Oxford Textbook of
Palliative Nursing

Advance Praise for *Oxford Textbook of Palliative Nursing, Fifth Edition*

"This is the ultimate go-to book for nurses caring for patients at end of life and a must for all libraries. The textbook is fresh, current, and clinician friendly. For nurses caring for children and their families, three new chapters in this edition offer critical new information on caring for adolescents, using social media to communicate, and accessing pediatric care. Congratulations to the editors for producing such a comprehensive resource for all nurses, including pediatric nurses."

—**Lisa C. Lindley, PhD, RN, FPCN**, Associate Professor, College of Nursing, University of Tennessee, Knoxville, TN

"What I immediately liked about this new edition of the *Oxford Textbook of Palliative Nursing* are the chapters from new authors that both encompass a multidisciplinary approach and address today's healthcare, including such topics as value-based care, advance care planning, and organ donation. The last chapter in particular, "The Ethos of Palliative Nursing," summarizes the essence of palliative care to guide nurses on focusing on the quality of life and support of patients and their family members."

—**Rose Virani, RNC, MHA, OCN, FPCN**, Senior Research Specialist and ELNEC Project Director,
Division of Nursing Research and Education, City of Hope, Duarte, CA

"Since its inception, the *Oxford Textbook of Palliative Nursing* has been the go-to resource for nurses and nurse practitioners caring for seriously ill patients and their families. The new Fifth Edition continues in that venerable tradition as an excellent resource for nurses at the bedside, in the classroom, and conducting research in the field of palliative care. This edition reflects the growth of the field of palliative care nursing, both in breadth as palliative care expands to new settings and populations as well as depth as the evidence base for palliative care continues to mature. Congratulations to the editors and authors for producing such an outstanding textbook."

—**Sally Norton, PhD, RN, FNAP, FPCN, FAAN**, Associate Professor and Independence
Foundation Chair in Nursing and Palliative Care, University of
Rochester School of Nursing, Rochester, NY

"The comprehensive scope and content of the *Oxford Text of Palliative Nursing, Fifth Edition,* is a testament to the growth in the specialty of palliative nursing. This book will serve as an essential resource for hospice and palliative nurses and other members of the interdisciplinary team, as well as for clinicians who practice in other clinical specialties, but provide care for seriously ill patients and their families. The last chapter, "The Ethos of Palliative Nursing," provides a great review of the moral nature of palliative nursing and provides a wonderful framework for self-reflection."

—**Sally Welsh, MSN, RN, NEA-BC**, Chief Executive Officer, Hospice and Palliative Nurses Association,
Hospice and Palliative Credentialing Center, Hospice and Palliative Nurses Foundation, Savannah, GA

Dedication

This fifth edition of the Oxford Textbook of Palliative Nursing is dedicated to Nessa Coyle PhD, RN, co-editor of each of the previous four editions of this textbook. While Nessa is not an editor for this book, her career contributions are evident in every chapter and her wisdom is well reflected in her chapter in this edition, "Advocacy in Palliative Nursing."

A textbook such as this is only possible once a field has evolved to the point of having both scholarly work and clinical experience to share. Nessa has been a pioneer in both of these worlds, a true clinician scholar who has lived the work of palliative nursing at the bedside while also contributing some of the most insightful scholarship that defines palliative nursing.

This year (2018) marks Nessa's 60th year as a nurse. Her pioneering work in cancer pain management helped advance not only the pharmacologic approaches to care, but also the palliative care rendered by the nurses at the bedside to ease the profound suffering of people living and dying in pain. Nessa was one of the first nurses to teach us about the existential aspects of palliative nursing and our role in supporting patients and families through grief, spiritual distress, and a search for meaning during serious illness. Her qualitative research provided insight for generations of nurses and other professionals as she shared the worlds of the real experts—patients—and the lessons they teach us about this field we know as palliative care.

