includes many states with large rural populations, 12.2% of the poor live in or near metropolitan cities.[24] Most of the poor have access to some type of housing or shelter, even if the basic accommodations (telephone, cooking and refrigeration, heat, water, private toilet, and bathing facilities) are inadequate. However, for a small subset, housing is marginal or unavailable. This subset is the focus of the following discussion.

Definition and Prevalence of Homelessness

Homelessness is defined in the Stewart McKinney Homeless Act as a condition under which persons "lack fixed, regular and adequate night-time residence" or reside in temporary housing such as shelters and welfare hotels.[25] Calculating the number of Americans homeless or marginally housed is extremely difficult. Most cross-sectional studies fail to capture persons transiently homeless—the hidden homeless, or those staying with family members, those living in cars or encampments, and others living in single-room occupancy hotels (SROs), sometimes known as *welfare hotels*.[26] Many of the poor and, in particular, the chronically homeless, avoid contact with social and health services, thus making the size of this population difficult to capture.

According to the National Coalition for the Homeless, on a given night in January 2016, 549,928 individuals were found to be homeless, and 40.6 million people experienced poverty over the course of that year.[25] Persons who are homeless are not members of a homogeneous group. Some are street people and chronically homeless, whereas others are homeless because of a financial crisis that put them out of stable housing. Street people may be more reluctant to accept services and may have much higher rates of concurrent substance abuse and mental illness (i.e., dual diagnoses).[27] Homeless persons frequently are veterans, victims of domestic violence, the mentally ill, and substance abusers. Although the rates of mental illness and substance abuse are higher in the homeless than among persons who are stably housed, assuming that all the poor or, for that matter, all the homeless suffer from these problems only contributes to stereotypes that fail to see the person who is before us. Domestic violence, mental illness, and substance abuse are not confined to the poor; while poverty does not cause these problems, poverty may well exacerbate them.

Health Problems Associated with Homelessness and Poverty

Those living in poverty tend to have more medical problems and decreased longevity than those who are not. In the United States between 2001 and 2014, higher income was associated with a longer life span, and the differences in life expectancy across income groups increased over time.[28] The gap in life expectancy between the richest and poorest 1% of the population was 14.6 years for men and 10.1 years for women.[28] There are several theories as to why this discrepancy in life expectancy exists. First, the poor likely have limited access to healthcare. Second, the poor tend to live in areas where the local environment negatively affects their health. Third, increased stress levels for the poor from lack of social cohesion negatively affect health. Finally, life expectancy is related to local labor market conditions.[28]

Interestingly, Chetty's study found that low-income individuals who live in highly educated cities live longer than similar individuals in lower educated cities. This suggests that city-wide public policies and/or living in close proximity to those with healthier habits has a positive impact on the poor. Geographic differences in life expectancy were significantly correlated with health behaviors, such as smoking.[28]

Numerous health problems are associated with homelessness. Many of these problems are related to environmental factors such as exposure to weather conditions, poorly ventilated spaces, unsafe hotels and street conditions, and high-crime neighborhoods where the poor are forced to live.[29] These health problems (Table 39.2) include malnutrition, lack of access to shelter and bathing facilities, problems related to drug and alcohol use, chronic medical conditions, chronic mental illness, and violence-related injuries.[26] One-fourth of the homeless have a major psychiatric illness; about one in three persons who are homeless abuse drugs and alcohol.[30] Drugs and alcohol are often used to self-medicate distressing psychiatric symptoms (e.g., anxiety, depression, post-traumatic stress disorder [PTSD]).

Table 39.2 Health problems common among the homeless

Causes	Manifestations
Malnutrition	Dental problems, tuberculosis, wasting
Lack of shelter and access to bathing facilities	Skin infections, lice, podiatric problems, hypothermia, tuberculosis, respiratory infections, sleep disorders
Drug and alcohol use	Overdose, seizures, delirium, infections transmitted through injection drug use or sex (such as HIV, hepatitis B, hepatitis C), trauma, falls, cirrhosis, heroin nephropathy, esophageal varices
Chronic mental illness	Paranoid ideation, antisocial behaviors, psychosis, suicide
Chronic medical conditions	Hypertension, arthritis, venous stasis ulcers, cellulitis
Violence-related injuries	Assaults, homicides, rape

Source: From Reference 26.

The individual effects of poverty on health status are irrefutable.[31] Consider the case of coronary artery disease (CAD): the link between onset of CAD and low SES has been established and is believed to be related to lifestyle factors such as poor dietary habits, tobacco use, and limited physical activity.[32,33] Poor cardiac outcomes among the underserved may also be related to limited access to standard medical care.[34] In Toronto, Canada, the homeless are five times more likely than non-homeless individuals to have heart disease.[35] In addition, the poor are twice as likely to have diabetes, 29 times more likely to have hepatitis C, and 4 times more likely to have cancer when compared with the general population.[35] The US national cancer registry of 2008 revealed that being poor was associated with being diagnosed with a more advanced disease stage and less aggressive treatment for individuals with breast, prostate, and colon cancer and with a higher mortality rate for those with breast and prostate cancer.[36]

A survey of the "hidden homeless" in Canada to identify housing, health, and social needs reported that, for many in the sample (aged 15–69 years), their first experience of homelessness occurred when they were in their teens.[26] Similar to other studies, most study participants were male, all had addiction problems, one-third had experienced violence in the prior 6 months, and about 25% reported avoiding being housed in shelters.[26] The medical problems most often cited were addiction, mental illness, dental problems, chronic pain, respiratory conditions, and sleep disorders.[26] Health and social needs identified included access to nutritious food, transportation, money management, addiction and mental health treatment, and healthcare services/providers that were respectful and not stigmatizing or demeaning.[26] Curiously, housing was not identified as a priority, perhaps in part because the researchers recruited most subjects from homeless service agencies that would have attempted to link services with housing.

In urban areas, healthcare services for the poor are often provided by public health departments, teaching hospitals, faith communities, and nongovernmental organizations—the so-called *safety net providers*. These services typically are overburdened and unable to meet the needs of the poor and the growing number of Americans who are uninsured who access them. For many of the poor, the emergency department (ED) has become the primary source of medical care.[10,37]

Where and How Homeless People Die

Limited data are available regarding the socioeconomic factors, places of death, and immediate causes of death of the homeless.[37] An important reminder for providers working with this population is the fact that "[h]omeless individuals have considerable experience with death and dying, and qualitative research has shown them to hold the expectation that their death will be both sudden and violent."[38] Similar to those who are not poor, most poor people die in institutions. For those who are homeless, dying on the street or in jail is also a fact of life.[39]

In the past, causes of death among the homeless included drug overdose; alcohol-related deaths; and hypothermia; accidents such as fires, falls, and pedestrian-motor vehicle accidents; and violent deaths related to homicide and suicide. Researchers in Boston analyzed mortality among the homeless for shifts in patterns from previous reports.[40] Electronic databases of a program that serves the homeless were searched along with the state death registry for causes of death noted on death certificates. For the 6-year study period (2003–2008), there were 1,302 deaths among the homeless.[40] Drug overdose was the leading cause of death, with opioids implicated in 81% of the drug-related deaths.[40] Younger homeless persons (25–44 years) were most likely to die of drug overdose.[40] In addition to opioids, 43% of drug-related deaths occurred in persons who were polysubstance users; alcohol was found in almost one-third of all drug overdoses.[40]

Heart disease and cancer (in particular trachea/bronchus/lung) were also significant causes of death in this population. Compared with matched adults in Massachusetts, the homeless aged 45–64 years, had a two- and threefold higher rate of death related to these chronic diseases.[40] Most of the deaths occurred in the hospital (53%) compared with community residence (27%) or nursing home (10%).[40] The demographic profile of the decedents was similar to past reports: male (81%), mean age 51 years (range 19–93), and white (60%).[40] Compared with prior studies, fewer homeless persons died of HIV disease; instead, drug overdose was the leading cause of mortality, and tobacco contributed to other potentially preventable chronic disease-related deaths.[40]

In light of all the contributing factors just explored, it is critical that palliative care interventions with homeless individuals are as tailor-made and specific as the interventions that better-resourced individuals have access to. Recognizing systemic inequities and continuing to consider social justice as a defining principle of quality palliative care allow application from a perspective that is person-first and equitable as a predominant characteristic. Best practices suggest palliative care for homeless individuals would be mobile (deliverable to people living in any location or situation), trauma-informed, and with an ongoing emphasis on harm reduction.[38]

Case Study: A Homeless Patient

Harold's referral to outpatient palliative care was ostensibly fairly straightforward: he was a 65-year-old Caucasian man with newly diagnosed high-grade bladder cancer, suspicious for bone and lung metastases, considering treatment options, with extreme pain. Upon closer inspection, however, some clear challenges immediately presented themselves: he had no phone or means of contacting him to arrange an appointment. The outpatient palliative care social worker found him in the urology clinic as he was having another appointment and escorted him to the outpatient palliative care clinic for his first visit.

Harold's life had recently changed dramatically. He had been homeless for 20 years and had made a living sorting recyclables. While dumpster diving the previous month, he had fallen and broken his hip. When he was taken to the hospital, it was discovered that, in addition to his broken hip, he had cancer. He became completely dependent on others for his activities of daily living. From the hospital, he received rehabilitation and physical therapy and moved into supportive housing with help from caregivers, meal delivery service, and case management. He was sorting through the rapid changes that had recently unfolded: his diagnosis, his change in housing status, and increased care needs.

Harold had an unusual intellect and story. He endorsed a significant trauma history: his mother was an alcoholic, and a desire to leave the abusive environment he had grown up in led him to join the military at a young age. He was able to complete some college under the GI bill and spoke fondly of his memories as an undergraduate. At no time, however, did he mention anyone he was close to or even in contact with. "I guess I have a hard time trusting people," he said. He was estranged from his only known living relative, a half-brother, and expressed no desire to reestablish contact with him. His life consisted of support staff, medical professionals, and his radio.

Harold was interested in completing an advance directive but posed a conundrum: he truly had no one to act as his proxy. Harold was more than willing to engage in conversations about his EOL preferences and even seemed to enjoy considering the theoretical outcomes of his choices and treatment course. When it came to choosing a person who could speak on his behalf, the only person he trusted was his case manager; she was unable to act as his decision-maker since she was part of his treatment team. Harold signed a physician order for life-sustaining treatment (POLST) and left his advance directive half-completed, filled in as much as he was able.

Poverty, Life-Threatening Illness, and Quality of Life

An enormous body of evidence has demonstrated health inequities related to race and ethnicity; indeed, eliminating health disparities has been a federal policy priority.[3,37] Understanding the role race and ethnicity play in the EOL experience of the urban poor, however, is complex, in no small part because, as Crawley observed, race and ethnicity have been conflated with SES.[41–43] For the purposes of this chapter a more focused review of the literature is presented without attempting to untangle the role of race/ethnicity from SES in explaining the poorer outcomes such as quality of life (QOL).

In a systematic review of the incidence, treatment, and mortality related to heart failure and SES, the researchers evaluated 28 studies that met inclusion criteria. The review concluded that disadvantaged persons had increased incidence of heart failure, higher rates of admissions and rehospitalizations, inconsistent use of beta blockers for treatment, and overall higher mortality rates than their comparison groups who were more advantaged.[44]

Solid organ transplantation is standard of care for end-stage organ diseases that would otherwise compromise QOL and shorten survival. The literature has documented disparities among racial and ethnic minorities related to both access to organs and poorer graft outcomes for those who receive organs.[45,46] Risk factors for poorly functioning kidney grafts match the profile of the urban poor: African American, male, older age, unmarried, unemployed, low income, living in poor neighborhoods, and geographic distance from transplant center.[45] Lacking a kidney transplant, for example, results in a person with end-stage renal disease (ESRD) being required to transport themselves to the dialysis center (if poor, this usually means on bus or on foot) and endure lengthy, uncomfortable hemodialysis treatments usually three times a week, indefinitely. This kidney function replacement therapy surely compromises the QOL.

Poor people endure a heavier burden of cancer according to several reports from the American Cancer Society and other researchers.[47] In a special report on cancer disparities and premature deaths, the American Cancer Society stated categorically that poverty was responsible for cancer disparities and premature cancer deaths regardless of race/ethnicity.[48] Edwards and colleagues used a community-based participatory research design to understand the factors that impact cancer disparities in East and Central Harlem compared with more affluent neighborhoods of New York City.[47] Forty study participants' interviews uncovered a number of themes. Many of those interviewed in Harlem believed information needs were vast and included available community resources, prevention and early detection of cancer, accessing cancer care, and symptom management. Additional themes that impacted cancer disparities in their community included unmet support needs that allowed discussion of cancer's impact and ways to cope, secrecy about the diagnosis, mistrust of healthcare systems, and strongly held beliefs of stigma, fear, and fatalism. Generally, poor people encounter substantial barriers to obtaining quality cancer care, present with more advanced disease, experience more pain and suffering, and are more likely to die earlier of cancer than their economically advantaged counterparts.[48] In addition, patients without insurance were found to have more advanced disease, pursue fewer treatments, and worse survival rates.[49] Findings of the impact of poverty on cancer care are summarized in Box 39.1.

Box 39.1 Poverty and Cancer

- Poor people lacking access to quality healthcare are more likely to die of cancer than non-poor people.
- Poor people experience greater cancer-related pain and suffering.
- Poor people facing significant barriers to getting health insurance often do not seek necessary care if they are unable to pay for it.
- Poor people and their families make extraordinary sacrifices to obtain and pay for care.
- Poor people lack knowledge of available community resources, lifestyle factors that contribute to poorer health outcomes, warning signs of cancer, symptom management strategies, and how to access follow-up cancer care.
- Psychosocial support, both individual and group, and outreach efforts at the community level are lacking.
- Mistrust of healthcare professionals, teaching hospitals, and researchers is common and a barrier to care-seeking.
- Fatalism, fear, and stigma about cancer are commonly held beliefs that prevent accessing care.
- Secrecy about cancer interferes with accessing care that may even be available in the nearby community.
- Cultural barriers between healthcare professionals and the community may result in services that do not take into account the community's needs, including health literacy. Many in impoverished neighborhoods are certain that environmental pollution may contribute to cancer rates.

Source: Adapted from References 5 and 47.

Barnato and colleagues conducted a national telephone/mail survey of community-dwelling Medicare beneficiaries to explore racial and ethnic differences regarding preferences for and concerns about EOL treatment.[50] The sample of 2,847 adults included 2,105 whites (non-Hispanic), 489 blacks (17.4%), and 113 Hispanics (4%).[50] When most subjects were asked about their preferences if they were diagnosed with terminal illness with less than 1 year to live, the responses were quite similar: to die at home, without life-prolonging medications with adverse effects, and without mechanical ventilation if such treatment extended life by 1 week to 1 month. However, compared with white respondents, minority subjects were more likely to prefer more medical interventions, including dying in the hospital, possible life-extending medications regardless of their side effects, and mechanical ventilation for 1 month or 1 week.[50]

In the ethnographic study *Dancing with Broken Bones: Portraits of Death and Dying Among Inner-City Poor*, Moller (2004) poignantly recounts and photographically documents the stories of poor patients followed by an oncology clinic in a Midwest city. His insights about the suffering of the urban poor are profound: "the dying poor are the quintessential violators of the American dream; they live in the shame of poverty and with the unpleasantness of dying."[10(p.10)] Because much of a person's worth in American society is connected with social status indicators such as occupation, income, and home ownership, the poor represent those who have not made it, have not lived up to their potential. Being poor then becomes a matter of personal failure rather than a social problem requiring public policy changes.[51] From Moller's longitudinal qualitative study of poor inner-city patients, their families, and their healthcare providers, the researcher drew a number of conclusions, which are listed in Box 39.2. His work can perhaps be summed up by saying that the indignities of being poor in America are only intensified when that person is also dying. Unlike persons who are not poor, dying is not always feared in the same way because, for some persons who are socially

Box 39.2 Insights about the Dying Poor

- Poverty inflicts substantial harm throughout life.
- Poverty exacerbates indignity and suffering throughout dying.
- Patients/families are often mistrustful and angry about the care received.
- Patients may, at the same time, be grateful for the care received.
- Spirituality plays an important role in providing strength and resilience when dying.
- Social isolation increases suffering.
- Hidden and sometimes unexpected sources of support can emerge from family and community.
- The emergency room is the front door to healthcare.
- The organization of medical care is frequently fragmented and lacks continuity.
- Funerals are important rituals, and their cost creates enormous stress for survivors.

Source: Adapted Reference 10.

or economically disadvantaged, dying may represent freedom from the misery of living.[10]

Clinical Presentations of Advanced Disease in the Poor

Persons who are poor frequently present with advanced disease, in part related to delays in diagnosis, mistrust of healthcare systems, and late discussions of advance directives and EOL care options.[52] In addition to the late-stage disease presentation, many have significant comorbidities that affect both the palliation of symptoms and the course and treatment of underlying illnesses. These clinical management issues usually occur within the context of complex psychosocial situations, as the following case illustrates.

Case Study: Dying Poor

Mary was a 55-year-old homeless African American woman with an extensive smoking history and substance abuse disorder who was diagnosed with metastatic lung cancer during a brief hospitalization. She was discharged to a local shelter and had been scheduled to follow up with the oncology and palliative care services as an outpatient. Mary did not make it to either of these appointments. Multiple attempts were made to contact her and reschedule, but with a full voicemail inbox, there was no way to leave her messages. Contact was made with Mary's mother, who refused to relay any messages to the patient.

Mary was not seen again until she presented to the hospital for dyspnea and pain about a month later. When she was discharged the second time, social work had arranged for Mary to stay at Medical Respite, a facility that offers specialized healthcare services and temporary housing to homeless patients. With the support from Medical Respite, Mary made it to her next appointment, palliative care. Mary made it abundantly clear that her goals were to seek treatment. Her main way of coping with her illness was by avoidance. She valued direct communication but often struggled with self-regulation and was prone to emotional outbursts. Unfortunately, Mary assaulted a fellow resident at Medical Respite and was discharged back to the streets before she was able to attend her oncology appointment. Repeated attempts were made to have Mary follow-up with oncology so she could get started with treatment, but she never made it to the clinic.

Mary was intermittently living on the streets and with friends. Her drug use made it challenging for her to attend regular appointments and complicated her pain management. At one point, transitioning to inpatient hospice was discussed; this would enable Mary to have access to housing and consistent symptom management, but she declined, mostly because she valued her freedom and didn't want to give up her dog, who was not allowed in the facility.

Mary intermittently presented to palliative care but was ultimately lost to follow-up for about 6 months. During this time, Mary did her best to get her chaotic life back in order. When she re-presented to palliative care, she was very proud to share that she had independently secured a room in a SRO and was seeing a new doctor at a public health clinic who was helping to manage her pain. Mary expressed the desire to be re-engaged in care and seek cancer-directed therapies. It wasn't until after her sixth hospitalization, approximately 14 months after her initial diagnosis, that she finally started palliative immunotherapy. During restaging, it was found that Mary's disease had progressed, and she had developed brain metastases. Her oncologist was planning to share this with her at their next appointment; however Mary was urgently admitted to the hospital for esophageal stricture that required stenting. Unfortunately, while Mary was being consented for this procedure, the gastroenterologist, unaware that the patient had yet to be been informed, disclosed the fact that she now had brain metastases. Mary's fragile world crumbled. She felt like her providers had purposely misled her, further complicating her fractured relationship with the medical system.

It was during this last hospitalization that Mary's body began to decline, her respiratory status worsened, and she became delirious. Mary admitted that her body was starting to fail; "I feel I'm coming to a stage . . . I don't want to think about it. . . . My body is changing." While her oncologist hoped that she would have a good response to the immunotherapy, it was too late. Mary became bed-bound and unable to care for herself; she ultimately decided to return to her apartment for home hospice. Mary died only 1 week later, just 4 weeks after her one and only dose of immunotherapy.

For many persons who are poor or lacking adequate health insurance, access to treatment is a significant factor that influences symptom management.[53,54] For example, if an antiemetic prescribed to relieve the recurrent nausea experienced by a poor person with hepatocellular cancer is not covered on the Medicaid formulary or the person is not eligible for any drug-assistance program, then the range of medications used to manage the nausea is limited. The newest high-tech strategies or methods to control symptoms are not an option for the person who lives in a tent encampment with no access to running water or electricity. Most poor persons are institutionalized to manage uncontrolled symptoms and to provide both chronic and terminal care that cannot be managed sufficiently on the street or in the shelter.[10] The management of symptoms associated with progressive illness is further complicated by end-organ diseases, such as liver or renal disease, that may alter the pharmacokinetics of medications used to palliate symptoms.[6] Determining whether a patient is experiencing an adverse drug reaction is not easy when the person has multimorbidities, has rapidly progressive disease, is malnourished, is detached from his or her body as a coping strategy from a history of trauma, or may be continuing to use alcohol or other substances.

Comorbidities also affect the healthcare providers' ability to realistically estimate prognosis and the nature of symptoms or problems that might occur down the road. Charting the dying trajectory for the chronic progressive illness may be conceivable, but superimposing the other illnesses and injuries that the very poor live with and manage creates jagged peaks and valleys in a downward course. How quickly the life-threatening illness will progress becomes a prognostication puzzle; some persons who have been living on the street truly seem to have had nine lives. On the other hand, despite the prevalence of substance abuse among the poor, lack of attention to self-care activities cannot be assumed in all drug users. Race, class, and housing status cannot be used as surrogate predictors of who abuses drugs and alcohol or who will adhere or not adhere to treatment demands.[55,56]

Case Study: An Alcoholic Patient in Detox

Adam was in the hospital for 3 weeks detoxing from life-long alcohol abuse before he could receive treatment for his liver cancer. “I can’t not drink,” he told his team. He started drinking when he was 12 years old and self-disclosed a multisubstance suicide attempt at 16, when he found a medicine cabinet full of benzodiazepines and washed a handful down with a glass of vodka. Compared to many patients, he was relatively well-monitored, and, during a routine 3-month abdominal scan for his liver disease, his doctors saw hepatocellular carcinoma. When he came to the hospital for his radiofrequency ablation treatment, he needed to be on high doses of lorazepam to mitigate the risk that he would seize as he had in the past when he attempted to stop drinking. Following his surgery, the inpatient palliative care team was consulted because he had articulated suicidal ideations and substantial pain in his abdomen. Adam was a stocky 39-year-old Caucasian man, his arms and chest were covered in an array of mismatched tattoos, and when he smiled, he revealed a mouth full of missing teeth. “I feel like I’m in jail,” he said of being inpatient in the hospital.

Adam quickly told the inpatient palliative care team about his life. He grew up on a farm in Ohio, and he had four children he barely knew because he had been incarcerated for much of their young lives. He missed his family and the goats he grew up taking care of, and he wanted very much to reconnect with his family. He also told the inpatient team that he was in tremendous pain that was being undertreated because the team was concerned about his mental status. His capacity would wax and wane, he could rarely recall specifics of conversations from even one day prior, but his desire to reconnect with his family stayed constant.

When Adam came to the outpatient clinic, he was accompanied by staff from Medical Respite, where he was living and recovering from his treatments. He was a known entity to them, however, from his many stays at the sobering center located on one side of the building: the sobering center social worker was listed as one of his emergency contacts. He requested that his outpatient appointments be scheduled early in the morning so he could make attempts to abstain from drinking beforehand. Even with these efforts, he would frequently come to appointments intoxicated, having needed a drink to steady his nerves, and smelling of urine.

As the outpatient team continued to engage Adam about his goals, reconnecting with his family remained his top priority. He would sporadically come to his outpatient appointments, often missing them because he was rehospitalized following falls and other injuries he sustained while intoxicated. He declined substance abuse referrals, mental health treatment, and assistance with housing. Together with the sobering center social worker, many attempts were made to contact his family; ultimately, his family declined to reconnect with him.

Barriers and Challenges to Providing Palliative Care

As suggested, there are many barriers (structural or community factors) that limit access to quality palliative care for the urban poor and an equal number of challenges (individual and illness-related factors) that are common among the urban poor with advanced disease.[10]

Barriers that influence the health status of anyone living in an inner city include high rates of violent crime and drug use; marginal or substandard housing; limited public transportation; convenience stores that sell more tobacco and alcohol than fresh fruits and vegetables; environmental pollution; oversubscribed and often charity-dependent community health services, if even available; lack of pharmacies and/or restricted drug formularies; and lack of insurance or a reliable income source to meet basic needs.[14,57,58]

Challenges to providing palliative care to the urban poor with advanced disease include person-specific or illness-related factors, summarized in Table 39.3. Illness-related challenges include the prevalence of serious mental illness, addiction, and

Table 39.3 Psychosocial challenges in providing palliative care to the urban poor with serious illness

Illness related	Prevalence of concurrent mental illness and substance abuse
	Decisional incapacity; presentation with advanced disease
	Multiple comorbidities
	End-organ diseases altering pharmacodynamics
Resource challenges	Health literacy
	Family or friend caregiver availability
	Lack of/need for designated health proxy/agent in the event of decisional incapacity
	Chaotic lives that have little space for day-to-day illness demands
	Limited ongoing therapeutic relationships with health or social service providers
	Survival or addiction may overshadow illness management
	Competing role responsibilities
	Functional impairments, geographic distances, and transportation limitation compromise appointment keeping
Relationships with healthcare system or providers	Cultural history of racism, discrimination, or rejection in healthcare system
	As a result of disrespectful, rude, or dismissive interactions in past, may present as angry, avoidant, suspicious, or nonadherent with care recommendations
	Healthcare providers often have different cultural and ethnic backgrounds/worldviews
End-of-life preferences	Reluctance to relinquish aggressive medical management
	Different assumptions about optimal end-of-life care, particularly in communities of color
	Lack of advance care planning because life is experienced moment to moment
	Tendency to equate goals of care modification with abandonment or continued poor care
	Spirituality may be a hidden resource for comfort and in guiding decision-making

PTSD; multiple comorbidities including end-organ disease and other chronic diseases; and presenting for care with advanced disease that may be less responsive to disease-modifying interventions even were such therapies available. Social resource challenges include fragile support systems, health literacy concerns, need for a healthcare proxy or agent if a family member or friend is not available, and chaotic lives in which survival frequently overshadows illness management.[59–61] Relationships with healthcare providers and systems may be frayed if they do exist, and providers may come with quite different worldviews and cultural backgrounds than the person presenting for care. In general, the barriers to providing quality palliative care to this population require community level or policy interventions, while some of the challenges noted require person-centered interventions. Both levels of approaches will be discussed following a review of the evidence base for providing palliative care to the urban poor.

Research from Kayser demonstrates five regularly occurring barriers that were found when delivering palliative care to those living in inner-city communities. First, an absence of family support; second, communication barriers with healthcare professionals; third, minority stress; fourth, caregiver burden; and, finally, a lack of spiritual support.[62] *Minority stress* is described as chronically high levels of stress faced by members of stigmatized minority groups.[63] Minority stress often enhances vulnerability, leading to isolation which in turn impedes development of trust. These themes demonstrate the paramount importance of an interdisciplinary team and culturally sensitive support.

Mistrust can come from many directions. Not only can patients have inherent distrust of authority-based institutions, but healthcare providers were also found to be distrustful of the underserved population.[63] This is further supported by Håkanson, whose research found that, in addition to the barriers felt by the healthcare provider, including lack of a fixed residence, mental illness, substance abuse, difficulty adhering to treatment recommendations, and lack of follow-up, the homeless patient felt that their healthcare provider often lacked adequate understanding or respect of their circumstances and related care needs.[64]

Evidence-Based Palliative Care for the Urban Poor

The evidence base to guide palliative care for the urban poor is sparse and includes reviews, program evaluations, and research that used both descriptive and clinical trial designs. The reviews were found in textbooks and journal articles.[8,17,65] The program evaluations described shelter-based, home care palliative care programs and the impact of hospital-based palliative care consultation services on family satisfaction and do-not-resuscitate (DNR) status.[66–68] Researchers used in-depth individual and group interviews, surveys, and clinical trial approaches. Researchers explored attitudes and beliefs about EOL care[11,12,69] and barriers to palliative care among low-income cancer patients,[14] tested methods for promoting advance directive completion among this population using low-literacy versions[70] or other methods,[15] and described the experiences of the urban poor with advanced disease who were community dwelling or in a dedicated AIDS nursing home unit[9] and the hopes and concerns about care at the end of life for inpatients with serious illness at a public hospital.[13]

Of the available "evidence" evaluated, only advance care planning using a fifth-grade reading level version or other methods including one-to-one coaching or independent self-completion was of a sufficient quality to support its translation into practice.[15,69,70]

Clinical Interventions and Community/Policy-Level Approaches

Clinical Interventions: Importance of Relationships

Developing trusting therapeutic relationships is at the very heart of all clinical interventions regardless of whether the person is impoverished and marginally housed or has social and financial resources. Therapeutic relationships take on a particular salience with those facing serious illness and death. However, developing trusting relationships with persons who have experienced rejection, abandonment, or felt unwelcomed in healthcare settings requires patience and time—scarce resources in busy clinical settings. Moreover, some groups seeking medical care may value and trust relationships more highly than data-driven guidelines,[71] thus increasing the importance of patient-centered, culturally sensitive palliative care.

Multiple qualitative studies of the urban poor with serious illness have demonstrated a desire for therapeutic relationships with healthcare professionals characterized by respect, by "sitting down and listening," and by honesty and consistency.[9,13,69,72] When patients and providers come from different life experiences, the most basic principles of therapeutic communication are crucial (see Box 39.3 for suggestions). These include addressing the person formally unless given permission to use the familiarity of first names, sitting at eye level when interacting, and appreciating that the palliative care philosophy and principles guiding care approach may be quite foreign or even suspect as a means of denying care (again) or as an "ethically charged" clinical intervention.[65,71]

Davis and colleagues interviewed homeless chronically ill adults about the case management services they received to stabilize their medical conditions and social situations.[72] Four themes emerged from the interview data: (1) participants described profound isolation prior to receiving case management services, (2) caring relationships with case managers were key to the program's benefit, (3) case managers assisted participants to navigate medical and social service systems, and (4) participants perceived improved health because of the interpersonal and practical interventions. The title of the study report perhaps says it all, "Because Somebody Cared About It. That's How It Changed Things."[72]

Assessment Considerations

A comprehensive assessment by a nurse includes history of illness, treatment, comorbidities, medication, self-care abilities, symptom management, a physical examination appropriate to the presenting complaint and history, and psychosocial information that may shape EOL care options. Obtaining psychosocial information over time, rather than in a single session, is more likely to promote a therapeutic connection and to uncover a richer narrative. Admittedly, appointment follow-up difficulties often justify trying to get as much information as possible during an

Box 39.3 Helpful Suggestions when Engaging a Difficult-to-Engage Client

- Address anyone older than 40 years of age by the title of Mr. or Ms. Ask permission to be on a first-name basis.
- Do not hesitate to shake hands.
- Be prepared to meet people who are more intelligent, more perceptive, and more wounded than you expect.
- Be tolerant. How would you react if you were in that situation?
- Don't make promises you can't keep.
- Don't take it personally.
- Taking time out helps prevent burnout.
- Get to know the community.
- If you feel you have to save the human race, do it one person at a time.
- Providing material assistance (e.g., clean socks, food, hygiene kits, taxi vouchers) opens people up.
- Usually the most difficult clients are those most in need. Throw the words "noncompliant" and "nonadherent" out of your vocabulary.
- Make eye contact. If the person does not like eye contact or becomes agitated, avoid using it.
- Keep in mind that people who live intense lives may not particularly like unasked-for physical contact.
- Don't be afraid to ask "stupid" questions; patients' answers are better than your assumptions.
- Adjust your expectations and accept small victories with satisfaction.

Source: From Reference 73.

Box 39.4 Recommended Areas to Cover during the Psychosocial Assessment

- *Housing*: Where do you usually stay at night?
- *Food*: Are there times when you are hungry from not having enough to eat?
- *Transportation*: How do you get to appointments or to the hospital?
- *Income*: Are you receiving any income or benefits?
- *Preferred communication methods*: How can we get in touch with you?
- *Caregiver availability*: Is there someone you can count on when you need help?
- *Use of other resources*: Do you have a case manager, peer advocate, sponsor, or patient navigator?
- *Literacy*: Are you much of a reader? How do you like to get information about your health?
- *Spirituality*: What role does faith or religion play in your life?
- *Cultural identity*: What beliefs or practices about health and healing are important for us to incorporate into your care?
- *Safety*: Do you feel safe where you're staying?
- *Coping resources*: How have you coped in the past when dealing with challenges?
- *Substance use*: Have you used alcohol or drugs to cope? If so, what difficulties have their use presented in your life?

initial encounter. While various screening or assessment tools for specific aspects of care are available and recommended in many practice guidelines, the timing of when, or whether, to use such standardized instruments needs to be evaluated on a case-by-case basis in a population that may be more hesitant to engage in care and suspicious of how this information may be used. See Box 39.4 for suggested questions[73] to include in the psychosocial assessment.

In addition to the interpersonal interventions to engage the client in a therapeutic interaction, nurses are often required to become knowledgeable about the availability of services provided by community agencies. Are pharmacies available, what are their hours, are they willing to accept telephone orders, and what medications are kept on hand? What supportive services are available, such as food/meal programs, case management services, representative payee programs, supportive housing, and crisis mental health and substance abuse programs? What home health or hospice program serves the community, and are there any restrictions on services because of concerns related to staff safety?

Knowing which agencies or services are involved with a client and communicating with them assures consistency of approach and continuity of care. Advocacy is often required to access services such as pain management, substance abuse treatment, mental health services, and social services for housing and money management. Being a steady, knowledgeable, and dependable presence in a marginalized person's life can be a quick road to building trust and rapport.

In summary, developing therapeutic relationships with the poor and homeless requires (1) expecting the person's trust to be earned over time (sometimes a long time) and not taking it for granted; (2) respecting the person's humanity, no matter how they look, what they say, and what feelings they evoke in us; (3) appreciating the person's unique story as influencing his or her response to illness and death; and, finally, (4) recognizing and addressing maladaptive behaviors.

Providing Palliative Care to LGBTQIA Individuals

Gender presentation and sexuality are additional factors that contribute both to homelessness and to accessing palliative care. According to a 2012 Gallup poll, one in five lesbian, gay, bisexual, transgender, queer/questioning, intersex, allies (LGBTQIA) people who live alone live at or under the federal poverty level.[74] The Annual Homeless Assessment Report states that "fewer than one percent (1,770) [of homeless individuals] are transgender."[75] It is known that transgender individuals are more likely to experience homelessness than are gender-conforming individuals, as well as other more blatant and disguised forms of discrimination and oppression.[76,77]

Based on previous experiences with healthcare providers and judgment, LGBTQIA individuals can be distrustful of healthcare providers, fearing judgment of who they are, their economic and employment histories, and their partners and "chosen families."[76,78] Previous generations' experiences of marriage discrimination created challenges in allowing LGBTQIA individuals' partners to assume next-of-kin status, and although we have made national strides in the area of marriage equality, the scars of prejudice still inform the fear and mistrust some LGBTQIA individuals have of the medical system: 20% of LGBTQIA individuals report not disclosing their gender and sexuality to their healthcare providers.[76,77]

As mentioned, many homeless individuals move into institutionalized environments at the end of their lives. Due to previous stigmatization and fear of emotional retribution or abuse, some transgender homeless individuals may choose to "detransition" as opposed to living their final days in the gender they feel themselves to be.[78–80] The choice to "detransition" for safety and acceptance is personal and can be deeply destabilizing and traumatic. It reminds us of the impossible choices associated with EOL needs in marginalized populations: treatment or housing? Identity or care?

Case Study: A Transgender Patient

Adele was a 54-year-old transgender male-to-female patient with human papillomavirus-related oropharyngeal squamous cell carcinoma. She had a history of methamphetamine abuse and sex work, was extremely distrustful of medical providers, and feared physical exams. Advance care planning with her was a challenge: she was estranged from her family, had few friends and limited support, and, in her own words, "[w]hen I don't know what's coming, I bolt."

Initially, Adele sought treatment for her cancer, but she needed to stop radiation after only one session due to claustrophobia and paranoia brought on by the restraints required. Additionally, her treatment was complicated by her nutritional and mental health needs. Before receiving chemotherapy, it was clear that she needed improved nutritional status, and she was amenable to and accepting of a percutaneous endoscopic gastrostomy (PEG) tube for additional nutrition. Shortly after receiving the PEG tube, however, she had a psychotic episode, requiring full physical and pharmacological restraints. She stated that she struggled to recognize her body with the PEG tube in it. In the hospital, surgical teams were concerned about her ability to heal should she pull out the PEG tube as she said she planned to.

Ultimately, with the support of medical ethics, surgery, oncology, and medicine teams, Adele was supported in removing her PEG tube and continuing to eat by mouth. There were many other challenges along the way: she insisted she needed to leave the hospital to smoke cigarettes, receive her monthly supplemental security income check, and connect with her dog—all reasonable desires, but again underlining the emphasis placed on immediate needs versus long-term health goals.

Much effort was made to engage Adele in care. Her circle of support, largely comprising community case managers, was brought to the hospital to contextualize her experience. She was briefly placed at a long-term care institution, but left after a few weeks, absconding on a day pass and never returning. She re-presented at the county emergency department and was admitted to the hospital with complaints of both abdominal pain and difficulty breathing, requiring another prolonged hospitalization. With much effort, she obtained emergency housing at a SRO with assistance from both an outpatient hospice agency and case management services. With support of hospice, she was able to live independently, focusing on her goals and desires, and ultimately died in an inpatient hospice facility. The hospice team was unable to contact her family.

Adele's story reminds us of a variety of factors that can complicate care both for gender nonconforming and impoverished individuals, and the intersectionality of these two populations. Her articulated distrust of the medical community, shifting goals between QOL and curative cancer treatment, and emphasis on immediate needs as opposed to long-term care planning made plotting a course trajectory with her a near impossibility. Part of working with Adele meant allowing her to feel she was in control; empowering her to make choices, even ones providers did not necessarily agree with; and managing provider expectations and distress around her choices.

Program-, Community-, or Policy-Level Approaches

While there are no clinical practice guidelines developed specifically to define palliative care of the underserved, *Clinical Practice Guidelines for Quality Palliative Care* does serve as a useful framework for developing and evaluating services to meet the unique needs of these populations.[81] In particular, preferred practices addressing social aspects of care; spiritual, religious, and existential aspects of care; and cultural aspects of care can be used to shape program development and service evaluation.

Two programs designed to meet the palliative care of the poor, one home-care based program in Hawaii[66] and the other a shelter-based program in Canada,[82] documented cost savings and favorable results for other quality indicators. These may serve as models for other communities with different needs and resources to consider in program development. Additionally, palliative care services in safety net hospitals have demonstrated improved family satisfaction and increased the likelihood of patients/surrogate decision-makers agreeing to DNR status when the patient is seriously ill and unlikely to survive this intervention.[67,68]

Obviously, at policy and community levels, stable housing is critical to providing a decent QOL for any human being. Researchers noted the benefits of supportive housing to minority elders in East Harlem, including better psychological outcomes and increased use of informal supports,[83] and to persons who were chronically homeless with severe alcohol problems in Seattle, which demonstrated cost savings.[84] Housing First is a policy advocated by advocates for the homeless and by professionals caring for them as the initial step in turning around the lives and hopefully preventing the premature deaths of those who are without a home (http://www.endhomelessness.org/pages/housing_first). Advocating for housing for the urban poor and those who are homeless is as critical as advocating for preventive care, chronic disease management, symptom management, the opportunities to articulate wishes about

EOL care, spiritual care, and for mental health and addiction services. Without safe housing, the opportunities for a good enough death may not be possible.

Several scholars have argued regarding the social justice implications of palliative and EOL care. Crawley noted that within the African American community premature deaths have been associated with both individual and institutional injustices.[85,86] Racism, discrimination and health disparities, and research abuses such as the Tuskegee syphilis study have betrayed the trust of many African Americans and in part explained the determination among some to "go down fighting" rather than embrace some notion of a good death. A provocative essayist, Krakauer warned that advocating for palliative care in situations where disease-modifying therapies are standard of care for resourced communities or countries was unjust, unacceptable, and perhaps unethical.[87] His argument was based on concerns about global efforts to offer palliative care to persons suffering with cancer or HIV disease because the costs of disease therapies were exorbitant and unattainable by resource-strapped developing economies. The same argument could be made for the poor in the United States. Palliative care should not be promoted as a substitute for society's failure to provide all Americans, rich and poor alike, with their basic needs for food, clothing, shelter, education, employment, community, or promising futures. In that way, palliative care must be part of a healthcare system and social contract that includes indicators of socioeconomic well-being alongside safe environments, food and shelter, meaningful employment, support for families and communities, health promotion, disease prevention, chronic disease management, and palliative care.

Conclusion

Providing palliative care to the poor, especially the homeless, is extremely challenging. Comorbid illnesses, illnesses associated with poverty, and clarifying the etiology of presenting symptoms may seem almost impossible at times. Psychosocial risk factors and strained relationships with healthcare providers sometimes result in the client receiving futile or unwanted medical interventions at an advanced stage of illness. Clarifying with a patient what constitutes a good death for him or her can be humbling when the patient tells you he or she wants simply to have shelter and to feel safe. Meeting the palliative care needs of this underserved population will require innovative practice and education models. To truly improve EOL care for the poor, nurses need to advocate for public policies that assure access to safe and stable housing, health insurance, and client-centered, community-based primary care.

Acknowledgments

The authors would like to thank the amazing patients who have let us into their chaotic lives in the hopes of finding some semblance of respite. Your struggles have taught us so much, most importantly how to be human and honor individuals in a sometimes cold and cruel world. Additionally, we would like to thank the countless providers who have dedicated their lives to the care of the underserved; your experiences and insights have taught us all how to honor and care for those who are less fortunate. Finally, we would like to thank our families who honor our work and support us with their unconditional love.

CHAPTER 40

Palliative Care for Patients with Mental Illness

John D. Chovan and Betty D. Morgan

Key Points

- Persons with severe and persistent mental illness (SMPI) die 10–25 years prematurely, and the majority die from chronic, life-threatening physical illnesses such as cancer, heart disease, chronic obstructive pulmonary disease (COPD), and dementia.
- Enhanced communication skills with an emphasis on therapeutic communication are needed to work with patients with SPMI.
- Ethical issues, including determination of capacity and competence, may arise when working with people with SPMI. Simply having a diagnosis of an SPMI, however, does not necessarily indicate lack of capacity or competence.
- Redefinition of family may need to take place in order to include the patient's support system in his or her care.
- Consultation and collaboration are essential to care for the population of people with SPMI to meet the needs of patients and their support systems.

Introduction

Severe and persistent mental illness (SPMI) is a classification of mental disorders characterized by serious functional impairment that interfere greatly with or limits one or more major life activities, such as self-care, independent living, interpersonal relationships, and ability to work or go to school. SMPIs include recurrent major depressive disorder, bipolar disorder, thought disorders—such as schizophrenia spectrum disorders and delusional disorders—and the personality disorders. An estimated 43.4 million adults (approximately 17.9%) in the United States were living with mental illness in 2015. A smaller number of people, 9.8 million adults or approximately 4% of Americans (1 in 25) live with an SPMI.[1] Among sexual minority adults, 3.9 million Americans had a diagnosis of mental illness, 1.4 million of which (24.3%) were living with SPMI. These percentages were greater than those among sexual majority adults.[2]

Comorbidity is common; almost half of the people who are diagnosed with a mental disorder meet criteria for a second mental disorder, with mood, anxiety, and substance use disorders being the most common comorbid mental illnesses.[3] The Global Burden of Disease study presented data revealing that mental illness accounted for the largest percentage (7.4%) of all disease-adjusted life years that measure disease burden.[4]

People with SPMI reportedly die 10–25 years earlier than the general population worldwide.[5] The increase in mortality has been associated with cardiovascular and respiratory diseases, suicide, and accidental death by alcohol or other drugs.[6] Comorbid medical illnesses that are commonly observed in those with SPMI include hypertension, cardiac disease, diabetes and other metabolic conditions, respiratory illnesses, obesity, renal disease, cerebrovascular disease, and cancer.[6] Sixty percent of premature deaths in persons with schizophrenia are due to medical conditions such as cancer, heart disease, chronic obstructive pulmonary disease (COPD), and dementia.[7,8] These illnesses can be related to lifestyle factors such as tobacco use and obesity, so, in these instances, they can be viewed as preventable. Additionally, an estimated 26% of homeless adults staying in shelters live with serious mental illness.[9]

This chapter examines what is known about palliative care and persons living with mental illness, especially those with SPMI. Special issues related to communication and treatment are presented, as are strategies for care for this population. Ethical issues, including capacity and competence for decision-making as it relates to those with SPMI and end-of-life (EOL) care, are also discussed. Collaboration and consultation between providers is essential in providing palliative care for those with SPMI.

Research Related to SPMI and Palliative Care

Although the call for additional research has begun to ring a bit louder, little research has been conducted in palliative care of people with SPMI.[10] Much of the existing research has focused on identifying the increase in morbidity and mortality in this population and understanding what factors contribute to the increase. Those who have SPMI have been underserved in terms of healthcare in general and specifically palliative care.[11] Barriers to both care and research have been cited as (1) capacity of patients to make EOL decisions, (2) provider concerns that EOL discussions would be upsetting or trigger behavioral outbursts, and (3) lack of provider training and comfort in conducting difficult conversations required to assure quality EOL care.

Barriers to Care for Patients with SPMI

There are several barriers to consistent medical care for those with a mental illness; these barriers exist in primary care settings and apply to palliative care settings as well. Lack of preventive care or an ongoing relationship with a medical provider is a key issue for people with mental illness. People with SPMI often seek care later in the course of the disease, resulting in costly services and complex care needs. The inadequate support systems that are common among those with SPMI affect their ability to access medical care and navigate complex health systems. Adherence is a major problem in the treatment of people with SPMI, and adherence to medical regimens for this population is compounded by mental health and substance use issues, homelessness, or lack of transportation to get to medical providers. Lack of financial resources may complicate the patient's ability to receive timely care or treatment.[12]

Symptoms of SPMI can have profound effects on communication, which can result in problems with developing the therapeutic relationship.[13] In addition, symptoms of SPMI can have an impact on reporting of problematic symptoms or the effect of treatment on the symptoms. Trachsel et al.[14] found that a palliative approach to treating symptoms of schizophrenia may improve symptom response and decrease the risk of over- or undertreatment, thus improving outcomes for persons living with schizophrenia. Finally, stigma affects communication about all aspects of care of the medical illness, including assessment, explanation of treatment options, adherence, and the development of a trusting relationship with the patient.[13]

Severe and Persistent Mental Illnesses

SPMI includes disorders such as schizophrenia spectrum and other psychotic disorders, bipolar and related disorders, major depressive disorder, and personality disorders. Depression is described in detail in Chapter 22, but a brief discussion of schizophrenia spectrum and other psychotic disorders, bipolar and related disorders, and personality disorders will be presented here. A major feature of SPMI that can influence how these patients interact with the world around them is if psychotic symptoms are present, such as delusions and hallucinations. Psychotic symptoms, however, are not only associated with SPMI and can be seen in some patients with substance use disorders, anxiety disorders, and cognitive disorders such as dementia.[15] Treatment issues and special concerns in communication for persons with SPMI will be discussed as they relate to palliative care. The burden of SPMI is very high, so appropriate disease management will improve access to care and may reduce cost.[12]

Schizophrenia Spectrum and Other Psychotic Disorders

Schizophrenia spectrum and other psychotic disorders (schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, brief psychotic disorder, and shared psychotic disorder or *folie à deux*) are characterized by delusions, hallucinations, disorganized speech and behavior, abnormal motor behavior (including catatonia), anhedonia, amotivation, blunted affect, and reduced speech.[3] Schizophrenia affects approximately 1% of the US population. However, it accounts for 40% of mental health facility beds and 9% of all hospital beds. It is a devastating illness to those who are affected—both the patient and the family of the patient. The symptoms of schizophrenia include what are categorized as positive symptoms (exaggerated or distorted function) and negative symptoms (diminution or loss of normal function). The positive symptoms include delusions, hallucinations, and disorganized and bizarre behavior and speech, as well as deterioration of social behavior. The negative symptoms include flattened affect, decreased range and intensity of expression, anhedonia, restricted thought and speech, amotivation, apathy, and difficulty in mental focus and ability to sustain attention. Other psychotic disorders share some or all of the same symptoms and differ by degree and the occurrence of additional characteristics.[3]

The symptoms associated with schizophrenia spectrum and other psychotic disorders may also be due to medications, substances, withdrawal from substances, and delirium due to other medical conditions. Such etiologies for the presenting symptoms must always be ruled out before assuming that there is a schizophrenia spectrum disorder or other psychotic disorder present. At the end of life, people with SPMI may appear to have a worsening of their condition when the issue may really involve an acute mental status change due to delirium in addition to their underlying illness.[3,15]

Some of the more limiting symptoms of schizophrenia spectrum and other psychotic disorders that are of particular concern in palliative care settings are the ability to participate in decision-making, perceptual difficulties that can affect sensory integration and concrete thought processes, and difficulty in attention and concentration. The effect of perceptual difficulties has been demonstrated in research related to pain sensation in people with schizophrenia. Patients with schizophrenia may have reduced sensitivity to pain, and this could lead to delays in care or treatment.[16]

Treatment of Schizophrenia Spectrum and Other Psychotic Disorders

Treatment of schizophrenia spectrum and other psychotic disorders is based on symptom management.[15] As in palliative care, there is no curative treatment for SPMI and all treatment can be considered palliative in nature. A diagnosis of an SPMI in the face of a serious or life-threatening illness indicates a referral to a palliative care program either in the hospital or in the community. Pharmacological and nonpharmacological interventions are both used to treat schizophrenia spectrum and other psychotic disorders. But nonpharmacological interventions may not be effective unless interfering hallucinations or delusions are brought under some degree of control first. The patient may then be able to participate in nonpharmacological interventions.

Pharmacological Treatment

Table 40.1 lists the first-generation antipsychotics, also known as conventional or typical antipsychotics.[17] These medications, developed in the 1950s and 1960s, are very effective in treating positive symptoms, and some—but not all—of these medications have an effect on negative symptoms. The side-effect profiles of these medications, including extrapyramidal symptoms (EPS), tardive dyskinesia (TD), and anticholinergic effects, have a profound negative effect on quality of life (QOL) and medication adherence.[17] Because the schizophrenia spectrum and other psychotic disorders are characterized by disordered thinking, patients who begin to feel better with treatment may still make bad choices, often leading them to discontinue their medication.

In the 1980s, development of the second-generation or atypical antipsychotics began (Table 40.1).[17] These medications reduced both the positive and negative symptoms associated with schizophrenia spectrum and other psychotic disorders, improved cognition, and were useful in the treatment of patients whose illness was refractory to the first-generation antipsychotics. The side-effect

Table 40.1 Medications used to treat schizophrenia and other psychotic disorders: generic and brand names

First generation, conventional, or typical antipsychotics	Second generation or atypical antipsychotics
Chlorpromazine (Thorazine)	Aripiprazole (Abilify)
Fluphenazine (Prolixin)	Asenapine Maleate (Saphris)
Haloperidol (Haldol)	Clozapine (Clozaril)
Loxapine (Loxitane)	Iloperidone (Fanapt)
Molindone (Moban)	Lurasidone (Latuda)
Perphenazine (Trilafon)	Olanzapine (Zyprexa)
Pimozide (Orap)	Paliperidone (Invega)
Prochlorperazine (Compazine)	Quetiapine (Seroquel)
Thioridazine (Mellaril)	Risperidone (Risperdal)
Thiothixene (Navane)	Ziprasidone (Geodon)
Trifluoperazine (Stelazine)	Olanzapine/Fluoxetine* (Symbyax)

* combination atypical antipsychotic and SSRI

Source: From Reference 17.

profile of the second-generation drugs showed lower rates of EPS and TD and fewer anticholinergic effects. The emergence of metabolic syndrome as a side effect of the second-generation antipsychotics—including pronounced weight gain, diabetes, hyperlipidemia, and hypercholesterolemia—has resulted in the need for close monitoring of their use in treating schizophrenia spectrum and other psychotic disorders.[17] These medications result in cardiovascular problems and compound the existing higher prevalence of cardiovascular problems in people being treated for schizophrenia spectrum and other psychotic disorders.[17]

Pharmacological treatment of psychotic symptoms in conjunction with palliative care treatment should be closely monitored by consultation with psychiatric providers. Hospital protocols for certain physiological presentations immediately trigger discontinuation of oral medications. In the case of a person with a schizophrenia or other psychotic disorder, this could initiate decompensation and a relapse. The palliative care nurse knows to advocate for alternate routes for antipsychotic administration in these cases.

Any change in mental status should be immediately evaluated. Screening for the presence of delirium, both hyperactive and hypoactive delirium, which can occur frequently at the end of life, should occur with any change in mental status. The nurse should not presume that the psychiatric illness is the cause of a mental status change until a physical cause is ruled out.[15]

Several of the typical and atypical antipsychotic medications share common metabolic pathways with opioid analgesics. Inhibition or potentiation of the antipsychotic or the opioid medication is possible; therefore, close monitoring is essential.[17] When caring for persons being treated with antipsychotics in palliative care settings, the nurse must be aware of the cardiac effects of adding haloperidol to treat nausea and vomiting, which is common in palliative care, such as QTc interval prolongation.[17]

Nonpharmacological Treatments

Nonpharmacological interventions for the treatment of schizophrenia spectrum and other psychotic disorders include psychotherapeutic strategies such as supportive psychotherapy, cognitive-behavioral therapy (CBT), group therapy, skills training, and integrative therapies such as mindfulness training and relaxation.[18] Collaborative care with psychiatric providers can include additional supportive therapy to assist patients facing a terminal illness. People with SPMI face the same EOL concerns as patients without mental illness, such as dealing with pain and suffering, fear of what lies ahead, fear of becoming a burden, spiritual concerns, financial concerns, and difficulty saying goodbye.[19] People with schizophrenia or other psychotic disorders may need additional support and extra time to process medical information. This extra support is best provided by professionals who already have a relationship with the patient. The patient's psychiatric providers, therefore, should be included in discussions of treatment options in the palliative care setting.[20]

Communication and Schizophrenia Spectrum and Other Psychotic Disorders

Communication issues and special strategies are involved when providing palliative care to those with schizophrenia spectrum and other psychotic disorders. The role of stigma affects all aspects of care and communication. Patients may conceal or not report pain and other symptoms because of fear of the meaning of the symptom, self-blame, guilt, anger, or denial. As mentioned previously, mental status changes should be evaluated for a medical cause of delirium before assuming that altered perceptions or hallucinations are the result of mental disorder.

If the patient is actively delusional or hallucinating, then a safety assessment should be completed and arrangements made to keep the patient safe from harm. The content of the hallucinations or delusions can be very important. Any thoughts or hallucinations that patients express concerning the need to die or to hurt themselves or others, or the presence of command hallucinations telling them they need to die or to hurt themselves or others require immediate psychiatric consultation. Patient safety interventions, such as clearing the environment of any potentially harmful items, evaluation by emergency services (for outpatient settings), or the use of sitters or frequent observation (for inpatient settings) should be instituted until the psychiatric assessment can occur.

Maintaining a calm presence and use of a quiet tone of voice and nonthreatening demeanor and stance are important strategies when dealing with all patients who are actively psychotic. Reducing environmental stimuli, such as turning off a radio or television, will decrease distractions and help the patient focus on the immediate medical care. Because the ability to concentrate or pay attention may be affected by the mental illness, detailed explanations may be needed, with additional time allowed for the patient to process the information. Conversations focused on understanding what the patient has processed about the information may need to take place over lengthened periods of time. Patients may also tend to focus on concrete parts of the information, and it can be helpful to provide alternative ways to view the situation if a patient appears to be stuck or focused on one particular aspect of the issue. Occasionally, people with schizophrenia spectrum and other psychotic disorders may become more focused and less psychotic in the face of a life-threatening illness.

Patients with SPMI who are actively hallucinating or delusional, as well as those who may be delirious and experiencing altered perceptions, should receive explanations of all physical care to be delivered. Before touching the patient, it is important to let him or her know what is to be done because the patient might misinterpret the touch and react as if he or she is being assaulted. Patients with SPMI may have a different sense of private space and may also react to violations of personal space.

Case Study: A Patient Living with Schizophrenia

JD is a 59-year-old male patient who was diagnosed with schizophrenia 35 years ago just after leaving college, where he studied engineering. He experienced command hallucinations telling him to not take his medication and to not answer the door because "they were going to hurt him." His immigrant parents did not understand what was happening to their only child and grew weary of trying to help. JD reports that they stopped calling and visiting 20 years ago.

Early in his illness, he was stabilized on clozapine, but, over time, he developed leukopenia and severe extrapyramidal symptoms including cogwheeling, akathisia, and tardive dyskinesia that became refractory to pharmacologic treatment. The trajectory of his schizophrenia included periods of recovery interrupted by him not taking his medicine and experiencing a relapse of his symptoms. He was switched to an oral formulation of risperidone, which helped reduce the frequency of relapses, but, at times, he was not physically present to receive his regular injection. Over the course of his illness, he has alternated between being homeless, living in a group home, and living in subsidized housing when he was not hospitalized to restabilize.

JD was diagnosed several years ago with COPD related to his chronic smoking habit. He continued to smoke despite the effect on his health, and, at this diagnosis, he was linked with a community palliative care program for symptom management. Recently, he was diagnosed with stage IV lung cancer and moved to a group home for persons with severe and persistent mental illness. The interdisciplinary palliative care team met with JD and with the mental health care team to determine JD's goals of care. He reported that although he was just diagnosed with lung cancer and was offered chemotherapy, he said, "I have been taking strong, awful medications all my life. I don't want to put all that extra poison in my body." The palliative care team looked to the mental health staff for guidance, who determined that although JD had cognitive impairments due to his schizophrenia, he could make decisions for his own healthcare, even if his track record was replete with poor choices. The mental health staff at the group home were concerned that they might not be able to provide the care JD needed as the course of his life ended, but the registered nurses on his mental health treatment team advocated for him and asserted that they would support his hospice needs in collaboration with the hospice team.

This case illustrates several issues of importance:

- The capacity and the ability of patients to make their own decisions should be assumed despite diagnosis, unless there is a clear reason to suspect impaired capacity.
- Regular medical care of patients with SPMI is paramount, particularly due to side effects of pharmacotherapy and the tendency for self-medication with tobacco, alcohol, and other substances.
- Chronic severe mental illness can deplete family coping resources.
- The definition of "family" must be expanded. Nursing staff are the ones with most regular contact and can advocate for patient's wishes regarding care.
- The collaborative approach is essential, crossing palliative care and psychiatric and mental health care to assure QOL in the face of a terminal illness for persons living with SPMI.

Bipolar and Related Disorders

Bipolar and related disorders have a fluctuating course that often results in recurrent episodes of inflated mood (hypomania or mania) with or without depressed mood (depression). They include bipolar I disorder, bipolar II disorder, and cyclothymia.[3] All persons have fluctuating moods. But with bipolar and related disorders, the normal controls are out of order, and mood fluctuations swing to beyond-normal extremes. People with bipolar and related disorders frequently discontinue their medication because of unwanted side effects and because the feelings associated with hypomania may result in increased productivity, creativity, and pleasure. Bipolar and related disorders are often comorbid with other psychiatric disorders, particularly with alcohol or substance use disorders. People with bipolar and related disorders have more co-occurring medical conditions—especially cardiovascular disease and other problems related to metabolic syndrome—than those with other chronic mental illnesses.[21] As with schizophrenia spectrum disorders, episodic exacerbations of mood often affect a person's ability to function within the context of his or her role in the family and at school or on the job. The use of atypical antipsychotic medications as mood stabilizers for those with bipolar and related disorders has increased the risk of diabetes and subsequent cardiovascular disease among people with this diagnosis.[17]

Symptoms of hypomania or mania include inflated self-esteem, grandiosity, decreased need for sleep, pressured speech, flight of ideas, increase in activities, and excessive involvement in pleasurable activities that have a high potential for negative consequences.[3] Severe mania can present more with symptoms of agitation than euphoria and often includes episodes of delusions, paranoia, and hallucinations, as well. Symptoms of depression can include sleep changes (insomnia or hypersomnia); anhedonia or loss of interest in things that were formerly of interest; feelings of guilt, hopelessness, or helplessness; decreases in energy; difficulty concentrating; changes in appetite (up or down); and psychomotor changes (agitation or slowing). Suicidal feelings, ideation, or attempts can also accompany depression, so safety is of utmost importance.[3]

Treatment of Bipolar and Related Disorders

Assessment of persons with bipolar and related disorders is the first step of the nursing process. See Chapter 4 for assessment of the patient and family. Accurate assessment is of particular concern in treating disordered mood. Inaccurate assessment of depressive symptoms as a part of differentiating major depression and bipolar depression may result in initiation of antidepressant medication that could precipitate a manic episode in someone with a bipolar disorder. Additionally, people with bipolar disorders are at a higher risk for suicidal ideation than those with any other psychiatric disorder.[15]

Pharmacological Treatment

Treatment of bipolar and related disorders includes first treating any delusions or hallucinations with an atypical antipsychotic and then adding mood-stabilizing medications such as lithium

Table 40.2 Medications to treat bipolar and related disorders: generic and brand names [17]

Mood stabilizers	Calcium channel blockers
Lithium (Eskalith, Lithobid)	Verapamil (Calan)
Lithium citrate	Nifedipine (Procardia)
	Nimodipine (Nimotop)
Anticonvulsants	Benzodiazepines
Valproic acid (Depakene, Depakote)	Alprazolam (Xanax)
Lamotrigine (Lamictal)	Chlordiazepoxide (Librium)
Carbamazepine (Tegretol)	Clonazepam (Klonopin)
Gabapentin (Neurontin)	Diazepam (Valium)
Oxcarbazepine (Trileptal)	Lorazepam (Ativan)
Pregabalin (Lyrica)	Oxazepam (Serax)
Topiramate (Topamax)	Prazepam (Centrax)
Tiagabine (Gabatril)	

Source: From Reference 17.

and other drugs (Table 40.2).[17] Benzodiazepines are often used to supplement the use of antipsychotics and mood stabilizers, and antidepressants can be used in the treatment of depressive symptoms along with the mood stabilizers.[15,17]

When patients are in a manic state or a severe depression, they may lack decision-making capacity but are then often capable of making decisions when they become stable. A psychiatric provider should be a part of the palliative care team and provide close follow-up. Any medications used in treatment of the underlying medical illness should be reviewed for their potential to induce a manic episode, such as dopaminergic anti-Parkinson's medications, sympathomimetics, corticosteroids and anabolic steroids, thyroxine, and amphetamines. As with schizophrenia spectrum disorders, there are many psychotherapeutic interventions that are used in the treatment of people with bipolar and related disorders. Patients frequently need to be stabilized with medications first, however, before these treatments can be used effectively.

Nonpharmacological Treatment

A variety of psychotherapies have been used with bipolar and related disorders; most often therapies are used in conjunction with psychopharmacological interventions once active mania has stabilized. Interpersonal therapy and CBT are two of the most widely used therapies with these disorders. Patient and family education is essential, as is social and coping skills training.[15] The application of integrative therapies in treating bipolar and related disorders, such as mindfulness training and the use of SAMe and omega-3 fatty acids, has been recorded, but their helpfulness has not been demonstrated.[22]

Communication Issues and Bipolar and Related Disorders

Communicating with someone during a manic episode can be difficult because patients may be emotionally labile and very talkative (with pressured speech), may not be able to stop and listen or concentrate, and often reject help.[3] Patients can be quite charming and even entertaining during some early stages of a manic episode. Staff members need to see these presentations as a part of the illness and not join in grandiose discussions or plans. Patients may need to be gently redirected so that they do not go off on tangents unrelated to the medical issue at hand. They may also need firm but caring limits set on behaviors that might affect others' care, such as wandering into other patients' rooms, becoming inappropriately involved in others' care, and intruding on staff conversations with other patients. Assisting patients in calming behaviors such as sitting quietly with the patient or closing the door to the room to decrease external stimuli are strategies that may be helpful. Inclusion of the psychiatric provider in the team will allow for communication of information about the best approach to take with an individual with a bipolar disorder.[13]

Often, one of the first symptoms of a manic episode is the decreased need for sleep.[15] Early reporting of changes in sleep habits is important because it is easier to help someone regain stability early during a manic episode. If the patient is beginning to exhibit signs of mania or psychosis, then assessment of safety issues and the potential for suicide must be considered. The importance of early intervention in escalating symptoms and good interteam communication cannot be emphasized enough when caring for someone with a bipolar or related disorder.

Case Study: A Person Living with Bipolar I Disorder

CA is a 40-year-old single African American female patient with a long-term diagnosis of bipolar I disorder. The course of her illness has been very difficult, punctuated by multiple hospitalizations after attempting suicide. As a patient of a community mental health service, she is seen by a psychiatric and mental health nurse practitioner (PMHNP) in the clinic, has an outreach registered nurse who follows up with her at home, and has a case manager who assists with getting to appointments and linking to community support services, including food banks, housing, and Medicaid. She takes lithium carbonate and valproic acid for mood stabilization. CA lives in an apartment that is paid for by her younger sister and who has been able to secure legal guardianship over CA's person and finances through the courts.

CA was obese, had metabolic syndrome, and had congestive heart failure. Her sister did not want to think about her sister being terminally ill, so she encouraged her to "get healthy, eat better, and exercise." Despite her frequent suicidal thoughts and previous attempts, CA said that she wanted to live and was determined to enjoy the time she had left with her sister and her sister's children. "I don't want to change a thing and I want to enjoy my life while I can." CA's sister took issue with this, but the palliative care team agreed to continue to work with CA and her symptoms, trying to keep her out of the hospital; subsequently CA's sister completed the paperwork to enroll her in hospice.

This case highlights several factors that are important in the palliative care of patients with mental illness:

- Some patients with suicidal histories may put suicidal tendencies aside in the face of a terminal illness and fight to live, in a different way than their history would indicate, as long as their QOL is satisfactory.
- Families may be in a crisis when encountering an unexpected medical illness in the context of a severe and persistent mental illness.

Personality Disorders and Palliative Care

People with personality disorders (PDs) can present major challenges for palliative care providers, in part because of the maladaptive coping strategies used in light of the associated personality traits and in part because of the stigma associated with PDs.[15] Personality traits are enduring patterns of perceiving, relating to, and thinking about the world and how one relates to it.[3] The enduring patterns of response and behavior deviate from social norms and present in the areas of:

- *Cognition*: Ways of perceiving self, others, events
- *Affectivity*: Range, intensity, lability, appropriateness
- *Interpersonal functioning*
- *Impulse control*

There is a lack of flexibility and also maladaptive behavior that can cause impairment in function and distress for the person and those with whom the person interacts.[3]

All humans have vulnerabilities that are accentuated when the person is under stress. Approaching personality traits as vulnerabilities that are accentuated by stress and that therefore result in the use of predictable coping mechanisms can be a useful way to change stigmatized attitudes toward people with PDs. It is important to identify traits or vulnerabilities and move beyond labels so that treatment can be geared to preparing for the expected response and minimizing maladaptive coping mechanisms and replacing them with more functional coping mechanisms.

In the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), personality disorders are grouped into three clusters based on some descriptive similarities.[3] Cluster A PDs include paranoid PD, schizoid PD, and schizotypal PD. People with Cluster A disorders often appear odd, eccentric, or paranoid. People with paranoid PD have a pervasive distrust and suspiciousness of others. The person will be reluctant to trust or confide in anyone and may suspect that others are trying to cause him or her harm.[3] The person with schizoid PD has a pervasive pattern of detachment from relationships, even with family. This person prefers solitary activities, lacks close relationships, and may be emotionally detached or have a flat affect.[3] People with schizotypal PD are uncomfortable with close relationships and have cognitive distortions, including ideas of reference, odd beliefs or magical thinking, unusual perceptions, odd thinking and speech, inappropriate affect, and social anxiety.[3]

Cluster B PDs include antisocial PD, borderline PD (BPD), histrionic PD, and narcissistic PD. People with this group of PDs often appear dramatic, emotional, or erratic, and it is this cluster that often presents the biggest challenge to healthcare providers. The person with antisocial PD has a pervasive disregard for and often violates the rights of others. They fail to conform to most social norms and can be impulsive, irritable, and aggressive at times.[3] People with BPD have a lifelong pattern of instability in interpersonal relationships and self-image and either idealize or devalue others, or fluctuate between these two views of the same person. People with BPD are impulsive in ways that are damaging to themselves and frequently have recurrent suicidal behavior. They have a chronic feeling of emptiness and therefore constantly seek attention and contact with others to fill themselves.[3] People with histrionic PD have a pattern of excessive emotionality and attention-seeking and can be inappropriately provocative or sexually seductive. People with these traits are easily influenced by others and often consider relationships to be more intimate than they actually are.[3] People with narcissistic PD need admiration, have a lack empathy for others, and have a sense of entitlement.[3]

Cluster C PDs include avoidant PD, dependent PD, and obsessive-compulsive PD. These disorders share anxiety and fear as their major characteristics. The person with avoidant PD is hypersensitive to negative evaluation, has feelings of inadequacy, and is severely restrained in relationships. This person is reluctant to take personal risks or engage in new activities.[3] Someone with dependent PD has an excessive need to be taken care of that exhibits itself by submissive and clinging behavior and fear of separation. People with this PD have difficulty making decisions and need a lot of advice and reassurance from others. They have difficulty expressing disagreement with others because of fear of loss of support.[3] Obsessive-compulsive PD is evidenced by a preoccupation with orderliness, perfectionism, and control. The person with obsessive-compulsive PD shows perfectionism that interferes with completion of tasks, is inflexible and overly conscientious, may be unable to throw out useless objects, and is miserly toward spending on self and others. This person may be quite rigid and stubborn in thought and behavior.[3]

Treatment of Personality Disorders

By description, PDs are enduring patterns and, therefore, are not likely to change rapidly. Current evidence does suggest that people with PDs can be treated, but realistic goals must be established for treatment. Symptom management and specific therapies such as CBT and dialectical behavioral therapy (DBT) have demonstrated effectiveness with specific PDs.[18] A relationship with a psychiatric provider is a primary tool in the treatment of people with PDs. There is no medication with a US Food and Drug Administration (FDA) indication for treatment for personality disorders. Comorbid psychiatric conditions are common with PD, so symptom management of anxiety, depression, and other psychiatric symptoms is important to improve QOL.[18]

Communication Issues and Personality Disorders

Some general principles related to communication with patients with PDs include:

- Provide clear information verbally and in writing, with repeated discussions about the information to help with distortions and misinterpretation that are common in people with PDs.
- A calm and nonjudgmental approach is also the cornerstone of good communication in the process of developing a therapeutic relationship with patients.
- All discussion of suicidal ideation should be taken very seriously and a thorough psychiatric assessment should be performed, even when repeated threats of suicide occur.
- The therapeutic alliance may take a long time to develop, but nonetheless the development of this alliance is a goal for treatment.
- The techniques of CBT are helpful for people with PD to examine maladaptive ways of viewing their environment.
- Supportive therapy is useful in helping people with PD adjust to the issues that arise in palliative and EOL care.

Obstacles to therapeutic communication that occur with people with PDs include issues such as resistance, transference, countertransference, and boundary violations.[15]

- *Resistance* is often unconscious and is usually employed by patients to avoid anxiety.
- *Transference* is an emotional reaction of the patient toward the healthcare provider in which the patient unconsciously transfers feelings or attitudes from someone in their personal life onto the healthcare provider.
- *Countertransference* is the emotional reaction of the healthcare provider toward the patient in which the healthcare provider unconsciously transfers feelings or attitudes from someone in their personal life onto the patient. When the provider feels a gut response toward the patient, countertransference is occurring and one's feelings must be checked in support of the therapeutic relationship.
- *Boundary violations* occur when one party—the patient or the healthcare provider—breaks down the professional curtain of the therapeutic relationship and enters into a more social relationship. This confounds roles and causes confusion, which is not therapeutic. The healthcare provider is charged with maintaining professional boundaries and to cueing the patient when he or she has violated boundaries with them or with others.

Communication issues with patients diagnosed with Cluster A disorders arise from distrust, suspicion, and withdrawal from personal interactions. Thus, therapeutic communication focuses on establishing and maintaining the therapeutic relationship. Presenting a nonthreatening approach and allowing the patient to engage with the provider at his or her own speed is very important. The intensity of a one-to-one conversation may be difficult for those with Cluster A PDs. Focusing conversation on an external issue or task, therefore, may be a helpful way to lessen the intensity.

Communication issues with people diagnosed with Cluster B disorders are often the most problematic for healthcare providers. People with these disorders tend to have an increased risk of suicide, violence toward others, and self-mutilating behaviors as well as chronic low self-esteem, ineffective coping, and impaired social interactions. Volatile changes in emotion as well as splitting behaviors—attempts to cause a rift between others so that the patient becomes the focus of the attention of those they have broken apart, such as the nursing staff—are characteristic of BPD. Development of a consistent approach will minimize the patient's ability to split staff and minimize the heightened feelings that can arise in caring for this population.

Providers should be alert for their own countertransference reactions toward patients with PD, which happens not infrequently. Patients with PD can evoke strong reactions from staff that may interfere with delivery of quality care. Staff support in working through these reactions so that care is not affected can be provided through consultative relationships with psychiatric providers. Many advanced practice psychiatric registered nurses (PMH-APRNs) have experience with staff support groups to handle such issues.

Communication issues with people diagnosed with Cluster C disorders also focus on the development of a therapeutic relationship geared toward assisting patients in identifying their fears and anxiety as it relates to palliative care treatment. Helping people identify their anxiety, decrease their maladaptive responses to anxiety, and increase their supportive relationships with others are essential issues in dealing with people with Cluster C diagnoses.

Case Study: A Person Living with Borderline Personality Disorder

LG is a 44-year-old single Caucasian female patient diagnosed with breast cancer with metastases to the brain and spine that has progressed to stage IV. She lives at home with her three late-teen daughters, their combined four children, and two of the four baby-daddies. She is enrolled in her third hospice program in the past year, having "fired" the previous two hospice programs because "they weren't taking care of me." One of the nurses from the first hospice program, BB RN, resigned because of this "difficult patient." When BB RN found that LG was later enrolled in the hospice program at which she was newly employed, she told everyone on the staff about her previous experiences with LG.

When the nurses came to LG's home, LG frequently was not home. Her daughters did not know where she was or when she would be back home, thus making scheduling visits difficult. When she was there, she would talk about the other nurses who were seeing her and tell today's nurse that he or she "was my favorite." When the nurses checked on her medication packets, medicines were missing and not recorded in the log. LG would call the triage nurse during the night "just to talk" and then complain profusely to the nurse manager that the triage nurse was not taking care of her pain. She demanded a direct phone number to call the nurse manager at any time day or night so she would have her needs met. LG would also call 911 and demand to be taken to the hospital for inpatient hospice because her symptoms were "out of control."

The team of hospice nurses were exasperated during team meetings and complained when they saw LG on their census. BB RN would incite uneasiness by regaling the team with stories from her previous place of employment. The nurse manager reprimanded BB RN for violating privacy policy in regard to this patient and wrote her up. He then asked the team to please try to be more patient with LG and to make sure they talked about things the patient was telling each one to minimize internal discontent.

On one visit, the RN noticed that LG was not her usual self. She was lying in bed and moaning, saying that she was in terrible pain and was not able to catch her breath. She had not slept at all the night before and said her pain was "10 or more" out of 10. The RN, following protocol, gave her a dose of her pain medicine, which improved her pain to "an 8" and called the triage nurse to facilitate transport to the hospital. Before transport arrived, LG said to the nurse, "I know I'm dying! I don't want to die! I'm too young to die! Please don't let me die!"

LG was admitted to the inpatient unit and the interdisciplinary team invited a psychiatric service to participate in care planning. The hospice nurse manager also established a round-table discussion for the outpatient RNs to process their experiences with LG and to assure that all patients, regardless of their diagnosis, were treated with dignity and respect.

This case highlights several factors in the care of people with personality disorders:

- The labeling of those with personality disorders as "difficult patients" can result in stigma and less than optimal care unless someone is able to be a role model in terms of providing the best care possible for the patient.
- Each encounter with patients with PD may be quite different.

- Identifying maladaptive coping mechanisms may help staff understand patient behavior and assist them in developing a nonjudgmental approach to the patient.
- Allowing time for staff to vent and examine their reactions to and feelings about dealing with patients who upset them can help nurses improve care to patients with PD.

Ethical Issues

Several ethical issues related to the care of people with mental illness, especially SPMI, in palliative care require consideration over and above the consideration given to people without mental illness. Care of vulnerable populations such as those with mental illness carries a greater obligation for nurses to provide advocacy and protection from violation of the patient's autonomy and right to make decisions about care.

Right to Refuse Medication

In the 1970s, psychiatric patients filed lawsuits related to their rights to refuse medication. Legal decisions in Massachusetts and New York, the states where the most prominent cases were filed, resulted in different approaches to the problem. The 1983 decision of *Rogers v. Commissioner of Department of Mental Health* (390 Mass 489) (1983) decreed that if a psychiatric patient refuses to take an antipsychotic and the patient is determined to be incompetent, a guardian must be appointed to implement the use of the psychiatric medication in question as determined by the judge. The concept of substituted judgment—that is, what the person would consent to if he or she were competent—is how the judge evaluated the question of whether to give the guardian the right to overrule the patient's right to refuse medication.[23] Other states have panels, independent consultants, or psychiatric care providers to make the decision about the right to refuse medication. The nurse must understand what his or her state nurse practice act says about the right of patients to refuse medication to provide safe, effective, and appropriate care to their patients with mental illness.

Advance Directives

The ability of a patient to document decisions about psychiatric care in the future is available, but not widely used. The palliative care nurse will know to ask patients with psychiatric diagnoses for these documents. The National Resource Center for Psychiatric Advance Directives (http://www.nrc-pad.org/state-by-state) has a directory of resources for professionals in each state with a psychiatric advance directive statute (currently, these are Arizona, Hawaii, Idaho, Illinois, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Montana, New Mexico, North Carolina, Ohio, Oklahoma, Oregon, Pennsylvania, South Dakota, Tennessee, Texas, Utah, and Washington). Providing a patient with the opportunity to discuss his or her wishes in advance has assisted with decreasing the need to have a legal competency hearing to determine a course of treatment during a crisis. Including a discussion of the patient's wishes for EOL care, however, needs additional research. Current evidence has indicated a low rate of advance directives for either psychiatric care or medical care in patients with SPMI.[24]

Capacity and Competence

The right of the patient to make decisions about goals of care and care planning is a cornerstone of palliative care. Controversy can occur when a person loses the ability to participate in informed decision-making about their healthcare or when a person refuses life-sustaining treatments.[25] A general rule is that all persons with the ability to make their own decisions have the right to make their own decisions, even when decisions conflict with what a majority would decide under similar circumstances. When the patient is a person who has a psychiatric disorder that affects cognition and judgment, the ability to make decisions may be compromised by their impairment. However, having a diagnosis of a mental illness, even one with cognitive impairment, does not automatically mean that a person does not have the ability to make his or her own decisions. When healthcare decisions must be made with or without advance directives, and the ability of the patient to make his or her own decisions is in question, then a psychiatric evaluation must be requested to determine the patient's ability to make healthcare decisions. If the answer confirms that the patient does not have capacity and advance directives had already been prepared, then these advance directives are followed.

The word "capacity" means the ability to understand the problem and make decisions. A psychiatric provider makes a clinical assessment of the patient's ability to function in certain areas. "Competence," however, is a legal term and is decided by a court of law based on the capacity assessment of a psychiatric provider and other data points. Competence is usually confined to a specific area or task, such as the ability to make a will, the ability to testify in court, the right to make the decision to leave the hospital, or the right to refuse treatment. In general, four criteria are used to determine capacity to consent to treatment:[26]

- Does the patient express a preference?
- Does the patient understand the illness, the prognosis with and without treatment, and the risks and benefits of the treatment (also known as factual understanding)?
- Does the patient appreciate the significance of the facts?
- Can the patient use the information in a rational way to reach a decision in a logical manner (also known as rationality of the thought processes)?

When all four questions are answered in the affirmative, the patient has capacity to consent to treatment.

Intense pain, depression, delirium, dementia, and psychosis are the most common causes of incompetence. The existence of one of these conditions, however, does not necessarily mean that a person is incompetent. Careful assessment of each individual is necessary to determine capacity and competence. A patient is not deemed competent or incompetent until a court of law rules. Once a determination of incompetence is made, a guardian is typically assigned to make decisions on behalf of the patient.[24]

Aggression and SPMI

Patients enter healthcare systems in great distress, and palliative care settings are no exception. When the patient has an SPMI, the distress may be even greater than in the general population because people with SPMI may have inadequate coping resources and are in a crisis state when dealing with a life-threatening illness. Most often, people become aggressive when they feel threatened in some way. The aggressive behavior may be the result of perceptual problems, such as hallucinations or delusions, and the aggressive behavior often masks a lack of confidence in self. Aggressive behavior may be a way to enhance self-esteem by overpowering others.[15]

There are some important predictors of aggressive behavior, including impulsivity, hostility, family history of violent or abusive behavior, substance use, and irritability.[15] Prevention of aggressive behavior focuses on early recognition of escalating behaviors, such as pacing, nonverbal expressions, yelling, or an angry tone of voice. Allowing the person a chance to talk may defuse the situation. The use of nonthreatening body language is imperative, as is communicating with a calm but firm voice while conveying respect for the patient and the patient's feelings. Allowing the patient some choice about the situation is often a way to help the patient gain some control.

Communication Issues and SPMI

One hallmark of both palliative care and psychiatric care is the importance of communication to establish and maintain a trusting, therapeutic relationship between the nurse and the patient. Traditionally, psychiatric providers are not comfortable with medically ill patients and medical providers are not comfortable with psychiatrically ill patients. Additionally, many people with mental illness are housed in nontraditional settings. Staff in any of these settings, including medical hospital units, palliative care units, or psychiatric units, as well as homeless shelters, prisons, and nursing homes, may be ill-equipped to deal with psychiatric problems and terminal illness. Education of all staff about mental illness and EOL care in these settings will result in better care for patients with SPMI.

Family Issues

For many people with SPMI, the ties with family members are strained, distant, or nonexistent. Some of this disconnection may be the result of years of strain, disappointment, financial burden, and fear caused by threatening behavior. Families of patients with SPMI may also have their own mental health issues and may use defensive strategies such as denial or anger in dealing with medical problems. Additionally, family members may have been dealing with chronic sorrow related to the mental health issues of the family member, may be overprotective, and may be psychologically fatigued due to years of care-taking responsibilities. Careful assessment of family functioning in these situations may be beyond the scope of the hospice and palliative care nurse and may require consultation with psychiatric providers.

When the patient is competent and there is discord in the family, conflict may arise if providers are restricted about the information they can give to the family due to the provisions in the Health Insurance Portability and Accountability Act of 1996 (HIPAA) or when the patient refuses to include family in healthcare discussions. A family member who has been the caregiver for the patient for years and is then shut out from information about the medical illness and treatment options may respond with anger and frustration. Family meetings may be of help in these situations; if there has been an involved psychiatric provider, this person should be included in the meetings. If there has been no psychiatric provider, then consultation with a psychiatric provider prior to a family meeting may be useful. Finding out which supportive services, if any, have helped the family in dealing with the mental health issues is vital. Groups such as the National Alliance on Mental Illness (NAMI, www.nami.org) have been a tremendous support to families with a member with a mental illness. NAMI also runs support groups for family members, and families may have established connections with these groups; if so, they should be encouraged to increase their participation in these groups. These NAMI groups may not be focused on EOL issues, but they are familiar with many of the ethical/legal aspects of caring for someone with a mental illness and may be more appropriate than a support group for families focused only on EOL issues. As with any patient and family, careful assessment will be key in developing the best treatment approach for the individual and their family.

Many people with SPMI are cared for by state governments, and long-term relationships with psychiatric providers or staff of mental health housing programs may have become a substitute for family. The inclusion of these staff into the palliative care team is essential to ensuring that the treatment will be properly performed and for providing the day-to-day intensive support that may be required for the patient. Like family, staff will also have their own particular needs for support because most psychiatric providers do not have EOL care experience or education. Fellow patients with SPMI make up the other component of family that needs to be considered in palliative care of people with SPMI. Occasionally, long-term relationships with other people with SPMI are the most significant relationships in the person's life. Special needs for support should be considered for this group of people as well. Although palliative care staff may not be involved in delivering this support, collaborative partnerships with psychiatric providers should be available to provide support for this group of people.

Conclusion

Palliative care providers often feel poorly prepared to deal with people with SPMI. Conversely, psychiatric providers feel poorly prepared to deal with medical care and palliative care, particularly at end of life. Efforts are being made to include more palliative care information in educational preparation programs, such as the American Nurses Association's End-of-Life Nursing Education Consortium (ELNEC; www.aacnnursing.org/ELNEC). Collaborative partnerships are key to enhancing the care given to people with SPMI who need palliative care services. Care delivery sites need to be examined for the optimal situation to provide both palliative care and treatment in an environment that also can provide optimal support and treatment by psychiatric providers. If the patient prefers a place to receive EOL care, all attempts possible can be made to address this preference. If the person considers a group home to be their home, and they desire to die at home, providing EOL care in that setting should be discussed just as it would be with a person wanting to die in a private home. Nurses have often been instrumental in making this kind of care possible in a situation that has not previously involved this level of care. As strong advocates for their patients, nurses have found a way to insert themselves into new arenas of care and have developed new collaborative partnerships for the ultimate benefit of their patients. For example, Chovan[27] has proposed a crosswalk of collaboration between psychiatric nursing and palliative care nursing that emphasizes the similarities and differences to assist nurses and nurse educators to prepare tomorrow's workforce. Collaboration between psychiatric providers and palliative care providers is an emerging area in which nurses can lead the way to ultimately provide new skills for each other and meaningful palliative care experiences for people living with SPMI and their families.

CHAPTER 41

Palliative Care for People Living with HIV

Jacquelyn Slomka

Key Points

- Over more than three decades, HIV has evolved from a terminal illness to a manageable chronic illness.
- People living with HIV (PLWH), especially those who are developing additional chronic diseases as they age, can benefit from early palliative care.
- In assessing PLWH for palliative care services, clinicians should be aware of the association of HIV with mental health issues and substance use.
- Perceptions of stigma associated with HIV/AIDS and marginalized lifestyles may interfere with effective care of PLWH.
- PLWH may be wary of advance care planning discussions because of the historic association of palliative care, hospice, and death prior to the extraordinary advances in treatment for HIV.

Introduction

People living with human immunodeficiency virus (HIV) present unique challenges for the provision of palliative care due, in part, to the nature of HIV infection and its medical and social history. Since the virus was identified more than three decades ago, the world has witnessed a remarkable evolution of a (then) newly emerged disease condition and its eventual clinical control. At its onset, HIV was a mysterious infection, associated first with gay men and not amenable to treatment with traditional antibiotics.[1,2] Individuals who contracted HIV in this early period most often experienced progression to acquired immunodeficiency syndrome (AIDS), with inevitable death. The spread of HIV and its progression to AIDS created a pandemic affecting people of all ages.[1,2]

Scientists learned that HIV infection was caused by a type of virus called a “retrovirus” which attacked the body’s immune system, causing a deficiency of CD4 (T) cells that allowed opportunistic infections and certain cancers to occur.[1,2] AIDS is generally defined as severe progression of HIV infection or as the presence of a CD4 count of less than 250.[1,2] The virus is spread through certain body fluids; risk of transmission was higher with certain activities such as sexual behaviors and injection drug use.[2] Over time, little progress was made in producing a vaccine to prevent HIV. But advances in drug treatments were made, and the deadly epidemic was transformed into a manageable chronic disease. Still without an effective vaccine, prevention efforts in recent years have focused on the use of pharmacological agents for pre- and postexposure prophylaxis.[3] As further evidence of the evolution of this once-deadly infection into a controllable chronic condition, the Center for Disease Control and Prevention (CDC) reported that studies now show viral suppression (i.e., reducing the levels of HIV in the blood and body to a very low or undetectable level) is the best way for PLWH to maintain health and prevent HIV transmission.[3,4,5]

HIV may not evoke the fear that it once did in the past, but it still remains a significant public health threat. The CDC estimates that 1.1 million people in the United States are living with HIV and that 1 in 7 individuals are not aware they are infected.[6,7] Although the CDC estimated that the number of HIV diagnoses decreased by 5% between 2011 and 2015, a reported 39,782 individuals were newly diagnosed in 2016.[6] According to the CDC, the largest number of diagnoses were among gay and bisexual men (26,570, 67%), varying by ethnicity: African American (10,223, 38%), Hispanic/Latino (7,425, 28%), and white (7,390, 28%). Twenty-four percent (9,578) of diagnoses were due to heterosexual contact; 19% (7,529) of women received diagnoses, with infection primarily due to heterosexual contact (6,541, 87%) and injection drug use (939, 12%). Overall, 9% (3,425) of HIV diagnoses were attributed to injection drug use.[6] The epidemiology of HIV transmission has changed over time, and infection rates are higher among young people, aged 20–29, who represented 37% (14,740) of individuals diagnosed in 2016. Disparities in HIV prevalence and treatment exist, with African American populations bearing a disproportionate HIV disease burden relative to Hispanic/Latino and white populations.[6]

HIV affects all organs of the body, and PLWH still die from HIV/AIDS. However, we know that today, with increasing survival rates, PLWH are more likely to die from non–AIDS-defining conditions (i.e., non-HIV/AIDS illness) than from HIV/AIDS. Although any chronic, potentially life-threatening illness is challenging for the individual, HIV may lead to additional stresses due to its social stigma. HIV infection has no social, economic, ethnic, or class boundaries, but perceived associations with marginalized or low-income life styles and fears of a potentially life-threatening condition may add stigma and additional stressors for the patient with HIV.

As with other chronic conditions, palliative care provides comprehensive treatment of the physical, psychological, and spiritual aspects of illness and management of symptoms. Ideally, palliative care begins at diagnosis of a chronic illness and continues throughout the trajectory of the disease.[8] This chapter identifies directions for the provision of palliative care for PLWH, beginning with identification of the need for palliative care, followed by potential interventions in various phases of coping with HIV. The focus will be limited to palliative care needs within the psychosocial context of HIV. Information on current medical treatment and prevention of HIV is constantly being updated as new research findings become available. Palliative care nurses who plan to work with PLWH are encouraged to enhance their familiarity with HIV and its clinical aspects, history, and current therapies through a variety of resources available to professionals and the public

The Need for Palliative Care in HIV

In the early epidemic, the trajectory of HIV/AIDS most often ended in palliative care, hospice, and death. By the early to mid-1990s, major developments in antiretroviral therapy (ART) had begun the transformation of HIV/AIDS into a controllable medical condition.[1] Pharmaceutical developments did not occur in isolation but were affected by patient activism leading to changes in the conduct of clinical trials to speed drug development.[9] PLWH who may have experienced and survived the terrors and uncertainties of the early HIV/AIDS epidemic may find themselves today facing other chronic diseases of aging.[10–12]

Among the current challenges of HIV is its chronicity and association with other comorbidities resulting in higher risk of mortality and increased symptom burden.[7] Studies have shown that, even with effective medical treatment, PLWH continue to experience both physical and psychological symptoms.[13,14] PLWH may benefit greatly from palliative care from initial diagnosis and throughout disease progression. In a review article focused on identifying palliative care needs from the beginning of recognized HIV illness, Simms and colleagues[15] evaluated and reviewed 34 studies of individuals diagnosed within their first 6 months. The authors chose this time period because of its common usage in research studies that support clinically observed differences between newly diagnosed and those diagnosed longer than 6 months ago.[15] Although studies varied in design, aims, sample size, world geographic area, income level of country, and quality of methodology, these authors were able to identify commonalities in palliative care needs in the early HIV diagnosis period. Key findings were that symptoms were prevalent at initial diagnosis in all dimensions of palliative care needs, including psychological and emotional distress, spiritual well-being, and physical symptoms such as pain, fatigue, itching, and weight loss.[15] These authors concluded that palliative care needs are present and manageable beginning with the diagnosis of HIV but may be overlooked by clinicians. They recommended patient-centered, multidimensional assessment, with early referral to palliative care specialists.[15]

A number of observational studies in a variety of settings in the United States and Canada have documented the needs of PLWH at mid- and late stages of disease, and these show a similarity to the needs of individuals at an early stage of illness. At one large HIV outpatient clinic, researchers noted that patients usually were referred to palliative care when the primary clinician could no longer manage the patients' symptoms.[16] Multidrug-resistant AIDS infection, AIDS-related dementia, progressive loss of function, and uncontrolled symptoms were major reasons for referral, leading the authors to conclude that better integration of primary care, palliative care, and mental health and substance abuse services could improve the care of PLWH.[16] These study findings document the complex needs of PLWH and support a growing advocacy for referral of PLWH to palliative care earlier in the disease trajectory.[16,17]

Others also have noted the greater need for multidisciplinary care and the higher illness burden sustained by PLWH as they reach the later stage of chronicity. Data from one study showed that physical, social, and mental health functioning were important to PLWH but were impacted by disease burden.[18] As PLWH grow older, a greater disease burden leads to lower quality of life (QOL) for individuals.[18,19] Caring for PLWH throughout the disease trajectory involves an understanding of complex interactions of physical and mental health, including cognitive disorders and substance use, as well as social factors (e.g., housing instability resulting from unresolved psychological issues) associated with HIV.[20] Furthermore, the high association of HIV, substance use, and mental health disorders, the so-called *triple diagnosis*, has been well-recognized in the literature.[21] Assessment of substance use and mental health should be a part of the complete assessment of PLWH.

While palliative care nurses alone cannot address all of the complex issues involved in caring for PLWH, they can serve as valuable members of the interdisciplinary team, primarily in the area of symptom management. Palliative care expertise is especially valuable in the management of chronic pain because primary care physicians may be reluctant to treat pain adequately in individuals with a psychiatric or substance use history.[22] In their description of an HIV palliative care clinic embedded within an HIV primary care clinic, Perry and colleagues noted that of 124 first-time admissions to the HIV palliative care clinic, 91% were referred for chronic pain, more than one-third had depression or anxiety, and more than one-half had a history of substance abuse.[22] A history of substance abuse is a risk factor in PLWH for unrelieved pain.[23] Pain is a frequently reported symptom among PLWH, and better systematic assessment and treatment of pain by clinicians is needed.[24] All clinicians should become familiar with the latest guidelines for management of chronic pain in PLWH.[25] These guidelines provide evidence-based recommendations for treatment of chronic pain in PLWH in a variety of patient situations (see Table 41.1).

Table 41.1 Management of chronic pain in people with HIV: Summary of content of guidelines

Screening, initial assessment, general approaches to management, and management approaches at end of life (I, II, III)
Nonpharmacological treatments (IV)
Pharmacological treatments for chronic neuropathic and non-neuropathic pain (V)
Opioid treatment for chronic non-neuropathic pain; assessing potential negative consequences; safeguards, and minimizing adverse effects of opioids (VI, VII, VIII, IX)
Prescribing controlled substances in the presence of a history of substance abuse; management of individuals undergoing pharmacological treatments for opioid use disorder (X, XI, XII)
Instruments for mental health screening (XIII)

Another important type of symptom cluster prevalent in PLWH is that of HIV-associated neurocognitive disorders, also referred to as "HAND." A pathological feature of HIV infection is the potential for cognitive impairment. Tedaldi and colleagues[26] reviewed the relationships among HIV infection, cognitive impairment, and physical and social comorbidities. They noted that cognitive impairment in PLWH can be due to many overlapping causes, both physical and psychosocial. Examples of physical effects on impairment include the HIV disease process, effects of medications, cardiovascular disease, hepatitis C virus (HCV) coinfection, sleep disorders, illicit drug use, depression and other mental illness, and the aging process.[26] The authors also describe possible systemic inflammation, biomarker, and cellular level factors that may be associated with HIV cognitive impairment. They note that social factors related to the physical assessment of HAND may include poverty and low literacy if the individual comes from a disadvantaged educational background. Having a low-income or marginalized lifestyle and exposure to trauma often related to poverty may lessen an individual's resilience and add to physically adverse effects on cognition.[26] The palliative care nurse should be aware of the potential for cognitive disorders in PLWH and their impact on the comprehensive care needs of the patient.

Multimorbidity and Aging with HIV

As length of survival with HIV increases, PLWH experience a more rapid physical aging process due to long-term effects of ART and cellular-level changes of inflammation and immune system damage.[11] In the ART-era literature, 50 years was generally considered the age of an "older" adult with HIV.[27] But many PLWH are living beyond age 50 and are likely to experience significant impacts on their health as HIV-related pathologies and the aging processes coincide.[28]

One of the greatest challenges of caring for the older patient with HIV is managing the chronic illness burden of multimorbidity, with many individuals having two or more chronic conditions. PLWH older than 50 years are likely to have one or more health problems in addition to HIV.[18] Types of comorbid conditions reported by PLWH commonly include hypertension, chronic pain, hepatitis, arthritis, diabetes, neurocognitive impairment syndrome, malignancy, cardiovascular disease, renal failure, bone disease and fractures, liver disease and frailty.[10,11,18,19]

Like other aging individuals, older PLWH are at risk for the development of geriatric syndromes. Rather than focus on a single disease, geriatric syndromes focus on the impact of multimorbidity on outcomes related to the ability to function in activities of daily life and to maintain independence and QOL.[10] Such syndromes are associated with multiple physical, psychosocial, and environmental factors and include function-related impairments such as frailty, sensory and/or cognitive deficits, falls, urinary incontinence, and depression.[12] In a study of geriatric syndromes in 155 older PLWH, the most frequent geriatric syndromes found were pre-frailty, difficulty in activities of daily living, cognitive impairment, and depression.[12] Managing geriatric syndromes is important to decrease age-related complications. Treatment and prevention of comorbid conditions and exercise and diet to control and maximize function and reduce inflammatory influences on aging have been recommended to decrease adverse effects of aging and geriatric syndromes in older PLWH.[10,29–32]

Living and Coping with HIV

A diagnosis of HIV can be devastating for an individual. Even if a person suspects HIV infection, the confirmation may come as shock. Newly diagnosed individuals may have difficulty accepting the diagnosis and delay initiation of treatment. Or they may have difficulty with adhering to a medication regimen or dealing with the emotional and psychological struggles of having HIV.[30,31] In contrast to situations of the newly diagnosed, many long-term HIV survivors have come to terms with their life-long HIV infection. Knowledge of how PLWH have positively coped with HIV over the long term may provide examples of coping strategies for other patients who must deal with the burdens of HIV infection.

A qualitative, in-depth interview study of 16 long-term survivors of HIV/AIDS described how these individuals coped and what positive traits and characteristics were helpful to their survival.[31] Time from diagnosis ranged from 8 to 26 years, with a mean of 17 years; age ranged from 38 to 67 years, with a median of 50 years. Thirteen (81%) were male. Based on this study, three categories of positive coping strategies (disease coping, practical coping, and emotional coping) and a context of social support were elicited from individual patient interviews.[31] Elaboration on the dimensions of coping and social support and their key representative qualities (Table 41.2) provides a framework for assessing and addressing the palliative care needs of older adults living with HIV.

These dimensions of positive coping have been experienced or utilized by PLWH at various times throughout the illness trajectory. However, each person has a unique life history. The most effective ways to address patient needs will depend on individual factors: age, health status related to HIV and comorbidities, socioeconomic level, geographic location, and the like.[32] For example, a 67-year-old man with diabetes, hypertension, chronic obstructive pulmonary disease (COPD), and arthritis; on ART for many years; and living on Social Security in a depressed rural area will have different needs than someone living in an urban area where access to medical and social supports is easier to obtain.[32,33] Listening carefully to the patient's story and allowing it to unfold over time will

Table 41.2 Dimensions of positive coping identified by long-term survivors of HIV

Disease coping	Practical coping	Emotional coping	Social support
Clinician–PLWH communication	Reasons for living	Resilience	Family/friends/pets
Medication challenges	Managing disclosure	Religion/spirituality	Support from professionals
Self-management of health	Giving back to others	Manage negative emotions	Peer support, individual and group

Source: From Reference 31.

enable the nurse to see the broader landscape of the individual's coping challenges.

Disease Coping

Disease coping involves the ability to deal with the medical and physiological aspects of HIV.[31] For a person newly diagnosed with HIV, addressing the psychological and emotional trauma of diagnosis may be the first hurdle for the patient. Developing a therapeutic relationship with primary care clinicians may help the patient move toward taking a greater role in his or her own healthcare.[34] For long-term survivors of HIV, having good physician–patient relationships, dealing with their multiple medications, and taking charge of their own health was important.[31] As older PLWH develop other chronic conditions, their diagnosis of HIV may become less prominent for them as they find themselves facing new diagnoses, medications, and treatments.[32,35,36] For patients with HIV and multimorbidity, additional medications are likely to accompany new diagnoses. Sorting out drug names, their target diseases, their dosages, timings, adverse effects, and interactions with other medications may be a significant challenge for PLWH and adds to the complexity of their healthcare.[32,35]

The palliative care nurse's role in disease coping will include support for the patient by communicating effectively and facilitating communication between the patient and multidisciplinary team members. The palliative care nurse may be the first to assess new symptoms or to identify inaccurate usage and other problems with medications. The role of patient educator is especially important but requires humility on the part of the palliative care nurse. Many PLWH who have lived with HIV long term and have successfully coped with the complexities of HIV infection are very knowledgeable about their condition. Learning from patients, as well as educating them, is an important aspect of patient-centered care of PLWH.

Practical Coping

Practical coping means the ability of long-term survivors to deal not only with the demands of everyday life with a chronic condition, but with the unique condition of HIV.[31] Individuals who successfully coped were able to find reasons to continue their everyday existence. PLWH identified children, grandchildren, pets, and meaningful employment as reasons to go on.[31] Ability to manage disclosure of one's HIV status or the outcomes of involuntary disclosure[37] also demonstrated practical coping. Research has shown that PLWH who voluntarily or involuntarily have their HIV status disclosed may risk stigmatization by some but gain social support from others.[37] Some patients choose to remain private to the extent that even closest family members may not know they have HIV, but they may risk accidental exposure during an illness or accident in which their medical history is evident.[38] Other PLWH choose partial disclosure, selecting the individuals to whom they wish to disclose and the timing of disclosure.[31,38]

The term "giving back" was often heard among PLWH and was seen as a component of practical coping.[31] This theme has been noted elsewhere as a component of resilience in aging with HIV.[39] Individuals who had overcome significant barriers in their struggle to survive HIV/AIDS often did so with help from many sources. They often expressed a desire to give back some of the help they received by volunteering to teach, counsel, or help others affected by HIV.[31,39]

The notion of practical coping by PLWH has implications for palliative care nursing. Important to the assessment of mental health of PLWH is understanding what is meaningful for them in their lives. Nurses may need to work closely with HIV social workers to address certain needs. For example, if having a job provides meaning, but the person is unable to find employment or lacks purpose in life, a social worker may be able to provide referrals to agencies or organizations that provide help targeted specifically for PLWH.

Understanding and maintaining confidentiality is essential for all patients but is especially important in regard to disclosure of HIV status due to the potential for stigmatization and discrimination. At the onset of care, the palliative care nurse should discuss with the patient which individuals know his or her status and with whom the nurse is able to discuss, or not discuss, the patient's healthcare. The nurse should take care to prevent an accidental breach of confidentiality that may occur by linking the patient to HIV-associated entities (e.g., a research study recruiting PLWH), leaving phone messages that may unintentionally disclose private information, or using unsecured social media to communicate with other healthcare providers. Furthermore, the palliative care nurse should become familiar with state laws regulating HIV confidentiality and sexual partner notification.

Emotional Coping

Emotional coping was viewed broadly as encompassing resilience, management of negative emotions, and spiritual/religious support.[31] Long-term HIV survivors often described an ability to take in stride setbacks in their health or social situation and continue with their lives. In a different interpretation of similar themes, Emlet and colleagues[39] characterized a concept of resilience in HIV as encompassing themes of self-acceptance, optimism (similar to "managing negative emotions"), a will to live ("reasons for living"), generativity ("giving back"), self-management ("taking charge of one's health"), relational living ("social support"), and independence. Consistency in some of the themes across the two studies, in spite of the difference in geographic locations (Midwest and Western United States), suggests reliability of these findings for older PLWH.

Although Emlet et al.[39] did not identify spirituality/religious support as part of resilience, Slomka et al.[31] found it to be a recurrent theme of positive coping with HIV for some study participants. Influences of spirituality/religious support on health-related outcomes have been addressed frequently in the HIV literature. In a review of 15 studies examining relationships between spirituality/religion and HIV outcomes, researchers identified 10 studies that showed positive outcomes such as increased CD4 count, undetectable viral load, and an association with increased survival.[40] Other studies in the review showed negative effects, no effect, or a mixed effect on HIV outcomes. According to the authors, some study results may have been affected by inadequately clarified concepts such as the meaning of "spiritual struggle" and views of God as either benevolent or harsh.[40] Findings from other studies showed that PLWH who had religious support after divorce or death of a spouse had slower increases in viral loads.[41] Contact with a spiritual advisor was associated with an absence of major depression, and spirituality/religion was beneficial in promoting medication adherence.[42] In another study focused on adherence and actual spiritual/religious practices, researchers associated praying once a day with 90% HIV medication adherence rate.[43] All authors agreed on the need to further clarify relationships between spirituality/religion and HIV outcomes. At this stage of research, say Doolittle et al.,[40] clinicians should neither encourage nor discourage spirituality/religion for PLWH, but try to understand its role in patients' lives.

Discussing spiritual/religious needs of the patient is part of the role of the palliative care nurse. PLWH may have strong spiritual beliefs but may have rejected or feel rejected by formal religion, especially if a religious institution stigmatizes HIV because of associations with illicit drug use or homosexuality. Spirituality/religion assessment by the nurse can help to clarify this aspect of care. In addition to support for spiritual/religious aspects of care, the palliative care nurse can further promote emotional coping by reinforcing patients' attitudes and behaviors that lead to resiliency. The nurse can also help the patient manage negative thoughts by suggesting ways to reframe them into more positive attitudes.

Social Support

PLWH described the importance of having supportive relationships in their lives, with family, friends, healthcare providers, HIV peer support groups, jobs, community-based social organizations, and even pets as part of their social networks.[31,39] In a more nuanced study of social support and HIV, Oetzel and colleagues[44] examined both social support and social undermining and its relation to health-related QOL (HRQOL). They found that social support positively related to QOL and that it was more important for PLWH to avoid negative interactions that undermined perceptions of support (e.g., low-paying jobs, disapproval by family, perceived stigmatization) than to have positive interactions. They also noted that work status was the strongest correlate of socioeconomic status in HRQOL, a finding that could have potential policy implications for funding such services as job training programs.[44] These authors suggest that healthcare providers, through positive, supportive interactions with patients, can help to mitigate some of the effects of social undermining that PLWH may experience.

That support from health providers may counteract some of the effects of undermining of social supports for PLWH is an important finding. Health professionals who work with PLWH may have an enormous impact on how the individual sees himself and his illness. The perception of stigma by PLWH is common and is one of a constellation of factors that can impede access to care.[45,46,47] While stigmatizing social context may be difficult for individual clinicians to change, it is within the role of nurses to educate themselves and engage in civic action to improve social determinants of health.[48] One area of social action might be to examine laws that may be inappropriately harsh and stigmatizing toward PLWH who, because of past drug use and/or felony convictions, may be prevented from obtaining jobs, voting, or otherwise engaging in society as active citizens.

Advance Care Planning and Advance Directives

Although advance care planning (ACP) and advance directives (ADs) are not part of the coping framework just provided, they are part of palliative care and the healthcare provider role. The engagement of PLWH in ACP and/or formal execution of ADs varies. Researchers who studied AD completion rates in a US inner-city hospital learned that 92% of PLWH did not have an AD upon admission, and this number only decreased to 86.3% during admission.[49] Others reported AD completion rates among PLWH at 8.7%,[50] 23%,[51] and 47%[52] compared to the overall US population rate reported as 23.3%.[53]

Hansen and colleagues[54] studied relationships among rates of occurrence of ACP discussions with physicians and PLWH and their association with drug use, experience of pain, and family and physician communication. Discussions of ACP were more likely to occur when patients had good relationships with their physicians, higher rates of chronic pain, family arguments about end-of-life (EOL) issues, and comfort with discussing problems with one's family.[54] These authors note the importance for clinicians to assess patient–family relationships and communications. Patients who have chronic pain and/or conflicts with families over EOL care may be more amenable to ACP discussions with clinicians.[54]

Instead of EOL issues driving the need for ACP as in the early days of the epidemic, peace of mind and documentation of decision preferences now support ACP for PLWH.[55] With relatively low numbers of PLWH engaging in ACP, perceptions of palliative care, hospice, and ACP were elicited by researchers[56] as part of a larger study on palliative care. Twenty-two PLWH who had at least one other chronic condition participated in four focus groups. Findings indicated that individuals were not familiar with the term "palliative care" or the relevance of palliative care to chronic illness. Those who were familiar with palliative care tended to conflate it with hospice care, which was associated with end of life and viewed negatively by a number of participants. Participants also misunderstood the meaning of ACP. When palliative care and its role in chronic illness management and ACP were explained to participants, they expressed acceptance of the concept.[56]

Although healthcare professionals and the general public may equate palliative care with hospice, PLWH (and HIV clinicians) may do so because of the history of HIV/AIDS.[56] Older PLWH and HIV clinicians may have had first-hand experience with the early AIDS epidemic, when medical treatments had not yet been developed, and palliation, hospice, and death was the inevitable endpoint of HIV/AIDS. Palliative care nurses should be aware that wariness in the acceptance of palliative care by PLWH may result from a collective memory of the history of HIV. Additionally, conversations with patients over time may reveal that some may have had conversations with family or friends about EOL care and may have chosen not to execute a formal AD. Nurses should be familiar with the AD laws in their state and encourage patients to reflect on who they would want to make healthcare decisions for them if they became incapacitated.

Case Example: A Patient Recently Diagnosed with AIDS

Ms. R is a 35-year-old, African American, divorced, single mother of a 7-year-old daughter. Ms. R has an MBA and had a well-paying job until she lost it as a result of postsurgery narcotic dependence that led to cocaine addiction. She contracted HIV from a sexual relationship with a male friend, a cocaine user who introduced her to the drug and who was unaware he was HIV-infected. Ms. R had been in drug treatment and sober for 10 months and was otherwise physically healthy. She was working two different jobs, trying hard to stabilize her life in order to regain custody of her daughter, who was under the care of grandparents (Ms. R's mother and father). Ms. R was diagnosed with HIV only 10 months ago, at the time she began drug treatment. Her HIV was under fairly good control with adequate CD4 count and viral suppression. She was having some trouble with adherence to ART due to some adverse medication effects and a fluctuating work schedule. She was dealing with her parents' anger and disappointment in her and with her own anger at herself and her ex-partner who infected her. Although her parents offered some emotional support, her social network deteriorated when she became addicted, and job and family stresses resulted in occasional episodes of depression. Ms. R felt she was young enough to rebuild her social and family life for her daughter. But she wondered whether she could have a "normal" life with HIV: Would anyone want to "date" her? Would she be able to remarry or become pregnant again? Would she live long enough to see her daughter grow up?

Comment

Ms. R was under an enormous amount of stress in dealing with a recent (<1 year) HIV diagnosis, HIV medication challenges, drug treatment, loss of her daughter, possible alienation from her parents, working two jobs, possible social isolation, and concerns about the future. Palliative care assessment and follow-up would involve coordination and collaboration with other health providers. Her current plan might include:

- Assessment of disclosure issues
- Medication review with patient, communication with primary HIV physician, diagnosis and assistance with adherence issues
- Symptom management for stress, anger; an HIV social worker may be able to advise regarding availability of individual counseling
- Assessment for clinical depression; encourage exercise; yoga
- Dealing with concern about future: ensure patient is linked to HIV resources online and in the community (e.g., AIDS Taskforce), peer counseling
- Assessment of family communication; need for counseling of child, grandparents
- Reinforce coping skills (e.g., daughter as "reason for living"), demonstrated resilience in seeking employment; self-management of health with goal of healthy, extended life; assistance in reframing negative thoughts; assess social isolation—suggest decreasing isolation by identifying a monthly group activity (participation in church or peer-support group) if job does not provide social support

Case Study: A Long-Term Survivor of AIDS

Mr. G was a 66-year-old, retired, white, homosexual male, diagnosed with HIV 25 years ago. He had been having an extramarital affair at the time with another man when he became gravely ill with Pneumocystis pneumonia (PCP) and AIDS. With intensive care and ART, he survived. His wife divorced him and gained custody of their two young children, a son and a daughter. His wife prevented him from seeing his children for a time, but as the children grew older he was able to re-establish a relationship with them. Mr. G had endured multiple other losses in his past, mainly a number of very close friends who contracted AIDS during the early years of the epidemic and did not survive. He considered himself lucky to be alive, having lived through a time when an HIV diagnosis meant an individual had no future. His life had not been very easy, but he was resilient. He had had to endure rejection from some family members who, lacking knowledge about HIV transmission, were afraid to associate with him, but he had had a good relationship with other family members. He experienced great anxiety in deciding to tell his children that he was gay and HIV-infected, but they now accepted his diagnosis and lifestyle. He remained physically and mentally active. He visited with grandchildren often and volunteered twice a week at a homeless shelter because he wanted to "give back" some of the help that people had given him over the past years. His HIV had been very stable, but in the past year his doctor had noted higher than normal fluctuations in his blood pressure. He also had chronic osteoarthritis pain, especially in his back and shoulders, that often kept him awake at night. He was unable to take nonsteroidal anti-inflammatory drugs (NSAIDs) due to gastric problems. Because Mr. G had a short history of illicit drug use more than 20 years ago, his physician still was reluctant to prescribe any medication that had the potential to become habit-forming.

Comment

In contrast to Ms. R, Mr. G has had many years to adjust to his HIV diagnosis and to cope with the challenges of living with HIV long term. He appeared to have stable and supportive social relationships and enjoyed meaningful activities. He was beginning to experience some of the comorbidities of aging and could benefit from symptom management. Pain management was complicated, but nonpharmacological therapies such as exercise might be helpful. He might also be at risk for comorbidities associated with HIV and with long-term ART use, as well as depression as a result of the losses in his life. The palliative care nurse would want to collaborate with the HIV team in monitoring Mr. G's symptoms, pain management, and depression risk.

Case Study: A Patient with AIDS and Multimorbidities

Mr. W was a 56-year-old African American diagnosed with HIV 15 years ago. He did not complete high school, dropping out at tenth grade. He had a former cocaine addiction and occasionally used marijuana. He had hypertension, diabetes, chronic kidney disease, anxiety, depression, and dental caries. He had a detectable viral load, but an acceptable CD4 count. He took a number of medications in addition to his HIV drugs. He sometimes skipped his drugs for anxiety and depression because he disliked how he felt when taking them. He also occasionally missed other medications when he ran out of them and could not afford to refill the prescriptions. Mr. W's only income was from disability and occasional odd jobs. He was incarcerated for a time for an offense related to his drug use. He lived in a poor neighborhood of the city and did not like to go out much because of the high crime rate. He did not rent or own a home or car, but had managed to keep off the streets because he stayed with friends or family, moving frequently so as not to burden those who took him in. He occasionally missed his clinic appointments because he had to take several buses to get to the clinic, depending on the time of day, and he sometimes did not have money for the fare. Sometimes he could get a friend to drive him, but his friends often cannot afford the extra gasoline necessary to transport him.

Comment

Mr. W. had a number of difficult problems related primarily to his poverty. His HIV needed to be controlled; he needed access to medicines and the ability to keep clinic appointments, but transportation and drug costs were problematic. His unstable housing situation and possible social isolation put him at risk for disease progression. His dental caries and possible food insecurity put him at risk for poor nutrition, infection, and other pathologies. The nurse could assess whether the patient had a therapeutic relationship with his physician and help him to establish one if lacking. The nurse may be able to provide continuity of care through home visits if the patient is unable to get to a clinic appointment. The team social worker should review Mr. W's situation to see if he is eligible for services to pay for food or medicine, a free dental clinic, or volunteers to help with transportation or to provide activities to decrease social isolation. Because Mr. W had a detectable viral load, he should be advised about condom use to prevent HIV transmission. Once the immediate "disease coping" challenges were addressed, the palliative care nurse/team can continue to assist the patient with other dimensions of coping.

Conclusion

The provision of early palliative care to PLWH is essential to manage symptoms and improve well-being for this challenging population. The palliative care nurse who chooses to work with PLWH can enhance his or her knowledge about the medical, psychosocial, economic, and historical aspects of this complex illness in several ways. Familiarity with clinical guidelines for HIV and chronic pain management[25] will enable provision of evidence-based care for a symptom that is often difficult to manage in this population. Professional HIV/AIDS literature is extensive and offers up-to-date clinical information. Organizations such as AIDS Taskforces can provide information on services for PLWH. Multiple websites, sponsored by government and private foundations, are publicly accessible with current information. Care should be taken to critically evaluate online information because disinformation based on "AIDS conspiracy" theories or denial of scientific therapies also abounds. Literature and films can offer historical views and insight into the "human" side of HIV infection. Numerous books and articles in the popular press, both fiction and nonfiction, are available about special groups such as ethnic and LGBT populations and about the experiences of drug users (Table 41.3). Such documents, films, and literature are not only informative, but also can help the palliative care nurse more fully understand the experiences of PLWH in the promotion of compassionate care.

CHAPTER 42

Caring for the Patient with Substance Use Disorder at the End of Life

Peggy Compton, Yu-Ping Chang,
and Salimah Meghani

Key Points

- With the changing face of treatments for cancer and other advanced diseases, patients are living for longer periods of time, which creates new challenges in treating pain and potential addiction issues on a longer term basis.
- Identifying substance use disorder in patients with advanced disease can be challenging, and old conceptions of addiction, such as tolerance and physical dependence, need to be reexamined.
- Patients with advanced disease and comorbid substance use disorder can be challenging to manage but can be successfully treated with careful documentation, planning, and a therapeutic approach.
- Remember that the patient with advanced disease and comorbid substance use disorder may have two conditions in need of concurrent treatment: one of drug addiction and one of pain.

Introduction

Substance use disorders are an endemic disease in the United States, with estimated base rates of 8–10%.[1] Although higher in certain subgroups, its presence certainly impacts all medically ill patient populations and can negatively affect how pain is treated. Despite the fact that national guidelines exist for the treatment of pain disorders including cancer pain, pain continues to be undertreated, even at the end of life. A recent meta-analysis found a high prevalence of pain (66%, CI, 58–75%) in persons with advanced, metastatic, or terminal cancer.[2] In some studies, more than 90% of patients with terminal cancer or other advanced diseases report unrelieved pain.[3–5] Inadequate treatment of cancer pain is even greater if the patient is a member of a racial or ethnic minority, less educated, older, or has mental health comorbidities.[6] Pain undertreatment is particularly likely to be the case in patients with a history of substance use disorder as the primary pharmacologic tool used to treat pain, the opioids, also have a high abuse potential. Stigma and biases associated with addiction can lead to poor pain management, mutual suspicion and alienation, and patient suffering unless adequately addressed. Although advanced illness does not preclude clinicians from practicing universal precautions related to opioid prescription, such as stratifying risks of opioid misuse and monitoring for aberrant drug-related behaviors,[7] clinicians must always remain alert to how conceptions and misconceptions about addiction could ultimately lead to pain undertreatment.

As is clear from current headlines and public health data, opioid use disorder and the misuse of prescription drugs are significant problems in the United States today.[8] However, abuse of any substance leading to a substance use disorder (the diagnostic term for addiction) can complicate the management of pain for patients at the end of life. While specific estimates of the prevalence of addiction in terminally ill patients are limited (see later discussion), evidence supports that substance use disorder is an issue for those with advanced illness, including cancer and hospice patients. Care of terminally ill patients with a history of or an active substance use disorder presents many unique challenges that may include poor compliance with therapeutic regimens, reliance on family caregivers to dispense medications, lack of addiction expertise on the part of providers, overarching tendency to prescribe controlled substances for symptom management, and the perception that addressing substance misuse or abuse in end-of-life (EOL) care is inappropriate. This chapter will provide an overview of the disorder, including definitions and terminology, and review what is known about the prevalence of opioid misuse and diversion in palliative care patients. Current clinical evidence surrounding the intersection of addiction and pain management in terminally ill patients, including assessment, management, and general practice guidelines, will be presented.

Substance Use, Abuse, and Substance Use Disorder

Drug and alcohol use are common behaviors in the United States and thus are not uncommonly encountered in cancer nursing practice, including palliative care and hospice settings. The great majority of persons who drink alcohol or use a psychoactive drug do so within a functional or recreational social context and never develop problematic use patterns. However, with repeated use, some substance users will develop a “substance use disorder”

(SUD), a chronic, treatable, neuropsychiatric disease which brings consequences that manifest in all life domains (health [physical and psychological], family, employment, financial, spiritual, functional, social). As such, SUD can have a significant impact on patient responses to all aspects of cancer and palliative therapy, most notably in the provision of pain care when opioids are used.

In attempting to estimate the prevalence or presence of SUD in patients with advanced diseases, terminology becomes important (see Table 42.1), especially in that lay language describing the disease is notably imprecise. It is increasingly understood that SUD is a behavioral disorder and is not defined by physical dependence and tolerance, which are simply predictable neurophysiologic consequences of repeated opioid use. Reflecting this, in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), tolerance and withdrawal are not counted as criteria for the SUD diagnosis if a patient is taking an opioid analgesic under medical supervision.[9] Not only does confusing nomenclature complicate the effort to distinguish appropriate from inappropriate drug-taking behaviors in patients with advanced disease, it also impedes the communication that is fundamental for proper pain management and medical care.

Alcohol is the most commonly used and abused drug in the United States. In 2016, 136.7 million Americans aged 12 or older reported current use of alcohol, 65.3 million reported binge alcohol use in the past month, and 16.3 million reported heavy alcohol use in the past month. Thus, nearly half of current alcohol users reported binge alcohol use (47.8%), and 1 in 8 current alcohol users reported heavy alcohol use (11.9%). Among binge alcohol users, about 1 in 4 (24.9%) were heavy users. Nicotine was used by approximately 51.3 million people (1 in 5 people) aged 12 or older in 2016, indicating that 19.1% of the population are current cigarette smokers, making it the second most commonly used drug in the United States. The percentage of people aged 12 or older who smoked cigarettes in the past month was lower in 2016 than in 2002–2014, but it was similar to the percentage in 2015[1]; some of this decrease may reflect the use of electronic vaporizing devices for delivering nicotine, such as e-cigarettes. With respect to illicit drug use, an estimated 28.6 million Americans aged 12 or older reported using an illicit drug during the month prior to the survey interview. The most commonly used drug was marijuana, which was used by 24.0 million people aged 12 or older. Following in prevalence, approximately 6.2 million people reported misusing prescription medications at least once in the past month, including 3.3 million people who were misusers of prescription pain relievers. Thus, the number of current misusers of pain relievers was second only to marijuana among specific illicit drugs of abuse.[1]

In 2016, an estimated 11.8 million people reported using heroin or misusing prescription opioid pain relievers in the past month (11.5 million pain reliever misusers and 948,000 heroin users). The most commonly misused type of prescription pain relievers were the hydrocodone products, including Vicodin, Lortab, Norco, Zohydro ER, and generic hydrocodone. An estimated 6.9 million people aged 12 or older misused these products in the past year, representing 2.6% of the population.[1]

These figures characterize rates of use and misuse of alcohol and drugs in the United States but do not reflect the numbers of persons suffering from a SUD. In 2016, approximately 20.1 million people aged 12 or older met the diagnostic criteria for SUD for alcohol or illicit drugs in the past 12 months as specified in the DSM-5,[9] including 15.1 million people with an alcohol use disorder and 7.4 million people with an illicit drug use disorder. Among those with an illicit drug use disorder, the most common disorder was for marijuana (4.0 million people), followed by an estimated 2.1 million people with an opioid use disorder, which includes 1.8 million people with a prescription pain reliever use disorder and 0.6 million people with a heroin use disorder.[1]

Table 42.1 Terms associated with substance use disorders

Term	Definition
Substance Use Disorder (SUD)	The clinical diagnosis of a problematic pattern of substance use behaviors leading to clinical impairment or distress, including the inability to control use, consequences related to use, and failure to meet major responsibilities at work, school, or home. SUDs are categorized as mild, moderate, or severe to indicate the level of severity, and are both preventable and treatable.
Misuse	Use of a prescribed medication for nonmedical use, or for reasons other than prescribed (i.e., altering dosing, route of administration, or combining substances). Misuse may or may not reflect SUD.
Abuse	Misuse with consequences (mild to moderate SUD). Potentially harmful consequences include accidents or injuries, blackouts, legal problems, and risky sexual behaviors.
Physical dependence	A state of neurophysiological adaptation to substance, evident in a drug class-specific withdrawal syndrome upon abrupt cessation, rapid dose reduction, and/or administration of an antagonist. Physical dependence may or may not reflect SUD.
Tolerance	A state of neurophysiological adaptation in which increased amounts of substance are needed over time to achieve desired effect. Tolerance may or may not reflect SUD.
Addiction	A chronic, relapsing, and progressive disease leading to significant impairment in all life domains (moderate to severe SUD).
Pseudo-addiction	Opioid drug-seeking behaviors secondary to inadequate pain control.
Opioid-induced hyperalgesia	A state of nociceptive (pain) sensitization caused by exposure to opioids.
Aberrant drug-use behavior	Taking a medication in a manner that is outside the boundaries of the prescribed treatment plan, such as using multiple pharmacies and prescribers, repeatedly losing medication, or requesting early refills. The presence of these behaviors may or may not reflect SUD.

Substance Use Disorders in Patients with Advanced Diseases

Although substance misuse and abuse and their associated morbidity and mortality are significant problems in the United States, specific estimates of substance abuse in terminally ill patients are limited. Whereas concerns about misuse and abuse of prescribed opioids have mainly been focused on patients with chronic noncancer pain, similar issues have been described in cancer patients and others with life-limiting illnesses. Today, cancer patients live longer, have extended exposures to opioids, and exhibit the same risk factors for opioid misuse as patients struggling with chronic but nonmalignant pain. In general, risk factors for inappropriate use of opioids appear to be the same for cancer and non-cancer pain patients, with a prior history of alcohol and illicit drug abuse being the most consistent predictor of current prescription opioid abuse in patients with pain, regardless of age. Other important risk factors for opioid abuse include family history of substance abuse, history of a mood disorder (e.g., current depression), pain-related functional limitations, current cigarette smoking, history of child sexual abuse or child neglect, involvement in the legal system, and significant psychosocial stressors.[10,11]

One electronic chart review study found that more than 40% of cancer patients receiving palliative care (n = 114) were screened to be at moderate to high risk for opioid abuse as measured by the Opioid Risk Tool,[12] and younger age (16–45) and a history of alcohol or illicit drug abuse were significant risk factors of opioid abuse; furthermore, more than half (62%) of these at-risk patients with a urine drug test (UDT) ordered had at least one abnormal result.[13] A recent chart review of 323 patients seen in a palliative care clinic showed that almost half (46%) of new patients had positive scores on the Screener and Opioid Assessment for Patients with Pain (SOAPP) screening tool,[14] and 15% had a positive Cut-down, Annoyed, Guilty, and Eye-Opener (CAGE) score. Of the less than 5% of visits that included a UDT, 56% had aberrant results.[15] In two separate studies assessing the risk of opioid misuse in patients with heterogeneous cancer types, the authors found that 25–29% of patients were at high risk for opioid misuse.[16,17]

Although few studies have been conducted to evaluate the epidemiology of SUD in patients with advanced illness, reports of opioid misuse among cancer patients have emerged in the literature.[18,19] In an examination of aberrant drug behaviors in cancer patients, Passik and colleagues found in a secondary analysis of a large controlled trial of fentanyl buccal tablet that 17% (n = 1,160) of participants exhibited an aberrant opioid use behavior.[20] However, aberrant behaviors do not necessarily translate into opioid addiction and diversion (see Table 42.1) and may indicate other issues including undertreatment of pain, self-treatment of psychological and spiritual distress, or sleep disturbances.[21–23] A survey of 57 hospice and palliative medicine fellows reported challenging encounters with patients with substance abuse issues, with 77% of fellows having seen at least one such patient, and 29% reporting more than two encounters within the past 2 weeks.[15]

Assessment of Substance Use Disorder in Patients with Advanced Disease

The co-occurrence of a SUD and advanced disease has a negative impact on therapeutic responses and health outcomes. Illicit drug use, actual or suspected misuse of prescribed medication, or actual SUD creates difficulties in the clinical setting and complicates pain management for patients with advanced disease. Effective management of SUD is fundamental to adherence to medical therapy and safety during treatment, including avoiding risks associated with the toxic effects of drugs on body tissues and adverse interactions between illicit drugs and medications prescribed as part of the patient's treatment. Continuous substance abuse may alienate or weaken an already tenuous social support network needed to help alleviate the chronic stressors associated with advanced disease and its treatment.

Therefore, it is important to incorporate substance use screening and treatment into care, and care coordination for both conditions is needed. The first goal of assessment is to determine whether the patient has a history of substance abuse and then to determine whether he or she is (1) actively abusing, (2) is in drug-free recovery, or (3) is being medically maintained (e.g., methadone or buprenorphine) in recovery. Several reliable and valid screening tools for substance abuse are available at www.integration.samhsa.gov/clinical-practice/screening-tools#drugs, including the SOAPP-R[14] and the ORT.[12] Some are generic and used to screen for many types of substance use, while others are used to screen for abuse of specific substance (e.g., alcohol, tobacco, opioids).

In an effort to not offend, threaten, or anger patients, clinicians may avoid asking patients about drug use. There is often the expectation that patients will not answer truthfully. However, obtaining a detailed history of duration, frequency, and desired effect of drug use is vital. Adopting a nonjudgmental position and communicating in an empathetic and truthful manner is the best strategy when taking patients' substance abuse histories.

In anticipating defensiveness on the part of the patient, it can be helpful for clinicians to mention that patients often misrepresent their drug use for logical reasons, such as stigmatization, mistrust of the interviewer, or concerns regarding fears of undertreatment. When taking a patient's substance use history, nurses should use a matter-of-fact approach and explain that drinking alcohol or using certain medications or drugs can influence responses to cancer medications and treatment. It is wise for the nurse to explain that, in an effort to keep the patient as comfortable as possible by preventing withdrawal states and prescribing sufficient medication for pain and symptom control, an accurate account of drug use is necessary.

The use of a careful, graduated-style interview can be beneficial in slowly introducing the assessment of drug abuse. This approach begins with broad and general inquiries regarding the role of legal drugs in the patient's life, such as caffeine, nicotine, and alcohol, and gradually proceeds to more specific questions regarding illicit drugs. This interview style can also assist in discerning any coexisting psychiatric disorders, which can significantly contribute to aberrant drug-taking behavior. As discussed later, once identified, treatment of comorbid psychiatric disorders can greatly enhance management strategies and decrease the risk of relapse. Questions regarding substance use patterns (e.g., onset, frequency, types, amounts, circumstances of use), including current use and the last episode of use, should be explored. Family history of addiction, as well as problems indicative of an SUD in legal, employment, and social domains must be asked. In addition, nurses must take note of obvious signs of intoxication or withdrawal. Other signs of chronic substance use, such as the medical sequelae of abuse (e.g., liver dysfunction, infection), can aid in identification of addicted patients.

With patients who are in remission (on medication-assisted therapy or in drug-free recovery), nurses should ask for how long and under what circumstances they have been in recovery. The primary substance of abuse should be noted, as well as any current relationship with a support/recovery therapy group and/or sponsor. Patients' concerns about exposure to medications with abuse liability (opioids, marijuana, benzodiazepines) over the course of treatment should be explored, with assurance that nonopioid and nonpharmacologic pain management interventions will be offered. For patients on medication-assisted therapy (MAT) who are taking methadone, buprenorphine, or naltrexone for the treatment of opioid use disorder, nurses should note the daily dose the patient receives and, with the patient's permission, initiate contact with the clinic or provider to ensure continuity of care. Patients should be assured that pharmacologic therapy for the treatment of SUD will continue throughout palliative care treatment and will not interfere with the provision of adequate analgesia as needed.

Challenges to Assessment

Case Study: A Patient with Breast Cancer

Mrs. C, a 65-year-old divorced woman with posttraumatic stress disorder related to early life abuse, underwent an uneventful lumpectomy for breast cancer at age 56. Although she responded well to the surgery and chemotherapy, within 3 months of the procedure, she returned to the oncologist's office with significant anxiety related to the recent onset of severe, constant lower back pain. The nurse practitioner on the palliative care team referred her to the pain clinic, and a magnetic resonance imaging (MRI) scan ruled out metastatic disease. The pain was deemed to be of neuropathic origin, exacerbated by a poorly treated anxiety disorder. With significant psychological support, cognitive-behavioral therapy, and psychotherapy, her symptoms became well-controlled with low doses of oxycodone and clonazepam, and her functionality improved markedly. However, upon her retirement at age 63 and change in insurance plan, her pain care was transferred to a new primary care clinician who was concerned about her daily opioid use and initiated a gradual opioid taper. As the taper progressed, Mrs. C's pain became increasingly severe and her anxiety worsened, making it difficult to sleep; she began to increase her use of clonazepam to manage these symptoms. A routine visit to her oncologist during this time revealed a recurrence of her breast cancer, necessitating mastectomy. The original palliative care team assumed management of her symptoms at this time, agreed to continue her opioid prescription, but became concerned about the escalation of her clonazepam use, knowing that, combined, the medications put her at high risk for overdose. With several attempts at a clonazepam taper, Mrs. C reported intolerable increases in pain, thus her opioid dose was increased. A urine toxicology was ordered, and although the benzodiazepine was present, oxycodone was not. When asked, Mrs. C eventually revealed to the palliative care psychologist that she had started skipping oxycodone doses and hoarding them for fear of untreated postoperative pain and that, related to this fear, was considering not undergoing the surgery at all. With reassurances that her postoperative pain would be adequately managed by the palliative care team and the identification of a primary care provider in her insurance network willing to provide ongoing pain medication, Mrs. C was able to return to appropriate and effective patterns of opioid and benzodiazepine use and proceed with the surgery.

Identification of SUD in patients with advanced disease can be challenging related to aspects of the disease process itself, the presence of pain, concurrent psychiatric disorders, sociocultural biases in opioid prescription, and EOL psychological responses. Changes induced by advanced disease and disease treatment can result in alterations in physical and behavioral functioning that may be hard to distinguish from the diagnostic indicators of SUD. For example, addiction-related behaviors may be difficult to discern in a patient who develops social withdrawal or cognitive changes after brain irradiation for metastases. Even if diminished cognition is related to pain medication, this effect might simply reflect a narrow therapeutic window rather than aberrant analgesic misuse. Similarly, the presence of mild mental clouding or the amount of time spent in bed may be less indicative of addictive disease than other behaviors, such as noncompliance with primary therapy or disrupted relationships with physicians, other healthcare professionals, and family members. To accurately assess drug-related behaviors in patients with advanced disease, explicit information is required regarding the role of the drug in the patient's life. Varied and repeated observations over a period of time may be necessary to categorize questionable behaviors properly.

Issues other than SUD should also be considered if questionable or aberrant opioid use behaviors arise during pain treatment. As previously reviewed, there is compelling evidence that pain is undertreated in populations with advanced disease,[3–5] and clinical experience indicates that the inadequate management of pain and related symptoms may motivate aberrant drug-taking behaviors, including so-called *drug-seeking*. For example, "pseudoaddiction," a term coined by Weissman and Haddox, describes drug-seeking behaviors that occur in the context of unrelieved pain, such as obtaining opioids from multiple sources or hoarding medication.[24] A defining characteristic of pseudoaddiction is that the aberrant behaviors cease with sufficient pain relief and control of nociceptive input. A related concept, "chemical coping," first described by Passik and colleagues, refers to patients being motivated to seek opioids to self-medicate spiritual and psychosocial distress,[22,23,25] including symptoms of anxiety, depression, insomnia, or problems of adjustment (including boredom caused by decreased ability to engage in usual activities and hobbies). A Delphi survey of international experts showed high consensus for several warning signs of chemical coping in cancer patients including depression, psychiatric comorbidity, history of substance abuse and alcoholism, and a positive score on the CAGE screening tool for alcoholism.[26] Unfortunately, pseudoaddiction and chemical coping syndromes pose diagnostic challenges as the boundaries of these two syndromes are not readily discernable; nevertheless, each is unique and requires different approaches for effective treatment.[23,26] Although it may be obvious that drug-related behaviors are aberrant, the meaning of these behaviors may be difficult to discern in the context of unrelieved symptoms.

There is good evidence to suggest that patients who are members of an ethnic minority are at greater risk of inadequate treatment of cancer pain. For many years, studies have documented that minority patients receive insufficient pain treatment compared with nonminority patients when being treated for pain caused by a variety of sources.[27–29] While being nonwhite is a risk factor for pain undertreatment,[6] members of certain racial subgroups, such as African Americans, have a disproportionate risk of pain undertreatment in the United States.[30] In one recent study, African

American cancer outpatients reported a higher burden of cancer pain and opioid-related adverse effects. They were also considerably more likely to be prescribed morphine regardless of their renal insufficiency status, and opioid-related adverse effects were partially mediated by the type of opioid prescribed to African American versus Caucasian patients.[31] Minority cancer patients are also more likely to have negative Pain Management Index scores indicating inadequacy of cancer pain treatment relative to the level of their reported pain.[32] Because minority patients with advanced illness are undertreated for pain, they may be at greater risk of being misdiagnosed if exhibiting aberrant behaviors. Clinicians should recognize that there is considerable heterogeneity within cultures and subgroups of patients. Thus, the best way to understand patients' cultural preferences is to directly elicit them from the patients.

Problematic opioid use may also be indicative of a psychiatric symptom or personality disorder, the diagnosis of which has important therapeutic implications. Patients with borderline personality disorders, for example, may impulsively use prescription medications that regulate inner tension or improve chronic emptiness or boredom and express anger at physicians, friends, or family. Psychiatric assessment is vitally important for both the population without a prior history of substance abuse and the population of known substance abusers who have a high incidence of psychiatric comorbidity.[33] On occasion, aberrant drug-related behaviors appear to be causally remotely related to a mild encephalopathy, reflecting confusion about the appropriate therapeutic regimen. These diagnoses are not mutually exclusive.

Clinical Management of Advanced-Disease Patients with Substance Use Histories

As patients face EOL planning, those with a history of SUD have unique needs. The intrapersonal and interpersonal stressors elicited by physical or emotional states, as well as exposure to psychoactive medications (benzodiazepines, opioids), may precipitate craving or relapse. Patients in stable recovery are likely to have good social and family supports in place, but for those with recent or frequent exacerbations of addictive disease, these may be more tenuous. In addition, all patients with this history are likely to face a certain amount of stigma from healthcare providers and others engaged in their palliative care and may receive suboptimal treatment as a result. Although opioid analgesic prescription should always be approached cautiously in patients with a history of addiction, it is not uniformly contraindicated. The degree to which the pain interferes with activities of daily living and quality of life must be balanced with risk for relapse and the effectiveness of nonopioid and multimodal interventions.

Patients with Untreated Addiction: Focus on Addiction Treatment

The most challenging issues in caring for patients with advanced disease typically arise from patients who are actively abusing alcohol or other drugs. For these patients, seeking and using drugs are their priority, as opposed to adhering to or engaging in the palliative care treatment plan. The sleep disturbances, mood states, and functional losses that accompany SUD, in addition to intermittent withdrawal and craving states, can make symptoms, especially pain, difficult to manage. If pain is undertreated, the risk of binging with prescription medications and/or other substances increases for drug-abusing patients.

Opioids should be used judiciously and under tightly controlled circumstances in patients with pain and active SUD, regardless of type(s) of substance abused. Patients meeting DSM-5 criteria for SUD are, by definition, unable to control their use and achieve the goals of optimal functioning and maximal quality of life. Untreated addiction results in impaired function and diminished engagement in satisfying life activities, thus will necessarily result in poor pain outcomes. In many care settings, the ability to provide the comprehensive services necessary to treat patients with both pain and current addiction are lacking. Patients with an active SUD must be referred to formal addiction treatment, thus, it is incumbent upon the palliative care provider to have available a referral network of substance abuse treatment providers willing to collaborate on providing care to patients with advanced illness, pain, and SUD. After referral, the palliative care clinician can continue to work closely with the SUD treatment provider to address pain symptoms and other EOL needs.

Patients who are actively abusing prescribed opioids must be seen more frequently (e.g., weekly, if possible) to allow close monitoring[5] as well as to build therapeutic rapport with staff and afford evaluation of symptom control and addiction-related concerns. Frequent visits allow the opportunity to prescribe small quantities of drugs, which may decrease the temptation to divert as well as provide a motive for not missing appointments. Until adequately treated, opioid prescriptions should be limited in length and dispensed by a family member or member of the healthcare team. Abuse-deterrent formulations should be considered, as should shorter-acting agents which contain less opioid than long-acting formulations. Perhaps most importantly, nonopioid (anti-inflammatory, anticonvulsants) and nonpharmacologic pain interventions should be implemented, including acupuncture, massage, mindful meditation, and distraction. These approaches will concurrently reinforce SUD treatment interventions as well as be useful for managing pain and other symptoms associated with advanced disease.

Patients with Addiction in Remission: Focus on Relapse Prevention

For individuals with addiction in remission, the goal of treatment is the same as for all palliative care patients: to decrease pain and optimize functionality. Indicators of successful pain management include the patient's ability to comply with pain management and palliative care regimens, engage in cognitive-behavioral pain management strategies, utilize positive coping skills to manage stress, and establish better social support systems. As noted, management of comorbid psychiatric complications, such as depression or anxiety, is critical to maximize functionality.

The literature provides evidence that patients with successfully treated addiction can be effectively managed with opioids for pain. For patients with opioid use disorder (OUD), disease remission may include MAT utilizing methadone, buprenorphine, or naltrexone in the context of broader psychosocial treatment. For patients receiving methadone or buprenorphine, it is commonly assumed that the treatment opioid can provide pain relief, however, the duration of analgesic action is shorter than the effects on withdrawal and craving, thus providing incomplete pain control.[34,35] Furthermore, patients on MAT typically have developed some degree of opioid analgesic tolerance and thus may require higher opioid doses to appreciate pain relief.[36,37] In addition, studies have provided evidence that methadone and buprenorphine maintenance patients may, in fact, have heightened pain sensitivity (opioid-induced hyperalgesia) and therefore have a higher opioid analgesic requirement than matched controls.[38,39]

Regardless of the type(s) of substance previously abused, exposure to opioid medications can lead to relapse in patients with a recently or poorly treated SUD. Thus, when providing opioid therapy, the palliative care treatment goals are expanded to include relapse prevention strategies into the plan of care. Relapse is a predictable event in the course of addictive disease and is understood to be a process that does not occur suddenly or spontaneously and is, therefore, preventable.[40] Central to avoiding relapse are learned cognitive and behavioral strategies the patients can employ in the face of high-risk relapse-promoting situations. These include techniques designed to assist the individual in anticipating and effectively coping with high-risk situations and more general self-control approaches designed to reduce relapse risk by promoting positive lifestyle changes. Specific intervention strategies include enhancing self-efficacy by setting achievable behavioral goals and incorporating stress-reduction activities into their daily life, such as exercise or meditation. The overall purpose is lifestyle balancing, which increases self-efficacy across life domains and therefore minimizes the risk of relapse.

Provider Challenges to Clinical Management

Challenging the provision of effective palliative care to patients with SUD is a relative lack of training for palliative care providers on the management of addiction and pain in patients with addiction. A survey of 57 hospice and palliative medicine fellows on their self-perceived competency in caring for patients who misuse opioids found that less than half (47.2%) stated that they have a working knowledge of addiction; a minority (36.8%) believed they knew how to differentiate undertreated pain from addiction, and only 1.4% agreed that their training prepared them to manage opioid misuse.[15] Furthermore, only 21.1% of fellows were satisfied with how they treat symptoms in this population, and the majority felt uncomfortable dealing with issues such as lost or stolen medications.[15]

Furthermore, palliative care and hospice settings lack policies requiring providers to screen for SUD and diversion in patients and their family members. A national survey regarding the management of substance abuse sent to 94 accredited palliative medicine fellowship program directors found that of the directors who responded (*n* = 39), less than half (40.5%) had policies for screening patients for SUD, and the use of a opioid risk screening tool was reported infrequently (32.4%). Even fewer reported having policies to deal with opioid diversion (27%) or screening family members for SUD (16.2%).[41] Despite this, more than half of respondents indicated that substance abuse and diversion was an issue for their clinics, with only 25% indicating substance abuse was not an issue. Less than half (47%) of staff received mandatory training for dealing with substance misuse. A similar survey of 23 Virginia hospice agencies found that less than half required mandatory training on substance abuse (43.8%) or had policies on screening for substance abuse in patients (43.5%); fewer reported policies for screening for substance abuse in family members (30.4%). With respect to potential diversion, far fewer screened for diversion in patients (21.7%) and families (17.4%). Less than one-third had policies in place to guide the use of opioids in patients with a history of SUD (33.3%) or diversion (30.4%).[42]

These data indicate that current practices for screening for SUD and diversion in palliative care patients and family members is inadequate and that education of hospice workers about SUD is equally insufficient. Despite widespread use of opioids and benzodiazepines as the mainstay of therapy for pain, dyspnea, anxiety, nausea, and insomnia in terminally ill patients, policies regarding safe use and best practices remain rare. Few guidelines address substance abuse and diversion in oncology, palliative care, or hospice,[43] and standard screening tools have not been validated in cancer patients. Consensus guidelines addressing substance abuse and diversion for palliative patients are needed to address this growing problem.[44]

General Guidelines

Recently, the Centers for Disease Control and Prevention (CDC) released guidelines for opioid prescribing in chronic pain.[45] The scope of the guidelines included cancer survivors and those beyond active cancer treatment, although patients with terminal disease and those receiving EOL care were excluded. Subsequently, the American Society of Clinical Oncology (ASCO) released its guidelines, which address risk stratification and adherence monitoring in cancer patients, including patients with advanced disease.[46] ASCO noted that many current recommendations are based on expert consensus and that research is urgently needed to generate empirical evidence to support long-term opioid prescribing in patients with chronic cancer-related pain, including those with concurrent substance abuse disorder. Thus, the following guidelines broadly reflect the types of interventions that might be considered in this clinical context and can be beneficial whether the patient is actively abusing drugs or has a high risk for substance abuse.[46,47] The principles outlined assist clinicians in establishing structure, control, and monitoring of addiction-related behaviors, which may be helpful and necessary at times in all pain treatment.

Multidisciplinary Approach

Pain and symptom management is often complicated by various medical, psychosocial, and administrative issues in the population of patients with SUD and advanced illness. The most effective team may include a physician with expertise in pain/palliative care, nurses, social workers, and a mental health care provider with expertise in the area of addiction medicine.

Monitoring for Risk

Patients with more recent history of drug or alcohol abuse, strong family history of drug or alcohol abuse, and those with a history of major psychiatric disorders are at the highest risk of opioid misuse.[46] These risks should be monitored every 2–3 months. Monitoring should include a detailed interview about drug behaviors, checking of the prescription drug monitoring program (PMDP) database for the evidence of doctor shopping, and a UDT.[47] Several monitoring tools are available to clinicians to monitor risk, including the Current Opioid Misuse Measure (COMM),[48] the Prescription Drug Use Questionnaire (PDUQ) and self-report version PDUQ-p,[49,50] and the Addiction Behaviors Checklist (ABC).[51] Note that all of these tools measure aberrant behaviors and behaviors in violation of treatment agreement (such as obtaining opioids from multiple providers, using other illicit drugs, or increasing dose or frequency) and are not diagnostic of SUD.

Use of Written Agreements

Written agreements that clearly state the roles of the team members and expectations for the patient with respect to medication use are helpful for patient education and for identifying signs of relapse.

These agreements typically stipulate that opioids are obtained from a single provider, that they are taken only as prescribed, outline procedures for refills and replacement of lost prescriptions, state the expectation that patients are engaged in SUD and palliative care treatment, describe use of regular and random UDT, and emphasize the importance of safe storage of medications. Basing the level of restrictions on the patient's behaviors, graded agreements should be enforced that clearly state the consequences of aberrant drug use.[52] Additionally, clinicians who are covering for the primary care provider must be advised of the guidelines that have been established for each patient with a substance abuse history to avoid conflict and disruption of the treatment plan.

Setting Realistic Goals for Therapy

Rates of relapse with SUD are high. The stress associated with advanced illness and the easy availability of centrally acting drugs increase this risk. Therefore, total prevention of relapse may be impossible in this type of setting. Gaining an understanding that complete compliance and abstinence are not realistic goals may decrease conflicts with staff members in terms of management goals. Instead, the goals might be perceived as the creation of a structure for therapy that includes ample social/emotional support and limit-setting to control the harm done by relapse.

Evaluation and Treatment of Comorbid Psychiatric Disorders

As previously noted, extremely high comorbidity of personality disorders, depression, and anxiety disorders exist in alcoholics and other patients with substance abuse histories.[33] The treatment of depression and anxiety can increase patient comfort and decrease the risk of relapse or aberrant drug-taking.

Preventing or Minimizing Withdrawal Symptoms

Because many patients with drug abuse histories use multiple drugs, it is necessary to conduct a complete drug-use history to prepare for the possibility of withdrawal not only from opioids, but also alcohol and benzodiazepines. Delayed abstinence syndromes, such as those that may occur after abuse of some benzodiazepine drugs, may be particularly diagnostically challenging because they emerge slowly and can last for extended periods of time.

Applying Pharmacological Principles to Treating Pain

Self-report remains the gold standard on which to prescribe opioids for pain, with the exact dose being individualized to identify a favorable equilibrium between efficacy and side effects. Individualization of the dose without regard to the absolute amount prescribed can be difficult in populations with substance abuse histories[28]; however, foregoing the principle of dose individualization may increase the risk of undertreatment in this population. The ASCO guidelines recommend using no more than one opioid (e.g., no prescription of a second short-acting opioid) in patients with a high risk of opioid misuse. As noted earlier, clinicians should assess the possibility that pain can be adequately managed with nonopioid therapies.[46]

Use of 12-Step Programs

Depending on the patient's stage of advanced illness and functional capabilities, the clinician may want to consider referring the patient to a 12-step program with the stipulation that attendance be documented for ongoing prescription purposes. If the patient has a sponsor, the clinician may wish to contact the patient's sponsor, depending on the stage of illness and individual capabilities, in an effort to disclose the patient's illness and that medication is required in the treatment of the illness. This contact will also help to decrease the risk of stigmatizing the patient as being noncompliant with the ideals of the 12-step program. If the patient is unable to participate in a 12-step program, other psychosocial and/or spiritual team members can provide care that supports sobriety.

Family Sessions and Meetings

As with all palliative care, in an effort to increase support and function, meetings with family members and significant others should be included in the treatment plan. These meetings will allow the clinician and other team members to become familiar with the family and additionally assist the team in identifying family members who may be using illicit drugs (see later discussion). Offering referral of these identified family members to drug treatment can be portrayed as a method of gathering support for the patient. These meetings will also assist the team in identifying dependable individuals who can serve as a source of strength and support for the patient during treatment.

Safe Storage of Opioid Medication

In the current context of the opioid crisis in the United States, the importance of safe storage of these prescribed medications deserves special mention. Improper storage and disposal of opioids increase the availability of these medications for abuse, diversion, and accidental poisoning. Among people aged 12 or older who misused pain relievers in the past year, about half (53.0%) indicated that they obtained the last pain relievers they misused from a friend or relative.[1] Cancer-related pain is one of the main reasons for prescribing opioids. Up to 90% of patients with advanced cancer require treatment with opioids,[52] and those with advanced disease are most commonly treated with high-dose opioids and therefore are a likely source of diversion of these medications into the community. Cancer patients can experience acute, chronic, and/or breakthrough pain and frequently undergo opioid titrations and rotations to help manage pain and opioid-induced neurotoxicity; consequently, they often possess multiple unused or expired opioids.[53]

Limited information is available about the storage, use, and disposal practices of patients receiving opioids in cancer patients specifically. A survey study of 300 cancer patients found that 56 patients (19%) reported unsafe storage, defined as storing opioids in plain sight; 208 (69%) kept opioids hidden but unlocked; and only 28 (9%) locked their opioids. Seventy-eight patients (26%) reported unsafe use by sharing (9%) or losing (17%) their opioids.[54] Overall, 223 of 300 patients (74%) were unaware of proper opioid disposal methods, and 138 (46%) had unused opioids at home. Patients who had a history of positive CAGE scores or illicit drug use were more likely to store their opioids securely but also were more likely to share or lose their opioids.[54] These findings suggest that many cancer patients improperly and unsafely use, store, and dispose of opioids, highlighting the need for patient education and drug take-back programs.

These findings also raise concern regarding family drug diversion; being a familial disease, it is not uncommon to find that relatives of the patient also have a history of SUD. Given significant debility in terminal illness, family members are often administering opioid medications, especially for patients with SUD. Patient education regarding safe use of opioids should include teaching them to avoid exposing family members with SUD to these medications. However, fewer than 20% of healthcare providers address caregiver history of addiction,[41] which can put the impaired family member, who now has regular access to these drugs, at increased risk. Prescribers who work in palliative care settings have a special responsibility to ensure that these medications are not misused or diverted into the community. Diversion can be difficult to detect, but the UDT can provide evidence that prescribed opioids are not being taken by the patient and are perhaps being diverted.

Conclusion

Treating patients with a history of SUD who are experiencing pain from advanced illness is both complicated and challenging because each condition can significantly complicate the other. Patients are living longer with advanced disease and pain concerns. In the current context of the opioid crisis, it is no longer acceptable to justify high-dose opioid therapy for pain in a vacuum without actively and knowledgeably assessing and managing the potential risks of addiction and diversion. The management of pain in a patient who is actively abusing drugs and/or is a member of an ethnic minority is further complicated due to issues of stigma, bias, and cultural differences that may exist. Using a treatment plan that involves a team approach that recognizes and responds to the complex needs of the patient with a history of SUD is the best strategy to facilitate optimal outcomes. Although pain management may continue to be challenging even when all treatment plan procedures are implemented, the health care team's goal should be providing the highest level of pain management for all patients with SUD.

In achievement of pain management goals, patients receiving palliative care are commonly prescribed opioids to treat pain and may have large amounts of controlled substances in their homes. Balancing the mission of pain relief with concerns about SUD and diversion is a difficult issue for palliative care providers. Many providers are not well prepared to screen for these problems in their patients or the family caregivers, and few work in settings with established policies outlining how to care for those with identified problems. Given the enormous public health implications of the increasing rates of opioid abuse and diversion in the United States, it is imperative that the palliative care community takes an active role in addressing the issue in order to provide adequate treatment of pain and other symptoms in patients with life-limiting illnesses.

CHAPTER 43

Cancer Survivorship

Anne Reb and Denice Economou

Key Points

- The palliative care approach to cancer survivors includes assessment of physical, psychological, social, and spiritual concerns as well as caregiver needs and concerns.
- Rehabilitation services can help to reduce unmet needs because they focus on improving function and managing common symptoms.
- A comprehensive geriatric assessment can inform the survivorship care plan and help to identify supportive care needs of older adults.
- Early palliative care improves quality of life and symptoms and may reduce caregiver burden.
- Additional training in palliative care for oncology nurses will help to address unmet needs and ensure that survivors receive supportive care services.

Introduction

As the number of cancer survivors is rising in response to new therapies and improved detection, people with cancer are living longer. "Cancer survivorship" is a term that includes many different stages along the cancer continuum, and it is difficult to identify the specific needs of cancer survivors based on that singular title. Additionally, the multiple models used to provide survivorship care as well as palliative/supportive care vary widely depending on the available resources in individual settings and communities. This is the challenge that organizations face as they attempt to incorporate palliative care into survivorship care.

Compared to childhood cancer survivors, in adult cancer survivors less is known about the incidence of symptoms and late and long-term effects. Some cancer survivors experience late or long-term effects that are related to their cancer treatment, age, comorbidities, genetics, and possibly health behaviors such as diet and exercise.[1] Palliative care is essential for high-risk survivors with multiple comorbid diseases as well as survivors with significant symptoms and unmet needs. However, suggesting that all cancer survivors be seen in a palliative care consult may not be helpful to either palliative care teams or cancer survivors who have minimal side effects related to their treatment and may be cured of their disease.[2] Understanding those patients with moderate to high risk of developing long-term and late effects of treatment is essential.[2] We use the terms "palliative" and "supportive" care interchangeably in this chapter.

Relationship of Palliative Care to Survivorship

The inclusion of survivorship care into palliative care fits well because the components and goals of care are similar (Table 43.1). Palliative care includes patients with potentially curable disease, while survivorship care can include people living with cancer and symptoms associated with disease and/or treatment.[3] The focus of care for cancer survivors overlaps with palliative care, the goal of which is to improve quality of life (QOL) by alleviating physical symptoms and distress.[4,5] The population of survivors can include those who have completed active treatment for curative intent and are dealing with difficult symptoms related to cancer or its treatment. Others will complete treatment and may experience late effects of their treatments that require a multidisciplinary approach to relieve their symptoms and meet their complicated needs. This population is similar to the chronic disease populations, where symptoms may improve but will never be cured.[3] The survivor population also includes cancer patients living with advanced cancer where their multiple comorbidities and complicated disease path require more aggressive multidisciplinary care to meet their needs.

Specialist palliative care provides services that cancer patients may not have access to in standard oncology care. Survivors' needs are similar to the needs of those who have traditionally been treated in palliative care settings. These needs include dealing with the impact of their disease on activities of daily living (ADLs), physical and psychological symptoms, and caregiver support.[3] The coordination of survivorship care within palliative care/supportive care programs and services can improve care and resources for survivors.

Survivorship Care and Palliative Care Planning

There are unique issues and challenges beginning with early survivorship and continuing through end-of-life (EOL) care. Discussions about palliative care should be included at the beginning of treatment for those at highest risk for long-term side effects and cancer recurrence.[4] The challenge has become categorizing who is at greatest risk for long-term side effects and at the highest risk for recurrence.[6] The focus for meeting the combined survivorship and palliative care needs is related to providing the correct services for the survivors' individual needs and recognizing who would most benefit from palliative care support.[7] This chapter will provide insight into the important symptoms and concerns that impact QOL in cancer survivors' follow-up care. Applying this information to a

Table 43.1 Palliative care domains and applications for survivorship care

Domains of palliative care	Key components/ symptoms in survivorship care	Interventions
1. *Structure and processes of care*: Emphasis on interdisciplinary team engagement and collaboration with patients and families early in the course of disease. Care plan based on values and goals of patient and family. Community resources ensure continuity of care.	Comprehensive assessment using validated tools Patient-reported outcome measures integrated in the electronic medical record when possible Geriatric assessment to identify need for supportive interventions in older adults Communication and care coordination[a]	Refer patients with advanced cancer to interdisciplinary palliative care teams. Outpatient programs should provide dedicated resources to deliver palliative care services to complement existing programs for patients with high symptom burden/ unmet needs. Services may include nurse navigation, advanced practice nurse-led programs, geriatric oncology, pain, rehabilitation, behavioral health/social workers, chaplains, integrative providers. Convey recommendations and care plan to the primary care physician.
2. *Physical aspects of care*: Interdisciplinary team approach; assessment and treatment of symptoms using validated tools. Manage symptoms with pharmacological, interventional, behavioral, and complementary therapy interventions. Referrals to appropriate specialists.	Fatigue, pain, sleep disturbance, physical function, bowel/bladder issues, cognitive issues, sexual function, nutrition Educate family and other healthcare providers on symptom management and provide resources for urgent needs.	Emphasis on nonpharmacologic approaches, behavioral interventions, complementary therapies. Short-term use of drugs if necessary or in conjunction with nonpharmacologic approaches. Referrals to rehabilitation services (physical therapy, occupational therapy, physiatrist). Self-management approaches to symptom management.
3. *Psychological and psychiatric aspects of care*: Collaborative assessment of psychological concerns; interventions based on patient and family goals of care. Grief and bereavement program for patients and families.	Distress, anxiety, fear of recurrence, depression, adjustment, mood, grief and loss; body image Concerns about family members' risk of cancer; family distress	Normalize referrals to social work/behavioral health. Provide palliative care support for family caregivers.
4. *Social aspects of care*: Interdisciplinary assessment and collaboration with patients-families to identify strengths; promote goals. Comprehensive assessment including family roles, communication, and decision-making patterns. Provision of emotional and social support	Roles and relationships Family, social support Work issues, finances Interdisciplinary team includes social worker	Referrals are made to social work, financial counselor. Facilitate patient and family coping with illness and grief including education and family meetings. Interventions support family structure, values, goals, and preferences.
5. *Spiritual, religious, and existential aspects of care*: Interdisciplinary team including chaplain to assess and manage spiritual issues of patient and family	Meaning, purpose in life, hopelessness, forgiveness, grief, guilt	Referrals are provided to chaplain, spiritual leader. Spiritual/religious rituals are honored. Promote spiritual and religious practices of patient and family.
6. *Cultural aspects of care*: Culture as source of resilience and strength for patient-family. Use plain language, tailor communication to health literacy.	Interdisciplinary team assesses cultural identification, strengths, and needs of the patient and family and tailors the plan of care.	Plan of care addresses patient–family's cultural concerns/needs Communicate and use written materials in preferred language. Identify referrals and community resources that serve various cultural groups.
7. *Care at the end of life*: Team communicates symptoms of dying process to patient and family. Team manages symptoms and provides care to meet physical, psychosocial, spiritual, and cultural needs of patient and family.	Hospice on-board; preparations for death Intensive assessment and management of pain and other symptoms Spiritual grief assessment for family including hopes, fears, and concerns about dying process Develop post-death bereavement plan	Provide guidance to family about what to expect in dying process and post-death period. Healthcare team member is assigned to support the family to assist with religious or spiritual practices, funeral arrangements.
8. *Ethical and legal aspects of care*: Assists with advance care planning, financial issues, ethics, and legal aspects of care.	Advance care planning and ongoing discussion about goals of care Completion of advance care planning documents: DNR orders, advance directives, or living wills Care plans and preferences are documented and communicated when patients transition from one care setting to another.	Educate patient and family about advance care planning. Designate surrogate decision-maker

[a] Communication and care coordination applies to all palliative domains and survivorship components.

Source: Based on information from *Clinical Practice Guidelines for Quality Palliative Care*, 3rd ed., National Consensus Project; References 4, 5, and 11.

case study will help illustrate these principles for integrating palliative care in the cancer survivor trajectory.

Common Concerns of Cancer Survivors

Early palliative care for cancer patients improves QOL. Although many of the same principles apply, the approach to palliative care for cancer survivors likely to be cured of their cancer differs somewhat from those with advanced or metastatic disease.[4] Cancer survivors are living longer as a result of treatment advances, and there is more uncertainty regarding prognosis and future needs. Although many survivors will be cured or in remission for extended periods, they may need support to manage long-term side effects and fears of recurrence.[3] Palliative care referrals should be based on patient and caregiver needs rather than on prognosis, and the focus of support and care planning should be tailored to address their concerns. Survivors are often concerned about recurrence and managing uncertainty, including understanding the meaning of symptoms and whether they may represent disease recurrence.[4,8] They frequently experience troubling side effects, which may persist during the early survivorship period or the side effects may become chronic. Common symptoms may include fatigue, sleep disturbance, neuropathy, pain, and anxiety. Data from the Livestrong Surveys assessed posttreatment concerns and receipt of care for a large heterogeneous group of cancer survivors within 5 years of diagnosis.[9] More than half of the respondents reported physical concerns including fatigue and cognitive problems and one-third reported problems with sexual function, neuropathy, or pain. Eighty percent reported fear of recurrence, and more than 60% reported grief, identity issues, or emotional distress. Fifty percent reported concerns about body image or family members' risk of cancer. In the 2010 survey, survivors reported that they received care most frequently for their physical concerns; they reported receiving care less frequently for emotional and practical concerns (45% and 44.2%, respectively). Women, younger survivors, and those who received chemotherapy plus surgery and/or radiation reported more physical and emotional concerns.[9]

The palliative care approach to survivors begins with an assessment of physical, psychological, social, and spiritual concerns. Psychosocial stressors and emotional issues may contribute to physical symptoms,[4] so it is important to do a comprehensive assessment including family and caregiver needs. Symptoms should be prioritized and psychosocial concerns should be managed. Nonpharmacologic approaches should be emphasized, and, if medications are needed, short-term use is preferable to long-term use and the side-effect profiles should be evaluated as they may exacerbate other symptoms.[4] Early palliative care may also benefit caregivers by decreasing caregiver burden and distress. Supportive interventions for caregivers may include telephone coaching by nurses; education in symptom management, problem-solving, communication skills, and self-care strategies; referral to behavioral health; or in-person meetings.[10,11]

Survivors with advanced cancer or high symptom burden should be referred to interdisciplinary palliative care teams. There is strong evidence that early palliative care improves QOL, depression, and satisfaction with care. During the early survivorship period, outpatient programs often address high symptom burden or unmet needs through models such as nurse navigation, geriatric oncology, pain services, and social workers and transition patients to palliative care programs in later phases of care.[11] Outpatient programs should have dedicated resources to deliver supportive services to complement usual oncology care.[11] There is a need for additional training of oncology clinicians in palliative care skills to address some of the barriers to accessing early palliative care in the outpatient setting.[11]

Although it is unclear which care delivery model is best to meet the growing needs of cancer survivors, rehabilitation interventions can be effective in improving function and managing symptoms such as pain and neuromuscular and cognitive deficits. Rehabilitation needs of survivors whose cancers are likely cured may be overlooked,[12] and referrals to rehabilitation services are underutilized.[13] Referrals to physiatrists, physical therapists, and occupational therapists may help to reduce unmet needs in cancer survivors.[12] An overview of some common symptoms and assessment strategies will be presented in the following sections, including physical, psychological, social, and spiritual concerns. Unique considerations for older adult survivors will be highlighted because almost half of cancer survivors are 70 or older.[14] Communication challenges and an overview of nonpharmacologic approaches to symptom management will be discussed as key considerations that impact survivorship and supportive care.

Case Study: A Cancer Survivor

Marie Lacosta was a 65-year-old female with Stage III ovarian cancer who completed chemotherapy and presented for her 3-month follow-up visit. The patient reported some worsening of neuropathy in her hands and feet and difficulty with walking secondary to pain and numbness. Marie had seen an interventional pain specialist in the past but had not followed up with him recently. Additional symptoms included difficulty sleeping, fatigue, and anxiety. She had a history of diabetes, depression, and anxiety and had been followed by a community-based psychiatrist in the past. Marie was a poor historian and did not recall all of the multiple medications she was taking. For example, her pain specialist was unaware of her past history, and there were medication overlaps.

The patient's husband, Paul, was her primary caregiver. Paul had complained that all Marie does is sit by the window and watch TV all day. She had been an active person who did cycling and attended a gym regularly in the past. She had been depressed about the changes in her body and her fatigue level. She was questioning her faith and felt unable to get back to her normal life. She was also inquiring about supplements that her friend recommended for anxiety and neuropathy.

Common Symptoms and Assessment Strategies

Fatigue. One-third of cancer survivors may continue to experience fatigue following treatment, and it is often undertreated.[15] Cancer-related fatigue (CRF) may occur as an isolated symptom or as part of a symptom cluster including depression, pain, menopausal symptoms, and sleep disturbance.[16] Fatigue may be exacerbated by metabolic and endocrine conditions such as hypothyroidism and adrenal insufficiency. Other contributing factors may be cardiac or pulmonary dysfunction, anemia, emotional distress, nutritional deficits, inactivity, and medications. Furthermore, disruptions in circadian rhythm and the hypothalamic-pituitary-adrenal (HPA) axis, immune dysregulation, and inflammatory cytokines may contribute to CRF. Cancer survivors should be routinely assessed for fatigue using brief screening measures such as the Brief Fatigue Inventory,[17] PROMIS fatigue, or other measures that include a fatigue subscale or single item.[16] The National Comprehensive Cancer Network (NCCN) provides guidelines on cancer-related fatigue posttreatment.[18] Referrals to physical and occupational therapy may be helpful to assist with energy conservation and activity recommendations. These services seek to improve function and QOL, and reduce risk of falling.[13]

Neuropathy. Patients with cancer are at risk of developing neuropathy related to cancer, its treatment, and comorbidities. Chemotherapy-induced neuropathy (CIN) can persist into survivorship and negatively impact functioning, QOL, and fall risk.[19,20] CIN can result in sensory and motor impairment; the most common symptoms include numbness and tingling in the fingers and toes; sensitivity to cold; burning, shooting pain in the toes and feet; and muscle weakness.[21] In a recent study of 512 women cancer survivors, nearly half continued to experience neuropathy symptoms many years after completing chemotherapy, and those with persistent symptoms reported poorer functioning and nearly twice the rate of falls compared with those without symptoms.[20] Increasing symptom severity is associated with worse functioning, increasing disability, and falls. These findings support the importance of early detection and treatment to limit symptom progression and functional decline and referral to rehabilitation services for strategies to reduce the risk of falls and disability.[20] Nonpharmacologic approaches are increasingly being recommended. Research is now focusing on lifestyle factors including exercise, diet, supplements, and natural products for reducing or preventing CIN.[22] The NCCN and the American Society of Clinical Oncology (ASCO) have published guidelines on the management of CIN in adults with cancer and cancer survivors.[23,24]

Distress. Many survivors experience emotional distress that ranges from normal feelings of vulnerability and fear of recurrence to significant depression, anxiety, and posttraumatic stress symptoms. Symptoms of anxiety and depression often overlap with other concerns such as cognitive difficulties and fatigue.[25] Fear of recurrence is common in adolescent and young adult (AYA) cancer survivors. A large cohort study of AYAs at least 5 years from initial diagnosis found that they reported more distress than the comparison group. Furthermore, many of the survivors had not seen a mental health professional in the past year and were more likely to report that they could not afford mental healthcare services.[26] Fifty percent of colorectal survivors in a large national survey reported fear of recurrence.[27] Factors associated with fear of recurrence included being female, of a younger age, from deprived areas, having received chemotherapy, and more recent completion of therapy. Survivors with lower levels of physical activity and current smokers were more likely to experience fear of recurrence.

Depression is common in cancer survivors and may be underdiagnosed, especially in older adults.[13,28] Other conditions that increase susceptibility to depression include thyroid dysfunction, anemia, polypharmacy, social isolation, functional dependence, and altered neurotransmitters. The clinician should provide reassurance about the patient's concerns, manage polypharmacy, examine possible contributing disorders and symptoms, and refer to supportive care if needed.[28] The identification of depression and distress may be improved with the routine incorporation of patient-reported outcome assessments. The NCCN has guidelines for screening distress.[29] Screening instruments may include the NCCN Distress Thermometer, the Hospital Anxiety and Depression Scale,[30] PROMIS instruments, and the Patient Health Questionnaire (PHQ-4).[31] Furthermore, the incorporation of a comprehensive geriatric assessment (GA) in follow-up visits may help to identify older survivors with depression and other unmet needs.

Comprehensive Geriatric Assessment

The Cancer and Aging Research Group (CARG) (http://www.mycarg.org/) recommends that survivorship care plans be tailored to address functional needs of older adults, including exercise, nutrition, polypharmacy, social support, and comorbidities. Research priorities include using a GA to outline health concerns, evaluating best models of care, and partnering with caregivers in care delivery.[32] Research supports that older adults are less likely to receive palliative care and may have different triggers for initiating palliative care; some may include frailty, functional dependence, cognitive impairment, distress, and caregiver problems.[33] It is important to assess and manage comorbidities and polypharmacy in addition to cancer-related side effects. Polypharmacy is common and can lead to poor adherence and adverse drug reactions.[34] A GA should be conducted to determine health concerns and guide treatment decisions and supportive care interventions.[13,35] This assessment typically evaluates functional status, comorbidities, cognition, social, psychological, depression, nutrition status, and polypharmacy.[36] If multiple disciplines conduct the GA, a comprehensive assessment may take 1–2 hours. However, Hurria and colleagues have shown that a computer-based GA provides a time-efficient method to collect data and includes a built-in algorithm for reporting results to clinicians and managing patients.[37] Since time constraints are often an issue in most settings, an abbreviated GA can be administered focusing on the most important needs and other tools can be administered at future visits.[38]

Unfortunately, GA has not been routinely implemented in oncology settings.[32] Incorporating a screening instrument may be useful to identify patients who are likely to have an abnormal GA and require further assessment.[38,39] The G-8 screening tool assesses multiple domains of the CGA and is useful for identifying patients who need a comprehensive assessment.[40] When a GA treatment plan is done, nurses should facilitate referrals to specialty services and followup with patients to assess adherence to recommendations. Communicating the plan to the primary care provider is essential to support adherence.[38] Advanced practice nurses have been proactive in identifying psychosocial issues and other needs of older cancer survivors.[41] Identifying patients at high risk for complications (e.g., high symptom burden, distress, and polypharmacy) is a proactive way to anticipate who may benefit from early palliative care consultation.

Case Study: A Cancer Survivor (continued)

During the initial follow-up visit after completing treatment, Marie reported significant physical, psychological, and spiritual symptoms and concerns. A brief GA confirmed significant neuropathic pain, increased risk for falls related to balance issues, and polypharmacy. The nurse practitioner (NP) asked Marie what was bothering her the most and she replied, "the pain in my feet keeps me awake at night." The NP recognized that the pain is likely influencing other symptoms, and she is concerned about the overlapping medications and her increased risk of falling. The NP contacted the pharmacist for a medication review and also notified Marie's psychiatrist of the overlapping medications. The NP placed an expedited referral to the pain specialist to evaluate the neuropathic pain and a referral for occupational therapy to assess balance and home modifications to reduce the risk of falling. The NP scheduled a follow-up appointment to address her other symptoms and asked Marie to bring all her medications to her subsequent appointments.

Social Considerations in Cancer Survivors

The social well-being of cancer survivors includes social functioning related to roles and relationships and financial and work-related aspects, as well as family concerns.[11] The intrinsic social needs of cancer survivors change over the course of their disease from diagnosis to long-term follow-up.[42] Treatment-related effects for the most part improve once treatment is completed, but other elements within this domain may become more problematic as time goes on. Work- and insurance-related issues may arise as treatments are completed and require referral to appropriate social services to assist with those needs. Family needs also change as treatment ends, as much of the task work of receiving and completing treatments is completed. Changes in the roles of not only the patient but also the caregiver can become problematic at this transition period. Roles may have shifted; patients may be trying to gain back their independence and resume work while still dealing with loss and residual symptoms. Caregivers may be uncertain of their roles and how to best help the survivor.

Work-related issues as perceived by nurse navigators found that the primary issues cancer survivors experienced were related to financial burdens (81%), conflicts between work and treatments (48%), and the need to take unpaid leave to receive care (48%). Only 17% of the navigators who participated in this study found no employment-related issues in their populations.[43] A needs assessment conducted in a cross-sectional convenience sample of more than 1,000 cancer survivors found significantly moderate to high concern responses related to finances and medical costs. This dropped to nonsignificant levels in survivors who were 2–5 years posttreatment. Additionally, moderately to highly concerned fears of recurrence or developing a second cancer dropped to nonsignificant levels after 5 years posttreatment.[42] The social domain is impacted by comorbidities, unrelieved symptoms, and financial concerns that contribute to decreased QOL. Applied to the case study, Marie's experience will help demonstrate the social domain and some of her social concerns may have some overlap with her spiritual and existential symptoms.

Case Study: A Cancer Survivor (continued)

At 3 months posttreatment, Marie was experiencing multiple symptoms that contributed to her feelings of depression, fatigue, and anxiety that severely impacted her social functioning. The symptoms of unrelieved pain and its influence on sleep problems, fatigue, and resulting depression demonstrated the importance of early assessment and management of symptoms during the initial posttreatment phase of survivorship. Lack of management of these key symptoms over time resulted in chronic symptoms that impeded Marie's ability to return to her pre-cancer social functioning. Her symptoms also impacted her relationship with her husband and primary caregiver. These unrelieved symptoms negatively impacted psychosocial functioning over time. For Marie, prioritizing her psychosocial symptoms and assessing their impact on physical symptoms was essential. A priority for her care was pain relief, so she could start to resume some of her usual activities. The NP discussed her concerns with Marie and asked if she would be willing to speak with a social worker with experience in survivorship care. She also spoke with Marie's husband about how he was coping and mentioned that counseling was available for him if desired. Assessing and providing psychosocial support for both Marie and her husband may be helpful to promote communication and well-being for them as a couple.

Spiritual and Existential Influence in Cancer Survivors

Spirituality has been shown to be an important part of the sense of QOL in patients experiencing cancer.[44,45] Examples of spiritual or existential concerns that arise for survivors include questioning the meaning of their illness or life purpose and dealing with grief, loss, and anger, as well as positive outcomes such as forgiveness and gratitude. People experiencing cancer have described the importance of spirituality in their ability to cope with their illness and strengthen their feelings of hope, meaning, and purpose of their life.[44] Spirituality is conceptualized as including three components: meaning, peace, and faith.[46] In a study done by Davis and colleagues (2017), spiritual well-being was examined longitudinally to describe its impact on emotional outcomes in ovarian cancer patients. Spirituality had a significant impact on positive well-being in ovarian cancer survivors 1 year post diagnosis. Lower depression, anxiety, and total distress was noted in follow-up and greater feelings of peace.[47] The experience of posttraumatic growth (PTG) in cancer survivors impacted positive well-being scores and adds to the importance of supporting spirituality in survivorship follow-up.[45,47] In an effort to improve spiritual well-being and help cancer survivors find meaning in their experience and inner peace, including a spiritual assessment and communicating spiritual support is essential.[45,48] Consideration of cultural issues and beliefs is key to communicating with survivors and families about spiritual concerns.

Cultural studies related to the meaning of spirituality in patients along the trajectory of their cancer illness have identified important impacts on coping and QOL.[49–51] Lung cancer patients described spiritual well-being as contributing to improved psychological well-being and lower symptom distress.[49] Older African American patients with colorectal cancer described the influence that their beliefs had on reducing fear and increasing acceptance of their prognosis.[52] Cultural considerations of the impact of spirituality on cancer survivors influence health behaviors and may help guide intervention choices that would have a greater chance at success. Spiritual beliefs about cancer that are related to a fatalistic belief that God provides divine control over their course of disease can be a barrier to self-management or motivation to change behaviors that contribute to poor outcomes and increased risk for recurrence, such as a healthy diet, increasing exercise, and smoking cessation.[52]

It is important for clinicians to ask about and assess spiritual concerns as research supports that patients would like providers to talk to them about spiritual concerns.

Spiritual Assessment to Meet Survivorship Needs

The FICA tool (*Faith,* belief, or meaning; *Importance* of spirituality; individual's spiritual *Community*; and interventions to *Address* spiritual needs) provides a clinically efficient method to screen for spiritual concerns of patients with cancer and helps provide individually focused care.[53] The Functional Assessment of Chronic Illness Therapy-Spiritual Well-being (FACIT-SP) provides a 12-item tool to measure spirituality with three subscales: meaning, peace, and faith.[46] These tools have been used to assess spiritual well-being and its impact on health–related QOL.[54–56] If spiritual distress is identified, referral to a chaplain or other spiritual counselor is needed for a comprehensive assessment of spiritual concerns.[29]

Case Study: A Cancer Survivor (continued)

Marie reported during her follow-up visit that she was questioning her faith. The nurse listened carefully and asked Marie to tell her more about how she was feeling. Although it may not require an immediate intervention based on the other priorities identified in this visit, including the FICA or a spiritual assessment as part of the survivorship needs assessment posttreatment may help to understand Marie's concerns and determine their impact on other aspects of her life. The nurse asked if Marie would like to meet with a chaplain or minister and Marie said that would be OK. The nurse placed a referral to chaplaincy for a more comprehensive assessment of her concerns. Addressing Marie's spiritual concerns might help her deal with other symptoms she was experiencing and help her find some meaning and peace.