We dedicate this 5th edition to Nessa. Every section and every chapter within it are a testament to her influence on nursing. Through her gentle yet profoundly strong voice, we have been guided to deliver the care described in these pages.

Contents

Preface *xiii*

Acknowledgments *xv*

Contributors *xvii*

SECTION I
General Principles

1. **Introduction to Palliative Care** *3*
Betty Rolling Ferrell

2. **National Consensus Project for Quality Palliative Care: Assuring Quality Palliative Care through *Clinical Practice Guidelines*** *5*
Constance M. Dahlin

3. **Hospital-Based Palliative Care** *13*
Patricia Maani-Fogelman

4. **Principles of Patient and Family Assessment** *32*
John D. Chovan

5. **Communication in Palliative Care: An Essential Competency for Nurses** *55*
Constance M. Dahlin and Elaine Wittenberg

6. **Advance Care Planning** *79*
Shigeko Izumi

SECTION II
Symptom Assessment and Management

7. **Interdisciplinary Palliative Care Teams: Specialists in Delivering Palliative Care** *89*
Polly Mazanec, Rebekah Reimer, Jessica Bullington,
Patrick J. Coyne, Herman Harris, II,
Mary Catherine Dubois, Catherine Rogers,
and Jennifer Aron

8. **Pain Assessment** *98*
Regina M. Fink, Rose A. Gates, and Kate D. Jeffers

9. **Pain Management** *116*
Judith A. Paice

10. **Fatigue** *132*
Edith O'Neil-Page, Grace E. Dean, and Paula R. Anderson

11. **Anorexia and Cachexia** *140*
Elizabeth E. Schack and Dorothy Wholihan

12. **Nausea and Vomiting** *149*
David Collett and Kimberly Chow

13. **Dysphagia, Hiccups, and Other Oral Symptoms** *163*
Rachel Klinedinst, Audrey Kurash Cohen,
and Constance M. Dahlin

14. **Bowel Management: Constipation, Obstruction, Diarrhea, and Ascites** *186*
Stefanie N. Mooney, Purvi Patel, and Sorin Buga

15. **Medically Administered Nutrition and Hydration** *206*
Katy M. Lanz, Michelle S. Gabriel, and Jennifer A. Tschanz

16. **Dyspnea, Cough, and Terminal Secretions** *217*
DorAnne Donesky

17. **Bladder Management in Palliative Care** *230*
Naomi Farrington and Catherine Murphy

18. **Lymphedema Management** *238*
Mei R. Fu, Bonnie B. Lasinski, Janet H. Van
Cleave, and Charles P. Tilley

19. **Palliative Wound, Ostomy, and Continence Care** *251*
Charles P. Tilley, Mei R. Fu, and Jana M. Lipson

20. **Pruritus, Fever, and Sweats** *285*
Angel Smothers

21. **Neurological Disorders** *291*
Margaret A. Schwartz

22. **Anxiety and Depression** *309*
Jaroslava Salman, Emma Wolfe, and Sunita K. Patel

23. **Delirium, Confusion, and Agitation** *319*
Wendy Goldberg, Greg Mahr, Amy M. Williams, and Michael Ryan

24. **Insomnia** *330*
Karla Schroeder

25. **Sexuality and Intimacy in Serious Illness and at the End of Life** *337*
Heather Shaw and Joshua Fronk

26. **Urgent Syndromes at the End of Life** *344*
Quinten Robertson and Kelli Gershon

27. **Sedation for Refractory Symptoms** *356*
Chandana Banerjee and Bonnie Freeman

28. **Complementary and Integrative Therapies in Palliative Care** *361*
Mary-Anne Meyer and Melinda Ring

29. **Withdrawal of Invasive Mechanical Ventilation** *371*
Margaret K. Campbell

SECTION III

Psychosocial and Spiritual Support

30. **The Meaning of Hope in the Dying** *379*
Valerie T. Cotter and Anessa M. Foxwell