Communication Considerations

Studies have documented the need for improved communication in the early survivorship period regarding symptoms and psychosocial concerns. In a national survey, cancer survivors reported their experience of patient-centered communication with their providers. About half of the respondents reported that providers did not always help them with managing uncertainty or attend to their emotional concerns, and one in three reported that providers did not allow them to ask all of their questions.[57] Various barriers including provider and patient factors, contribute to this communication gap. Clinicians should understand that survivors may use indirect cues in expressing emotional concerns or may not bring up these issues unless the clinician specifically inquires. Nurses should ask open-ended questions such as "Do you have any concerns or worries?" When survivors share their emotions or discuss psychosocial concerns, the clinician should validate their feelings and ask clarifying questions rather than minimizing or changing the topic. Good communication should acknowledge what is known, possible outcomes, and uncertainty.[4] Uncertainty regarding the effectiveness of treatment can be a source of anxiety. Clinicians should clarify the source of the uncertainty, address the anxiety or emotions associated with uncertainty, and offer some coping resources or referrals depending on patient preferences.[58]

Dean and Street (2014) provide a three-stage model to help manage emotional distress, including recognition, exploration, and therapeutic action. Recognizing emotional distress can be challenging as patients may be reluctant to report symptoms and clinicians may not respond appropriately. Active listening, practicing mindfulness, and asking about the survivor's concerns can facilitate rapport and promote discussion of concerns.[59] Acknowledging and validating emotions and being empathetic can encourage the patient to elaborate on his or her concerns. Therapeutic action can involve various strategies to manage distress, including providing information, discussing options to help manage uncertainty, and identifying resources, referrals, or interventions to manage distress. ASCO recently published guidelines regarding communication skills and tasks that are applicable across the cancer trajectory, including various topics such as goals of care, prognosis and treatment, facilitating family involvement, EOL care, and communication skills training.[60] Assessing survivors' information needs and preferences, ascertaining their understanding of the plan of care, and helping them evaluate various sources of information can facilitate patient-centered communication.[61] For example, survivors may have questions regarding lifestyle measures and complementary therapies to manage symptoms, and providing evidence-based recommendations will facilitate informed decisions.

Nonpharmacologic and Integrative Approaches to Symptom Management

Survivors are often interested in learning about strategies to reduce their risk of recurrence and may inquire about nutrition, lifestyle factors, or integrative approaches for symptom management. Obesity is a known risk factor for several cancers and is associated with cancer recurrence, new primary cancers, cancer-related mortality, and the development of comorbidities.[62] Demark-Wahnefried and colleagues provide a review of practical interventions for weight management, physical activity, and diet to promote healthy lifestyle behaviors in cancer survivors.[63] The NCCN survivorship guidelines also provide suggestions for physical activity, nutrition, and weight management.[18]

Cancer survivors frequently use complementary therapies such as imagery/relaxation, yoga, meditation, hypnosis, and tai chi to improve QOL and manage symptoms and side effects of treatment.[64,65] Recent publications review the evidence base for the use of various complementary therapies in cancer care[64,65] and dietary and herbal supplements in survivors.[66,67] Dietary supplements are frequently used by cancer survivors for risk reduction and symptom management. However, studies exploring the effects of supplements on cancer outcomes have mixed findings and outcomes can be influenced by lifestyle factors, type of cancer, supplement dose and formulation, and other factors.[66] Survivors should be encouraged to report any supplements they are taking, and clinicians should discuss the evidence base including possible benefits and adverse effects. The Natural Medicines database (http://naturaldatabase.therapeuticresearch.com/home.aspx?cs=CEPDA~CPCE&s=ND) and the National Center for Complementary and Integrative Health (https://nccih.nih.gov/) provide evidence-based information on natural products and integrative therapies for a variety of symptoms and conditions.

Case Study: A Cancer Survivor (continued)

The NP asked Marie about her lifestyle and physical activity level before she developed cancer and how the cancer has impacted her. The NP also asked if she was currently taking any nutritional or herbal supplements. She asked Marie what supplements her friend recommended and why she thought they may be helpful. The NP stated that she would review the supplements and discuss them further at the next meeting. She planned to ask Marie if she would like a referral to the integrative cancer program to learn more about complementary therapies that might be beneficial for her symptoms. Since Marie had been active and exercised regularly prior to her cancer, the NP also discussed referral to physical therapy for conditioning exercises and recommendations once her pain was under control.

Palliative Care in Advanced Cancer Survivors

The definition of cancer survivor in the United States includes any patient who is diagnosed with cancer, from diagnosis until death. Therefore, survivorship care includes a rapidly growing new population of cancer survivors living with advanced disease.[68] These survivors may be receiving continuous treatment to maintain stable disease or palliative chemotherapy for symptom control. This population poses a significant challenge for palliative care teams as well as survivorship care teams. These patients may be receiving active treatment for multiple symptoms, have follow-up needs that go along with treatment, and additionally are facing the reality of advanced cancer and its probable shortening of their lives. These patients are candidates for palliative care to address symptoms and advance care planning needs. From a palliative care perspective, this population combines the traditional living with chronic disease patient with the reality of advanced-stage cancer and living with stable disease where death is inevitable. This presents a challenge for palliative care teams who can bring symptom management and advance care planning to a population experiencing significant needs and an uncertain illness trajectory. Assessing the needs of this population is essential and requires that palliative and survivorship teams are especially focused on identifying this population as one of highest risk for unmet needs requiring care that supports their needs.[69]

Conclusion

Providing appropriate care to survivors with significant symptom burden or those at high risk for long-term and late effects of cancer and its treatment is a priority. Identifying the survivors who will benefit the most from palliative/supportive care interventions can be challenging. Triggers based on symptom burden and patient and caregiver needs and not prognosis alone is essential. Recognizing that many survivors' highest unmet needs are related to psychosocial concerns can be a starting point for assessment and referrals that can improve care.[9]

Ongoing assessment of symptoms and unmet needs is necessary to identify high-risk survivors as candidates for multidisciplinary palliative/supportive care follow-up. A comprehensive assessment using validated tools should include physical, psychological, social, and spiritual domains and will provide a roadmap to guide supportive care interventions and referrals to appropriate services. Recognizing that survivors and caregivers have different needs along the trajectory of survivorship from diagnosis to death supports the need for ongoing assessment. Survivors who are in transition from active treatment or in remission may benefit from early referrals to rehabilitation services to manage symptoms and prevent long-term effects. Survivors with metastatic or advanced disease recurrence with high symptom burden will benefit from focused assessment and multidisciplinary planning provided by palliative/supportive care teams. Hospitals and community practices should assess their current resources and identify ways to improve or supplement the supportive care services available to their patients. Additional training in palliative care for oncology nurses and clinicians will help to ensure that survivors receive supportive care services especially in areas where palliative care teams are not readily available or are overburdened.

CHAPTER 44

Veterans

Deborah Grassman

Key Points

- Veterans who served in dangerous duty assignments may have deaths complicated by traumatic memories or paralyzing guilt, depending on the extent to which they were able to integrate and heal traumatic or guilt-inducing memories. This sometimes manifests as agitation at the end of life.
- A high incidence of alcohol and other substance abuse or other "flighting"-type behaviors are often used either to avoid confronting locked-up feelings or to numb traumatic memories.[1] These factors may contribute to "unfinished business" as veterans face the end of their lives.
- *Moral injury*, a subcategory of *soul injury*, may surface at the end of life, resurrecting feelings of guilt and shame that can complicate peaceful dying.[2]
- Veterans often acquire wisdom because they have reckoned with trauma, stoicism, addiction, and soul injury. Understanding these four elements helps access their wisdom and has been referred to as *posttraumatic growth*.[3]
- Veterans and their families have unique bereavement needs to consider when providing care.

Introduction

Military experiences often change veterans in fundamental ways that shape, mold, destroy, and help them find meaning in the rest of their lives and at end of life. There are 1,800 veterans dying every day in America—about 25% of all dying Americans. Only 4% of these veterans die within the Veterans Affairs (VA) medical system. Many of the remaining 96% receive end-of-life (EOL) care in community home or non-VA inpatient hospice programs.[4] Education is needed to inform those working in home and non-VA facilities to help understand the special needs of veterans at the end of life.

Stoicism: Early Indoctrination that Continues at the End of Life

Veterans are often noncomplaining, "grin-and-bear-it" types who endure their sufferings silently. The few times that tears or fears break through their stoic facades, they feel embarrassed, apologize, and quickly retreat behind walls of stoicism; these walls offer protection. Unfortunately, their "fight to the bitter end" attitudes sometimes mean just that—fighting toward a death that is, indeed, bitter. Survival-mode mentality interferes with letting go at end of life.

It is important that clinicians know how to create safe emotional environments. Otherwise, dying veterans will underreport their physical and emotional pain as well as any fear they are experiencing. A clinician's ability to breach a veteran's stoic facade can be important because walls of stoicism might contribute to agitation and lack of peace as veterans die. Stoicism is necessary on the battlefield, as it is in many life situations, but the walls that stoicism erects can outlast their usefulness. The walls keep out necessary feelings—and other people. Although it is important to respect veterans' silence when they choose to maintain stoic fronts, it is also important to offer alternatives. Helping veterans use stoicism like a door instead of a wall can be useful. A door can be opened or closed at will and as often as they want, leaving the safety of their stoicism available to them.

Stoicism might be conceptualized as comprising three components: pride, control, and independence. Inability to let go of pride, control, and independence so that a veteran can reach out for help increases suffering. Physical limitations and emotional displays can embarrass veterans and create fears that others will perceive them as weak. They might feel helpless and vulnerable to attack. Letting go might be viewed as admitting defeat or an act of surrender—something good soldiers do not do. Yet mature mental health includes identifying needs and asking for help when it is needed. Both require vulnerability. Stoicism often keeps people from saying what they need or allowing others to meet their needs. This mask of invulnerability sometimes will not even allow them to admit they *have* needs. This can cause frustration for family members and professional caregivers who desperately want to do whatever they can to help.

Many dying veterans are able to let go of control, allowing themselves to become completely human, growing in humility as they learn how to ask for help and how to become a gracious receiver, discovering connection and compassion in the process. This takes courage, and it is as heroic an effort as facing any enemy in battle. Sooner or later, a veteran's stoic walls have to crumble. Later means fighting to the bitter end; sooner means a weary soldier is finally able to surrender to hope for a peaceful death.

The Culture of Combat

Embedded within the stoic, military culture is another culture: the culture of war.[5] Many soldiers sustained emotional, mental, social, spiritual, and moral injuries that sometimes caused a lifetime of soulful suffering. This suffering might be submerged in the unconscious, but, at the time of death, wartime memories sometimes emerge.

It is important to remember that many veterans who did not serve in a declared "combat zone" have also experienced the consequences of a combat culture. Dangerous missions are required for numerous military assignments. In fact, sometimes the trauma they sustain can be even more damaging because it often goes unacknowledged or is minimized because "I didn't see combat." All veterans have set aside prime years in their lives, delayed personal goals, separated from loved ones, and went to strange and sometimes dangerous parts of the world. They were expected to do difficult jobs that they may or may not have been inclined to perform. All were trained to defend their country and be willing to risk their lives if necessary to do so.

A Combat Subculture: Posttraumatic Stress Disorder

Stoicism permeates military culture, whether a veteran served in combat or not. Combat veterans and others who have served in dangerous-duty assignments have to additionally cope with traumatic memories.[6] For some, the memories crystallize into a constellation of symptoms known as *posttraumatic stress disorder* (PTSD).[7]

Many people with PTSD have successfully coped with their traumatic experiences by learning lessons that help them live their lives, deal with trauma, and reckon with PTSD.[8] If they have received PTSD treatment, they can often say what helps them feel better. They might already have a PTSD network of friends who can provide support. Family members usually know how to respond to breakthrough episodes of PTSD because it is familiar territory.

When patients with PTSD are admitted to a hospital and/or hospice or palliative care unit, they are sometimes anxious, suspicious, or angry. Leaving their home to enter an unknown hospital environment is threatening, increasing their feelings of danger. The hospital environment itself can act as a trigger, with its somewhat militarized processes. Their own anticipated death can act as a PTSD trigger. And PTSD, especially when combined with alcohol abuse or misuse of other substances, has often taken its toll on their relationships, leaving much unfinished business to be resolved so a peaceful death can ensue. Sometimes they arrive at the end of their lives broken, with bitterness poisoning their souls. However, it is never too late. Opportunities for growth abound when death approaches, and many people—even those who are bitter—avail themselves of the lessons.

Interventions: Responding to the Unique End-of-Life Needs of Veterans

Penetrating Stoic Facades

Stoicism is important, even essential, especially on a battlefield. It creates protection from untrustworthy influences. It is the *relationship to* stoicism that might need modification. It can be used inappropriately to block energy and emotion from the self or can interfere with expressing love to others. Stoicism can also contribute to veterans' underreporting their fear, emotional pain, and physical pain. The healthcare provider can help reeducate veterans by offering alternatives for them to consider, such as: "I know a lot of veterans put on a macho front and don't want to take pain medication, but pain can consume your energy. You need your energy for other things now."

Helplessness and losing control are especially threatening: "Sometimes veterans tell me feeling helpless makes them angry. I imagine it's hard for a soldier to learn how to surrender, to let go," or "Some veterans tell me asking for help is humiliating. Tell me how helplessness makes *you* feel."

Creating Environments of Comfort and Trust for Combat Veterans

Veterans might talk about past experiences with death—deaths that were often violent and mutilating. They bring these experiences with them when they are enrolled in hospice programs or admitted to a hospital or community program for palliative care. To allay these fears, it can be helpful to discuss the peacefulness of their expected death and the plan for how that will be achieved.

It can be important to eliminate as many "triggers" for PTSD as possible. Coming into a hospital (especially a VA hospital) can trigger past military memories of barracks, military procedures, unsafe environments, past combat hospitalizations, and visiting injured comrades. Loud or unexpected sounds will startle people with PTSD, and they should not be touched without warning; the clinician should first call the patient's name or make sure that he or she is within their line of sight. The use of bed alarms should be limited; they exacerbate the startle response. Restraints should also be avoided; even tight bed clothes or linens can trigger memories of being confined in prison if the veteran was a prisoner of war.

Trust plays an important role in helping veterans with PTSD because these veterans do not trust easily. They have been taught *not* to trust. In a hospice or palliative care program, trust may need to be gained quickly because the veteran may not have long to live; time to build a trusting relationship is simply a luxury that is not always available. The clinician's movements, tone of voice, and open language become important opportunities to convey trustworthiness. Additionally, people with PTSD will often "test" clinicians to see if they are trustworthy.[9] Thus, dialogues about death should be done openly and directly when a veteran with PTSD is admitted to a hospice program or to a traditional hospital for end-of-life care. These veterans faced death before when they were in combat. In fact, they were required to complete advance directives and wills *whenever* they went into a combat zone, so they are used to an open dialogue about dying.

If the veteran becomes agitated with wartime memories, especially if he is in the last several days of life, the "anchoring heart" technique can support emotional safety.[10] In this technique, the clinician places his or her hand firmly on the veteran's chest or, alternatively, on the back. This is usually very calming because anxious energy usually rises: the voice gets higher pitched and energy gets flighty. A calm, centered person's energy usually resides lower and deeper. If a calm person places his or her hand on an unsettled person's sternum, it can often help the anxious person to feel secure, grounded, less anxious, and safe to feel whatever they are experiencing. (This securing gesture is often practiced *unconsciously* when people get bad news. They will gasp and place their palm over their own sternum to anchor themselves.) Family members can be taught to do the anchoring heart technique with the veteran. It not only helps the agitated veteran, it helps family members with their own sense of helplessness.

Box 44.1 provides resources that can help veterans, their families, and professional caregivers. These resources provide clinicians

Box 44.1 Resources for Veterans, Their Families, and Care Providers

Opus Peace is a nonprofit organization with a mission of providing programs that respond to soul injuries. Additionally, Opus Peace helps communities and agencies provide Fallen Comrade ceremonies to heal unmourned grief and unforgiven guilt that veterans may still be carrying. Go to www.OpusPeace.org or www.SoulInjury.org for more information.

Four Final Life Lessons and *Caring for Veterans* are two booklets available free of charge at https://www.opuspeace.org/Shop.

We Honor Veterans is a program by the National Hospice and Palliative Care organization that provides information and toolkits to provide EOL care for veterans. Learn how to "earn your stars" as an agency that cares about veterans. Go to www.WeHonorVeterans.org for more information.

Soldiers Heart is a nonprofit organization whose purpose is to "alleviate the symptoms of PTSD by developing a new and honorable warrior identity." They also promote, train, and guide community-based efforts to heal the effects of war. Go to www.SoldiersHeart.net for more information.

Hospice Foundation of America's Living with Grief series 2013 focuses on improving care for veterans facing illness and death. Go to www.Hospice Foundation.org for more information on their educational program.

Honor Flight is an organization that flies combat veterans to Washington DC to see their memorial monuments. This program is provided free of charge to veterans. It currently emphasizes World War II veterans, but serves any war veteran nearing the end of life. In subsequent years, it will focus on post–World War II vets. Go to www.HonorFlight.org for more information.

Veterans Families United Foundation (1-405-535-1925) helps veterans and their families cope with the aftermath of war and provides information about accessing benefits. Go to www.VeteransFamiliesUnited.org for more information.

Military One Source (1-800-342-9647) provides counselors 24 hours a day. Go to www.militaryonesource.com for more information.

National Center for Posttraumatic Stress Disorder provides information about PTSD. Go to www.ncptsd.va.gov for more information.

National Alliance on Mental Illness (NAMI) describes various mental health issues affecting veterans. Go to www.nami.org/veterans for more information.

America Supports You is a Department of Defense website that connects veterans with organizations willing to provide services: www.americasupportsyou.mil.

Vet Centers (1-800-905-4675;1-866-496-8838) provide readjustment counseling and outreach services to all veterans who served in any combat zone, as well as services for their family members for military-related issues. Services are provided at no cost. There are 232 community-based Vet Centers located in all 50 states. Go to www.vetcenter.va.gov for locations.

Gold Star Mother provides support for mothers who have had a child killed in the military. Go to www.goldstarmom.com for more information.

Gold Star Wives provides support for wives who have had husbands killed in the military. Go to www.goldstarwives.org. for more information.

A monograph has been written by Larry Beresford about veteran issues surrounding the end of their lives. Read it online at www.va.gov/oaa/archiva/ Va_Transforms_End_of_ Life_Care.pdf.

with tools that will develop their skill and confidence in not only providing care for veterans but also learning principles about EOL care for *anyone* who has been traumatized.

Moral Injury: A Subcategory of Soul Injury

A *soul injury* is an overlooked, unassessed wound that separates a person from his or her authentic self, corrupting their identity and sense of "being."[2] The concept of soul injury applies to veterans and nonveterans, traumatized and nontraumatized, alike. Soul injury can be experienced by victims of sexual assault, crime, accidents, natural disasters, bullying, abuse, and neglect; people who have experienced heartache, loss of personal health or a loved one's health, death of a loved one, or betrayal by a significant other; minorities and marginalized members of a society, culture, or group; and veterans, first responders, and civilians living in war-ravaged countries.[2]

Soul injury is a spectrum of wounds that range from traumatic to insidious. "Traumatic soul injury" might accompany PTSD in veterans if the trauma changed how they perceive themselves. For example, a combat veteran's action or nonaction harms a comrade, he subsequently feels ashamed, and he no longer feels like a person of worth. Less apparent is "insidious soul injury," which occurs more gradually and becomes chronic before it becomes obvious. For example, a veteran has an unfair military administrative action taken against him or is labeled as "weak" when unable to maintain a stoic façade. Over time, this might cause the veteran to feel defective or inadequate—hallmarks of soul injury. Unmourned loss, unforgiven guilt or shame, and diminished self-compassion often keep the soul injury alive throughout a lifetime.

Moral injury is a specialized subcategory of soul injury that is primarily associated with combat veterans. It is especially relevant for veterans as they prepare for the end of life. The term originated with VA psychiatrist, Jonathan Shay. Shay sought a name that could describe the moral damage experienced by veterans during dangerous military assignments. He believed that much of the distress that veterans suffer represents an inner conflict between their moral beliefs and their actions during military service, such as killing children. He called this ethical conflict "moral injury."[11] The term has subsequently been adopted by both the VA and the Department of Defense: "Events are considered morally injurious if they transgress deeply held moral beliefs and expectations."[12]

Experiencing or witnessing violence can be disturbing for anyone, but the difference with veterans is that they also *committed* violence. This might cause a moral injury, as this case example depicts.

Case Study: A Patient with Moral Injury

Jim, a World War II vet, was weak with a cancer that would take his life in a few days. The palliative care nurse introduced herself and asked if there was anything from the war that might still be troubling him. He said there was, but he was too ashamed to say it out loud. Motioning the nurse to come down close to him, he whispered, "Do you have any idea how many men I've killed?" The nurse shook her head, remained silent, and met his Jim's gaze. He continued. "Do you have any idea how many throats I've slit?" The nurse remained silent, but her eyes began to tear, as did Jim's. They remained silent, sitting together, sharing his suffering. No words were needed. This was a sacred moment that words would only interrupt.

After several minutes, the nurse asked, "Would it be meaningful if I said a prayer asking for forgiveness?" Jim nodded. The nurse placed her hand on Jim's chest, performing the anchoring heart technique and said: "Dear God: This man comes before you acknowledging the pain he has caused others. He has killed; he has maimed. He hurts with the pain of knowing he did this. He hurts with the pain of humanity. He comes before you now asking for forgiveness. He needs your mercy to restore his integrity. He comes before you saying 'forgive me for the wrongs I have committed.' Dear God, help him feel your saving grace. Restore this man to wholeness so he can come home to you soon. Amen."

Jim kept his eyes closed for a moment, tears streaming down from beyond unopened lids. Then he opened his eyes and smiled gratefully; his new sense of peace was almost palpable. It was a reminder of just how heavy guilt weighs.[9]

Soul Injury Interventions

Whereas PTSD affects a person's brain (especially the amygdala, the part of the brain that reacts to real or perceived threats), a soul injury affects a person's sense of being. Soul injury interventions, including the subcategory of moral injury, focus on learning how to mourn losses, forgive self and others, and cultivate love and compassion. These interventions are not routinely taught in healthcare or trauma curricula. However, providing these interventions at the end of life, when soul injuries tend to surface, can have a dramatic impact on a dying person's quality of life, as well as that of their family. It is essential that clinicians know how to create a safe emotional environment that allows soul injuries to surface. This includes not dismissing or minimizing guilt with well-intentioned platitudes such as: "You were following orders" or "You were being a good soldier; we have our freedom because of you." Instead, the clinician needs to create a safe emotional environment so guilt and shame can be revealed *if the veteran so chooses.* However, this needs to be done cautiously. At no time should the clinician overtly, covertly, or subtly convey that the veteran "needs to forgive," for example, saying, "You need to forgive ______ so you can have peace." This can actually add another layer of damage by causing additional guilt about the inability to forgive themselves or others. Rather, the clinician should simply offer the consideration of forgiveness and invite the veteran to stay open to its possibility. "Now is a time to look back over your life. Is there anything that might still be troubling you? Anything about the war that might still haunt you?" Then, sit quietly. These are not the kind of answers that can be hurried.

A tool has been developed to self-identify soul injuries (Box 44.2).[13]

It can be a useful tool for initiating conversations about unresolved issues that might complicate peaceful dying. This self-awareness tool should not be understood as providing any type of diagnosis or healthcare recommendations. Self-administered screening tools such as the Soul Injury Self-Awareness Inventory are designed to enhance awareness of one's own experiences for the purpose of raising awareness of feelings and experiences related to possible soul injuries. Highlighting these experiences may offer an opportunity to reflect on them at greater length or to consider their relevance in a broader life context. It provides an opportunity to consider seeking the advice of counseling professionals (such as physicians, mental health counselors, clergy, social workers, or others) who specialize in grief, loss, forgiveness, and self-compassion.

Honoring Veterans: A Portal for Healing

Honoring veterans and thanking them for their service to their country is a simple act that often precipitates the story-telling process. Bearing witness to a veteran's story can begin the healing process. There are many ways to honor veterans. Ceremonially pinning veterans with an American flag pin or presenting them with a military certificate that cites their service and displays the seal of their branch of service are simple, yet effective ways. If the veteran served in Korea or Vietnam and they express sentiments about not being welcomed home or being mistreated by the American public, it is not too late to apologize: "I am so sorry for the indignities you've had to suffer because of our nation's ignorance about war. I want you to know that you *are* a hero. And *unsung* heroes are the *most* worthy kind."

Fallen Comrade Ceremony

Ceremonies are an effective way to respond to soul injuries, even long after they occur. Native Americans have long recognized the soul injury of war and designed rituals that help warriors "decontaminate" their hostile energy before reintegrating into the tribal community.[14] The ceremony acknowledges the hardships, provides information about how to face the challenges, and integrates the experience symbolically. Well-designed ceremonies are effective because they access the *unconscious*; they access the deepest levels of the soul.

Opus Peace, an organization dedicated to tending to soul injuries, has developed ceremonies that respond to the hardships incurred by veterans and their families. The Fallen Comrade ceremony originated when Opus Peace was providing consultation services for a long-term care facility to assist staff in caring for the unique needs of aging veterans. One veteran was asked, "Is there anything from the war that might still be troubling you now?" The veteran started crying, saying, "My brother and I both went to Vietnam, but I was the only one who came back." Then, he added, "I didn't even get to go to his funeral." A memorial service was subsequently provided for him, as well as all the veterans at the facility who held similar losses. Unmourned loss and unforgiven guilt were finally liberated and the result was visibly evident.[2]

The Fallen Comrade ceremony is carefully designed to provide a safe sanctuary where losses are acknowledged, honored, mourned, and redeemed. Such losses might include the loss of comrades who

Box 44.2 Soul Injury Self-Awareness Inventory

Many people have acquired soul injuries at one time or another. The definition of soul injury is:

1. An overlooked, unassessed wound that separates one from one's "real" self, causing one to feel less than whole
2. An aching wound perpetuated by unmourned loss, unforgiven guilt/shame, and diminished self-compassion that is often manifested as a sense of emptiness, loss of meaning, or a sense that a part of self is missing
3. A long-lasting response to a person or situation that causes one to feel personally defective, inadequate, or incomplete

Circle the answer that most closely reflects your experience most of the time:

1. I am not able to be my real self.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
2. I engage in some activities to help me avoid uncomfortable feelings.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
3. When I avoid uncomfortable feelings, it often causes problems with people in my life.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
4. I have a hard time facing loss, change, disappointments, or transitions.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
5. Guilt and/or shame haunt me.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
6. I feel defective, inadequate, or unworthy.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
7. Self-compassion is difficult for me.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
8. I struggle to find meaning in my life.
   1 Always true 2 Often true 3 Sometimes true 4 Never true
9. Have you identified a possible *soul injury?*
   Yes _____ No____ Not Sure _______
10. Do you think a past *soul injury* is affecting your life now?
    Yes _____ No____ Not Sure _______

Score of 8–16: Consider consulting a professional who specializes in loss, grief, forgiveness, and self-compassion.
Score of 17–24: Explore www.OpusPeace.org and/or www.Soul Injury.org websites for more information about the impact that soul injury might be having on your life.
Score of 25–32: You have probably worked hard to achieve and maintain a strong sense of self.

died in battle, loss of physical and mental health, or the loss of their prewar self. Family members are encouraged to attend because they are secondarily impacted by their loved one's trauma, and they are the ones providing support on a regular basis. Civilians and staff are encouraged to attend so they can learn how to provide care that supports the unique needs of veterans. Opus Peace is now training leaders to provide Fallen Comrade ceremonies throughout the nation so the wounds that veterans sustained in the public's name can be healed together.

Bereavement for Families of Veterans

Stoicism can affect whole family systems.[15] Grief might be hidden by a silent or angry facade. If the veteran was "career military," the family may have lived in numerous places for short periods of time. This can have different effects on bereavement. Because they have no established roots, there may not be a network of support that facilitates effective grieving. On the other hand, because of frequent moving, families of veterans may readily reach out for support because they have learned how to ask for help and form new bonds quickly.

PTSD does not exist in isolation; it affects whole family systems—even generations of family systems. Living with someone who is easily triggered, suspicious, and wary is difficult. If the PTSD becomes exacerbated during the dying process, the family caregivers may be exhausted and not have the energy required for grief work. They may have become so consumed with caregiving that they have lost their own life or sense of self, which makes grief recovery more difficult.

If PTSD is identified for the first time as a veteran is dying, the impact on the family needs to be factored into their bereavement needs. Some feel relieved, saying, "I'm so glad to know it has a name. I knew something was wrong but I didn't know what. Now this makes sense." Others might feel guilty. "I wish I would've realized this sooner, I would have (listened more carefully, gotten him help, been more patient and understanding, etc.)."

All of these factors need to be taken into consideration when providing bereavement care to families of veterans. They, too, have unique needs because of their loved one's military service.

Conclusion

Healthcare providers need to become sensitized to how military service influences veterans in ways that can sometimes complicate peaceful dying. Stoicism, PTSD, and soul injury are a few of the issues that healthcare professionals need to consider when intervening with veterans. Responding to the unique needs of this underserved population helps to ensure that the men and women who served our country will receive the honor they earned.

CHAPTER 45

Organ Donation

Lissi Hansen and Lauren F. Dunn

Key Points

- The palliative care team can play a critical role in symptom management of patients who may be candidates for organ donation after circulatory death (DCD) and in support of the families of these patients.
- Early referral to an Organ Procurement Organization (OPO) gives the OPO staff time to gather information to determine whether a patient is a candidate for donation. If the patient is a potential candidate, the family will not be approached about donation options until the appropriate time.
- OPO-designated requestors are specially trained in communication and should be the ones to approach families about organ donation. Preferably, someone who has not been part of the direct care team initially presents the topic of donation to the family.
- There is no age limit to sign up on the donor registry or be evaluated as a potential donor.

Introduction

Organ donation is the process of giving an organ, organs, or a part of an organ to transplant into one or more people.[1] Most organ donations occur after the donor has died, but some organs can be donated by living donors, such as a kidney or part of the liver. In 1954, American Ronald Lee Herrick was the first living organ donor.[2] He donated a kidney to his identical twin brother, Richard J. Herrick, in what is recognized as the world's first successful organ transplant.[2,3] Receiving an organ is perceived by most as a great opportunity that is rarely needed. However, the reality is that the need for organ donations is great and the opportunity rare. The opportunity is becoming increasingly rare because of a widening gap between organs available for transplantation and the growing number of individuals waiting.[4,5] In the United States approximately 1% of all individuals die in medical settings (e.g., intensive care units), and this facilitates organ donation.[6] According to United Network for Organ Sharing (UNOS) August 2017 US data, more than 116,800 individuals were on the transplant waiting list for a life-saving organ.[7] From January 1, 2017 to July 31, 2017, a total of 20,183 transplants were performed, and the total number of donors was 9,503. In 2016, 5,891 died while waiting on the transplant waiting list and 6,392 were too sick to be transplanted.[8] Every 10 minutes, someone is added to the waiting list.[7]

Global Organ Donation and Transplantation Statistics

The Global Observatory on Donation and Transplantation (GODT) compiles a worldwide database concerning activities in organ donation and transplantation.[9] Their data collection is led by the joint World Health Organization (WHO) and the Spanish Transplant Organization, Organización Nacional de Trasplantes (ONT). There are 77 countries with donor programs. In 2014, worldwide, a total of 119,873 solid organs were transplanted, and 27,397 organs were donated from deceased individuals. GODT estimates that the number of organs transplanted is 10% or less of the need globally.[9]

US State and Federal Regulations

In the United States since 1968, federal and state legislative bodies have enacted laws to govern organ donation, including safeguarding standards for organ procurement organizations and hospitals.[10] State laws primarily cover issues related to the donation process, public education programs, and the composition of donor registries. Federal laws primarily address organ procurement, allocation, and transplantation processes.[11]

Uniform Anatomical Gift Act of 1968, 1987, and 2006

In 1968, the Uniform Anatomical Gift Act (UAGA) was drafted by the National Conference of Commissioners on Uniform State Laws. The UAGA was the first legislation enacted by all states. It establishes the Uniform Donor Card as a legal document to address donation of organs as a gift to someone who may be in need of an organ. The UAGA states that anyone over the age of 18 can legally donate his or her organs upon death.[12,13]

The 1987 version of the UAGA was developed to address significant advances in the science and practice of organ transplantation since 1968. The 1987 UAGA addresses the prohibition of the sale of human organs, the guaranteed priority of decedents' wishes with respect to the donation of their organs, the streamlining of processes for completion of necessary documents for organ donation, the mandate for hospital personnel to develop procedures of "routine inquiry/required request," and the permission for coroners to provide transplantable organs from subjects of autopsies within certain conditions.[14,15] The 2006 UAGA revised the earlier UAGAs and focused on donations from deceased donors as a result of gifts made before or after their deaths.[16] Individuals who do not have a document of gift in place may have their organs donated by people close to them based on a list of legal next of kin.[16]

National Organ Transplant Act of 1984

In 1984, Congress passed the National Organ Transplant Act (NOTA) and established the Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients. NOTA prohibits the buying and/or selling of organs. The goal of the OPTN is to ensure equitable allocation of donated organs. The contract to develop conditions for the operation of OPTN was awarded to the United Network for Organ Sharing (UNOS) in 1986. UNOS is a private, nonprofit organization. The mission of UNOS is to "advance organ availability and transplantation by uniting and supporting our communities for the benefit of patients through education, technology and policy development."[17]

The Omnibus Budget Reconciliation Act of 1986

The Omnibus Budget Reconciliation Act of 1986 requires hospitals to be affiliated with a federally mandated OPO, which is responsible for the coordination of the procurement and transplantation process.[18] The Reconciliation Act also mandates that hospitals are in compliance with UNOS and have in place policies that offer all families of patients who die the opportunity to donate their relatives' organs.[18,19]

Centers for Medicare and Medicaid Services (CMS)

In 1998, as part of the 1997 National Organ and Tissue Donation Initiative, the Health and Human Services (HHS) Health Care Financing Administration (HCFA) revised its Hospital Conditions of Participation for Organ, Tissue, and Eye Donation.[20] The HCFA is now known as Centers for Medicare and Medicaid Services (CMS). The HCFA revision maximizes opportunities to donate by requiring all Medicare-participating hospitals to (a) report all deaths or imminent deaths to the local OPO, (b) have an agreement with a tissue bank in addition to the OPO, (c) determine who makes the potential organ donation request to families and requires that person to be a designated requestor, (d) ensure that families of all potential donors are informed of their options to donate, and (e) educate staff about organ donation and working cooperatively with the OPO to medically support potential donors throughout testing and placement of organs.[10,18] Potential donors include individuals with nonsurvivable injuries in need of life-supporting medical management. For hospitals that are noncompliant with the terms listed in the Hospital Conditions of Participation in Medicare and Medicaid programs, their Medicare reimbursement may be affected.

Organ Donation Attitudes and Perceptions

People who donate their organs give others a second chance for life or an improved life (e.g., corneal transplant). The shortage of organs for transplantation is a universal problem. There are many social, cultural, and religious factors contributing to the shortage, and misconceptions and myths about organ donation persist. In general, public attitudes toward deceased organ donation are positive; however, positive attitudes have not translated into registration as a donor.[21,22] In the US 2012 National Survey of Organ Donation and Attitudes and Behavior, 94.9% of the nationally representative sample of 3,200 adults supported organ donation, but only 60.1% had granted permission for donation on their driver's license.[22] Women were significantly more likely than men to strongly support donation. Those aged 66 and older and those with an education level of high school or less were less likely to support organ donation. In the United States, African Americans and Hispanics have been found to be less likely to grant permission for organ donation than whites. African Americans are the largest minority group in need of organ transplants. In 2017, 30% of those waiting for a transplant were African Americans. In 2014, 16% of all deceased donors were African Americans.[23]

Reasons for not wanting to donate after death include a desire not to have one's organs removed, religious beliefs, and issues with trust in the fairness of the organ allocation system.[4,21,24] The main reason given for being an organ donor is a chance to help others and to save lives.[25,26] Other factors supporting organ donation by survivors are explicit knowledge of the deceased's wishes by families or that organ donation would be consistent with the deceased's personal qualities and values.[27]

Although the first priority of healthcare professionals is to save lives, some question whether professionals will try hard enough to save their lives if it is known that they are organ donors.[21] Others perceive age, illness, or physical defects to be contraindications for being an organ donor. However, everyone is a potential donor, regardless of age or health status, and can register as an organ and tissue donor. A 107-year-old Scottish woman donated her corneas after her death.[28] Teddy, a newborn with anencephaly lived for 100 minutes. After his death, his parents donated his kidneys.[29]

Clinical Trigger for Organ Donation

One of the most important roles of the bedside nurse in regards to donation is recognizing patients who should be referred to the local OPO. Each OPO establishes triggers for making a referral, which generally include the loss of one or more brainstem reflexes or discussion by family to withdraw mechanical life support. Although the specific criteria for the trigger may vary by region, the goal is for early identification of patients who may die during the current hospitalization. Many patients with neurologic injuries (e.g., anoxia, cerebrovascular accident, or trauma) meet the clinical criteria on admission, so the referral may happen very early in the hospitalization. These patients are ventilator-dependent with either (a) a Glasgow Coma Score of 5 or lower; (b) meet two of the following indicators: no response to painful stimuli, no spontaneous respirations, no corneal reflex, no pupillary response, no cough, no gag, no doll's eyes, no response to cold calorics; or (c) there is a plan to withdraw life support.[30] It is important to know that making a referral to the donation agency has no impact on the medical treatment that is being provided to the patient. This early referral simply gives the OPO staff time to gather information and determine whether the patient is a candidate for donation. Then, if the patient becomes brain dead or if the family decides to withdraw life support, the OPO staff is informed and can present the family with their options for donation.

Organ Donation and Palliative Care

Although palliative care and organ donation may seem to be two mutually exclusive paradigms, there is significant potential for synergy between them. Most patients with serious illness who are admitted to medical settings would benefit from early referral to palliative care. As a patient's medical condition deteriorates, members of the palliative care team can establish a close relationship with families by devoting time to intensive communication and assessing and addressing their needs. The palliative team can explore and establish goals of care based on patient and family values and wishes, manage complex symptoms, and coordinate care among the patient's various healthcare teams. For patients who are not brain dead but may be candidates for organ donation after circulatory death (DCD), the palliative care team can continue to play a critical role in managing their symptoms (e.g., pain, air hunger). Working with these patients and their families, members of the palliative care team may receive information about organ donation wishes. Such wishes may be expressed by family members during their communication about the patient and should be shared with OPO staff.

Referral Process

The referral process is designed so that hospital staff members do not have to be trained in the variable rule-out criteria for the three types of donation: organ, tissue, and eye. Rather, this determination can be left to the donation professional; hospital staff simply need to contact them. Referring a patient to the local OPO can be done by any hospital staff member, including the physician, nurse administrator, or chaplain, but is generally the responsibility of the bedside or charge nurse. The Health Insurance Portability and Accountability Act (HIPAA) includes an exemption for hospital staff to release patient information to the OPO without obtaining consent to do so from the patient or family.[18] In fact, hospitals must provide this information to be compliant with the CMS Hospital Conditions of Participation.

During the initial call to the donor referral line, a triage operator will take general patient information including name, date of birth, admission diagnoses, and mechanical ventilation status. An Organ Donation Coordinator will receive the referral if the patient is on mechanical ventilation. If the patient is not on a ventilator, they will be evaluated for eye and tissue donation only.

When the Organ Donation Coordinator receives the referral, the nurse will then be asked to provide additional information about the patient, including the hospital course of events, past medical history, current laboratory values, and sometimes diagnostic testing results. If the patient does not have any automatic exclusions for donation, the coordinator will review the full medical record, either remotely or onsite. The coordinator may also gather more information from hospital staff regarding the patient's plan of care and family dynamics. If the patient is considered a potential organ donor candidate, the OPO will followup with the hospital for daily updates. The family will *not* be approached about their donation options until the appropriate time. Many patients who are referred improve neurologically, at which time the OPO coordinator will sign off and stop following the patient as a potential donor.

Donation Discussion with Family

The optimal time to speak with a family about donation is generally thought to be after they have accepted that their relative is not going to survive. If a family is still hopeful for their loved one's recovery, it is not an appropriate time for them to be approached about donating organs.[31] Acceptance of impending death can be demonstrated in many ways. The family may begin discussing the withdrawal of life support, the patient has formal brain death testing performed and the family understands this diagnosis, or, in some cases, the family asks about the possibility of donation. The hospital staff is vital in keeping the donation team updated about the patient's clinical status and any end-of-life (EOL) discussions with the family. The OPO has designated requestors who are specially trained in speaking with families about donation. Some hospitals have in-house staff who are trained by the local OPO as designated requestors as well. It is preferred that the topic of donation is initially presented to the family by someone who has not been part of the direct care team. This decoupling between the medical team and the donation team prevents false perceptions that the care team has any motive in the treatment of the patient other than saving the patient's life.[32] The designated requestor will also have important information about whether the patient is registered as a donor through the Department of Motor Vehicles (DMV) or online registry.

If a family asks about donation, the nurse can offer to contact the donation agency and have a requestor speak with them about their options and answer any questions. For example, the nurse could say something like "we can definitely see if donation is an option; let me contact the donation representative." If it is early in the hospitalization, it might feel more appropriate to say something like "right now we are doing everything we can for (loved one), but we work closely with the donation agency and they will inform you of your donation options if we get to that point." The nurse should contact the OPO to update them that the family has asked about donation. The requestor may also be able to provide language for the nurse to use that is appropriate for the specific situation. In addition to keeping the OPO informed, bedside nurses serve as familiar, trusted caregivers to the family. When it is time for the donation discussion, the information that the nurse has provided to the OPO helps set the stage for a successful conversation. The goal of the conversation is for the family to feel supported and to be given accurate information so they can make the best decision for their loved one.

Donor Designation

When an individual has registered to be an anatomical donor through the DMV or online registry, it is considered first-person authorization. This is similar to an individual having an advance directive for medical treatment. The donation discussion with the family is very similar to when a patient is not registered, but, instead of having to make a decision about donation, the family is informed about the process of honoring the patient's directive. The designated requestor is trained to work through concerns with the family in the event that they are not in agreement with the registry status. When a patient has expressed his or her intent to donate by signing up on the donor registry, the OPO makes every attempt to honor that decision.

Family Concerns

As public education organizations such as Donate Life America work to increase public awareness about donation, registry rates across the country are increasing.[33] Even with increased knowledge, myths about the donation process continue to persist. Designated requestors are trained to address family concerns or questions about the process. It is important to always have an OPO representative involved when family members have questions to ensure that they are given the most accurate information.

Timing

Many families expect donation to progress as it is seen on television, where the family signs the consent and the patient is immediately taken to the operating room (OR). In reality, the process takes time, and sometimes this is concerning to families. The OPO representative will explain that the time is needed to perform tests and to identify the best possible recipients for the organs. The OPO will always work with the family to attempt to meet any timing needs.

Cost

No additional expense will be incurred by the family if their loved one is a donor. All of the hospital costs associated with the donation process are covered by the donation agency. The family remains responsible for pre-donation hospital expenses (the portion of the hospital bill prior to authorization for donation), funeral expenses, and the cost associated with cremation/burial arrangements. The family will not receive any monetary compensation for the donation, as prohibited by federal law.

Pain/Discomfort

If family members express concern that their loved one is in pain or that the process is prolonging their suffering, there are a number of ways to address this. If the patient has been formally declared brain dead, families can be assured that this is the legal time of death, and their loved one is no longer feeling any pain. If a patient is not brain dead, the hospital staff will be called upon to discuss their plan regarding comfort care medications and EOL symptom management (e.g., secretions, pain). If the palliative care team is not already involved in the patient's care, a consult should be made at this time.

Allocation

For potential recipients to be listed to receive an organ, they have to go through an extensive screening process and be approved by a transplant center. The federally regulated, nonprofit organization UNOS maintains information on all listed patients and generates organ-specific lists for each donor. Potential recipients on the lists are prioritized by factors such as total wait time, medical urgency, blood type, and geographic location.[34] Wealth or fame cannot get a patient moved up on the list.[35]

Religion

All major religions either support organ donation or support the individual's right to choose.[36] Families are encouraged to consult with their faith leader if they have questions.

Paths to Deceased Organ Donation

There are two ways to be legally declared dead in the United States: by neurological criteria (brain death) or by cardiopulmonary arrest (circulatory death). Donation proceeds differently depending on the type of death.

Brain Dead Donation

The Uniform Determination of Death Act defines brain death as the "irreversible cessation of all functions of the entire brain, including the brain stem." The three clinical findings that are necessary to confirm brain death include unresponsiveness (coma) due to a known cause, absence of brainstem reflexes, and apnea (complete absence of respiratory effort).[37] Formal testing has to be performed by a physician for a patient to be legally declared brain dead. Brain death testing varies by state and by hospital policy on details such as the type of physician who may perform the testing, whether it should be repeated by a second physician, and any requirement for ancillary testing, so it is important to be familiar with the policy of the hospital in which testing is being performed.

If a patient is not displaying any brainstem reflexes, it is imperative that the hospital staff perform this testing. It is important to note that brain death testing is not performed for the purposes of organ donation. It is a clinically indicated, diagnostic test that provides the care team and family with definitive prognostic information. Having the diagnosis of brain death also eliminates the emotional burden on the family of having to decide if and when to withdraw life support.

After a patient has been declared brain dead and authorization for donation has been given, the OPO staff take over medical management of the patient. The bedside nurse continues to provide care and works closely with the donor team staff to fulfill patient care orders. Because the goal of care is no longer to preserve brain function, the priority shifts to optimizing organ function. It is important for all potential organ donors to remain hemodynamically stable for perfusion and oxygenation of the organs. The Organ Donation Coordinator will educate the nurse about treatment goals and provide parameters on vital signs and urine output. Hypotension, hypothermia, electrolyte imbalances, and diabetes insipidus are common in brain-dead patients, and the coordinator will watch for and treat these conditions. Blood is drawn for infectious disease testing, and labs sent to begin the evaluation of organ function. The goal of the coordinator is to optimize the gift being given, so every organ without automatic exclusions will be evaluated. The brain dead patient can potentially donate heart, lungs, liver, kidneys, pancreas, and intestine. Diagnostic imaging and procedures that may be performed include an echocardiogram, coronary angiogram, electrocardiogram (EKG), bronchoscopy, chest x-ray, chest or abdominal computerized tomography (CT) scans, and abdominal ultrasound. Hospital staff will be consulted to perform these tests and to place arterial or central intravenous lines as needed.

As organs are evaluated, a list of potential recipients for each organ is generated through UNOS. UNOS uses an algorithm of many factors to rank patients on the organ-specific lists. The algorithm is designed so that the recipients are organized by best match with the highest medical urgency or total wait time. These standards are designed so that the distribution of organs is fair and ethical while attempting to minimize the number of patients who die while waiting for an organ.[32] The Organ Donation Coordinator moves systematically down the generated list, directly contacting the transplant centers where recipients are listed. The transplant center will evaluate the donor information to make the final determination about whether the organ is a suitable match for its patient. Once a recipient for each transplantable organ is identified, the coordinator will schedule a time for the organ procurement operation. The family is kept informed about the donation process as it progresses. However, identifying information about potential recipients is kept confidential. Some families choose to stay at the bedside until the patient is ready to be taken to the OR; others say their final goodbyes after brain death is declared. The organ donation team, unit staff, and palliative care team are there to offer ongoing support to the family during this time.

Donation After Circulatory Death

A patient who is not brain dead, but who is not expected to survive after being taken off mechanical ventilation, could be a candidate for DCD. In this type of donation, the surgical recovery of organs occurs after a patient is taken off life support, allowed to expire naturally, and declared dead by cardiopulmonary arrest. These patients include those with severe neurological injuries but with some preserved neurological function, or with a condition in which they will not be able to continue breathing effectively on their own, such as amyotrophic lateral sclerosis (ALS) or a spinal cord injury. The family will only be presented with the option of DCD once they have decided to withdraw mechanical life support. This way, the decision to pursue organ donation is not a factor in a family deciding to stop aggressive life support measures.

When discussing DCD, families are informed that the withdrawal of life support will happen in a controlled setting, and their relative will remain under the care of the hospital team and receive the same EOL treatment as in a typical withdrawal of support. The hospital staff continues to provide medical management of the patient while the donation team evaluates organs and identifies recipients. Because the patient is not legally dead at this point, the organ donation team plays no part in the patient's medical care. If the hospital has a palliative care team, they will frequently be consulted to provide comfort care management during the donation process and withdrawal of life support. After donation details are in place (organs evaluated, recipients identified, OR ready, and procurement surgeon on standby), the medical staff will remove the patient from ventilator support. If they choose, the family can remain with their loved one during the dying process. The bedside nurse, respiratory therapist, and physician will be present to remove the ventilator, provide comfort care medications as needed, and pronounce the patient deceased after the heart stops. If the patient dies in the time frame needed for organ donation to occur, typically 1–2 hours, the patient will then proceed quickly to the organ procurement operation. If the patient continues to have a pulse longer than 2 hours, the organs will have suffered from hypoperfusion and hypoxia and will no longer be transplantable. At that point, organ donation efforts will cease and the patient will continue on comfort care. After cardiac death, tissue and eye donation are still a possibility. During the initial discussion of DCD, families are made aware that there is no way of definitively knowing how long their relative will live after the withdrawal of life support and that donation is not guaranteed.

If a patient expires within the required time frame, the procurement surgery has to occur quickly as the organs are no longer being perfused by oxygenated blood. A waiting period of 5 minutes has to occur after the heart stops beating to watch for any signs of autoresuscitation before the surgery will begin. The family will say their final goodbyes and the patient will be transported to the OR (if the withdrawal of support did not occur there) and prepped for surgery during this time. The organs suffer a period of ischemia during this type of donation, so, in general, a candidate for DCD has slightly tighter criteria in terms of age and health to qualify. Also, because of this period of ischemia, heart and intestine are not usable from DCD donors, but the deceased can still potentially donate liver, kidneys, pancreas, and lungs.

Operating Room: Organ Procurement Surgery

The organ recovery surgery is a complex procedure that takes the expertise of surgeons specially trained in procurement and the assistance of the hospital OR staff. Typically, one local surgical procurement team will recover the abdominal organs with separate surgical teams from the accepting heart and lung transplant centers. The OPO staff will help with logistics of the surgery including coordination and communication among teams, organ packaging, and transportation. Before the surgery begins, a team pause is observed in which the donor will be honored for the gift that he or she giving. Some families choose to prepare a brief statement about their loved one, which is read during the pause.

With a brain dead donor, the surgery will begin with the patient still on the ventilator and the heart beating. A single midline incision is made to access the abdominal and thoracic cavities. The organs and vasculature are isolated and a visual inspection of the organs is performed. The surgical teams place cannulas in the major blood vessels that supply each organ. Simultaneously, a clamp is placed on the aorta and preservation solution is started to flush the organs. The cold preservation solution stops the heart and begins to cool the organs. The warm blood is vented out through an incision in the vena cava and suctioned from the abdominal and thoracic cavities. Sterile ice is packed into the body cavity to cool the organs while they are individually removed.

As the organs are being recovered and teams are traveling back to the transplant centers, recipients are being prepared for their transplant surgery. Much coordination goes into minimizing the time frame between organ removal and transplant into the recipient. The less time the organ spends on ice, the better it will function after being transplanted. See Figure 45.1.

Aftercare Services

OPOs have donor family aftercare specialists who provide ongoing support for families in the months and years after their relative's death. After the donation process is complete, the donor family will receive a letter with nonidentifying information about the recipients whose lives were saved by the gift of an organ. Any correspondence between recipients and donor families is facilitated by the aftercare specialist unless both parties agree to release their information. Aftercare programs also hold events in honor of donors, in which families can choose to participate. Many families find the donation community to be a source of comfort and support during their time of grief.

Case Study: An Organ Donation

Mr. James Peterson is a 72-year-old man who was admitted to the trauma intensive care unit (ICU) from the OR. He was the driver in a head-on collision with his wife Maria in the passenger seat. Mr. Peterson was intubated in the field and provided ventilatory support. Mrs. Peterson suffered only minor injuries. She was treated in the emergency department (ED) and then released.

Mr. Peterson suffered a severe closed-head injury. A computed tomography (CT) scan of his head revealed a large subdural hematoma with right-to-left shift. He was taken to the OR for a craniotomy. After surgery, Mr. Peterson was medically treated including hyperventilation to reduce cerebral edema. Forty-eight hours after

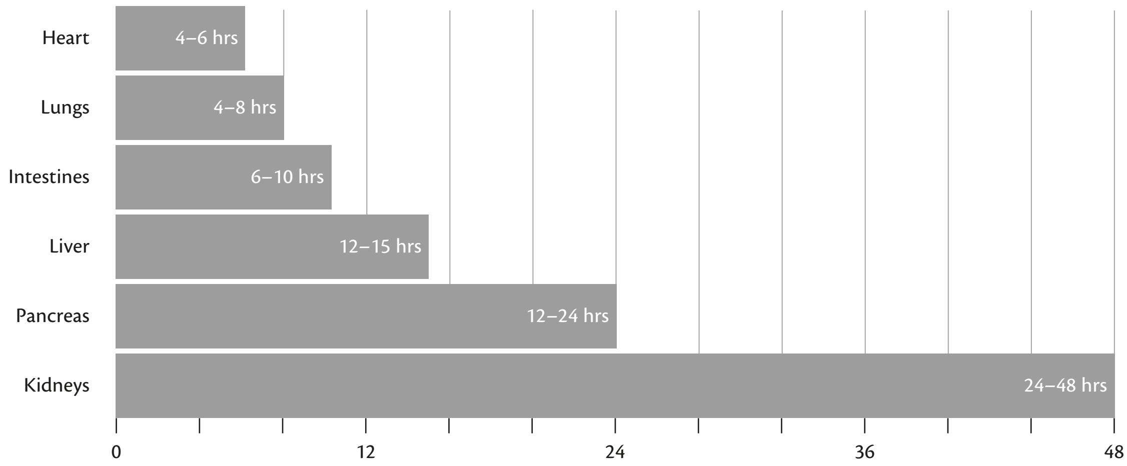

Figure 45.1. Organ preservation times.

surgery, he showed no sign of improvement. His body posture decerebrated to noxious stimuli and his pupils were unequal and with sluggish reaction to bright light. The neurosurgeon spoke to Mrs. Peterson and her two daughters about Mr. Peterson's condition and grim prognosis. The neurosurgeon made a referral to the palliative care team with a request for the team to speak with Mr. Peterson's family about goals of care. The family wanted everything done for Mr. Peterson. They could not imagine a life without him.

The following day Mr. Peterson experienced a sudden episode of hypertension and irregular heart rate followed by hypotension. The staff acted quickly to normalize his blood pressure by giving a fluid bolus and starting dopamine. Findings of Mr. Peterson's neurological examination had changed. He had a Glasgow Coma Scale score of 3, fixed and dilated pupils, no gag and cough reflex, and no spontaneous respirations or purposeful movements to noxious stimuli. After the consulting neurologist had completed her brain death testing and evaluation of a cerebral blood flow (CBF) study, Mr. Peterson was pronounced brain dead.

The intensive care nurse who had taken care of him for the past 2 days contacted the Donor Referral Line. The nurse regretted that she did not speak with the OPO earlier, as Mr. Peterson met the clinical trigger for referral 3 days earlier. She had recently learned that there was no age limit to signing up on the donor registry or to be evaluated to donate. An earlier referral of Mr. Peterson to the OPO would have facilitated information gathering about him by the OPO. This medical evaluation can take several hours and would have been completed prior to the herniation event.

The nurse from the palliative care team was visiting with Mrs. Peterson and her daughters when the neurosurgeon informed them about the death of Mr. Peterson. The family was understandably very upset upon hearing that Mr. Peterson had died because they had held out hope that he could pull through.

The Organ Donation Coordinator arrived onsite and had to quickly review Mr. Peterson's medical record to see if there were any donation options to offer the family. Luckily, the family had asked his bedside nurse for more time to gather additional friends and family members to say goodbye. The coordinator found that Mr. Peterson was previously very healthy and active, and his current labs values were normal. The coordinator also checked the donor registry and found that he had not signed up to be a donor. The coordinator talked with the bedside nurse, palliative care nurse, and the neurologist to learn about the family and where they were in their understanding. The neurologist stated that, despite their initial shock, the family was fully understanding of the brain death diagnosis. The bedside nurse mentioned that the family had asked what happened after they all said their goodbyes. Everyone was in agreement that now was a good time to present them with information about donation.

The palliative care nurse, who now had a relationship with the family, asked Mrs. Peterson and her daughters if they would come to the conference room to discuss some additional decisions. They met with the donation coordinator and were surprised to learn that Mr. Peterson had the potential to be a donor. They shared that Mr. Peterson worked as a teacher and was always volunteering in the community. They knew that he would have wanted to help others in any way he could. They went through the paperwork with the coordinator and decided that they wanted to say their final goodbyes and leave the hospital. The coordinator agreed to keep them updated about the process.

Ultimately, Mr. Peterson was able to donate his liver and both kidneys to three fortunate recipients. He was also able to donate his corneas, skin, bone, and vascular tissue of the heart, which would improve the lives of countless recipients nationwide.

Six months later, the Peterson family received a letter from one of the kidney recipients. She was a 65-year-old retired nurse who thanked them for their decision to donate. She no longer required dialysis and was so grateful to spend more time with her grandchildren. The Peterson were so proud that Mr. Peterson's final act was one that helped so many.

CHAPTER 46

Pulmonary Palliative Care

Patricia A. Maani-Fogelman
and Ruby A. Weller

Key Points

- The American Thoracic Society (ATS) has issued a Clinical Policy Statement on Palliative Care for Patients with Respiratory Diseases and Critical Illness.
- There are available triggers to use to identify patients in need of referral to a pulmonary-palliative medicine clinic.
- Regardless of prognosis, much can be done to optimize management of the advanced pulmonary patient.
- This chapter provides an overview for the rationale and justification of early integration of palliative care for the advancing/chronic lung disease patient.

Introduction

Patients with advanced/terminal lung disease require a more comprehensive approach to assure relief from suffering and distress as well as reassurance that they will be cared for through the trajectory of their chronic, progressive illness.[1] Additionally, family/caregiver support is also a priority. Patients with advanced lung disease have physical, psychological, social, and spiritual issues that reduce their quality of life (QOL). The emotional dimensions of chronic conditions are often overlooked when medical care is considered, and, while it may be difficult to diagnose depression in the medically ill, diagnosis and treatment are essential.[2,3] Data show 18% of US gross domestic product is spent on healthcare, with $3 trillion spent on healthcare annually in the US (twice the amount spent on food) and 33% spent on hospitalization costs. By 2037, the percentage of gross domestic product is expected to increase to 25% and this spending is unsustainable.[4] Furthermore, despite these high expenditures, health outcomes in the US are not considerably better than in other high-income countries.[4]

Today's healthcare providers are well-equipped for the biomedical aspects of care but not for the challenges of understanding the psychological, social, and cultural dimensions of illness and health. Clinicians on every level can play an important part in helping their patients to develop and maintain healthy coping skills.[5]

Of all the advanced lung diseases, chronic obstructive pulmonary disease (COPD) is the leading diagnosis for respiratory failure–related deaths[6]:

- The Global Burden of Disease Study reports a prevalence of 251 million cases of COPD globally in 2016.
- An estimated 3.17 million deaths were caused by the disease in 2015 (this is 5% of all deaths globally).
- More than 90% of COPD deaths occur in low- and middle-income countries.

On average, more people die every day from COPD than from diabetes or breast cancer: 377 per day from COPD versus 193 per day from diabetes or 112 per day from breast cancer.[6,7]

Most people nearing the end of life are not physically, mentally, or cognitively able to make their own decisions about care. Of people who indicate their end-of-life (EOL) care preferences, most choose care focused on alleviating pain and suffering.[5] Frequent clinician–patient conversations about EOL care values, goals, and preferences are necessary to avoid unwanted treatment. Incentives, quality standards, and system support are needed to promote improved communication skills and more frequent conversations.

Recommendations from the American Thoracic Society,[8] Institute of Medicine (IOM),[2,3] National Consensus Project (NCP) Clinical Guidelines,[9] and the American Society of Clinical Oncology[10] (ASCO) provide support for the framework of this comprehensive care plan. Much of the data stem from cancer-based research. However, the 2013 NCP report analyzed patients of any age with multiple comorbid/chronic conditions, with the intent to offer the focus of palliative care interventions for the most seriously ill. The NCP integrates central quality assessment and improvement initiatives into palliative care, and it describes the comprehensive care necessary for patients at the end of life. These clinical guidelines emphasize the patient- and family-centered focus of palliative care, promoting access to palliative care across all patient populations and all health settings. In addition, there is expansion of the composition and necessary education of the intradisciplinary team beyond chaplaincy, medicine, nursing, pharmacy, and social work to include rehabilitation therapists, respiratory care, and other therapies.[8–10]

The American Thoracic Society (ATS) issued a Clinical Policy Statement: Palliative Care for Patients with Respiratory Diseases and Critical Illnesses, which delineates the obligations of pulmonary providers to the patients we serve. The ATS acknowledges that pulmonary providers routinely care for patients with chronic or advanced respiratory diseases and critical illnesses.[8] The ATS recognizes the growing importance and complexity of palliative care for patients with life-threatening and life-limiting diseases and disorders and the need for improving professional competence and teamwork in providing such care. The statement strongly endorses the concept that palliative care should be available to patients at all stages of illness and should be individualized based on the needs and preferences of the patient and the patient's family. Finally, the ATS believes that clinicians should consult with palliative care specialists as appropriate for managing palliative care situations beyond the clinician's level of competence.[8]

Dyspnea: Why Is It Important?

Before reading this next section, please see the Dyspnea Empathy Exercise in Box 46.1 developed by Dr. Betty Ferrell. Dying patients fear dyspnea and pain; therefore, symptom control is one cornerstone of pulmonary palliative care. Dyspnea is a prominent symptom of the patient with advanced respiratory disease of any cause: Nearly all patients with COPD had dyspnea during the last 3 days of their lives.[11,12] Since the publication of the original ATS consensus statement in 1999, there has been substantial progress made in research into mechanisms of dyspnea. However, there has been little progress in treatment of dyspnea.[13] Despite advances in the therapy of several cardiopulmonary disorders, there are millions of patients who are severely disabled by breathlessness. Efforts to cure disease are the focus of much biomedical research and tend to grab the public's attention. However, the duty to alleviate suffering must remain a top priority. The ATS concludes: "It is our hope that this document summarizes the progress that has been made and what remains to be done to allow our patients to enjoy one of our most primal needs—breathing."[13]

Pulmonary-Palliative Clinic: A New Construct

Although those with advanced lung disease may receive "palliative" or life-prolonging treatment, this usually does not address their physical, psychological, social, or spiritual issues—and may worsen them. In our work at Geisinger Medical Center, we hoped to establish a dedicated clinic with the time and staff educated to address these issues in a safe forum for our patients and their families, a place that would allow a continued dialogue with patients and their families. The reality is that earlier involvement of palliative care leads to improved QOL for patients and families, as well as a more efficient utilization of medical resources in a more appropriate, even cost-saving, manner[14,15] and higher patient satisfaction when the "unknown" is no longer a dark, scary mystery. The intention of the Pulmonary-Palliative Medicine clinic is to encourage these discussions earlier in the trajectory of chronic, progressive illness. In keeping with the tenets of palliative care, the earlier referral and integration of palliative care services into the management of advanced disease led ultimately to improved QOL and higher patient and family satisfaction.[16] Practice is carried out with the realization that there are different levels of training among providers of palliative care:

Box 46.1 Dyspnea Empathy Exercise

While seated, take a normal resting breath but only exhale partially.

Wait a few seconds and take another resting breath and only exhale partially.

Wait a few seconds and repeat.

After a few more seconds, breathe normally.

After this simple exercise, ask yourself these questions;

What was your experience? How did you feel? Were you a little anxious? Did you feel some stress? Was it unpleasant?

This exercise causes a 4–5 mm Hg elevation in CO_2 from your baseline, with an associated dyspnea and affective (fear/anxiety) response. While this is a temporary, controlled exercise that can be stopped at any time, it does effectively reflect minor dyspnea. Now take a moment to imagine if this feeling was dramatically amplified, as it is with advanced lung disease patients who have no recourse or relief from the severity of their lung disease.

Specialist: Professionals with advanced palliative care training/certification who specialize in providing symptom management and support to those with serious medical illness in parallel with their treatment as well as at end of life. The Palliative Care Specialist is adept at managing complex and refractory symptoms that may occur with disease progression as well as being an experienced navigator of the psychosocial challenges and family dynamics which accompany these circumstances.

Generalist: Professionals from other specialties with training in basic palliative care concepts/content who identify the need for and initiate advance care planning, symptom management, and QOL support for their patients. Ideally all providers should be familiar with providing basic palliative care and then refer to and collaborate with palliative specialists as needed.

The goal is to improve education and outreach to be able to arrive at an equipoise where all professionals provide basic palliative care to most patients but will refer to palliative care specialists when higher intensity/higher levels of palliative care are required to optimize patient care.[17]

Palliative Care for People with Advanced Lung Disease

Palliative care encourages and supports family involvement in planning and providing care to the extent desired by the patient. This is because chronic or advanced respiratory diseases and critical illnesses impact both patients and their families. All patients with symptomatic or life-threatening diseases, particularly those with chronic or advanced respiratory diseases or critical illnesses, regardless of age or social circumstances, should have access to palliative care. Perhaps more importantly, healthcare providers should have an appropriate level of competence in palliative care, where training and educational experiences equip the pulmonary provider with the core competencies necessary to provide compassionate and individualized palliative care.[18,19] The ATS supports efforts of public education about the availability and value of incorporating palliative care in the care of patients with chronic or advanced respiratory diseases or critical illnesses, including advocacy for research and professional education to improve the quality and availability of palliative care services.[8]

Advanced Lung Disease and Unique Circumstances

Historically, palliative care has focused on patients with malignancy. Recently, considering the mortality and morbidity of COPD as delineated earlier, there is increasing recognition of the need for similar services for individuals with respiratory conditions. This includes other nonmalignant end-stage pulmonary diseases such as cystic fibrosis, interstitial lung disease (ILD), pulmonary arterial hypertension, sarcoidosis, and occupational lung disease. Often, these conditions are treated without a concomitant palliative component until there is a sudden change in the trajectory of the illness or a decline, necessitating a sort of crisis approach to their needs.[20,21] Symptom management should address air hunger, exertional dyspnea, chest tightness, anxiety/panic, increased work of breathing as evidenced by increased accessory muscle use, increased oxygen needs, spiritual or existential distress, and grief.

Uncertainty in Prognosis and Disease Trajectory

Time from onset of symptoms to diagnosis may be delayed. With ILD, this delay has been noted to be 3 years or more, with patients seeing three providers or more before receiving a definitive diagnosis. This impacts their trajectory, delaying advanced therapies developed to slow disease progression.[22]

The disease trajectories of nonmalignant chronic lung diseases, such as COPD, ILD, pulmonary hypertension, and cystic fibrosis, are variable and characterized by considerable uncertainty. With COPD and pulmonary fibrosis, patients typically have a gradual decline, but the trajectory can change abruptly due to exacerbation of the underlying lung disease or an event caused by a comorbid condition. With this exacerbation, patients may not be able to return to their previous level of functioning.[21–23]

The disease trajectories for lung diseases such as pulmonary hypertension or lung transplant recipients differ depending on the cause of the disease, comorbid conditions, complications related to therapy, response to treatment, or surgery. These are changing with the advent of newer therapies and experienced centers for treatment.[24]

Advanced therapies to slow the progression of illness present special challenges at end of life. Patients may not understand that these are not curative. These therapies are expensive, and, with current regulations, the patient must often choose between continuing therapy and hospice.

Idiopathic pulmonary fibrosis (IPF) is a progressive disease with median survival of 2 to 7 years. IPF now has therapies available which do not reverse damage but have been shown to slow the decline in the loss of lung function as measured by forced vital capacity (FVC) on the pulmonary function test. Further drugs or drug combinations can be expected in the future. These medications may cause side effects which impact QOL. This leaves patients trading-off coping with drug-related symptoms for a hopefully longer life span.

Early Integration of Palliative Care in Advanced Pulmonary Disease

Despite recommendations for early integration of palliative care, few studies are available on end-of-life recommendations for this population. Patients may continue to have a significant symptom burden, most commonly dyspnea and cough. Their oxygen need increases over time. According to a recent study, IPF has a major impact on daily living and family relationships.[24] This slowing rather than reversal or stopping of progression may be difficult for patients and families to understand. It is important when initiating these therapies that their efficacy be clearly explained and that this information be reviewed periodically. Early referral to a lung transplant center, if applicable and if the patient agrees, is recommended.

More than 100 types of ILDs have been identified, and, for most of these patients, lung transplant is not an option.[22] Therapy varies depending on etiology, and, for some, no therapy is available. Most of these patients die in a hospital setting with ongoing life-prolonging procedures until death. Often EOL decisions are still made very late. Early integrated palliative care with advance care planning could improve their EOL care. Further studies on the care received and ways to improve end of life for this population are needed.[22,25]

Providers should begin conversations early in their care concerning when to expect to stop or reduce therapy. This should include integrating advance directive decisions. Patients and families may find it difficult to stop therapy even in the face of a decline in functional status. In the face of irreversible functional decline, the focus should be to continue treating comorbidities and be directed toward aggressive symptom management. Pulmonary rehabilitation can be considered to attempt to improve functional status and QOL.[21]

Medication Dilemmas

Pulmonary hypertension medications have their own special challenges because their efficacy often is limited and continual use may contribute to functional decline. Many of them are titrated or combined to maximize efficacy and carry the risk of rebound if abruptly stopped.[24] Patients also note improvement when they are started, so they may be reluctant to reduce or stop them for fear of becoming symptomatic. However, as the disease progresses beyond the ability of medications to control it or the patient experiences a functional decline or a dying process for another reason, this may become necessary. As with other end-of-life planning, the patient and family should be consulted on the timing of tapering medications down. The plan should include aggressive measures to manage dyspnea, hypertension, edema, or related symptoms. With oral medications, it may consist of reducing the number of tablets or frequency stepwise over time. With intravenous infusions, a gradual stepping down of rate of infusion may take days to a week or more to mediate symptoms. If possible, consider tapering off inhaled or intravenous therapy but continue PD5 inhibitors or another oral pulmonary hypertension medication. Diuretics should be continued as possible and as tolerated for management of edema and breathlessness.[24] These medications have been the patient's lifeline, many times for years, so patients may approach the process of tapering or stopping them with fear and with questions about hastening their demise despite indications of loss of clinical efficacy and functional decline.

Advanced Ventilatory Technology

Noninvasive ventilation (NIV), bimodal positive airway pressure (BiPAP) therapy, and nocturnal ventilation via tracheotomy are becoming increasingly common therapies. In the latter stages of disease and at end of life, home NIV may provide symptom relief and rest periods to offset the increased work of breathing.[25,26] In an acute situation, it may provide time for decision-making or family interaction. Patients and providers may elect noninvasive support to treat a possibly reversible comorbidity such as infection. It should be combined with aggressive management of dyspnea for patient comfort but also to facilitate the patient's ability to remove the device for communication with family and pleasure feeds. Both opioids and anxiolytics should be considered.[27] Like other advanced therapies, an early conversation about this being a temporizing therapy and when to discontinue it should occur before initiating therapy. Patients and families should be encouraged to participate in this decision as it may involve waiting for a distant member to arrive or meeting or avoiding a special date or milestone.[26]

Forecasting

Identifying which individual with an advanced pulmonary diseases will have a rapid versus more indolent progression of their illness remains the challenge. Efforts are underway to broaden our understanding. Diffusion capacity for carbon monoxide (DLCO) is a measure done as part of a full pulmonary function test; it measures the transfer of gas from air in the lung to the red blood cells in lung blood vessels. A DLCO of less than 40% predicted, desaturation with exercise, and concomitant pulmonary hypertension are poor prognostic signs. The prognosis of combined pulmonary fibrosis and emphysema (CPFE) is worse than either disease alone. For ILDs, worsening fibrotic changes on radiology, decline in diffusion capacity, increasing oxygen need and dyspnea, decline in distance on 6-minute walk test, and decline in FVC are longitudinal indicators. Unintentional weight loss, repeated hospital admissions, and progressive decline in functional status are general clinical indicators.[25]

With pulmonary arterial hypertension, accepted guidelines use N-terminal pro b-type natriuretic peptide (NT proBNP) and renal function as markers of disease severity. Other inflammatory markers such as interleukin 6 (IL-6), growth differentiation factor 15, and red cell distribution width are useful but not commonly available. Research is under way to find other markers, for example a nine-protein panel that will provide information on prognosis and response or lack of response to therapy. These could be beneficial in guiding therapy as well as in decision-making.[28]

Toll of Serious Illness on Patients and Families/Caregivers

Like many patients with advanced illness, those with advanced lung disease fear they will be a physical and financial burden.[29,30] Studies have demonstrated that caregivers of patients with advanced lung disease report needing/desiring support with physical care and education/information about advanced illness and end-of-life processes, as well as the all too important but all too often underacknowledged need for emotional and spiritual support.[30] Patients and family often worry about if "nothing more can be done," will healthcare providers abandon them? They are often consumed with worries about how their families and caregivers adjust to role changes: many drain life savings or go bankrupt to cover medical costs.[29] Approximately 40% of all COPD patients are affected by severe depressive symptoms or clinical depression, with the prevalence of depression as high as 57%, and this can often be a challenge to diagnose because of overlapping symptoms between COPD and depression.[6,8,12,29,30] As a result, advanced lung disease patients often feel helplessness or powerlessness due to their loss of mobility and freedom and their growing weakness; they report tense relationships with friends and family, often developing panic attacks with episodes of uncontrolled dyspnea and increasing social isolation as they interact less and less with their world. This can often lead to more depression, anxiety, insomnia, or sleep disturbance.[6,12,27,30]

As the Medicare data confirm, many older adults may be cared for by an aging/also chronically ill spouse; additionally, older children caring for a parent may also have acute or chronic illnesses.[31] Strategies for coping with advanced lung disease include regular exercise (which can often be "jump-started" by enrollment in pulmonary rehabilitation for qualified patients); cognitive behavioral therapy; support groups, such as the Better Breathers Club; keeping oneself emotionally open to those seeking to assist and care for them; and the positive reinforcement felt by engaging in activities which promote happiness such as time with friends and family, hobbies that bring personal joy, or meditation.[32]

The Pulmonary-Palliative Medicine Clinic at Geisinger Medical Center

At Geisinger Medical Center, a level 1 shock-trauma academic medical center located in rural north-central Pennsylvania, a shared modality clinic was initiated and developed by Nurse Practitioners with the goal of providing advanced lung disease patients with palliative and pulmonary care. This clinic allows patients and their families the opportunity to integrate ongoing management of lung disease with advanced illness planning and symptom management. Preliminary research found no previous existence of such a clinic; therefore, the need to build this from inception using evidence-based medicine became the necessity. The Geisinger Medical Center's Pulmonary-Palliative medicine is a dedicated clinic with the time and trained staff to address the multifaceted issues of advancing lung disease in a safe forum for patients and their families to pursue discussions that are an ongoing dialogue across the continuum of clinical care.

This enterprise began in 2008, with the Geisinger Medical Center's Divisions of Pulmonary and Palliative Medicine. This clinic was started by Patricia Maani-Fogelman DNP with the leadership support of respective division directors, Drs. Paul Simonelli (Pulmonary-Critical Care) and Neil Ellison (Palliative). In this setting, patients with advanced lung disease are seen by Pulmonary-Palliative Care Nurse Practitioners (the authors of this chapter) with extensive pulmonary, critical care, and palliative care backgrounds. Specific attention is given to the management of advanced lung disease symptoms, especially dyspnea, anxiety, depression, and fatigue, as well as to initiating discussions to establish goals of care, advance directives, code status, and more. When appropriate, hospice discussions and referrals are initiated with these patients subsequently managed by the Pulmonary-Palliative NPs through the course of their progressive lung failure. The guidelines for the clinic's practice mission came from the ATS policy and consensus statements as well as from the National Consensus Project, which issued clinical practice guidelines (updated in 2018) for the delivery of quality palliative care for patients with advanced disease. These guidelines were not cancer-specific and included patients of any age living with progressive chronic conditions as well as those who are seriously and terminally ill. These are patients for whom intensive palliative care is the predominant focus for the remainder of their lives.[8,9,12,13,15–17]

Difficulty with managing the advanced lung disease patient is often due to the unpredictability of their illness and difficulties in prognostication.[8,21,27] The advantage of this clinic is that by integrating early discussions into their routine care, one can provide follow-up and continued dialogue across the continuum of the patient's disease trajectory. A barrier often encountered is that the delivery of palliative care has traditionally been viewed as a role for specialists, when (and as advocated by the ATS) it truly should be an integrated, fundamental component of comprehensive pulmonary care.[1,6,8]

There is a need for education and training for healthcare and social care professions to plan and provide high quality EOL care, and this is intensified in pulmonary medicine where patients have incurable, progressive illness with relatively high mortality and morbidity as disease advances.[6,8,9] Pulmonary-palliative care consults and ongoing care emphasize patient dignity, autonomy, and comfort. The first focus is to determine the patient/family understanding and goals. Part of this process is often early discussion and intervention for advanced illness planning in hopes of avoiding inappropriate medical interventions in favor of those that will not prolong a process of dying, but serve to prolong a process of living.[33,34]

If indicated, the Pulmonary-Palliative NPs arrange aggressive, state-of-the-art medical care for patients with advanced illness which may include measures such as high-flow nasal cannula, NIV, and continuous or bi-level positive airway pressure therapy. Underlying this is ongoing medical management and psychosocial support for patient, family, and caregivers. All too often, there is the need to dispel myths concerning mechanical ventilation, as most think death is swift and sudden or they will be unconscious if on life support. The experience of this clinic has beautifully demonstrated that human beings are adaptable—because patients control their breathlessness by decreasing what they do on a daily basis, they are surprised when told they have a life-limiting illness and should consider palliative care.

When assessing readiness or suitability for pulmonary-palliative intervention, there are various triggers we use embedded within our daily pulmonary medicine practice:

- The *BODE index* (*B*ody-mass index, airflow *O*bstruction, *D*yspnea, and *E*xercise) is a scored index used to assess patients with COPD to predict long-term outcomes for them.[35] The degree of airflow obstruction is determined by the forced expiratory volume percentage predicted after using a bronchodilator to open airways from the pulmonary function test, the dyspnea is as reported by the patient, and the exercise component is measured using a 6-minute walk test distance. While it should not be used alone to guide treatment, the BODE score is a helpful adjunct to promote early conversations about advancing lung disease, allowing a focused conversation on the reality of their prognosis using clinical evidence. In general, patients with a higher BODE are at increased risk of mortality and often have increased frequency of COPD exacerbations and hospitalizations. This score can be calculated with an online calculator: https://www.mdcalc.com/bode-index-copd-survival#creator-insights.
- The *GAP index* is a risk assessment system used for clinical prediction of prognosis in patients with IPF. Using the frequently measured clinical and physiologic variables of gender (*G*), age (*A*), and two lung physiology variables (*P*) (FVC and DLCO, described earlier), the GAP index provides an estimation of individual risk of mortality. This score can be easily determined using the online calculator: https://www.acponline.org/journals/annals/extras/gap/.

Tools like BODE and GAP assist in shaping prognostic conversations, but providers are encouraged to remember that end-stage lung disease patients, especially those with COPD, remain a notoriously difficult population to predict. Patients can lose ground with a viral illness and never regain it, or they can plateau and remain there for months, even years. Clinically, we also look at severity of lung function, frequency of exacerbations, need for oxygen, and declining functional status. Early identification and intervention is key because the symptom burden in severe COPD can be as high as in patients with lung cancer, but COPD patients may have a longer survival.[34] We continue usual management of dyspnea with opioids, inhaled medications, and oxygen. Even for those with respiratory derangement, doses of opioid are safe and effective. Other considerations include anxiety (a result of and contributor to breathlessness), depression, fatigue, and pain. Patients with end-stage lung disease have significantly impaired QOL and emotional well-being. Those with end-stage COPD have needs that are not as well met as patients with lung cancer, and, at times, their survival is shorter.[12,19,20,26]

The majority of patients seen in this clinic are those with COPD or ILD, a statistic that correlates with the national prevalence of COPD as the leading lung disease and ILD as a more fatal though less frequently occurring lung disease.[31] This clinic initiated a change in practice based on the rising national recognition of palliative care, access to palliative care for all chronic illness patients,[36] and, most specifically, the needs of advanced lung disease patients and their families.[8] It is the commitment of the providers to assure that all lung disease patients have access to high-quality palliative care earlier in their advancing disease trajectory. The projected outcome is to provide a more comprehensive paradigm of care for advanced lung patients. In essence, this clinic epitomizes a new construct, built to provide palliative care in conjunction with best practice guidelines for the care of advanced lung disease patients. We recognize this new construct/model has broad application potential for other chronic disease management clinics—as seen with similar models of palliative care delivery and the evidence established in oncology patient management.[9–12]

Case Study: A Patient with COPD

Mrs. C is an 85-year-old woman seen in clinic following admission for severe oxygen-dependent COPD with a past medical history of motor vehicle collision resulting in long-term sequelae of functional limitations and dysphagia with percutaneous gastric feeding tube. At baseline, she had dyspnea at rest and pulmonary function testing indicating lung function of 30% predicted. During her admission, it was discovered that she had elevated right heart pressures on echocardiogram, suggesting pulmonary hypertension; her right heart catheterization found no right or left heart dysfunction and no true pulmonary hypertension. She was unable to tolerate pulmonary rehabilitation due to the severity of her musculoskeletal complaints. She continued to decline, with progressive shortness of breath and frequent exacerbations which were not ameliorated with best-practice efforts and medical maximization. Due to continued decline in functional state, she was referred to the Pulmonary-Palliative clinic. At the initial visit, her chief complaint was increased cough and sputum. She was taking nectar-thick liquids, and a careful assessment of her intake revealed two cans of nutritional supplements but not much more hydration.

The Pulmonary Palliative NP added hydration via gastric tube, began daily airway clearance with a flutter device, and continued nebulizer therapies (initially, a recommendation to increase nebulizer frequency was made; however, the patient refused to escalate frequency of nebulizer due to the time factor). The Pulmonary-Palliative NP conducted ongoing advance illness planning discussions across multiple clinic visits, which included discussion of advance directives, code status, end-of-life care, and hospice education. Both the patient and her spouse expressed great relief at being able to begin this discussion. With continued visits, hospice was discussed further and code status was addressed: the patient was aware of her circumstances and verbalized satisfaction and happiness that she could be in control of her end-of-life decisions. Also during these visits, life and legacy reviews were conducted in conjunction with logotherapy—the patient shared that in her past she has been a performer who had at times worked on Broadway; during one memorable clinic visit she sang her favorite song, in a fair Irish brogue complete with gestures, from one of her performances. She called a few weeks later and elected hospice—which the Pulmonary-Palliative Medicine NP arranged in conjunction with her primary care office. During telephone visits with the Pulmonary Palliative NP, the patient expressed tremendous appreciation and gratitude for the focused care provided after inquiring about her wishes and preferences and for allowing her to share a part of herself that brought her extraordinary pride and joy. There was a reinforcement of her dignity with this—it was important that we knew her as a person, from the time before she was a “patient.” With several weeks of attentive hospice and palliative care, she died at home, in peace and comfort, holding her husband’s hand.

Conclusion

The advanced lung disease patient suffers from multifaceted symptoms which, in combination, contribute to a loss in QOL, emotional distress, and, perhaps the most egregious loss of all, their functional independence. Preserving the dignity of the advanced lung disease patient with early palliative care interventions, strong symptom management, and comprehensive management of their global needs will lead to true optimization of patient care and well-being. As Rachel Naomi Remen once said: “Our power to heal is far less limited than our power to cure. Healing is not a relationship between an expert and a problem . . . it is a relationship between human beings.”[37] In nursing, the art of our work, with its essence of caring and compassion, should remain the foundational core of all our actions when engaging in the care of others.

CHAPTER 47

Palliative Care in Heart Failure

J. Nicholas Dionne-Odom, Rachel Wells, and Keith M. Swetz

Key Points

- The heart failure disease trajectory is progressive although highly unpredictable, with periods of high function interspersed with sudden life-threatening exacerbations leading to emergent hospitalizations and often rapid deterioration and death.
- The focus of supportive care is on promoting positive health behaviors (diet, exercise, and smoking cessation) and symptom management, particularly shortness of breath, fatigue, and leg swelling.
- Management of advanced heart failure is treated with medicines and devices to sustain adequate circulation and prevent life-threatening arrhythmias.

Introduction

Heart failure is a complex syndrome resulting from any functional or structural disorder of the heart that lowers the ability of the heart to pump blood and/or leads to systemic or pulmonary congestion.[1] Heart failure is not a disease, but a syndrome, and hence diagnosis relies on a myriad of clinical indicators and functional ability assessment. Since the 1970s, heart failure in the US has been described as an epidemic as newer therapies have increased survival.[2,3] Heart failure can be a slowly developing condition that results from coronary artery disease, hypertension, diabetes, and valvular disease or one that develops precipitously after a myocardial infarction.[4] Those living with symptomatic heart failure experience lower quality of life (QOL) and high morbidity and mortality; however, advances in therapies including angiotensin converting enzyme (ACE) inhibitors, beta blockers, coronary revascularization, implantable cardioverter-defibrillators, and cardiac resynchronization have substantially improved outcomes for patients.[3,5]

An estimated 6.5 million Americans and 37.7 million individuals worldwide are affected by heart failure.[1,6] In the United States, there are 960,000 new cases of heart failure each year and just over 300,000 deaths.[1] It is estimated that, by 2030, the number of Americans with heart failure will increase to 8 million.[7] African Americans have the highest incidence of heart failure, followed by Hispanic, white, and Chinese Americans, with many of these differences mediated by differences in hypertension, diabetes, and low socioeconomic status.[1] The morbidity and symptom burden due to heart failure is often high. Nearly 3 in 4 suffer from at least one comorbidity, the most prevalent of which include chronic kidney disease, anemia, diabetes, and chronic obstructive pulmonary disease (COPD).[8]

The toll of heart failure on economic and healthcare utilization resources is considerable.[9] Worldwide, the economic cost of heart failure has been estimated at $108 billion per year.[9] In the United States, medical costs directly related to heart failure amounted to $20.9 billion in 2012,[5] with estimates predicting an increase to $53 billion in 2030.[7] These costs nearly triple in the last 3 months of life, mostly due to increased number and length of hospitalizations.[10] Indeed, periodic exacerbations of heart failure require intensive treatments that nearly always require hospitalization. Close to 1 million hospitalizations occur each year due to heart failure, and it is the leading cause of hospitalization for individuals 65 years of age and older in both the United States and Europe.[2,6]

To help persons and families affected by heart failure manage the high symptom burden, complex decision-making, and ever-present risk of exacerbation and death, the early integration of palliative care is critical and has been recommended in numerous organizational statements in both the United States and worldwide.[11–19] Palliative care in the setting of heart failure seeks to mitigate complex symptoms and maximize function; promote positive coping, psychological health, and spiritual behaviors; enhance communication and decision-making; facilitate prognostic understanding and advance care planning; and coordinate care, including transitions to hospice care when appropriate. To describe the role of palliative care further, this chapter provides an overview of the palliative care aspects of heart failure care.

Heart Failure Pathogenesis

Cardiac output is the primary indicator of cardiac performance. It equates to the product of the number of beats per minute (heart rate) and how much blood the heart pumps with each beat (stroke volume). *Heart rate* increases through activity of the sympathetic nervous system that speeds up the heart and is decreased by the parasympathetic nervous system. *Stroke volume* is determined by preload, afterload, and myocardial contractility. *Preload*, also called *end-diastolic volume*, is the amount of blood present in the ventricle at the end of diastole just prior to the heart pumping (or systole). As preload increases, myocardial muscle fibers stretch and eject with a proportionate force according to the Frank-Starling mechanism.

The fraction of blood ejected by the ventricle relative to the preload is called *ejection fraction* and is the most commonly used metric for assessing heart failure. *Afterload* is the amount of resistance against which the ventricles must contract in order to eject blood and is a function of systemic vascular resistance and ventricular wall tension. The higher the systemic vascular resistance, the more forceful the systolic contraction must be to push blood out of the ventricle. *Contractility*, or *inotropy*, is the ability of the heart muscle fibers to contract against a load in the atria and ventricles. Myocardial contractility is governed at the cellular level by calcium ions (Ca^{++}) and the sodium-Ca^{++} exchange pump, hence many drugs for heart failure affect these cellular mechanisms.

Heart Failure with Reduced Versus Preserved Ejection Fraction

Based on measurement of the left ventricular ejection fraction (LVEF), heart failure is most commonly characterized as having reduced (≤40%) or preserved LVEF (≥50%). In *heart failure with reduced LVEF* (HFrEF) (also referred to as systolic dysfunction), myocardial contractility has been weakened, resulting in a lower ejection fraction and cardiac output. Primary causes of HFrEF include coronary artery disease, hypertension, ischemic heart disease (i.e., myocardial infarction or ischemia with associated ventricular remodeling), and valvular disease (e.g., aortic stenosis). Common co-occurring conditions are supraventricular tachycardias (e.g., atrial fibrillation), ventricular arrhythmias, bradycardia, venous thromboembolism, anemia, and sleep disruption.

In contrast, and occurring in fewer cases, *heart failure with preserved LVEF* (HFpEF) (also called diastolic dysfunction) retains a normal ejection fraction (40–65%) but the ventricles are stiff, less compliant, and unable to stretch normally. Consequently, venous blood returning from systemic circulation is unable to adequately fill the ventricles, thereby compromising preload and reducing stroke volume. As heart rate increases, diastolic filling time decreases, and hence, HFpEF worsens with tachycardia. Common causes of HFpEF are those that impede expansion of the ventricle (e.g., pericardial effusion, constrictive pericarditis), those that increase myocardial wall thickness and reduce chamber size (e.g., hypertrophic cardiomyopathy), and those that slow diastolic relaxation (e.g., ischemic heart disease). Resultant co-occurring conditions mirror that of heart failure with reduced LVEF.

Right Versus Left Ventricular Dysfunction

Heart failure can be classified according to whether the right or left ventricle is primarily affected (although both ventricles are typically affected over the long term). Right ventricular heart failure is the inability of the right ventricle to move deoxygenated venous blood from systemic circulation into the pulmonary circulation. Major effects include dependent peripheral edema, reduced left ventricular cardiac output, and hepatomegaly due to blood backing up into the hepatic veins. If hepatic circulation remains congested for a prolonged period, blood will begin engorging the spleen and the gastrointestinal tract resulting in decreased hepatocellular function, ascites, altered nutritional uptake, and gastrointestinal discomfort. The most common cause of right ventricular heart failure is left ventricular heart failure. Other causes include chronic pulmonary hypertension (also called cor pulmonale) due to thromboembolic disease or structural lung disease, tricuspid or pulmonic valve stenosis or regurgitation, right ventricular infarction, cardiomyopathy, and congenital heart defects (e.g., Tetralogy of Fallot, ventricular septal defect).

Left ventricular heart failure occurs when oxygenated blood from the pulmonary circulation is not effectively pumped into systemic circulation. This lower cardiac output results in blood backing up into the left ventricle, left atrium, and the pulmonary circulation. Consequently, pulmonary capillary pressures increase and, if high enough, cause intravascular fluid to infiltrate the lung interstitium resulting in impaired gas exchange (i.e., hypoxia) and pulmonary edema. The most common causes of left ventricular heart failure are hypertension and myocardial infarction. Aortic or mitral valve stenosis or regurgitation may also cause this type of heart failure.

Disease Trajectory and Prognosis

Illness Trajectory

The heart failure disease trajectory is progressive yet highly unpredictable, with periods of high function interspersed with sudden life-threatening exacerbations leading to emergent hospitalizations and sometimes rapid deterioration and death. For many, heart failure begins with an emergent presentation to the emergency department with severe breathlessness and chest pain or discomfort (e.g., acute myocardial infarction); for others, the onset is gradual with increasing breathlessness and fluid retention that might be first evaluated by a primary care provider. Though depending on the severity of the initial insult, medications combined with lifestyle modifications (e.g., low-sodium diet, increased physical activity, weight loss) and fluid management can effectively ameliorate nearly all symptoms, helping patients reach a state of near-baseline functioning that can potentially last several years. As heart failure progresses, however, symptoms begin to reoccur that require management beyond medication therapy and include consideration of implantable cardiac devices, such as pacemakers and left ventricular assist devices. How people die with heart failure varies considerably. For some, a spontaneous cardiac event, such as a lethal arrhythmia, can occur unexpectedly and result in rapid deterioration and sudden death. For others, the dying phase is prolonged due to progressive pump failure marked with episodes of acute decompensation and severe symptoms.

Classification

Two classification systems are most commonly used to grade the severity of heart failure: the American College of Cardiology/American Heart Association (ACC/AHA) Stages and the New York Heart Association (NYHA) Classes (see Table 47.1).

The two classification systems have some similarities; however, the ACC/AHA system includes criteria for both physical symptoms and structural abnormalities of the heart, whereas the NYHA system only includes physical symptom criteria. An individual's NYHA class can fluctuate based on clinical status, but their ACC/AHA Stage progresses unidirectionally; hence, one's stage and class are not direct corollaries of one another.

Estimating and Communicating Prognosis

Estimating and communicating prognosis in heart failure is critical to help patients and families plan and make decisions about treatment. However, accurate prognosticating is extremely difficult due to the interactions of frailty, polypharmacy, and comorbidities (the average patient is on nine medications and has

Table 47.1 Classification systems for heart failure and typical treatments[15,16,29]

ACC/AHA heart failure stages		NYHA heart failure classes		Typical treatments
Stage A (At risk)	No limitations or symptoms of HF. No structural heart abnormalities. Often presence of hypertension, diabetes, coronary artery disease, and metabolic syndrome.	No comparable class		Lifestyle changes including regular exercise, smoking cessation ACE inhibitor or ARB if confirmed coronary artery disease, diabetes, and hypertension Beta-blockers if post-myocardial infarction or hypertension
Stage B (Asymptomatic)	No limitations or symptoms of heart failure. Structural heart abnormalities present (e.g., left ventricular hypertrophy or other evidence of remodeling). Decreased ejection fraction. Often subsequent to myocardial infarction, valvular disease, and/or cardiomyopathy.	Class I	No limitations of physical activity. Ordinary physical activity does not cause fatigue, dyspnea, or palpitation.	ACE inhibitor or ARB Beta-blockers if post-myocardial infarction Aldosterone inhibitor if the symptoms continue while taking beta-blockers and ACE/ARB medications Surgery for coronary artery repair and valve repair or replacement Implantable cardiac defibrillator (ICD)
Stage C (Symptomatic)	Shortness of breath, fatigue, and activity intolerance with activities of daily living. Structural heart abnormalities present.	Class II	Slight limitation of physical activity. Comfortable at rest. Ordinary physical activity causes fatigue, dyspnea, and/or palpitation.	ACE inhibitors and beta-blockers Hydralazine/nitrate combination if symptoms persist Diuretics and digoxin if symptoms persist Aldosterone inhibitor if symptoms severe and other medications have been initiated ARBs and neprilysin inhibitors Biventricular pacemaker Implantable cardiac defibrillator
		Class III	Marked limitation of physical activity. Comfortable at rest. Less than ordinary activity causes fatigue, dyspnea, and/or palpitation (e.g., walking distances of 20–100 meters).	
Stage D (End-stage)	Presence of progressive and/or persistent severe signs and symptoms of heart failure driven primarily by the heart failure syndrome itself despite optimal medical, surgical, and device management.[19] Frequent hospitalization, severely limited exertional tolerance, and poor quality of life are typically present.	Class IV	Physical activity not possible without discomfort. Heart failure symptoms at rest.	Strict fluid and sodium restriction Surgery (e.g., valve replacement) Heart transplantation Ventricular assist devices Continuous intravenous inotropic support

ACE, angiotensin converting enzyme; ARB, angiotensin II receptor blocker.

four or more comorbidities),[20,21] discerning treatment-responsive from treatment-nonresponsive situations, and wide variations in end-of-life events.[17] While survival has improved since the 1970s,[3] approximately 25% of individuals newly diagnosed with heart failure will die within 1 year and 50% within 5 years. However, these rates vary by age and type of heart failure, with individuals 80 years of age or older and those with HFrEF experiencing the highest mortality rates.[22,23] It is also important to note that about half of heart failure deaths are due to complications of comorbidities, particularly respiratory conditions and cancer.[22,24]

Despite the challenges in accurate prognostication, recommendations in the current literature suggest using a combination of objective risk models and clinical gestalt.[12] The Seattle Heart Failure Model (SHFM) and the Meta-Analysis Global Group in Chronic Heart Failure (MAGGIC) risk calculators are well-validated multivariable models and are available online (https://depts.washington.edu/shfm/ and http://www.heartfailurerisk.org). While predicting death in heart failure using these models is imperfect, predicting *nonsurvival* outcomes of importance to patients and families—such as QOL, symptom burden, and rehospitalizations—using prognostic models is even poorer.[25,26]

Despite the many challenges to accurate prognosis, prognostic assessments are recommended yearly and subsequent to hospitalization and stabilization after major health changes and events.[12] Such events represent “inflection points” that warrant reappraisal of goals of care, patient and family preferences, and treatment modalities. Approaches to “serious illness,” “bad news,” and “prognosis” conversations are covered in greater depth elsewhere,[27,28] and the palliative care nurse clinician is encouraged to continually enhance skills and prepare in advance for these conversations.

Overview of Assessment and Medical Management in Stage D Heart Failure

A number of major guidelines are published and regularly updated for the treatment of advanced Stage D heart failure, including the 2013 American College of Cardiology/American Heart Association guideline with 2017 focused update,[15] the Canadian Cardiovascular Society guidelines, the 2016 European Society of Cardiology guidelines,[16] and the National Institute for Health and Care Excellence chronic heart failure guideline (available at http://pathways.nice.org.uk/pathways/chronic-heart-failure). The following overview of heart failure clinical assessment and treatment is consistent with these guidelines.

Health History

Important health history information to collect during assessment includes:

- History of present illness including heart failure progression history and precipitating factors for most recent episode
- Heart failure risk factors and preventive behaviors (e.g., exercise, weight loss)
- Exacerbation episodes and hospitalizations
- Current and past treatments, therapy response, and compliance
- History of physical (e.g., diabetes, COPD, dyslipidemia) and psychosocial (e.g., anxiety, depression) comorbid conditions
- Symptom assessment, particularly dyspnea, fatigue, pain, edema, anorexia and cachexia, depression, and anxiety, focusing on exacerbating and relieving factors (see section on "Management of Symptoms in Stage D Heart Failure")
- Patient and family's understanding of the illness and prognosis, to date, as well as current goals for care and treatment preferences
- Spiritual and faith-based practices and beliefs that may impact care

Physical Exam

The physical exam should begin with assessment of vital signs, height and weight, overall appearance, and mood/affect. In general, physical exam findings in heart failure lack sensitivity; however, a head-to-toe assessment may be remarkable for several of the following findings:[29]

- *Blood pressure and heart rate*: Tachycardia and systolic blood pressure less than 90–100 mm Hg is common if treatment is suboptimal. Presence of a weak, thready pulse and/or pulsus alternans (alternating strong and weak pulse) may indicate decreased cardiac output.
- *Jugular venous distension*: Assessed with the patient supine at a 45-degree angle. A distance of more than 3 cm between the sternal angle and the top of the internal jugular venous pulsation is a specific but not sensitive sign of elevated left ventricular filling.
- *Point of maximal impulse*: Assessed with finger palpation, the point of maximal impulse is typically located at the midclavicular line at the fifth intercostal space. Presence of cardiomegaly will shift this point laterally and downward.
- *Third and fourth heart sounds*: One or both of these heart sounds are present in nearly all cases of heart failure.
- *Pulmonary assessment*: Auscultation often reveals rales and/or wheezing. In some cases, increased lymphatic drainage compensates for increased pulmonary congestion over time.
- *Liver size and hepatojugular reflux*: Hepatomegaly may present in right-sided heart failure and can be assessed using the hepatojugular reflux. With the patient supine at a 45-degree angle and instructed to keep the mouth open (to prevent Valsalva maneuver), moderate pressure is applied to the middle of the abdomen for 30–60 seconds. Hepatojugular reflux is present if the height of the neck veins increases by 3 cm or more and remains increased during compression of the abdomen.
- *Lower extremity edema*: Usually detectable when the extracellular volume exceeds 5 L. The edema may be accompanied by stasis dermatitis, a chronic, eczema-like condition characterized by edema, hyperpigmentation, and sometimes ulceration.

Laboratory Data and Diagnostic Tests

Laboratory data and diagnostic tests are often performed prior to palliative care evaluation. Relevant tests and data to assess in relevance to heart failure include:

- *Hypokalemia*: Possibly due to thiazide diuretics.
- *Hyperkalemia*: Possibly due to potassium-sparing diuretics and ACE inhibitors.
- *Elevated blood urea nitrogen (BUN) and creatinine*: Consider prerenal azotemia related to pump failure and decreased renal perfusion.
- *Elevated liver enzymes, including serum transaminase and bilirubin*: Potentially hepatic congestion from right-sided (or left-sided) heart failure. Jaundice may be present. In cases of chronic hepatomegaly, cardiac cirrhosis may occur, signaled by hypoalbuminemia, hypoglycemia, and increased prothrombin time.
- *Decreased hemoglobin*: May indicate (1) normocytic anemia secondary to decreased production of erythropoietin (and thus decreased red blood cell production) due to chronic kidney disease (comorbid kidney disease is present in 20–40% of heart failure patients) and/or (2) anemia secondary to hemodilution through plasma volume expansion triggered by the renin-angiotensin system.
- *Elevated cardiac biomarkers including B-type natriuretic peptide (BNP), and N-terminal pro-B-type natriuretic peptide (NT-proBNP)*: Abnormally high levels typically indicate presence of acute and/or chronic heart failure and can be used to assist in diagnosis or exclusion of heart failure as a cause of symptoms (e.g., dyspnea, weight gain), inform prognosis, and estimate the likelihood of hospital readmission. Utility may be limited with concurrent renal failure.[15]
- *Electrocardiogram (ECG)*: Abnormalities in advanced heart failure are typically present and may indicate atrial and ventricular arrhythmias, heart block and other conduction problems due to electrolyte disturbances, ischemia (new and old infarctions), and cardiac remodeling.
- *Echocardiography*: Used to assess left ventricular size, mass, and function; valve function; regional wall motion; and ACC/AHA heart failure staging. Also allows for the estimation of ejection fraction.

- *Chest radiograph*: Can be used to evaluate heart size, pulmonary edema, and pleural effusions.
- *Cardiac catheterization*: Assesses coronary artery occlusion and pressure gradients across heart valves. Can also be used as a platform for stent placement of occluded vessels. Right-sided catheterizations can assess pressures on the right side of the heart and pulmonary pressures.
- *Stress test*: Used to assess cardiac function in response to external stress induced through either physical exertion (e.g., walking on a treadmill, pedaling on an exercise bicycle) or intravenous medications (e.g., adenosine).[30]

Treatment

Pharmacologic Treatment

Table 47.2 lists commonly used medications in the management of advanced heart failure by class. The primary goals of pharmacologic management are to improve cardiac function and reduce symptoms. While pharmacologic therapies can improve a

Table 47.2 Common medications in heart failure

Medications	Dose routes and ranges	Side effects	Special considerations
Angiotensin converting enzyme inhibitors (ACE inhibitor)			
Captopril	6.5–50 mg three times a day PO	**Hyperkalemia; dizziness;** cough; less frequent: pruritus, skin rash, taste loss (dose-related and reversible); agranulocytosis, renal impairment, angioedema	Frequent urinary/blood analysis needed. Monitor liver enzymes. Do not use in patients with history of angioedema or patients taking aliskiren with diabetes, lithium, gold, or mTOR inhibitors (sirolimus). Caution with patients with renal insufficiency. Dose adjustment required for hemodialysis.
Enalapril	2.5–20 mg twice a day PO		
Lisinopril	2.5–40 mg daily PO; 2.5 mg starting dose with hyponatremia or creatinine clearance <30 mL/min		
Angiotensin II receptor blockers (ARB)			
Losartan	25–150 mg daily PO; recommended hepatic initial dose: 25 mg PO daily	**Cough; dizziness; muscle ache**; hypotension; renal insufficiency; hyperkalemia	Caution with patients with low systemic blood pressure. Caution with concomitant use of potassium-sparing diuretics or NSAIDs. Do not use in diabetic patients taking aliskiren. Caution with patients on lithium—monitor serum lithium levels.
Valsartan	20–160 mg twice daily PO		
Angiotensin receptor-nephrolysin inhibitor			
Sacubitril/Valsartan	49/51–97/103 mg twice daily PO; 24/26 mg starting dose for patients ACE inhibitor/ARB naïve, creatinine clearance <30 mL/min, or moderate hepatic impairment	**Hypotension**; **hyperkalemia**; dizziness; renal insufficiency; angioedema	Not all doses tested in HF trial. 36-hour wait period switch to/from ACE inhibitor. Risk of angioedema. High cost due to lack of generic availability—might not be covered by some insurances. Do not use in diabetic patients taking aliskiren.
Loop diuretics			
Furosemide	20–80 mg daily PO	**Hypotension; dry mouth**; muscle pain/cramps; hyperglycemia; dermatitis; tinnitus; systemic vasculitis; pancreatitis	Do not use in patients with anuria or those taking aminoglycoside antibiotics or ethacrynic acid (ototoxicity). Caution with patients with sulfonamides allergy. Caution with patients with hepatic cirrhosis, ascites. Caution with digitalis—may exaggerate hypokalemic metabolic effect.
Bumetanide	0.5–10 mg daily PO	**Muscle cramps; dizziness**; hypotension; hypokalemia; ototoxicity; pruritus; EKG changes; thrombocytopenia	Do not use in patients taking Indomethacin. Caution in patients with hepatic impairment or allergic to sulfonamides. Caution with patients on lithium—monitor serum lithium levels.
Thiazide diuretics			
Metolazone	2.5–20 mg daily PO	**Dizziness; hypotension; fatigue; electrolyte disturbances**; agranulocytosis; hepatitis; necrotizing vasculitis; seizures	Do not use in patients with anuria. Caution in patients with hyperglycemia or taking NSAIDs, digitalis glycosides, lithium.
Chlorothiazide	250–500 mg twice daily PO	**Photosensitivity; hyperglycemia; gastrointestinal distress; dizziness**; agranulocytosis; pancreatitis; hepatic impairment; renal failure	Do not use in patients with anuria. Caution in patients with hyperglycemia or taking NSAIDs, digitalis glycosides, lithium.
Hydrochlorothiazide	25 mg once or twice daily PO	**Hypotension; dizziness; phototoxicity**; hyperglycemia; electrolyte disturbances; pancreatitis; glaucoma; renal impairment	Do not use in patients with anuria or taking dofetilide (risk of QT prolongation). Caution in patients with hyperglycemia or taking methotrexate, cyclophosphamide, NSAIDs, digitalis glycosides, lithium.

(continued)

Table 47.2 Continued

Medications	Dose routes and ranges	Side effects	Special considerations
Chlorthalidone	12.5–100 mg once daily PO	**Hyperuricemia**; cardiac arrhythmias; pancreatitis; pulmonary edema	Do not use in patients with anuria. Caution in patients with hyperglycemia or taking NSAIDs, digitalis glycosides, lithium.
Aldosterone antagonists			
Spironolactone	25–50 mg daily PO; starting dose of 12.5 mg/day for patients with creatinine clearance 30–50 mL/min	**Hyperkalemia; dizziness**; hypotension; gynecomastia; renal dysfunction; leukopenia	Do not use in patients with anuria, Addison's disease, hyperkalemia, or taking other potassium sparing diuretics. Caution in patients with hepatic impairment, or taking NSAIDs, cholestyramine, heparin, lithium, trimethoprim.
Eplerenone	25–50 mg daily PO	**Hyperkalemia; renal dysfunction;** angina; myocardial infarction	Do not use in patients with hyperkalemia, or taking other potassium-sparing diuretics. Caution in patients taking strong CYP3A4 inhibitors (clarithromycin, itraconazole, ketoconazole).
Cardiac glycosides			
Digoxin	0.25 mg daily PO or IV; 0.0625–0.125 mg daily for patients with renal impairment; use with caution in age >70 years	**Bradycardia; gastrointestinal distress**; headache; yellow vision	Use with caution in patients taking amiodarone, cholestyramine, cyclosporine, erythromycin, loop diuretics, metoclopramide, methotrexate, oral aminoglycosides, thiazide diuretics, thyroid hormone, or verapamil.
Beta-blockers			
Metoprolol succinate extended release	12.5–25 mg daily PO	**Dizziness**; **bradycardia**; **fatigue**; bronchospasm; exercise intolerance; gastrointestinal distress; laryngospasm; paresthesia; hypoglycemia unawareness	Do not use in patients with second- or third-degree AV block, severe sinus bradycardia. Taper to discontinue. Caution in patients with renal impairment or patients taking cimetidine, clonidine, epinephrine, hydralazine, lidocaine, NSAIDs, prazosin, rifampin, verapamil.
Carvedilol (also has alpha-blocker properties)	3.125–50 mg twice daily PO for 2 weeks; may adjust starting dose with patients with hepatic impairment	**Bradycardia**, bronchospasm; hepatic injury; tinnitus; constipation; fatigue; headache; hypoglycemia unawareness	Do not use in patients with second- or third-degree AV block, severe sinus bradycardia. Taper to discontinue. Frequently monitor serum glucose level in diabetic patients. Caution in patients taking amiodarone, clonidine, cyclosporine, digoxin, diltiazem, rifampin, verapamil.
Bisoprolol	1.25–10 mg daily PO	**Bradycardia**; rhinitis; gastrointestinal distress; fatigue; headache; hypoglycemia unawareness	Do not use in patients with second- or third-degree AV block, severe sinus bradycardia. Taper to discontinue. Frequently monitor glucose level in diabetic patients. Caution in patients taking anticholinergics, hormonal contraceptives, insulin, NSAIDs, prazosin, aspirin.
Vasodilators (Combination Hydralazine + Isosorbide Dinitrate indicated for HF)**			
Isosorbide Dinitrate**	25–50 mg four times daily PO	**Headache**; dizziness; hypotension; rebound hypertension; tachycardia; weakness	Need to be taken with hydralazine for heart failure. Not for acute angina episodes. Headache common upon discontinuation. Potential for nitrate tolerance. Do not use in patients taking phosphodiesterase inhibitors (Viagra, etc.) or soluble guanylate cyclase (Riociguat). Caution in patients taking calcium channel blockers.
Hydralazine**	20– 30 mg four times daily PO	**Tachycardia; palpitations;** anorexia; headache; back, arm, or chest pain; shortness of breath; blood dyscrasias	Need to be taken with isosorbide dinitrate for heart failure. Not for acute angina episodes. Caution in patients with renal insufficiency or lupus or patients taking adrenergic blockers.

Common medications as indicated by the 2013 ACCF/AHA Heart Failure Guideline & 2017 ACC/AHA/HFSA Focused Update of the 2013 Guideline; typical dose ranges provided; dosing for patients is dependent on individual health status, comorbidities, and institutional recommendations; Consultation with pharmacy is recommended.

patient's clinical status and symptoms, underlying cardiac structure and function are not restored to normal states. As heart failure worsens, a patient's condition may become refractory to maximal doses of medications, prompting consideration of surgery, mechanical circulatory support devices, and heart transplant options.

Lifestyle Recommendations

While evidence for the impact of lifestyle modifications on morbidity and mortality in advanced heart failure is limited to observational studies, patients with advanced heart failure should be generally encouraged to (a) quit smoking, (b) limit or abstain from alcohol intake and illicit drug use, (c) restrict sodium intake to 1,500 mg/day, (d) restrict fluid intake to 1.5–2 L/day (patients with HFrEF), (e) lose weight if obese, and (f) monitor daily weight to track fluid retention and overload.

Implantable Cardioverter-Defibrillators

Implantable cardioverter-defibrillators (ICDs) are medical devices implanted inside the body that perform cardioversion and/or defibrillation upon detection of a lethal arrhythmia (e.g., ventricular fibrillation, ventricular tachycardia). The benefits of ICDs are most frequently observed in terms of prolonged survival in patients who have HFrEF and are at risk for sudden cardiac death. The devices alone do not improve cardiac function and are not recommended for patients with diastolic dysfunction or for patients with poor functional status and a prognosis of less than 1 year. ICDs are also not recommended for NYHA Class IV patients with medication-refractory congestive heart failure who are not candidates for heart transplantation. Patients should be informed *prior to ICD placement* about the option to deactivate the device as they approach end of life.[17]

Mechanical Circulatory Support

For patients with HFrEF who are symptomatic despite optimal pharmacological management, mechanical circulatory support devices (MCSD), including left ventricular assist devices (LVADs) and total artificial hearts (TAHs), may be viable options to partially or completely replace the function of the heart. The field of MCSD support is rapidly evolving, with numerous clinical trials in process and devices in queue for testing and approval. MCS is considered an approach that can bridge a patient to recovery, heart transplantation, and medical stabilization so that optimal decision-making can occur. LVADs are also used as a *destination therapy*, where the device's goal is to improve functional status and QOL for those who will not be considered for heart transplantation. Considerations for placement of a MCSD include (but are not limited to) type and severity of heart failure, likelihood of potential complications, presence of significant comorbidities, ability to tolerate long-term anticoagulation, adequate psychosocial and family caregiver support, and feasibility of future heart transplantation. The most recent guidelines, published in 2013 by the International Society of Heart and Lung Transplantation, recommend palliative care consultation for any patient being considered for MCSD as destination therapy.[13] Furthermore, the US Joint Commission now requires that a palliative care specialist be part of accredited LVAD destination therapy programs.[31] Palliative care nurses working frequently with the MCSD population should consult the most recent MCS clinical guidelines as well as seek more detailed guidance in working with patients and families considering and living with MCSDs.[32–35]

Heart Transplantation

Patients receiving heart transplantations have a median survival of 10 years and typically experience marked improvement in functional capacity. While heart transplantation may be a viable option for eligible patients with advanced heart failure, this option is constrained by the relatively limited number of donor hearts, the contraindications in patients with comorbidities, and the risk of posttransplant complications.[1] Patients considering transplantation should be made aware of the tradeoffs involved, including the risks of organ rejection and side effects of immunosuppression,[12] the details of which can be found in the most recent clinical guidelines.[36]

Intravenous Inotrope Therapy

Intravenous inotrope therapy, using medications such as dobutamine and milrinone, is initiated in the inpatient setting to stabilize heart failure patients with decompensation not improving to decongestive treatment with diuretics. While many patients are able to wean off these mediations, others become dependent and must consider either chronic intravenous inotrope therapy that is managed in the community setting or another destination therapy (e.g., heart transplantation, LVAD). Before decisions are made to receive chronic continuous infusions for symptom relief, patients' and families' treatment and prognostic understanding should be assessed, and they should be guided in goals of care discussions. Nearly all patients on home inotrope therapy die within 1 year.[37,38]

Renal Replacement Therapies

For heart failure patients with symptomatic fluid overload that is refractory to diuretic therapy, hemofiltration or hemodialysis can provide relief of symptoms. Generally, this occurs when patients have concurrent renal failure and require intermittent hemodialysis for clearance of nitrogenous toxins, maintenance of electrolyte status, and management of volume status. However, in severe cases of volume overload, hemofiltration is used to manage excess volume even if glomerular filtration and electrolyte balance remain preserved. This has been shown in clinical trials to improve outcomes for some over intravenous diuretics.[39]

Management of Symptoms in Stage D Heart Failure

Patients with Stage D heart failure often experience multiple symptoms that can compromise function and reduce QOL. In the following sections, palliative care considerations in managing some of the most commonly encountered symptoms in advanced heart failure are summarized; however, nurses are encouraged to refer to cited and other material for further clinical guidance.

Dyspnea

When the heart is unable to effectively pump blood forward into systemic circulation, the lung vasculature can become congested, impairing gas exchange and making breathing difficult.[40] This makes dyspnea one of the most common symptoms experienced in heart failure and has been reported to affect up to 88% of heart failure patients in the last 6 months of life.[41] Dyspnea management focuses on reducing fluid overload through prudent diuretic use, fluid and sodium restriction, and optimization of cardiac performance.[17] For HFrEF, ACE inhibitors, angiotensin II receptor blockers (ARBs), and mineralocorticoid antagonists can be considered for optimizing volume status chronically. Digoxin and intravenous inotropic agents (e.g., milrinone, dobutamine) are also commonly initiated and titrated to relieve symptoms. First-line adjunctive therapies include low-dose opioids (e.g., morphine, hydromorphone, oxycodone) that can be used safely with careful monitoring. Hydromorphone or oxycodone are safer short-acting agents than morphine or codeine for patients with compromised kidney function, given that the risk is less of accumulating toxic metabolites. For chronic use, transdermal fentanyl and oral methadone should be considered with appropriate monitoring for side effects. Oxygen should be administered only if patients become hypoxemic (oxygen saturation less than 88%), and benzodiazepines are considered if patients experience dyspnea-related anxiety.[42]

Fatigue

Reduced cardiac output results in diversion of blood away from skeletal muscles, interference in waste product removal, deconditioning and cachexia, poor sleep, depression, and decreased red blood cell production.[40] For all these reasons and others, fatigue is one of the most common symptoms in heart failure and yet it is one of the most underassessed and undertreated. Treatment should be focused on optimizing cardiac performance, exercise as tolerated, energy conservation, sleep hygiene, and nutritional support and in identifying concurrent comorbid contributors such as hypothyroidism.[43] Corticosteroids (e.g., dexamethasone 2–8 mg/day) may be considered for short-term relief (i.e., 4–6 weeks) but caution is warranted due to potential for fluid overload; it may be of limited benefit in patients with longer prognoses.[40] Modafinil and methylphenidate may be beneficial in the treatment of fatigue, but more research is needed.[43]

Pain

Pain attributable to underlying heart failure includes pressure from edema (especially in the legs below the knees), anginal pain, and musculoskeletal pain from decreased perfusion, immobility, and deconditioning.[40,44] Approaches to pain should generally follow the World Health Organization analgesic ladder; however, in one study, the only medication reported to provide relief was opioids.[44] Given the high prevalence of comorbidities in heart failure patients, causes of pain should also be assessed that are non–heart failure related, such as arthritis and diabetic neuropathy. Nonsteroidal anti-inflammatory drugs, whether nonselective or COX-2 specific, are generally contraindicated in heart failure due to risk of renal failure, worsening of sodium and water retention, and increased risk of stroke and myocardial infarction. Opioids are appropriate for moderate to severe pain; however, careful monitoring of opioid-induced hypotension (particularly when patients are intravascularly hypovolemic) is prudent, especially if coadministered with benzodiazepines.[45] Methadone and buprenorphine may prolong QTc and thus ECG monitoring at baseline and following dose titration is warranted.[45]

Edema

Edema is a nearly universal sign in heart failure. The site of edema can vary depending on the type of heart failure. In right-sided failure, fluid accumulates in the lower extremities and often produces ascites. In left-sided failure, pulmonary edema and pleural effusions may result, potentially causing dyspnea and respiratory distress. Adding to the obstructive effects of underperforming ventricles, edema may result from underperfused tissues that activate the sympathetic and renin-angiotensin systems, thereby promoting sodium and water retention and plasma volume expansion. Therapeutic approaches include optimizing cardiac performance, diuresing excess fluid, and restricting sodium and fluid intake.[40] Nonpharmacologic interventions include lower extremity elevation, use of compression stockings, and paracentesis and thoracentesis for relief of refractory ascites and pleural effusions, respectively.

Cachexia

Cachexia is a poor prognostic indicator in heart failure and is defined as a 6% or greater loss in nonedematous total body weight over a 6-month period.[46] The mechanisms of cardiac cachexia are not fully understood but appear to be multifactorial and mediated by changes in endocrine function, insulin uptake, nutritional malabsorption in the gut, catecholamines, cortisol, natriuretic peptides, and pro-inflammatory cytokines.[46–48] Management includes optimizing nutrition and exercise as tolerated. There are no approved medications for cardiac cachexia; however, there may be some protective benefit of ACE inhibitors and beta blockers; more information can be found in cited reviews.[46,48]

Depression

While estimates vary, approximately 40% of patients with advanced heart failure experience depression,[49] which has been associated with poorer medication adherence and other outcomes in this population,[49] including higher mortality.[50] Treatment approaches include cognitive behavioral therapy, spiritual support, and medications.[51] First-line medications include low-dose selective serotonin reuptake inhibitors (SSRIs; e.g., sertraline[52]); however, these drugs can result in fluid retention, hyponatremia, and may prolong the QTc interval.[53] Other medication options include selective serotonin norepinephrine reuptake inhibitors (SNRIs) and psychostimulants (e.g., methylphenidate), but tricyclic antidepressants are rarely utilized due to adverse cardiac events.

Primary Palliative Care in Heart Failure and Indications for Specialty and Hospice Referral

Due to the difficulties of prognostication in heart failure, it has been recommended that palliative care approaches and specialty referral be symptom-centered rather than prognosis-driven.[54] In a recent randomized controlled trial of interdisciplinary palliative care plus usual care versus usual care alone,[55] hospitalized heart failure patients with high risk of mortality and rehospitalization were recruited. The investigators found improvements in QOL, anxiety, depression, and spiritual well-being favoring the intervention group, suggesting that prognosis-type factors may be useful indicators for specialty referral.

In the United States, hospice services are eligible under Medicare funding and most private insurer coverage if a patient with heart failure is deemed by two physicians or one physician and one nurse practitioner to have an estimated prognosis of 6 months or less, and the patient is willing to forego curative-intent therapies. Guidelines stipulate that patients have NYHA Class IV heart failure and are either (a) optimally treated with medications or (b) experiencing angina at rest despite nitrate therapy and have been deemed ineligible or have opted out of invasive cardiac procedures. Other supporting indications for hospice include left ventricular ejection fraction of 20% or less, treatment-resistant symptomatic arrhythmias, concomitant acquired immunodeficiency syndrome, and histories of cardiac syncope, embolism, and resuscitation.

End of Life Care

Advance Care Planning

To optimize shared decision-making, the ACC/AHA encourage an "annual heart failure review" where discussions about current and potential therapies and anticipated and unanticipated events can be discussed.[12] To this end, a discussion about one's goals of care and assessing understanding of the disease process is necessary to determine what the optimal future care plan should be. Because many patients lose their ability to make their wishes known during a serious, life-threatening event of illness, strong consideration to create an advance directive or living will is encouraged.[12] Critics of advance directive documents have noted that these documents are not effective in allowing sufficient control over future events; however, the process of advance care planning is more about devising a strategy to approach the anticipated and unanticipated events by best understanding patients' goals, values, and preferences.[56] Given the complexity of some life-sustaining therapies used in heart failure, it is encouraged that wishes about management of treatments like MCSDs should be explored proactively.[35] However, work to date has suggested that patients with implanted devices rarely have advance directives, and, of those that do have a directive and concurrently have an ICD,[57] pacemaker,[58] LVAD,[59] or TAH,[60] such directives rarely address how to manage the device as end of life approaches.

Withdrawal of Life-Sustaining Therapies

It is generally accepted that patients (or their surrogates, if the patient is not able) have the right to refuse unwanted medical treatments, even if such refusal results in one's death. While patients may opt to forego ICDs, pacemakers, or MCSDs, some may opt to receive these therapies with the hopes of achieving specific life goals such as prolonged survival or ability to complete important life work. If the treatment is no longer effective, it is legally and ethically acceptable that the treatment be discontinued, and this discontinuation does not constitute physician aid in dying, manslaughter, or suicide.[61] Patients will succumb to the underlying cause of the disease process (i.e., advanced heart failure) whether the treatment is never started, or discontinued at a later point. However, it is important to recognize that the discontinuation of life-sustaining treatment and resulting death may emotionally feel different for providers, patients, and surrogates alike.[61,62] Careful discussion of how the life-sustaining treatment will be handled in the future is encouraged at the time of implantation and iteratively as goals of care evolve. Box 47.1 describes steps clinicians should be aware of when deactivating LVADs.

Box 47.1. Important Steps and Pointers for Left Ventricular Assist Device (LVAD) Deactivation

Prior to Deactivation

1. Inform key members of the healthcare team, including (but not limited to): physician of record, cardiologist, cardiothoracic surgeon, LVAD coordinator, bedside nurse, unit nurse manager, palliative care consultant, social worker, chaplain, and ethics consultant (if needed).
2. Confirm and document the presence of advance directives, do-not-resuscitate orders, and designated healthcare proxy or durable power of attorney for healthcare.
3. Confirm and document the treatment plan goals and the content of any family meetings.
4. Discuss with patients and families, noting (a) any ethical concerns; (b) the process for deactivation, including the unpredictable timing of death after deactivation (minutes to short days); (c) who would like to be present at the time of deactivation; (d) what religious preferences or rites the patient or family would like to have recognized and/or performed; and (e) decisions that may need to be made after death such as organ donation, autopsy, and funeral arrangements.
5. After eliciting patient and families values and goals of care, make direct recommendations about other treatments besides the LVAD that should be stopped (e.g., mechanical ventilation, defibrillator) to align with those values and goals.
6. Discuss goals of comfort during and after LVAD deactivation and what treatments will be offered to meet those goals. Reassure the patient and family that patients can be kept comfortable without life-sustaining treatment.
7. Set the date and time for LVAD deactivation, assuring appropriate resources are present.

During Deactivation

1. LVAD deactivation is similar in many respects to mechanical ventilator withdrawal. Clinicians should be prepared to treat the rapid onset of dyspnea/labored respirations, agitation, and other signs of discomfort.
2. Check that all family members who expressed a desire to be with the patient during deactivation and that all appropriate healthcare staff are present.
3. Discontinue all monitoring that is not symptom-directed.
4. There are many different LVAD models with different steps to deactivation. Be familiar and review the specific steps to deactivate the device before performing the task in front of patients and families (especially alarm silencing, which can be distressing to patients and families). Consult your institution's LVAD coordinator as needed.
5. Once the LVAD is deactivated, cardiovascular circulation may greatly diminish. Thus, it is strongly encouraged to bolus with appropriate medications such as morphine for pain and dyspnea, lorazepam for agitation, and glycopyrrolate for secretions *prior* to deactivation and prior to withdrawal of other life-sustaining therapies. Have additional medication drawn up and ready to administer after deactivation if needed.

(*continued*)

Box 47.1. Continued

6. Once any post-LVAD deactivation symptoms have been appropriately managed, proceed with withdrawal of other life-sustaining treatments.
7. Monitor carefully for any signs of distress or discomfort, treat accordingly, and educate those present as needed regarding signs and symptoms observed.

After Deactivation and Death

1. Spend time with the family to discuss any concerns or questions.
2. After death occurs, encourage the family to spend as much time at the bedside as they desire.
3. Provide acute grief support and follow-up bereavement support.

Case Study: A Patient with Heart Failure

Charles Bennett, a 57-year-old man, presents to clinic for progressive dyspnea, a 3-lb weight gain over the past week, and depressed mood. Point of care BNP is greater than 150 pg/dL (normal value: <100 pg/dL). He has a past medical history of hypertension, myocardial infarction (2013, multivessel disease with coronary artery bypass grafting × 3), type II diabetes (A1c 7.3%), and a history of generalized anxiety disorder. He was diagnosed with progressive systolic dysfunction 4 years ago and has been followed by a cardiologist. At the time of diagnosis, Mr. Bennett worked as a plant manager at a local lime refinery, a physically demanding job with daily exposure to high kiln temperatures. He often oversaw student engineers during their internship experiences and regaled them with stories of kiln malfunctions and 20-hour days. Over the past 4 years, as his LVEF decreased from 40% to 20%, he could not keep up with the physical demands of his job and retired early from the company he had been with for more than 30 years. He was hospitalized 5 months ago with acute, decompensated heart failure and started home milrinone infusions. At a prior follow-up where his prognosis was discussed, his primary caregiver, his wife of 32 years, frequently brought up discontinuing the infusion. Upon further questioning by the nurse, the caregiver disclosed her growing discomfort with handling her husband's complex medical needs and Mr. Bennett's desire to remain at home due to "all these tubes." At that appointment, Mr. Bennett also added that he had nowhere he was supposed to go and affirmed feelings of depression. He was treated with an SSRI. Although his mood improved as noted during the assessment, Mr. Bennett still expressed sadness and frustration over his fluctuating functional status, his unexpected retirement, and his medication regimen, growing more frustrated by the noticeable breathlessness during conversation. Picking up on the discordance between the treatment plan and patient's desires, the nurse practitioner questioned Mr. Bennett about his understanding of his illness and disease trajectory as well as his care preferences. While Mr. Bennett understood that heart failure was a serious diagnosis, he felt sure that he could continue to be "tuned up." The nurse practitioner queried about Mr. Bennett's preferences regarding the milrinone and other therapies, and they discussed other potential treatments for his heart failure. Guided by the nurse practitioner, Mr. Bennett expressed some goals of care, including a desire to take less medicine and visit friends. Plans were made to discuss possible titration of milrinone with Mr. Bennett's cardiologist, and Mr. Bennett was connected to the heart failure support group sponsored by the local hospital.

Conclusion

Providing palliative care for patients with heart failure may start at the time of diagnosis concurrent with traditional treatment, marked by periods of increased utilization during acute exacerbations. Given the high prevalence of comorbidities in heart failure patients as well as the rise in first-time heart failure diagnosis in the elderly population, the focus of supportive care in heart failure is improved QOL, self-care, symptom management, care coordination, prognosis understanding, and decision-making. Despite poor functional status and significant symptom burden, including frequent emotional symptoms (of anxiety and depression), patients with advanced heart failure are often referred to palliative care services late or are resistant to palliative approaches due to optimal treatment response during exacerbations and unpredictable disease trajectory. Yet the burden of heart failure is ripe for palliative approaches by informed nurses guided by recent evidence-based practice guidelines. Relying on symptoms, not prognosis, might result in greater uptake of specialty palliative services, especially in the outpatient setting. While pharmacological and nonpharmacological therapies may be used to address common symptoms of breathlessness, pain, fatigue, and depression, goals of care discussions support the patient and their caregivers (or support persons) during medical decisions such as heart transplantation, mechanical circulatory support devices, or home inotrope infusion considerations. Palliative care addresses the multifaceted burden of those living with heart failure, whether through symptom management or advance care planning, with improved QOL and relief of suffering a priority and with nurses at the forefront.

SECTION V

End-of-Life Care across Settings

CHAPTER 48

Improving the Quality of Care across All Settings

Marilyn Bookbinder, Romina Arceo,
and James T. McDaniel

Key Points

- Quality palliative care is a result of intelligent systematic efforts to raise standards of care throughout an organization.
- Tools are available to assist in the monitoring and measurement of structure, process, and competency in the delivery of palliative care.
- Outcome measures are needed to evaluate the impact of innovative change on patient and family quality of life, healthcare systems, and professional practice.

Quality Improvement and End-of-Life Care Defined

The term quality improvement (QI) is now commonplace in the lexicon of industry and government healthcare systems in the United States. In this chapter, QI in healthcare is defined generically as the philosophy driving a systematic approach to improving clinical practice processes and patient outcomes, systems, education, and research. End-of-life (EOL) care refers to care received in the final hours or days of life and includes care to patients and families living with a terminal illness or condition that has become advanced, progressive, and incurable. Quality palliative and EOL care is a result of intelligent systematic efforts to raise standards of care throughout an organization.

The Need for Better Palliative Care and End-of-Life Care in the United States

The World Health Organization defines palliative care as "the active total care of patients whose disease is not responsive to curative treatment when control of pain, of other symptoms and of psychological, social and spiritual problems is paramount."[1] Palliative care is often referred to as supportive care or comfort care that seeks to prevent, relieve, alleviate, lessen, or soothe the symptoms of disease without effecting a cure. The Institute of Medicine's (IOM) landmark report in 1997, *Approaching Death: Improving Care at End of Life*, informed the field about areas most deficient and those of highest priority for improvement. In the decade following the report, professional and national associations addressed the priorities, including the need for a synthesis of the state-of-the-knowledge in EOL care, evaluation methods for measuring outcomes, factors impeding high-quality care, and steps toward agreement on what constitutes "appropriate care" at the end of life.[2] The IOM report includes results from the national SUPPORT study, which produced more than 104 publications supporting the deficiencies in care and citing the frequency of aggressive medical treatment at the end of life (deaths occurring in the intensive care unit [ICU]) and the lack of adequate symptom management (conscious patients with moderate to severe pain).

Since the IOM report, national and professional organizations and field experts have been addressing these gaps in knowledge and the need for better symptom management and more awareness by professionals of patient preferences for care at the end of life. For example, the Agency for Healthcare Research and Quality'(AHRQ) sponsors technical evidence panels (TEP) and, with the National Institutes of Health, offers national symposiums to provide updates in the field about quality indicators and areas of greatest need. Research efforts to address the deficiencies in EOL care are increasing; however, little progress has been made in standardizing the assessment of the delivery of quality care and quality outcome indicators.

Most quality professionals agree that "If it can be measured, it can be managed." Hence the search for the best quality indicators. A 2007 systematic review revealed psychometrically sound measures of outcomes in EOL care and results of interventions. Of 24,423 citations reviewed, 99 measures met criteria for inclusion. Of these 99, 35 measures were recommended in a prior systematic review, and 64 measures of the EOL care experience were added by the reviewers. They found the most robust measures in the areas of symptoms, quality of life (QOL), and satisfaction, with significant gaps existing in continuity of care, advance care planning, spirituality, and caregiver well-being. The authors call for more rigorous development and testing of measures and for designs that facilitate comparability across care settings, populations, and clinical conditions.[3]

The cost of providing EOL care has become an important area of study in the United States as we move away from fee-for-service reimbursement structures to capitation models whereby a fixed amount of money is given per patient per unit. In one report, palliative care experts urge hospital executives to pay attention to the

5% of patients who are driving 50% of their spending budgets. They insist that this 5% group is the growing number of over-85 elders—expected to reach 8.5 million by 2030. They estimate that 27% of Medicare dollars are spent on the last year of life when most of these elders will spend some time in the hospital. The report emphasizes the need to manage this 5% of the population well and to encourage better access to palliative care.[4]

Palliative care increases patient and family satisfaction and quality of care and supports better bedside care and resource allocation.[5] The number of US hospitals with palliative care programs tripled over the past decade, with US registries in 2016 showing that 90% percent of hospitals with 300 beds or more had a palliative care program. Hospitals face the pressures of Medicare's value-based purchasing programs, which require use of quality metrics and patient and family satisfaction measures. Further support for the positive outcomes of palliative care programs is found in a recent study of heart failure patients who were randomized to usual care plus palliative care versus usual care alone over a 6-month period. Those advanced heart failure patients receiving an interdisciplinary palliative care intervention showed consistently greater benefits in QOL, anxiety, depression, and spiritual well-being compared with usual care alone.[6]

Early EOL care discussions are prospectively associated with less aggressive care and greater use of hospice at end of life. In one retrospective study of 6,122 decedents over a decade, an upward trend was seen in the proportion of elderly (>60 year) with an advance directive, an increase from 47% in 2000 to 72% in 2010. Patients who had EOL care discussions with their physicians before the last 30 days of life were less likely to receive aggressive measures at end of life, including chemotherapy ($P = .003$), acute care ($P < .001$), or any aggressive care ($P < .001$). Such patients were also more likely to receive hospice care ($P < .001$) and to have hospice initiated earlier ($P < .001$).[7] In another study of 332 advanced cancer patients followed until death (for nearly 5 months), only 37% reported having had an advance care planning discussion with their physician.[8]

National- and state-level initiatives are increasing the quality and frequency of discussions and completion of advance directives. For example, in 2012, the Institute for Healthcare Improvement (IHI) in collaboration with The Conversation Project, launched a public engagement campaign to encourage people to "have the conversation" about their wishes for EOL care with loved ones, with the goal that everyone's wishes are expressed and respected. The Conversation Project has received national attention for its starter toolkits in various languages and educational webinars addressing the barriers to having conversation for professionals, patients, and families. For more information, visit http://www.ihi.org/Engage/Initiatives/ConversationProject/Pages/default.aspx.

Quality Principles Spread from the Car Industry to Healthcare

Nearly a century ago, W. Edwards Deming, the American engineer who assisted Japan in its quest for quality after World War II, continues to influence healthcare organizations.[9] His QI principles and methods for systematic and statistical thinking are being woven into the fabric of everyday work life. It is important for clinicians to understand the history behind the quality movement from countries like Japan and the car industry and their influence on today's US healthcare culture.

Mastering the concepts and tools of QI is critical to building a skill-set for the improvement process. The tools we still use today date back to 1920, nearly a century ago, and were developed by pioneers such as Deming, Juran, Shewhart, Ishikawa, and Pareto. These tools are described in the following paragraphs.

IHI, LEAN, and Six Sigma

The IHI, led by Don Berwick, was the first organization to adopt Deming's teachings and work with US healthcare organizations to "fix broken systems" that were creating poor-quality and unsafe care, such as high medication error rates in hospitals. Known as the Triple Aim, IHI engaged healthcare organizations in the largest effort to improve the experience of care and the health of populations and to reduce national per capita costs. The Triple Aim has recently been called the Quadruple aim, to include improved clinician experience and the work life of healthcare providers.

Another quality framework is the Lean and Six Sigma's 7-Step Problem-Solving Method. John Krafcik coined the term "lean" as an approach aimed at improving efficiency by removing waste. In his study of Japanese car companies, he observed that Toyota did "everything with half of everything": half the people, half the space, half the inventory, half the resources, yet with very high quality. The ground-breaking book, *The Machine that Changed the World* (1990), with its focus on the automotive sector, was the origin of lean thinking and made a compelling case for its adoption in any industry.

LEAN Six Sigma, a popular framework driving change today in healthcare, focuses on reducing error or defects, as measured by a *sigma level*. The sigma level or how much the process varies from perfection, is measured as the number of "defects per million opportunities." Three standard deviations above and below the mean create the upper and lower control limits of the six sigma framework by following six basic steps, known as DMAIC: *define* the problem in detail, *measure* defects (in terms of "defects per million," or sigma level), *analyze* in depth using process measures and tools such as flow charts and defect analysis to determine under what conditions errors or defects occur, *improve* by defining and testing changes aimed at reducing defects, and *control* by defining what steps will be taken to maintain performance.

In their book *Lean Thinking* (1996), authors distill Lean into five principles: (1) specify the value desired by the customer, (2) identify the value stream for each product providing that value and challenge all of the wasted steps (generally nine out of ten) currently necessary to provide it, (3) make the product flow continuously through the remaining value-added steps, (4) introduce pull between all steps where continuous flow is possible, and (5) manage toward perfection so that the number of steps and the amount of time and information needed to serve the customer continually falls.

By the 1990s, Lean thinking and Six Sigma techniques spread to US healthcare when the Healthcare Reform Act of 1992 challenged all agencies to adopt QI methods to achieve better control over inconsistencies and waste in services. Training is easily accessible for those interested in QI. With the help of web-based learning systems, virtual teams of professionals are offering mentorship and resources in international, national, and regional collaborative efforts to improve care around specific content areas. For more readings and online courses in QI visit http://www.shmula.com and https://www.lean.org/WhatsLean/ and http://www.ihi.org and https://www.villanovau.com.

The important point here is not which framework you choose; rather it's choosing the one that works for you in your setting and helps to improve outcomes of care and how it is delivered. Four tools and their inventors are presented next because they are fundamental to all frameworks previously reviewed and are key in understanding how systematic and statistical thinking promote quality and making improvements. The *Pareto Principle* (aka, *80:20 rule*) implies that 80% of any problem is accounted for by 20% of the contributing factors. It is wiser to concentrate on the "vital few" rather than the trivial many. Figure 48.1 shows a Pareto chart. Clinicians are deciding where to target their efforts next to reduce patients' episodes of sustained pain. The second tool is Shewhart's four-step management method, *plan–do–study–act* (PDSA). Also called the *Deming wheel*, it is used to study a problem in quality control. An example of results of a repeated PDSA cycle are displayed in a control chart. Figure 48.2 features one hospital unit's stability on one patient satisfaction item asking patients how well staff were managing their pain. The third concept, created by Joseph Juran, stressed the "costs" of poor quality, such as wasted effort, extra expense, and increase in defects (or errors). Juran's manufacturing techniques are fundamental to the quality *lean thinking movement* of today. The fourth tool is the *Ishikawa fishbone diagram* or *cause-and-effect diagram*. Fishbones display specific root causes of an event, and the sources of the error are commonly grouped into five categories: Machine (equipment, technology), Method (process), Material (includes raw material, consumables, and information), Man/mind power (physical or knowledge work), and Measurement/medium (inspection, environment). See a sample fishbone diagram in Appendix 48.1.

Federal and Professional Groups Adopt Standards and Metrics Across Settings to Evaluate Quality End-of-Life Care

A seminal document for palliative care professionals is the guidelines published by the National Consensus Project for Quality Palliative Care.[10] These clinical practice guidelines, based on both available scientific evidence and expert professional opinion, have become the accepted means of promoting consistency, comprehensiveness, and quality across eight domains of healthcare: structure and processes of care; physical, psychological, social, spiritual, cultural, ethical and legal aspects of care; and care of the imminently dying. Guidelines that cross all domains include assessment, information sharing, decision-making, care planning, and care delivery at the end of life. Adoption of these guidelines in the United States will help to promote high-quality care to persons living with life-threatening and debilitating chronic illness. In 2006, another seminal document, the *National Framework and Preferred Practices for Palliative and Hospice Care Quality*, endorsed by the National Quality Forum (NQF), serves as a foundation on which quality measurement and reporting systems are currently being built. The most recent 2015–2016 Palliative and End-of-Life Standing Committee 2015–2016 endorsed 23 measures to improve palliative and hospice care.[11]

The Centers for Medicare and Medicaid Services (CMS) has taken the lead in setting quality outcome measures at the end of life across settings. CMS Certified hospices deliver approximately 45% of the nation's EOL care and are the focal point for measuring the overall value of the federal benefit offered to those meeting eligibility in the last 6 months of life. In August 2017, CMS unveiled the Hospice Compare website, posting seven quality measures that allow consumers to compare hospices on their performance

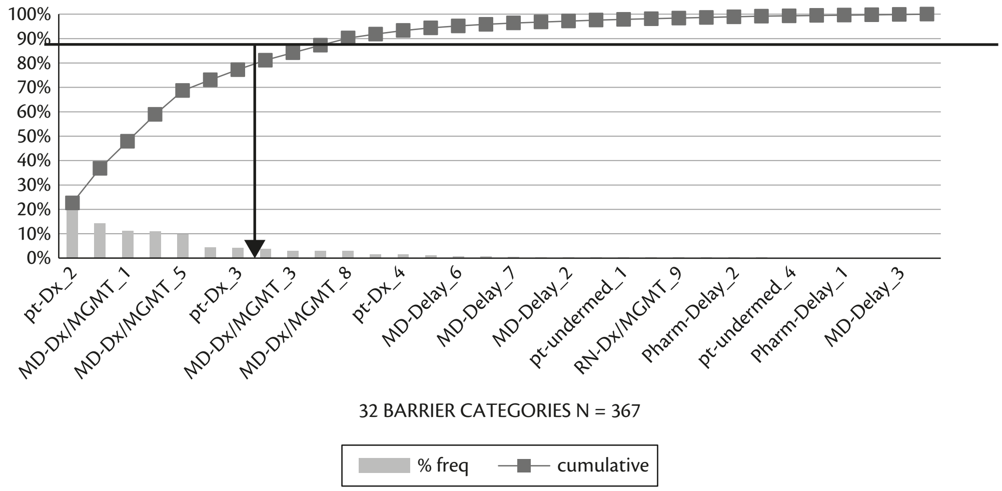

Figure 48.1 The Pareto Chart. *Problem/Issue*: The NP of a medical unit was charged with improving communication between the pain specialists and hospitalists to identify the factors that were contributing to patients with sustained pain (i.e., pain scores of 5 or greater [0, no pain, 10 worst pain] over 2 consecutive days). *Methods*: Data were collected on 367 patients, including their demographics and clinicians' suspected reasons for the unrelieved pain. The NP used a Pareto Chart to display the data about possible barriers creating the most resistance to improved pain management. A frequency distribution of the 32 barriers documented was sorted (high to low), and the top 20% (7 barriers) were uncovered. These 20% were contributing to 80% of the problem. These included the patient's specific pain diagnoses. *Outcome*: The most frequent diagnoses included sickle cell disease (pt-Dx_2) and chronic pain (pt-Dx_3). They were identified as the top diagnoses for patient admissions through the emergency room (ER), followed by the treatment they received (MD-DX/MGMT_1 and MD-DX/MGMT_3), which were not adequate to relieve the sustained high pain scores. Specific care plans were developed to meet this population's pain needs. *Action plan*: The pain specialist and hospitalist teams created a pathway for both patient groups as they entered the ER including a prompt call to pain specialists and a pathway with standing orders for admission.

Source: https://betterexplained.com/articles/understanding-the-pareto-principle-the-8020-rule/

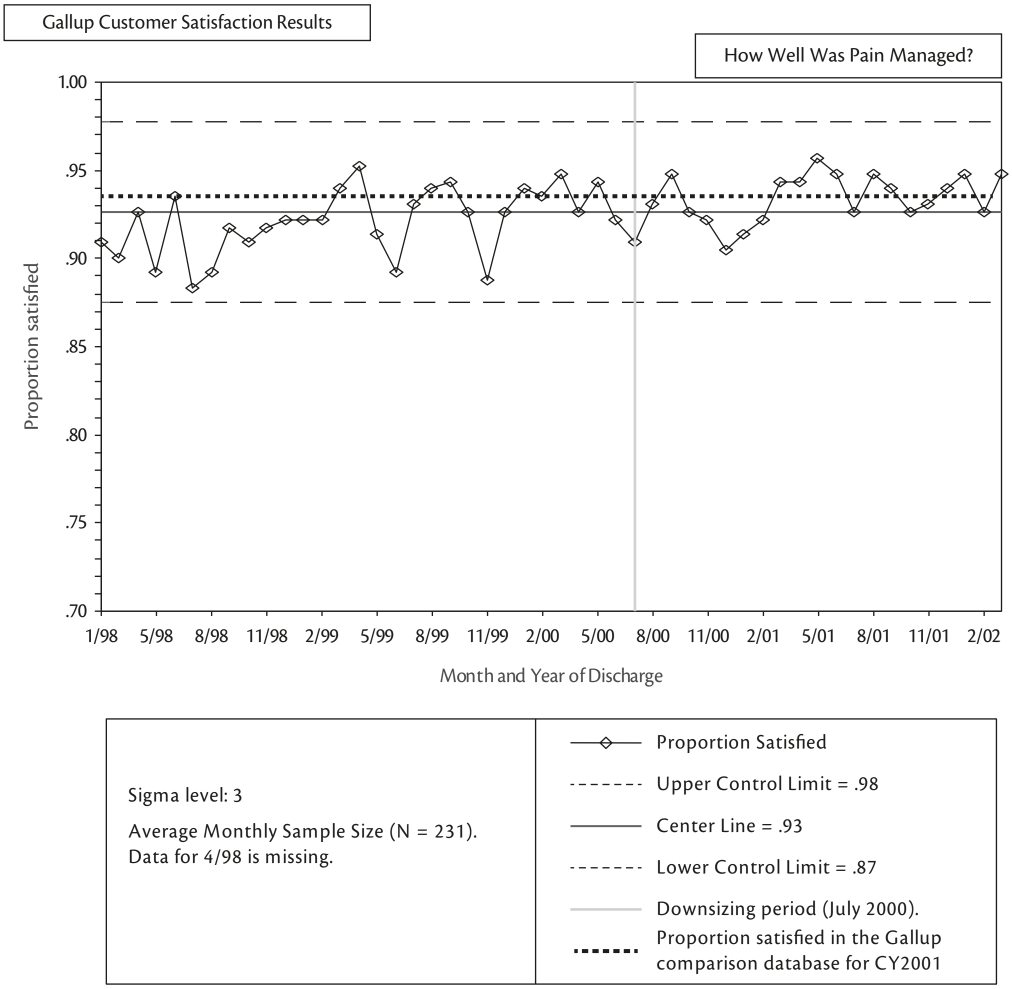

Figure 48.2 A control chart showing statistical control and stability of a process: managing pain.
Problem/Issue: A clinical nurse specialist (CNS) from pain management services has patient satisfaction data spanning several years. She has prepared a control chart with results of one question in the survey "How well was your pain managed?" She plans to showcase the good work by the oncology unit staff and demonstrate a process that is in control. *Methods*: By plotting the satisfaction scores and creating upper and lower control limits (3 standard deviations from the mean), the CNS teaches the value of displaying data and how to look for common and special causes of variation. She uses the "rule of seven tests" to interpret the control chart and look for special causes (along with points beyond the limits). The tests reflect an out-of-control situation in the data: (1) seven points in a row above the average, (2) seven points in a row below the average, (3) seven points in a row trending up, or (4) seven points in a row trending down (a string of seven low or seven high scores indicates the need to look further and seek reasons for the pattern). *Outcome*: The CNS illustrated with a control chart that the pain management process was within statistical control. Patients reported high levels of satisfaction over a sustained period.

Source: https://www.isixsigma.com/tools-templates/control-charts/a-guide-to-control-charts/; https://www.spcforexcel.com/knowledge/control-charts-basics/interpreting-control-charts#rule-of-seven-tests; and http://www.au.af.mil/au/awc/awcgate/navy/bpi_manual/mod10-control.pdf

and assist them in making decisions about where to receive care. The Hospice Item Set (HIS) used in Hospice Compare was chosen from the National Quality Forum (NQF). The standardized 7-item set is intended to capture patient-level data on each hospice patient admission: patient preferences, beliefs and values, pain assessment and screening, dyspnea screening and treatment, and if bowel regimens are in place for patients receiving opioids.[12]

In addition to evaluating the quality of care being delivered, hospices are required to evaluate quality care using post-death family satisfaction surveys: the Consumer Assessment of Healthcare Providers & Systems (CAHPS) Hospice Survey instrument evaluates the following categories: hospice team communication, getting timely care, treating family member with respect, getting emotional and religious support, getting help for symptoms, getting hospice care training, rating of hospice, and willingness to recommend the hospice.[13]

Long-term care, skilled nursing facilities, and rehabilitation centers are also required to collect data on the quality of care delivered for each resident in a Medicare- or Medicaid-certified nursing home. Data are obtained at admission, quarterly, annually, and whenever the resident experiences a significant change in status. Known as the Minimum Data Set (MDS), information is collected on the resident's health, physical functioning, mental status, and general well-being. These data are used by the facility to assess the needs of and develop a plan of care unique to each resident. On September 18, 2014, Congress passed the Improving Medicare Post-Acute Care Transformation Act of 2014 (the IMPACT Act). The Act requires the submission of standardized data by long-term care hospitals, skilled nursing facilities, home health agencies, and inpatient rehabilitation facilities.[14]

The IMPACT Act requires the reporting of standardized patient assessment data with regard to quality measures, resource use, and other measures. Data collected across settings will support the exchange of data among various providers using common standards and definitions. This effort will provide access to longitudinal information for providers and facilitate coordinated care and improved Medicare beneficiary outcomes.

In 2018, hospital and community settings will publicly report their outcomes on patient and family satisfaction with care during and after episodes of care.

Other CMS quality initiatives around EOL care include improving transitions between care settings, preventing medical errors, preventing unnecessary hospitalizations and readmissions, support for consumers' preferences and choices, and avoiding duplication of services. For more information about other CMS initiatives, visit https://www.medicaid.gov/medicaid/quality-of-care/improvement-initiatives/care-transitions/index.html.

The American Academy of Hospice and Palliative Medicine (AAHPM) and the Hospice and Palliative Nurses Association (HPNA) has launched the "Measuring What Matters" campaign with 10 performance measures for all hospice and palliative care programs to use for improvement. The 10 quality indicators shown in Box 48.1 could eventually enable benchmarking in the field.[15]

Box 48.1 Ten Quality Indicators for Seriously Ill, Palliative Care, and Hospice Patients

1. A comprehensive assessment (physical, psychological, social, spiritual, and functional) soon after admission
2. Screened for pain, shortness of breath, nausea, and constipation during the admission visit
3. If screen positive for at least moderate pain, receive treatment (medication or other) within 24 hours
4. Documented discussion regarding emotional needs
5. Documentation of the surrogate decision-maker's name and contact information or absence of a surrogate
6. Documentation of their preferences for life-sustaining treatments
7. Patients or their families are asked about their experience of care using a relevant survey
8. Hospice patients have a documented discussion of spiritual concerns or preference not to discuss them
9. Patients with advanced or life-threatening illness are screened for shortness of breath and, if positive to at least a moderate degree, have a plan to manage it
10. Vulnerable elders with documented preferences to withhold or withdraw life-sustaining treatments have their preferences followed

Application of the FOCUS_PDSA Model to Improve End-of-Life Care

QI experts agree that "quality is never an accident" and that it is "always the result of intelligent effort, intent, and vigilance to make a superior thing." To achieve this, QI teams need a systematic methodology to follow. In the following study, a multidisciplinary QI team applied Deming's six key principles of QI and the FOCUS-PDSA model to improve inpatient EOL care in a large New York City hospital. The case describes a 1-year study led by palliative care experts on three pilot units: oncology, geriatrics, and hospice. Two medical units—intensive care and step-down—served as control units. A Palliative Care for Advanced Disease (PCAD) pathway for care of the imminently dying inpatient was developed and tested. Table 48.1 illustrates Deming's six principles applied to the PCAD QI Study.[16]

We illustrate the process with the PCAD Pathway team's application of each step in the QI rapid cycle (see Appendix 48A.1). The PDCA (plan–do–check–act) is also commonly known as the PDSA cycle.[9] The FOCUS part of the model is aimed at team-building, clarifying the nature and scope of the improvement needed, exploring innovative interventions through literature and experts to reduce variation in care, finding measures for evaluation, and gathering information about the culture and setting where the study will be done.

Focus

- *Find a process to improve*. The process to study was delivery of EOL care to imminently dying inpatients on the five hospital units known to have the highest volume of patient deaths. Chart reviews of patient deaths investigated 2 years earlier identified a need.
- *Organize to improve a process.* A 28-member QI team of stakeholders spanned departments and disciplines to address EOL care issues such as ethics, social work, chaplains, pharmacists, nurses, and physicians. Pain and palliative care experts took the lead.
- *Clarify what is known.* Flowcharts were created to map the ideal process of care and increase dialogue among the team's disciplines about "why" EOL care varied. The team regrouped into four concurrent subcommittees: (1) care-path development, (2) implementation, (3) education, and (4) evaluation, including searches of internal and external sources of evidence and rationale in EOL care.
- *Understand variation.* Brainstorming helped the team elicit reasons for variations in the care process and identify potential barriers. An Ishikawa diagram (to display cause and effect) was used to show the barriers related to materials, methods, people, and equipment. All subcommittees considered the barriers when planning and implementing the program.
- *Select a process improvement.* The four subcommittees developed evidence-based interventions: the three-part PCAD care path (a multidisciplinary care path, a flow sheet for daily documentation of care, and a physician's order sheet that includes suggested medications for treating 15 of the most prevalent symptoms at EOL care); nurse, physician, other staff, patient, and family educational materials; a timeline and detailed plan for implementation, education, and evaluation of PCAD; and tools to measure professional, patient and family, and system outcomes. Goals of the PCAD care path are listed in Box 48.2.

Table 48.1 Deming's quality principle and application to the PCAD pathway pilot project

Principle	Discussion	Application
1. Customer-driven	The focus is on customers, both internal and external, and understanding them. Teams strive to achieve products/services to better meet needs and exceed expectations of customers.	Chart reviews of patient deaths reveal areas to improve: Documentation regarding advance directive discussions, symptom management effectiveness, spiritual and psychosocial care, treatment decisions in last 48 hours of life. Focus groups with caregivers reveal need for better communication with health professionals about patient's progress.
2. System optimization and alignment	Organizations/teams are systems of interdependent parts, with the same mission and goals for customers.	Hospital-wide multidisciplinary continuous quality improvement (CQI) team is formed to reduce variation in EOL care with three standardized tools that provide guidelines for care (care path), documentation, and physician orders.
	Optimizing performance of the entire system means aligning the processes, technology, people, values, and policies to support team efforts to continually improve.	Ongoing resources from Pain and Palliative Care available to pilot unit staff (one advanced practice nurse).
3. Continual improvement and innovation	Focus shifts to processes of care and using a systematic and scientific approach. Methods seek to reduce and control unnecessary process variation and improve outcomes.	Flowcharting and brainstorming techniques help identify current activities and unit norms for EOL care regarding establishing goals of care, advance directives, respecting patient and family preferences, and barriers to implementing goals of project.
4. Continual learning	Resources are available to develop a culture in which people seek to learn from each other and access new sources of evidence. Feedback mechanisms support the use of evidence to drive improvements	Extensive literature searches and team expertise guide development of clinical tools and educational materials. Team members receive education regarding issues in EOL care, viewing of Education in Palliative and EOL Care (EPEC, ELNEC). Adult learning principles guide sequencing and content of educational session for unit staff (e.g., physiology of dying).
5. Management through knowledge	Decision-making is based on knowledge, confirmed with facts about what is "best practice," and guided by statistical thinking.	Team uses FOCUS-PDSA methodology to structure study processes. Content experts in EOL care, measurement, outcomes, and QI guide sampling, selected outcome measures, and graphic display of data.
6. Collaboration and mutual respect	Organizations/teams engage everyone in the process of improvement and in the discovery of new knowledge and innovations. Mutual respect for the dignity, knowledge, and potential, contributions of others is valued by members.	Team forms subcommittees to develop materials in these areas based on expertise and interest: Care-path development, flow sheet, physicians' orders. Implementation (timeline for phases of planning, launching, rollout, evaluation, dissemination, and decisions to adopt practice changes). Education (staff, patient, and family). Outcomes (patient, family, staff knowledge, process audit of new tools).

EOL, end-of-life.

Box 48.2 Goals of the Palliative Care for Advanced Disease Pathway

- Respect patient autonomy, values, and decisions.
- Continually clarify goals of care.
- Minimize symptom distress at the end of life.
- Optimize appropriate supportive interventions and consultations.
- Reduce unnecessary interventions.
- Support families by coordinating services.
- Eliminate unnecessary regulations.
- Provide bereavement services for families and staff.
- Facilitate the transition to alternate care settings, such as hospice, when appropriate.

The PDSA Cycle: Plan–Do–Study–Act

Also known as the *Shewhart cycle*, PDSA rapid-cycles are the evaluation aspect of the study and its iterative problem-solving process. The next step is to test the change in the real work setting. The PDSA cycle is shorthand for testing a change—planning it, trying it, observing the results, and acting on what is learned. Similar to an audit and feedback approach, the user is given results about the new intervention, and, if goals are not met, users provide feedback and the intervention is either changed and tested or remains the same. This is the scientific method, using action-oriented learning. We explain the PDSA cycle using the education subcommittee's goal to achieve a greater than 90% total score on the Palliative Care Quiz for Nurses with all nursing staff.

- *Plan*. In this step, a timeline of activities for the 1-year pilot prepared administration, team members, and others with direction, goals, and resources. The sample timeline in Figure 48A.5 illustrates the various phases involved in launching the pilot

Table 48.2 Principles for assuring the quality of data

Principle	Key point
Validity/reliability	There is accuracy and consistency in data collection.
Completeness	Measurement system includes a policy for missing data and timeliness of collection.
Sampling method	Sample size is determined by power analysis to ensure representativeness of population.
Outlier cases	Measurement systems make efforts to validate or correct outliers.
Data specification	There are standardized definitions and terminology for transmission/use of data across departments.
Internal standards	Prespecified data-quality standards are tailored for individual performance measures.
External standards	There is a commitment to implementing data sets, codes, and methodologies developed by accrediting bodies (e.g., government, professional organizations) for data use across healthcare systems.
Auditability	Data are traceable to the individual case level.
Monitoring process	Ongoing data-measurement process in place is based on prespecified standards.
Documentation	Data standards and findings are recorded and available for review.
Feedback	Performance systems regularly provide summary reports on data quality to organization leadership.
Education	Performance systems provide support through education, on-site visits, and guidelines to ensure quality data.
Accountability	Measurement systems are responsible for data quality and dissemination to participating members.

project: the planning phase; rollout or introduction phase; and the implementation, evaluation, and dissemination, and reporting phases. Then the study design is crafted. This includes determination of sample size and selection, what data will be collected and by whom, what tools will be used and when they will be applied, what training will be conducted and by whom, and who will perform data analysis. Table 48.2 outlines principles for assuring the quality of data.

- *Do*. Baseline measures are obtained, interventions are implemented, and data collection begins. In the PCAD study, several premeasures were obtained, including baseline knowledge using Ross's Palliative Care Quiz for Nurses,[17] chart reviews, and focus groups with staff.
- *Check/Study*. The results of data collection are checked and analyzed by the team and the next steps formulated. The audit and feedback loop of discussions ensues again. For example, the EOL care group used the findings from the knowledge pretest to identify areas for continuing education. Through consensus, members agreed that knowledge items answered incorrectly by 15% of staff would be targeted for continued education.

Measures and Repeated Use of the Cycle

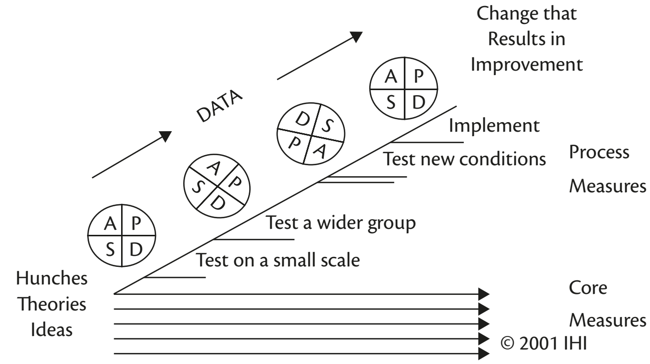

Figure 48.3 General approach to sequential plan–do–study–act (PDSA) cycles.
Source: Institute for Healthcare Improvement (IHI).

- *Act*. Action plans are developed, including a timeline and those accountable for completion. The study team gave monthly feedback to the QI team, pilot units, and the hospital QI department quarterly. Knowledge scores on pilot units were lowest on items about the dying process. Staff requested specific education in "the physiology of dying." Palliative care experts gave education to all staff on the intervention floors. Knowledge tests were repeated at 3- and 6-month intervals to identify additional gaps in understanding palliative care and EOL care.

Measures and Repeated Use of the Cycle

Figure 48.3 shows the general approach to sequential PDSA cycles. Teams are encouraged to make small changes rapidly and, once goals are met, to repeat the PDSA cycle with the next phase of the process or move to another process. Unlike an experimental research protocol, teams are encouraged to make changes in the intervention at each cycle test if they don't reach their targets. The tweaking of the new change, based on feedback from front-line users, encourages innovation and engagement. Encouraging teams to reach their targeted goals quickly reinforces team-building and motivates the teams to examine other processes. More detailed readings on the rapid cycle testing are available at http://www.ihi.org/resources/Pages/HowtoImprove/default.aspx.

The audit and feedback approach has shown positive outcomes. A Cochrane systematic review of 140 studies shows that audit and feedback interventions generally lead to small but potentially important improvements in professional behaviors and patient outcomes. In this process, an individual's professional practice or performance is reviewed against a standard or target, and then results are given back to the individual. The aim of the process is to encourage the individual to follow professional standards.[18]

Developing Key Performance Indicators to Improve End-of-Life Care

The next segment gives the reader strategies for improving quality palliative care and EOL care using Donabedian's classic structure, process, and outcome framework.[19] Table 48.3 presents selected

priority measures and tools for professionals performing QI in and across settings in EOL care.

Structure

Standards of Care Provide Structure

The beacon of quality standards in US healthcare remains The Joint Commission (TJC), a nonprofit organization which accredits and certifies more than 20,000 healthcare organizations and programs in the United States to meet certain performance standards, including EOL care. TJC has led the nation with standards for quality care in palliative care and EOL care in hospitals and the community: the Advanced Certification Program for Palliative Care, launched in 2011, has certified 90 US hospital programs as of 2017.[20] In July 2016, TJC launched a Certification Program for Community-Based

Palliative Care and has certified 21 US home-based agencies.[21] The certification status is designed to recognize programs that demonstrate exceptional patient- and family-centered care that aims to optimize the QOL for patients with serious illnesses.

In QI, the term "benchmark" is used to refer to "the search for the best practices that consistently produce best-in-the-world results"—the gold standard. QI teams are increasingly joining benchmarking associations, such as the Association for Benchmarking Healthcare and the Six Sigma Healthcare Benchmarking Association that offer mentorship, education, newsletters, and participation in benchmarking studies relevant to healthcare needs.[22,23] Clinicians seeking to make improvements in the appropriateness, effectiveness, and cost-effectiveness of care can look to their national and specialty organizations for standards, guidelines, position papers, and research models for EOL care.[24,25] Guidelines can describe appropriate management of specific symptoms and provide a basis for assessment, treatment, and outcomes. When the evidence is weak, as is the case for much of EOL care, guidelines or standards need to be supported with recommendations made through expert consensus. Standards, policies, procedures, and assessment tools for palliative care clinicians can be found at the Center to Advance Palliative Care (CAPC), whose website is updated frequently. Its intent is to assist programs in implementing quality palliative care in accordance with TJC standards. The documents can be accessed at www.capc.org.

Process

Process refers to the series of linked (but not necessarily sequential) steps that, by design, deliver a set of results. Answering the question "What are the key processes for delivering 'best practices' to a dying patient?" can generate many work flows and ideas for QI. QI operates on the principle that people do their best but are constrained by systems and processes that need to be addressed. Nurses' routine processes include screening, assessment, diagnosis, reassessment, treatment, evaluation, and documentation of patient care: all critical to producing positive patient and family outcomes. Assessment and reassessment of symptoms such as pain, dyspnea, agitation, delirium, nausea, diarrhea, and constipation are important processes leading to nursing interventions that can reduce the suffering of dying patients.

As clinicians have been challenged to deliver high-quality care at lower cost, there has been an explosion of tools developed to reduce variability in the processes of care. *Algorithms* and *clinical pathways* and *protocols* are three such tools that offer streamlined workflows for teams to monitor and manage the processes of patient care. These tools define desired patient outcomes for specific medical conditions and delineate the optimal sequence and timing of interventions to be performed by professionals. Those interested in adopting validated assessment tools for EOL care are referred to the PEACE Project sponsored by the Carolinas Center for Medical Excellence (CCME) and the University of North Carolina-Chapel Hill, under contract with CMS. Twenty-two hospices participated in a national Quality Improvement Collaborative (QIC) to pilot-test the usability and feasibility of potential quality measures and data collection processes for hospice and palliative care programs. The 23 quality measures for EOL care are organized into eight domains and described at http://www.med.unc.edu/pcare/files/assessment-instruments-for-end-of-life-care.

Algorithms and Standardized Orders Streamline Processes

Algorithms are step-by-step guides for clinicians to use in their day-to-day work. Figure 48.4 shows an example of a simple tool

Respiratory Distress Observation Scale © (Margaret L. Campbell, PhD, RN 2/19/09)

Variable	0 points	1 point	2 points	Total
Heart rate per minute	<90 beats	90-109 beats	≥110 beats	
Respiratory rate per minute	≤18 breaths	19-30 breaths	>30 breaths	
Restlessness: non-purposeful movements	None	Occasional, slight movements	Frequent movements	
Paradoxical breathing pattern: abdomen moves in on inspiration	None		Present	
Accessory muscle use: rise in clavicle during inspiration	None	Slight rise	Pronounced rise	
Grunting at end-expiration: guttural sound	None		Present	
Nasal flaring: involuntary movement of nares	None		Present	
Look of fear	None		Eyes wide open, facial muscles tense, brow furrowed, mouth open, teeth together	
Total				

1. RDOS is not a substitute for patient self-report if able.
2. RDOS is an adult assessment tool.
3. RDOS cannot be used when the patient is paralyzed with a neuromuscular blocking agent.
4. RDOS is not valid in bulbar ALS or quadriplegia.
5. Count respiratory and heart rates for one-minute; auscultate if necessary.
6. Grunting may be audible with intubated patients on auscultation.
7. Fearful facial expressions:

to measure respiratory distress developed by a leading nurse researcher in critical care, palliative care, and EOL care, Dr. Margaret Campbell.[26] The tool offers clinicians a validated method for assessing and monitoring one of the three most distressing symptoms for patients and their families at end of life: pain, dyspnea and agitation. Nurses are encouraged to build validated tools into their daily practice protocols, which include treatment options of pharmacological and nonpharmacological interventions.[27]

Clinical Pathways and Protocols Reduce Variation in Processes of Care

The term "pathway" refers to clinical trails that form a structured, multidisciplinary action plan. It defines the key events, activities, and expected outcomes of care for each discipline during each day of care. Pathways are evidence-driven, reflect best practices, and delineate the optimal sequence and timing of interventions. The goal of using a pathway is to "reduce variation in services and practices, thus reducing costs and negative patient outcomes."[16,28] Box 48.3 shows a six-step process for developing pathways. Box 48.4 lists commonly used elements of care and interventions. Reducing variation in any process (clinical decision-making or care delivery) takes three steps. The first step is to study the process as it currently operates (usually done through flowcharting and brainstorming) to identify potential sources of variation and to learn about which activities are likely to achieve the desirable outcomes. The second step is to stabilize the process by getting everyone to use the same procedures, equipment, and materials, and still recognize the need for individualized patient care. This is usually done by repeated audit and feedback of results to users, educating about procedures, and involving users in tweaking the process and in individual responses. The third step is to measure again and again and repeat the process until control within agreed-upon limits is reached. Standardizing care, however, should never compromise an individual's care needs.

Outcomes

Outcome measures evaluate the impact of innovative change on patient and family QOL, healthcare systems, and professional practice. Outcomes are the results of actions or nonaction to structures, processes, patients and caregivers, professionals, and systems in the organization. Examples of outcomes include reduced symptom distress, improved family satisfaction, improved perceived support of professional caregivers, and reduced costs of EOL care.

Clinicians will need to become proficient at measuring the outcomes of their care. Federal and state governments, private purchasers, physicians, nurses, insurers, labor unions, health plans, hospitals, and accreditation organizations, among others, have placed pressure on organizations to address some of the significant quality problems in US healthcare systems (http://www.ahcpr.gov/qual).[29,30] The Centers of Medicare and Medicaid Services' pay-for-performance initiative is designed to support better quality care of Medicare beneficiaries. About 100 such initiatives are in progress across the country. The general intent is to reward hospitals and doctors for providing better care. We will need to improve our ability to measure and report the quality of care being delivered. Such reporting prompts a closer look at provider and healthcare practices, both as feedback for clinicians and as publicly available score cards for consumer evaluation.

Measuring Patient, Family, and Clinician Satisfaction with End-of-Life Care

"Achieving and producing health and satisfaction, is the ultimate validator of the quality of care."[19] There has been limited research in examining satisfaction among terminally ill and dying patients and families and yet, for most dying patients, satisfaction may be the most important outcome variable for themselves and their families, notes Professor Irene J. Higginson, an international leading researcher for more than two decades. She has been using the audit cycle and feedback process to improve outcomes in palliative care and notes the difficulties in obtaining outcome information—such as QOL—from the weakest group of patients. She supports the need to test the use of proxies to obtain this important information. The Palliative Outcome Scale is one such tool that is used by many clinicians in palliative care in a variety of settings to measure physical and psychological symptoms, spiritual considerations, practical concerns, and psychosocial needs. Readers seeking measures to be used in clinical audits are referred to the work of Dr. Higginson.[31]

The quality of care provided to dying patients is being obtained through after-death interviews of families. One such tool, the Family Assessment of Treatment at the End of Life Short Form (FATE-S)[32]

Box 48.3 The Six-Step Process to Developing a Care Path

1. Identify high-volume, high-priority case types, review medical records, review and evaluate current literature to characterize the specific problems, average length of stay, critical events, and practical outcomes.
2. Write the critical path, a flow chart defining the sequence and timing of functions to be performed by physicians, nurses, and other staff.
3. Have nurses, physicians, and other disciplines involved in the process review the plan of care.
4. Revise the pathway until consensus on care components is reached.
5. Pilot-test the pathway and revise as needed.
6. Incorporate pathway patient management into quality improvement programs, which include monitoring and evaluating patient care outcomes.

Box 48.4 Routine Elements of a Care Path

- Physical elements
- Medications
- Nutrition and dietary
- Vital signs, intake and output, weight
- Comfort assessment
- Safety and activity
- Diagnostic lab work
- Intravenous use
- Transfusions
- Diagnostic tests
- Psychosocial and spiritual needs
- Referrals and consultations
- Patient and family counseling and education

is routinely used in the Veterans Administration (VA) system in at least 70 hospitals and 60 nursing homes. The validated tool has 14 items, including one global rating, and assesses the domains of communication, treatment preferences, dignity, spiritual support, psychosocial support, pain control, planning for death, and overall care to patient.

Another widely used tool in commonwealth nations is FAMCARE. Based on qualitative research methods, family members are asked to list the indicators of quality of palliative care from the patient's and their own perspective.[33]

Obtaining the perspective of clinicians caring for patients and families at end of life offers another view on the quality of care given to the imminently dying. Figure 48.5 presents a new validated audit tool for conducting an EOL care Tracer that can guide assessment and rate care when used to evaluate the quality of care for the dying inpatient. *Tracers* are used by TJC surveyors to evaluate whether standards of care are being followed. Before reviewing a patient's record for the presence of quality care, they might interview the nurse caring for the patient, the doctor, a social worker, and a chaplain, in addition to interviewing the patient and/or family members about their satisfaction with care.

The EOL care Tracer began with an initial pool of 248 items to evaluate overall quality in eight specific content areas of palliative care (e.g., symptom management). Collected into three instruments,

Tracer EoLC v1

Conducting the Review: **Date:**

Please rate the quality of care that the patient and family received during the 48 hours before the patient died. Base your ratings on personal observations, the medical record, and interviews. Mark "NA" if you are unable to evaluate the care.

		N/A	Poor	Fair	Good	Very Good	Excellent
Care of the Patient							
1.	Overall, how would you rate the quality of care the patient received for symptom control?						
2.	Overall, how would you rate the quality of care the patient received to address goals of care discussions?						
3.	Overall, how would you rate the quality of care the patient received to address religious and/or spiritual concerns?						
4.	Overall, how would you rate the quality of care the patient received to address psychosocial concerns?						
5.	Overall, how would you rate the quality of care the patient received during the last hours before death?						
6.	How would you rate the overall care the patient received during the last 48h of life?						
Care of the Family							
7.	Overall, how would you rate the quality of care the family received to address communication concerns?						
8.	Overall, how would you rate the quality of care the family received to address goals of care discussions?						
9.	Overall, how would you rate the quality of care the family received to address advance care planning issues?						
10.	Overall, how would you rate the quality of care the family received to address traditions and customs?						
11.	Overall, how would you rate the quality of care the family received to address religious and/or spiritual concerns?						
12.	Overall, how would you rate the quality of care the family received during the patient's last hours before death?						
13.	Overall, how would you rate the quality of care the family received after the patient's death occurred?						
14.	How would you rate the overall care the family received during the patient's last 48h of life?						

Probe items to consider in completing Tracer EoLC-v1

Figure 48.5 Tracer end-of-life care V1.

Source: Reference 35.

1. Symptom Control for moderate to severe symptom distress

- ☐ Repeated assessments conducted?
- ☐ Medication given around the clock?
- ☐ Reassessments indicating relief?
- ☐ Additional action taken if symptoms not relieved/reduced?

2. Communication (among patient and family and whole team)

- ☐ Opportunities to communicate with patient and/or family?
- ☐ Interpreter sought for language barriers answered by medical team?
- ☐ Patient and family supported?
- ☐ Care consistent with patient and family concerns?

3. Goals of care and advance care planning

- ☐ Goals of care discussed with patient and/or family?
- ☐ Care consistent with goals of care?
- ☐ Attempts to avoid/reduce invasive tests and procedures?
- ☐ Advance directives: Planning for future medical care
  - ○ Surrogate decision maker identified (or attempt made)?
  - ○ Resuscitation orders clear?
  - ○ Care consistent with patient advance care directives?

4. Traditions and customs

- ☐ Care adequately addressed language difficulties, family involvement, respect for elders, decision-maker, deference to authority of doctor
- ☐ Patient's environment appropriately adjusted to meet preferences (noise, odor, light, private room, family space, special cultural items allowed)?
- ☐ Specific care-related traditions, customs or way of life supported?

5. Religious and/or spiritual care

- ☐ Religious/spiritual needs appropriately assessed and efforts made to support those needs?
- ☐ Preferences related to post mortem care identified?
- ☐ Access to acceptable chaplain/pastoral care?
- ☐ Access to religious rituals appropriate to beliefs?

6. Psychosocial care

- ☐ Psychosocial assessment of patient and family conducted?
- ☐ Efforts made to meet psychosocial needs?
- ☐ Family given opportunity to be present during dying period?
- ☐ Family supported during dying phase?
- ☐ Bereavement needs addressed?
- ☐ Family identified if high risk for complicated grieving?

7. Last hours

- ☐ Environment adjusted to meet patient/family preferences?
- ☐ Environment adjusted to support dignity of patient and family during dying phase?
- ☐ Patients personal hygiene attended to (e.g., mouth, eyes, wounds)?
- ☐ Patient and family treated with respect?
- ☐ Family given appropriate, timely and empathic information about death when it occurred?

8. After the death

- ☐ Dignity of the deceased preserved (traditions and customs upheld re: post mortem care/ funeral plans)?
- ☐ Family given appropriate, timely and empathic information about what would happen to body upon leaving unit?

With permission from Bookbinder, M et al, (in press) Development and Field-Test of a Tool and Methodology for a Self-Assessment Tracer to Evaluate the Quality of End-of-Life Care, *J Pain Symptom Manage*: 2017, Elsevier, 2017.

Figure 48.5 Continued

the items were used to interview professional caregivers and evaluate the charts of hospitalized patients who died. Evidence that this information could be validly captured using a small number of items was obtained through factor analyses, canonical correlations, and group comparisons. Chart reviews of 145 deaths and data from 445 professional interviews (26 physicians, 108 nurses, 18 social workers, and 9 chaplains) about care given in the last 48 hours of life yielded the 14-item Tracer EOL care v1 shown in Figure 48.5.[34, 35]

The United States participates in international research on EOL care. The Quality of Death Index Ranking in palliative care ranks palliative care and EOL care experiences across the world. In 2015, the United States ranked 9 out of 80 countries providing data on 20 indicators across five categories: the palliative and healthcare environment, human resources, the affordability of care, the quality of care, and the level of community engagement.[36]

Process Indicators

These indicators measure a specific aspect of nursing practice that is related to flow of work: flow of information, materials, or patient care. Examples of process indicators might include pain screening, assessments, implementation of an intervention, reassessment, prompt management of complications, and documentation. These indicators describe "how care is to be delivered and recorded." Sometimes it may be difficult to separate process indicators from outcome indicators. For example, if an improvement study is directed toward reducing discomfort related to dyspnea in dying patients, then the indicator might involve the process of assessment of respirations, obtaining an order, and giving appropriate medication within a designated time period. The indicator might read that 100% of patients with severe dyspnea will be assessed and treated with appropriate medications within a 2-hour period. Another segment of the same process may produce an indicator that reads that 100% of patients treated for severe dyspnea will achieve relief (reduction to mild dyspnea) within 8 hours.

INDICATOR: Number of patients with severe dyspnea reaching mild dyspnea within 8 hours/The total number of patients experiencing severe dyspnea (designated period)

Low results on this indicator might prompt a special QI team to investigate the barriers to reaching the goal of the indicator. The team may learn that the dyspnea measure is too difficult to administer, too time-consuming, or too confusing to assess mild, moderate, and severe dyspnea. Is the computer screen's field for documenting care not easy to use? Were physician's orders not appropriate for treating severe dyspnea? Were calls made to providers with delays in answering? Any of these pieces of the process could trigger a new look at the process of reaching mild relief of this symptom, including testing the use of a dyspnea algorithm.