31. **Bereavement** *390*
Inge B. Corless and Janice Bell Meisenhelder

32. **Supporting Families and Family Caregivers in Palliative Care** *405*
Kelli I. Stajduhar and J. Nicholas Dionne-Odom

33. **Planning for the Actual Death** *420*
Patricia Berry and Julie Griffie

34. **Spiritual Screening, History, and Assessment** *432*
Elizabeth Johnston Taylor

35. **Spiritual Care Intervention** *447*
William Rosa

36. **Meaning in Illness** *456*
Tami Borneman and Katherine Brown-Saltzman

SECTION IV

Special Patient Populations

37. **Cultural Considerations in Palliative Care** *469*
Carrie Cormack, Polly Mazanec, and Joan T. Panke

38. **Older Adult Patients in the Community** *483*
Carol O. Long

39. **Poor, Homeless and Underserved Populations** *490*
Caroline Olney, Sarah Stroe, and Anne Hughes

40. **Palliative Care for Patients with Mental Illness** *503*
John D. Chovan and Betty D. Morgan

41. **Palliative Care for People Living with HIV** *513*
Jacquelyn Slomka

42. **Caring for the Patient with Substance Use Disorder at the End of Life** *521*
Peggy Compton, Yu-Ping Chang, and Salimah Meghani

43. **Cancer Survivorship** *530*
Anne Reb and Denice Economou

44. **Veterans** *539*
Deborah Grassman

45. **Organ Donation** *545*
Lissi Hansen and Lauren F. Dunn

46. **Pulmonary Palliative Care** *552*
Patricia A. Maani-Fogelman and Ruby A. Weller

47. **Palliative Care in Heart Failure** *559*
J. Nicholas Dionne-Odom, Rachel Wells, and Keith M. Swetz

SECTION V

End-of-Life Care across Settings

48. **Improving the Quality of Care across All Settings** *573*
Marilyn Bookbinder, Romina Arceo, and James T. McDaniel

49. **Long-Term Care: Focus on Nursing Homes** *606*
Joan Carpenter and Mary Ersek

50. **Palliative Care in the Community** *615*
Nancy Robertson and Barbara Sutton

51. **The Intensive Care Unit** *624*
Jennifer K. McAdam and Céline Gélinas

52. **Palliative Care Nursing in the Outpatient Setting** *639*
Pamela Stitzlein Davies and Kathleen Broglio

53. **Palliative Care in the Emergency Department** *652*
Rebecca Wright and Benjamin Roberts

54. **The Role of Nursing in Caring for Patients Receiving Palliative Surgery or Chemotherapy** *660*
Virginia Sun, Tami Tittelfitz, and Marjorie J. Hein

55. **Rural Palliative Care** *670*
Richard A. Taylor, J. Nicholas Dionne-Odom, Erin R. Currie, Macy Stockdill, and Marie A. Bakitas

56. **The Role of PT, OT, and Other Therapies in Palliative Care for Seriously Ill Patients** *682*
Dennis Lin, Megan Borjan, Seanell D. San Andres, and Christina Kelly

57. **Value-Based Care** *690*
Finly Zachariah and William Dale

SECTION VI

Pediatric Palliative Care

58. **Symptom Management in Pediatric Palliative Care** *699*
Joan "Jody" Chrastek and Camara van Breemen

59. **Pediatric Hospice and Palliative Care** *708*
Vanessa Battista and Gwenn LaRagione

60. **Pediatric Goals of Care: Leading through Uncertainty** *727*
Christina McDaniel and Jordan M. Desai

61. **End-of-Life Decision-Making in Pediatric Oncology** *736*
Deborah A. Lafond and Katherine Patterson Kelly

62. **Palliative Care in the Perinatal Setting: Neonatal Intensive Care Unit, Labor and Delivery Unit** *749*
Cheryl Ann Thaxton, Diana Jacobson, Heather Murphy, and Tracey Whitley