Quality Improvement Indicators: Measuring Organizational Performance

A *clinical indicator*, also called a *key performance indicator* (KPI), is typically defined as a quantitative measure that evaluates the quality of important patient care and support-service activities. Indicators that directly affect quality services typically include such factors as timeliness, efficiency, appropriateness, accessibility, continuity, privacy and confidentiality, comfort, participation of patients and families, and safety and supportiveness of the care environment. Although they are not direct measures of quality, indicators serve as "screens" or "flags" that direct attention to specific performance areas that should be targets for ongoing investigation within an organization.

Institutions surveyed by TJC in the past two decades have experienced the shift in focus of performance from competence and skills ("Is the organization able to provide quality services?") to productivity and outcomes ("To what extent does the organization provide quality services?") and efficiency ("To what extent does the organization use resources efficiently?"). For example, rather than requesting a review of the institution's policy and procedure manual for a pain or palliative care program, surveyors might evaluate whether pain standards have been implemented and to what extent relief was obtained and the patients' satisfaction with care and their understanding of side effects associated with analgesics. The "tracer" methodology is standard procedure for TJC surveyors. Nurses and other clinicians will need to be knowledgeable in this area as the accreditation process promises to become more rigorous in areas affecting our largest and most costly group of citizens: the ill elderly.

Indicators can reflect a performance measure such as competence or safety. *Competence* means that individuals or the organization have the ability (e.g., education, behavioral skills) to provide quality services; *safety* means that those abilities are translated into actions that achieve quality outcomes without untoward effects. Results of indicators can reveal deviations from the norm and may warn of impending problems. Indicators may require a single-item measure, multiple items, or multiple tools. Indicators are typically expressed as an event or ratio (percentage). Examples of structure, process, and outcome indicators that are clinical (patient care), professional (competence), and administrative (satisfaction) are described here.

Structural Indicators

These are derived from standards of care and need to be aligned with the mission, philosophy, goals, and policies of the organization (e.g., community agency, hospital, department, or unit). Structure standards measure whether the authorized norms in the field are being followed. For example, a standard and its accompanying policy may read that all (100%) patients admitted to the hospital or hospice require discussion and documentation about advance directives within 48 hours of admission. The percentage obtained would indicate the extent to which adherence to the 100% goal is being met. A structural indicator on an oncology unit might read:

INDICATOR: Number of records with documentation of a discussion of advance directives/Total number of patients who were admitted to the oncology unit (determined period)

Staff competence is another structural indicator. This indicator may reflect a standard and policy that requires all geriatric unit staff pass a competency in EOL care. The competency might consist of written exam (cognitive) and demonstration of skill (behavioral) in the use of an EOL care pathway (see Figure 48A.5 for a sample knowledge quiz in palliative care). For this indicator, a threshold is determined for successful completion, such as 90% on the written exam plus three return demonstrations in the use of the pathway. Low results on this indicator might suggest the need to send key staff to an EOL care training for nurses such as the End-of-Life Nursing Education Consortium (ELNEC). Readers can visit http://www.aacn.nche.edu/ELNEC/ to read more about ELNEC's national effort and courses available.

Outcome Indicators

These indicators measure what does or does not happen after something is or is not done. Most organizations have shifted their focus from examining the documentation of processes of care to measuring outcomes of care and learning which treatment works best, under what conditions, by which individuals, and at what cost. Examples of outcome indicators for quality EOL care include family

Box 48.5 Areas for Improving Quality Care at the End-of-Life

- Physical and emotional symptoms
- Support of function and autonomy
- Advance care planning, including goals of care discussions
- Aggressive care near death, including preferences about site of death, CPR, hospitalization, nutrition, and hydration
- Patient and family satisfaction
- Religious and spiritual and cultural preferences
- Global quality of life
- Caregiver burden (family and professionals)
- Survival time
- Provider continuity, competency, and skill
- Transitions in care settings
- Bereavement services

satisfaction with care (family), symptom control (patient), respect for patient cultural and religious preferences, family support and communication at the time of the patient's death, and referral for ethics consultation if no healthcare agent is identified. Outcome indicators such as these might be appropriate following the implementation of a multidisciplinary pathway to improve care of dying inpatients. The goal might be to achieve a family satisfaction with care rating of 90% very satisfied, using a 0–5 scale (0 = very dissatisfied to 5 = very satisfied). An oncology unit might decide that designated family members will be contacted at 3 to 4 months following the patient's death for an interview about satisfaction with care.[34] The indicator would read: 90% of families will report being very satisfied with care when asked about overall satisfaction with the patient's care in the last days of life. In this example, the response rate from families should ideally be more than 50% so that findings are used with confidence and not viewed as biased.

INDICATOR: Number of families scoring very satisfied with overall care/Number of persons completing satisfaction surveys following the death of a family member (Designated Period)

See the preceding section on patient, family, and clinician satisfaction with EOL care for examples of outcome measures. Box 48.5 summarizes priority areas to improve quality care at the end of life.

Conclusion

Nurses, especially those in advance practice roles, are poised in pivotal roles across settings to improve the quality of care of the dying in the decades ahead. Our professional and advocacy organizations and the literature can lead us to which areas of EOL care are priorities for improvement. Many were outlined earlier. Advanced practice nurses need to have skill sets in quality improvement and in using research so that we can study with confidence "what works and what does not work" for patients and families and professional caregivers in our practice settings. We need to keep reading the literature, and we must stay active in developing and testing QI models, tools, and interventions toward better EOL care. We need to test interventions for improved symptom management, especially dyspnea and agitation; develop models for assuring "best practices" using research in vulnerable populations; and integrate QI methods into everyday palliative care practices. Palliative and EOL care is gradually being integrated into basic and advanced practice registered nursing (APRN) curricula, and the number of graduates from APRN fellowships[37] and externships[38] and doctoral programs in pain and palliative care centers of excellence is increasing, providing leadership in academic and clinical settings.[39-45] Nurses will need to strengthen their involvement in national and international efforts that educate professionals and consumers and influence healthcare policy in EOL care issues.

To survive, our healthcare systems must be able to change and improve rapidly. As with any other service operation, health systems require systematic innovation efforts to remain competitive, cost-efficient, and up to date. If the quality of EOL care is to improve, nurses will need to have expert knowledge about making change: how to encourage, measure, manage, and evaluate changes within and across organizations and settings. This knowledge needs to be coupled with the methods and know-how to produce change. Clinical audits and feedback are evidence-based strategies that are known to increase accountability and encourage dialogue among all ranks of staff, disciplines, and services. We will need to evaluate and compare EOL care across settings. Work is needed to develop standardized measures and definitions that are applicable to the setting and stage of illness while maintaining patient-centeredness. Nurses with expertise in quality and QI methods can provide the leadership needed to shape a practice culture that supports continuous testing of innovative strategies for improving care at the end of life.

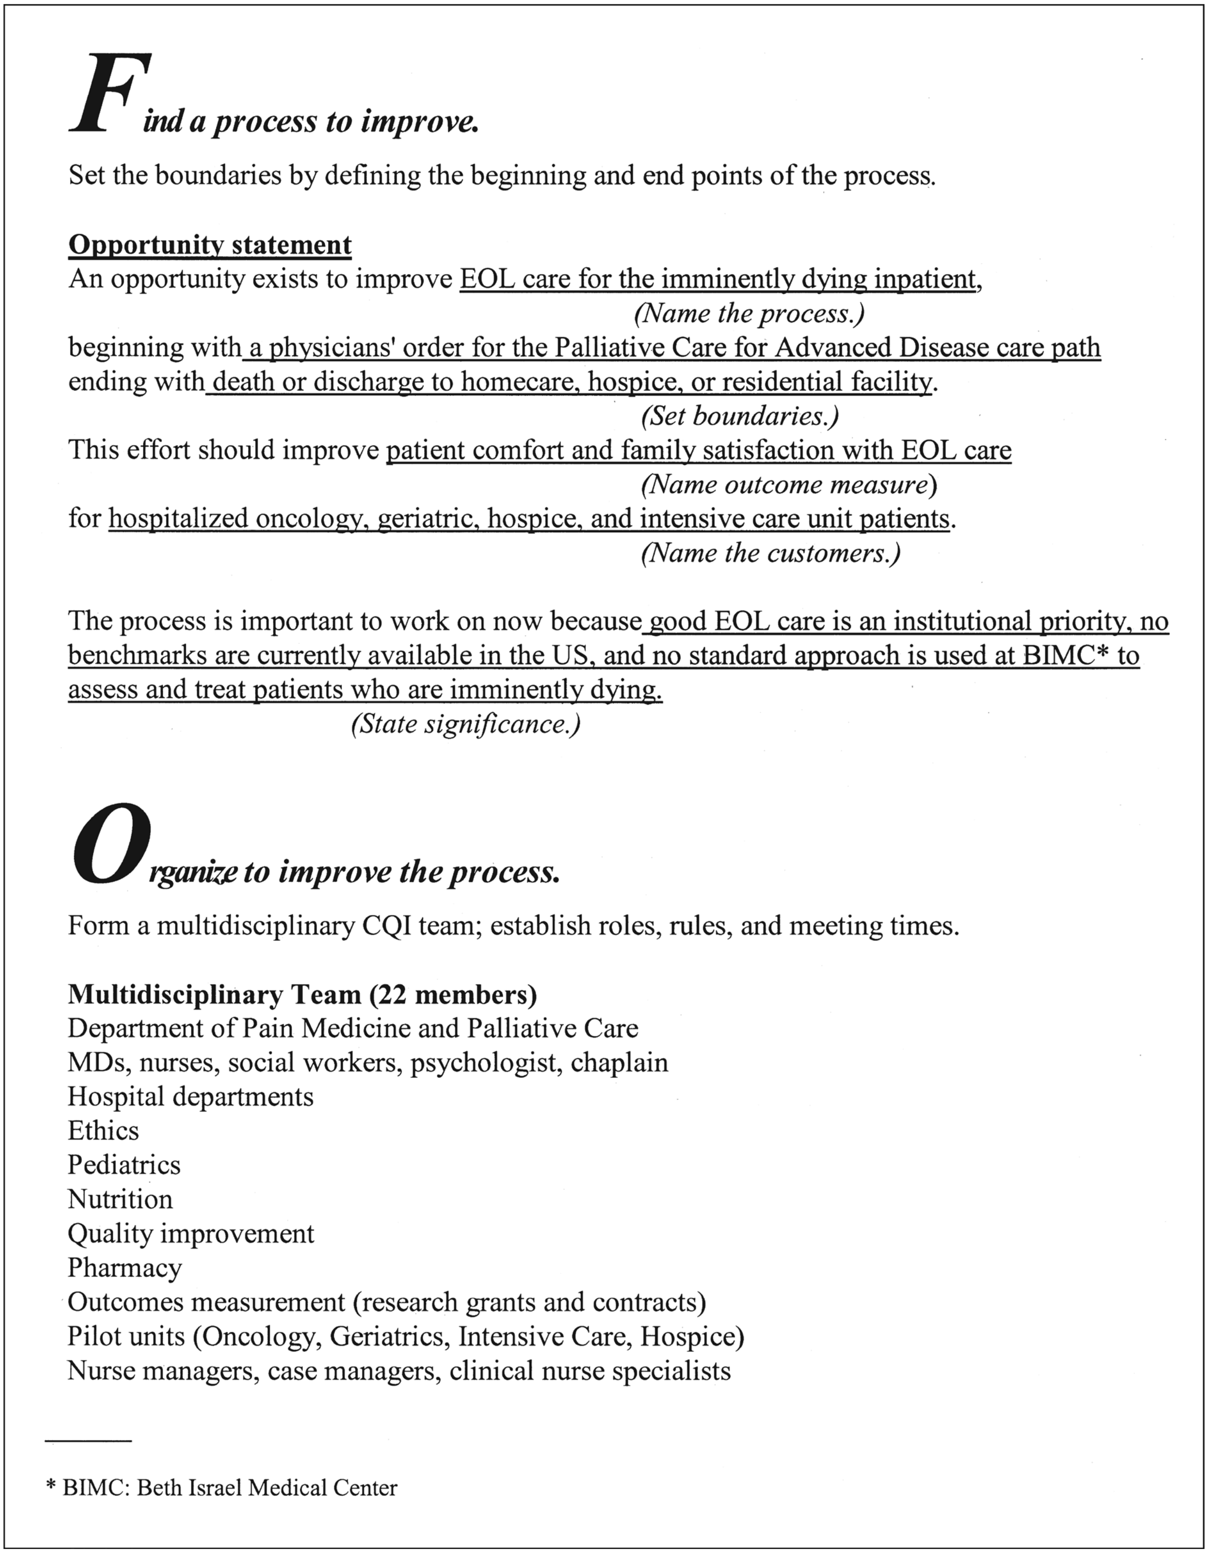
Appendix 48.1



Find a process to improve.

Set the boundaries by defining the beginning and end points of the process.

Opportunity statement

An opportunity exists to improve EOL care for the imminently dying inpatient,
(Name the process.)
beginning with a physicians' order for the Palliative Care for Advanced Disease care path
ending with death or discharge to homecare, hospice, or residential facility.
(Set boundaries.)
This effort should improve patient comfort and family satisfaction with EOL care
(Name outcome measure)
for hospitalized oncology, geriatric, hospice, and intensive care unit patients.
(Name the customers.)

The process is important to work on now because good EOL care is an institutional priority, no benchmarks are currently available in the US, and no standard approach is used at BIMC* to assess and treat patients who are imminently dying.
(State significance.)

Organize to improve the process.

Form a multidisciplinary CQI team; establish roles, rules, and meeting times.

Multidisciplinary Team (22 members)
Department of Pain Medicine and Palliative Care
MDs, nurses, social workers, psychologist, chaplain
Hospital departments
Ethics
Pediatrics
Nutrition
Quality improvement
Pharmacy
Outcomes measurement (research grants and contracts)
Pilot units (Oncology, Geriatrics, Intensive Care, Hospice)
Nurse managers, case managers, clinical nurse specialists

Understand the variation

Brainstorm with those at the grass roots level about why the process varies. Categorize sources of variation by people, materials, methods, and equipment. Display data using a cause-and-effect diagram.

Brainstorming Session with CQI Team on End-of-life (EOL) Care Question:
What barriers could be encountered in implementing an EOL Pathway at BIMC?

EOL awareness/ discomfort/readiness:

- What is "end-of-life care?" When is treatment palliative vs. life ending? How do we choose?
- Patient, family, readiness/awareness of dying
- Physician, family, patient willingness to acknowledge that death is imminent
- Issues of truth telling: family may not know status of patient prior to the pathway
- Physician discomfort with stopping treatment
- Medical uncertainty about when to stop treatment

Team communication:

- Physician and nurse discomfort in discussing change in treatment strategy
- Is it the physician's decision alone? The heath care team as a whole needs to be acknowledged in decision.
- Definition of terms. Need to define who the team is. May need a new model.
- Nurses' comfort—may be put in the middle of team/family attending and decisions.

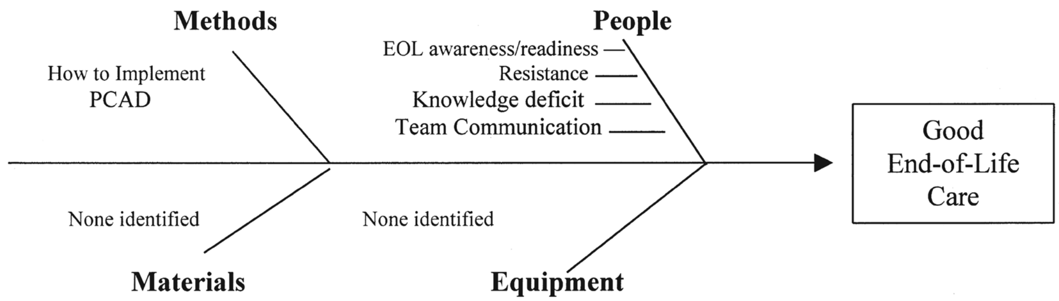
Unit resistance:

- Resistance of unit teams. May see this project as "another thing to do."
- Large-scale resistance. Some may not see that there is something to "fix."
- Organizational pressure to discharge quickly.

Knowledge deficit:

- Assumptions about pastoral care (patient, family, staff) and what the experience will be.
- Knowledge deficit about medical and nursing interventions
- How to implement the care path and encourage people to speak up front rather than later
- Large cultural diversity at BIMC
- Education needed about biomedical analysis and ethical problems
- Physician/patient and physician/family communication skills

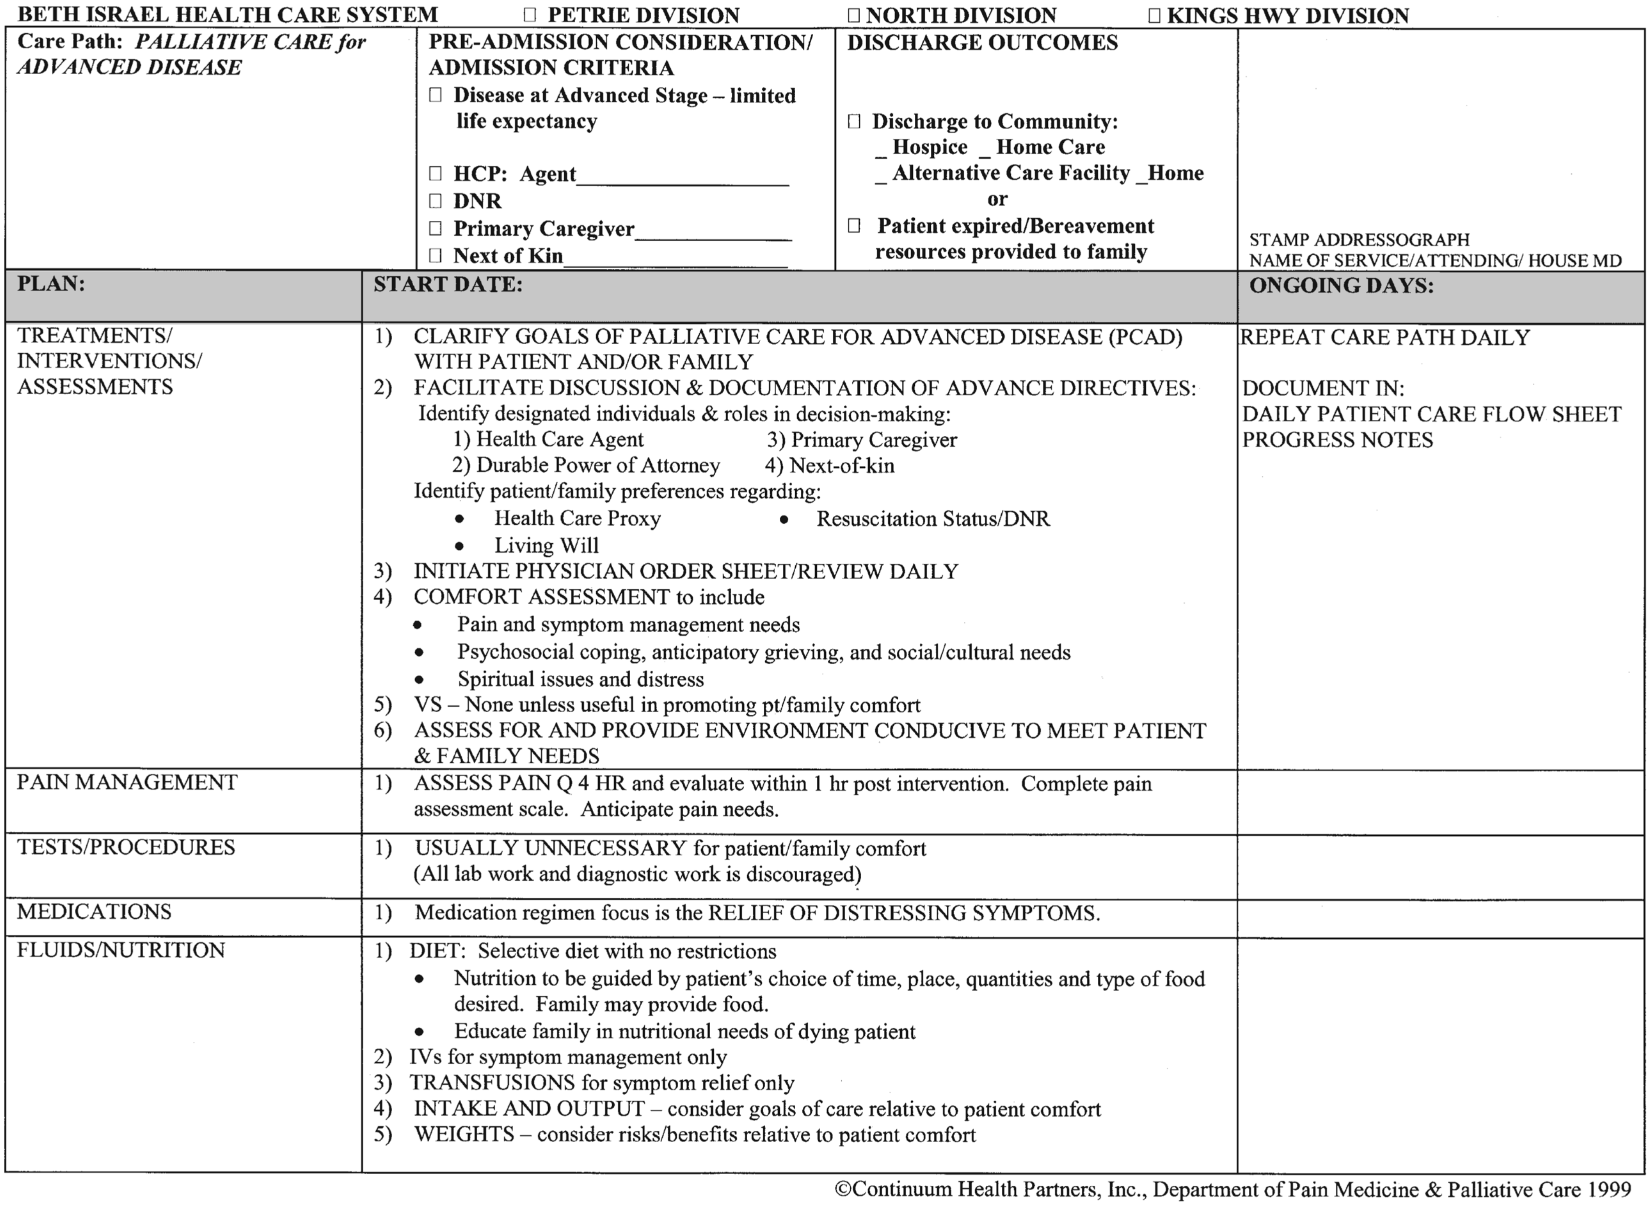
Cause and Effect (Ishikawa) Diagram (Barriers to implementing PCAD)—Themes above



Select the process improvement.

Describe the new intervention in detail. Palliative Care for Advanced Disease (PCAD) Care Path: Care Path, Flow Sheet, and Physicians' Order Sheet **(see following pages)**

Figure 48A.1 Continued



BETH ISRAEL HEALTH CARE SYSTEM ☐ **PETRIE DIVISION** ☐ **NORTH DIVISION** ☐ **KINGS HWY DIVISION**

Care Path: ***PALLIATIVE CARE for ADVANCED DISEASE***	**PRE-ADMISSION CONSIDERATION/ ADMISSION CRITERIA** ☐ **Disease at Advanced Stage – limited life expectancy** ☐ **HCP: Agent__________________** ☐ **DNR** ☐ **Primary Caregiver_____________** ☐ **Next of Kin__________________**	**DISCHARGE OUTCOMES** ☐ **Discharge to Community:** **_ Hospice _ Home Care** **_ Alternative Care Facility _Home** **or** ☐ **Patient expired/Bereavement resources provided to family**	STAMP ADDRESSOGRAPH NAME OF SERVICE/ATTENDING/ HOUSE MD

PLAN:	**START DATE:**	**ONGOING DAYS:**
TREATMENTS/ INTERVENTIONS/ ASSESSMENTS	1) CLARIFY GOALS OF PALLIATIVE CARE FOR ADVANCED DISEASE (PCAD) WITH PATIENT AND/OR FAMILY 2) FACILITATE DISCUSSION & DOCUMENTATION OF ADVANCE DIRECTIVES: Identify designated individuals & roles in decision-making: 1) Health Care Agent 3) Primary Caregiver 2) Durable Power of Attorney 4) Next-of-kin Identify patient/family preferences regarding: • Health Care Proxy • Resuscitation Status/DNR • Living Will 3) INITIATE PHYSICIAN ORDER SHEET/REVIEW DAILY 4) COMFORT ASSESSMENT to include • Pain and symptom management needs • Psychosocial coping, anticipatory grieving, and social/cultural needs • Spiritual issues and distress 5) VS – None unless useful in promoting pt/family comfort 6) ASSESS FOR AND PROVIDE ENVIRONMENT CONDUCIVE TO MEET PATIENT & FAMILY NEEDS	REPEAT CARE PATH DAILY DOCUMENT IN: DAILY PATIENT CARE FLOW SHEET PROGRESS NOTES
PAIN MANAGEMENT	1) ASSESS PAIN Q 4 HR and evaluate within 1 hr post intervention. Complete pain assessment scale. Anticipate pain needs.	
TESTS/PROCEDURES	1) USUALLY UNNECESSARY for patient/family comfort (All lab work and diagnostic work is discouraged)	
MEDICATIONS	1) Medication regimen focus is the RELIEF OF DISTRESSING SYMPTOMS.	
FLUIDS/NUTRITION	1) DIET: Selective diet with no restrictions • Nutrition to be guided by patient's choice of time, place, quantities and type of food desired. Family may provide food. • Educate family in nutritional needs of dying patient 2) IVs for symptom management only 3) TRANSFUSIONS for symptom relief only 4) INTAKE AND OUTPUT – consider goals of care relative to patient comfort 5) WEIGHTS – consider risks/benefits relative to patient comfort

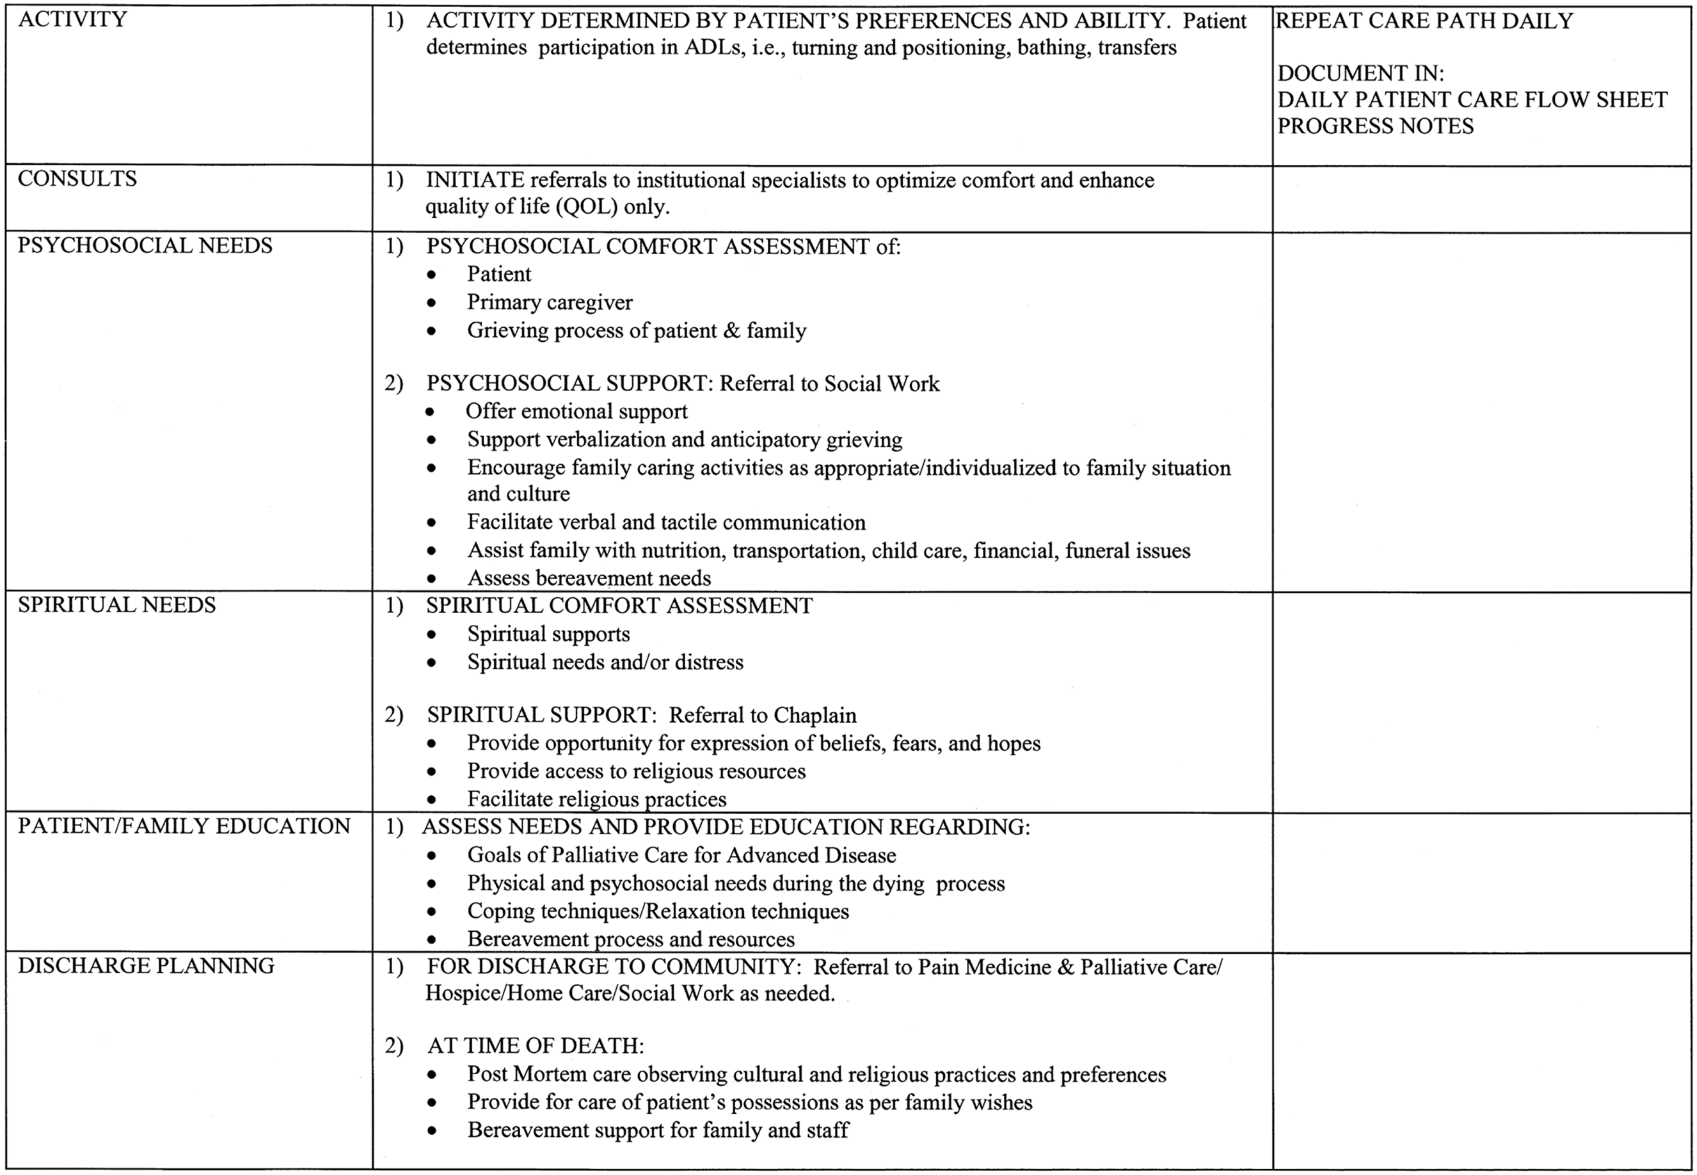
Figure 48A.2 Care path: The interdisciplinary plan of care.

Source: Continuum Health Partners, Inc., Beth Israel Medical Center, Department of Pain Medicine and Palliative Care, New York. Palliative Care for Advanced Disease (PCAD) Care Path; CQI Team on End-of-Life Care.



ACTIVITY	1) ACTIVITY DETERMINED BY PATIENT'S PREFERENCES AND ABILITY. Patient determines participation in ADLs, i.e., turning and positioning, bathing, transfers	REPEAT CARE PATH DAILY DOCUMENT IN: DAILY PATIENT CARE FLOW SHEET PROGRESS NOTES
CONSULTS	1) INITIATE referrals to institutional specialists to optimize comfort and enhance quality of life (QOL) only.	
PSYCHOSOCIAL NEEDS	1) PSYCHOSOCIAL COMFORT ASSESSMENT of: • Patient • Primary caregiver • Grieving process of patient & family 2) PSYCHOSOCIAL SUPPORT: Referral to Social Work • Offer emotional support • Support verbalization and anticipatory grieving • Encourage family caring activities as appropriate/individualized to family situation and culture • Facilitate verbal and tactile communication • Assist family with nutrition, transportation, child care, financial, funeral issues • Assess bereavement needs	
SPIRITUAL NEEDS	1) SPIRITUAL COMFORT ASSESSMENT • Spiritual supports • Spiritual needs and/or distress 2) SPIRITUAL SUPPORT: Referral to Chaplain • Provide opportunity for expression of beliefs, fears, and hopes • Provide access to religious resources • Facilitate religious practices	
PATIENT/FAMILY EDUCATION	1) ASSESS NEEDS AND PROVIDE EDUCATION REGARDING: • Goals of Palliative Care for Advanced Disease • Physical and psychosocial needs during the dying process • Coping techniques/Relaxation techniques • Bereavement process and resources	
DISCHARGE PLANNING	1) FOR DISCHARGE TO COMMUNITY: Referral to Pain Medicine & Palliative Care/ Hospice/Home Care/Social Work as needed. 2) AT TIME OF DEATH: • Post Mortem care observing cultural and religious practices and preferences • Provide for care of patient's possessions as per family wishes • Bereavement support for family and staff

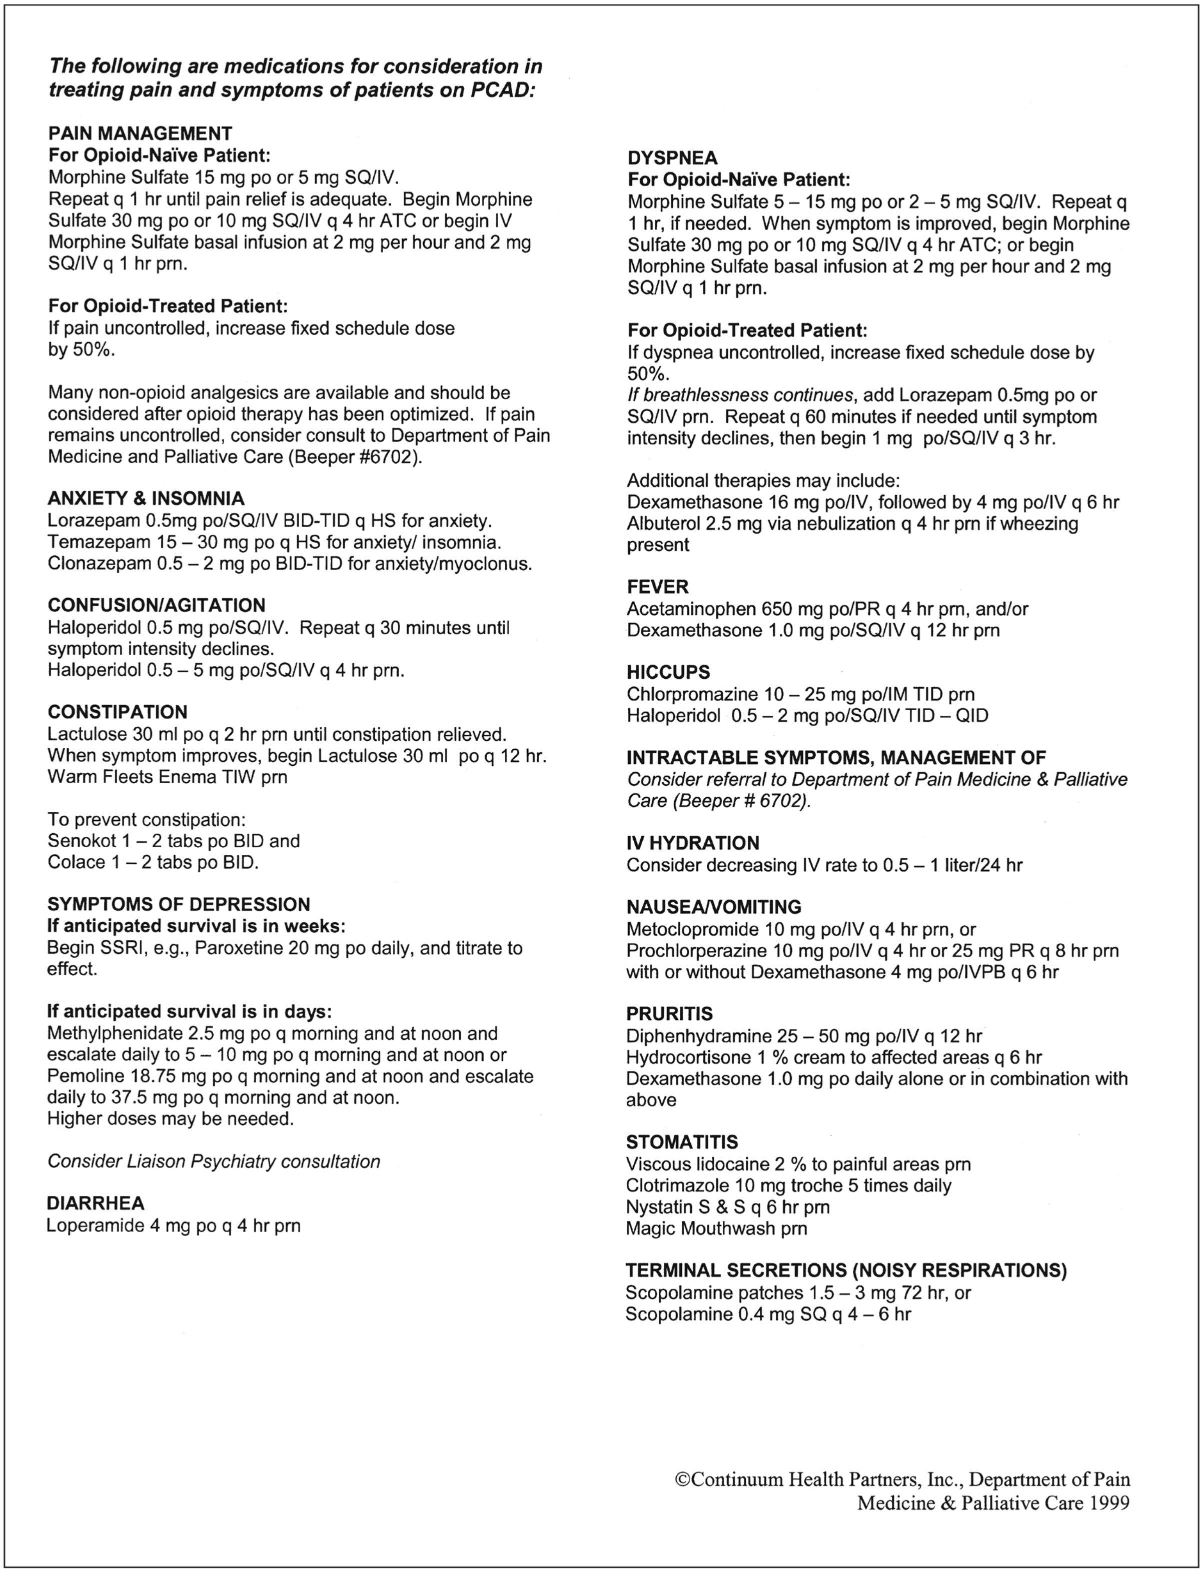
Figure 48A.4 A standardized physician order sheet, with suggestions for medical management of 15 symptoms prevalent at the end of life.

Source: Continuum Health Partners, Inc., Beth Israel Medical Center, Department of Pain Medicine and Palliative Care, New York. Palliative Care for Advanced Disease (PCAD) Care Path; CQI Team on End-of-Life Care.



The following are medications for consideration in treating pain and symptoms of patients on PCAD:

PAIN MANAGEMENT
For Opioid-Naïve Patient:
Morphine Sulfate 15 mg po or 5 mg SQ/IV.
Repeat q 1 hr until pain relief is adequate. Begin Morphine Sulfate 30 mg po or 10 mg SQ/IV q 4 hr ATC or begin IV Morphine Sulfate basal infusion at 2 mg per hour and 2 mg SQ/IV q 1 hr prn.

For Opioid-Treated Patient:
If pain uncontrolled, increase fixed schedule dose by 50%.

Many non-opioid analgesics are available and should be considered after opioid therapy has been optimized. If pain remains uncontrolled, consider consult to Department of Pain Medicine and Palliative Care (Beeper #6702).

ANXIETY & INSOMNIA
Lorazepam 0.5mg po/SQ/IV BID-TID q HS for anxiety.
Temazepam 15 – 30 mg po q HS for anxiety/ insomnia.
Clonazepam 0.5 – 2 mg po BID-TID for anxiety/myoclonus.

CONFUSION/AGITATION
Haloperidol 0.5 mg po/SQ/IV. Repeat q 30 minutes until symptom intensity declines.
Haloperidol 0.5 – 5 mg po/SQ/IV q 4 hr prn.

CONSTIPATION
Lactulose 30 ml po q 2 hr prn until constipation relieved.
When symptom improves, begin Lactulose 30 ml po q 12 hr.
Warm Fleets Enema TIW prn

To prevent constipation:
Senokot 1 – 2 tabs po BID and
Colace 1 – 2 tabs po BID.

SYMPTOMS OF DEPRESSION
If anticipated survival is in weeks:
Begin SSRI, e.g., Paroxetine 20 mg po daily, and titrate to effect.

If anticipated survival is in days:
Methylphenidate 2.5 mg po q morning and at noon and escalate daily to 5 – 10 mg po q morning and at noon or Pemoline 18.75 mg po q morning and at noon and escalate daily to 37.5 mg po q morning and at noon.
Higher doses may be needed.

Consider Liaison Psychiatry consultation

DIARRHEA
Loperamide 4 mg po q 4 hr prn

DYSPNEA
For Opioid-Naïve Patient:
Morphine Sulfate 5 – 15 mg po or 2 – 5 mg SQ/IV. Repeat q 1 hr, if needed. When symptom is improved, begin Morphine Sulfate 30 mg po or 10 mg SQ/IV q 4 hr ATC; or begin Morphine Sulfate basal infusion at 2 mg per hour and 2 mg SQ/IV q 1 hr prn.

For Opioid-Treated Patient:
If dyspnea uncontrolled, increase fixed schedule dose by 50%.
If breathlessness continues, add Lorazepam 0.5mg po or SQ/IV prn. Repeat q 60 minutes if needed until symptom intensity declines, then begin 1 mg po/SQ/IV q 3 hr.

Additional therapies may include:
Dexamethasone 16 mg po/IV, followed by 4 mg po/IV q 6 hr
Albuterol 2.5 mg via nebulization q 4 hr prn if wheezing present

FEVER
Acetaminophen 650 mg po/PR q 4 hr prn, and/or
Dexamethasone 1.0 mg po/SQ/IV q 12 hr prn

HICCUPS
Chlorpromazine 10 – 25 mg po/IM TID prn
Haloperidol 0.5 – 2 mg po/SQ/IV TID – QID

INTRACTABLE SYMPTOMS, MANAGEMENT OF
Consider referral to Department of Pain Medicine & Palliative Care (Beeper # 6702).

IV HYDRATION
Consider decreasing IV rate to 0.5 – 1 liter/24 hr

NAUSEA/VOMITING
Metoclopromide 10 mg po/IV q 4 hr prn, or
Prochlorperazine 10 mg po/IV q 4 hr or 25 mg PR q 8 hr prn with or without Dexamethasone 4 mg po/IVPB q 6 hr

PRURITIS
Diphenhydramine 25 – 50 mg po/IV q 12 hr
Hydrocortisone 1 % cream to affected areas q 6 hr
Dexamethasone 1.0 mg po daily alone or in combination with above

STOMATITIS
Viscous lidocaine 2 % to painful areas prn
Clotrimazole 10 mg troche 5 times daily
Nystatin S & S q 6 hr prn
Magic Mouthwash prn

TERMINAL SECRETIONS (NOISY RESPIRATIONS)
Scopolamine patches 1.5 – 3 mg 72 hr, or
Scopolamine 0.4 mg SQ q 4 – 6 hr

PLAN—DO—CHECK—ACT (the Shewhart cycle)

Plan

Create a timeline of resources, activities, training, and target dates. Develop a data collection plan, the tools for measuring outcomes, and thresholds for determining when targets have been met.

Timeline for One-Year Pilot CQI EOL Project

Phase 0 – Planning

Jan – June	Formalize CQI Team for the development of a clinical pathway. Clarify knowledge of processes: review literature and existing data sources, conduct brainstorming, flowcharting with pilot units. Evaluate and synthesize literature, tools, other data gathered. Identify content for Care Path. Develop and pilot audit tool for chart reviews. Create database, codebook, and scoring guidelines for data entry. Identify patient outcome assessment tools. Identify family outcome assessment tools. Identify staff assessment tools. Refine study tools/procedures. Develop staff education. Develop caregiver educational materials.
June 21	Medical Records review
Aug 2	Tools Committee review
July 3	Committee on Scientific OSA Application and Approval

Phase I – Launching the Project

August 2	Meet with hospital leadership—Introduction to Palliative Care for Advanced Disease Care Path • PCAD Care Path, MD Orders, and Flow sheet • Timeline for Education/Evaluation
August 11	Introduction of PCAD Care Path to medical staff

Figure 48A.5 The PDCA portion of the FOCUS-PDCA cycle.

Source: Continuum Health Partners, Inc., Beth Israel Medical Center, Department of Pain Medicine and Palliative Care, New York. Palliative Care for Advanced Disease (PCAD) Care Path; CQI Team on End-of-Life Care.

Phase II – Unit Implementation and Education of PCAD Care Path

	Cohort 1	Cohort 2		Cohort 3
Meet with unit leaders of pilot units	June 21	September 15	July 21	October 11
Pre-test	August 23–25	September 27	September 14	TBS
Unit leadership team meeting	TBS	October 5	October 12	TBS
Introduction of PCAD Care Path to unit staff	August 31–September 1	September 27–September 30	October 22	TBS
In-service of unit staff	September 1 September 2 September 3	October 4–October 6	October 25–October 26	TBS TBS TBS
Rollout of Care Path	September 6	October 11	November 1	TBS
Brainstorming—educational needs	October 11	November 8	December 13	December 6
Educational series	September–February	October– March	November–April	November–April
Focus groups	October & January	November & February	December & March	December & March
Feedback / closure / continuation	March	April	May	May
Post-test	March	April	May	May

Phase III – Evaluation

Chart Reviews using Chart Audit Tool (CAT) (Total =330)

June–Aug	• 20 retrospective audits for 5 pilot units	(Total = 100)
Sep 1999–Mar 2002	• 20 retrospective audits for 2 control units	(Total = 40)
	• 10 during implementation audits for 5 pilot units	(Total = 50)
	• 20 post implementation audits for 5 pilot units	(Total = 100)
	• 20 post implementation audits for 2 control units	(Total = 40)
	Each patient on PCAD Care Path as admitted.	
Sep 1999–Mar 2002	Tool: Teno's After Death (interview or mailed survey)	
Dates TBD	Staff survey post-tests (4 mo post-initiation of PCAD) Tool: Palliative Care Quiz	
Sep 1999–Mar 2002	Process Audits (PAT) Ongoing throughout time patient on PCAD Care Path	
Sep 1999–Mar 2002	Brainstorming sessions and focus groups with staff to identify education 1–2 mo after each unit begins PCAD	

Phase IV – Reporting

April 15, 2002	Report to grant agency, hospital, and unit staff

Figure 48A.5 Continued

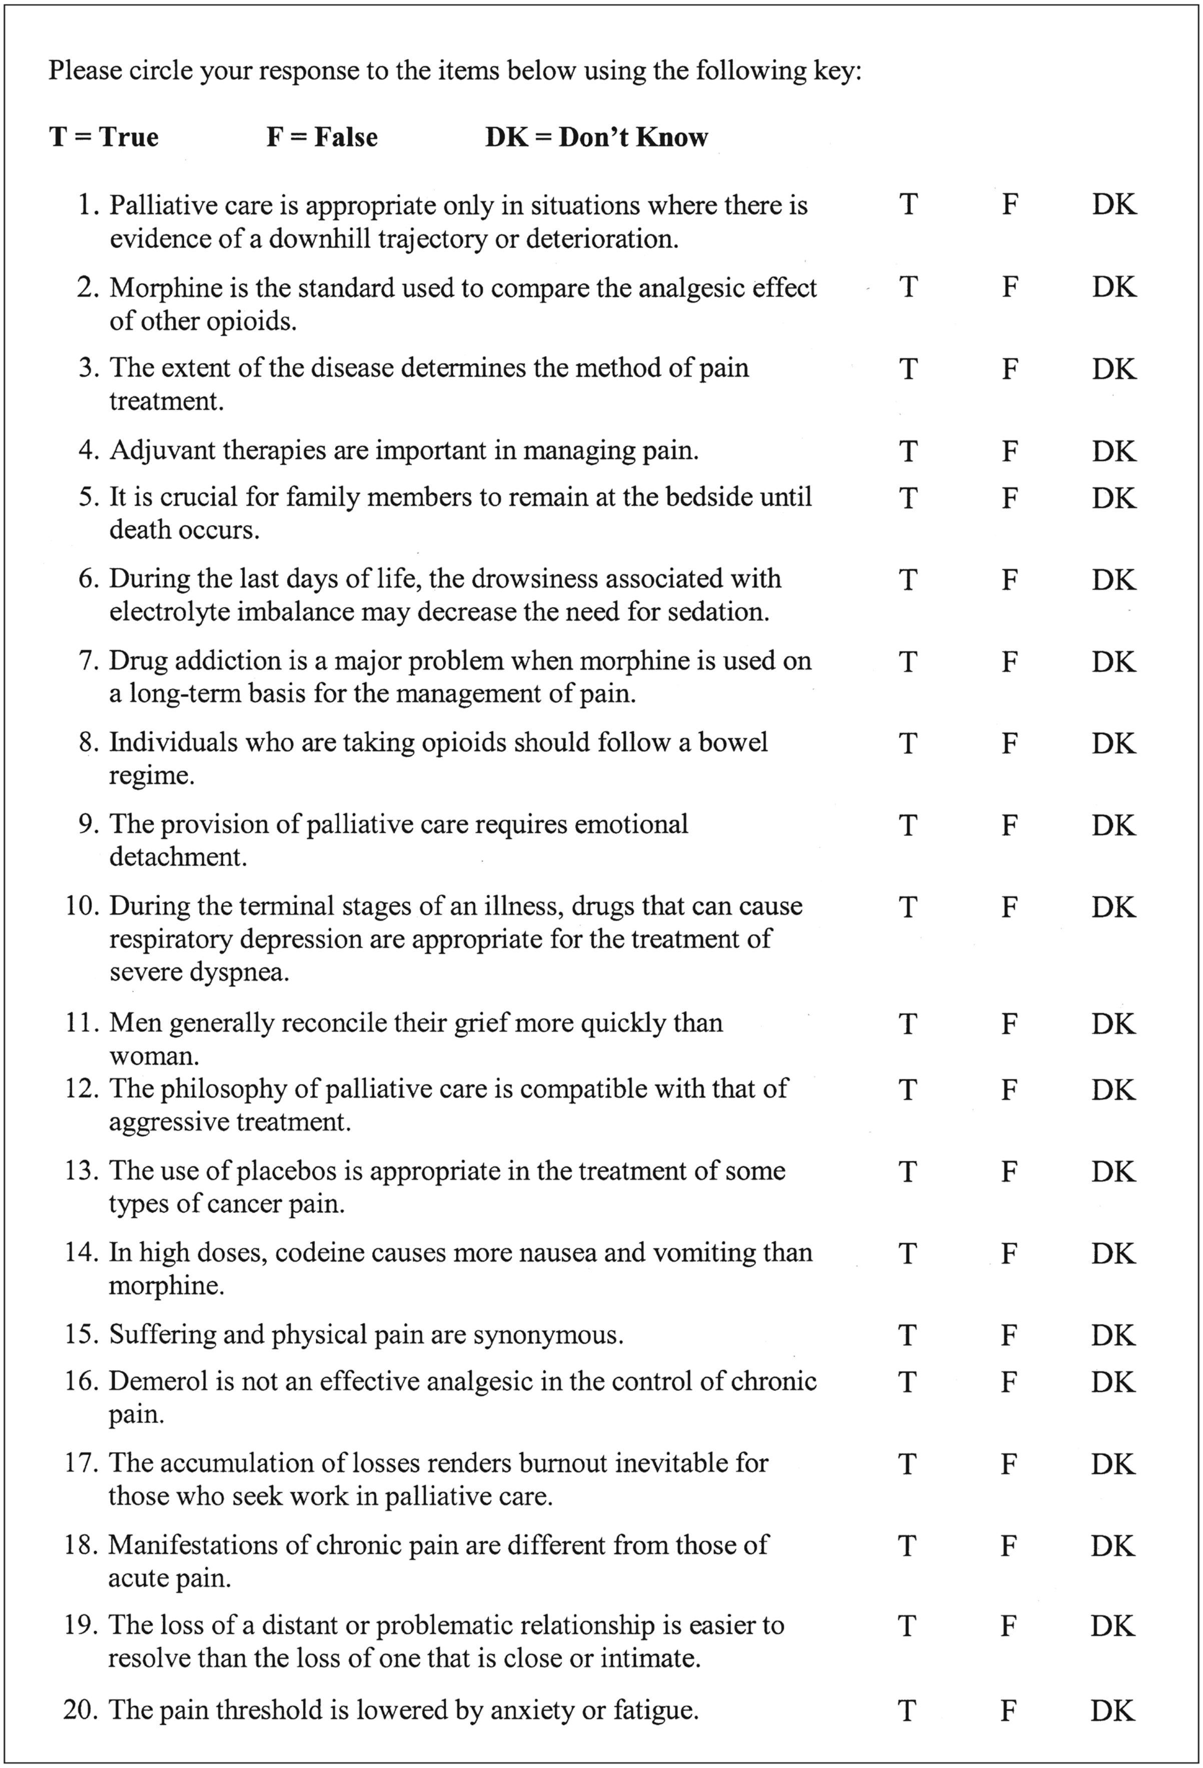
Figure 48A.5 Continued



Please circle your response to the items below using the following key:

T = True **F = False** **DK = Don't Know**

1. Palliative care is appropriate only in situations where there is evidence of a downhill trajectory or deterioration.	T	F	DK
2. Morphine is the standard used to compare the analgesic effect of other opioids.	T	F	DK
3. The extent of the disease determines the method of pain treatment.	T	F	DK
4. Adjuvant therapies are important in managing pain.	T	F	DK
5. It is crucial for family members to remain at the bedside until death occurs.	T	F	DK
6. During the last days of life, the drowsiness associated with electrolyte imbalance may decrease the need for sedation.	T	F	DK
7. Drug addiction is a major problem when morphine is used on a long-term basis for the management of pain.	T	F	DK
8. Individuals who are taking opioids should follow a bowel regime.	T	F	DK
9. The provision of palliative care requires emotional detachment.	T	F	DK
10. During the terminal stages of an illness, drugs that can cause respiratory depression are appropriate for the treatment of severe dyspnea.	T	F	DK
11. Men generally reconcile their grief more quickly than woman.	T	F	DK
12. The philosophy of palliative care is compatible with that of aggressive treatment.	T	F	DK
13. The use of placebos is appropriate in the treatment of some types of cancer pain.	T	F	DK
14. In high doses, codeine causes more nausea and vomiting than morphine.	T	F	DK
15. Suffering and physical pain are synonymous.	T	F	DK
16. Demerol is not an effective analgesic in the control of chronic pain.	T	F	DK
17. The accumulation of losses renders burnout inevitable for those who seek work in palliative care.	T	F	DK
18. Manifestations of chronic pain are different from those of acute pain.	T	F	DK
19. The loss of a distant or problematic relationship is easier to resolve than the loss of one that is close or intimate.	T	F	DK
20. The pain threshold is lowered by anxiety or fatigue.	T	F	DK

Figure 48A.5 Continued

Check

Analyze findings, graph results, and evaluate reasons for variations. If targets are reached, set a date to stop or decrease the frequency of monitoring. Summarize what was learned.

Sample: Results of Palliative Care Knowledge Quiz, Preimplementation of PCAD

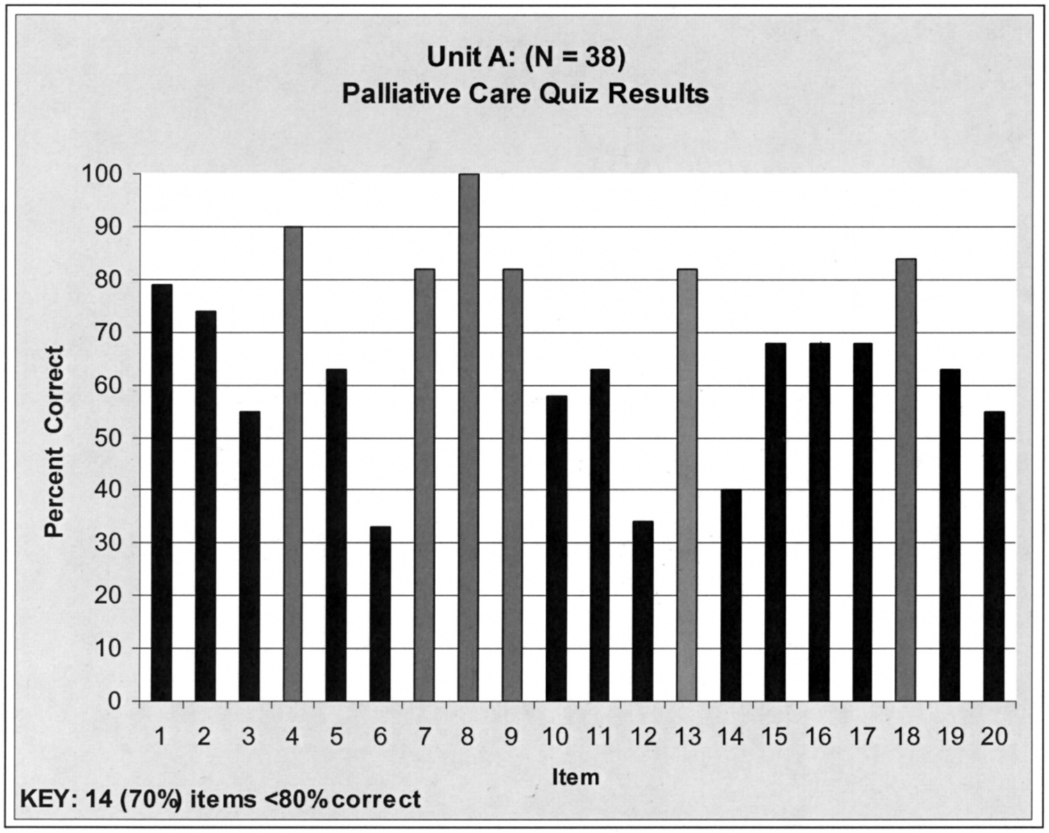


Figure 48A.5 Continued

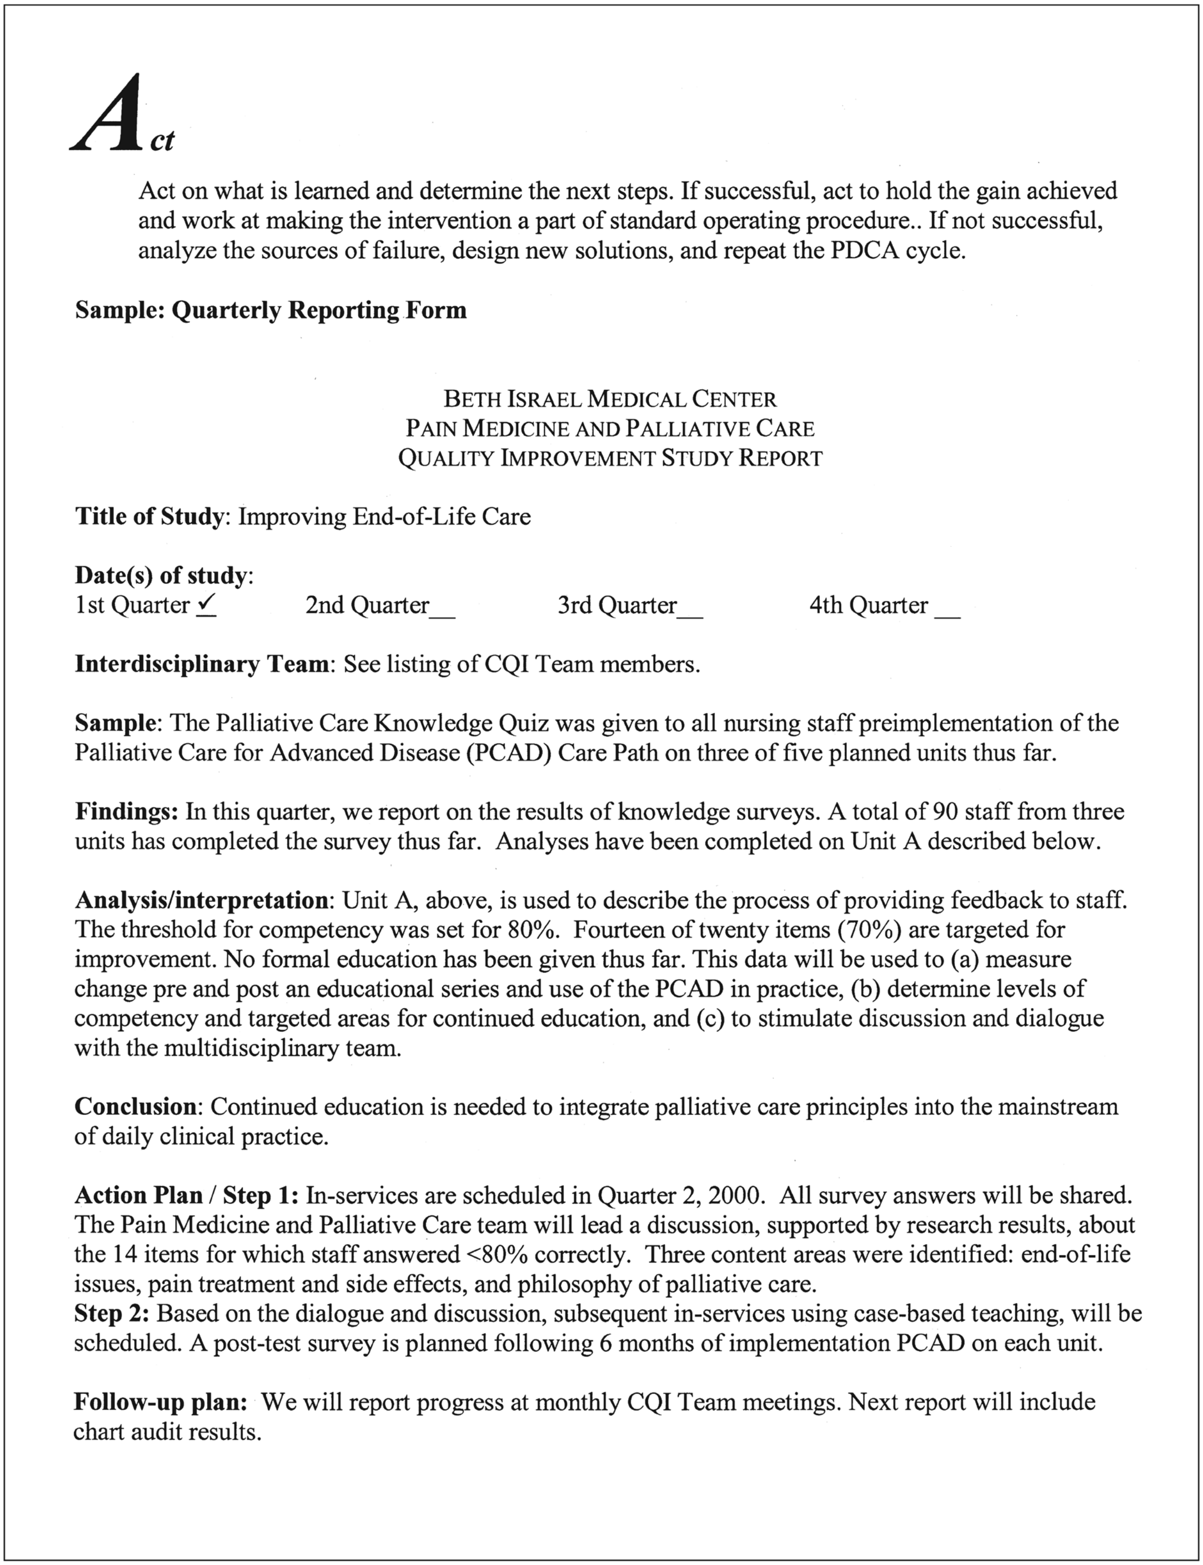

Act

Act on what is learned and determine the next steps. If successful, act to hold the gain achieved and work at making the intervention a part of standard operating procedure.. If not successful, analyze the sources of failure, design new solutions, and repeat the PDCA cycle.

Sample: Quarterly Reporting Form

BETH ISRAEL MEDICAL CENTER
PAIN MEDICINE AND PALLIATIVE CARE
QUALITY IMPROVEMENT STUDY REPORT

Title of Study: Improving End-of-Life Care

Date(s) of study:
1st Quarter ✓ 2nd Quarter__ 3rd Quarter__ 4th Quarter __

Interdisciplinary Team: See listing of CQI Team members.

Sample: The Palliative Care Knowledge Quiz was given to all nursing staff preimplementation of the Palliative Care for Advanced Disease (PCAD) Care Path on three of five planned units thus far.

Findings: In this quarter, we report on the results of knowledge surveys. A total of 90 staff from three units has completed the survey thus far. Analyses have been completed on Unit A described below.

Analysis/interpretation: Unit A, above, is used to describe the process of providing feedback to staff. The threshold for competency was set for 80%. Fourteen of twenty items (70%) are targeted for improvement. No formal education has been given thus far. This data will be used to (a) measure change pre and post an educational series and use of the PCAD in practice, (b) determine levels of competency and targeted areas for continued education, and (c) to stimulate discussion and dialogue with the multidisciplinary team.

Conclusion: Continued education is needed to integrate palliative care principles into the mainstream of daily clinical practice.

Action Plan / Step 1: In-services are scheduled in Quarter 2, 2000. All survey answers will be shared. The Pain Medicine and Palliative Care team will lead a discussion, supported by research results, about the 14 items for which staff answered <80% correctly. Three content areas were identified: end-of-life issues, pain treatment and side effects, and philosophy of palliative care.
Step 2: Based on the dialogue and discussion, subsequent in-services using case-based teaching, will be scheduled. A post-test survey is planned following 6 months of implementation PCAD on each unit.

Follow-up plan: We will report progress at monthly CQI Team meetings. Next report will include chart audit results.

IV. COMMUNICATION

14. METHOD OF COMMUNICATION
    [1] Speaking [2] Language Barrier [3] Sign Language (*for hearing impaired*) [4] Writing Only [5] None

15. DEGREE OF INDEPENDENCE IN COMMUNICATING
    [1] Functional; independent with all aspects of communication (speaking, hearing, sight), with or without glasses, hearing aids, or communication devices
    [2] Moderate assist; communicates ż 50% of the time
    [3] Dependent; unable to communicate with others

V. PHYSICAL/ACTIVITY STATUS

16. PRESSURE ULCERS
    [1] None
    [2] Mild [Stage I/II]: Injury to skin, Partial loss of skin layers
    [3] Severe [Stage III/IV]: Deep craters in skin that extends down to but not through underlying fascia; breaks in skin exposing muscle or bone; extensive destruction, tissue necrosis, or damage to muscle, bone or supporting structures (e.g., tendons)

17. BOWEL AND BLADDER FUNCTION
    [1] Independent in bowel and bladder function, with full self-care, including ostomy/catheter, if present
    [2] *Not* incontinent, but some assistance needed in managing bathroom or bedpan or ostomy/catheter, if present
    [3] Rarely incontinent; requiring substantial assistance in managing bathroom or bedpan or ostomy/catheter, if present
    [4] Occasionally incontinent; requires full assistance in managing bathroom or bedpan or ostomy/catheter, if present
    [5] Fully incontinent or unable to assist in management of ostomy/catheter, if present
    [6] Don't know

18. PERFORMACE STATUS
    [0] Normal activity
    [1] Capable of all self-care, is ambulatory, but restricted in physicallythan 50% of waking hours strenuous activity, able to carry out work of a light or sedentary
    [2] Ambulatory, capable of all self-care activities, but unable to carry out any work activities; up and about more than 50% of waking hours
    [3] Capable of only limited self-care; confined to bed greater
    [4] Completely disabled; cannot carry on any self-care; nature (e.g., light housework, office work) totally confined to bed/chair

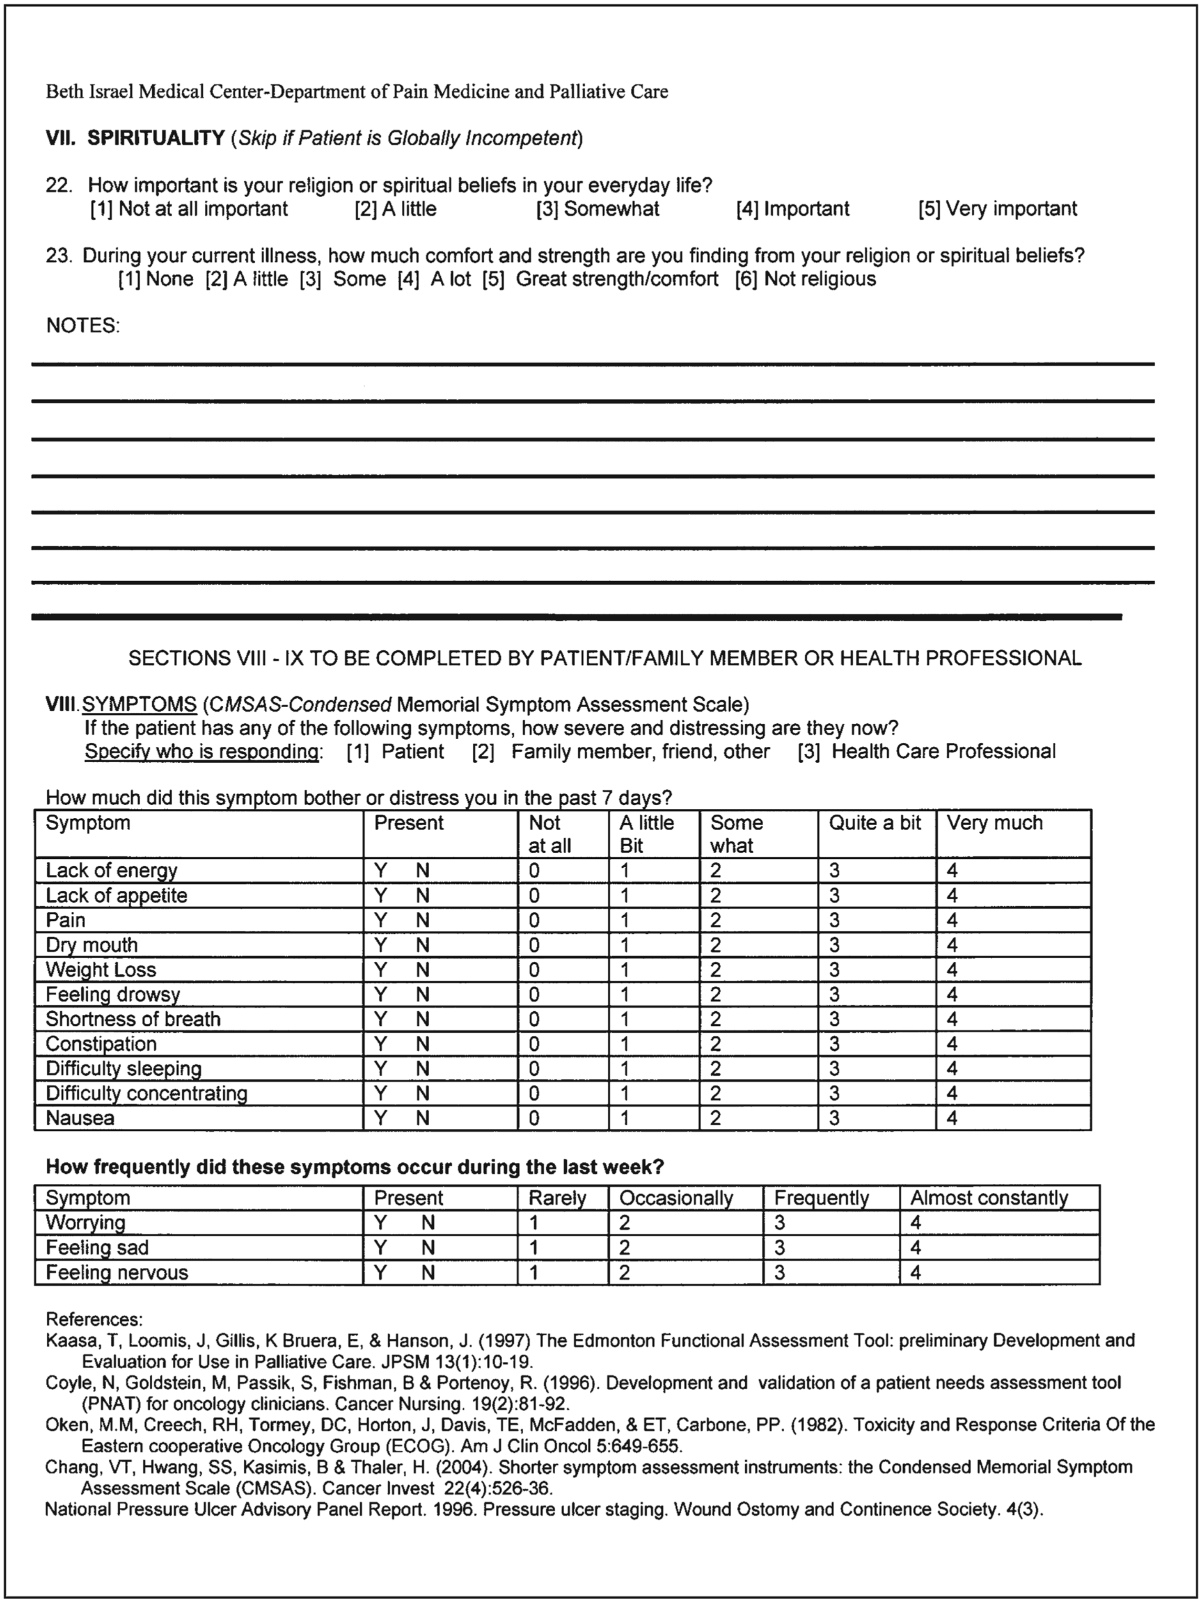
19. NUTRITIONAL INTAKE
    [1] Normal
    [2] Modified Independent; intake limited, need for modification unknown
    [3] Requires diet modification to swallow solid foods and liquids (puree, thickened fluids)
    [4] Combined oral and tube feeding
    [5] Tube feeding only
    [6] No oral intake (NPO) and no tube feeding

20. PRACTICAL SUPPORT WITH ESSENTIAL TASKS (e.g., cooking, cleaning, shopping)
    [1] Needs assistance in essential tasks which is not available
    [2] Needs assistance in essential tasks which is often unreliable or incomplete
    [3] Needs assistance in essential tasks which is sometimes inadequate or available only for less critical tasks such as banking
    [4] Needs assistance in essential tasks is usually available; assistance in less critical tasks is incomplete and unreliable; other responsibilities limit helper availability
    [5] Assistance is available and adequate for any need

VI. SOCIAL SUPPORT

21. The emotional support I have had from my family and friends has been:
    [1] As much as I wanted [2] Very adequate [3] Adequate [4] Inadequate [5] Very Inadequate

Figure 48A.6 Continued



Beth Israel Medical Center-Department of Pain Medicine and Palliative Care

VII. SPIRITUALITY (*Skip if Patient is Globally Incompetent*)

22. How important is your religion or spiritual beliefs in your everyday life?
[1] Not at all important [2] A little [3] Somewhat [4] Important [5] Very important

23. During your current illness, how much comfort and strength are you finding from your religion or spiritual beliefs?
[1] None [2] A little [3] Some [4] A lot [5] Great strength/comfort [6] Not religious

NOTES:

SECTIONS VIII - IX TO BE COMPLETED BY PATIENT/FAMILY MEMBER OR HEALTH PROFESSIONAL

VIII. SYMPTOMS (C*MSAS-Condensed* Memorial Symptom Assessment Scale)
If the patient has any of the following symptoms, how severe and distressing are they now?
Specify who is responding: [1] Patient [2] Family member, friend, other [3] Health Care Professional

How much did this symptom bother or distress you in the past 7 days?

Symptom	Present	Not at all	A little Bit	Some what	Quite a bit	Very much
Lack of energy	Y N	0	1	2	3	4
Lack of appetite	Y N	0	1	2	3	4
Pain	Y N	0	1	2	3	4
Dry mouth	Y N	0	1	2	3	4
Weight Loss	Y N	0	1	2	3	4
Feeling drowsy	Y N	0	1	2	3	4
Shortness of breath	Y N	0	1	2	3	4
Constipation	Y N	0	1	2	3	4
Difficulty sleeping	Y N	0	1	2	3	4
Difficulty concentrating	Y N	0	1	2	3	4
Nausea	Y N	0	1	2	3	4

How frequently did these symptoms occur during the last week?

Symptom	Present	Rarely	Occasionally	Frequently	Almost constantly
Worrying	Y N	1	2	3	4
Feeling sad	Y N	1	2	3	4
Feeling nervous	Y N	1	2	3	4

CHAPTER 49

Long-Term Care

Focus on Nursing Homes

Joan Carpenter and Mary Ersek

Key Points

- More than 25% of older adults and almost 70% of persons with advanced dementia live their final days in nursing homes.
- While the number of hospice patients living in nursing homes has increased dramatically over the past decade, other comprehensive palliative care models have not been widely adopted or tested in nursing homes.
- Hospice and palliative care nurses play critical roles in collaborating with nursing home staff to enhance end-of-life care and outcomes for older persons.

Introduction

Quality end-of-life (EOL) care in nursing homes is important. Over 1.4 million Americans live in nursing homes.[1] More than half of these nursing home residents require extensive assistance or are completely dependent in bathing, dressing, toileting, and mobility. Of those nursing home residents over 65 years of age, 80% are 75 years or older. Despite the efforts to keep frail elders in the community, the nursing home population is expected to increase as the numbers of older persons in the United States and other developed countries increase. Although nursing homes were not established as sites for EOL care, as more people live in nursing homes for short or long periods, they are increasingly becoming the place where many people die.

Long-Term Care

Long-term care refers to a continuum of services and supports addressing the health, personal care, and social service needs for persons who need help with activities of daily living (ADLs) as a result of cognitive, physical, or functional impairment.[2] Services may be provided in residential (nursing homes, assisted living facilities, residential care communities, group homes) or home and community settings (private homes, adult day service centers). About two-thirds of people receive long-term care services in residential settings despite efforts to increase long-term care in community settings.[3] Thus, the demand for high-quality nursing home care continues and is expected to increase with the aging population.

Non–Nursing-Home Residential Long-Term Care Settings

Assisted living facilities (ALFs) are residential settings that house people who need help coordinating day-to-day healthcare activities and supportive services but do not need 24-hour skilled nursing care. Services include meal preparation and planning, assistance with ADLs, medication monitoring and administration, and recreational activities.[4] State governments certify and regulate ALFs, and there is much variation among states with regard to regulations, definitions, and Medicaid support.[5] Residents and/or their families pay most expenses because there is relatively little state or federal government support for ALFs. After residing in assisted living for about 2 years, 60% of residents will move to a nursing facility for a higher level of care.[6] Increasingly, ALFs are becoming a setting of EOL care. ALF residents often report that they expect to die in this setting, and although ALF staff express confidence in caring for dying residents, they are unprepared to initiate EOL discussions.[7,8]

Continuing Care Retirement Communities (CCRCs) are for-profit or not-for-profit organizations that offer a full range of services including independent living, assisted living, and nursing home care. CCRCs provide different, as-needed levels of service in one location with a stepwise approach. For example, residents who experience physical or cognitive decline can receive additional ALF services, such as assistance with medications and ADLs. For short-term skilled care or longer term nursing care, a resident can move to the CCRC's nursing home. Most costs are paid out of pocket, and many facilities require that residents have Medicare coverage for skilled nursing care if and when needed.

Group homes (also called "adult family homes," "boarding homes," "personal care homes," and other names, depending on the state) are small dwellings where residents with similar needs live and receive help with ADLs. Residents in group homes do not need 24-hour skilled nursing care. These facilities are not as strictly regulated and often do not receive payments from Medicare or Medicaid programs.

Nursing Homes

There are almost 16,000 nursing homes in the United States.[1] All nursing homes provide 24-hour nursing care for residents. Many facilities provide short-term, rehabilitative care after hospitalization (i.e., skilled nursing care or post-acute care) and/or long-term care. Nursing homes that provide skilled care are often referred to as skilled nursing facilities (SNFs). SNFs can be stand-alone facilities, part of an acute care hospital, or facilities within a larger campus. The purpose of a SNF is to provide a place for residents to receive intensive medical and nursing care (e.g., giving intravenous fluids, changing dressings, administering tube feeding) and/or rehabilitation for a period of days to several weeks, with a goal of returning to a more independent level of activity. Following rehabilitation, residents are discharged home or admitted to another care setting for long-term care if they are unable to return home. For long-term care residents, the average length of stay in a nursing home is slightly more than 2 years.[9] However, the average length of stay for SNF decedents is 5 months.[10]

Nursing homes are not-for-profit, for-profit, or government facilities. Not-for-profit and for-profit facilities may be privately owned and operated by a single owner or part of a large organization with many facilities (e.g., a "chain"). Government facilities include about 132 Veterans Affairs (VA) nursing homes, referred to as Community Living Centers (CLCs).[11] State veterans homes are nursing facilities for veterans that are owned and managed by individual state governments.

In nongovernmental-run homes, there are three sources of payment: private pay (i.e., paid for using residents' financial assets or private long-term care insurance), Medicare, and Medicaid. Medicare pays for most short-term, skilled nursing care, while private pay and Medicaid covers most long-term nursing home care. Long-term care residents are often obliged to exhaust their life savings (i.e., "spending down") and then apply for Medicaid to cover costs associated with nursing home care. About two-thirds of older nursing home residents receive Medicaid benefits.[12]

From 2002 to 2012, Medicare spending for care in skilled nursing facilities grew by an average of 6% each year and is expected to increase through 2023.[12] The national median rate for skilled nursing home care in 2017 was between $7,000 and $8,000 per month. This is significantly more compared with the average monthly cost of care in an ALF ($3,750).[13] However, ALF care may be prohibitively expensive for residents and families since Medicare does not pay for these services and Medicaid coverage is limited and variable across states.[14]

History and Growth of Nursing Homes

Nursing homes have been described as the offspring of the almshouse and boarding house and the stepchild of the hospital.[15] In the mid-nineteenth century, older people who were poor, sick, or disabled and without family support had few options other than the alms-house. Private homes for the aged emerged as an alternative to public alms-houses after the passage of the Social Security Act in the 1930s.

The growth of nursing homes from the 1930s to the 1960s was related to several key factors. First, establishment of the Old Age Assistance (OAA) program in 1935 allowed some older adults to purchase long-term care services in private homes. Second, the Hill-Burton Act was amended in 1954, granting federal support for construction of public institutions, including those that housed older adults. Third, the American Association of Nursing Homes became a strong lobby for this new industry. With the creation of Medicare and Medicaid in 1965, the "nursing home" became fully established.[16]

The 1986 Institute of Medicine report, "Improving the Quality of Care in Nursing Homes," described many deficiencies in nursing home care and regulatory policies. In response, Congress passed the Omnibus Reconciliation Act of 1987 (OBRA-87). Contained in this bill was the Nursing Home Reform Act, which called for sweeping changes, including a focus on person-centered care and residents' quality of life (QOL).[17] In 1997, a large group of providers, regulators, researchers, and advocates formed the Pioneer network bringing together expertise, models, and other resources to promote this "culture change."[17]

The Affordable Care Act (ACA) of 2010 was the first legislation since OBRA-87 to address nursing home care quality and improve federal and state surveillance.[18] The ACA included transparency provisions allowing consumers to access information to help them choose a nursing home and monitor the quality of care (e.g., hours of nursing care that residents receive, consumer complaints, and staff turnover rates).[18] This information currently is available on the Nursing Home Compare website (www.medicare.gov/nursinghomecompare/). The ACA also incorporated a provision that nursing assistants receive training in dementia care and resident abuse prevention.

The Nursing Home Environment

Long-Term Care Residents

According to 2014 statistics, more than 80% of nursing home residents are aged 65 years or older and two-thirds are female.[1] More than 40% of residents need assistance with three of five ADLs (i.e., bed mobility, dressing, eating, mobility, or toileting), and 60% have moderate to severe cognitive impairment.[1]

Interdisciplinary Care Team

Nursing home staff and providers form an interdisciplinary team (IDT) consisting of medical staff, licensed nursing staff, certified nursing assistants, recreation therapists, and occupational and physical therapists. Other administrative staff (i.e., nursing home administrator, director of nursing) serve in leadership roles and oversee the daily operations in the facility. Dietary workers, environmental services personnel, and beauty shop employees also play important roles because they are part of the residents' home.

Nursing assistants, also called direct care workers, represent more than one-third of the staff in nursing homes; they provide personal care (e.g., bathing, dressing, grooming, toileting) and assist with ADLs.[19] Many nursing assistants have no formal education beyond high school, work for low pay, and receive few benefits.[20] Because nursing assistants spend the most time with residents, they often see more death and dying than other staff and experience the accompanying grief.[21] Despite their role in caring for dying residents, nursing assistants have the least amount of formal training in EOL care.

Licensed nursing staff include registered nurses (RNs) and licensed practical/vocational nurses (LPN/LVNs). They are responsible for administering medications, delivering treatments, assessing and managing physical and psychosocial problems, and communicating with primary care providers. RNs often manage and coordinate the overall care of residents and assume leadership positions, although the LPN/LVNs perform these duties when no RN is available. Compared with staff in the acute care setting, nursing home staff nurses are less likely to have baccalaureate or advanced degrees, and the less educated LPNs/LVNs generally outnumber the RNs.[22] These characteristics exacerbate the lack of palliative care knowledge and skills that have been documented among long-term care nursing staff.[23]

Nurse practitioners (NPs), physician assistants (PAs), and physicians provide primary care for nursing home residents. Since 2000, there has been considerable growth in NP and PA practice in nursing homes, although shortages of providers in nursing homes remain.[24] Between 2007 and 2014, the number of NPs and PAs who describe their practice as "skilled nursing facility specialists" doubled, and billable visits by NPs and PAs were greater than that of physicians.[25] Research demonstrates that greater NP/PA presence in nursing homes is associated with better nursing home care quality.[26]

Ethical Issues

Autonomy is based on the right of an individual to make decisions freely, including the right to accept or refuse a treatment. Nursing home routines, regulations, and restrictions result in an environment that is structured according to staff schedules, thereby hindering resident autonomy. Allowing residents choices, especially in directing their own care, is important. Nurses need to advocate for residents' autonomy.

One common and sometimes difficult ethical issue involves decisions about medically administered nutrition (i.e., tube feeding). Food in all societies is part of the ongoing cycle of daily interaction, and families may continue to try to feed their relatives when they are no longer able to eat. The use of feeding tubes to provide medically administered nutrition has not been shown to improve survival in individuals with end-stage dementia who are residing in nursing homes.[27]

Nursing home staff can assist families by explaining that it is normal to lose appetite or develop feeding difficulties at the end of life and that the body only takes in what it needs. Trying to force a resident to eat may cause more burden than benefit to the resident and increase distress for the caregiver. Nursing staff may encourage families to offer "comfort feeding" with small amounts of favorite foods and drinks. The goal of comfort feeding is to provide the most satisfying type of food during careful hand-feeding. Hand-feeding offers human interaction and therapeutic touch. Resources on the Choosing Wisely website (http://www.choosingwisely.org/patient-resources/feeding-tubes-for-people-with-alzheimers/) can help guide discussions with family members about feeding tubes and other treatments at end of life.[27]

Challenges and Opportunities for Palliative Care Delivery in Nursing Homes

Despite the benefits, implementing palliative care philosophy and approaches to care in nursing homes often is difficult. There are many barriers to delivering high-quality EOL care, although several characteristics facilitate the adoption of palliative care practices.[28]

Challenges to Palliative Care Delivery

Regulatory structures, reimbursement policies, workforce issues, and resident characteristics hamper the delivery of palliative care services in nursing homes. For example, regulations tend to favor restorative rather than palliative care.[29] In addition, efforts to administer palliative care are sometimes misinterpreted by facilities and regulators, leading to citations for poor care. For example, nursing home surveyors often cite facilities for residents' weight loss, which could reflect inattention to nutritional needs in some residents. In many instances, however, weight loss is an inevitable result of the dying process and aggressive interventions such as tube feeding are ineffective and inappropriate. Therefore, it is essential for interdisciplinary teams to document residents' life-limiting diagnoses, discuss care goals and preferences for life-sustaining treatments, and review and update the care plan accordingly.[30]

Reimbursement also promotes more aggressive therapy. Generally, Medicaid and Medicare pay nursing homes a per diem for the care they provide. Specifics of care are accounted for in the facility's *case mix index*, a composite score reflecting the complexity of care delivered to residents. In facilities providing more medical interventions, therapy services, and assistance with ADLs, the case mix index is higher, thereby increasing reimbursement rates to the nursing home. Therefore, facilities are financially incentivized to accept residents requiring "skilled" treatments. In addition, payment for a resident's room and board at the facility is generally covered under the Medicare SNF benefit for the first 20 days of care, following a qualifying hospitalization. Many seriously ill residents and their family caregivers find this financial assistance advantageous because out-of-pocket spending is reduced. These policies act as incentives to nursing homes to provide skilled nursing services and to residents and their family caregivers to accept them even though these services may not match the residents' and families' goals of care or improve residents' QOL.[28]

In addition to regulatory and financial pressures, workforce issues are challenging. Nursing home staff tends to lack training in palliative care approaches and therefore have difficulty recognizing and implementing palliative treatments when needed. Another workforce issue is staff turnover, which is staggeringly high. The annual turnover among nursing assistants is 52% and that of LPNs and RNs is 36% and 50%, respectively.[31] High turnover is associated with lack of care continuity and poorer care, resulting in a workforce that is constantly changing, overwhelmed, and dissatisfied. It also requires offering educational programs on a continual basis to keep knowledge and skills current.[28]

Until recently, there was little empirical research investigating the direct correlation between staff turnover and the ability of nursing home staff to deliver high-quality EOL care. However, one research team found significant associations between high staff turnover and residents' poorer quality of dying. They also found that family members believed that the lack of staff contributed to worse quality of dying for their loved one.[32]

Finally, many residents have complex physical and psychosocial needs that are difficult to assess and manage because of cognitive impairment.[1] Severe impairment interferes with residents' ability to provide reliable self-report, thereby hindering pain and symptom assessment and management. When pain and other symptoms are identified, multiple comorbidities and polypharmacy further complicate effective treatment.

Facilitators to Providing Palliative Care

Although there are hindrances, some nursing home characteristics facilitate palliative care delivery. These factors include daily interaction between direct care staff and residents, the existing team approach to care, family meetings, and use of the Minimum Data Set (MDS).[28]

Daily interaction between staff and residents who are familiar with each other establishes a rich context for developing relationships congruent with palliative care philosophy. Nursing home staff frequently describe themselves as part of the resident's family.[33] These close relationships can improve mutual understanding of residents' goals of care, values, and preferences, and result in better symptom management.

The existing IDT—RNs, LPNs, nursing assistants, social work, rehabilitation specialists, dietitian, and wound care specialists—also supports the palliative care philosophy. Nursing homes are required to schedule quarterly IDT care planning meetings with residents and/or their family members to discuss the comprehensive physical, emotional, mental, and social care plan for each resident. Care plan meetings provide a designated time that the IDT, resident, and/or family can review and share information; discuss values, goals, and treatment preferences; ask and answer questions; and revise the care plan to match the resident's needs.

The MDS is a mandated assessment tool for Medicare and Medicaid beneficiaries in nursing homes. Its goal is to create a comprehensive evaluation and to identify opportunities to improve functional status. The tool is completed by an RN at specified intervals using medical records, staff input, and observation in combination with a resident interview. The resident interview consists of discussions of preferences for routines and activities—including goals of care—and questions about pain, mood, and cognition.[34,35] The MDS can be used to identify residents with life-limiting illness who have unmet symptom management and psychospiritual support needs; these residents are candidates for palliative care.

Models to Deliver Palliative Care in Nursing Homes

There are three approaches to delivering palliative care in nursing homes: hospice-nursing home partnerships, external palliative care consultation teams, and in-house teams and specialized palliative care units.[28] Although these models have been operating for decades—for example, hospice services for nursing home residents have been Medicare-funded for almost three decades—there is limited evidence regarding their effectiveness in enhancing resident and family outcomes.

Hospice Care in Nursing Homes

Hospice care is the most common and well-established program for delivering palliative care in US nursing homes.[36] The Medicare Hospice Benefit (MHB) was extended to nursing homes in 1989, and, by 2004, 78% of nursing homes reported having at least one contract with a hospice agency.[37] In 2013, the Center for Medicare and Medicaid published requirements for nursing homes when they enter into a contract to provide hospice services to residents. One important regulation requires nursing homes that do not have a contract with a hospice agency to either (1) arrange for hospice services when appropriate or (2) assist with the resident's transfer to a facility that offers hospice if a resident chooses to use the MHB.[38]

The MHB pays for the hospice agency to oversee the plan of care and provide all medical supplies, IDT visits, and medications related to the terminal condition. The facility continues to deliver 24-hour nursing care for the resident. The MHB does not pay for room and board or for care focused on rehabilitation; as a result, hospice generally serves only long-term care residents and not those receiving care under the Medicare SNF benefit.[39,40]

The use of hospice in nursing homes is associated with improved symptom management, fewer hospitalizations, and increased satisfaction with care. Facility leadership report heavy dependence on formal agencies such as hospice to provide both palliative care to residents and palliative care education to their staff.[41] Research comparing EOL care for residents with and without hospice demonstrates that hospice care is associated with better psychosocial support, bereavement care, and pain management.[42,43] The challenge for hospice agencies, facilities, and providers is that many nursing home residents have a life-limiting illness with an uncertain trajectory, making it difficult to decide when the illness is "terminal" according to existing guidelines.[44] Hospices are required to discharge patients who no longer meet the MHB enrollment guidelines because they have either outlived their 6-month life expectancy or their health unexpectedly improves. For example, up to 14% of nursing home hospice residents with dementia are discharged from the MHB before death.[45] This raises serious concerns about the mismatch between the MHB guidelines and the illness trajectories of nursing home residents. Another challenge with hospice care occurs when there is poor communication and inadequate care coordination between nursing home and hospice staff. Bereaved family members report concerns about nursing home and hospice staff collaboration and communication. Two major concerns are delegation of patients' care tasks (e.g., who is responsible for what care) and information coordination (e.g., timely updates and sharing information).[46]

External Consultation Teams

An increasingly common and practical option for nursing home palliative care is external palliative care consultation teams who provide specialized services in nursing homes and make recommendations for the residents' care. Receipt of a nursing home palliative care consultation is associated with significant reductions in emergency room visits and hospitalizations, as well as fewer depressive symptoms.[47,48] Consultation teams often are an extension of a hospice agency's services, an existing hospital-based palliative care team, or independent practitioners. Depending on the team and resources, consultations focus on symptom management, advance care planning, or assisting with prognostication and/or hospice entry. Need for a consult is typically identified by staff and/or leadership, then formally requested by the primary care provider. The consultant bills for services under Medicare part B, and thus the costs for these services are not incurred by the nursing home.

The outcomes of external palliative care consultation depend on several factors. First, the consulting clinician needs to understand the nursing home environment and have knowledge of interventions that can and cannot be carried out. For example, the ability to administer and titrate intravenous opioids may be limited. Second, implementing recommendations depends on the nursing home medical provider being made aware of the consultant's clinical impression and his or her willingness to accept recommendations. Research has shown that miscommunication between hospital-based palliative care teams and nursing home providers and staff often result in a failure to implement recommendations.[49] Third, each nursing home has its unique culture. Depending on that culture, facility staff may feel EOL care is at odds with the philosophy of a restorative and rehabilitative model of care.[28]

Integrated Palliative Care

Over time, more facilities report that they provide internal palliative care services and train their staff in palliative care knowledge, practice, and skills. In 2016, one-third of nursing homes reported palliative care interdisciplinary rounds, 50% had instituted comfort-care policies, and 60% had instituted policies for palliative care.[36] Incorporating palliative care into daily routines requires a commitment to person-centered care and improving EOL care. Nursing homes that report higher palliative care knowledge and practice scores are associated with a lower likelihood of residents being exposed to burdensome treatments and transitions (e.g., artificial feeding tubes and emergency department visits).[50]

A major hindrance to developing internal nursing home palliative care services is the lack of funding and competing priorities. Baseline findings from a recently published randomized controlled trial entitled Improving Palliative Care through Teamwork (IMPACTT) suggests that the focus on SNF reimbursement and skilled care inhibits allocation of resources to facility-based palliative care.[51]

Another challenge to integrated palliative care is understanding what palliative care practices are practical and reasonable for nursing homes. In a recent Delphi study, researchers used national guidelines to identify preferred practices that were both important and potentially feasible to implement in nursing homes.[52] Additional work is needed to verify the usefulness of the findings because guidelines and recommendations, in and of themselves, are unlikely to change practice.

Specific Strategies for Enhancing Palliative Care

Some nursing homes incorporate specific palliative care approaches in addition to, or instead of, comprehensive models. These targeted areas often are pain and symptom assessment and management, advance care planning, and interventions to decrease hospitalizations.

Pain and other symptoms are common in nursing home residents. More than one-third of nursing home residents have intermittent or persistent pain.[53] Symptom assessment is particularly difficult in nursing home residents with advanced dementia due in part to their inability to communicate. Evidence from several studies show that, in people with dementia, pain and shortness of breath are the most common symptoms at the end of life and are challenging to control.[54–57]

Several intervention trials to improve pain management have been conducted. These studies used a variety of approaches, including quality improvement, pain management algorithms, specialized pain teams, and staff education.[15] The effectiveness of these approaches has been mixed.[58] Moreover, there are no high-quality trials of interventions aimed at non-pain symptoms.[15] Despite the lack of empirical evidence about effective ways to change pain and symptom management practices, many excellent resources are available to promote quality palliative care symptom assessment and management in nursing homes (Table 49.1).

Advance Care Planning

The number of nursing home residents with advance directives (ADs) increased dramatically since the PSDA was enacted.[59,60] When a resident lacks medical decision-making capacity, a resident's family member (acting as an appointed healthcare agent or surrogate decision-maker) will ideally use the AD as guidance when making decisions regarding medical treatments and EOL care. Most ADs for older nursing home residents reflect preferences for less aggressive EOL care. As a result, advance care planning and ADs are associated with decreased hospitalization rates, reduced antibiotic use, and increased likelihood of residents dying in the nursing home rather than the hospital.[60,61]

Although documented preferences about resuscitation are common, documented preferences about other interventions such as medically administered nutrition and hydration, hospitalization, antibiotics, and comfort measures are not.[62] The use of structured advance care planning interventions that result in portable life-sustaining treatment orders (i.e., POLST) is one way of encouraging discussion about, and documentation of, residents' and families' decisions about specific therapeutic approaches.[63] POLST programs increase concordance between residents'/families' preferences and care received.[64]

Despite the potential effectiveness of POLST, completing a POLST requires skilled, open discussion among clinicians, patients, and families. There is evidence that the quality of conversations is often less than ideal.[65–67] POLST forms can be difficult to interpret and explain. In addition, the amount of time advance care planning requires has been cited as a barrier to POLST form completion.[63,65,66] However, Hickman et al. demonstrated that a structured approach to discussions about care preferences that includes staff support and resource allocation increased advance care planning conversations and POLST form completion with a focus on preferences for less aggressive treatment.[63]

Decision aids can increase effective communication about values and goals at the end of life. Hanson and colleagues trained staff to use a goals-of-care intervention consisting of a video decision aid, along with a structured discussion guide for family decision-makers of nursing home residents with dementia.[68] Decision-makers reported better overall EOL communication and residents experienced less potentially burdensome transitions.

End-of-Life Transitions

Many nursing home residents are hospitalized in the final weeks of life[30,69] and receive burdensome treatments with little benefit and post-acute, rehabilitative-focused care.[39,49] EOL hospitalizations are costly and often avoidable.[26]

To address this problem, Ouslander et al. examined the effectiveness of several treatment algorithms and other tools designed to reduce hospitalizations.[70] Findings indicated that these tools can decrease hospitalization rates and healthcare costs. Packaged into a program, the Interventions to Reduce Acute Care Transfers (INTERACT)[71,72] tools were implemented in demonstration projects funded by the Center for Medicare and Medicaid Innovations (CMMI) (https://innovation.cms.gov/initiatives/rahnfr-phase-two/index.html).

Another promising approach to decreasing hospitalizations and promoting palliative care in nursing homes is the Optimizing Patient Transfers, Impacting Medical Quality, and Improving Symptoms: Transforming Institutional Care (OPTIMISTIC) project. This ongoing CMMI demonstration project is a multicomponent intervention aimed at improving medical care, managing care transitions, and supporting palliative care by placing specially trained registered nurses and nurse practitioners in nursing facilities. Findings show that the intervention reduces

Table 49.1 Palliative care resources for nursing home staff and other providers

Resource	Description
End-of-Life Nursing Education Consortium (ELNEC) Geriatric curriculum	Comprehensive training for nurses and nursing assistants, as well as social workers, chaplains, and others working in nursing homes. Also useful for hospice staff who serve nursing homes. ELNEC website: http://www.aacnnursing.org/ELNEC; Online training website: https://www.relias.com/elnec
Advancing Excellence in America's Nursing Homes	Initiative of the Advancing Excellence in Long-Term Care Collaborative; goal of the campaign is to ensure quality of care and quality of life for nursing home residents. Website contains resources on palliative care topics such as advance care planning and pain assessment and management organized within a quality improvement framework. Website: https://www.nhqualitycampaign.org/default.aspx
Core Curriculum for the Long-Term Care Nurse	Comprehensive curriculum in detailed outline, book format Organized by the National Consensus Project Domains.[77] Available from the Hospice and Palliative Nurses Association: https://www.hpna.org/HPNA_Item_Details.aspx?ItemNo=978-1-934654-30-9
Palliative Care in the Long-Term Care Setting	Developed for medical directors and primary care providers in nursing homes. Contains a variety of resources to improve palliative and end-of-life care through leadership, education, best-practice guidelines, and quality assurance. Available from the American Medical Directors Association: https://paltc.org/product-store/palliative-care-long-term-care-setting
Geriatric Pain Website	Website containing evidence-based materials to guide nurses and other nursing home staff in assessing and managing residents' pain, including those with dementia. Available at https://geriatricpain.org/
Palliative Care for Advanced Dementia	Developed by the Beatitudes Campus Dementia and Aging Research Department and Hospice of the Valley in Phoenix, Arizona, this interdisciplinary program specifically targets the knowledge and skills needed to provide person-centered comfort care to persons with dementia and their families. Available at http://www.comfortmatters.org/
Choosing Wisely website	Website includes clinician and patient/family resources to guide decision-making around several end-of-life issues for nursing home residents including: Feeding tubes: http://www.choosingwisely.org/patient-resources/feeding-tubes-for-people-with-alzheimers/ Hospitalizations: http://www.choosingwisely.org/clinician-lists/amda-aggressive-or-hospital-level-care-for-frail-elder/ Use of lipid-lowering medications: http://www.choosingwisely.org/clinician-lists/amda-lipid-lowering-medications/
Consult Geri_RN	Website with articles and videos relevant to the care of older adults, including pain assessment in nonverbal persons and avoiding restraint use. Available at https://consultgeri.org/
Palliative Care in the Nursing Home Setting[78]	National Hospice and Palliative Care Organization resource to guide collaboration between nursing homes and palliative care programs. Available at https://www.nhpco.org/sites/default/files/public/palliativecare/PALLIATIVECARE_PC_NursingHome.pdf
Nursing Home Palliative Care Toolkit[79]	Comprehensive toolkit developed by Healthcentric Advisors for long-term care facilities and stakeholders in Rhode Island. This 138-page guide contains nursing home-specific resources, assessment tools, and interventions. Available at http://healthcentricadvisors.org/wp-content/uploads/2015/01/nursing home-Palliative-Care-Toolkit_2014.pdf

potentially avoidable hospitalizations.[73,74] Furthermore, nursing home staff report that they find value in having access to specially trained project staff who can devote time to goals of care conversations and advance care planning discussions.[75]

Resources for Enhancing Palliative Care in Nursing Homes

Over the past several years, many professional and industry groups have developed curricula, websites, and other palliative care resources for nursing homes (Table 49.1). However, a recent systematic review revealed that education alone does not improve staff clinical practice and resident EOL outcomes.[76] Multifaceted programs that include education in addition to leadership support for EOL care processes and capacity-building for comprehensive palliative care delivery are more likely to be effective.

Conclusion

While nursing homes represent a unique short- and long-term care environment, modifications can help facilities in delivering high-quality EOL care. The nursing home staff should address the physical, psychological, social, and spiritual needs of all residents. Primary care clinicians need to recognize the regulations and guidelines under which facilities operate. Palliative care delivery models and targeted strategies can be integrated into nursing homes. The principles of palliative care should be an integral part of nursing home care.

Case Study: A Nursing Home Resident

Mr. X is an 87-year-old man with congestive heart failure, a pacemaker for sick sinus syndrome, and mild dementia. He was recently hospitalized with syncope related to anemia and diagnosed with myelodysplastic syndrome. Prior to the hospitalization, he lived in an assisted living facility and was able to care for himself. However, during the hospitalization, he experienced confusion, hallucinations, and significant functional decline. Mr. X was now receiving post-acute skilled nursing care and rehabilitation in a local nursing home. He was not making significant progress in physical therapy, slept a majority of the day, and had a poor appetite. On multiple occasions, he had told the nursing staff he was tired and wanted to be left alone. During the most recent MDS assessment, the staff noted his overall decline and worsening cognitive function and contacted the family to discuss his care. Mr. X's children were concerned that the new myelodysplastic syndrome diagnosis was causing his symptoms, and they wanted him to pursue "a little bit" of chemotherapy treatment "to see if it would help."

Mr. X clearly had many unmet needs. What was the first step? Could Mr. X make his own decisions? How would one know? What should one do now to ensure that Mr. X's goals of care are known? How should one document these goals in writing? How could palliative care help? What challenges could one anticipate? How could the nursing home staff support Mr. X? In what ways could the staff ensure that Mr. X's children are supported? Is hospice care appropriate? Why or why not? How could one ensure that Mr. X received treatments that matched his care preferences?

CHAPTER 50

Palliative Care in the Community

Nancy Robertson and Barbara Sutton

Key Points

- The number of seriously ill homebound patients is increasing. The goals of care of this population reflect a desire for the quality of days to take precedence over the extension of life. Yet many end up cycling in and out of healthcare facilities and even dying in the hospital when their preference for death is to be at home.
- The number of unpaid caregivers is approximately 43.2 million. The estimated economic value of their unpaid contributions is approximately $470 billion. These caregivers are called upon to act as navigators and coordinators of an increasingly siloed and confusing healthcare system. There is an increasing understanding of the gap in care for this hidden, suffering population.
- Palliative care in the community is effective, decreases hospitalizations, and impacts positively symptom burden and caregiver distress. Individuals receiving community-based palliative care are more likely to complete advance care planning documents and to die at home.
- There is an urgent need for nursing education to prepare a qualified workforce to serve this population. Palliative care nurses at all levels must be trained, qualified, and competent to deliver high-quality palliative care to each suffering patient and family they touch.

Introduction

Informal palliative care has been delivered by nurses in the home for centuries. Managing symptoms, advocating for patient goals, and supporting caregivers are within the nurses' scope of practice as well as in their hearts. As the United States' healthcare system grew and became increasingly industrialized and siloed, these very important aspects of care have often been overlooked. Now that formalized palliative care is rising out of the arms of hospice and into its own specialty, nurses are positioned to impact positively the trajectory of patients and families as they face end-of-life (EOL) suffering.

Palliative care services are making great headway into the establishment of teams in the hospital settings. Among hospitals with more than 300 beds, more than 90% now have a palliative care team.[1] More recently, this specialty is expanding and migrating out from these hospital environments into the communities where people live and congregate. However, at this point, *community-based palliative care* services vary greatly in availability and standardization.

Background

Assuredly, medical advancements have had a positive impact on the human race. With the advent of hand-washing and sanitation, life expectancy has jumped 20–30 years. Add in major medical discoveries, such as penicillin and the development of state-of-the-art technologies, and it is now estimated that the average American will live to see 78.8 years of life.[2] Yet living longer presents challenges of its own. Currently, 45 million Americans are living with one or more chronic conditions that impact their function in a negative way.[3,4] This cohort accounts for 56% of all healthcare expenditures, an estimated $1 trillion.[3]

Of this highly complex population, almost 2 million are older adults who are homebound, while another 5.5 million are semi-homebound and requiring assistance from others to leave their homes.[5] These people face challenges of access to even the most basic healthcare and thus find themselves seeking much of their care through emergency services. They cycle in and out of hospitals and skilled nursing facilities. This fragmented care and multiple chronic conditions cause them to become the costliest patients in the US healthcare system.[6]

The goals of this population reflect a desire for the quality of days to take precedence over the extension of life.[7] In addition, greater than 80% of Medicare beneficiaries aged 65 years and older want to die at home. Yet, in 2013, one-third of the 1,904,640 deaths among patients of this cohort occurred in the hospital.[8] As this population experiences the advances of serious disease, family members are pressed into caregiving roles. This is creating a crisis of a proportion previously unknown in the United States. As the baby boom generation (those born between 1946 and 1964) grows older, a substantial shift in the age composition of the US population is taking place. By 2029, more than 20% of the US population will be over 65 years of age.[9] With advanced age comes increased debility, need for assistance, and caregiving.[10]

Caregiver Crisis

Family caregivers have historically been the mainstay of care in the home for ill members of the family. Today, this care has morphed into a highly complex, stressful, and costly burden. Caregivers are now called upon to act as navigators and coordinators of an increasingly siloed and confusing healthcare system. They find themselves monitoring chronic conditions as well as acute illnesses as hospitals are discharging patients who are sicker and less prepared to leave the arms of the 24-hour professional staff.[11]

In 2014, an estimated 43.2 million adults provided unpaid care to an adult living with serious disease.[12] They performed assistance with all activities of daily living including shopping, transportation, managing finances, and meal preparation as well as bathing and dressing. More than half performed nursing duties such as managing medical equipment, handling incontinence, caring for wounds, and overseeing the administration of medications.[11] These caregivers reported an average of 24.4 hours a week spent providing care to their loved ones. Sixty percent of family caregivers were employed either full-time or part-time. Of those working caregivers, 40% were aged 50 years and older.[12]

Caregivers increasingly suffer from anxiety, depression, compassion fatigue, and burnout.[13,14] More than half of all caregivers work full-time, and six in ten report at least one impact or change to their job situations as a result of caregiving, such as being admonished for a poor performance or attendance or needing to take a leave of absence. Four of ten caregivers report high stress, and 38% report increased financial stress. More than half report that caregiving has negatively impacted their job performance.[13]

Caregivers also experience a high incidence of physical problems, including an increase in heart disease, hypertension, stroke, poorer immune function, sleep problems and fatigue, and even death among highly stressed spouse caregivers.[13,15–17] Caring for a loved one with dementia is particularly stressful, with the added burden of experiencing all of the preceding conditions as well as social isolation, visits to the emergency department, or hospitalizations.[12,18]

The estimated economic value of unpaid contributions in caregiving was approximately $470 billion in 2013, up from an estimated $450 billion in 2009.[12] Additionally, 9.7 billion in healthcare dollars are spent on caregivers themselves due to the physical and emotional toll caregiving takes.[19]

Palliative care in the community has the capability to answer many of the challenges currently being faced by patients with serious illness and the families who are struggling to care for them. Impact of community-based palliative care programs has demonstrated improved caregiver burden and a better maintenance of caregiver quality of life and family satisfaction.[20]

Palliative care services, utilizing the interdisciplinary team (IDT) model, can assess and intervene with symptom burden, identify and work to decrease caregiver burden, coordinate appropriate community resources, establish goals of care and treatment preferences, coordinate care, and assist in providing a badly needed and critical layer of support.

Effectiveness of Palliative Care in the Home

Though more research is needed to validate the effectiveness of the palliative care community-based programs, the preliminary evidence is highly encouraging. Enhanced symptom management, improved patient quality of life, reduced aggressive care at the end of life, increased advance directive completion, reduction in hospitalization rates and emergency room visits, and decreased days in the intensive care unit (ICU), as well as improvement in patient and family satisfaction scores is seen in observational data and evidence from randomized trials.[3,20–22]

A 2016 Cochrane review revealed strong evidence that home palliative care increases the chances of one dying at home if that is the desire. Home palliative care was also found to reduce symptom burden, in particular for patients with cancer, without impacting the grief experienced by the caregiver.[23] What is even more intriguing are the results found by Dr. Higginson and colleagues in a small randomized trial conducted in 2013. These researchers questioned the effectiveness of integrating palliative care early in the disease trajectory of patients with advanced disease and refractory breathlessness. Fifty-three of the participants were randomized to a breathlessness support service, while fifty-two received usual care. Their results strongly support the early integration of palliative care for patients with diseases other than cancer and breathlessness, as well as for those with cancer. In addition, they found a statistically significant longer survival rate for patients with chronic obstructive pulmonary disease and interstitial lung disease in those patients receiving palliative care in community settings as compared with others with the same diagnosis but not receiving this specialized care.[24]

Delivery Models of Community-Based Palliative Care

As of 2017, there existed no standardized approved delivery models for community-based palliative care services. Most of the current models of community-based palliative care are driven by reimbursement and finances. As the majority of the disciplines that serve on a palliative care team are not covered under current payment structures, hiring a full complement of staff is extremely difficult. Social workers, chaplains, care coordinators, and all nurses not licensed as advance practitioners are not eligible for reimbursement. This leaves only licensed clinical social workers (LCSW), advance practice registered nurses (APRN), physician assistants (PA) and physicians as being able to bill. As APRNs receive 85% of the physician fee schedule, this further reduces the ability to generate income.

Community-based palliative care practices must be smart and creative to keep their doors open. Some may, for example, decide to focus their geographical catchment in order to minimize expensive drive time for their staff. Practices may see patients in certain zip codes limit their services to specific facilities such as independent living facilities (ILFs), assisted living facilities (ALFs), skilled nursing facilities (SNFs), or senior communities. A short description of various models follows.

Consultative Programs

Consultative community-based palliative care programs work with primary care providers. Their staff assesses seriously ill patients and families then makes recommendations to the primary care team to meet the identified palliative care needs. The OACIS Lehigh Valley Health Network is one such example. OACIS utilizes palliative care-trained APRNs and RNs to work closely with primary care providers, often using telehealth, home visits, and 24/7 access. The community-based palliative care staff functions as a consultant service and does not provide primary care.

Home Health

Home healthcare agencies (HHC) may provide primary palliative care in order to meet the needs of their medically complex patients who may not yet be eligible for hospice or whose goals of care do not reflect the hospice philosophy. Home healthcare agencies are primarily reimbursed through Medicare A, Medicaid, and commercial insurances for episodic care for nursing or therapy needs. Patients must meet criteria for home healthcare and must demonstrate progression toward improvement. RNs are reimbursed within the per diem rate, whereas APRNs may bill for their palliative care services under Medicare B, Medicaid, or commercial insurances per visit. Patient and referral source satisfaction lead to increased referrals for the HHC agency, increasing revenue, and support of the community-based palliative care practice.

Hospice

Community-based palliative care may be provided by hospice agencies as a separate service line. For patients who are not currently eligible for the hospice benefit or who are continuing to seek curative or life-prolonging treatment, the hospice agency's palliative care service will deploy APRNs, RNs, and occasionally social workers and chaplains to render these services. APRNs and LCSWs bill under Medicare B, Medicaid, or commercial insurance, although fee-for-service billing is rarely adequate for a sustainable practice. The hospice agency justifies this service arm by metrics such as earlier referrals to hospice, improvement in quality care, and increased length of hospice stays.

Private Duty Nursing Agencies

Private duty nursing agencies may offer palliative care provided by certified nursing assistants (CNAs) and RNs, primarily in support of the plan of care developed by palliative care specialists. Payment is through long-term care insurance or as an out-of-pocket expense.

Primary Care Practices

Primary care practice in the home is a growing field that is providing care to people with multiple medical morbidities and complex illness right where they live. There is no medical specialty more appropriately positioned to deliver palliative care than those practicing in the general practice setting. They know the medical, psychosocial, and environmental challenges faced by their patients better than any other provider. As such, general practice APRNs are seeing the demand for addressing palliative care during their home-based primary care visits. Most community-based primary care programs are reimbursed by Medicare B, Medicaid, and commercial insurance. They are often available 24/7. Home-based primary care programs vary widely from the multistate VA system, which utilizes the MD/APRN model, to solo APRNs making house calls.

Independence at Home (IAH) Demonstration is a Medicare Innovation Model providing home-based primary care through programs led by nurse practitioners or physicians. IAH has shown substantial savings in overall care of enrolled patients, as well as fewer hospitalizations and emergency room visits.

Within this construct, those primary care providers who are palliative care–trained make a valuable impact to meeting the palliative care needs of their seriously ill patients. However, their approach is somewhat "grass roots" at this moment. Primary care providers who have advanced their palliative care skills and knowledge are able to identify and address palliative care needs, but the approach is reactive in nature. As this area matures, ways to incorporate the identification and treatment of palliative care needs from a systematic viewpoint will emerge.

Free-Standing Palliative Care

There are palliative care programs that exist without attachment to other service lines. These exist in those hospital systems that often wish to impact negative metrics such as the 30-day rehospitalization metric. Various forms of teams consisting of nurses, social workers, and administration staff work to provide palliative care to their patients after discharge from their hospital setting. Their reimbursement is in the form of fee-for-service billing (if they have clinicians with licensure to bill) or by avoiding the penalties associated with frequent readmission rates.

Another version of the free-standing palliative care model is profit, multistate organizations. These companies are reimbursed by insurances on a per-patient per-month basis. The goal is to reduce the hospitalizations and increase hospice referrals for enrollees with high utilization rates. These patients are often defined through an algorithm using data held by the insurance company. APRNs and RNs work in tandem with a physician to manage symptoms, provide education and support, and discuss goals of care and advance care planning.

Pediatric Palliative Care

Pediatric palliative care in the community is complex. Children covered by state Medicaid or Children's Health Insurance Program (CHIPs) and who have a terminal illness are able to receive hospice care and curative therapies simultaneously. A child may be eligible to receive skilled intermittent and 24-hour nursing along with respite care and other therapies. There are few pediatric community care programs in the United States due to cost and payment limits.

Rural Palliative Care

The use of telemedicine in providing palliative care in the community is more common in remote areas. An office-based RN monitors the telemedicine units for changes in patient condition or symptoms and dispatches the appropriate service, which could be in the form of a phone call or a physical or virtual visit. Resolution Care in Eureka and Mendocino, California, is one such example. This delivery model has been found to reduce ED visits and to increase satisfaction and referral to hospice.[25–27]

Payment for Palliative Care Services in the Community

Reimbursement for palliative care in the community is in a state of flux. As the traditional model of paying for services rendered is moved to value-based payment structures, there is increased opportunity for community-based palliative care. Moving to value-based and risk-sharing partnerships may allow the hiring of a full complement of IDTs and allow the right kind of care to be delivered to the right kind of patient at the right time.

The traditional fee-for-service billing incorporates ICD-10 codes and Current Procedural Terminology (CPT) codes. Please see Table 50.1 for the most common palliative care ICD-10 codes currently being utilized and Table 50.2 for CPT codes.

Delivering palliative care services often entails more time than most other medical services. It is imperative that the community-based palliative care teams understand how to bill for palliative

Table 50.1 Commonly used International Classification of Disease (ICD-10) codes for palliative care

Use prolonged codes 99354 and 99355 if the visit goes over the typical time requirement and meets the threshold of time for these prolonged codes.

than half of that time was spent on counseling and coordination of care. New advance care planning codes were released by Medicare in January 2017. Though the reimbursement rate is relatively low, there is value.

Value-based billing made up 38% of all US healthcare payments at the end of 2015.[28] Tightly woven into the value-based payment structures is the need to identify, collect, analyze, and report on measurements and metrics of the palliative care programs. Measuring the quality of care delivery is integral to hospice and palliative care programs, as specified by the National Consensus Project (NCP) Clinical Practice Guidelines and the Joint Commission Advanced Certification Program for Palliative Care, as well as by stakeholders and payers.[29,30] Currently, no national standards for measurement or databases that would support benchmarking exist in palliative care.

The Quality and Practice Standards Committee of the American Academy of Hospice and Palliative Medicine (AAHPM) along with the Hospice and Palliative Nurses Association (HPNA) initiated the Measuring What Matters (MWM) consensus project. The overall goal of the project was to recommend a concise portfolio of valid, clinically relevant, cross-cutting performance indicators for internal measurement for hospice and palliative care programs.[31]

Roles and Responsibilities of the Specialized Palliative Care Team in the Community

There is much discussion in healthcare literature about how healthcare disciplines, operating in numerous silos, interact to care for patients. The traditional model of multidisciplinary teams incorporates the hierarchical structure with physicians typically carrying the full weight of the ultimate responsibilities for the decisions made by the team. Each member on this traditional team has clearly identified roles and responsibilities. They contribute to the overall care of the patient in relative isolation from the others on the team.

In palliative care, however, this approach is less than ideal as the patient and the family are the ultimate decision-makers for the plan of care. To advocate, honor, and respect individuals' choices, the interdisciplinary approach is much more applicable. IDTs base their function as a team on interdependent interaction, which results in a synergistic effect that happens when the members possessing specific expertise work closely together.[32]

The IDT grows to understand each other's disciplines, expertise, and opinions. They learn from each other and add to their skill set with tools learned from their colleagues. This allows team members to support and cover for each other to an extent they could never do before.

Many teams in the community do not have complete coverage by all disciplines. The majority of palliative care teams in the community are primarily made up of care coordinators, caregivers, nurses, and social workers, though for completeness, other disciplines do participate in community-based palliative care IDTs. Please refer to Table 50.3 for roles and responsibilities of the disciplines typically found on a palliative care team.

Table 50.3 Roles of palliative care interdisciplinary team (IDT) members

Caregivers	Provide daily or around-the-clock custodial care. Often family members or may be paid professionals
Registered nurses/ licensed practical nurses (RNs/LPNs)	Deliver skilled care as directed by care plan
Advanced practice registered nurses/ physician assistants (APRNs/PAs)	Coordinate total patient care to complex patients; supervise/delegate to other nurses; assess and diagnose; prescribe medications
Physical therapists	Deliver skilled care to increase strength and function, assess for assistive devices
Psychologists	Address stress, body image, depression
Occupational therapists	Address patients' abilities to perform their everyday tasks with greater independence and efficiency.
Speech therapists	Improve speech and swallowing problems, address hearing loss, language problems
Chaplains	Address spiritual issues, adjustment to "new normal"
Physicians	Coordinate/oversee nursing and therapists staff, certifies care plan
Nutritionists	Provide diet counseling for special nutritional needs
Pharmacists	Review medications, make recommendations for adjustments, cost, contraindications
Volunteers	Assist patients and families in meeting goals, legacy work, socialization
Home health aids	Perform personal care and basic nursing tasks
Homemakers	Provide cleaning, tidying, shopping, pet care
Social workers (MSW/LCSW)	Identify needs of family and patient, refer to community resources, counselling

Rules and Regulations of Palliative Care Nursing in the Community

State regulations, Medicare, and commercial insurance companies each impact the practice of community-based palliative care nursing. State nurse practice acts vary widely in the scope of practice for RNs and APRNs. It is recommended that nurses familiarize themselves with the state regulations guiding their practice. The National Council of State Boards of Nursing provides resources and can be found at https://www.ncsbn.org/nurse-practice-act.htm.

Guidelines for community-based palliative care are generally similar to those for home-based primary care. Medicare does not require patients to be homebound as long as the justification is documented and the visit is not for convenience or at the patient's request.[33]

Academic Requirements for Community-Based Palliative Care Nurses

Palliative care, as its own area of expertise, has grown significantly since the American Board of Medical Specialties approved the creation of hospice and palliative medicine as a subspecialty in 2006. This approach to care is so new that generations of healthcare professionals have had no exposure to it. This presents a significant challenge to palliative care academia to keep up with the demand for quality curriculum and programs to educate its clinicians. In 2000, the End-of-Life Nursing Education Consortium (ELNEC) project was funded by The Robert Wood Johnson Foundation. This national education initiative to improve palliative care developed and delivers nursing curriculum in EOL care. This project has been extremely successful in impacting the knowledge curve for all nurses' caring for patients living with serious illness. In 2013, ELNEC debuted its curriculum for the APRN community. The ELNEC website states that it has trained "over 21,400 nurses and other healthcare professionals, representing all 50 US states, plus 90 countries."[34]

Outside of this highly contributive body of work, the availability of accredited programs is few and at present remains small. In 2017, the Hospice and Palliative Care Nursing Association's website listed 15 master's and doctoral palliative care graduate programs available and another three with electives in Palliative Care.[35] Two newly created, innovative programs launched at the University of Colorado and another at the University of Maryland offer interprofessional master's degrees and certifications in palliative care. These programs incorporate students and faculty from all palliative care disciplines.

Although these novel programs and others segregated by discipline are currently developing, schools will require years to graduate the estimated 10,000 educated clinicians this field requires.

While the opening of community-based palliative care programs is hailed as filling a rapidly growing need, there is currently a dearth of trained, qualified, palliative care professionals. As the understanding and acceptance of specialty palliative care is increasingly understood and embraced, the appreciation for integrating palliative care earlier in the disease trajectory creates an exploding demand for these nurses and other healthcare professionals.

Community-based agencies struggling to meet the demands of increased referrals have no other choice but to recruit and hire untrained, unqualified clinicians.

The Institute of Medicine "Dying in America" report released on September 17, 2014, draws attention to this serious problem. As a result of this committee's exhaustive work analyzing the current state of EOL care in the United States, their third recommendation calls upon academic institutions, national and state accrediting bodies, and healthcare delivery organizations to assure appropriate training and certification for all clinicians who care for patients and families living with serious illness.[4]

Fortunately, leading national palliative care organizations anticipated this need years ago and have published guiding principles for the education of future practitioners. The National Consensus Project for Quality Palliative Care, a subcommittee of the Hospice and Palliative Care Coalition, is one such organization. This project drew upon five major US palliative care organizations to develop clinical guidelines for quality palliative care services. The guidelines, originally released in 2004, have undergone two revisions and are now in their fourth, released in 2018.

Specifically for the nursing discipline, the Hospice and Palliative Care Nurses Association established standards of care in their important document "HPNA Standards for Clinical Education of

Hospice and Palliative Nurses," originally created in 2005, with their second edition released in 2015.[36]

The Joint Commission, a national accrediting body, launched their certification program for hospital-based palliative care in 2011, closely followed with their certification for community-based palliative care programs in 2016. The Joint Commission requires that clinicians are trained in palliative care.

The Center to Advance Palliative Care (CAPC) is a national organization that has created an in-depth platform of education, mentoring, tools, training, and measurements. These can be found at the Center to Advance Palliative Care website www.capc.org.

Since 1965, Community Health Accreditation Partners (CHAP) has been working to elevate and standardize care delivered in the community. In 1992, CHAP began a relationship with Centers for Medicare and Medicaid Services; compliance with CHAP standards can be used by organizations to demonstrate that they meet the conditions of participation for home health, hospice, and HME Medicare/Medicaid programs.

The establishment of these curricula and position statements is a critical step. Moving to an accepted standard for entry-level palliative care clinicians is the next. It is imperative that agencies ensure that their palliative care clinicians are adequately educated, trained, and supported, as well as having appropriate certification.

Community-based Palliative Care Summary

The United States is struggling under the burden of an overpriced, procedurally driven healthcare system that minimizes patient autonomy and self-determination. The growth of palliative care is one answer to redirecting the course. Great headway has been made in the hospital system and is now evolving to impact other healthcare settings. Delivering the right service to the right patient at the right time is essential. Providing services to the home where patients and their struggling caregivers live is the next phase, and it has begun. Models of delivery are as individual at this point as there are agencies to deliver these services. But national projects are under way to develop a consensus as to what these services should entail and the payment structures needed to sustain these services.

What is very clear is that palliative care services need to be delivered by multiple disciplines in multiple settings. Blending these disciplines into one efficiently running IDT and delivering this approach wherever patients and families live holds great promise to answering many of the healthcare struggles the US currently faces.

> I had a good friend who died from brain cancer. She was 63 years old. I gave her a copy of "Being Mortal" and talked to her about hospice 6 months before her death. Her doctor kept encouraging her to try to get accepted into experimental treatment trials. She finally referred her to hospice 10 days before she died. I was so angry! I am not a medical professional, but I do know that people do not recover from glioblastoma tumors. I also know that palliative care could have made the last several months of her life so much easier for her and her family. (Written permission given by Elaine Sanchez to share with readers of this textbook)

The Future for Nurses in Palliative Care in the Community

Nurses have been bringing care, including unnamed palliative care, into people's homes since the 1800s. The current move of healthcare back into the community brings with it the opportunity for nursing to continue to positively impact the trajectory of patients' and families' experience of serious illness. Through exemplary communication skills and a wide-ranging knowledge base, the nursing force is set to deliver multifaceted care while acting as liaisons and guides for seriously ill patients attempting to navigate the increasingly complex healthcare system. Nurses, with their ability to respond quickly to changing patient needs, fulfill the large unaddressed gap in care. By effectively orchestrating much-needed difficult conversations around advance care planning, managing immense symptom burden, intervening with caregiver strain, and coordinating care, nurses impact the very heart of suffering.

Now, more than ever, the need is great for nurses from all backgrounds of healthcare to seek out and obtain advanced education in palliative care. Identifying patient wishes and goals of care along with treatment preferences, then advocating for these desires, is one of the true callings of the nursing discipline. Our discipline must be trained, qualified, and competent to deliver high-quality palliative care to each suffering patient and family we touch.

Case Study: A Patient in Palliative Care

Agnes is an 84-year-old woman with hypertension, chronic kidney disease, atrial fibrillation, congestive heart failure (CHF), dementia, recurrent urinary tract infections (UTIs), falls, and arthritis in her knees and hips. She was hospitalized a year ago for a CHF exacerbation. During that hospitalization, she and her daughter, Gina, met with the palliative care team. Together they helped Agnes define her goals of care. She wanted to be home, avoid all hospitalizations if possible, and not be a burden to her daughter. Agnes felt she had lived a long and happy life, and, when it was her time, she was ready to go.

Upon discharge, Agnes was referred to a home health agency with a palliative care practice. At the palliative care APRN's first visit, she found Agnes weak, fatigued, and at high risk for falls. Agnes was taking Lisinopril, memantine, furosemide, potassium, warfarin, donepezil, atenolol, trimethoprim-sulfamethoxazole, acetaminophen, omeprazole, and atorvastatin. These medications cost $750 out of pocket each month.

The rest of the admission exam revealed a blood pressure (BP) of 104/60, weakness, a chronic cough, and a pain rating of 6/10 in her knees on most days, which is aggravated with walking. The APRN's assessment of Agnes's chronic cough, hypotension, and weakness led her to stopping the angiotensin converting enzyme inhibitor (ACEI). Following this one change, Agnes's blood pressure rose, the ACEI cough stopped, and the daily pill burden decreased.

Gina had been giving her Mom acetaminophen only when she asked for it, about once every other day. The APRN taught Gina about pain management and the necessity of assessing the pain often, as well as the treatment plan and asked her to keep a pain diary to be reviewed on each visit.

Working with the primary care team as well as with Gina and Agnes, the palliative care APRN outlined the benefits and risks of all Agnes's medications. Collaboratively, it was decided to stop the omeprazole and taper down the donepezil and memantine. Gina felt strongly that she wanted her Mom to continue the trimethoprim-sulfamethoxazole as Agnes's last UTI was a rough event, but she did question the need for the warfarin with all its needs for laboratory monitoring. Her cardiology team authorized stopping both the atorvastatin and the warfarin but, with Agnes's atrial fibrillation, recommended a daily 81 mg ASA in the warfarin's place. A trial of lowered dosing of the furosemide and potassium was conducted. The BP remained below 120 systolic and no edema presented. Eventually, these two medications were stopped as well. The pill burden decreased to four pills and a zero out-of-pocket expense.

Building on the goals of care conversations started in the hospital, the APRN talked with Gina about the benefits of hospice. This early discussion, before Agnes was eligible for the hospice benefit, allowed Gina to consider the option while there was no crisis or urgency. When the topic of a feeding tube was brought up to address Agnes's continued weight loss, Gina asked the APRN about it. She was relieved to find out that it was not recommended for older adults with dementia and that she would not be in "trouble" if she does not have one inserted.

Agnes felt better than she had for a long time with only four pills, twice weekly visits from her RN, and every-other-week visits from the APRN. Scheduling the acetaminophen had decreased her pain, as exhibited by her active participation in activities, no acting out, and no grimacing when she was assisted in moving. During one of the home health visits, Gina shared with the RN that she continued to feel completely overwhelmed, despite the current support. Gina had called in sick to work three times since her Mom had been home, and she worried this would impact her job performance. The RN notified the home health licensed clinical social worker (LCSW) who began working to impact the caregiver strain Gina was experiencing.

Agnes's condition stabilized. With no more skilled needs, the home health agency discharged her from their services. Fortunately, as the palliative care team did not have the insurance restrictions imposed on them as the home health agency did, Agnes and Gina continued to be supported by their palliative care providers.

Over the next several months, Agnes became less verbal, unwilling to walk even short distances, refused to take her medications, and was incontinent of her bowels and bladder. She rarely smiled at her daughter. By her 85th birthday, Agnes was completely homebound. Though Agnes was no longer able to get out to see her primary care provider (PCP), the palliative care APRN continued to visit in the home and medically managed her conditions by working collaboratively with her PCP team. With a FAST scale of a 7c, Agnes was now eligible for her hospice insurance benefit. As the team had spoken numerous times with Gina as the disease progressed, she was fully on board with this transition. The same APRN who worked on the palliative care team also worked as the hospice attending, and she accepted Gina's request to assume her Mom's care.

With the hospice benefit, a full array of team members came to care for Agnes and Gina. Another month went by and Agnes's function continued to decrease. Now Agnes rarely got out of bed. Two weeks later, Agnes died with Gina sitting by her side, holding her hand.

Case Study Summation

This case study illustrates what the early integration of palliative care in the disease trajectory can do. In this example, three hospitalizations were avoided: one sub-acute stay and one nursing home admission. Pain was identified and aggressively treated from the start, allowing Agnes to enjoy her days. Agnes did not have a feeding tube inserted. The caregiver stress, burden, and grief were positively impacted. Hospice was accessed sooner, bringing with it substantial aid and support to the situation.

Perhaps the most important illustration that the case study with palliative care provides is that Agnes's goals of care and treatment preferences were identified, advocated for, and honored. She received the kind of excellent medical care she wanted from the beginning of her serious illness until she passed away in the place she requested and in the presence of her loved one.

Acknowledgments

It is with deep gratitude that we thank the people who helped us create this chapter. To Paul Deane, MILS, Medical Librarian for his librarian skills. To Elissa Kolva, PhD, assistant professor at the University of Colorado Denver School of Medicine Division of Medical Oncology, for her vast knowledge of caregiver burden. To Debra Liebrecht, RN, CPHQ, for her meticulous editing and talented wordsmithing. To Barbara McCann, CEO of CHAP, for her contribution in understanding the vital role her organization plays to elevating the standards of home health services. To Laura Nemec, FNP, DNP, for proofreading and astute suggestions. Thank you all!

CHAPTER 51

The Intensive Care Unit

Jennifer L. McAdam and Céline Gélinas

Key Points

- All intensive care unit patients deserve palliative care, whether the goal is cure or a peaceful end of life.
- Although an ICU is rarely the place where patients would choose to die, transition from aggressive care to end-of-life care is a frequent occurrence.
- Optimal transitional care in ICUs requires clear communication among patients, families, and care providers from multiple disciplines.
- The appropriateness of procedures should be assessed, unnecessary procedures eliminated, and the pain associated with necessary procedures treated appropriately.
- Analgesics should be administered in the amounts necessary to decrease pain and symptoms without concern about the milligram dose required.
- Pain and symptom assessment and management, although challenging in an ICU setting, are primary roles and contributions of the ICU nurse.
- Conducting family meetings early in the ICU stay, establishing goals of care, and helping patients and families with decision-making are important aspects of quality palliative and end-of-life care.
- Decisions to forgo life-sustaining therapies are made when the burden of aggressive treatment clearly outweighs the benefits. There are two methods of withdrawing ventilator therapy: immediate extubation and terminal weaning. Guidelines exist for each of these methods of withdrawal.
- Optimal family care occurs at any point along the patient's illness trajectory by providing access, information, support, and involvement in caregiving activities.

Introduction

An intensive care unit (ICU) is, by tradition, the setting in which the most aggressive care is rendered to hospitalized patients. However, many patients die in ICUs. It is estimated that more than 500,000 people die after admission to ICUs in the United States each year.[1] In a recent retrospective cohort study, researchers reported that 35% of patients older than 80 years of age were admitted to the ICU and either died in the ICU or shortly thereafter in the hospital.[2] Investigators comparing Medicare beneficiaries' places of care and sites of death reported a significant increase in ICU usage during the last 30 days of life, with 29% of the decedents experiencing ICU care in the last month of life.[3] In addition, 36% of patients with poor-prognosis cancers who were not receiving hospice care were admitted to the ICU within 30 days of death.[4] Therefore, it is clear that management of the process of dying is common in ICUs.

In the high-technology environment of an ICU, it may be difficult for healthcare professionals and families of dying patients to acknowledge that there are limits to the effectiveness of medical care. However, it is important to focus on providing the type of care that is appropriate for the individual patient and the patient's family. This chapter discusses the provision of palliative care in ICUs, with an emphasis on end-of-life (EOL) care. Specifically, challenges and barriers to providing such care in ICUs are described, and recommendations are offered for the provision of symptom assessment and management. Current issues related to holding family meetings, establishing patient goals of care, surrogate decision-making, and withholding and withdrawing life-sustaining therapies are covered. Finally, recommendations are offered for attending to the needs of families as well as healthcare professionals who care for ICU patients at the end of life.

The Limitations of End-of-Life Care in Intensive Care Units

The ICU is rarely a place where one would choose to die.[5] Healthcare professionals in ICUs, frequently uncertain about whether a patient will live or die, are caught between the opposing goals of preserving life and preparing the patient and family for death. It is important for professionals to realize that a patient's death is not necessarily an indication of ineffective care. Yet there remain serious limitations to the care provided to seriously ill and dying patients and their families. Communication between physicians, patients, and families may be poor[6]; patients and families may be overly optimistic about the outcomes of cardiopulmonary resuscitation (CPR)[7] and have unrealistic expectations of ICU technological treatments[8]; EOL decision-making can be challenging and present conflicts[9]; and many hospitalized patients die in moderate-to-severe pain and with other troubling symptoms.[10]

Planning Palliative Care for Intensive Care Unit Patients

Providing comfort to patients should accompany all ICU care, even during aggressive attempts to prolong life. However, if a patient is not expected to survive, the focus shifts to an emphasis on palliative care. A transition period occurs during which healthcare professionals, the patient's family, and sometimes the patient recognize the appropriateness of withdrawing and/or withholding

Box 51.1 Establishing Goals of Care during ICU Family Meetings

- Ascertain whether the patient has an advance directive, a durable power of attorney, and has communicated a preference about CPR.
- Hold a patient and family meeting early in the ICU stay to identify and communicate the goals of care for the patient and discuss and update them daily.
- Outline the steps that need to be taken to accomplish the goals of care and evaluate their effectiveness.
- Use an interdisciplinary team approach whenever possible.
- In a situation where the patient lacks decision-making capacity and surrogate representation, it is recommended that a court appoint a guardian on behalf of the patient or that safeguards be put in place, such as mandatory ethics committee review, to protect the patient's interests.
- Develop and communicate the palliative care plan to professionals and family, and identify the best persons for implementing the various actions in the plan.

Source: From References 14, 15.

life-sustaining therapies (LSTs) and begin to make preparations for death. The transition period may be a matter of minutes or hours, or it may be a matter of weeks. Clearly, this time difference must be recognized as a factor that can influence the experience of a patient's family. When patients rapidly approach death, their families may not have time to adjust to the possibility of death. On the other hand, when death is prolonged, family frustration and fatigue may be part of their experience. Healthcare professionals who are sensitive to these different experiences can individualize their approaches and interventions for families.

The transition from aggressive care to death preparation has not been well operationalized. The transition period may be uncomfortable for many healthcare professionals because clinically useful prediction models recognizing which patients have the highest risk of death in the ICU remain elusive.[11] Therefore, it is important for healthcare professionals to integrate palliative care principles early in the patient's ICU stay. Researchers have found that the use of palliative care triggers and protocols resulted in prompt referrals to palliative care, lowered the use of ICU resources without changing mortality, and increased palliative care specialists for patients and families most in need.[12,13] Of equal importance is to hold patient and family meetings early in the ICU stay in order to address goals of care (see Box 51.1).[14,15]

Symptom Assessment and Management: Essential Components of Palliative Care

Pain Assessment

In spite of advances in pain assessment and management techniques, hospitalized patients continue to receive inadequate pain management.[16] Pain research focusing specifically on dying ICU patients remains scarce but advances that have been made in the assessment of pain in other critically ill patient populations can be applied to dying patients.[17,18] The patient's report of pain is still considered to be the most valid source. ICU patients, even if they are being mechanically ventilated, may be able to use simple numeric or word rating scales, word quality scales, and body outline diagrams. A 0–10 visually enlarged, horizontal numeric rating scale was found to be the most valid and feasible of five pain intensity rating scales.[17] In addition, an enlarged vertical thermometer of a self-report pain intensity scale has demonstrated validity and is preferred by older adults and critically ill patients.[19]

Many critically ill patients are unable to self-report because of their disease process, technological treatment interventions, or the effects of medications. For example, the use of high doses of benzodiazepine (BZD) infusions may make patients too sedated to respond to pain, although pain may still be present. On the other hand, the use of neuromuscular blocking agents (NMBAs) such as vecuronium may limit or entirely mask the patient's ability to express or show any behavioral signs of pain. It is essential that clinicians understand that some medications, such as propofol and NMBAs, have no analgesic properties, although visible signs of pain disappear during their use. If these agents are used, they must be accompanied by infusions of analgesics, sedatives, or both. In addition, nurses can elicit the assistance of the patient's family to help assess the patient's pain. In a study by Puntillo and colleagues, the families' ratings compared with the ICU patients' reports of pain intensity had a moderate level of agreement (intraclass correlation coefficient = 0.43).[20] In a recent qualitative study, families could describe common as well as specific behaviors indicative of pain in their loved one.[21]

When patients are too ill to communicate their pain through self-report, behavioral scales are recommended as alternative measures of pain.[22,23] According to a systematic review, the Critical-Care Pain Observation Tool (CPOT) and the Behavioral Pain Scale (BPS) have sound psychometrics[24] and are recommended by the Society of Critical Care Medicine for pain assessment of critically ill adults unable to self-report.[23] A BPS version is also available for non-intubated patients (BPS-NI) in which a vocalization item can be used instead of compliance with mechanical ventilation.[25] A new tool, the Behavior Pain Assessment Tool (BPAT), underwent validation at the international level with translation in 12 languages and testing in 3,851 ICU patients from 28 countries. Its feasibility of use in daily practice continues to be investigated.[26]

Behavioral scales are not applicable in unresponsive patients. In such a situation, no other alternative measures of pain are available. Vital signs are not valid indicators of pain,[23] but evidence has shown that they could be considered as adverse events of severe pain.[27] Exploration of other physiologic measures (e.g., pupil dilation reflex) and novel technologies is needed to provide nurses with alternative tools to use in the pain assessment process of this vulnerable population.[28] Another strategy nurses can use is their imagination to identify possible sources of pain by asking the question, "If I were this patient and had intact sensations, what might be making me uncomfortable?" Even if patients are not exhibiting behavioral or physiological signs of pain, it does not mean that they are pain-free.[23]

Procedural Pain

Critically ill patients undergo many diagnostic and treatment procedures. Many of these may be unnecessary, and some procedures such as central line placements, chest tube removal, and endotracheal suctioning, are quite painful and may be the primary cause of suffering at the end of life.[29] Nurses can act as "gatekeepers" by evaluating the appropriateness of procedures being planned for patients, especially after a decision has been made to withdraw life-sustaining treatment, and they can advocate for their omission. Practice guidelines recommend that anticipating and treating pain be part of procedural instructions.[30]

Pharmacological Management of Pain

Numerous categories of analgesics and types of modalities exist for administration to critically ill patients.[31,32] As in all situations, the selection of analgesics should depend on the specific pain mechanism, and the route and modality should be matched to their predictability of effectiveness. Although no comprehensive survey of pain management techniques used for dying ICU patients has been reported, the most common analgesic intervention is use of intravenous opioids.[31,32] Choosing the best opioid and method of delivery will depend on factors such as the patient's body composition (e.g., amount of adipose tissue), development of tolerance, and the adverse effect profiles of the various opioids.[31,32] Use of a continuous infusion of an opioid allows for titration of the drug to a level of analgesic effectiveness and for maintenance of steady plasma levels within a therapeutic range. Additionally, healthcare professionals may consider the administration of intermittent opioid boluses for breakthrough pain. Box 51.2 presents basic tenets in using opioids in critically ill patients, and Table 51.1 provides information on opioids commonly used in the ICU setting.[17,22, 31–33]

Box 51.2 Tenets of Pain Management

- Healthcare professionals should be patient advocates for effective pain control.
- Most critically ill patients will experience pain during their ICU stay.
- Healthcare professionals should assume that pain may be present especially when the patient cannot self-report or when objective measures of pain are conflicting.
- Early recognition and assessment of pain is more effective in controlling and managing pain.
- If there is any notion that the patient has pain, analgesics should be given prior to sedative agents (i.e., "analgesia first"), especially with agents that possess little or no analgesic effects.

Source: From References 22, 31.

Concerns about patients becoming tolerant of or dependent on opioids are misplaced during terminal care. What is important is that professionals recognize the development of tolerance, which is the need for larger doses of opioid analgesics to achieve the original effect,[34] and increase the dosage as necessary. There is no ceiling effect from opioids; the dose can be increased until the desired effect is reached or intolerable side effects develop. Opioid-dependent patients are at high risk of developing withdrawal symptoms,[34] which would seriously increase their discomfort. In this situation, physical dependence can be addressed by gradually lowering the opioid dose while carefully assessing for signs of pain or withdrawal.

Titration of analgesics to achieve the desired effect is one of the most challenging and important contributions that ICU nurses

Table 51.1 Pharmacology of commonly used opioids in the intensive care unit (ICU)

Agent	Equianalgesic dose (mg)		Onset	Half-life	Intermittent dose	Infusion dose range	Active Metabolites	Unique Concerns[a]
	IV	Oral						
Fentanyl	0.1	N/A	1–2 min	2–4 hr	0.35–0.5 mcg/kg IV every 0.5–1 hr	0.7–10 mcg/kg/hr	No metabolite, parent accumulates in fatty tissues	Less hypotension than morphine Accumulation in hepatic impairment Muscle rigidity
Hydromorphone	1.5	7.5	5–10 min	2–3 hr	0.2–0.6 mg IV every 1–2 hr	0.5–3 mg/hr	None	May work in patients tolerant to morphine or fentanyl Accumulation in hepatic/renal impairment
Morphine	10	30	5–10 min	3–4 hr	2–4 mg IV every 1–2 hr	2–30 mg/hr	6- and 3-glucuronide metabolite	Bradycardia/hypotension Bronchospasm Accumulation in hepatic/renal impairment
Remifentanil	N/A	N/A	1–3 min	3–10 min	N/A	1.5 mcg /kg loading dose, then 0.5–15 mcg /kg/hr	None	Bradycardia/hypotension No accumulation in hepatic/renal failure Use ideal body weight if > 30% IBW

IV, intravenous; IBW, ideal body weight; N/A, not applicable

[a] Common adverse effects associated with all opioids, such as respiratory and central nervous system depression are not listed.

Source: From References 17, 22, 31–33.

can make to the comfort care of dying patients. The desired effect can often be described as use of the least amount of medication necessary to achieve the greatest comfort along with the optimum level of tranquil awareness. In ICU settings, there may be concerns that administration of analgesics in the amounts necessary to provide comfort could "cause" death. It is essential that ICU health professionals understand the "double-effect" principle. In brief, the double-effect principle states that administration of analgesics to dying patients in the amounts necessary to decrease pain and suffering—although possibly causing unintentional hastening of death—is an ethically sound way to treat a dying patient.[35] When the ICU patient is approaching death, the most important aim of care should be to make the patient as comfortable as possible.

Nonpharmacological Management of Pain

Nonpharmacological interventions for pain management complement, but do not substitute for, the use of pharmacological interventions. Numerous therapies are available to promote patient comfort, and many of these therapies are low-cost, safe, and easy to implement. There is research evidence that ICU nurses use these therapies in their practice.[36,37] In one study, more than 92% of patients received at least one nonpharmacologic intervention while being repositioned. In this study, nurses reported that what they used the most was a calming voice and providing information.[36] In another study, ICU nurses, patients, and families described music therapy, distraction, massage, and family presence as the most relevant and feasible nonpharmacologic interventions for ICU pain management.[37]

Anxiety, Agitation, and Sedation

An important part of palliative care in the ICU is assessment and treatment of anxiety and agitation. Simple numeric rating scales for anxiety can be used if the patient can self-report. Healthcare professionals and patients are familiar with the use of the 0–10 numeric rating scales for pain. "Anxiety" word anchors can be substituted for pain word anchors so that the numeric rating scales also can be used to quantify the degree of anxiety. Unfortunately, no tool is available to assess anxiety in patients unable to self-report. However, common behavioral or physiological signs of anxiety include trembling, restlessness, sweating, tachycardia, tachypnea, difficulty sleeping, and irritability.[33]

Several agitation/sedation assessment scales are available. It is recommended to use validated scales (e.g., the Richmond Agitation Sedation Scale [RASS] and Sedation Agitation Scale [SAS]).[33,38,39] These scales can be printed on the patient flowsheet, on a separate form, or in the electronic medical record and used as a bedside assessment tool. The frequency with which the scales are used depends on the patient's condition and the schedule for evaluating treatment interventions.

Pharmacological Management to Promote Sedation in Anxious or Agitated Patients

Along with opioids, other categories of sedating drugs are frequently used in the ICU, especially for patients who are mechanically ventilated. Guidelines[22] exist regarding the use of analgesics and sedatives. Often, the goal of combined analgesic-sedative therapy is to promote physical and psychological comfort. Practice decisions include choosing the right type and combination of medications, determining whether to use interrupted sedative infusions or continuous infusions, determining appropriate clinical endpoints for pharmacological interventions,[40] and evaluating the effectiveness of sedation protocols on practices and outcomes.[41]

The appropriate pharmacological agent to control agitation and anxiety is selected according to the desired effect.[40] Benzodiazepines (BZDs) are excellent agents for anxiolysis, but they possess no analgesic or psychological properties. Concomitant use of BZDs, opioids, and certain neuroleptic agents may relieve anxiety-provoking symptoms through a synergistic action. When used together, these drugs can be administered in lower doses less frequently, have fewer side effects, and can decrease or delay development of tolerance or dependence through the use of smaller doses of each drug. At lower doses, BZDs reduce anxiety without causing central nervous system sedation or a decrease in cognitive or motor function. With increasing dosages, inhibition of motor and cognitive functions as well as central nervous system depression does occur. Sufficiently high doses can induce hypnosis and coma.[40]

The most frequently used BZDs in critical care are midazolam and lorazepam.[22] (see Table 51.2). Lorazepam gives effective sedation and anxiety relief over a longer period than midazolam. Cardiovascular and respiratory effects occur less frequently with this drug than with other BZDs. It may also act synergistically with haloperidol, a neuroleptic agent. As with opioids, tolerance to BZD effects can develop in critically ill patients. BZD dependence is evidenced by symptoms such as dysphoria, tremor, sweating, anxiety, agitation, muscle cramps, myoclonus, and seizures on abrupt medication withdrawal.[40] BZDs should also be used with caution as they may be a risk factor in the development of ICU delirium.[40]

Propofol is a highly lipophilic IV sedative/hypnotic agent that has a very rapid onset of action and short duration (see Table 51.2). It is indicated for use in the ICU to control agitation and the stress response in patients who are mechanically ventilated and those who require deep sedation for procedures.[40] However, propofol has no analgesic properties and must always be used in conjunction with analgesics whenever the patient might experience pain. During initial use of propofol, a drop in systolic blood pressure, mean arterial blood pressure, and heart rate may occur in patients with fluid deficits and in those receiving opioids.[40] The short effective half-life of propofol allows rapid clinical evaluation of the patient's level of consciousness and determination of the minimum dose required for effective sedation. This may make it a useful drug during situations in which intermittent interaction with professionals and families is desired.

Dexmedetomidine is a potent, centrally acting alpha-2-adrenergic agonist that can be used for ICU patients requiring light sedation.[42] Even though this medication does have analgesic properties, most patients will require additional opioids for pain management.[42] Continuous infusions of dexmedetomidine have been associated with bradycardia and hypotension, whereas frequent bolus doses have been associated with hypertension. Due to side effects occurring from rapid bolus dosing, it may not be the preferred choice for patients with acute agitation.[42] In addition, because this medication is metabolized by the liver, it should be used with caution in those with liver disease.[42] Current pain, agitation, and delirium guidelines suggest the use of non-BZD sedatives, such as propofol and dexmedetomidine, as the preferred choice for sedation medications.[22]

Table 51.2 Pharmacological symptom management

Symptom	Drug type most frequently used	Method of administration	Usual dose[a]
Pain	Opioids (e.g., morphine, fentanyl, hydrocodone, methadone)	Continuous IV infusions with use of intermittent boluses for procedure-related pain or during treatment withdrawal	Continuous infusion: 1–10 mg/hr morphine equivalents
			Bolus: 2–5 mg IV morphine equivalent slow push; titrate to effect
Anxiety/ Agitation	Benzodiazepines (e.g., lorazepam, midazolam)	Same as for opioids	Continuous midazolam infusion: 1–20 mg/hr
			Bolus midazolam: 2–5 mg IV
			Continuous lorazepam infusion: 1–10 mg/hr
			Bolus lorazepam: 2–6 mg IV every 4–6 hours
	Haldol	IV boluses	Bolus: 0.5–20 IV
	Propofol	Continuous IV infusion	Continuous: 50–150 mcg/kg/min
Dyspnea	Oxygen	Multiple methods (e.g., nasal cannula, mask, ventilator)	Concentration as needed
	Opioids (e.g., morphine)	Continuous IV infusion and/or IV bolus; or per nebulizer	See above for IV doses
			Per nebulizer: 2.5 mg in 3 mL saline (preservative free) or sterile water q4h
	Benzodiazepines	See above	See above
	Bronchodilators (e.g., Alupent)	Per nebulizer	Alupent: 2.5 mL 0.4–0.6% solution
	Diuretics (e.g., Lasix)	IV bolus, slow push	Bolus Lasix: 20–40 mg IV
	Anticholinergics (e.g., atropine)	Per nebulizer	Atropine: 0.025 mg/kg diluted with 3–5 mL saline three or four times daily; doses not to exceed 2.5 mg

[a] Drug doses are general recommendations. Dosing should be individualized to a particular patient. Under usual circumstances, start with low doses, wait for effect, and titrate to desired effect.

Source: From References 17, 33.

It is important that patients in ICUs be routinely assessed for the presence of delirium using validated tools such as the Intensive Care Delirium Screening Checklist (ICDSC) or the Confusion Assessment Method for ICU (CAM-ICU).[16,33,38,43] Haloperidol is a frequently used neuroleptic for critically ill patients with delirium.[33] In one study, short-term prophylactic administration of low-dose intravenous haloperidol given to elderly ICU patients after noncardiac surgery led to a significant decrease in the incidence of postoperative delirium.[44] However, there is no published evidence that haloperidol actually reduces the duration of delirium.[22] This drug does have the benefit of fewer cardiovascular effects unless given rapidly, in which case vasodilation and hypotension may occur. Haloperidol does not depress respirations; rather, it has a calming effect on agitated, disoriented patients, making them more manageable without causing excessive sedation. However, haloperidol has some significant adverse effects, such as reduction of the seizure threshold, precipitation of extrapyramidal reactions, and prolongation of the QT interval leading to torsades de pointes.[33] Clinicians may try other atypical antipsychotic medications instead of haloperidol (e.g., olanzapine, quetiapine, and ziprasidone) in treating delirium with fewer side effects.[33] Recent guidelines suggest evidence that atypical antipsychotics may reduce the duration of delirium, but they do not prevent delirium in ICU patients.[22] More robust clinical trials are needed to justify the most appropriate pharmacological treatment of delirium.[33]

Nonpharmacological Interventions for Anxiety and Agitation

Numerous interventions exist that may promote tranquillity and sedation in a critical care environment. In a recent study, Chlan and colleagues reported that patients in a self-directed music group had a reduction in sedation frequency, intensity, and medication use when compared with patients with usual care.[45] The act of physically caring for a patient and providing gentle touch is a major source of comfort for patients in critical care. Taking the time to provide simple measures such as back rubs and massages, repositioning the patient, smoothing bed linen wrinkles, removing foreign objects from the bed, providing mouth and eye care, and taping tubes to maintain patency and inhibit pulling effectively promotes comfort and decreases anxiety. For alert patients, increasing opportunities for control is a strategy that can reduce the sense of helplessness that often accompanies patients who are critically ill. Finally, facilitating communication with clergy, psychologists, or psychiatrists, if appropriate, can help to alleviate the distress experienced by both patients and families.

Dyspnea Assessment and Management

Dyspnea is a subjective experience of feeling short of breath and is one of the most distressing symptoms that can be experienced by critically ill patients at high risk for dying.[33] The gold standard for assessing dyspnea is patient self-report. A 0–10 numerical rating scale can also be used to establish the intensity of dyspnea.[46] However, most critical care patients at high risk of dying cannot self-report and give a yes or no answer.[46] In this case, the Respiratory Distress Observation Scale (RDOS) is the only known tool to assess dyspnea in these patients.[17,33,46] Management of dyspnea in patients at high risk of dying includes oxygen therapy, opioids, BZDs, bronchodilators, diuretics, and anticholinergics (see Table 51.2).[17,33]

Other Distressing Symptoms

Puntillo and colleagues[16] are one of the few investigators studying the self-reported symptom experiences of ICU patients at high risk of dying. These investigators used a 10-item symptom checklist measuring both the intensity and distress of symptoms such as pain, fatigue, shortness of breath, restlessness, anxiety, sadness, hunger, fear, thirst, and confusion. Their sample consisted of 171 patients (mean age: 58 years; 64% male); 34% were mechanically ventilated, and 19% died during their ICU stay. The most prevalent symptoms included fatigue (75%), thirst (71%), and anxiety (56%). Symptoms lower in prevalence but reported to be moderately distressful by patients included shortness of breath, pain, confusion, fear, and sadness. This study demonstrated that a significant proportion of patients at high risk of dying in ICUs experience substantial emotional and physical symptoms.

ICU nurses play a major role in alleviating distressing symptoms experienced by patients at the end of life, especially thirst. Nurses can use topical dry mouth products containing olive oil, betaine, and xylitol.[17] In addition, a recent randomized trial reported that patients using a "bundle" of thirst interventions (sprays of cold water, swabs of cold sterile water, and mouth and lip moisturizer) had significantly decreased thirst intensity and distress when compared with patients in a "usual care" group.[47] Because nurses are constantly at the bedside, they can assess the presence of the multitude of symptoms patients experience, advocate for effective pharmacological therapy, use additional nursing comfort measures, and provide for continuity of therapy. Symptom management is a special contribution that ICU nurses can make to their patients at the end of life.

End-of-life Practice Issues: Withholding and Withdrawing Life-Sustaining Therapies

Limiting LSTs in the ICU is common. It is estimated that withholding or withdrawing of LSTs occurs in 50–84% of deaths in ICUs.[48,49] Generally, LSTs are withdrawn when death is believed to be inevitable despite aggressive interventions. The American College of Physicians (ACP)[50] supports the right of a competent patient to refuse LSTs. They also note that there is no moral difference between withholding and withdrawing therapy. In addition, critical care–related professional organizations have published position papers in support of the patient's autonomy regarding withholding and withdrawal decisions.[51,52]

If patients are unable to make treatment decisions, then these decisions must be made on the patient's behalf by surrogates or by the healthcare team.[53] When surrogates are asked to participate in decision-making, it is recommended that a family-centered,[54] shared decision-making approach be used.[53] Holding interdisciplinary family meetings is an effective way for families to arrive at decisions about the patient's goals of care and may help reduce the burden and distress they experience during this time.[55] Because problems with decision-making and communication deficits around EOL care are still frequent sources of conflict in the ICU,[56,57] having a guideline to follow for conducting family meetings (see Box 51.3)[58–60] as well as using various

Box 51.3 Useful Guidelines in Conducting ICU Family Meetings

Plan and Prepare

- Review the patient history, medical problems, and treatment plan to date.
- Coordinate who on the healthcare team will attend the meeting (should be interdisciplinary and include the attending MD, bedside RN, social worker, palliative care clinician(s), and other relevant healthcare team members).
- Discuss goals of the meeting with the healthcare team, confirm understanding of the plan of care, anticipate conflicts and challenges beforehand.
- Identify one team member as meeting leader.
- Discuss which family members will be present.
- Arrange a private, quiet location with seating for all.

Open the Meeting

- Introduce all in attendance.
- Provide a succinct summary in easy-to-understand language and allow families the opportunity to correct or provide missing information.
- Establish the overall goal of the meeting and elicit family goals as well.
- Acknowledge that this is a difficult time and situation.
- Set rules for the discussion (e.g., time frame for the meeting).

Elicit Family Understanding

- Ask questions of families and listen.
- As they respond, think about questions such as, What do they understand? What do they believe will happen? What are their emotions?

Identify Preferences for Decision-Making and Information Sharing

- Identify how families prefer to receive information and the level of detail they would like to receive.
- Assess the family's preference for their role in decision-making (this can range from letting the physician decide to the family member assuming all responsibility for the decision).

(*continued*)

Box 51.3 Continued

Give Information

- Give brief information (e.g., two points you really want them to understand) and allow time for family to ask questions.
- Avoid medical jargon and try not to talk too much or focus on technical matters.
- Be transparent about uncertainty.
- If the patient is dying, be sure to use the words "death" or "dying."

Respond with Explicit Empathy to Family Emotions

- Use the VALUE, Ask-Tell-Ask, and N-U-R-S-E mnemonics (see Table 51.3).
- Don't fight but rather join family statements of hopefulness, using wish statements (e.g., "I wish I could promise that things would get better. I hope he gets better soon, too").
- See if the family can hope for the best but prepare for the worst.

After Giving Information, Ask about Concerns and Questions

- "You just got a lot of information. What questions do you have?"

Elicit Patient and Family Values and Goals

- Ask about the patient's goals, values, and previous discussion about end-of-life care.
- Frame those wishes within the context of the current medical situation.
- Avoid asking family, "What do you think we should do?" Instead, ask what they know about their loved one's preferences and maintain focus on the patient's perspective.
- Identify pertinent cultural, ethnic, or religious beliefs that may influence communication, decision-making, family relationships, and concepts of death and dying.

Deal with Decisions that Need to be Made

- Make a recommendation based on patient and family goals.
- Time-limited trials with clear endpoints may make sense in certain clinical situations.
- Do not offer treatments that are inappropriate, as when the burdens outweigh the benefits.
- Do not speak of "withdrawing care." Affirm ongoing quality of care and reassure the family that care will never be withdrawn but that the focus of care may change.

Close the Meeting

- Offer a brief summary of what was discussed.
- Offer to answer questions and assure the family that the team is accessible.
- Check in to make sure the family heard what you wanted them to hear.
- Express appreciation and respect for the family.
- Facilitate referrals to support services.

communication approaches (Table 51.3)[59–61] may be helpful. In a current systematic review on family satisfaction with EOL care, investigators found that the use of palliative indicators such as quality communication, support for shared decision-making, and specific patient care measures resulted in increased family satisfaction with EOL care.[62] In another study, families reported significant improvement in satisfaction with care when they participated in interdisciplinary family meetings using a standardized approach to communication.[63]

Nurses in the ICU can be integral in family meetings and improving surrogate decision-making. One group of researchers reported that the use of a nurse as a family navigator was feasible and well received by both families and staff. This family navigator satisfied informational and emotional communication needs through daily contact using structured clinical updates, emotional and informational support modules, family meeting support, and follow-up phone calls.[64] Another group of investigators found that when nurses demonstrated concern, built rapport, demonstrated professionalism, provided factual information, and supported decision-making, families had more positive experiences. They reported that they had better coping, had hope, and had more confidence and trust in the ICU, and that it helped them make decisions and better prepared them for the impending death.[65]

When a decision to forgo LST is made in the ICU, there should be a concerted effort made to evaluate all therapies to assess whether these treatments could make a positive contribution to the patient's comfort.[38,66] Withdrawal of therapies should be preceded by chart notations of do-not-resuscitate (DNR) orders and a note documenting the rationale for comfort care and removal of life support.[49] There should be a clear plan of action and provision of information and support to the family.[67] Adequate documentation of patient assessments, withdrawal decisions and plans, therapy withdrawal orders, and patient and family responses during and after withdrawal is essential.[66]

Withdrawal of Ventilator Therapy with Consideration of Analgesic and Sedative Needs

It is important to understand the methods by which mechanical ventilation may be removed. Withdrawal of this treatment deserves the same clinical preparation as any other ICU procedure.[68] The primary goal during this process should be to ensure that patients and families are as comfortable as possible, both psychologically and physically. Two primary methods of mechanical ventilation removal exist: immediate extubation and terminal weaning (Table 51.4).[33,35,68] Debates continue as to which of these methods is optimal for the patient, and often the method is determined according to the physician's, patient's, or families' comfort levels.[69] However, in one study, Thellier and colleagues reported greater acceptance by families with immediate extubation before the death of their loved one in the ICU.[70]

Although there is considerable variability regarding the preferred approach to withdrawal,[38,54,66] recommendations regarding specific procedures for withdrawal are available.[71] Box 51.4 presents a protocol for withdrawal of mechanical ventilation for the clinician's consideration that includes specific recommendations regarding use of analgesics and sedatives.[33,35,38,66,68,71] One group of researchers found that, when using a standardized protocol for withdrawal of LSTs, 90%

Table 51.3 Helpful mnemonics for family meetings

Value Technique	NURSE	ASK-TELL-ASK
V—Value and appreciate what the family has said A—Acknowledge family emotions L—Listen to the family U—Understand the patient as a person through the family E—Elicit family's concerns and questions	N—Name "You seem distressed [or angry or worried, etc.]" U—Understand "This must be very difficult for you." R—Respect "I can see how much you are trying to honor your Dad's wishes." S—Support "We will be there to help advise you." E—Explore "Tell me more about what you are thinking/feeling."	Ask—the family to explain the situation in their own language Tell—the family the information the team needs to communicate (focus on 1–2 key points) Ask—Check for understanding, "What questions do you have?"

Source: From References 59–61.

of the patients were adequately sedated before and after withdrawal and fewer than 6% displayed symptoms such as terminal restlessness, death rattle, and stridor.[71]

It is important to provide comfort to dying patients who could experience pain and other distressing symptoms during withdrawal of mechanical ventilation. One group of investigators studying patients receiving morphine or morphine equivalents and BZDs prior to mechanical ventilation withdrawal reported that these agents did not cause unintended harm and shorten survival time.[71] In addition, patients should be withdrawn from NMBAs before withdrawal from life support.[38,66] The use of NMBAs makes it almost impossible to assess patient comfort; although the patient appears comfortable, he or she may be experiencing pain, respiratory distress, or severe anxiety. The use of NMBAs prevents the struggling and gasping that may be associated with dying but not the patient's suffering.[72] The withdrawal of these agents may take considerable time for patients who have been receiving them chronically, and patients continue to have effects from lingering active metabolites.[66]

Research to guide the practice of ventilator withdrawal and factors associated with withdrawal is limited. One group of researchers found wide variation among physicians on how and when LSTs were withdrawn. They found most used a sequential withdrawal process and preferred to withdraw forms of life support that are perceived to be scarce, expensive, invasive, or unnatural. They also found that the order of withdrawal typically included blood products, hemodialysis, vasopressors, mechanical ventilation, total parenteral nutrition, antibiotics, and intravenous fluids.[66]

Regardless of the processes used to withdraw LSTs, the critical care nurse plays a major role during the decision process and implementation of withdrawal of patients from mechanical ventilation. Specifically, the nurse can be an active member at family meetings where patient prognosis and goals of care are discussed. In addition, the nurse can ensure that a rationale for, and all elements of, the plan have been adequately discussed among the team, patient, and family. The nurse can ensure that adequate time is given to families and their support persons, such as clergy, to reach as good a resolution as possible.[67,73] The family needs reassurance that they and the patient will not be abandoned and that the patient will be kept comfortable with the use of medications and other measures.[54]

Table 51.4 Methods of mechanical ventilation withdrawal

Immediate extubation	Terminal weaning
Description	
Abrupt removal of the patient from ventilator assistance by extubation after suctioning (if necessary). Humidified air or oxygen is administered to prevent airway drying.	Physicians or other members of the ICU team (e.g., respiratory therapists, nurses) gradually withdraw ventilator assistance. This is done by decreasing the amount of inspired oxygen, decreasing the ventilator rate and mode, removal of positive end-expiratory pressure (PEEP), or a combination of these maneuvers. Usual time from ventilator to T-piece or extubation: 15–60 min.
Positive aspects	
Patient free of technology; dying process less likely to be prolonged; intentions of the method are clear.	Allows titration of drugs to control symptoms, maintains airway for suctioning if necessary, patient does not develop upper airway obstruction, longer time between ventilator withdrawal and death, moral burden on family may be less because method appears less active.
Negative aspects	
Noisy breathing, dyspnea may be distressful to patient/family.	May prolong dying, patient unable to communicate, machine between patient and family.
Time course to death	
Unpredictable. Usually shorter than with terminal weaning.	Unpredictable.

Source: From References 33, 35, 68.

Box 51.4 A Protocol for the Withdrawal of Mechanical Ventilation

I. Anticipate and prevent distress
  A. Review process in advance with patient (if awake), nurse, and family. Identify family goals during withdrawal (e.g., ability to communicate vs. sedation). Arrange a time that allows the family to be present, if they wish.
  B. Provide for special needs (e.g., clergy, bereavement counselor). Assess respiratory pattern on current level of respiratory support.
  C. Use opioids and/or benzodiazepines* to control respiratory distress (i.e., respiratory rate >24 breaths per minute, use of accessory muscles, nasal flaring, >20% increase in heart rate or blood pressure, grimacing, clutching). In patients already receiving these agents, dosing should be guided by the current dose.
  D. Discontinue therapies not directed toward patient comfort:
    1. Stop neuromuscular blockade after opioids and/or benzodiazepines have been started or increased.†
    2. Discontinue laboratory tests, radiographs, vital signs.
    3. Remove unnecessary tubes and restraints.
    4. Silence alarms and disconnect monitors.

II. Optimize existing function
  A. Administer breathing treatment, if indicated.
  B. Suction out the mouth and hypopharynx. Endotracheal suctioning before withdrawal may or may not be advisable depending on patient distress and family perception. There are no standard recommendations on the routine use of atropine (1–2.5 mg by inhalation q6h), scopolamine (0.3–0.65 mg IV q4–6h), or glycopyrrolate (1–2 mg by inhalation q2–4h) for excessive secretions. The use of these medications are individualized for each patient.
  C. Place the patient at least 30 degrees upright, if possible.

III. Withdraw assisted ventilation‡
  A. In general, the sequence should be individualized for each patient with comfort as the main goal§:
    1. Titrate down FiO_2
    2. If the patient is on assist control, change to pressure support
    3. Down-titrate pressure support 5–10 cm H_2O while maintaining RR <30
    4. Silence ventilator
    5. Deflate cuff and remove endotracheal tube (ETT)
    6. Suction excess secretions
    7. Turn off ventilator
  B. Mechanical ventilation should be withdrawn quickly with the goal to extubate to room air
  C. Constant reevaluation for distress is mandatory. A physician and nurse should be present during and immediately after extubation to assess the patient and to titrate medications. Treat distress with additional bolus doses of opioids and/or benzodiazepines as appropriate.
  D. Consider inhaled epinephrine for postextubation stridor in conscious patients.

[*] Drug doses are difficult to specify because of the enormous variability in body weight and composition, previous exposure, and tolerance. Opioid-naïve patients can be started on a bolus of 2 mg intravenous morphine titrated to effect. Patients receiving a continuous infusion of morphine can receive a bolus dose of 2 times the hourly infusion rate every 15 minutes. Patients receiving a continuous infusion of fentanyl can receive a bolus dose equal to the hourly infusion rate every 5 minutes as needed. If a patient receives 2 bolus doses in an hour of either morphine or fentanyl, it is reasonable to double the infusion rate.

[†] Usually the effects of neuromuscular blocking agents (NMBAs) can be reversed within a short period, but it may take days to weeks if patients have been receiving NMBAs chronically for management of ventilatory failure. Neuromuscular blockade masks signs of discomfort. Therefore, clinicians should feel that the patient has regained sufficient motor activity to demonstrate discomfort.

[‡] There is no one sequence applicable to all patients because the clinical situations are so variable. The pace of changes depends on patient comfort and may proceed as quickly as 5–15 minutes or, in an awake patient to be extubated, over several hours.

[§] Patients who require high levels of ventilatory support may die after small adjustments such as reduction or elimination of PEEP or decrease in FiO_2 to 21%. In such patients, the physician should be present during and immediately after the change in therapy to assess the patient.

Care for the Family of the Dying Intensive Care Unit Patient

Although the focus of care in many critical care areas is on the critically ill patient, nurses and other clinicians with family care skills realize that comprehensive patient care includes care of the patient's family. A family-centered approach to care is strongly supported by evidence-based guidelines.[54] Current research indicates that an ICU experience for families can be stressful (especially when their loved one dies in the ICU) and has been associated with symptoms of PTSD, anxiety, depression, and complicated grief.[74,75] "Family" is defined here as any significant other who participates in the care and well-being of the patient. Caring for ICU families encompasses major aspects of access, information and support, and involvement in caregiving activities.

Access

A crucial aspect of family care is ensuring that the family can be with their critically ill loved one. Historically, critical care settings have severely restricted family access and discouraged lengthy family visitation. Commonly cited rationales for this include concerns regarding space limitations, patient stability, infection, rest, and privacy; the negative effect of visitation on the family; and clinicians' performance abilities.[76,77] Some of these concerns have merit, whereas others, such as adverse patient-related issues and a negative effect on the family, have not been borne out in the literature.[78]

Many ICUs around the world routinely limit visitors to two at any one time.[79] Space limitations in critical care areas can be profound because most ICUs were designed for efficient use of life-saving machinery and staff and were not intended for EOL vigils by large, extended families. Ensuring that all interested family members have access to their loved one's bedside can present challenges to the often already narrow confines of the ICU. However, families of dying loved ones should be allowed more liberal access.[54] Patients are confronting what may be the most difficult of life passages, and they may need support from their families. Researchers assessed 153 families and 128 ICU nurses regarding their perceptions of unrestricted visiting hours in the ICU. The authors reported that families' satisfaction improved with the waiting room atmosphere, the convenience of visiting hours, and their interaction with the ICU staff. ICU nurses reported an improvement in keeping families updated about the patient's condition and also noted an improvement in families' satisfaction with care. However, nurses did report moderate interruptions to patient care.[78] Although healthcare professionals may feel that family visitation interferes with some aspects of patient care, the benefits far outweigh the risks.

Visitation of children should also be considered when a family member is dying. There is support for letting children visit the patient, become familiar with the care the patient is receiving, and allow them to understand what is going on.[54,80] Visitation has the potential to help the child cope and gives the child a chance to say goodbye. If ICU clinicians account for the child's developmental status and properly prepare the child, then children can visit a critically ill family member in the ICU without ill effects.[54,80]

Supporting family presence during invasive procedures and resuscitation is a practice supported by the Society of Critical Care Medicine.[54] Family presence during resuscitation and invasive procedures is an ethically sound practice, and ICUs should develop policies around offering this experience to families.[81] One group of researchers found that family presence during CPR significantly reduced posttraumatic stress disorder, major depression, and prolonged grief in families when compared to those who were not offered this option.[82] In addition, studies examining family presence have found that family presence may improve family satisfaction with care and improve family coping.[83]

Family presence may be stressful for healthcare professionals.[84] However, current literature reveals that family presence during resuscitation may help humanize the patient, improve communication, and help families with the grief process.[81] Currently, it has been recommended that hospitals establish formal programs that allow immediate families to be present during resuscitation. This program should include trained staff to support the family, assess the family for distress, educate the family regarding the process, and debrief after the process.[85]

Information and Support

Information has been identified as a crucial component in family coping and satisfaction in critical care settings.[62] Support, in the form of clinicians' caring behaviors and interactions, is enormously influential in shaping the critical care experience for both patients and their families.[86] In the context of caring for a critically ill, dying patient, however, nurses and physicians alike have reported high stress related to notifying families of the patient's death or terminal prognosis.[87] In general, very few healthcare professionals feel they have the skills and knowledge necessary to counsel families effectively during this emotionally charged time. However, a group of researchers designed a workshop to enhance critical care nurses' skills and confidence in discussing prognosis and goals of care with families and physicians. They found that, after the workshop, the nurses' confidence and skills in assessing families' understanding of prognosis and goals of care, addressing families' needs, and contributing to family meetings were significantly improved.[88]

Overall satisfaction with EOL care has been shown to be significantly associated with completeness of information received by families, support and care shown to the patient and family, consistency in staff, and satisfaction with the amount or level of healthcare received.[15] Interdisciplinary family conferences have been used extensively as a means to improve communication between healthcare professionals and families. Using best practices in relation to the timing, content, and participants necessary for optimal communication during a family conference have shown to lower emotional distress for families, maintain consistency with the patient's goals and values, and achieve consistent communication throughout the ICU stay.[62] Encouraging families to attend rounds has been shown to improve family satisfaction with the frequency of communication with physicians and in support with decision-making.[89] In addition, diaries may help lower distress for families. Researchers found that families who recorded a diary during their loved one's ICU stay had improved understanding of the medical information provided to them, felt a stronger connection with the patient, were able to maintain hope, and, finally, felt that diaries humanized the medical staff and the patient.[90]

Finally, because feelings of grief in surviving families are still commonly unresolved 6 months to 1 year after a loved one's death, many critical care units have organized bereavement programs.[91,92] These programs may involve providing a bereavement brochure, contacting the surviving family by telephone or mail, sending a condolence card, and holding a memorial service.[91,92] In addition to remembering and supporting the family, these programs have also been shown to help healthcare professionals cope with the loss as well.[93]

Involvement in Caregiving Activities

Few interventional studies have examined the effect of family involvement on critically ill patients and their families, yet families should have the opportunity to be helpful. One study qualitatively assessed the benefits of family caregiving. These families reported that caregiving allowed them to feel close to the patient and have confidence in the care the patient received.[94] Other researchers found similar benefits of family caregiving at the end of life. These authors reported that most families wanted to be involved in the direct care of the patient and that it would help bring them peace of mind after the death and help them feel needed and useful.[95] Acknowledging the contributions of families and involving them in caregiving activities can be beneficial. These activities can range from minor activities (such as assisting with oral care or rubbing the dying patient's feet) to major activities (assisting with post-mortem care). Nurses' facilitation of family involvement in their dying loved one's care is a practical family intervention that should be more widely employed if humane and comprehensive palliative care is desired.