63. **Grief and Bereavement in Perinatal and Pediatric Palliative Care** *758*
Rana Limbo, Kathie Kobler, and Betty Davies

64. **Pediatric Pain: Knowing the Child Before You** *773*
Juliana H. O'Brien and Maggie C. Root

65. **Supporting Adolescents with a Parent in Hospice** *783*
Denice Sheehan, Pamela Stephenson, M. Murray Mayo, Diane Snyder Cowan, and Dana Hansen

66. **Use of Social Media as a Communication Tool for People with Serious Illness and Their Families** *791*
Dana Hansen, Amy Petrinec, and Nidal Harb

67. **Access to Pediatric Hospice and Palliative Care** *800*
Lisa C. Lindley and Jessica Keim-Malpass

SECTION VII

Special Issues for the Nurse in End-of-Life Care

68. **The Advanced Practice Registered Nurse** *809*
Clareen Wiencek and Alexander Wolf

69. **Self-Care** *817*
Kathy G. Kravits

70. **Ethical Considerations in Palliative Care** *824*
Maryjo Prince-Paul and Barbara J. Daly

71. **Palliative Care and Requests for Assistance in Dying** *837*
Carey T. Ramirez, Kathleen Fundalinski, Judy Knudson, and John Himberger

72. **Nursing Education** *844*
Pam Malloy and Andra Davis

73. **Nursing Research** *855*
Terrah Foster Akard, Karen Hyden, and Mary Jo Gilmer

74. **Advocacy in Palliative Nursing: A Conceptual Model** *861*
Nessa Coyle and Timothy W. Kirk

75. **Global Palliative Care** *868*
Virginia LeBaron and Annette Galassi

76. **The Ethos of Palliative Nursing** *877*
Mark Lazenby and Michael Anthony Moore

Index *881*

Preface

The first edition of this Textbook was published in 2001 with the primary intent of helping to define the field of Palliative Nursing as a very new specialty. There has been enormous progress over these years, far exceeding even our own expectations, and each of the subsequent editions of the book has reflected the progress of the field and the contributions of nursing as members of interdisciplinary teams dedicated to competent and compassionate care of the seriously ill.

This fifth edition of the Oxford Textbook of Palliative Nursing moves the field a very big step forward as our field is now recognized as a critical nursing specialty in healthcare but also vastly growing in demand as essential to primary care practice in all settings of nursing. From the neonatal ICU to the long-term care setting for elders, palliative care provides attention to the physical, psychological, social, and spiritual needs of patients and families. The best definition of palliative care is that it is the kind of care we would want for our loved ones. It is the care that nurses have defined, imagined, and brought to life through expert clinical practice and scholarship. This edition reflects the broad terrain of our care, the ever-growing populations in need of palliative care and the solid evidence base for our practice.

Betty Ferrell and Judith Paice

Acknowledgments

We are grateful for the authors of the 76 chapters in this textbook. Their writing and their careers have built the discipline of Palliative Nursing and each chapter is a labor of love and dedication to better care for seriously ill patients and families. We also thank Andrea Hayward and Ellen Friedmann whose editorial assistance on every chapter of this text helped to create this textbook to guide the practice of nurses around the world.

Duarte, California

SECTION I

General Principles

CHAPTER 1

Introduction to Palliative Care

Betty Rolling Ferrell

Key Points

- Palliative care is a vital and necessary tool for nurses caring for an aging population.
- Properly assessing and managing the symptoms of chronic and advanced disease ensures that patients have the best quality of life possible during their illness journey.
- Psychosocial support and spiritual care are a fundamental part of palliative care that supports patients and families and helps them find hope and meaning in illness and in death.
- Palliative care must be made available to special patient populations: the poor, the homeless, the elderly, the drug-addicted, veterans, and those patients affected with mental illness among others.