Care for the Caregiver of the Dying Intensive Care Unit Patient

In a recent systematic review of compassion fatigue and burnout, numerous studies have described the tension and moral distress between the cure-oriented critical care setting and palliative care.[96] The nurse often feels caught between differing perceptions held by physicians and families concerning patient progress and treatment goals.[97] Facilitating and coordinating dialogue and consensus between these groups as well as caring for the dying patient and family can cause conflicts and can be physically and emotionally exhausting. If the dying process is prolonged, the nurse can become frustrated and fatigued. Although healthcare professionals often cope with this stress by emotionally disengaging themselves from the charged atmosphere, emotional distancing has been shown to hamper skill acquisition and the development of involvement skills and lead to burnout.[98] This section discusses two strategies to help healthcare professionals sustain their caring practices and extend their involvement skills: sharing narratives and death education.

Sharing Narratives

Debriefing has been used effectively in many settings to discuss and process critical incidents; analyze healthcare professionals' performance in terms of skill, knowledge, and efficiency; and learn, both personally and institutionally, from mistakes and system breakdown.[99] Sharing stories or narratives of practice can be used to achieve the same goals, but telling stories from practice also enables clinicians to (1) increase their skill in recognizing patient and family concerns; (2) learn to communicate more effectively with patients, families, and other healthcare professionals; (3) reflect on ethical comportment and engaged clinical reasoning; and (4) articulate clinical knowledge development.[100]

Death Education

Closely coupled with sharing clinical narratives is the use of seminars and other reflective exercises aimed at preparing nurses and other healthcare professionals for the care of dying patients and their families. Death education often consists of didactic and experiential classes. Participants in these classes are encouraged to reflect on and share their own perceptions and anxieties about death, as well as their attitudes toward care of the dying patient and his or her family. This approach has been used with varying degrees of success with nurses and physicians.[101,102] Because many healthcare professionals feel ill-prepared to effectively care for terminally ill patients and have also identified barriers to delivering quality EOL care, this strategy deserves more implementation and research.[103] Box 51.5 discusses key educational components in integrating palliative care into the ICU.[62,63,88,101,104]

Box 51.5 Key Educational Components to Incorporating Palliative Care into the ICU

- Educate critical care staff about palliative care (e.g., principles of shared decision-making, communication techniques, symptom management, and practices of withdrawal of life support) through lectures, workshops, pamphlets, teaching videos, simulation, role play, and poster boards.
- Train local ICU champions who can serve as role models and facilitate behavior change through half-day or full-day training sessions.
- Collect feedback on quality improvement data (e.g., families' satisfaction with care or families' ratings of the quality of death and dying).
- Utilize system supports and hospital resources to develop family informational pamphlets (e.g., "get to know me" posters for patients' rooms and developing withdrawal of life support forms).

Case Study: A Patient in the ICU

From: "I Was Afraid That There Was a Window and It Was Closing": Primary Palliative Care as Bridge to Transplant.

—Kathleen Turner, RN, BSN, CHPN, CCRN-CMC

Adult Medical-Surgical ICU, University of California San Francisco Medical Center

With acknowledgment and gratitude to the patient and family whose story follows, and who not only gave permission for it to be told but took time after leaving the hospital to tell it to me in their own words.

Seth Palmer was looking forward to going back to college in the fall, but was concerned about the fatigue, shortness of breath, and loss of appetite that only seemed to be getting worse. One night, Seth dropped down the rabbit hole of critical care as a spontaneous pneumothorax sent him to his local emergency department (ED), then on a 3-month journey from ICU to ICU. A lung biopsy indicated fibrotic nonspecific interstitial pneumonia. As it was unknown whether Seth's lungs would recover even with maximal medical therapy, he was moved to a regional transplant center for further management and workup.

When Seth arrived from the referring hospital, he reported insomnia, weight loss, severe pain, anxiety, and dyspnea. Palliative care became a central theme of his 3-month journey through critical illness. Seth and his family, particularly his mother Carol, were active partners. The Palliative Care Consult Service provided expert guidance on managing his challenging symptoms in ways that minimized impact to his fragile respiratory status.

On his first day in the ICU, Seth overheard a physician rounding outside the room saying "We're probably going to need to look at a trach." The following day, a person came in with a clipboard to get consent. Carol walked the physician out into the hall. "At this point, you're building trust and this is what is happening?" The trach went ahead, and more attention was paid to involving Seth directly in conversations and decisions regarding his treatment. Care conferences were held at the bedside. "They listened. They knew you brought something to the table. They gave credit for our contribution to the team." Clinicians prioritized work with speech and respiratory therapists in using a Passy-Muir valve on Seth's trach so that he could speak. For months, Seth most often communicated by writing on a white board, so these opportunities to have a literal voice were especially precious.

Traditionally, sedation and delirium have hindered ICU patients' attempts to communicate their symptoms, questions, and goals of care. Multiple disciplines collaborated on Seth's behalf to develop medication and ventilator support regimens to maximize his awake time during the day while promoting sleep at night. This proved to be tremendously challenging from the start and only became more so as time went on. He initially received dexmedetomidine infusion for sedation and fentanyl infusion with PRN boluses for analgesia. Dexmedetomidine was weaned off with assistance from an enteral clonidine taper. Fentanyl was transitioned to oxycodone. These changes seemed to exacerbate insomnia, so mirtazapine and melatonin were added at bedtime. Seth's worst pain was centered on the chest tube insertion site, so lidocaine patches were placed at that area.

Seth identified time with family and friends and opportunities to be creative as coping strategies that had worked for him in the past. The ICU volunteer team brought art supplies and visited him on days when fewer family members could make the 3-hour round trip to the hospital. Music therapy, animal-assisted therapy, and Spiritual Care Services were crucial in alleviating anxiety, promoting resilience, and transforming Seth's quality of life in the ICU. As Seth said later, "The music thing was HUGE. I was able to smile and the first time I felt like singing was when they brought in the guitarist." He looked forward to visits from Duke, Hank, and Smidge—the ICU's therapy cat and dogs.

Having clinicians come into his room rather than observing from the hall meant a lot. They were "looking out for the patients, looking in and acknowledging them when walking by." This was especially important at night, which Seth noted was a particularly scary time in the ICU. Other times, though, "it felt like I was in a viewing box and they were examining me as a patient not as a person—it was dehumanizing." Seth's ICU had a Continuity of Care (COC) program, in which nurses could sign up to be preferentially assigned to a particular patient with whom they had established rapport. Having these nurses for Seth improved all three domains of primary palliative care: symptom management, communication, and family support. These nurses carried the longitudinal memory of effective pharmacologic and nonpharmacologic measures and could identify opportunities for early intervention. As Seth reported later, "The continuity of care list—that was huge. . . . I was proactive in trying to get those nurses. I advocated for myself to get my COCs." For someone spending 3 months on a ventilator in the ICU, the value of having an opportunity to advocate for yourself is hard to overstate.

Seth described his focus during those early weeks as "getting better on my own. I was not considering a transplant, didn't even want to think about it." He had become very deconditioned already due to the steroids required for his pulmonary disease as well as profound dyspnea with exertion and difficulty maintaining adequate nutrition. "A lot of times I did NOT want to do it. I was so weak . . . it was really difficult . . . couldn't get out of bed. [The physical therapist] made a huge difference trying to get up." Seth's respiratory therapists worked with him on identifying which transport ventilator was easiest to breathe with during activity, as well as which modes and settings were most comfortable. During ambulation, staff would follow behind with a wheelchair so that he could pause to catch his breath mid-walk and then continue rather than cutting the session short. "Over time I could push myself further. To get physical again . . . to reclaim my body. To be able to go further, faster, seeing my body come back again was big." Physical and occupational therapists tried to stagger visits to permit rest in between sessions.

The Palmers continued to meet with the team. Their goal became "get better, go home and maybe down the line . . . a transplant." Oxygen and suctioning needs increased over the next 6 weeks. Additional chest tubes were placed as Seth's lungs repeatedly collapsed and were more resistant to re-expanding. The transplant team was checking in daily. While Seth was willing to consider transplant as a hypothetical distant possibility, that was as far as he could go. "I was the last one to get on board with that. Everyone was pushing me in their own ways." Carol was solidly in Seth's corner advocating for him no matter who came in the room. "I was pushing my agenda . . . I was afraid that there was a window and it was closing."

Seth's weight had dropped to 44 kg, too low for transplant even if he consented to have one. As Seth told one of his nurses, "I need to eat more but the thought of food grosses me out." Nausea made it difficult to keep food down. Promethazine and prochlorperazine were added with positive results. Family members were encouraged to eat with Seth and help him maintain as close to a regular diet as possible. Calorie count logs showed that food by mouth was not meeting his energy and protein requirements. A feeding tube was placed and enteral nutrition started. Oxandrolone was added and Seth's weight increased to 50.9 kg, bringing his BMI into the transplantable range.

As Seth's respiratory function worsened, his quality of life did as well. All teams and disciplines involved in his care looked to what could be done differently to improve each day. Around-the-clock acetaminophen and tramadol were added to the pain regimen. Oxycodone was initially weaned due to concern for respiratory depression but then restarted for pain refractory to all other interventions. This was eventually augmented with rescue fentanyl. Mirtazapine was increased and trazodone added at bedtime to promote sleep. During the daytime, Seth reported, "I felt really claustrophobic and anxious. The therapy dog really helped." Seth downloaded a mindfulness app onto his phone and worked with it each day. The Palliative Care Service chaplain and social worker led guided meditations. Seth continued to receive frequent visits from the hospital chaplain and Roman Catholic priest for prayer and sacraments.

Seth identified breathlessness as a key instigator of anxiety during this time. He had developed a chronic cough, which exacerbated his shortness of breath and placed him at increased risk for additional pneumothoraces. Gabapentin was added as an antitussive. The various teams involved in managing Seth's ventilator support worked with respiratory therapists, nurses, and Seth himself on setting a schedule of brief trach collar episodes with bracketing periods of bilevel positive pressure ventilation. Seth described the use of positive pressure ventilation, particularly at night, as being more comfortable than the trach collar. The speech therapist returned to work with him on using the Passey-Muir valve in line with the ventilator, so that he could still enjoy periods of speaking.

Physical therapy sessions became 5 days per week, twice per day. On the best days, this would involve ambulating in the hall with a walker, initially 25 feet but over time working up to 150 feet. Other sessions focused on core and upper body strength by sitting at the edge of the bed and using resistance bands. Diarrhea briefly made participating in physical therapy difficult, but resolved with changing to a non-soy-based enteral formula and starting loperamide.

Seth and Carol endorsed the impact of the ICU environment on his symptoms. Low lighting and therapeutic music were helpful, whereas the bright lights and frequent alarm sounds were stressful. “One of the biggest things to comfort me was adding that human factor in. My mom kept bringing things in . . . to make my room my own as much as it could be.” A favorite object was a Himalayan salt rock lamp, which cast a warm glow at night. Seth found a creative outlet working with Legos and his room became populated with a multitude of figures.

Staff had a profound influence on Seth and his family. “The biggest difference between a good nurse and a bad nurse to me is empathy. Treating me like a human being, like someone they knew—with respect, with love. They made conversation, made me laugh. They didn’t treat me like a specimen.” What this said to Seth was that he was still himself. Underneath the tubes and wires and problem lists and closing windows, he was a human being with a life. The trust that this team had missed on that first day had built over weeks of relieving suffering, supporting Seth and his family, and cultivating open communication. Eventually, “I told them—‘put me on the list’ and it all happened within a week.” It was a whirlwind final week, with Seth being emergently transferred from the medical to the cardiac ICU to be placed on extracorporeal membrane oxygenation (ECMO) and finally taken to the OR for his transplant. Throughout the big night, his family waited back in the medical ICU with the nurses who had hoped and prayed right alongside them for 3 months.

We are grateful to our colleagues on the Palliative Care team for everything they taught us that helped bring Seth successfully to transplant, and to our cardiac ICU and stepdown unit colleagues for their part in the rest of his story. Seth told many of his ICU caregivers that what matters is to be a source of support and inspiration to others. Hopefully in his story, as told here, there is something to bring back to your own practice to help the next Seth rise to whatever challenge he or she is facing.

Conclusion

Striving to relieve suffering from pain and other distressing symptoms and providing a dignified death is the right of all ICU patients. Research has offered some guidance for managing the issues that surround ICU patient deaths. However, Peden-McAlpine and colleagues[105] present important goals to consider during an ICU patient’s dying process: (1) honor the patient’s life, (2) ensure that the patient and the family are not abandoned, (3) provide a sense of moral stability, (4) ensure the patient’s safety and comfort, and (5) facilitate saying goodbye. Intensive care unit nurses can feel privileged to strive toward the accomplishment of those goals.

CHAPTER 52

Palliative Care Nursing in the Outpatient Setting

Pamela Stitzlein Davies and Kathleen Broglio

Key Points

- The ambulatory setting is an important site for the provision of palliative care as the majority of care for chronic life-limiting illnesses is provided in outpatient clinics.
- Nurses and advance practice registered nurses play a key role in the provision of palliative care in the outpatient setting.
- Studies show early involvement of outpatient palliative care in the setting of advanced illness can promote better quality of life, reduce emergency department visits and hospitalizations, promote earlier hospice enrollment, and may prolong life.
- Palliative care in the ambulatory setting is expanding from its initial focus on oncology to other disease settings such as cardiology, pulmonology, nephrology, neuromuscular diseases, and gerontology.
- *Primary palliative care* refers to the first-line management that should be a part of the management of any chronic disease. All nurses in the outpatient setting should be able to provide fundamental pain and symptom management and coaching in basic advance care planning.
- Involvement by palliative care specialists is appropriate for patients with complex pain and symptom problems, high levels of psychosocial distress, or unusual disease characteristics.

Introduction

The vast majority of healthcare in the United States is provided in ambulatory care clinics. Patients are living longer and with greater disabilities than ever before.[1] In addition to advanced cancer, other terminal diseases that are managed in ambulatory care include end-stage heart failure, chronic lung diseases, advanced cirrhosis, kidney failure, and terminal neurological disorders such as advanced dementia and amyotrophic lateral sclerosis (ALS).

Primary and specialty care providers are central in the care of these advanced illnesses, but they receive minimal training on end-of-life (EOL) care and are challenged to find the time to address these essential issues.[2,3] Nurses and advance practice registered nurses (APRN), with their extensive psychosocial training, and in conjunction with an interdisciplinary team, play an important role in helping ambulatory clinic patients and caregivers navigate concerns that arise as the disease progresses.[4] This chapter addresses the provision of palliative care in the adult outpatient setting, with a focus on the role of nurses and APRNs.

Key Studies in Outpatient Palliative Care

Although experts agree that the well-defined benefits of inpatient palliative care in terms of improving clinical care, quality of life (QOL), and healthcare utilization probably extend to the outpatient setting, research in this area is still in the early stages.[4,5] Rabow and colleagues summarized some of the seminal studies in outpatient palliative care.[5] The key findings of the studies were improved symptoms, improved patient and family satisfaction, increased survival in those with lung cancer, and decreased healthcare utilization.[5] Discussed here are some important studies in outpatient palliative care which utilized APRNs.

The landmark study by Temel et al. examined the effect of providing early palliative care to patients recently diagnosed with metastatic non–small cell lung cancer (NSCLC; which typically has a prognosis of less than a year) in a non-blinded randomized controlled study.[6] An APRN was part of the palliative care team.[7] The patients in the palliative care arm lived 30% longer than the control group (11.6 vs. 8.9 months) and reported better QOL with fewer symptoms of depression despite receiving less aggressive treatment. Patients in the palliative care group also enrolled in hospice earlier, thus benefitting from that service for a longer period of time.[6]

In a pilot study led by an APRN, Prince-Paul et al. examined the impact of palliative care in adults with advanced cancer in an outpatient oncology clinic. Those in the palliative care arm were 84% less likely to be hospitalized and 25 times more likely to be alive at 4 months compared to the usual care group.[8]

Murphy et al. analyzed the impact of an APRN-led service providing both primary care and palliative care in the outpatient setting at a large county hospital. They found a 27% reduction in use of emergency services and a 20% reduction in hospital admissions. Patients with dementia, heart failure, chronic obstructive pulmonary disease (COPD), and those who lived in adult family homes or skilled nursing facilities had the most significant reductions with this model. However, patients with end-stage renal disease (ESRD) and chronic noncancer pain had minimal changes in these two endpoints.[9]

Primary, Secondary, and Tertiary Palliative Care

Primary palliative care describes the role of each nurse, APRN, physician, and other healthcare provider in recognizing and addressing palliative care needs.[10] The ability to provide core palliative care competencies such as symptom management, advance care planning (ACP), and communication are essential skills in all primary care and specialty care settings because there will never be a sufficient number of specialty palliative care providers to meet all needs.[2,11] In this chapter, the term *primary clinician* is used to refer to the provider who directs the care related to the life-limiting illness. The primary clinician may be a primary care provider, oncologist, cardiologist, pulmonologist, neurologist, nephrologist, surgeon, or other provider.

As palliative care continues to evolve, the majority of services will be delivered in ambulatory settings over a longitudinal basis.[12] Thus, when a patient arrives in a pulmonary clinic for a posthospitalization visit after a COPD exacerbation, the nurse may inquire whether any discussions occurred regarding ACP and code status during the recent inpatient stay. Information on advance directives (AD) must be provided to patients at the time of admission, but the paperwork may not be completed. The pulmonary clinic nurse can assist with finalizing the AD forms during the clinic visit or request a social worker to meet with the patient and family. Another example of “primary palliative care” in symptom management is the oncology nurse who assesses the patient’s response to a bowel regimen for opioid-induced constipation and makes further recommendations based on an agreed upon treatment algorithm. Ambulatory care nurses and social workers also play a key role in providing education and support in the decision to transition to hospice care. In other words, every clinician fulfills a role in “primary palliative care” on an ongoing basis.

Secondary palliative care, also known as *specialist palliative care*, refers to the formal involvement of palliative care experts to assist with more complex cases.[13,14] Problems addressed may relate to complicated pain or symptom management, maladaptive coping and distress, or assistance with particularly challenging EOL situations. As outpatient palliative care expands into nononcology fields, such as cardiology or neurology, palliative care specialists must become familiar with the specific topics that arise in various fields. Some topics are common to all fields, such as ACP and discussing patient goals and preferences for care. Other topics are unique to a specialty, such as decisions regarding cessation of dialysis in the patient with ESRD, organ transplant decisions, or initiation of advanced heart therapies such as left ventricular assist devices (LVAD) as a destination therapy.[11]

Tertiary palliative care describes major palliative care programs usually located in academic medical centers with a focus on research and teaching to advance the specialty and may include a palliative care fellowship program.[10]

Models of Care

Three basic models exist in the delivery of outpatient palliative care: collaborative, consultative, and medical home.[10] The *collaborative* model (also known as embedded, integrated, or concurrent model) is the most popular style found in the outpatient setting and has been utilized extensively in the oncology setting.[3,14] In this model, the palliative care team takes the lead in managing certain aspects of care, such as writing prescriptions for management of pain and symptoms, counseling for existential distress, and facilitating goals of care discussions, thus allowing the primary clinician to focus on the overall management of the patient’s disease condition. An advantage of this model is that it combines “the best of both worlds,” with specialists from both fields contributing to personalized care and working together to improve QOL in distinct, yet complementary roles.[15] Embedded clinics, discussed later, create the opportunity for a shared visit with the clinician, thus improving communication and coordination of care. This model is usually more convenient for the patient, especially if palliative care visits are on the same day and location as another clinic appointment. However, it creates special challenges for the scheduling of palliative care visits for this coordination.[16] The palliative care team must foster a good relationship with the referring clinician and be flexible and willing to work within the framework of the individual clinician’s style of practice.[10]

In the *consultative* model, the palliative care provider evaluates patients and forwards management recommendations to the team for implementation. The palliative care team does not actually implement the recommended plan of care (such as initiation of an antidepressant and a referral to psychology), nor does it typically follow patients on an ongoing basis. Consequently, this model suffers from a lack of follow-through on the palliative care recommendations. Rabow found a low percentage of patients had their plan of care implemented when utilizing a consultative model in a primary care clinic to address pain and depression, among other issues.[5] Nonetheless, patients showed improved scores on multiple measures, indicating that the consultative visit had an impact even if the recommendations were not instituted by the primary clinician.

The final model of care in outpatient palliative care is the *medical home model* (defined in the literature as the “primary palliative care” model, but this is different from the same term discussed earlier). In addition to managing typical palliative care issues, in this model, the palliative care team functions as the “medical home” or “primary care provider” and addresses *all* aspects of the patient’s care, from management of the life-limiting illness (such as liver failure) to other chronic conditions such as hypertension and osteoarthritis.[3] This model is excellent for medically underserved populations, high utilizers of medical services, and those in adult family homes.[9] The clinician must have a broad knowledge base and access to specialists for formal or informal consultation. In many ways, this model is comparable to services traditionally provided by general practitioners for decades.[3,13]

Benefits and Challenges Faced in the Outpatient Setting

The ambulatory setting is ideal for providing palliative care, as the pace is less crisis-driven than inpatient care, and patients can benefit from long-term trusting relationships that form with the medical team over months and years. These factors permit dialogues regarding ACP and the patient’s goals of care to be held over a series of visits. The clinic setting provides the opportunities for patients and families to work together with the palliative care team to develop plans for future care.

Presence of an outpatient palliative care team can assist with seamless transitions between inpatient and outpatient care to address ongoing supportive care needs in both settings.[13] Early involvement of palliative care in the outpatient setting may improve

QOL, reduce emergency department visits and hospitalizations, reduce healthcare costs, and reduce inappropriately aggressive care in late-stage illness, while promoting transition to hospice enrollment in a more timely manner.[5,6,9] Although more research is needed, the results of several studies suggest that early involvement of outpatient palliative care may have a survival benefit when compared to usual care in the oncology setting.[6,8]

Many challenges faced in the outpatient setting are common to palliative care teams in any setting, such as receiving late referrals (when a patient is actively dying) and funding issues.[3,5] Determination of prognosis is a challenge with any life-limiting illness, but is particularly difficult for those with heart failure, COPD, renal failure, and dementia, making the timing of hospice referral uncertain.[17–19] Other issues are specific to the outpatient setting, such as coordinating outpatient palliative care visits with the primary team's appointments. Providing seamless coordination of care with the primary clinician takes time, which may present a challenge for teams with limited personnel. Likewise, the ability to provide a 24-hour on-call presence is usually limited to larger services.

A unique issue faced by some outpatient palliative care programs is referrals for management of chronic pain not related to the primary diagnosis (e.g., chronic low back pain requiring opioid therapy in a patient with a curable leukemia) or ongoing management of chronic pain in a cancer survivor years after completion of therapy.[3] Because most outpatient palliative care programs focus on patients with life-limiting illness, the long-term management of complex chronic pain problems may be beyond the parameters of what a palliative care team can offer and may decrease the availability of practitioners to see new consults.

Practical Details in Providing Palliative Care in the Outpatient Setting

Many questions arise when developing or expanding an outpatient palliative care program. This section will address common issues in implementation of palliative care.

Team Members

The outpatient palliative care team may range from a single part-time nurse to a fully staffed interdisciplinary team working in a wide range of outpatient settings and with clinic appointments available daily. In a survey of 20 outpatient palliative care programs in a variety of practice settings, 19 clinics utilized physicians, 10 sites had APRNs, 14 had registered nurses, and 12 had social workers.[3] Other palliative care team members may include chaplaincy, pharmacy, nutrition, and rehabilitation medicine staff such as physical, occupational, or speech therapists.[20] Inclusion of a social worker in the outpatient palliative care team may increase the rate of AD completion, in addition to providing psychosocial support.[21]

Palliative Care Referrals

Leaders in oncology, cardiology, and pulmonology recommend palliative care involvement for those with serious illness.[22–24] Although such widely inclusive referral criteria are ideal, they are probably not realistic due to limitations in palliative care resources. The National Comprehensive Cancer Network (NCCN) guidelines on palliative care list a broad range of referral criteria, but a strategy is needed to identify those most in need of a referral to secondary- or tertiary-level palliative care specialists.[25,26] Glare and colleagues developed a screening tool for palliative care referral in an outpatient gastrointestinal oncology clinic based on the NCCN palliative care guidelines. By the broadest criteria, *all* patients seen in that clinic met the threshold for a referral to palliative care.[27] Instead, the authors suggest screening for distinctive palliative care needs at the initial visit, posthospitalization, and every 6 months thereafter. In a quality improvement project at a National Cancer Institute (NCI) cancer center, the Edmonton Symptom Assessment Scale was utilized in the oncology clinics to measure symptom burden as a trigger to palliative care referral. The implementation increased referrals from 1 per month to 10 per month with the use of this tool. However, the authors noted that the referral rate remained low despite the reportedly high symptom burden in many patients.[28]

Referrals to outpatient palliative care also depend on multiple factors unique to the individual provider, clinic milieu, and organizational setting. In a profile of four outpatient palliative care programs, Smith reported the following referral sources: inpatient palliative care service (10–50%), oncologist (20–60%), and primary care provider (20–30%).[3] Other referral factors include the needs and expertise of the referring clinician's access to supportive care services in the referring clinic (such as a social worker), percentage of patients in the practice with complex needs, and availability of palliative care clinicians. Close physical proximity to the referring clinician appears to play a major role in generating consults.[10,16] However, each referring clinician has different evaluation criteria for who would benefit most from employing the palliative care team.[29] Triggers for referral may be based on diagnosis, symptoms, or psychosocial factors.[26]

The results of a qualitative survey at three academic cancer centers identified oncologist barriers to referrals. The three reported barriers were the mistaken belief that palliative care was not compatible with cancer therapy, the belief that palliative care should be provided by the oncologist, and knowledge deficits of local resources.[30] Thus, palliative care referral patterns may be influenced by many factors, and there is a continuing need for education and work to improve collaboration and appropriate referrals. Box 52.1 lists common criteria for a consult to outpatient palliative care.

Establishing an ongoing referral base is important when building and maintaining a palliative care outpatient practice. The embedded palliative care practice model creates the most referrals, especially if the team can see a new consult soon after, or even concurrently with, the referring clinician to assist with "bad news" discussions, complex treatment decisions, or complicated symptom management.[10]

Embedding palliative care in a clinic associated with high symptom burden and psychosocial distress allows for palliative care concerns to be addressed promptly.[10] Examples of such models exist at several major medical centers with multidisciplinary clinics treating pancreas cancer, breast cancer, or heart failure. Patients who would benefit from palliative care intervention, such as those with metastatic malignancies, uncontrolled pain or symptoms, or significant psychosocial distress are identified during the case discussions with the entire team. The palliative care provider meets the patient that same day, as part of the multidisciplinary clinic's "package" of visits, with follow-up visits as needed. This embedded model is favorably viewed by patients, caregivers, oncologists, cardiologists, and medical center administration while increasing palliative care visibility

Box 52.1 Some Suggested Referral Criteria to Outpatient Palliative Care

Patient/Symptom Characteristics

- Poorly controlled pain, or other symptoms
- Limited treatment options, or declining functional level, accompanied by significant distress
- Frequent hospitalizations
- Diagnosis of highly fatal malignancies, such as metastatic non–small cell lung cancer, glioblastoma multiforme, metastatic pancreas cancer, or esophageal cancer
- Malignancies associated with high symptom burden, such as pancreas cancer
- Brain or leptomeningeal metastasis, spinal cord compression
- Anticipated poor outcomes, such as elderly patients with acute myelogenous leukemia, or pretransplant for a "high-risk" stem cell transplant
- Enrollment in a Phase I or Phase II chemotherapy trial
- Patient election for advanced heart therapies or preoperative for left ventricular assist device (LVAD)
- Decisions regarding feeding tubes or tracheotomy for neuromuscular diseases such as amyotrophic lateral sclerosis (ALS)
- Patient election to forego or discontinue renal dialysis
- Complex symptom management or decision-making in end-stage cardiac, pulmonary, renal, hepatic, or neurological diseases

Psychosocial Circumstances

- High levels of psychological, social, or spiritual/existential distress
- Poor social support
- Inability to engage in advance care planning discussions
- Family discord in decision-making
- Requests for hastened death

and generating ongoing referrals.[5] Use of palliative care rounds, such as the Schwartz Rounds, in which complex patient cases are discussed, are other sources to generate referrals.[31]

In most settings, a formal medical provider referral is required as a billing requirement for an initial consultation. However, in one NCCN oncology center, any clinician—including nurses, social workers, physical therapist, and chaplains—can refer to outpatient palliative care, and many referrals are initiated by nursing. Nurses form close relationships with patients over months and years of cancer therapy and frequently have in-depth discussions about coping with disease and uncertainty. If the patient experiences worsening symptoms or distress that is not well managed at the primary palliative care level (e.g., nurse or oncologist level), the team nurse may request palliative care involvement for expert assistance. Additionally, patients are allowed to self-refer to palliative care in that setting.

Timing of Outpatient Palliative Care Referrals

The literature supports early referral to outpatient palliative care to have the best effect.[6,24] In a comparison of early versus late referrals, early palliative care predominantly provided in the outpatient setting resulted in improved quality outcomes, less intense medical care, and lower cost; whereas late palliative care referrals were mostly delivered in the hospital setting and were associated with higher medical costs.[32] Unfortunately, many referrals to outpatient palliative care are late in the disease trajectory, when hospice referral is more appropriate.[26] This makes outpatient palliative care consultation less effective, although there are concerted efforts to move outpatient palliative care referrals "upstream" for greater benefit.[5]

New Patient Referrals

When receiving a palliative care referral in the outpatient setting, it is important to ascertain several key points.[16]

- First, *what is the purpose of the consult?* If the referral only indicates, "palliative care, evaluate and treat," it is helpful to speak with the referring team to ask what specifically triggered the request for this patient. Are there signs of maladaptive coping with progressive disease? Is the caregiver insisting on aggressive treatment when the patient desires to stop therapy? Is the patient experiencing ongoing severe symptoms despite standard treatment? A few minutes spent clarifying the consult can help the palliative care team determine the appropriateness of the consult and better understand the situation.
- Second, *what is the urgency of the consult?* Should the consult be scheduled immediately, or can the initial palliative care visit be held when they return for the next outpatient clinic visit in a few weeks? An important observation is that what is deemed urgent by the referring source may not appear urgent to the palliative care team, or even to the patient.[10] For example, the patient may express high levels of distress to the team, asking for help as soon possible, but then decline to schedule a next-day appointment with the outpatient palliative care team.
- Third, *is the patient and caregiver aware of the consult?* Even if they are aware, it is surprising how many perceive the palliative care referral as abandonment and ask the scheduler: "Is this how Dr. Jones is telling me he's given up on me?" Therefore, the scheduler has an important task when setting up the initial visit, which is to explain the purpose of palliative care involvement. If there appears to be any confusion or hesitation, the referring team should be notified and asked to assist with communication regarding the referral.

The wait-time from referral to first outpatient palliative care appointment is ideally less than 2 weeks, with urgent consults seen earlier if possible.[3] This may be a challenge for many programs due to provider staffing limitations. If the palliative care physician or APRN schedule is filled and an urgent consult cannot be accommodated, a palliative care nurse, if available, may assist by assessing the patient's needs in person or by phone and make recommendations to the primary provider until the patient can be scheduled with the outpatient palliative care provider.

Maintaining a Good Relationship with the Referring Provider

Success in providing outpatient palliative care in the collaborative model requires maintenance of positive relationships with the referring clinician, the team nurse, and other team members.[16,29] It may be helpful to think of the referring provider as the "customer" and palliative care as the service they are "buying." Close communication and a respectful approach are key, along with negotiation of "who does what" in patient care.[16] For example, opioids for pain management and cough are prescribed by the palliative care service, but the oncologist prescribes 3 days of steroids to reduce chemotherapy-induced nausea with each cycle. It is important for the supportive care team to respect the provider's specialized skills, acknowledging that he or she has known the particular patient for years, even decades. In addition, it is helpful to recognize that the referring clinician, as the "captain of the ship," may feel a bit threatened when referrals to palliative care are generated by another source, especially if he or she perceives that symptoms and distress are well managed.[16] Direct voice-to-voice communication with the primary team should be a priority if major issues arise, such as the patient requests to discontinue disease-directed therapy and enroll in hospice. Although this coordination of care can take a significant amount of time, such coordination may help maintain positive relationships, avoid misunderstandings, assure future referrals, and optimize patient-centered care.

Because there are many drug interactions with disease-directed therapies, especially in oncology care with the emergence of immunotherapy, it is incumbent upon the supportive care team to consult with the team pharmacist or pharmaceutical references before writing new prescriptions. This will prevent serious drug interactions (e.g., methadone, ondansetron, and citalopram all cause QT prolongation) and will highlight the contraindication of use of certain medications with certain therapies (such as avoiding acetaminophen in the immediate posttransplant setting because it will mask a fever). In centers with ongoing clinical trials, it is essential to check with the research team to ensure that any new medications (such as antiemetics) are not contraindicated by the study protocol.

Components of the Palliative Care Visit

Patients dealing with serious illness have many needs impacting multiple domains of suffering. Determining which issues to address at the initial outpatient palliative care visit depends on the needs identified by the patient and the stated purpose of the consult (e.g., symptom management, assistance with goals of care), as well as by the specialty of the supportive care clinician (chaplain vs. a pain specialist).

Three key domains are the focus of most outpatient palliative care visits: (1) pain and symptom management, (2) addressing psychosocial and spiritual needs, and (3) discussing future care decisions.[6] At the initial visit, the palliative care provider introduces the palliative care team's role, shares the referring provider's consult request, and asks the patient what are the most important issues he or she would like addressed during the visit. Thus, the palliative care provider addresses the patient's priorities as well as the referring provider's, with additional issues deferred to follow-up visits.

Length of Palliative Care Visits

The literature indicates a variety of visit lengths for outpatient palliative care, but a key consensus is that providing palliative care takes time, and quality care cannot be rushed.[5] Initial visits generally range from 60 to 90 minutes and follow-up visits from 30 to 60 minutes.[3] However, many clinicians discover that returning patients often need as much time as patients at the initial visits.[16] This is because disease progression leads to an increase in the number and intensity of symptoms, news of progressive illness creates worsening distress, and EOL decision-making becomes more of a priority. In addition to the patient visits, a significant amount of palliative care time is spent in coordinating care with the specialty clinician, which may take 5–15 minutes before and after each visit.[20] Such coordination helps to synchronize treatment approach, delineate roles, and maintain a strong relationship with the primary clinician.

Clinical Measures Utilized in Outpatient Palliative Care Visits

A variety of instruments are utilized to gather research data during palliative care clinic visits.[6,33] These fall into the major categories of functional scales, global symptom scales, pain scales, psychological and social measures, spiritual assessment, and QOL scales.[20] However, it is not clear which measures are optimal for use in everyday clinical (nonresearch) practice. Use of an assessment measure is optimal; one study found a 10-fold increase in reported symptoms with a formal tool as compared to open-ended questioning by a provider.[34]

The following scales are commonly used in ambulatory palliative care clinical practice:

- Edmonton Symptom Assessment Scale[35] (ESAS; a global scale of distressing symptoms, such as pain, fatigue, appetite, anxiety)
- Memorial Symptom Assessment Scale-Short Form[36] (MSAS-SF; a global scale of distressing symptoms, includes assessment of "distress or bother" for each item)
- Brief Pain Inventory, Short Form[37] (BPI-SF; which includes pain intensity; word descriptors; pain interference with activity, mood, sleep; and a body diagram)
- Patient Health Questionnaire[38] (PHQ; depression screening)
- Distress Thermometer (screening for psychosocial distress; recommended for all patients by the National Comprehensive Cancer Network)[39]

Many clinical practices use a standardized template for palliative care consultation and follow-up visits. The *Serious Illness Conversation Program* has been studied in eliciting patients' preferences for care[40] and can be included as part of the history-taking and charting template to provide an evolving source of information for goals of care discussion.

Funding the Outpatient Palliative Care Program

A practical aspect of clinic viability is the need to secure sources of ongoing funding. Billing revenue is insufficient for ambulatory palliative care programs to become self-sustaining, especially for APRN-led clinics, due to lower reimbursement rates for nonphysician providers.[10,21] Most clinics require institutional support to survive.[3] Other sources of funding include philanthropy, private foundation support, and research grants.[13]

Management by telephone is a major aspect of the provision of outpatient palliative care. Although these calls can make the difference between a patient remaining comfortably at home, rather than making a trip to the emergency department, data on such cost avoidance are difficult to capture.[41] Thus, in some settings, the palliative care team may be challenged to find unique methods to demonstrate to leadership that the palliative care nurse role makes a difference and is not simply another salary expenditure. This may be easier to demonstrate in a managed care setting in which emergency department visits, hospitalizations, and rehabilitation care are paid by the same healthcare system.[2,3] More research is needed to support the cost benefit of outpatient palliative care, especially for the nonreimbursable costs of nursing, social work, and chaplaincy.

Telephone Support and Patient Education

Providing patient support via the telephone is a key function for the palliative care nurse. Prior to the initial visit, the nurse may clarify the role of the palliative care team and the purpose for the referral, then followup after the visit to check on symptom management and distress and to address any concerns. Telephone visits are a source of patient education, encourage adherence to the plan of care, and provide emotional support.

Offering patient education is a core component of nursing care and is a significant focus for the supportive care services. Topics of education may include strategies to address worsening pain and distressing symptoms, tips to improve sleep, steps to reduce anxiety, or methods to prevent and manage constipation. Preparing written materials on these topics will streamline the educational process and is a useful resource for patients and caregivers at home.

Outpatient Palliative Care Needs in Selected Disease States

Palliative care has been most widely studied in the oncology population. However, as the specialty grows, there is an increasing acknowledgment that palliative care, whether primary or specialty, may be beneficial in other disease states. In this section, a brief overview of select disease states that are managed in the outpatient palliative care setting is highlighted.

Oncology

Palliative care has an increasing presence in the ambulatory cancer setting.[13] The 2010 Temel study, with its astonishing findings of improved survival rates and improved QOL despite decreased use of chemotherapy and earlier hospice referrals, firmly established the essential role for outpatient palliative care.[6] Early referral to palliative care for those with a new diagnosis of advanced cancer is recommended by the American Society of Clinical Oncology.[24] Addressing complex pain and symptom management is a frequent consult request for the palliative care team, in addition to assisting with goals of care discussions, EOL planning, and managing psychosocial distress.[11] With the emergence of revolutionary immunotherapies, determination of prognosis has become less dependable in some oncology specialties, such as melanoma, renal cell carcinoma, non-small cell lung cancer, and certain hematological malignancies, thus impacting recommendations and care options during goals of care discussions.[19]

A particular area of need for palliative care services is for patients enrolled in phase I or II oncological studies. Patients tend to have unrealistically high expectations from the investigational agent to achieve a cure or significant improvement in disease control. Most do not understand that the purpose of a phase I study is to determine a drug's safety in humans and a phase II study is to determine safe dosing ranges, but not necessarily trialing more effective therapies. Patients and families often face crushing disappointment when the "new miracle cure" does not work. For this reason, all patients enrolled in phase I or II studies should be offered a referral to outpatient palliative care.[42]

Cardiology

Almost 6 million people in the United States live with heart failure.[22] The course of heart disease is not predictable, and people may experience many exacerbations and hospitalizations prior to death, but about 50% will die within 5 years of diagnosis.[22] Additionally, the prognosis and course have changed due to the increased use of advanced heart therapies.

The American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines for the management of heart failure recommends palliative care for patients with advanced heart failure.[45] In addition, The Center for Medicare and Medicaid Services (CMS) has recommended ACP and involvement of palliative care for those patients who will have LVADs implanted as destination therapy.[46] The Joint Commission also mandates involvement of palliative care for those cardiac centers seeking advanced certification in these therapies.[47] Recognizing that palliative care specialists may not be available in many ambulatory areas, leaders recommend that cardiology practitioners become proficient in providing primary palliative care.[45]

Palliative care in heart failure is a growing field. In a recent, randomized controlled clinical trial, patients who received palliative care in addition to usual care (in both inpatient and outpatient settings) had improved QOL, less depression and anxiety, and improved spiritual well-being. In this study, a certified palliative care APRN coordinated the care in collaboration with a palliative care physician and the cardiology team.[51] In a smaller Canadian study of embedding palliative care into the heart failure team, patient and family satisfaction was improved and there was an increase in ACP.[52] Palliative care was embedded in a heart failure clinic at a large medical center, and, in a retrospective chart review, pain management and ACP were the top two issues addressed, followed by other symptoms often seen in the oncology population. The authors concluded that embedding palliative care in cardiology was feasible.[53] In another study of early palliative care in heart failure conducted at two different medical centers in the northeastern and southeastern United States, patients received an outpatient palliative care consultation followed by nurse phone calls. In this pilot study, patients had improvements in QOL and symptoms and some improvements in hospital stays, intensive care unit admissions, and emergency department visits; however, there were significant differences between the sites in terms of enrollment and attrition, which will necessitate thoughtful application when implementing these programs' processes.[54] Although palliative care in heart failure is in its early stages, experts have concluded that establishing relationships, working with the primary cardiology team in ACP, and providing support and symptom management may benefit those heart failure patients who have complex needs. Additionally, primary palliative care delivered by cardiologists may be the way to move the care upstream (earlier) in the disease trajectory, resulting in improved QOL.[55,56]

Patients with advanced heart failure often experience problematic symptoms secondary to the side effects of the therapy, in addition to disease-related symptoms, and may benefit from the expert symptom management provided by palliative care. Goals of care and EOL care planning can be unique in this population as some patients may utilize intravenous therapies (such as dobutamine and milrinone) to manage symptoms.[57] Even if patients are eligible for hospice, many hospices cannot afford to maintain the patient on intravenous therapy in the home, and there is no consensus as to when to discontinue such therapy.

LVADs are used in two clinical settings: as "bridge therapy" (BT-LVAD) for patients awaiting a heart transplant or as "destination therapy" (DT-LVAD) to extend life and improve symptoms. DT-LVAD was approved in 2003 for those who are not candidates for heart transplant, have severe and worsening heart failure, a life expectancy of less than 2 years, and meet other criteria.[43] As of December 2016, more than 22,000 people have been implanted with LVADs, with half of those implanted for destination therapy by 2015.[44] Recent data indicate that DT-LVAD therapy prolongs life by 15–22 months, with 70% surviving to 24 months in some studies.[44] However, many patients experience significant adverse effects including strokes, bleeding, infection, and device malfunction.

Use of a comprehensive palliative care team (APRNs, physicians, nurse, social worker, and chaplain) is beneficial to increase meaningful understanding of ACP for patients scheduled to receive LVADs. One study found that use of a palliative care consultation style focusing on "preparedness planning" increased family awareness of the importance of ACP prior to LVAD placement and may have influenced EOL decisions.[48]

Although the majority of patients with an LVAD die in the hospital, usually in the intensive care unit,[49] the outpatient palliative care team can assist with preparatory discussions regarding decisions for EOL care. These conversations, which may occur in both inpatient and outpatient settings, include discussions about discontinuation of LVADs and the ethical dilemmas that may surround discontinuation since some clinicians[48] or family members[50] may equate discontinuation of this therapy as euthanasia or suicide. In a survey of 303 clinicians' attitudes toward withdrawal of LVAD support for those approaching end of life, 46% had discontinued LVAD support in two or more patients. Only 26% felt comfortable with discontinuing LVAD support, and 13% considered LVAD discontinuation physician-assisted death.[48] In semi-structured in-depth interviews with bereaved caregivers, 6 of 8 considered LVAD discontinuation as suicide, and one caregiver described discontinuation as murder.[50]

Timing of transition to hospice is impacted in communities where hospice nurses are not familiar with the care of patients with LVADs and may result in a delay in hospice enrollment. The palliative care team can collaborate with the cardiology and local hospice agencies to ensure proper education, including protocols for discontinuation of DT-LVAD therapy.[50]

Another area in which outpatient palliative care can play a crucial role is for those patients with pulmonary hypertension who are not candidates for lung transplant and who require intravenous therapies. In an Internet-based survey, patients reported poor QOL, fatigue, decreased social well-being, and pain. Patients were satisfied with their providers' care of the disease, but not QOL management, and few had been seen by palliative care[58]; thus, an opportunity to improve care exists in this population. Goals of care and EOL care planning can be unique in this population. Most hospices cannot afford to maintain the patient with pulmonary hypertension on the unusually expensive intravenous therapy. Thus, if hospice enrollment is delayed because of intravenous therapy use, outpatient palliative care will be instrumental in managing care until end of life in these cases.

Pulmonology

Chronic lower respiratory diseases are the third leading cause of death in the United States.[59] People with chronic lung disease, such as COPD, may have a longer estimated survival than those with cancer, but they often have severe symptom burdens similar to those with lung cancer.[60] In a retrospective case series of an outpatient palliative clinic for those with COPD ($n = 36$), the topics addressed included ACP, symptoms such as dyspnea and fatigue, and social and psychologic concerns. These patients had significant comorbidities and high symptom burden that had not been addressed prior to a palliative care consultation.[61] Like cardiac disease, these illnesses are chronic and are often marked with exacerbations, hospitalizations, a decline in function over time, and an uncertain prognosis. As the disease progresses, patients face choices about the use of noninvasive or mechanical ventilation. In a study of pulmonologists in the Netherlands, there was no consensus about when to refer to palliative care. The pulmonologists indicated the need for ACP, the need for identification of the "palliative phase," and the need for communication with the primary care providers.[62] Phillip and colleagues, through the evaluation of qualitative and cohort data, formulated recommendations for palliative care delivery for COPD in Australia.[63] They recommend triggering a palliative care consultation during clinical transitions, regardless of symptoms or prognosis, and embedding palliative care into the ambulatory care setting. The tasks defined for the palliative care team were similar to those seen in other disease states—symptom management, support for patient and family, and goals of care decisions.[63] Although there is limited research, based on findings from other disease states, palliative care integration into the ambulatory setting may improve symptom management and QOL for those with advanced pulmonary illnesses.

Nephrology

By the end of 2016, more than 700,000 people had ESRD, and almost 500,000 people with ESRD were undergoing renal replacement therapy (dialysis) in the United States, and more than 100,000 are older than 75 years.[64] People with ESRD often have significant symptoms and comorbid conditions affecting QOL. Although research is still needed, there is a growing awareness of the need to integrate palliative care into this population.[65,66] A major decision in ESRD is whether to initiate or discontinue dialysis. In a study that analyzed survival in patients older than 70 years with ESRD who either chose renal replacement therapy or conservative therapy, those older than 80 who had multiple comorbidities and received renal replacement therapy did not survive longer than those who chose conservative management. Seventy-six percent of those in the conservative management group received palliative care services compared to none in the renal replacement group. Those receiving palliative care were less likely to be hospitalized or die in the hospital.[67] Thus, even though the research in nephrology is still in its nascent stages, outpatient palliative care involvement may improve symptom management and QOL while addressing goals of care and ACP needs.

Neuromuscular Diseases

Those living with ALS have a vital need for supportive care services. ALS is a life-limiting illness in which ACP and goals of care are essential as patients must face decisions related to initiation of enteral feeding and, ultimately, respiratory support. Although experts agree that palliative care involvement is recommended, the integration of it is variable.[18,68] Palliative care specialists partnering with patients in shared decision-making should possess knowledge about the issues unique to this population to best assist with complex decision-making and symptom management.[69,70] For example, early placement of a feeding tube is preferred as a means to improve QOL by maintaining hydration and nutrition, and noninvasive positive-pressure ventilatory support is the standard of care, rather than invasive mechanical ventilation.[69]

The integration of palliative care may be best accomplished by embedding a palliative care specialist in the clinic as patients often come for half-day sessions to see all the specialists involved in their care (neurology, rehabilitation medicine, occupational and speech therapy) as a way to conserve the patient's energy. Neuromuscular disease is an ideal setting to provide enhanced primary palliative care. Nurses and APRNs working in ALS clinics may seek additional education and certification in palliative care, thus creating the ability to address the disease-specific needs as well as palliative care needs of this unique patient population.

Gerontology

The baby boom generation is aging. According to the Center for Disease Control and Prevention (CDC), every day between 2011 and 2030, 10,000 persons are turning 65-years-old in America.[1] By 2030, one in five (20%) adults will be an elder. This unprecedented wave of older adults, known as the "Silver Tsunami," will have a significant impact on palliative care in the ambulatory setting. Goals of care decisions may be complex in the geriatric setting, in which high symptom burden is juxtaposed with increased risk of poor outcomes, decreased tolerance to physical stress of procedures, and limited life expectancy[71,72]

Consults to the outpatient palliative care team may be generated with the initial diagnosis of dementia to assist with complex ACP. These deliberations are important to have in the early stages of debility, when a patient still has decisional capacity and can clearly state his or her wishes.[73] The American Geriatrics Society has a variety of publications applicable to palliative care specialists, including a position statement on the use of feeding tubes in advanced dementia.[74]

When working with elders, it is essential to provide individualized care and not make assumptions about preparedness for death based on age alone. For example, a 94-year-old patient is deemed too frail to undergo a transcatheter aortic valve replacement (TAVR) for improved QOL.[75] Despite being quite old, news of this decision may abruptly thrust the elder into existential crisis by a sudden realization of advancing age, frailty, and approaching death. Compassion and sensitivity by the palliative care team will aid with coping and encourage completion of needed preparations for eventual demise.

Managing Opioid Analgesics, Benzodiazepines, and Other Controlled Substances in the Outpatient Palliative Care Setting

Opioid analgesics, benzodiazepines, and stimulants are essential for pain and symptom management in palliative care. Given the high utilization of these medications in advanced disease, especially in oncology, healthcare teams have an obligation to institute strategies to maintain safety and prevent abuse and diversion in order to ensure ongoing and appropriate access to these vital pharmacological therapies.[76] Although some may question the necessity for screening and monitoring of patients on controlled substances in the palliative care setting, it is clearly needed given the current epidemic of opioid-related deaths in America.[77,78]

In 2016, 29 million (or 1 in 10) Americans ages 12 or older used an illicit drug within the previous month surveyed, and more than 20 million people in the United States had a substance use disorder (SUD).[79] Importantly, patients with cancer screened for substance abuse risk had similar risk characteristics as those with chronic nonmalignant pain,[80–83] with estimates that 1 in 5 cancer patients are at risk of opioid use disorder.[84] Additionally, more than 65% of persons who abuse opioids bought, took, or were given them from family members or friends with a legitimate prescription.[85] Such diversion may put the patient at risk for inexplicably running out of medications early and developing acute opioid or benzodiazepine withdrawal.[86]

When a person with a current or former SUD develops a life-limiting illness, it is not uncommon for maladaptive coping strategies to emerge. "Chemical coping" is a term used to describe those who use opioids or other substances to try to deal with the stress associated with diagnosis or progression of disease.[87] In a prospective study of 432 patients with advanced cancer, 18%, or nearly 1 in 5, were diagnosed as chemical copers.[87] An additional form of prescription drug abuse involves patients or caregivers selling their prescription drugs as a means to supplement lost income due to illness. Medications that are not stored safely, such a partially used fentanyl oralet, may expose children or pets to overdose death. Because of the abundance of opioids, benzodiazepines, and stimulants in the outpatient palliative care setting, strategies are needed to assess and monitor patients receiving these drugs.

Universal precautions in pain medicine is a strategy advanced by Gourlay and Heit for chronic noncancer pain and is based on the concept of universal precautions used in infectious disease.[88] Similarly, every person receiving an opioid or other controlled substance should be screened for risk of drug misuse and regularly monitored. Such screening does not imply that a person with a history of drug abuse cannot receive opioid therapy to manage pain or dyspnea. Rather, these are tools to help to identify those who would benefit from additional safety monitoring, and informs the prescribing process.[89,90] Components of universal precautions include assessment of risk for substance misuse, informed consent, treatment agreements, urine drug screening, and review of the state prescription drug monitoring program. These guidelines have been successfully adopted in outpatient palliative care clinics.[80,82] Patients and caregivers are more accepting of screening and monitoring when informed that they are universally applied, "just like TSA screening at the airport." Nurses play a key role in assisting with the patient screening and follow-up in terms of tracking analgesic use and educating patients on safe use, storage, and disposal of opioid analgesics.[91,92] See Box 52.2 for additional details on universal precautions when prescribing controlled substances. Table 52.1 provides example guidelines for using risk stratification to determine the intensity of monitoring that may be required in the outpatient palliative care setting.

Treating cancer-related pain with multimodal analgesia is the foundation for safe and effective pain management and has been recommended by leaders in cancer care.[93,94] Nurses can be strong advocates for inclusion of nonpharmacological and complementary therapies to manage pain, anxiety, and insomnia as an alternate to relying only on controlled substances.[95] Alternate therapies are especially important considerations in the growing geriatric population, who have a narrow therapeutic window of safety with controlled substances.[96,97]

Finally, the highly publicized epidemic of opioid-related deaths in America has made many patients even more fearful of utilizing prescribed opioids for the management of pain from advanced cancer or other conditions. Nurses in the outpatient palliative setting are in a strategic position to educate patients on the appropriateness of using opioids to manage pain from a life-limiting illness.

Conclusion

This is an exciting time of momentum in the field of outpatient palliative care. As the discipline grows and matures, attention is turning toward clinics with large numbers of patients with serious illness such as cardiology, pulmonology, nephrology, neurology, and geriatrics. The imperative of reducing healthcare costs can be positively impacted by outpatient palliative care in reducing emergency department visits and hospital admissions and readmissions.

Because there are more patients than can be seen by the limited palliative care resources, use of screening methods should be utilized to identify those who are in the greatest need of referral. For the remainder, clinicians and nurses must learn the skills for providing primary palliative care in the outpatient setting.

Nurses play an important role in the provision of outpatient palliative care, with research showing that nurses and APRNs provide much of the staffing in these settings. Nursing skills are well-adapted for issues commonly addressed by the palliative care team. With additional training in programs such as End-of-Life Nursing Education Consortium (ELNEC), every nurse can indeed become a palliative care nurse.[101]

Box 52.2 Best Practices for Opioid and Other Controlled Substance Prescribing in Outpatient Palliative Care

Practice universal precautions: All palliative care patients receiving opioids and other *Controlled substances* should be approached using these criteria.

1. Utilize a screening tool (such as the Opioid Risk Tool [ORT][99] or Screener and Opioid Assessment for Patients with Pain—Revised [SOAPP-R][100]) to identify individuals at increased risk for drug misuse or abuse.
2. Review the state prescription drug monitoring program (PDMP) before each prescription for a controlled substance.
3. Complete a patient-provider treatment agreement to clearly delineate expectations.
4. Consider urine drug testing at baseline and at least annually thereafter.
5. Specify maximum daily or monthly usage (e.g., "maximum 3 tabs per day," or "must last 30 days") or inclusion dates on the prescription.
6. Consider prescribing naloxone for emergency home reversal of opioid overdose, per CDC guidelines, when the prescribed morphine equivalent daily dose is more than 50 mg/day.
7. Continue to evaluate risks at each visit because they may change over time.
8. Educate patient and family about safe storage, administration, and disposal.
9. Educate patient and family on what to do in the event of adverse side effects from opioids.

Case Study: A Patient with an LVAD

Ron was a 56-year-old single man who lived a comfortable life in a large city. He worked in the arts and had an active social life. He was independent and had many acquaintances but no significant social support. He had a small family, with only a sister who lived across the country. He had survived testicular cancer that afflicted him in his early twenties. Ron did not attend to his medical care and was completely unprepared when he suffered a myocardial infarction and developed severe heart failure. He was told he needed a heart transplant and that LVAD implantation would improve his symptoms while he waited for the transplant. Prior to the LVAD implantation, he met with the palliative care APRN and social worker. He completed his advance directives and made plans to continue visits with the palliative care team as he was experiencing significant psychosocial distress. Six months after the LVAD transplant, Ron began experiencing indigestion, back pain, and weight loss. After multiple visits to the emergency department, he underwent a scan, which showed a pancreatic mass with liver involvement. Life again changed for him as he now had to deal with the fact that he had an incurable cancer and that he would never have a heart transplant. After meeting with the oncology team, he agreed to start chemotherapy, but quickly

Universal screening of all patients			
Baseline screening at first or second palliative care visit.	1. PDMP review 2. SOAPP-R 3. Calculate and document MEDD 4. Controlled Substances treatment agreement signed, scanned, original to patient 5. Urine drug testing 6. Risk stratification determination.		
Criteria for risk stratification	Clinically assessed low risk, SOAPP-R ≤ 9, and MEDD <100 mg	Clinically assessed medium risk, SOAPP-R 10-21, or MEDD ≥100 mg	Clinically assessed high risk or SOAPP-R >22
Risk stratification potential for opioid misuse	Low ("standard")	Medium	High
Palliative care social worker participation in care	Provider discretion	Joint visit provider and social work at next appointment and at future visits as needed	Joint visits provider and social work at all future visits
Additional monitoring and consultations	Provider discretion	Provider discretion	Consider additional consult services (addictionology, psychiatry); additional monitoring at provider's discretion
Follow-up visit (minimum frequency)	Every 1–3 months	Every 1–2 months	Every 2 weeks until adherence is established, then minimum of every month thereafter
UDT (minimum frequency)	Annually	Every 6 months	Every 3 months
PDMP	Before each visit and each Rx renewal	Before each visit and each Rx renewal	Before each visit and each Rx renewal
MEDD calculation	Every visit	Every visit	Every visit
Pill count	Optional	Consider, random	Consider, random or every visit
Naloxone nasal spray[a]	Consider offering prescription (based on comorbidities)	Consider offering prescription	Offer prescription
Pain diary[b]	Optional	Optional	Yes

MEDD, morphine equivalent daily dose; PDMP, prescription drug monitoring program; SOAPP-R, Screener and Opioid Assessment for Patients with Pain—Revised[100]; UDT, urine drug testing.

[a] Naloxone nasal spray per CDC guidelines, to emergently reverse opioid overdose in the home setting, indicated for those receiving morphine equivalent daily dose of 50 mg or higher and for individuals at higher risk of opioid overdose at lower MEDD.[77]

[b] Used to track patient use of *as needed* opioid doses.

developed worsening symptoms. The palliative care APRN and social worker worked to manage his increasing symptom burden. Ron developed increased despair as he became more limited in his activities and ultimately decided to forego further chemotherapy. He was conflicted because, although he knew he could decide to discontinue the LVAD therapy, he was afraid to end his life in this manner. His sister came to visit and also felt helpless to provide care. The palliative care team met frequently with them to provide support and work on EOL care planning. Ultimately, Ron went to live in a residential hospice facility. The palliative care team initiated support from the cardiac team to train the hospice nurses in the care of the LVAD until Ron's death. The multispecialty coordination, championed by the outpatient palliative care team, allowed for improved symptom management for Ron in his final days and weeks of life.

CHAPTER 53

Palliative Care in the Emergency Department

Rebecca Wright and Benjamin Roberts

Key Points

- Palliative care is still an evolving specialty in the emergency room (ED), requiring further research and development of tailored, interdisciplinary training and education programs and care processes.
- Research has demonstrated that safe and effective delivery of ED-based palliative care is possible, with growing numbers of tools and models to support care delivery and goals of care conversations.
- Community-based nurses and other healthcare professionals involved in referring patients with palliative care needs to the ED should encourage use of advance directives or documented care plans to support shared decision-making and treatment congruent with patient wishes.
- Once in the ED, assessments for patients with long-term, incurable conditions should also address palliative care needs, including social, spiritual, and family needs.
- An ED visit can provide an opportunity to identify unmet or exacerbated palliative care needs for patients and families.

Introduction

The emergency department (ED) is not typically associated with palliative care. The traditional model of "resuscitate, stabilize, transfer" is seemingly at odds with the holistic, in-depth approach of palliative care. This is emphasized by the use of ED visits and acute care utilization as an indicator for poor outcomes and failures in coordinated, community-based care.[1] However, despite efforts to reduce ED visits and return visits by improving provision of palliative care in community settings, a significant number of people with palliative care needs continue to visit the ED in times of crisis, viewing it as a "safety net."[2] Further complicating matters are the growing complexities of caring for an aging population with comorbidities, meaning that some ED visits may be due to underlying, complicated palliative care needs.[3]

The ED serves as the gateway for access to healthcare for many people, and there is a growing consensus that it can and should play a vital role in the provision of palliative care.[4] Despite many challenges, the ED represents a place of safety and refuge in times of crisis. People with complex and unpredictable conditions, along with those who may struggle to access healthcare due to financial challenges and inequalities in healthcare access, particularly benefit. Nurses have a responsibility to work with the ED and support ED clinicians to provide palliative care in what often represents the most distressing times of illnesses.

This chapter presents the epidemiology of palliative care patients who use the ED and reviews the main barriers to provision of ED-based palliative care, drawing on published examples of patient and clinician experiences. These barriers are addressed by outlining facilitators to ED-based palliative care including new models, approaches, and tools. The role of the ED within the wider healthcare context of palliative care is emphasized. To illustrate the challenges for clinicians caring for palliative care patients in the ED and how to address them, a three-part case study will be presented with practice-based discussion points.

Epidemiology: Incidence, Prevalence, Causes

There are limited data regarding the incidence and nature of ED patients with palliative care needs, along with a lack of a uniform definition of palliative care in the ED setting. This presents a challenge in generalizing a clear concept of the ED patient with palliative care needs.[4,5] For example, numerous site-specific studies present a wide variety of information regarding the demographics and characteristics of ED patients with palliative care needs, including gender, race, and disease.[4] A small body of qualitative research exploring the experiences of palliative care patients seen in the ED identified common themes triggering visits (see the section "Needs and Experiences of the Palliative Care Patient"). These included uncontrollable symptom burden and inability to cope at home[6] and inability to access or lack of access to community-based care services.[2] Lack of access to care and financial reasons were noted particularly for minority populations in the United States.[7] In some cases, patients were directed to the ED by their community providers, for example, cancer patients receiving chemotherapy in response to a spiking temperature.[2] The notion of the ED as a safety net in times of crisis was raised by patients with some relief, but with the caveat that there was also no alternative.[2]

Patients admitted to the ED who then receive palliative care consultation present with a wide variety of traits and conditions. It is critical to reach consensus about these traits in order to identify palliative care needs and provide timely care.[5] This is particularly important given an increasing usage of the ED by patients with palliative care needs.[4] Complicated factors must be addressed; for example, data suggesting different conditions, such as cancer and chronic obstructive pulmonary disease (COPD), have different drivers for ED visits, different palliative care needs, and report different experiences.[2,6]

Still, studies suggest certain trends, such as a common need for symptom management and life-prolonging interventions.[4] Green et al. (2016) found that, within a large urban hospital, the leading causes of ED visits by people with palliative care needs were shortness of breath and pain. Other common complaints included falls, neurological symptoms, nausea and vomiting, fever, dehydration, diarrhea, and fatigue.[8] However, a clear distinction was made to differentiate between these presenting symptoms and the "underlying palliative conditions," such as cancer, COPD, and dementia.[8] Not all palliative care admissions are from complicated causes; in some cases, the reason for the visit are classified as a "palliative emergency"; these are instances occurring in patients with an incurable condition that will lead to death or decreased quality of life (QOL). Common palliative emergencies include uncontrolled pain, acute dyspnea, hemorrhage, hypercalcemia, acute anxiety, and acute loss of function.[9]

Some of these trends span continents. For example, a high incidence of cancer-related health problems, as well as age greater than 60 years, was found to be common across a rural setting in New Zealand and an urban academic medical center in the United States.[10,11] Taken together, especially in light of increased ED utilization in the final 12 months of life, the palliative care needs of the ED patient emerge.

Drawing this information into the first of a three-part case study, Part 1 highlights the issues outlined in a common ED visit from a patient with underlying palliative care needs. The barriers and facilitators to integration of palliative care in the ED are introduced.

Case Study: A Patient in the ED–Part 1

MB is a 72-year-old Spanish-speaking woman who presented to the ED from home in respiratory distress, with a chief complaint of shortness of breath. Her past medical history revealed COPD, right-sided recurrent pulmonary effusion with repeated episodes of pneumonia, left ventricular heart failure (LVHF) with right ejection fraction (rEF) to 15%, poorly managed type 2 diabetes, arthritis to bilateral knees and hands, depression, and chronic severe pain to the lower back. MB lives with her husband of the same age, who was able to help her with basic activities of daily living (ADLs) but was often too weak or exhausted to manage his own health issues as well as his wife's. MB could afford to be visited once a week by a home health aide who was able to assist with medical management, daily cares, and provide some degree of emotional support to both MB and her husband. Most days, however, errors were made in her medication regimen, hygiene was minimal, and MB felt "too frail and depressed" to pursue her lifelong passion of photography. Most days, she did not go outside. She has had five visits to the ED over this past year, which was an increase from three the previous year and only one the year prior.

In the ED, her SaO_2 began to rapidly decline, and she became tachypneic, tachycardic, and hypotensive. The ED providers ordered multiple large-bore intravenous placements, bolus fluids, stat blood gasses, and 100% nonrebreather facemask. MB was afraid, in tremendous pain, confused, and felt unable to speak. Her husband had not yet arrived, and there were no advance directives (ADs) in place. A chest x-ray revealed right-sided pneumothorax and possible pleural effusion. A chest tube was inserted emergently at bedside, and both fluid and air escaped. Only 5 cc of a local analgesia was administered subcutaneously—no systemic pain control was considered. As the team discussed emergent intubation, her SaO2 began to stabilize at roughly 90%, her breathing became less labored, and she became more alert and calmer.

Discussion Points

Barriers to palliative care:

- Adequate care at home for frail individuals is expensive and often unavailable, leading to loss of ability to accomplish daily tasks and participate in activities of passion and enjoyment and increased depression.
- The standard ED model focuses on life-saving care, paying less attention to alleviating suffering and increasing QOL.
- There are no advance directives in place to speak for the patient when the patient cannot speak for herself and her proxy is not yet present.

Ways to integrate palliative care:

- In the case study, notice the recent increase in visits to the ED in the past year. Each ED can pay careful attention to frequent visits, particularly for patients suffering from life-limiting illness, and create automatic triggers for palliative care referral and delivery for these patients.
- Every visit to the ED is an opportunity for education about advance directives and advance care planning. No one near the end of life need leave the ED for the fifth time in 1 year without a documented patient-centered care plan.
- If emergency procedures such as chest tube insertion are to be carried out, the administration of sufficient systemic and local analgesia can be prioritized for the patient with palliative care needs.

Barriers and Challenges to ED Palliative Care

Having outlined the triggers for an ED visit and demonstrated the need for a palliative care-prepared ED, the following is a discussion of the issues that prevent high-quality palliative care delivery. It is important to understand these barriers for effective integration of palliative care into the ED. Current barriers include, but are not limited to, the traditional ED model of care delivery and care processes, the physical environment, and changes in the clinical presentations of the population served by the ED. Patient, family caregiver, and clinician experiences are also reviewed because an understanding of their perceptions enables better understanding of how to tailor strategies and implement new models of care to address issues specific to palliative care populations.

The Current ED Model

The ED is a time-sensitive environment, influencing hospital admission and discharge rates and serving as the gateway to healthcare for many people in times of crisis.[12] The current ED emerged from the "casualty" model employed on battlefields, where saving lives was the focus.[13] While there are many successful stories of ED-based palliative care,[14,15] the ED model of care still largely retains the "triage, resuscitate, stabilize, transfer" approach. The "resuscitate, stabilize" focus poses a challenge to ED clinicians when caring for patients with complex needs who require a more holistic and broader assessment.[5] Even when faced with palliative emergencies, ED clinicians require an understanding of the underlying trajectory and plan of care to conduct necessary conversations with patients and families and rapidly focus or refocus treatments.[9] Clinicians require training and education to refocus on symptom control and QOL over life-sustaining measures. As discussed later, this can be acutely distressing for ED clinicians who can feel they are not "doing enough."[16]

The ED model extends to the physical environment, and here, too, there are challenges for delivery of palliative care. In line with the need for practical and immediate, unplanned emergent care, the majority of EDs are brightly lit and contain different treatment areas according to severity of patient need (e.g., minor and major injuries and resuscitation). Even in modern EDs, space is often limited and lacking in privacy.[17] High patient numbers, distressing conditions and sounds, and a constant flow of patients and staff result in a noisy environment. The ED functions as a streamlined department in which its clinicians are highly trained and operating within routines and standardized procedures. However, to many patients, particularly those who are more vulnerable, the constant movement and noise can make it appear chaotic and unorganized.[17] This can exacerbate tensions and concerns for palliative care patients and families whose needs may be prioritized below other more obviously acutely ill patients.[16,18] Indeed, some palliative patients report feeling that they are competing for attention against other patients (see the section "Needs and Experiences of the Palliative Care Patient").

Palliative Care–Specific Patient Complexities

"Traditional" ED patients can be classified as those experiencing "spectacular" medical or surgical crises (e.g., myocardial infarction, shortness of breath, road traffic accidents, falls, and other injuries).[18] However, advances in healthcare delivery, treatments, and improved QOL have seen people living longer with multiple conditions.[19] Some community programs and resources are available but, as highlighted, people may not be connected to them or are unable to access them.[8] As a result, ED clinicians increasingly care for patients with "subtacular" needs.[18] Coined by Bailey, subtacular patients in the ED include those with end-of-life (EOL) or hospice care needs, nontraditional palliative emergencies, and complex psychosocial needs as people approach the end of life.

Clinicians also need to be careful to retain an individual, holistic approach, recognizing different patterns across conditions. Patients with cancer may be more likely to attend the ED having tried alternative routes first, whereas people with COPD may be more likely to bypass other services and seek out emergency care, ensuring that they carry pertinent information with them.[6] Additional complications for ED clinicians trying to identify palliative care needs include multiple conditions, different condition trajectories, and underlying palliative needs not immediately identified in the presenting complaint.[11] In many of these cases, a major barrier is the lack of preexisting clinician–patient relationships.[18] When faced with complicated family relationships and patients with varying degrees of cognition, clinicians may struggle to identify patient goals and preferred care. Many clinicians avoid these complex discussions with patients.[18] Furthermore, use of ADs is not systematically employed, meaning that patients may not have participated in advance care planning or may not know to alert ED clinicians to the existence of this information. This and other gaps in communication between patient, family, and provider lead to worsened outcomes and conflict surrounding life-sustaining interventions (see the section "Clinician Training and Perceptions").[16]

Needs and Experiences of the Palliative Care Patient

Palliative care research and services aim to support patients and families by identifying and working to meet their goals and preferences. However, there are limited data exploring ED-specific preferences and experiences. This is likely due to the inherent ethical and practical challenges of conducting palliative care research with a vulnerable population in a challenging environment.[20–22] To date, a small number of qualitative studies have sought to explore patient and family caregiver perspectives. Studies reflect a global interest in the patient experience, providing findings predominantly from the United Kingdom,[6,21,23] the United States,[15,24–26] and Australia.[2] Interestingly, the ED structure is consistent across numerous countries and healthcare systems, with similar patient-family experiences reflected throughout.

Patient and family experiences in the ED and their reactions to palliative care measures fall broadly into "positive" and "negative" categories, with patients expressing a mixture of "anxiety, uncertainty and relief."[2] Clinicians sending patients to the ED or admitting and caring for them should be aware that the ED can be seen as either a place of reassuring assistance or a regretfully unavoidable outcome.[21] The ED environment, in addition to being challenging for delivery of palliative care, has also been cited as hectic and overwhelming.[2] Factors increasing uncertainty are particularly distressing, such as long wait times and a lack of clarity regarding referral processes and navigation between settings.[6,16] Some patients and family caregivers noted that ED care focused more on diagnostics than on symptom management.[2] Patients who recount positive experiences of using the ED when experiencing palliative care needs highlight "soft skill measures," such as communication about wait times and ED processes that were impactful in reducing anxiety.[6,21] Given that symptom control is a major reason for use of the ED, this is a key area for staff training and education in palliative care assessment. Indeed, it may be beneficial to introduce palliative care measures, such as consults or other supportive measures, during long wait times to alleviate distress and promote progress with care planning.[6]

When palliative care was provided, the integration of care sometimes caused concerns when ED staff lacked the training to implement specific measures (e.g., higher medication doses and more frequent administration of analgesics).[16] When reflecting on ED-initiated referrals to palliative care services or seeing palliative care clinicians in the ED, patients and families had varying responses depending on their familiarity and understanding of palliative care.[27] Prior knowledge of palliative care meant less concern. General misunderstandings of palliative care can lead some patients to relate it directly to EOL care and a sense of "giving up."[27]

Notably, patients with palliative care needs or certain conditions (such as cancer) may see themselves as being different from other patients due to the severity of their conditions.[27] Coming to the ED meant they needed help but did not mean they wanted all possible treatments.[6] Clinicians should note that this emphasizes the need and opportunity for shared decision-making.[28] Often patients were dealing with their reactions to the intense environment of the ED in conjunction with the changes in their physical condition and personal lives. When considering goals of care, ED clinicians can be mindful that palliative care patients and family caregivers are grappling with multiple changes. The ED visit may often represent unplanned or unmanageable changes in condition, capacity, or disease trajectory, thus triggering further anxiety.[21] Patients with cancer or older patients were most concerned about the potential implications of the ED visit (death, irreversible decline),[6,29] whereas patients with COPD were more likely to find the environment reassuring and be more familiar with the documentation needed to ensure appropriate care.[6]

The implications affect both the patient and the informal caregiver. Clinicians should include caregiver needs as part of their assessment, not least because of their pivotal role as a major source of support and reassurance.[2,21] This role is emphasized in the ED, where caregivers often help maintain a sense of normalcy for the patient.[6] Thus, while the ED may represent a decline in condition or caregiver capacity to cope at home, the visit provides opportunity for assessment of caregiver burden and referral to support or palliative care services while acknowledging and validating their role.

Clinician Training and Perceptions

Clinician buy-in is essential if palliative care is to be routinely offered in the ED. Palliative care ED training and education for physicians has been developing since the implementation of co-certification in palliative and emergency medicine in the United States in 2006. Importantly for nurses, there is still no standardized certification in ED-based palliative care, although the End-of-Life Nursing Education Consortium (ELNEC) training program does include the ED.[30] While there are a small number of palliative care ED training modules available,[31] most focus on doctors.[3,32] While these are important programs, the lack of inclusion of an interdisciplinary team (IDT) jeopardizes the opportunity for the collaborative work required for both palliative and ED care. Often, nurses and physicians will seek out palliative care training[33] because standardized palliative care education and training is not routinely provided in most EDs. Generic palliative care training may address emergencies, but does not routinely equip clinicians to engage in smooth transfer and care delivery processes. Few programs address some of the more unique challenges of the ED whose solutions will not be possible to implement, despite inventive adaptation. There remains a need for standardized, tailored, IDT, ED-based palliative care training.

In response to the increased presence of palliative patients in the ED and the initiation of palliative care as a subspecialty of emergency medicine, several small-scale qualitative studies have explored ED clinician experiences, perceptions, and beliefs about the provision of ED-based palliative care.[33,34] Again, the focus is predominantly doctors and/or nurses, with very limited inclusion of other members of the IDT (e.g., social workers[35] and administrators[24]). Rarely do studies examine multiple members of the IDT together.[21,34]

Studies have found a mixed response from ED staff considering palliative care. Resistance to palliative care often stems from the desire to provide the best care for patients and concerns that the ED should not encourage palliative care patient visits because it may not be the best location in which to treat such patients.[34] Limited time and space and noise were often cited as barriers to delivery of palliative care by ED clinicians.[33] Some stated that, even if it were appropriate, integration of palliative care into the existing model would be too costly and challenging.[34] Those in favor of integrating palliative care state that it is a core part of the role of the ED and that the ED at its core must respond to the needs of the patients who are seeking care.[36] These clinicians are often highly skilled in palliative care delivery or have a particular interest in the topic. However, even among those in favor of integration of palliative care into the ED, there were concerns about the ability of providers to offer the type of care required under current conditions. Given the algorithmic approach to patient care that supports the ED model, a lack of clarity in such a vital aspect of healthcare delivery must be addressed to support the practice of ED clinicians.

As with patient and family experiences, ED clinicians have witnessed a variety of positive and negative experiences. Beyond these personal experiences, additional challenges include difficulty accessing key information when patients are admitted from the community (e.g., ADs and goals of care).[25,33] ED clinicians expressed concern that care is impeded by limited access to palliative care teams, particularly outside of normal working hours.[25,36] These reflections were tied to a common theme of role confusion over palliative care delivery, questions about who should implement palliative care, and if it is part of the role of the ED clinician at all.[33] The frequency of role confusion in several studies suggests this is an area for focus in ED-based palliative care training and education, where clarifications and agreed processes can support practice. Embedded in this role confusion is an issue of significant concern: that there continues to be a lack of agreement and understanding of *what* palliative care actually is.[33,34]

Considering their clinical practice and values, the life-saving focus of the ED means that some ED clinicians struggle with the underlying concepts of palliative care. For some, palliative care means giving up or betraying their patients by taking alternative courses of action that focus on QOL and symptom management as opposed to full resuscitation measures.[16] This sentiment is exacerbated in instances where patients are unknown to ED staff.[16] Inpatient and community nurses can play an important role in supporting ED clinicians, for example by educating patients and families about what information is required if an emergency visit occurs. This can include completing ADs and care plans with contact details for core care providers that patients can carry with them should they require ED services. A more integrated community ED could also support those ED clinicians who may be reluctant to look beyond the immediate presenting cause. Such actions can be particularly useful in instances when ED clinicians may be reluctant to question current treatment regimes even when verbally requested by patients and families.[16] Standardized or easily accessible documentation could also improve the quality of difficult conversations between ED staff and medical teams overseeing some patients and between ED staff and patients/families.

Limited Knowledge and Research

Increased recognition of patients with palliative and end-of-life needs in the ED has encouraged a growing field of research and study. Much of this work is still in exploratory stages,[28,33,37,38] and there is much to understand in terms of generalizing prevalence and incidents rates.[4,39] As outlined earlier, a handful of small-scale qualitative studies have provided valuable insight into clinician perceptions and experiences, but these tend not to have an IDT focus. Patient- and family caregiver–centered research is gradually increasing but tends to focus on patients with cancer.[2,40–43]

Numerous ethical and feasibility challenges can deter researchers and impact the validity of quantitative research, while some may deem qualitative research overly draining or inappropriate for patients at the end of life.[44] Ultimately, in both clinician and patient–family populations, a limited body of research has moved beyond exploration of perceptions and experiences, although this rich source of data can provide a foundation on which to build. A small number of more rigorous studies have studied the impact of palliative care measures implemented into the ED which demonstrate feasibility and impact (see the section "Facilitators to ED Palliative Care").[14,45] Sadly, patient and family caregiver involvement remains limited, thus decreasing the generalizability and applicability of new models. Certainly, the current body of knowledge is not yet broad or rigorous enough to conduct comparative effectiveness trials to inform evidence-based best practice guidelines. However, the development of consensus statements and research agendas is beginning to address different aspects of ED-based palliative care, for example, shared decision-making.[28]

To demonstrate the practical implications of these barriers, Part 2 of the case study demonstrates how different approaches to and understandings of palliative care among ED clinicians can confuse and affect the trajectory of a patient's condition. The value in written documentation to support shared decision-making processes is highlighted.

Case Study: A Patient in the ED–Part 2

The resident leading the response to MB's respiratory distress told MB that she needed mechanical ventilation if she continued to desaturate. MB was not entirely sure what it meant to be on a respirator. English was not her native language, and she did not know what "mechanical ventilation" meant, but she agreed to the resident's recommendation. Then, MB's husband arrived and he explained to the primary RN that MB wanted never to be intubated. The RN asked the husband if there were any written ADs and the husband said there were not. The RN then said, "Until we have that, we have to do everything we can to save your wife." The husband sat with his wife, who continued to stabilize, and held her hand. "I don't want to live if I'm going to live like this," she told him. The husband found the resident and relayed this message. The resident replied, "We are doing everything we can for your wife—she is in very good hands. As you can see, she is already in better condition than she arrived in." Another RN overheard this conversation and asked the husband if he had ever heard of palliative care. The husband said, "No, but he had heard of hospice," and asked if MB might need hospice care. The RN approached the resident and stated, "MB and her husband are not on board with aggressive treatments. Can you order a palliative care consult?" The resident looked at MB, saw her slowly rising SaO_2, and said, "Are you kidding, look at her! We've got her stabilized, we can send her to the floor in no time."

Discussion Points

Barriers to palliative care:

- The lack of patient-centered communication and shared decision-making led MB to agree to a procedure she had previously determined she did not want. Language barriers and health literacy issues may be present in addition to difficulty understanding medical jargon.
- The ED practitioners are unable or unwilling to accept verbal desires about treatment limitations in lieu of formal ADs. In an emergency, the absence of ADs could lead to unwanted interventions.
- Because of the standard ED model's focus on life-saving and the myth of palliative care as being only useful for actively dying patients, the resident does not see the utility of a palliative care consult for a patient whose emergency is improving.

Facilitators to palliative care:

- The second RN is able to talk with the family and patient about their treatment goals and introduces the possibility of palliative care.
- This RN is willing to ask the doctor to order a palliative care consult, even though he shows resistance.

Ways to integrate palliative care:

- ED providers can communicate with their patients in clear, nonmedical terms and ask for teach-back to ensure the patient understands. Furthermore, patients who speak a foreign language must be offered formal interpreter services, especially during consenting procedures.
- ED providers can clearly document any preferences and concerns raised by patients to support their transfer and future care.
- The ED can incorporate nurse-managed palliative care consult orders to avoid the difficult situation of convincing a doctor that palliative care is necessary. With standardized education, all practitioners will have a better sense of when palliative care is appropriate. However, nurses are on the front line of patient advocacy and are in a prime position to ensure palliative care delivery is timely and effective.

Facilitators to ED Palliative Care

Despite the barriers to ED palliative care, a number of commonalities between the two specialties demonstrate the capacity and potential for integration. Both deal with highly emotive interactions and provide for care of patients of all ages, many with a variety of chronic or life-threatening diseases, often focusing on controlling the presenting and distressing symptoms or cause.[15] Over the past decade, researchers, policymakers, and palliative care and ED clinicians have sought to develop and test different models, approaches, and tools to provide for patients with palliative care needs in the ED. This process is still in its infancy, and currently there is no consensus on the most effective mechanisms for integration.[14] This marks a key challenge for nurses working in and outside of the ED to know how best to support patients and facilitate smooth and appropriate transfers and referrals. Small review studies have now begun to collate the research literature in order to analyze the effects of different models. Thus, while there are no standard or internationally agreed upon guidelines, some key findings and features that demonstrate innovative ways that nurses can recommend and support patients with palliative care needs in the ED are known.

Models and Approaches

A report published in 2013 by the Improving Palliative Care-Emergency Medicine (IPAL-EM) initiative described 11 clinical demonstrations of ED palliative care integration, focusing on ED-initiated palliative care consultations.[15] The report identified that palliative care integration is on a spectrum ranging from traditional consultation to basic integration, advanced integration, and ED-focused advanced care. The practical delivery within this spectrum ranges from contacting the palliative care team in specific, individual situations, to fully integrated care with ED-owned responsibility for palliative care delivery. In the latter case, there may still be a relationship with the palliative care team, but features can include dual-certified ED practitioners, provision of individual case management for high-risk palliative care patients, palliative care training and education from the palliative care team, specific palliative care processes and procedures integrated into routine care, and an IDT approach.[15] Drawing from this report, ED nurses can review their own ED and hospital setting to identify local resources to improve quality of care. Examples of practice that can be adapted include working with in-hospital palliative care and specialty medical teams, developing or improving access to palliative care training programs, and collaboration with ED and community-based members of the IDT to create tailored processes for high-need patients.[15]

Encouraging emerging research is beginning to evaluate the impact of these different mechanisms. On the lower end of the spectrum (traditional consultation), there was one randomized clinical trial that compared QOL, depression, healthcare utilization, and survival in ED patients with advanced cancer between those randomized to ED-initiated palliative care consultation or to care as usual.[45] Results were statistically significant for QOL, with longer survival rates for those seen by the palliative care team.[45] An example of ED-focused care was conducted in Taiwan.[14] Led by a hospice and palliative medicine specialist, ED nurses and doctors received palliative care training, and residents rotated on hospice wards. Their program included education programs, monthly interdisciplinary meetings with the palliative care team, use of an app to communicate information and experiences, and identifying a specific emergency hospice room for dying patients. The study reports that initiation of do-not-resuscitate orders (DNRs) increased, as did palliative care consultation and ED nurse knowledge, timing, and method of consultation with the palliative care team.[14]

Where ED-focused advanced mechanisms are not possible, ED nurses can make use of different palliative care needs assessment tools to support their practice and improve quality of care. A systematic review of currently available tools, triggers, and criteria for palliative care ED patient assessment found a range of approaches. Nurses can find assessment tools for different patient populations, such as cancer, dementia, and older people.[5] Some draw on the expertise of different members of the IDT, such as social workers, nurses, and physicians.[5] Others can be applied at different points in the process of ED care, for example at triage, for palliative care consultation while in the ED, to trigger a palliative care evaluation while in the hospital, or to assess for the need for community or hospice services.[5] EDs should identify which tools most suit their patient populations and care processes and draw on the different members of the IDT, including social workers and case managers, to help implement high-quality care. The third and final part of the case study demonstrates in practical terms how such integration can take place.

Case Study: A Patient in the ED–Part 3

The RN returned to the husband and wife, who were sitting again, holding hands. MB had been weaned to a 3 L nasal cannula, on which her SaO_2 was stable at 89%, normal for her COPD. Her work of breathing had decreased, her anxiety had subsided, but she had a sharp pain in her right side from the chest tube placement, and her lower back was in spasm. The RN knew that, despite the pushback regarding the palliative care consult, she could still provide palliative care in the ED. She asked MB, “What is your main goal right now?” MB replied, “Right now I just want to have less pain, and to stay calm with my husband by my side.” The RN asked what she could do to alleviate some of the pain and anxiety, offering hot packs, a cool beverage, and a light massage, all of which MB accepted. The RN asked, “Is there anything you want to make sure does not happen tonight?” MB replied, “I don’t want another tube in my chest, or anywhere else for that matter.” The RN noted this in the patient’s chart and provided education to MB and her husband regarding ADs. With some time left before traveling to the floor, the RN asked MB about her passion for photography and about what prevented her from continuing to take photographs. MB cited her arthritis as the primary deterrent. The RN educated the patient regarding medication adherence and the benefit of a warm compress in the morning for osteoarthritis. Their conversation was interrupted by the transport team, who were there to take MB to the medical inpatient unit. The RN was able to identify a different doctor in the ED who had ordered palliative care consults in the past, and, after the RN shared the information about MB, the ED physician agreed with the nurse’s assessment and paged the palliative care team to ask if they could see her as soon as possible.

Discussion Points

Facilitators to palliative care:

- This RN has shown determination, enacting fundamental principles of palliative care in her care of MB despite resistance from her team. She asks the patient about what interventions she does *not* want during this hospital stay, an important step toward creating her AD and code status.
- The RN engages the patient on a personal level, offering complementary methods of symptom management and investigating what is important to the patient in her life. Education is provided where necessary.
- The RN identifies a provider who is “palliative friendly” and successfully ensures MB will receive a palliative care consult during her inpatient admission.

Ways to integrate palliative care:

- ED practitioners do not need to be palliative care specialists to offer palliative care. Finding out what matters to the patient, taking seriously those priorities even when they conflict with those of the ED, and offering creative solutions to address those needs can be done in any encounter with a patient. Standardized education for all ED practitioners can encourage these smaller scale incorporations of palliative care.
- Identifying allies, and therefore building support from within the ED team, will be crucial to creating lasting change within the ED setting.

Current Gaps and Next Steps

Despite increasing attention on the role of palliative care in the ED, further steps will be critical to meeting the demands of an aging population with extensive palliative care needs. High-quality research into the costs and comparative effectiveness of implementing palliative care in the ED setting may influence stakeholders to ensure that adequate palliative care consultation services exist. Moreover, while education is lacking for RNs, APRNs, PAs, and MDs alike,[46] there is minimal evidence of multidisciplinary approaches with tailored ED palliative care training, education, and certification.[14] It is recommend that EDs implement a systematized training on the basics of palliative care, as well as a standardized protocol for involving palliative care specialists in patient care. Education will reduce confusion over definitions and roles in palliative care, while increased access to palliative care professionals, including bereavement support services, social work, and homecare services, could eliminate much of the gap between the patients' and the providers' goals.[16] Finally, no palliative care program in an ED will be entirely successful unless the total hospital system also values palliative care. Of particular importance is the negative impact of delaying or avoiding advance care planning on the quality of a person's final months of life.[47] A greater ubiquity of ADs may increase the presence of patient-centered and palliative care delivery in the ED. Being at the front line of direct patient care, nurses are optimal resources for education and advance care planning discussions.

Conclusion

Palliative care in the ED has traditionally been highly challenging for multiple reasons, including the environment and "identity" of the ED and its staff and misunderstandings of palliative care among clinicians and patients. Despite this, growing numbers of palliative care patients are seen in the ED, reflecting a shift in the aging population. While there are numerous challenges, new models of care are emerging and showing good outcomes. ED palliative care will need to continue to evolve as the patient population changes. The nurse needs to be at the forefront and adaptable to such changes in order to best support patients and their families.

CHAPTER 54

The Role of Nursing in Caring for Patients Receiving Palliative Surgery or Chemotherapy

Virginia Sun, Tami Tittelfitz,
and Marjorie J. Hein

Key Points

- Patients and their families facing surgery or chemotherapy for advanced disease are often caught between the dichotomy of continuing aggressive treatment and the focus on quality supportive and palliative care.
- Palliative surgery and chemotherapy affect the physical, psychological, social, and spiritual well-being of both patients and families and impact healthcare system-related outcomes.
- Patients and families require support as they make decisions regarding the benefits and burdens of treatments for advanced disease.
- Nurses can help alleviate suffering by supporting patients and families through changes in treatment intent, the decision-making process, and supportive care needs during palliative surgery or chemotherapy.