The Textbook as a Resource

This fifth edition of the *Textbook of Palliative Nursing* comes at a time when palliative care is at the center of a healthcare system in need of urgent solutions to overwhelming challenges. An aging population, an uncertain healthcare payment system, growing chronic illnesses, and escalating costs have created opportunities to extend palliative care into settings and populations which were not even thought of when the last edition of this Textbook appeared only a few years ago.

Since the first edition of the Textbook in 2001, our hope as editors has always been that it would serve as an evidence-based resource for nurses searching for practical applications at the bedside. I keep a copy at my desk, at arms-length. Over the years, my own quality measure of the book has been to reach for it often to see if I can find useful information as I address daily questions in my professional life as a nurse and researcher. Almost always, I find the Textbook to, indeed, be a resource to answer real questions from real clinicians about real patients and families.

The Patient

The true test of the Textbook occurs at the bedside. Does this book really tell the story of the people we serve? As you read its pages, can you see the face of the patient?

As I prepared to edit this fifth edition, I had the opportunity to be involved in the care of an 85-year-old woman, Grace, who had chronic obstructive pulmonary disease (COPD). I had known Grace for approximately 5 years and witnessed her pulmonary disease progress from a well-managed chronic illness to become a life-altering disease that tried hard to squelch her radiant spirit and succeeded only in the last days of her life.

Grace was born and lived in Europe for the first 20 years of her life. She was a tall, beautiful, spirited woman whose last job before coming to America was as a flamenco dancer in a cabaret—quite a colorful job for a woman in 1950. She came to the United States for further adventure and began a long career as a "Girl Friday" in the movie studios of Hollywood. The next decades were filled with what she recalled as a wonderful life, filled with travel, interesting friends, constant stimulation, and glamour. Grace herself was a picture of glamour—she was tall and graceful, always impeccably dressed, and never without her French perfume.

At the age of 60, Grace was diagnosed with uterine cancer, and her fast-paced life came to an abrupt halt as she endured surgery and chemotherapy. She recovered completely but never returned to work. She did continue to enjoy her Hollywood friends, lunches, and travel to her family home in Europe.

Her zest for life was matched by a very deep religious faith, born from a devout Anglican religious upbringing from childhood. She was a person whose life was full of friends, family, cherished memories of her career, and a desperate desire to maintain her independence and her dignity.

Grace's pulmonary disease, which she attributed to the Hollywood days of women smoking, slowly took over her life. Her frequent respiratory infections limited her outings, and she eventually became oxygen-dependent. Although her body began to decline, her spirit persisted, and I watched over the course of the last 5 years of her life as the COPD took its toll on this beautiful woman and threatened her survival.

Grace insisted on living alone and refused assistance in her home. She had one short stay in assisted living after a hospitalization but then left the facility against all advice. She was determined to have her privacy at home. Fortunately, she was part of a healthcare system that seemed perfectly in step with Grace's needs. She received home care services and then later progressed to home-based palliative care. The palliative care team was astute in recognizing her decline over her last year of life but was also respectful of her intense need for independence.

Her COPD then seemed to advance over the course of a couple of months with several bouts of pneumonia and resultant challenges with dyspnea, insomnia, fatigue, and anorexia. She gave in and finally accepted the help of nursing assistants in her home, largely motivated by her desire to be well-dressed and to maintain her appearance despite the obvious decline in her body. One of her last outings was to attend a book signing by a Hollywood celebrity she had admired for years, a man who had just published his memoirs. This 85-year-old dyspneic, cachectic woman was transformed back into a young ingénue, totally enamored by a leading man.

A few months before Grace died, while visiting her at home, I noticed that she had recently framed a photograph of herself with a man, a picture that was probably taken of her in her late 20s. When I asked about the photo, she became very uncharacteristically quiet and serious and then she said, "I have loved three men in my life." I sat silently, recognizing that the person before me was reflecting deeply on her life. What followed was a lovely conversation as I listened intently and she told me about each of her three loves. As the stories were shared, I listened to this elegant woman tell her life story of loves, losses, betrayals, of good choices and bad; I heard this woman grieve for children she had never had, of her life that was both full and vibrant, but at times a life that was lonely and unfulfilled.