Introduction

For patients with advanced cancer, treatment options are often limited. It is usually at this stage of the cancer continuum that discussion of palliative modalities of treatment occurs. These palliative modalities often include—but are not limited to—radiation, surgery, and chemotherapy. Patients with advanced cancer are often caught between the dichotomy of continuing aggressive treatment and the focus on quality supportive and palliative care.[1] Faced with these difficult decisions, patients and families become especially vulnerable and may experience heightened physical, psychological, social, and spiritual distress.[2] This chapter describes the use of surgery and chemotherapy/cancer investigational agents as a palliative treatment for patients with advanced cancer.

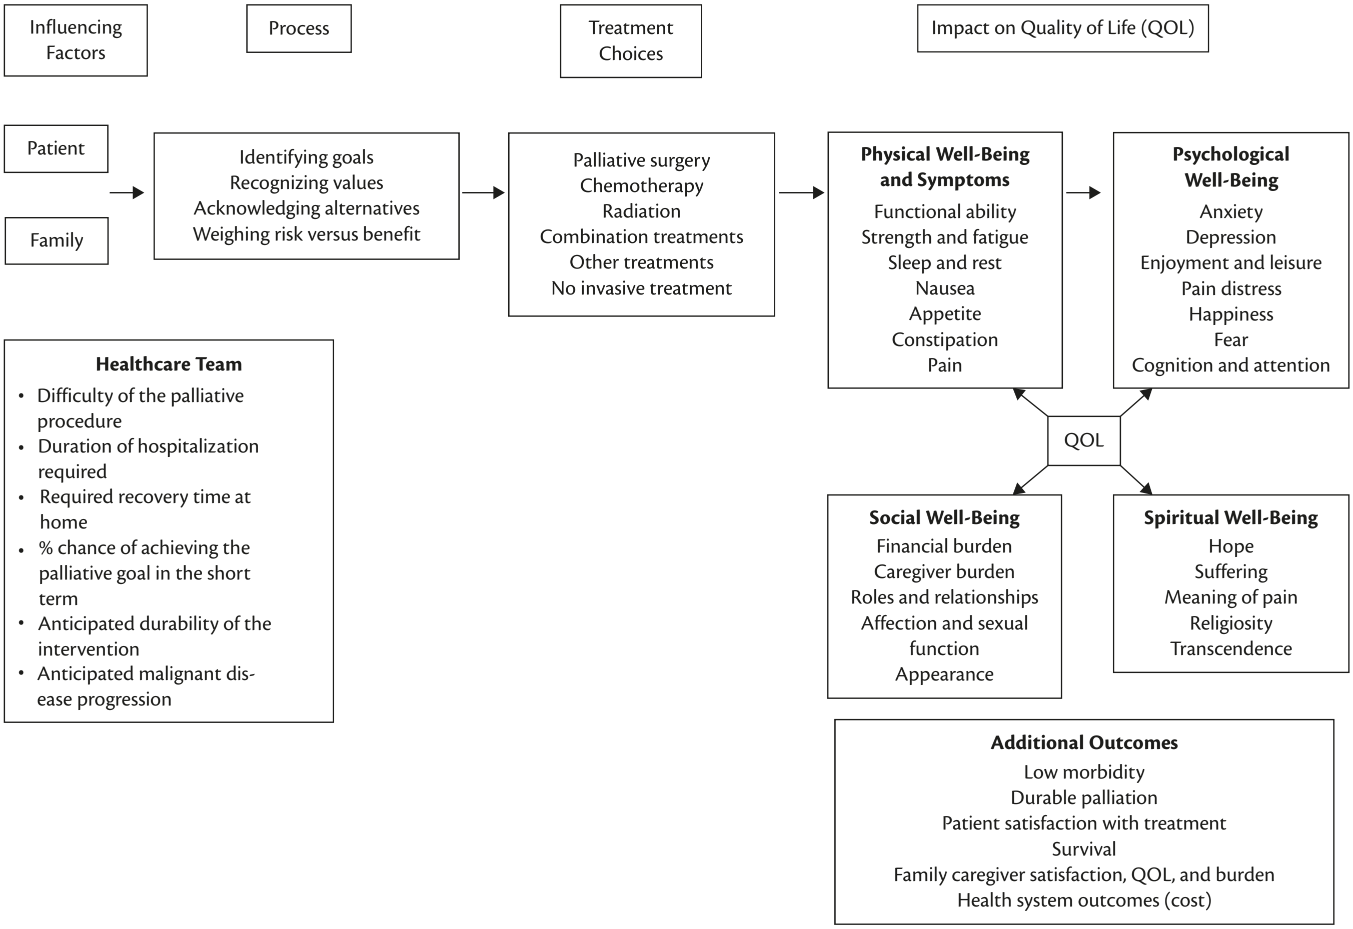
Palliative Surgery

Palliative surgery is defined as any surgical interventions in patients with incurable malignancy; the treatment intent is focused on symptom management and quality of life (QOL).[3,4] Data from the current literature suggest that approximately 21% of surgical procedures are performed with a palliative intent,[5] while 40% of inpatient surgical consultations meet the criteria for palliative evaluation.[5–7] A relatively novel approach in oncology care, the field of palliative surgery is rapidly increasing and becoming recognized as a key component of comprehensive cancer care.

Decision-Making and Goals of Care in Palliative Surgery

Figure 54.1 depicts the treatment decision-making process in palliative surgery; it is derived from research conducted at the City of Hope Medical Center. The decision-making process in palliative surgery involves perspectives from the patient, the family, and the healthcare team and impacts all dimensions of QOL. Patients and families must weigh the potential benefits and harms of the surgery proposed, whereas the healthcare team considers factors such as the difficulty of the procedure, the duration of hospitalization, recovery time, and anticipated disease progression.[8,9] For patients contemplating palliative surgery, the primary decision-making factor is focused on the physical impact of uncontrolled symptoms.[10] Patients often perceive surgery as their best option, even though surgical risks are inherent and may influence decision-making.[11] Other factors for decision-making include the social impact of symptoms, preservation of normal functions (i.e., the desire to eat and drink), prolonged life expectancy, and maintenance of hope.[12–14] Common reasons for declining surgery include complication concerns, physician recommendations, and religious issues.[14]

Family caregivers typically participate in the decision-making process, and they also experience significant disruptions in QOL preoperatively.[15,16] Psychological issues were most pronounced, and common concerns included uncertainty, fears regarding the future, and loss.[15] Surgeons experience challenges in maintaining patients' health while trying to communicate an honest assessment of their prognosis.[12]



Influencing Factors
Process
Treatment Choices
Impact on Quality of Life (QOL)

Examples of Common Indications for Surgical Palliation

Table 54.1 presents a list of common indications for surgical palliation. Malignant bowel obstructions (MBO) are a common complication associated with advanced cancer usually of gastrointestinal or gynecological origin. MBO is defined as luminal narrowing of small or large bowel with clinical evidence of bowel obstruction in the setting of metastatic intraabdominal cancer; the obstruction can be either partial or complete. Colorectal and ovarian cancers are the most common intraabdominal cancers associated with MBO, whereas breast cancer and melanoma are the most common extraabdominal causes. It is a common complication associated with metastatic disease and/or peritoneal carcinomatosis. Patients will often present with one or more of the following symptoms: nausea, vomiting, abdominal pain, obstipation, diarrhea (a result of bacterial overgrowth secondary to blockage of fecal material), distended abdomen, and fevers. MBO can be either partial or complete. Patients with MBO will often have shorter prognoses and have a diminished QOL, with a median survival of 95 days.[17]

Table 54.1 Common indications for surgical palliation

Indications	Symptoms to palliate
Malignant bowel obstruction	Nausea and vomiting Pain
Gastric outlet obstruction	Nausea and vomiting Early satiety
Biliary obstruction	Pruritus Liver failure
Malignant ascites	Dyspnea Pain
Malignant pleural effusions	Dyspnea

The pathophysiology of bowel obstruction is related to mechanical obstruction (extrinsic or intrinsic occlusion by tumor) or functional obstruction/adynamic ileus (caused by tumor infiltrating the bowel wall, nerves, and plexus). MBO can be classified by partial versus total obstruction and proximal versus distal bowel obstruction. The algorithm of care for a proximal versus distal bowel obstruction varies. Patients with gastric or proximal small-bowel obstruction may present with bilious vomiting; postprandial periumbilical, intermittent abdominal pain; and intolerance to oral intake, but no abdominal distention. Malignant small-bowel obstructions often occur at the level of the duodenum, as a result of extrinsic compression or direct invasion by the tumor. Pancreatic adenocarcinoma, cholangiocarcinoma, and gallbladder carcinoma are the most common tumors to cause duodenal obstruction. In contrast, distal small-bowel or large-bowel obstruction may present with malodorous emesis; localized deep, visceral pain, occurring at longer intervals; and abdominal distention.[17,18]

Obtaining a thorough subjective/objective history and assessment from the patient coupled with a complete physical exam are key elements in the optimal diagnosis and care of a patient with MBO. Although the diagnosis of MBO can often be established based on history and physical exam, obstruction is confirmed with imaging studies and begins with an abdominal x-ray followed by a computed tomography (CT) scan. Once an obstruction site is identified, direct visualization by endoscopy by a gastroenterologist may aid in the evaluation and care for a patient with MBO. The abdominal x-ray is used to look for dilated loops of bowel, air–fluid levels, or both. The abdominal CT is useful in making the diagnosis of bowel obstruction, evaluating for complications, and staging and choosing surgical or endoscopic intervention. An abdominal CT has a sensitivity of 93%, a specificity of 100%, and an accuracy of 94% in determining the cause of bowel obstruction.

Initial assessment of the patient includes determination of whether an acute abdominal emergency requires surgical intervention. Surgical treatment options for MBO include debulking, diverting colostomy, intestinal bypass, and resection. In general, surgical candidacy is based on performance status, the extent of malignancy, and prognosis. Resection should be considered in patients with good performance status and localized disease.[19] In advanced cancer, the benefit of surgical intervention is less clear and is incumbent on patients' comorbidities and prognosis. Poor prognostic indicators include age greater than 63 years, malnutrition, low albumin levels, ascites/peritoneal carcinomatosis, metastatic effusions, multiple sites of obstruction, prior radiation to abdomen, prolonged bowel passage time, and short diagnosis to obstruction time. Perioperative mortality ranges from 20% to 40%, with complication rates as high as 90% in advanced cancer patients.

Nasogastric tubes are often initially placed for decompression but are temporary (although terminal cancer patients placed on hospice care have also kept these in place, but these situations are rare and exceptional). Nasogastric tubes are very uncomfortable, and are not a long-term treatment option as they can negatively impact a patient's QOL. Nonsurgical patients with chronic or recurrent obstructions who respond symptomatically from nasogastric tube decompression and have ongoing high gastric output are often considered for a venting percutaneous gastrostomy (G) tube for palliative purposes. While symptomatic relief with a G tube may be achieved in 83–93% of patients, there is insufficient evidence to show that tube placement improves nutritional status or QOL. G tubes are usually avoided in patients with portal hypertension, large-volume ascites, and high bleeding risk.

Placement of self-expanding metallic stents (SEMS) offers palliation to nonsurgical candidates with a single point of obstruction at the gastric outlet or proximal small bowel. These stents can be placed endoscopically by gastroenterologists or by interventional radiologists. SEMS may be a good option for patients with a single site of proximal obstruction and intermediate life expectancy. Successful palliation of symptoms with duodenal stent placement has been reported to be as high as 90%. Covered SEMS have been shown to maintain patency longer but are not available in the United States. Complications include perforation (1.2%), stent migration (5%), and stent obstruction (18%). There are limited data comparing stenting to surgical bypass.[20,21]

Metal stents placed for malignant colorectal obstruction also have a high palliative success rate, with improvement in symptoms in about 75% of patients. Complications are similar to those with upper gastrointestinal obstruction stenting and include perforation (4.5%), stent migration (11%), and reobstruction (12%). Technical success is less likely with proximal colonic obstruction than distal obstruction, and with obstructions related to extrinsic compression than intraluminal obstruction.

MBO is a negative indicator of a patient's prognosis, with an average survival rate of 3–8 months in patients who undergo surgery and 4–5 weeks in inoperable cases. Because most patients with MBO are not surgical candidates, medical therapy and palliation (i.e., supportive care) of symptoms is the common management for these patients. Spontaneous resolution of obstruction in an inoperable patient with MBO utilizing nasogastric decompression and medical therapy has been reported to occur in 30% of patients. Intravenous hydration and electrolyte repletion are critical in the acute stages of management. A multifaceted approach to symptom management includes the use of parenteral opioids, antiemetics, antispasmodics, and antisecretory agents, and hospitalization is common.

Opioids can be administered via intravenous, subcutaneous, or transdermal routes to prevent exacerbating nausea. Antiemetics are often a staple in MBO treatment. Combination medical therapy with different mechanisms is more effective. While metoclopramide is favored over other antiemetics in patients with functional obstruction, it should be avoided in complete bowel obstruction or if it seems to worsen abdominal pain or nausea. Other antiemetics that can be used are neuroleptics (haloperidol, prochlorperazine, chlorpromazine) and/or antihistaminic drugs. Antagonists of the 5-HT3 receptors (ondansetron or granisetron) are another option, though they may have more of a constipating effect than the other drug classes.

Anticholinergic agents such as scopolamine and glycopyrrolate can alleviate symptoms (by reducing gastrointestinal fluid secretions and cramping related to peristalsis), but side effects may be dose-limiting. Evidence supports the use of somatostatin analogues such as octreotide (Sandostatin) to decrease gastrointestinal secretions and increase water/electrolyte absorption. This medication is usually well tolerated. Antihistamines and proton-pump inhibitors can be used as adjunctive therapy as well. Corticosteroids are recommended for their bimodal benefit of relieving nausea and decreasing tumor-related inflammation and edema. Dexamethasone may even reduce bowel obstruction and lead to spontaneous resolution in MBO related to advanced gastrointestinal and ovarian cancers.[22]

MBO represents an advanced stage of cancer and can signal the transition toward palliative treatment for many patients. The decision to pursue medical versus surgical treatment depends on a patient's general health status and the extent of cancer spread. It is important for all nurses to be proactive and knowledgeable in identifying and managing symptoms with medications and coordinating the care with a multidisciplinary team. Initiation of discussions about goals of care, focused on nutrition and code status, is also appropriate and can guide transition of care decisions at discharge. The approach to treatment of MBO should be individualized to each patient.[23]

The following case study illustrates the treatment decision-making process for MBO and subsequent treatments for managing symptoms and QOL.

Case Study: A Patient with Malignant Bowel Obstruction

A 64-year-old Korean American man recently diagnosed with poorly differentiated gastric adenocarcinoma containing signet ring cell features on active chemotherapy was admitted with a 1-day history of severe left lower quadrant abdominal pain radiating throughout the abdomen, associated nausea, and 2 days without bowel movements or flatus. He had a low-grade temperature, was tachycardic, and on physical exam had an abdomen that was distended, tympanic, and markedly tender with faint bowel sounds. A complete blood count (CBC), basic metabolic panel, and liver function tests were unremarkable. An abdominal x-ray revealed multiple dilated loops of small bowel and a "string of pearls" appearance in the left mid-abdomen with multiple air–fluid levels at differing levels. A CT scan showed a moderate- to high-grade small-bowel obstruction with a transition point in the pelvis approximately 25 cm proximal to the ileocecal valve, with evidence of omental metastases.

The patient was subsequently admitted to the hospital and had a nasogastric tube inserted and was connected to low-intermittent wall suction. Intravenous fluids were initiated with pain medications and antiemetics were ordered. General surgery was consulted, but, due to extensive metastatic disease, including suspected peritoneal carcinomatosis on CT scan, the patient was felt to be a poor surgical candidate, and conservative management was continued. Total parenteral nutrition (TPN) was started, and dexamethasone/Octreotide was added.

The patient was subsequently evaluated by the gastroenterology team and underwent a percutaneous venting G tube placement for palliation of his abdominal obstruction. When pain and nausea had finally improved, he was transitioned to full liquid diet and maintained on total parenteral nutrition after discharge. He was discharged on oral metoclopramide and a course of dexamethasone.

Gastric outlet obstruction (GOO) is a consequence of advanced cancer that produces a mechanical impediment to gastric emptying. Patients present with intermittent symptoms that progress until obstruction is complete. Vomiting is the cardinal symptom. Initially, patients may demonstrate better tolerance to liquids than solid food. In advanced GOO, patients may develop significant weight loss and protein malnutrition. Malnutrition is a late sign. In the acute or chronic phase of obstruction, continuous vomiting may lead to dehydration and electrolyte abnormalities.[24,25]

Intrinsic or extrinsic obstruction of the pyloric channel or duodenum is the usual pathophysiology of GOO. When obstruction persists, patients may develop significant and progressive gastric dilatation. The stomach eventually loses its contractility. Undigested food accumulates and may represent a constant risk for aspiration pneumonia. The most common malignancy to cause GOO is primary gastric adenocarcinoma, followed by carcinoma of the pancreas and gallbladder, although it is also not uncommon to find presentations in patients with lobular breast cancer.

GOOs are either benign or malignant. As part of the initial workup, as in MBO, the patient must undergo a series of tests to differentiate between benign and malignant processes because definitive treatment is based on recognition of the specific underlying cause. These include baseline blood work, especially the electrolyte profile of a patient. Additionally, barium swallow studies and upper endoscopy are the main tests used to help make the diagnosis to help guide the management of patients diagnosed with GOO.

The treatment for GOO depends on the extent and cause and is usually managed surgically or medically. Both surgery and gastroenterology teams are often co-managing this patient population. GOO due to benign ulcer disease may be treated medically if results of imaging studies or endoscopy determine that acute inflammation and edema are the principal causes of the outlet obstruction (as opposed to scarring and fibrosis, which may be fixed).

Surgical management is considered when medical therapy fails. Contraindications for surgery relate to the extent of obstruction and the patient's medical condition as well as the extent of the cancer. Most patients benefit from an initial period of gastric decompression, hydration, and correction of electrolyte imbalances, TPN, or distal tube placement for feeding (e.g., placed via a percutaneous jejunostomy). Palliation via endoscopically placed stents are considered to improve QOL when terminal cancer is imminent and life expectancy may be limited to a few months. The underlying cause of GOO must be considered. Medications to combat symptoms including proton pump inhibitors (ulcer-related GOO), antiemetics, and pain medications are staples in caring for patients with GOO, in addition to an endoscopic or surgical intervention for palliation.[26]

Biliary obstructions occur when the bile ducts, the tubes that carry bile from the liver to the gallbladder and small intestine, become blocked. Bile is secreted in the liver and contains cholesterol, bile salts, and waste products such as bilirubin. They help to digest fats. Bile passes out of the liver through the bile ducts and is stored in the gallbladder. After a meal, it is released into the small intestine. Biliary obstructions can lead to obstructive jaundice due to an accumulation of bilirubin levels, and patients will often present with pruritus, bilateral scleral icterus, and yellowed discoloration of their skin. They may even note clay-colored stools and dark amber urine. The possible causes of a blocked bile duct include cysts of the common bile duct, enlarged lymph nodes in the porta hepatis, gallstones, inflammation of the bile ducts, narrowing of the bile ducts from scarring, gallbladder surgery injury, and bile duct or pancreatic cancers. Other gastrointestinal-related cancers with tumor spread to the biliary tree are also common. Infections and immunosuppression are also associated with biliary obstructions.[27]

Clinical diagnosis of biliary obstruction includes a complete CBC to rule out infection and a comprehensive panel including a liver function panel, prothrombin time, urine bilirubin, and amylase/lipase levels. Commonly used imaging to evaluate the patency and extent of a blocked bile duct include an abdominal ultrasound and CT scan, endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiogram (PTCA), and magnetic resonance imaging (MRI).[27]

Patients with biliary obstruction are often a diagnostic and therapeutic challenge due to the site and complexity of biliary obstruction and wide differential diagnosis. Multidisciplinary decision-making is required after laboratory and imaging workup. The gastrointestinal team is an asset in caring for these patients, likely with advanced cancer. Endoscopic approaches to biliary drainage are preferred in most scenarios, and recent advances in therapeutic endoscopic ultrasound allow drainage where the previous alternatives were only percutaneous or surgical. The goal for treatment is to address the biliary obstruction. If left untreated, prognosis is very poor with short life expectancy. Long term, patients may develop worsening liver complications including hepatic encephalopathy and cirrhosis. A percutaneous transhepatic biliary drain is often used to help decompress the biliary tree, in addition to biliary stenting, as guided by the gastroenterology team. Infection-related biliary obstructions are not only palliated by an interventional/endoscopic approach but with supportive care measures to control symptoms and antimicrobials to combat infection.[28–30]

Ascites is defined as fluid accumulation within the peritoneal cavity. Although ascites can be seen in patients with cirrhosis and resulting portal hypertension (approximately 85% of cases), in 7–10% of patients with ascites the condition develops secondary to a malignancy. The most common malignancies associated with the development of ascites include colon/rectum, ovary, breast, lung, pancreatic, and liver cancers, as well as lymphoma. About half of patients with malignant ascites have peritoneal carcinomatosis, with an additional 13% of patients having extensive liver metastases resulting in portal hypertension. Ascites is a common manifestation in patients with advanced cancer. The most common cancers associated with ascites are adenocarcinomas of the ovary, breast, colon, stomach, and pancreas.[31]

Malignant ascites can develop through several mechanisms: blocked lymphatic channels as a result of malignancy, direct production of fluid into the peritoneal cavity by advanced malignancy, and when "functional" cirrhosis develops in patients with extensive liver metastases resulting in portal hypertension. The development of malignant ascites carries a grave prognostic sign, with the median survival reported anywhere between 1 and 4 months.

Cancer patients with malignant ascites manifest symptoms similar to noncancer patients with ascites secondary to cirrhosis. Clinically, one may visualize spider angiomas, distended umbilical veins (caput medusa), sclera icterus, jaundice, anasarca, and a distended abdomen. They may have increased dullness to percussion or shifting dullness. Patients can complain of increasing abdominal girth, generalized abdominal pain, and shortness of breath from fluid overload.

Depending on the clinical presentation and expected survival, a diagnostic evaluation is usually indicated because it will impact both prognosis and the treatment approach. Key tests include serum albumin and protein and a simultaneous diagnostic paracentesis checking ascitic fluid, white blood cell (WBC) counts, albumin, protein, and cytology. An abdominal ultrasound can be performed to confirm the presence of ascites within the abdomen. Upon verification of ascites, patients can undergo paracentesis in order to remove ascitic fluid for analysis. If the ascitic fluid is characterized by malignant cancer cells, the patient is diagnosed with malignant ascites.[32]

Management of patients with ascites in gastrointestinal malignancies will vary. There are different approaches to the treatment of malignant ascites, ranging from symptomatic relief with simple drainage procedures such as paracentesis to chemotherapy and debulking surgery aimed at treating the underlying cancer. Medical management is often used, including diuretics, beta blockers, and anti-hypertensive medications to reduce fluid accumulation related to portal hypertension. Malignant ascites impacts QOL and can be improved with these interventions. Optimizing nutritional intake and protein is important. If ascites continues to progress despite drainage procedures, appropriate patient candidates can undergo interventional radiology-guided procedures such as a tunneled abdominal catheter, peritoneal shunts, and pigtail drains, which allow for patients to drain the abdominal fluid on an as-needed basis. While this modality runs a potential risk of infection or leakage, it allows patients to drain in the comfort of their own homes, or drains may even be placed to optimize supportive care measures in patients transitioned to hospice care. A multidisciplinary approach is needed to care for these types of patients because their care requires input from the oncology/hematology team, the nursing staff, interventional radiology, a dietary team, and a hospice team, if appropriate.[33,34]

In advanced stages, malignancies are frequently complicated by *malignant pleural effusions* (MPE) that can present along with or as a recurrence of primary malignancies. MPE is a condition whereby fluid accumulates within the pleural space. This is caused by direct pleural invasion by tumor cells, which results in increased permeability of the pleural micro-vessels, a disturbance of the normal Starling forces regulating reabsorption of fluid in the pleural space, and involvement of local and mediastinal lymph nodes causing reduced fluid reabsorption of the parietal pleura.[35] The increased fluid accumulating within the pleural space prevents full expansion of the lung, preventing it from approximating to the chest wall. The mere presence of a MPE implies disseminated or advanced disease and reduced survival. Left untreated, a symptomatic effusion impacts significantly on performance status and QOL. The symptoms associated with MPE can be disabling and distressing, leading to dyspnea, pain, cough, discomfort, emotional distress, anxiety, chest heaviness, and fatigue, with dyspnea being the most common presenting symptom, occurring in more than half of the cases.[36] Because MPE causes distress and disability and is associated with brief survival, initial management has chiefly been palliative with either drainage of fluid serially over time or obliteration of the pleural space by pleurodesis. The ideal goals of treatment for this patient population, given the poor prognosis and short life expectancy, include symptom relief or, better yet, symptom avoidance; restoration of near normal activity; palliation of symptoms with reduction of adverse effects; decreasing complications (trapped or loculated lung); decreasing cost of care by minimizing urgent care or emergency room visits or hospital admissions; improvement in performance status; improvement in QOL; and potentially increased survival.

Generally, there are a variety of methods available for palliative treatment of MPE, and there is little compelling evidence to guide clinicians in the choice of the best methods. Thoracentesis is the first step in management in almost all cases of MPE to confirm histology and also to determine the need for a more definitive intervention. Utilizing intermittent thoracentesis can be an option for treatment and provides an opportunity for periodic symptom relief on an as-needed basis; and it may be the best option for patients with a short anticipated survival time. Pleurodesis aims to produce adhesions of the pleura by chemical or surgical means in order to obliterate the pleural space and, by doing so, prevent fluid recurrence. Multiple physical techniques have been used to produce adhesions between the parietal and visceral pleura, obliterate the space, and prevent recurrence. They include open or thoracoscopic pleurectomy, gauze abrasion, or laser pleurodesis. Surgical decortication is an option not routinely utilized as this potentially dangerous procedure may result in severe complications such as bronchopleural fistula and empyema. In carefully selected cases with early multiloculated malignant pleural effusion, gentle thoracoscopic debridement can restore a single lung cavity and allow effective pleural drainage or pleurodesis. Surgical methods have not been demonstrated to have any advantage over simpler chemical pleurodesis techniques in the treatment of malignant effusions. Chemical agents utilized for pleurodesis include antibiotics such as tetracycline, doxycycline, minocycline, erythromycin, and bleomycin or utilizing a talc aerosol or slurry.[37]

An indwelling pleural catheter (IPC) involves the insertion of a tunneled, small-bore, cuffed, silicone catheter into the pleural cavity. IPC placement is aimed to optimize emptying of the pleural space by intermittently draining the effusion in order to preserve adequate lung expansion. The site for the insertion is identified with thoracic ultrasonography. The guide wire is inserted at the thoracic inlet area, then the pleural catheter is tunneled under the soft tissue of the chest wall to the guide wire area for insertion into the pleural space.[38] The procedure can be performed at the bedside under sterile conditions or on an outpatient basis under local anesthesia. This is followed by home drainage performed by a home care provider or trained family members.

Palliative Chemotherapy

Palliative chemotherapy, in its broadest sense, is the use of systemic antineoplastic agents in noncurative settings to optimize symptom control and maintain QOL.[39] The literature clearly supports the role of chemotherapy in managing troublesome symptoms and maintaining QOL[39] in advanced pancreatic cancer, non–small cell lung cancer, and breast cancer. This is in contrast to "end-of-life" chemotherapy, which is prescribed and given close to death (within 7–14 days of death). Here, chemotherapy does not improve survival and may likely worsen symptoms and QOL.

Trends in the aggressiveness of cancer care at the end of life have been explored in the literature. Indicators of aggressive care include intensive use of chemotherapy, low rates of hospice use, emergency room visits, hospitalization, and intensive care unit (ICU) admissions.[40] Rates of palliative chemotherapy use continue to rise in older adults on Medicare and are estimated to be close to 30%.[41] For patients who received palliative chemotherapy, 15.7% received treatments up to 2 weeks before death.[41] Most palliative chemotherapy treatments are initiated within 30 days of death.[42] An increasing proportion of patients used hospice services, but the services were primarily initiated within the last 3 days of life.[43] The elderly, female, nonwhite, and unmarried patients were less likely to receive aggressive care.[42,44–46]

Decision-Making and Goals of Care in Palliative Chemotherapy

Similar to palliative surgery, the primary goal of palliative chemotherapy in advanced disease is to control symptoms and maintain QOL. Prognostic factors have been used to guide treatment decision-making in palliative chemotherapy. One of the most important prognostic factors is performance status.[47–49] A severely debilitated patient with a restricted performance status is more likely to sustain excessive chemotherapy toxicity. The decision to treat or not to treat is based not only on prognostic indicators but also on the patient's perspective. Chemotherapy involves a commitment on the part of the patient and family to travel to the treating institution on a scheduled basis.[50] Repeated hospitalizations, venipunctures, cannulations, investigations, and assessments over and beyond the actual administration of chemotherapy are inevitable routines of cancer treatment. Aside from assessing antitumor effects and the toxicity of chemotherapy, the overall positive or negative impact of the treatment on QOL must also be addressed.[51] These factors need to be addressed with patients and families in an effort to facilitate the decision-making process.

Clear communication between providers, patients, and families is a critical component of the treatment decision-making process in palliative chemotherapy. The current evidence suggests that patients with advanced, incurable cancers are often unclear about the survival gain of palliative chemotherapy.[1] Patients and families with advanced cancer may perceive more benefits from cancer treatments in general. They are often more likely to accept intensive treatment with debilitating toxicities in exchange for a small probability of cure, prolongation of life, and symptom relief.[2,52,53] Patients may choose chemotherapy for a likely survival benefit of 3 months only if the treatment positively affected QOL as well.[52,54] Conflicts between patients' preferences and the actual care they received greatly affected their decision-making.[2]

When curative intent of treatment becomes impossible, practitioners should begin to address the intent to treat as palliation of disease-related symptoms. This initial communication is traditionally the domain of the treating physician. However, with increasingly more collaborative practices emerging among nurses, advanced practice registered nurses (ARPNs), and physicians, an interdisciplinary approach offers the best support for patients and families during this difficult and vulnerable time.[39,47] Communication of difficult news should best be conducted in a prearranged consultation session in which the treating physician, nurse, and social worker together deliver the information to the patient, the family, and other individuals who are integral to the decision-making process. Nurses can foster this interdisciplinary approach of delivering difficult news through collaboration and communication with experts across disciplines. Nurses are often the first to recognize the need for dialogue between the healthcare team and the patient and family regarding treatment intent and prognosis.[53–55] Therefore, nurses can advocate for patients by recommending and organizing these important communication sessions to alleviate unnecessary suffering for patients and families.

When discussing the possibility of palliative chemotherapy as a treatment choice, it is essential to learn about other specific factors that may affect the decision-making process. Nurses can facilitate and perform the assessment to obtain this vital information. This assessment may include (1) questions and decisions that need to be addressed in the patient's or family's lives and (2) a special upcoming event or specific unfinished business that must be completed.[4] Recent studies of concurrent palliative care with standard oncologic care have demonstrated that advanced cancer patients treated with palliative chemotherapy had improved health-related QOL, reduction in symptom burden, and potential to reduce use of aggressive treatment at end of life[56] while having improvement in survival.[57] Therefore, patients should have access to palliative care early in the decision-making process and throughout the treatment course.[58]

Case Study: A Patient with Lung Cancer

Mr. L is a 73-year-old man with a 40-pack-year history of smoking who was diagnosed with metastatic non–small cell lung cancer. At the time of diagnosis, he had widespread disease to his bones. Because of the bone metastasis, Mr. L had been experiencing escalating pain. He spent most of his days at home and in bed due to the escalating pain as well as cancer-related fatigue. Mr. L was recently started on immunotherapy through a clinical trial. He had decided to continue with treatment because of his grandchildren. After approximately 4 months of treatment, Mr. L's condition deteriorated, with worsening shortness of breath, increasing fatigue, and worsening of pain. He was finally transferred to an inpatient hospice facility, and he died 3 days following admission.

In this case, a focus on watchful waiting or aggressive supportive care was indicated. Mr. L's performance status was gradually declining; therefore, he could be anticipated to experience more difficulties with treatment side effects. The immunotherapy did not have a long-term effect on Mr. L's pain. Aggressive supportive care involving experts such as pain specialists would have been beneficial for symptom management and QOL for this patient immediately following diagnosis. Another important aspect of caring for Mr. L was to support his family. Because Mr. L's decision to continue with treatments was for his grandchildren, supportive care experts who specialize in working with young families or children could have been included to aid Mr. L in treatment decision-making.

Clinical Trial Participation and Advanced Cancer

Patients with advanced cancer are frequently offered the opportunity to enroll in a phase I clinical trial. It is important to note that phase I studies are designed to determine the toxicity and maximum tolerated dose of potential treatments, mostly for currently incurable cancers. These studies are not designed to have, and do not have the intended purpose of a therapeutic effect. In fact, studies have shown that therapeutic effects from cancer investigational therapeutic agents occur in only 2–4% of subjects enrolled in a phase I clinical trial.[47,59] Patient expectations for participation in clinical trials include a response to therapy, a reduction in symptoms, and improved and increased communication with their physicians.[60–67]

The current evidence suggests that there is controversy about whether patients with advanced incurable cancers, when faced with decision-making regarding their plan of care, fully understand the choices that are available to them. Studies have found that patients are aware of other alternatives at the end of life, but their overwhelming need to fight their cancer at any cost prevents them from seriously considering the other alternatives.[68–70] Patients who would qualify for hospice services as regulated by Medicare often have very little understanding of admission criteria and services rendered. The impact of clinical trial participation on physical symptoms related to advanced cancer is complex, and there is a paucity of data regarding the extent of these symptoms.[71] Although the structure and requirement of a clinical trial protocol mandates the inclusion of a plan of action for unexpected physical symptoms, these plans often are focused on pharmacological interventions only. For example, if nausea and/or vomiting is an anticipated or expected side effect, a protocol of which antiemetic agents to use is written into the clinical trial protocol itself. However, the psychological and social distress from this side effect is not included in the plan. A clinical trial protocol generally does not include plans that specifically state the need for referrals to other allied health professionals, such as palliative care specialists and psychologists.[71]

The psychological and cognitive symptoms of patients participating in research studies vary. Some patients may be distressed to be told that they are not eligible for inclusion into clinical trials. Research subjects may also have difficulty when an experimental treatment fails, which often mandates the withdrawal of subjects from the treatment protocol. One potential advantage of enrollment in clinical trials is that several members of the research team care for these patients. There are regularly scheduled visits, and that attention may affect the patient's psychological well-being. This added attention might lead to early detection of psychological symptoms that are indicative of depression, sadness, anxiety, or irritability.[71–73] Subtle changes in psychological effects might be readily detected by research personnel, and nurses are an integral part of this team. However, for this added attention to be beneficial to patients and families, it is important for research teams to work collaboratively with allied health professionals and palliative care specialists to address concerns in all areas of patient and family well-being.

Economic demands and caregiving needs may also be affected by clinical trial participation.[73] Financial burdens may be increased for clinical trial participants even if the experimental agents are provided free of charge. The usual intensive monitoring and testing that can sharply increase with participation in clinical trials may not be covered by either the trial budget itself or the patient's insurance. The frequent visits for treatment, physician assessment, and various other procedures that are often mandated in clinical trial protocols may incur further economic burdens in terms of expenses for travel and room and board.[73]

The needs of caregivers and families may also change with clinical trial participation. Families experience tremendous physical, psychological, social, and spiritual concerns that are related to the patient's well-being. Physical symptoms such as fatigue can plague caregivers and families who are faced with the complex care of patients with advanced cancer.[50,58] The complexity of navigating through the healthcare and insurance systems can place tremendous burdens on both patients and caregivers. Social exposure may be diminished for caregivers because much of their days are spent caring for their loved ones.[15,51,61] Finally, the agony of being a witness to a loved one's suffering and the prospect of grief and bereavement in terminal illness may present caregivers with spiritual and existential distress.

Attending to the spiritual and existential needs of patients with advanced cancer is an important factor in the overall experience of patients and families facing the inevitability of terminal illness. It is often at this point in the cancer trajectory that patients experience the needs of altruism.[66,74] Patients and families who recognize the diminishing hope of survival may find comfort and solace in the possibility of contributing to the advancement of science through participation in clinical trials.[62] Others may choose to focus on using precious time to concentrate on more personal goals, such as unfinished business and QOL.

The Role of Nurses in Palliative Surgery and Chemotherapy

The care of patients undergoing palliative surgery is often focused more on the medical aspects, yet nursing care is essential throughout all phases of preoperative, intraoperative, immediate postoperative, and postoperative recovery and discharge. This is a critical time, with numerous transitions between care settings, and nurses play a vital role in ensuring continuity across settings such as the operating room, ICU, postoperative surgical unit, and home care. A prime example is the role of nursing in ensuring pain management by assessing a patient's chronic pain problem at the time of admission to plan adequate analgesia as the patient is admitted for surgery. The nurse then collaborates with the physician and pharmacist to plan the analgesic orders for the transition from the oral analgesics used preoperatively to an appropriate regimen postoperatively. Additional monitoring is needed as the patient's pain may escalate after major surgery. The nurse should also ensure that the appropriate changes are instituted as the patient goes from chronic oral medications taken at home to parenteral administration required in the postoperative period and in the ICU. Maintaining adequate analgesia after discharge from the ICU to the postoperative unit and then to home care is essential for the patient's timely discharge to home and remains a requirement during recovery. This is a simple example of just one aspect of care in pain management, illustrating the vital role of nursing during this very acute phase of treatment.

Oncology nurses have many different roles in the conduct of cancer clinical trials. First and foremost, the process of obtaining true informed consent is a critical factor, not only in improving patient accrual into clinical trials but also in the overall well-being of patients and their families. The informed consent process is an opportunity to provide accurate information regarding important factors that affect the patient's and family's decision-making process in advanced cancer. These factors include trial procedures and potential risks and benefits.[65] The initial informed consent process is also a time to correct any misconceptions and allay unfounded fears and to provide sufficient time for patients and families to thoughtfully consider clinical trial participation.[74] A pre-decisional support process provided by oncology nurses may influence the soundness of patients' decisions to enroll in clinical trials.[70] Nursing interventions that would assist in well-considered decisions include helping patients gather additional relevant sources of information, describing patients' roles and rights in studies, encouraging patients to define their own reasons for participating in clinical trials, and supporting patients in making decisions that correspond with their personal values and wishes.[75,76] APRNs, such as clinical nurse specialists and nurse practitioners, can be important factors in the conduct of clinical trials. Expertise in symptom management and clinical problem-solving is a key asset for APRNs in the research setting. For example, nurse practitioners working in a clinical trial setting have an expanded scope of practice that allows them to perform routine follow-up physical examinations as well as diagnose and manage treatment complications. This level of participation in patient and family care may enhance patient satisfaction, compliance, and retention.

Nurses will often encounter end-of-life situations. During these difficult times, patients and their loved ones will desire accurate and honest information. Quality communication skills are an essential element in navigating these families through the cancer trajectory. Palliative nursing care extends across all treatment modalities, and patients undergoing palliative surgery and chemotherapy require rigorous support and care. Nurses play a critical role in patient and family communication, establishing goals of care and providing expert management of symptoms. There is a need for continued research to address this area of palliative care and for persistent advancements of clinical nursing expertise to best serve these patients and families. These include (1) the inclusion of outcomes that are patient- and family-centered and not only focused on clinical/surgical outcomes, (2) continued development of measures to evaluate high-quality care in palliative surgery and chemotherapy, (3) focus on communication and decision-making (i.e., preoperative advance care planning), and (4) evidence-based interventions to integrate palliative care principles into the routine care of patients in palliative surgery and chemotherapy.[4,77]

CHAPTER 55

Rural Palliative Care

Richard A. Taylor, J. Nicholas Dionne-Odom,
Erin R. Currie, Macy Stockdill,
and Marie A. Bakitas

Key Points

- Providing palliative care to persons living in rural areas across the globe presents significant barriers including transportation, geographical and economic challenges, and the absence of local palliative care experts and resources to meet the needs of patients with complex, serious illness.
- Telehealth, phone-based care, and specially trained lay community workers are some strategies being applied to increase access to palliative care in rural settings.
- Palliative care research, especially focused on the issues germane to rural culture and socioeconomic factors, is needed to address the specific evidence gaps for this unique environment.

Case Study: Lack of Access to Advanced Heart Failure Therapies

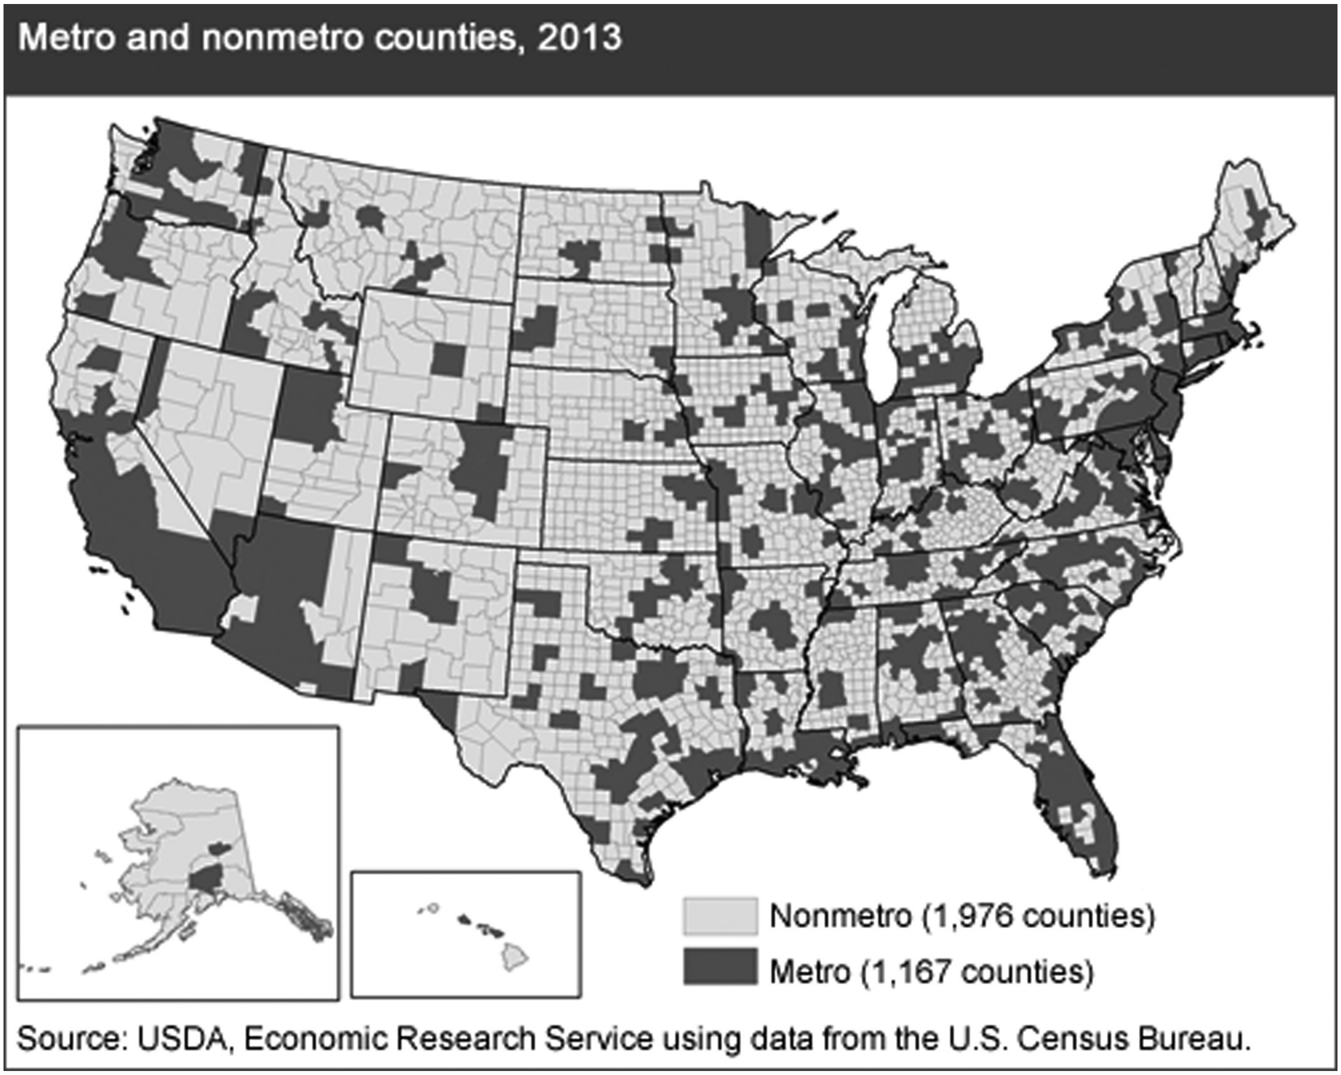
Denise is a widowed 62-year-old African American middle school teacher with a history of myocardial infarction, hypertension, and diabetes who was recently diagnosed with Stage D heart failure after an emergent admission for respiratory distress. Denise was flown by helicopter from her rural town's (pop. 5,000) critical access hospital to the tertiary care academic center as there were no cardiac specialists within 3 hours of her town. Denise was in the intensive care unit (ICU) receiving continuous intravenous inotropic support to keep her ejection fraction high enough to maintain her blood pressure and high-dose diuretic therapy. Denise's kidneys were still not perfusing well enough to maintain adequate urine output. The cardiologist believed that the best option to optimize her cardiac output and overcome her prerenal failure was a left ventricular assist device (LVAD). The home health agency serving her rural town was contacted, but they reported that none of their staff was trained in LVAD care. Palliative care had been consulted to discuss goals of care with Denise and her two adult daughters who lived in a different state. Denise was faced with a decision to consider hospice or to receive an LVAD that would require intensive daily maintenance without the hands-on assistance of home health and regular (weekly for several months) long-distance trips to the academic healthcare center.

Case Study: Lack of Access to Pediatric Specialists in Rural Communities

Charlotte is a 7-month-old twin who was born prematurely at 26 weeks' gestation. She and her twin sister were hospitalized immediately after birth in her local neonatal intensive care unit (NICU); however, within Charlotte's first week of life she developed necrotizing enterocolitis and was transferred to the only free-standing children's hospital in the state, 2 hours from her home in rural Alabama, for surgery to remove necrotic bowel. Postoperatively she remained in the distant NICU because she had only 12 cm of functional bowel remaining, had severe liver disease, and required long-term total parenteral nutrition. As her liver function declined, her symptom burden increased, and her illness trajectory was uncertain. Charlotte's only hope of survival was contingent on an intestinal transplant at 2 years of age; however, her medical team did not believe she would survive to the age of transplant candidacy. Charlotte's mother, a full-time daycare worker, and her father, a privately employed mechanic, struggled with visiting Charlotte more than 2 hours away from their home while also caring for her surviving twin who was now living at home but had chronic health needs. Because of Charlotte's serious illness, she was receiving pediatric palliative care. However, there were no specially trained pediatric hospice and palliative care providers in her rural community. If she was transferred to her community hospital where she would be closer to family, she would not have access to specialized pediatric or palliative care services.

Rural Palliative Care: What Is Different?

Globally, almost half of the population must overcome multiple factors, such as poverty, educational, and employment challenges that accompany rural living. In 2015, approximately 46.2 million US citizens (about 15%) lived in rural (also called "nonurban" or "micropolitan") areas (see Figure 55.1).[1] Nearly half (46.7%) of all people living in US rural areas (28 million people) are in the South.[2] However, depending on the definition, estimates of the rural US population can be as high as 40%.[1] Twenty-five percent of Europeans, 25% of Canadians, and 11% of Australians also reside in rural areas. Asia and Africa remain the most rural continents with 58% and 60%, respectively, of the population living in rural areas.[3] Box 55.1 provides additional information about rural definitions and rural health facts.



Source: USDA, Economic Research Service using data from the U.S. Census Bureau.

Figure 55.1 Nonmetropolitan counties include some combination of (1) open countryside; (2) rural towns (places with fewer than 2,500 people); and (3) urban areas with populations ranging from 2,500 to 49,999 that are not part of larger labor market areas (metropolitan areas). The US Census Bureau uses much smaller geographic building blocks to define rural areas as open country and settlements with fewer than 2,500 residents. Most counties, whether metro or nonmetro, contain a combination of urban and rural populations.

Two main challenges that persons with serious illness residing in a rural locale face are access to and acceptability of palliative care resources.[4–6] A number of reports found that living in US regions served by small rural hospitals put patients at high risk for limited or no access to hospice and palliative care services.[4,5,7,8] Only a quarter of US hospice programs are located in rural areas, and while hospice programs are increasing in general, hospice programs in rural areas are declining.[9] Even when palliative and hospice services are available, persons in rural and minority groups are less likely to use them, in part due to culturally insensitive healthcare systems and mistrust of healthcare providers.[10,11] Cultural mores about illness and death in indigenous and native populations differ significantly from the predominant Caucasian, Western traditions that are at the foundation of many palliative and hospice programs. Caxaj and colleagues'[12] scoping literature review identified priorities and challenges to providing palliative care to rural indigenous populations such as (1) environmental and contextual issues, (2) institutional barriers, and (3) interpersonal dynamics challenging client–clinician interactions. They recommended recognizing the essential role of family connections in building culturally based community partnerships to build palliative care capacity.[12] Hence, limited access and lack of culturally acceptable palliative and hospice resources are major challenges to providing equitable care to persons who are seriously ill and dying in rural areas worldwide.

Seriously ill rural patients are particularly vulnerable, may be socially isolated, and are at high risk to experience care disparities.[10,11,13] Long distances and low population density impose logistical and financial barriers that can impede specialty care access and diffusion of innovations such as comprehensive hospice and palliative care.[10] Local primary care clinicians are most often multiskilled generalists who may see few seriously ill or dying patients, thus limiting their ability to develop needed palliative care expertise.[10] In small rural communities with scarce palliative care

Box 55.1 Defining Rural

Sometimes population density is the defining concern; population thresholds used to differentiate rural and urban communities range from 2,500 up to 50,000, depending on the definition. Two commonly used methods for defining rural are described here.

Rural Urban Commuting Area Classification

The rural-urban commuting area (RUCA) codes classify US census tracts using measures of population density, urbanization, and daily commuting.

They are classified as:

Metropolitan (population 50,000 or greater)

Large Rural[a] (10,000 through 49,999)

Small Rural[a] town (2,500 through 9,999)

Isolated Small Rural[a] town (2,499 or less)

Urban, Urban Area, Urban Clusters, Rural

For the 2010 Census, an *urban area* comprises a densely settled core of census tracts and/or census blocks that meet minimum population density requirements, along with adjacent territory containing nonresidential urban land uses as well as territory with low population density included to link outlying densely settled territory with the densely settled core. To qualify as an urban area, the territory identified according to criteria must encompass at least 2,500 people, at least 1,500 of whom reside outside institutional group quarters. The Census Bureau identifies two types of urban areas:

- Urbanized Areas (UAs) of 50,000 or more people;
- Urban Clusters (UCs) of at least 2,500 and less than 50,000 people.

"Rural" encompasses all population, housing, and territory not included within an urbanized area or urban cluster (http://www.census.gov/geo/reference/ua/urban-rural-2010.html).

Facts about Rural Health Issues

- Rural employment has risen modestly as the national economy has recovered since employment levels bottomed out in 2010. Increases between 2013 and 2015 were 1.3%.
- Poverty rates in both rural and urban areas fell slightly in 2014 and more markedly in 2015—by 0.9 percentage point in rural areas and 0.8 percentage point in urban areas—but remain well above pre-recession levels.
- Population growth was uneven across rural and small-town America: more than half of the 2,053 urban counties lost population, whereas in more than 350 others, population growth was higher than the national average rate of 0.7%.
- Rural America had just over 46.2 million residents in July 2015, a slight decrease since 2010. The rural population declined by 136,000 or 0.3% between 2010 and 2014 but leveled out in 2015.
- The rate of rural population growth in America has slowed dramatically since the onset of the housing mortgage crisis in late 2006 and the recession a year later.

[a] Rural is also categorized/known as "micropolitan" in some US government schemas.

resources, clinicians may also face the challenge of being called on to care for their own family, life-long friends, and neighbors at their end of life.[10,14]

Rural location has often been related to less and later hospice use (see Table 55.1) and higher rates of hospitalization at end of life,[10] particularly in rural nursing home residents.[15–17] Most rural patients are unlikely to have access to the "gold standard" interdisciplinary team (IDT) provided by palliative and hospice services.[18,19] Hence, these patients may have to choose between "going without" or being transferred to a distant site for care.[10] Patients transferred to distant tertiary care settings are at high risk of spending their last days or weeks of life far from home and loved ones. Rural patients with advanced disease, severe pain, or related symptoms who remain in a local facility may suffer during their last weeks of life because state-of-the-art techniques for treating pain or other causes of distress are scarce. The opening cases provide vivid examples of the suffering that can occur when local specialty resources are not available at end of life.

Challenges to Providing Palliative Care in Rural Settings

Box 55.2 lists the numerous challenges and barriers to accessing and providing rural palliative care.[10–12,20–25] These barriers can include patient, provider, and health system factors. Patients and their family caregivers may be fearful of traveling to receive care from unfamiliar providers even though local providers may lack adequate expertise to provide state-of-the-art palliative and hospice care. Clifford and colleagues' survey of 23 community cancer centers identified lack of physician acceptance as a major barrier; in communities with palliative resources, only 17% of patients were referred.[26] In that survey, physicians believed that patients' needs were already being adequately addressed without the addition of palliative care services.[26] Physician "gate-keeping" (i.e., lack of referral of patients for palliative care services) is not unique to rural settings; however, the extent of this phenomenon needs to be more fully explored. If a trusted physician does not recommend palliative services, then patients and family members are unlikely to seek them out. Rural geography can be isolating,[20,23,27] making visits infrequent and creating difficulty in providing a rapid response to patients and families in distress.[8,10,11]

Inadequate rural clinician education can limit knowledge of best palliative care practices.[28–31] Therefore, access to distance education, online resources, specialty journals, and textbooks is essential. However, learning complex palliative care communication techniques may be best acquired through in-person and role-play strategies, which may not be readily available.[31,32] A comprehensive review found very little research on the best

Box 55.2 Barriers/Challenges to Rural Palliative Care

Patient/Family

Lack of patient/family knowledge and acceptance of palliative care

Lack of transportation and long travel distances to palliative care centers (for patients and family/friend visitors)

Patient/family preference to stay in home community for care

Patient/clinician concerns that they will lose touch with community providers if they seek care at centers far from home

Mistrust of unfamiliar providers

Provider

Limited community clinician access to palliative care experts

Limited community clinician exposure to palliative care patients in their practice (e.g., inadequate primary palliative care skills)

Limited availability of palliative care education in the community

Limited scope of practice (e.g., inability of advanced practice practitioners to admit patients to hospice, prescribe opioids)

Health System/Policy/Regulatory

Poor communication/coordination of care between academic and rural community settings

Limited evidence of palliative care benefits in rural palliative care

Lack of availability of technology/techniques used for complex patients (e.g., pain pumps, left ventricular assist devices (LVADs)

Scope of practice and regulatory disincentives

Source: From References 10, 11.

ways to provide quality palliative care education that actually had an impact on patient outcomes. Further distance and interactive learning approaches for nurses were also scarce.[31] These authors recommended the need for more research on palliative care education best practices in information technology targeted to meet the needs of rural learners.[31]

Delivering Rural Palliative Care beyond the United States

Outside of North America and Europe, research on rural palliative care is sparse, but existing studies highlight many common experiences and challenges.[10,20,33–39] In developing and industrialized nations, the demand for palliative care services in rural areas far outweighs the supply, and this disparity is increasing.[40] This widening gap corresponds to an increase in average life expectancy; however, these populations are living long enough to acquire serious, chronic illnesses.[41] In rural communities, lay people may provide the bulk of palliative care services.[11] European,[39,42,43] South African,[37,44] and Australian[45–47] studies report limited formal palliative care training programs and a high demand by generalists, who may feel underprepared. As in the United States, successful programmatic efforts have prioritized mentoring and educating local community home care providers and volunteers in delivering palliative care,[48–50] rather than developing centralized, urban centers attempting to serve rural areas. Unfortunately, similar to the United States, these services are usually provided only at the very end of life after all curative treatments have been exhausted.[12,20,51,52] Hence, the patterns of underutilization and late timing of palliative care are equally prevalent.[53]

Rainsford and colleagues'[11] review of 22 studies of rural end-of-life (EOL) care across both developed and developing countries found that long geographic distances to specialized palliative care was the greatest negative influence. Rural residents in developing countries, particularly indigenous populations who valued highly dying in their community, also found it very challenging to coordinate visiting palliative care and other home health services to come to their communities. Overarching themes for rural dwellers regardless of country of residence was receiving personalized care that demonstrated "presence," honoring their customs and ways of making meaning, and having generous volunteer support from local community members.

Although many challenges in rural settings outside of the United States are similar, in developing nations, they are often more pronounced and extreme. This is partly because the public and healthcare infrastructure of many developing nations is markedly less amenable to the delivery of palliative care services and medications in remote areas. Examples include insufficient inventory or lack of access to pain medications, especially opioids,[11,54–56] severely decrepit or nonexistent highways and roads combined with considerable distances between remote areas, limited legal scope of practice for nurses resulting in the inability to administer pain medications, [57] and physical dangers including fear of violence and infectious disease, particularly for home care providers.[52] Thus, the role demands of the palliative care clinician or team are often vastly greater in scope and can include providing food, shelter, and transportation.[11]

Taboos can also often be extreme: for example, Singer et al.[58] note that Israeli Bedouins seldom speak the word "cancer" because there is great shame associated with having this illness. The shame is such that a Bedouin girl of a family where someone has cancer may have difficulties marrying. In another study, Campbell[59] found that male palliative care health workers in South Africa were perceived by female patients as more likely to perpetrate physical abuse, thus hindering the delivery of palliative care. Finally, the types of life-threatening illnesses addressed by palliative care clinicians in foreign rural areas are often not the advanced cancer and heart failure populations seen in the United States and other developed countries but instead are patients with HIV/AIDS and tuberculosis, as is prevalent in sub-Saharan Africa.[52] All this said, such stark contrasts in rural palliative care are more salient when the distinction is between industrialized and developing countries as opposed to the United States and all other countries.

Creative Strategies to Meet the Palliative Care Needs of Rural Patients

Technology-Enabled Healthcare

A major challenge to palliative care delivery in rural areas is the need to provide high-quality care across distances with limited resources. A wave of new strategies that capitalize on eHealth or technology-enabled approaches has great potential in improving palliative care for rural environments. Technology-enabled health is a synergy between the fields of telehealth, mobile health, electronic health informatics, informatics, and health information exchange. The overall goal is to improve access and care quality in a cost effective environment.[60]

Remote monitoring involves the use of devices that transmit data in real time or that can be later downloaded to a providers' office or computer. A trial of remote symptom monitoring overseen by a nurse in which cancer patients used a web-based method to report on 12 symptoms was found to improve quality of life (QOL) and 1-year survival in patients with metastatic solid tumors receiving chemotherapy treatments compared with usual cancer care.[61] Community-based models in which providers go to patients' homes to provide palliative care services have been developed specifically to address the needs of patients in rural and remote areas.[62] ResolutionCare, a professional corporation in Northern California developed by Michael D. Fratkin, in 2014, was created from a successful crowdfunding campaign to provide home-based palliative care via home visits and videoconferencing. It uses an IDT to see patients within a 150-mile radius of a physical office (patients are not seen in the office).[63] They also provide palliative care "telementoring" in partnership with Project ECHO (Extension for Community Healthcare Outcomes) to train healthcare practitioners to provide primary palliative care.[64] Project ECHO is a telehealth model that links rural primary care clinicians with specialists to perform real-time learning using inexpensive videoconferencing technology. The program's novel approach allows physicians, nurse practitioners (NPs), and other clinicians to jointly manage complex illness and promotes the use of best practices while enabling patients to receive treatment in their home communities.

Using Telehealth to Increase Access to Palliative Care

Telehealth uses advanced information and communication technologies to improve access to care. Telehealth is a heterogeneous collection of clinical practices, technologies, and organizational arrangements that can be grouped into three categories (see Box 55.3). Telehealth strategies have been found to be cost-effective and have been associated with high-quality clinical outcomes and patient satisfaction in a variety of pediatric[65–67] and adult palliative care settings.[24,68] Barriers to telehealth, such as start-up and maintenance costs and concerns over equipment costs, privacy, and security, have begun to decrease. Furthermore, adoption of electronic medical records has contributed to staff training and comfort levels with telehealth. Though technology may be seen as dehumanizing and impersonal, conflicting with core principles of palliative care,[69] increasing evidence demonstrates that it is possible to overcome these barriers, and high satisfaction has been reported as telehealth improves access to palliative care.[70] Palliative care telehealth approaches being implemented in rural areas around the world can provide access to consultations, education, and collaboration for providers, patients, families, and caregivers.[60,71–76]

Monitoring and measuring health data over geographical, social, and cultural distances is being facilitated by the use of smartphones and an explosion of wearable technology, monitoring devices, and mobile applications available for almost any health and illness condition.[77] The Health Information Technology for Economic and Clinical Health (HITECH) Act, enacted by Congress in 2009, accelerated the adoption of meaningful use of information technology (IT) for clinical purposes.[78] The HITECH Act defined meaningful-use objectives for participants in Medicare and Medicaid programs aimed at improving quality, safety, efficiency, and care coordination; engaging patients and families; improving public and population health; and ensuring privacy and security for personal health information. In 2003, the Federal Communications Commission (FCC) funded a rural healthcare support mechanism to expand access to broadband, especially in rural areas. This was intended to encourage the creation of healthcare networks and use of technology to improve care, lower costs, and improve patient experiences.[79] The use of information technology and mobile applications continues to grow.[80]

Box 55.3 Types of Telehealth Technology

There are three main categories of telehealth technology: remote patient monitoring, store-and-forward, and real-time audio/video encounters.

Remote Patient Monitoring

Remote patient monitoring, sometimes called *self-monitoring* or *self-testing*, is a means of monitoring patient health and clinical information at a distance. It helps to simplify patient adherence to testing and it lowers the cost of frequent monitoring. It is often used to treat and manage chronic illnesses like asthma, cardiovascular disease, and diabetes.

Store-and-Forward

Store-and-forward is the oldest form of telehealth technology. It refers to the transmission of images or information from one provider to another. An example of store-and-forward telehealth technology is when a clinician sends a digital image of an x-ray to a radiologist for analysis. State telemedicine reimbursement laws, even in states that require parity for real-time communication, do not always cover store-and-forward telehealth.

Real-Time Audio/Video Communication

Real-time communication is what many consider the most common use of telehealth technology. An example is when a patient is at one location and the provider is at another and they connect using a video-enabled device and a telephone or computer audio. Patients may be at a healthcare facility with a provider, and they establish communications with a specialist at a remote location, or a patient might not be at a medical office but at home or in a state health department office. Many state laws require insurers to reimburse for these types of video visits. Most don't have a similar requirements for telephone calls that don't involve video.

Source: http://telehealthdirectory.org/; http://www.cchpca.org/what-is-telehealth

A collaborative model using Internet-conferencing between a rural palliative care NP and an urban palliative care physician expert was able to improve access for underserved patients and families. A Canadian study used regional palliative care experts to provide telehealth assessments and coordinate with local providers to improve symptom management.[72] A Canadian province developed a 24-hour telephone hotline to provide expert palliative care consultation, which was most frequently accessed by rural communities.[81]

Canada's Rural Palliative Telehealth Project,[81] aided by provincial and national funding, examined telehealth to conduct direct palliative care consultations and care conferences with distant primary care teams, deliver staff education, and link rural patients with their urban specialists for palliative care case conferences. Often difficult treatment decisions could be discussed and future plans established without the need to travel to an urban center. Telehealth was beneficial for discharge planning between the urban tertiary palliative care unit and the rural care team when patients with complex issues were being transitioned back to their home communities.[81]

Remote monitoring, in combination with the application of adult learning and cognitive behavioral theories applied to telehealthcare delivery and practice, can promote improved patient self-efficacy with disease management.[82]

Project ENABLE (Educate, Nurture, Advise, Before Life Ends) was an early use of telehealth to provide early concurrent oncology palliative care.[83,84] ENABLE, based on the World Health Organization continuum of care[85] and Wagner's chronic illness care[86,87] models, includes a face-to-face standardized palliative care consultation and a nurse-coach delivering the standardized "Charting Your Course" curriculum (see Table 55.2) to patients and care partners. Approximately 1,000 patients with cancer (and their family caregivers) have participated in ENABLE clinical trials. Published trial results have demonstrated gains in QOL, improvement in symptoms, less depression, and improved survival.[68,83,88] The primary focus of ENABLE is coaching patients to learn new skills of problem-solving, patient empowerment and activation, proactive symptom management, healthcare decision-making, advance care planning, communication, and legacy/life review. Another feature is assisting the patient and family to identify local, community primary care, and palliative/hospice resources to reduce dependence on distant care providers and allow them to stay in their home communities. Family caregivers participating in the program report lower depression scores and lower burden.[88] Others have also found telehealth to be an important resource for family caregivers who have generally expressed satisfaction with this approach.[89]

Table 55.2 ENABLE Charting Your Course curriculum

The Veterans Health Administration (VHA) began the VA Hospice and Palliative Care initiative in 2002, collaborating with the National Hospice and Palliative Care Organization to improve care to veterans and families. In addition to establishing hospice and palliative care teams in all its medical centers, the initiative developed a telehealth model to provide holistic EOL care. The Advanced Illness/Palliative Care (AIPC) program utilized text messaging and videophones to monitor patients and provide symptom management and spiritual support. Participants reported that technology helped them feel more connected to the care team.[90]

Telehealth may provide an opportunity for the limited number of specialty trained pediatric palliative care providers to educate, consult, and manage seriously ill children in rural areas. For example, a case report of rural pediatric palliative care patients followed by a hospital-based pediatric palliative care team found that patients and families found it to be helpful, especially for receiving counseling that would normally not have been available.[65] Although broadband may not be universally available, many rural communities can obtain Internet access in community clinics and thus can access telehealth services. In the case of pediatric palliative care, where specialization is such that most rural areas would otherwise lack services, telehealth may be able to reduce disparities.[65–67,91]

In 2015, the American Association of Retired Persons (AARP) conducted an online survey of 1,028 US family caregivers about how they use mHealth, telehealth, and other technologies and what their interests were in technology solutions to potentially meet their caregiving needs.[92] The survey found that 71% of caregivers were interested in technology to assist with their caregiving but that only 7% were currently users, indicating a wide gap between demand and use. The biggest barriers to technology use by caregivers was a lack of awareness about available technologies, cost, and the time it would take to learn a new technology and incorporate it into their everyday routine. The report indicated that technology use among younger caregivers was higher than older caregivers (8.5% vs. 4.6%), and thus technology use in caregiving was likely to rise over the coming decades. The tasks that caregivers would like to see technology assist them with the most included monitoring a loved one, helping them manage medications, and care coordination that is seamlessly integrated across platforms.[92]

Web-Based Resources

Palliative care resources are available through the Internet to anyone with electronic access. The Center for the Advancement of Palliative Care (CAPC.org) offers Internet-based educational programs and links for patients and caregivers. The American Academy of Hospice and Palliative Medicine (AAHPM.org) and the Hospice and Palliative Nursing Association (HPNA.org) offer online resources. Healthcare networks and advocacy groups are using electronic media to make educational programs available to healthcare providers, patients, caregivers, and the general public. The National Hospice and Palliative Care Organization has resources for rural providers available online at https://www.nhpco.org/access-outreach/resources-rural-providers. In Australia, oncology specialists developed an educational program on palliative oncology for health professionals that focused on the needs of rural providers. Participants reported that they improved their knowledge, and 75% planned to review or change their practice as a result.[74] The Minnesota Rural Palliative Care Initiative partnered with rural communities to expand access to palliative care using web-based educational sessions, a dedicated web page with resources for program development, links to national guidelines, clinical tools, and shared draft documents.[71]

Developing Clinical Capacity in Rural Palliative Care

As the population over age 65 doubles by 2030, with the highest numbers being in the rural areas as they "age-in-place," a shortfall is projected over the next 20 years for many physician specialties.[93] The older US rural population compared to those in urban areas are female, live in higher poverty, have more chronic conditions and disability, and have a lower QOL due to health conditions.[93,94] The elderly are the largest population to use palliative care services, so the growth in their numbers will further strain their access to palliative care.[10] Distribution of palliative care resources is noted to vary by geographic region, and globally is inaccessible to a majority of the country's population, with rural regions most frequently underserved.[95–97] As the need for medical services expands in the coming years, the IDT and addressing statutory laws limiting NPs' and physician assistants' scope of practice[10] will be increasingly important, including in palliative care and particularly in rural areas.[98] The palliative care workforce issue among physicians is well-defined, with conservative models estimating the current shortfall at between 6,000 and 18,000 physicians. This prediction has not taken into consideration the anticipated growth in palliative outpatient care.[99] The mismatch between the predicted increase in palliative care–eligible patients and the physician workforce by 2030 results in a ratio of 1 physician for every 26,000 patients, certainly an impending crisis.[100] Providers receive sparse formal education in graduate or medical school and are unprepared for the complex life-limiting disease conditions and associated symptom management of patients in palliative care, resulting in patients suffering.[101] Enhancing palliative care education and skills at the early learner level and with policy support to mandate inclusion of palliative care content in all training programs should increase the number of physicians with adequate training to address primary palliative care needs.[102,103]

The Institute of Medicine[60] has called for nurses to fill new and expanded roles to increase access to care. However, the workforce is "graying" and approximately 40–48% of palliative care nurses are over 50 years of age. A large number of nurses are expected to leave the workforce in the next 10–15 years, with few replacements, thus leaving a significant gap in care.[104] The use of palliative care–trained advanced practice registered nurses (APRNs) to lead consult services[105] and to be integrated into routine intensive care units teams[106] and pediatric care teams[107] is growing. APRNs have also led the way in providing outpatient care and acting as IDT coordinators.[108] A Pennsylvania health network utilized NPs to provide home-based nonhospice palliative care consultation that improved access to palliative care and reduced inpatient costs for EOL care.[109] The VA model for palliative care has also successfully used advanced practice registered NPs.[110] The HPNA offers educational programs, promotes networking, and provides for specialty certification for APRNs (www.HPNA.org). As more APRNs are added to the workforce, they are improving access to quality palliative care.

Lay Health Workers

Given that most persons with chronic or serious illness are located in community settings[99] and the relative scarcity of outpatient palliative care support,[111,112] strategies to address the palliative care needs of persons living in rural areas must include innovative health services. Lay health workers (community health advisors or community health workers) have been effective in serving as a bridge between healthcare institutions and the community, disseminating public health, and providing healthcare services including behavioral strategies and interventions to improve health outcomes.[112,113] Community health workers trained in palliative care principles can have a role in delivering components of palliative care, including advance care planning, in regions where access to formal healthcare systems with palliative care resources is limited.[112,114,115] In developing countries, volunteer community health workers have been trained in the basics of palliative care and supported in the delivery of that care. Evaluations have found these programs to be beneficial to both patients and the volunteer health worker.[112,116] In some areas, community health workers include health system "navigators," thus extending the role of the lay navigator to help in the reduction of cancer disparities by encouraging early screening and prevention in high-risk groups across the entire palliative care spectrum.

The effectiveness of this approach has been demonstrated in some established cancer navigation programs. The Deep South Cancer Navigation Network demonstrated important gains in cancer screening rates, especially among African American women, using community health workers in the Deep South.[117] The University of Alabama at Birmingham (UAB) Health System Cancer Community Network (CCN) trained nurse and lay navigators (community health advisors) in palliative care principles including communication skills related to conversations and decision-making about advanced disease and in symptom recognition and advocacy to reduce barriers to cancer care.[118,119] The program was feasible and demonstrated improved self-efficacy in the lay navigators after training, a significant increase in advance care planning discussions in the African American population, identification and resolution of psychosocial distress, and a statistically significant decline in Medicare spending, emergency room visits, and hospitalization over time.[119–122] In rural regions with high levels of hospice penetration, lay health workers may also be engaged as "sitters." "Sitters" are persons without formal medical training who may assist in the care of a seriously ill person by providing companionship, assistance with activities of daily living, and assistance with other practical and logistical issues. Persons with limited healthcare training (in the United States identified as certified nursing assistants [CNAs] or in Canada they may be personal service workers [PSWs]) have a role in caring for persons with chronic and serious illness and fill a gap in service in a rural setting.[123,124] Data from Canada and Great Britain indicate that these workers find caring for palliative care patients challenging,[125] but no data were identified related to workforce capacity or rural locations in the United States. Hospice and palliative care volunteers in rural regions may also have an expanded scope. This expanded role of volunteerism provides valuable assistance while interacting with both informal and formal caregivers of palliative care and hospice patients.[102] The available literature indicates that, in rural regions, support for palliative care patients may include a complex web of individuals including informal caregivers, community volunteers, and trained healthcare workers who form an organic and site-specific network of caring for the seriously ill and dying.[126,127] While evidence supporting lay health workers in palliative care and hospice is sparse, it is expanding in capacity for the provision of palliative care in rural regions.[128,129] Important areas for research include defining the role that community health workers or community health advisors may play in enhancing access to palliative care in rural regions. Understanding the potential impact of using lay personnel on palliative care outcomes and defining the best way to integrate training for this potential new workforce in rural palliative care should be active areas of investigation.

The Role of Critical Access Hospitals

Rural hospitals provide essential healthcare services to nearly 54 million people, including 9 million Medicare beneficiaries, low-income individuals, and Medicaid populations who are often in need of palliative care services. With the closure of 63 rural hospitals between 2010 and 2015, 1.7 million people are at higher risk for poor health outcomes due to lack of local access to acute care.[130] Rural hospitals care for, on average, a higher percentage of Medicare patients since rural populations are typically older than average urban populations.[131] Medicare reimbursement issues, sustained workforce shortages, rising healthcare insurance costs, aging rural hospital facilities, and the demand for expensive new information systems all contribute to the daily challenges of providing adequate care in rural settings. To deal with some of these issues, in 1997, through the Balanced Budget Act (BBA) of 1997, a designation of Critical Access Hospitals (CAHs) was developed that would receive cost-based reimbursement. To be designated a CAH, a rural hospital must meet defined criteria, such as 24-hour emergency services, a medical provider on premises or the ability to be there within 30–60 minutes, an annual length of stay of 96 hours or less, less than 26 beds, and an established referral/transfer policy and agreement with an acute care hospital (see Box 55.4).[132,133]

Box 55.4 Critical Access Hospital Criteria

- Must be rural, located within a state participating in the Medicare Rural Hospital Flexibility program
- Must be more than a 35-mile drive from any other hospital or critical access hospital (CAH) (or, in the case of mountainous terrains or in areas where only secondary roads are available, more than 15 miles from any other hospital or CAH)
- Must have 15 or fewer acute inpatient care beds (or, in the case of swing bed facilities, up to 25 inpatient beds that can be used interchangeably for acute or skilled nursing facility-level care, provided no more than 15 beds are used at any one time for acute care) as reported on the cost report
- Must restrict patient length of stay to no more than 96 hours unless a longer period is required because of inclement weather or other emergency conditions, or a physician review organization (PRO) or other equivalent entity, on request, waives the 96-hour restriction (the 96-hour length-of-stay limitation was modified in 1999 to a per-patient annual average)
- Must offer 24-hour emergency services
- Must be owned by a public or nonprofit entity (modified in 1999 to extend eligibility to for-profit hospitals)

Source: From Reference 140.

The goal of CAHs can at times be at cross-purposes with the goals of palliative care. For example, there is a financial incentive for brief stays to essentially stabilize and transfer the patient to a larger hospital or academic center.[133] In many cases, for these chronically ill, older adults, the more appropriate approach would be to establish goals of care and identify appropriate local care resources rather than transfer these patients to academic centers from which they might not ever return. In many cases, it might be more appropriate for these rural hospitals to keep patients for EOL care or to stabilize the patient and, if possible, arrange for return home with hospice care. The nursing and medical staff at the CAH are expert generalists. The nurse may be the first point of contact for the patient and family in the CAH, being responsible for assessing and stabilizing the patient before transfer to the urban hospital. The traditional multidisciplinary specialty palliative care team is rarely available at a CAH, but it is generally available at the urban hospital to guide and coach the rural staff throughout the process. This collaboration is an opportunity to extend palliative care through the local rural providers to the patients they serve.[133]

Creating Academic–Community Partnerships and System-Wide Improvements

Patients with palliative care needs located in rural or isolated areas have been able to take advantage of local community resources and to rely on local primary care and other clinicians through partnerships with an academic or other palliative care program that is well-resourced. Access to palliative care resources to meet rural, indigenous communities' needs remains a challenge, but progress in partnerships to address their unique social, cultural, and geographic needs and barriers to care is being made.[96,134] A guide developed by the Health Research and Educational trust for small and rural hospitals in the United States focuses on strategies to improve care by concentrating on better population health management. This is achieved through well-structured relationships between rural hospitals and community care partnerships.[131] This is best achieved through a continuum of types of population health partnerships: (1) networking, (2) coordination, (3) cooperation, and (4) collaboration.[131] The reader is referred to the guidebook *The Role of Small and Rural Hospitals and Care Systems in Effective Population Health Partnerships* for excellent resources in developing such relationships (available at http://www.hpoe.org/small-rural-partnerships).

In the United States, there are palliative care programs that serve as tertiary centers. These centers should have, as part of their mission, strategies to bring their expertise to the community. Using community capacity development theory, a learning collaborative model, and focusing on the National Quality Forum *Consensus Report: National Framework and Preferred Practices for Palliative and Hospice Care Quality*, a partnership called the Minnesota Rural Palliative Care Initiative (MRPCI) was formed between Stratis Health, an independent nonprofit organization, and Fairview Health Services' palliative care program. The goal was to improve care across 10 rural communities. The MRPCI partnered with rural communities to expand access to palliative care using web-based educational sessions, a dedicated web page with resources for program development, links to national guidelines, clinical tools, and shared draft documents.[71,135]

Another innovative partnership was the Centers for Medicare and Medicaid Services Healthcare Innovation (CMMI) awarded to Four Seasons Compassion for Life in Western North Carolina (WNC). This innovation award was to extend the existing community-based palliative care model to increase inpatient and outpatient interdisciplinary palliative care services from 4 to 24 counties in WNC and parts of South Carolina. The number of collaborating facilities (skilled nursing, community hospitals, etc.) were markedly increased through this award. The program's community educators traveled to various sites in these states to educate community groups, churches, providers, and others about the program and how to refer patients to the program. The outcomes indicate that the community-based palliative care model is scalable and that the efficiency and effectiveness of a program is increased by implementing a risk-screening and referral guide that aligns patients and local community resources to address their biopsychosocial needs.[136]

Clinical and Research Implications

There have been many outstanding efforts made in the past two decades to improve and articulate standards for the emerging specialty of palliative care.[137] Yet existing guidelines and models of palliative care delivery have mostly overlooked a key multifaceted variable that is critical to achieving better outcomes at the population level: that of geography and the unique obstacles faced by palliative care clinicians delivering care to rural populations. When it comes to disparities in palliative care, *where* one lives matters. Overlooking this reality can result in an underappreciation of the differences between rural and urban populations that significantly impacts the approach one takes in delivering optimal palliative care. As illustrated in this chapter and described in a number of reviews,[1,10,11] rural populations in comparison with urban populations have proportionally more older adults over 65, higher unemployment rates, higher numbers of uninsured, higher numbers of individuals below the poverty line, greater sensitivity to economic downturn, lower population densities, longer travel distances to healthcare facilities, fewer numbers of healthcare specialists and generalist providers, narrower scope of available healthcare services, higher rates of chronic disease, and, in the United States, greater dependence on Medicare and Medicaid.

Accounting for these and other unique characteristics of rurality, the question is how palliative care clinicians and researchers should respond. For palliative care clinicians, the priority challenge will be to ask explicitly about and address any misperceptions about palliative care expressed by rural patients and families and local generalist providers. We recommend that this be a requisite item of discussion with any new interaction or consultation with patients, families, and providers. Clinicians might also consider taking a more proactive approach and initiate regular check-ins with generalist providers in outlying areas to offer expertise and consultation on difficult cases in their areas. CAPC now has national Palliative Care Leadership Centers (PCLC) focused on developing community-based palliative care programs beyond the hospital setting. This program provides online curriculum, webinars, virtual office hours with palliative care experts, onsite training, and more, all focused on incorporating palliative care into the local practice patterns of the community providers.[62,69,138]

For palliative care researchers, a change in perspective is needed, one that migrates from the familiar territory of health as seen at the pathophysiological, individual, and social levels to the more uncharted terrain of palliative care at the level of living conditions, communities, geography, and social and economic policies and climates. Given the growing use, prevalence, and capabilities of communications and other technologies, researchers are called on to propose and test innovative solutions that incorporate the use of such technologies to overcome many of the geographical obstacles of rural healthcare delivery. If but one message comes across, we hope to convey that where one lives makes a huge difference as to whether or not a patient and family receive adequate palliative care.

CHAPTER 56

The Role of PT, OT, and Other Therapies in Palliative Care for Seriously Ill Patients

Dennis Lin, Megan Borjan,
Seanell D. San Andres, and Christina Kelly

Key Points

- Progressive loss of function and increasing symptom burden throughout varying stages of a terminal illness have a profound impact on patients and their caregivers, presenting an essential need for rehabilitation.
- Palliative rehabilitation is guided by the following key principles: communication and collaboration, addressing disability, easing symptom burden, adapting through all stages of illness, and cultivating quality of life.
- Rehabilitation can assist in managing fatigue, pain, dyspnea, dysphagia, anxiety, and depression through the primary disciplines of physical therapy, occupational therapy, speech language pathology, and recreation therapy.

Introduction

This chapter defines the roles of each rehabilitation discipline and describes what each service offers in the realm of palliative care. The approaches of palliative rehabilitation and the interventions that address different aspects of function and quality of life (QOL) will be detailed, with the goal of supporting interdisciplinary collaboration between nurses and rehabilitation therapists.

Case Study: A Patient in Rehabilitation Therapy

At age 58, JP was diagnosed with non–small cell lung cancer after his oncologist confirmed stage II disease with a right upper lobe mass. JP had hoped that his initial treatment of chemotherapy would allow him to reach a state of remission; unfortunately, however, he responded with mixed results, with the cancer continuing to spread following several months of subsequent lines of therapy. He and his family struggled with the aggressive nature of the disease as he experienced progressive decline in health and losses in function. Understanding that aggressive treatment was no longer viable, JP decided to focus on palliative treatment to be able to spend his remaining life with greater comfort and purpose.

JP's cancer had gradually damaged his spinal cord and recurrent laryngeal nerve, resulting in lower extremity weakness, shortness of breath, persistent fatigue, hoarse voice, and risk of aspiration. As a result, he could no longer continue working as a construction manager, maintain his home, or fully engage in his favorite activities of coaching boxing and hosting family barbecues. He lost self-confidence in maintaining his safety, prompting consultation with the rehabilitation team to address his impairments. Throughout outpatient visits and inpatient stays, he worked with his therapists to prevent further disability and adapt to the challenges that impacted his daily life.

During JP's final admission for a clinical trial and palliative radiation, the rehabilitation team provided him a great benefit that positively altered his experience of palliative and end-of-life care. Despite becoming bed-bound from paralysis, dependent on a feeding tube, and eventually transitioning to hospice, his rehabilitation team played a key role in helping him function as well as possible to maintain the highest possible QOL.

The Role of Rehabilitation

Palliative Rehabilitation

Progressive loss of function and increasing symptom burden throughout varying stages of a terminal illness have a profound impact on patients and their caregivers, presenting an essential need for rehabilitation. Interdisciplinary palliative care includes rehabilitation, which provides patients with the opportunity to address specific functional impairments and adapt to each stage of illness. The rehabilitation team can assist nursing and the care team to offer additional support to patients and caregivers to achieve their functional goals and improve the quality of their care.

The role of rehabilitation in palliative care is to help patients maintain or maximize their independence and enhance their QOL as it relates to patient and family priorities.[1] Palliative care addresses common symptoms including fatigue, pain, dyspnea, dysphagia, anxiety, and depression, which can result in a decline of overall function.[2] If not addressed, this symptom burden can lead to impairments in mobility, daily activity, coping, and caregiver burden, causing decreased QOL.[2] Rehabilitation can assist in managing these conditions through the primary disciplines of physical therapy (PT), occupational therapy (OT), speech language pathology (SLP), and recreation therapy (RT). Each discipline provides its own expertise in evaluating impairments and implementing specialized interventions to maximize function and reduce symptoms.

Despite a clear need for rehabilitation within palliative care, palliative rehabilitation is often underutilized in actual practice.[3] This is due to a limited understanding of palliative rehabilitation held by the interdisciplinary team as well as the assumption that terminally ill patients do not require or benefit from rehabilitation.[3] Palliative rehabilitation goes beyond the common misconception that therapy only consists of exercise. Rather, it delivers a diverse approach that addresses multidimensional aspects of the patient's physical, social, emotional, and spiritual well-being.[3] Patients with advanced cancers undergoing a structured palliative rehabilitation program can experience improvements in physical endurance and mobility, decreases in symptom burden, and creation of social support systems.[4] Palliative rehabilitation can also benefit patients with cardiovascular, pulmonary, or neurological diseases; improve coping; and decrease caregiver burden.[1]

Nurses play a key role in screening and identifying those who can benefit from palliative rehabilitation. Patients can be screened using a variety of functional assessments (e.g., Karnofsky Performance Score, Palliative Performance Scale) as well as tools that assess for safety and fall risk. While palliative rehabilitation can be initiated at any point during patients' trajectories, earlier integration of these services can result in better care.[4] These services are traditionally utilized in acute care and subacute care settings but can also be provided through outpatient and home health care. They are available for adult and pediatric populations and are typically covered by most health insurance providers.[2] Educating patients about these services and how they can be accessed allows them the opportunity to address their rehabilitative needs.

Rehabilitation Services

Physical Therapy

The focus of PT is to strengthen muscles, improve mobility, restore function, and limit functional decline. Patients may seek PT for a wide variety of reasons, such as balance impairment, gait disturbance, range of motion deficits, symptom and pain management, and postsurgical rehabilitation. Interventions focus on bed mobility and transfer training to allow for greater independence and safety at home, gait and balance training to improve ambulation and safety in the community, strengthening programs to address weakness, energy conservation to promote maximal tolerance for activities, manual therapy to lessen connective tissue restriction, and modalities such as ultrasound or electrical stimulation to address pain management. Using these interventions to treat impairments helps patients to regain function and maintain independence throughout their daily lives.

Occupational Therapy

Occupational therapists assist patients in making the most of their abilities to perform their desired activities so that they may live their lives to the fullest. They evaluate the impact of a patient's disability on daily life, ranging from self-care to important roles, and provide interventions that support physical recovery and recovery of cognitive, psychosocial, and general health. Interventions focus on enhancing performance in everyday tasks by strengthening physical abilities, modifying activities and environments, training in the use of assistive devices, and building the skills to overcome symptoms (e.g., cognitive rehabilitation, coping, energy conservation).[5] Occupational therapists help patients break down the activity demands of a valued task and create the right challenges during treatment to facilitate successful performance. Furthermore, they use an evidence- and occupation-based approach in which patients engage in relevant activities to treat their impairments and promote functional recovery.[5]

Speech Language Pathology

SLP provides interventions focused on assessment and treatment of speech, language, cognitive, and swallowing disorders. Speech language pathologists provide essential services to improve QOL and offer treatment that is both curative and preventative across numerous disorders. Therapy addressing communication and cognition may include strategies to improve intelligibility or memory, alternative and augmentative communication devices to improve personal expression, or the use of specialized prosthetics or valves to allow voicing. Swallowing treatment may focus on optimizing oropharyngeal strength and function through exercise or improving oral intake and minimizing aspiration with compensatory strategies (e.g., chin tuck, head rotation) and diet modification (e.g., pureed food, nectar-thick liquid).

Recreation Therapy

RT helps maintain QOL through the use of recreational activity or community-based interventions. By assessing patients' leisure interests and lifestyles, therapists can assist in skill development, knowledge, and behaviors for daily living and community reintegration.[6] They work with patients and their families to incorporate specific interests and community resources into therapy to achieve optimal outcomes that carry over to the patient's daily life.[6] By addressing these factors, the therapeutic process becomes more meaningful and relevant, resulting in improved engagement in therapy and functional improvement for all areas of life.[6]

Palliative Focus

When patients transition to palliative care, rehabilitation therapists apply a fluid treatment approach to properly address the specific needs of this population. Specifically, rehabilitation therapists modify treatment goals throughout the palliative process by providing therapy that may initially focus on reduction of impairment and then transition to care that is centered on comfort and QOL. Physical therapists provide more compassionate care by assisting patients in maintaining their mobility and transitioning to training in adaptive equipment as physical capabilities decline.[7] Occupational therapists present remedial and compensatory strategies to address evolving barriers to participation and find creative ways to foster the best level of independence for meaningful activities.[8] Speech language pathologists provide compensations that transition from minimizing aspiration to those focused on improved comfort and social engagement in the process of eating and drinking.[9] Recreational therapists address patients' abilities to cope with their emotional responses to progressive illness and help patients re-engage in previously enjoyed leisure interests through adaptive methods.

Rehabilitation Interventions

Key Principles in Palliative Rehabilitation

Palliative rehabilitation is guided by the following key principles: communication and collaboration, addressing disability, easing symptom burden, adapting through all stages of illness, and cultivating QOL. Each of these principles guides the therapy process to help a patient achieve his or her palliative goals.

Communication and Collaboration

Communication and collaboration are integral components of creating successful partnerships between patients and therapists. Efforts to foster effective communication require therapists to have a holistic understanding of patients and for patients to be aware of the benefits rehabilitation can provide. During the screening process, the palliative care team educates patients on the range of rehabilitation services available and the types of interventions to address their needs. Nurses play a key role in providing this education and initiating referrals so that patients can understand how rehabilitation applies to their care. Nurses can also share concerns regarding patient safety and needs between therapists and other disciplines.