Just a few weeks before Grace died, the home-based palliative care program advanced her care into the hospice program. She remained in her home after finally accepting 24-hour care: her symptoms were well-controlled, and she insisted on getting all her affairs in order, advance directives completed, and everything well-organized—the perfect "Girl Friday" to the end.

My last visit with Grace was 6 days before she died. I had visited her over the years in my role as a volunteer and Eucharistic visitor through our shared faith community. We talked about her declining health, I shared communion with her, and we ended the visit by her telling me about her days as a flamenco dancer. It was the perfect last visit. Her death was peaceful, calm, and "Graceful."

The Textbook

Grace is in so many ways the model case example of the palliative care patients that we serve at the time of publication of this 5th edition of the Textbook. She represents an aging population, a person who has survived serious illnesses but has lived long enough to develop other serious illnesses with a prolonged trajectory of care.

How can this Textbook guide nurses to care for the "Graces" in our service? I think of Grace as I look over the contents of this book. Section I of the book presents General Principles, including chapters on national palliative care guidelines, hospital-based palliative care, principles of patient and family assessment, communication, and advance care planning. This section includes a chapter on palliative care team effectiveness, which is very reflective of the care Grace received. Her final months of life could have been quite different as a person with COPD, living alone, and at great risk of dying hospitalized and with severe uncontrolled symptoms.

Section II of the Textbook is on symptom assessment and management. Grace, like so many of our patients, at some point in her illness probably had almost every symptom listed across the 23 chapters in Section II. As these chapters illustrate, her care was dependent on competent symptom assessment, the best of pharmacologic and nonpharmacologic treatments, and attention to side effects such as pain, fatigue, anorexia, cachexia, dyspnea, and a whole host of other debilitating medical sequelae.

Section III of the Textbook introduces psychosocial and spiritual support, areas also critical to the whole-person care Grace needed and the care that all patients deserve. The chapters focus on spiritual care assessments and interventions, concepts of hope and meaning at the end of life, supporting families through the dying process and bereavement, and planning for actual death.

Section IV addresses the unique needs of Special Patient Populations. This part includes chapters addressing issues such as culture; older adults in the community; the poor, homeless, and underserved; veterans; and other populations in special need of palliative care, such as patients with mental illness or personality disorders, drug-addicted patients, AIDS patients, and pulmonary/critical care and heart failure patients. This section also includes chapters on organ donation and cancer survivorship, so important today to many receiving palliative care.

The fifth section reviews palliative care across settings. Grace—not at all distinct from most patients living with serious illness—was cared for across many settings, including home care, home-based palliative care, hospice, the intensive care unit, the emergency department, and the outpatient setting. This Textbook is dedicated to providing excellent care for patients across all settings of care and recognizes that nurses are the constant in each setting. This unit also addresses palliative care in rural communities; improving the quality of care across all settings; the role of the nurse caring for patients receiving palliative surgery or chemotherapy; and the role of PT, OT, and other palliative care therapies. This edition includes a new chapter on value-based care. Grace's care was not only high-quality care that met her needs but also delivered by a coordinated system that undoubtedly avoided costly admissions, futile care, and truly reflected her values and goals.

Section VII, Special Issues for the Nurse in End-of-Life Care, recognizes that nurses, as the ever-present support for end-of-life patients, encounter ethical considerations unique to this type of care and that they serve as advocates for this very vulnerable population. The chapters in this section address the need for nurses to practice self-care, the importance of nursing education and research, the role of the advanced practice nurse, the concept of caring in palliative nursing, and palliative care on the global scale of today's world.

Summary

As this fifth edition of the Textbook is published, I will again apply the "arm's-length" test of quality. As with earlier editions of the Textbook, this edition will be within easy reach in my office as I address the daily questions of nursing and research that arise in my professional life. I am confident that this book reflects the care that patients like Grace need and deserve and that it will serve as a valuable tool for the palliative care nurse at the bedside.

CHAPTER 2

National Consensus Project for Quality Palliative Care

Assuring Quality Palliative Care through *Clinical Practice Guidelines*

Constance M. Dahlin

Key Points

- The National Consensus Project for Quality Palliative Care (NCP)'s *Clinical Practice Guidelines* promote access to and the development of comprehensive quality palliative care through the delineation of eight key domains of care.
- The NCP's *Clinical Practice Guidelines* are the basis of specialty palliative care certification for hospitals, hospices, and home health agencies as well as professional certifications.
- The NCP's *Clinical Practice Guidelines* are the foundation of specialty palliative care education.

The National Consensus Project Initiative

The poor status of care at end of life and dying in America was the backdrop for the development of the National Consensus Project for Quality Palliative Care (NCP). Shortly after the Institute of Medicine (IOM)'s two separate reports on dying in America for adults in late 1997 and children in early 2000, national discussion began about how to improve care.[1,2] With hospice care already codified within the Medicare Hospice Benefit, a strategy to create guidelines for people ineligible for hospice, but palliative care–appropriate, was essential. In 2001, hospice and palliative care leaders convened in New York City to discuss standards in palliative care to guide the growth and expansion of palliative care in the United States. This meeting laid the foundation for the creation of the NCP (Box 2.1).

The first edition of the *Clinical Practice Guidelines for Palliative Care* was published in 2004. In 2005, the structure of the NCP moved to one of collaborative governance under the National Coalition of Hospice and Palliative Care. In 2006, the National Quality Forum (NQF) used the *Clinical Practice Guidelines* as a basis of its document *A National Framework and Preferred Practices for Palliative and Hospice Care Quality: A Consensus Report*.[3]

With a mission to "improve American healthcare through the endorsement of the consensus-based national standards for measurement and public reporting of healthcare performance data,"[3] this adoption by NQF was significant in its support of hospice palliative care standards and preferred practices, with implications for reimbursement, internal and external quality measurement, regulation, and accreditation.[3]

In 2009, just 5 years after the initial release of the NCP *Clinical Practice Guidelines*, the landscape of palliative care had changed. The number of palliative care and hospice programs had substantially

Box 2.1 History of the National Consensus Project for Quality Palliative Care *Clinical Practice Guidelines*

2001	Meeting in New York City of national palliative care leaders.
2002	Development of the clinical guidelines.
2003	Initial Review by advisory committee.
2003	Release of the first edition of the *Clinical Practice Guidelines for Quality Palliative Care* in March at the Annual Assembly received official endorsement by 40 organizations and associations.
2005	Disseminated to 90 organizations and associations.
2006	Served as the basis of NQF's document *A National Framework and Preferred Practices for Palliative and Hospice Care Quality: A Consensus Report.*
2009	Release of the second edition of the *Clinical Practice Guidelines for Quality Palliative Care* at the Annual Assembly of the American Academy of Hospice and Palliative Medicine (AAHPM) and the Hospice and Palliative Nurses Association (HPNA). Aspects of palliative care featured in review of healthcare reform under the Obama administration.
2011	The *Clinical Practice Guidelines for Quality Palliative Care* used as underlying principles for the Joint Commission *Advanced Palliative Care Certification.*
2013	Release of the third edition at the Annual Assembly of the AAHPM and HPNA endorsed by 54 organizations and associations.
2017	Funding for the creation of community-based palliative care guidelines specific to care in the home, skilled facility, assisted-living facility, group homes, shelters, prisons, etc.
2018	Expected completion of new guidelines with specific attention to palliative care in the community.

Box 2.2 National Consensus Project Clinical Practice Guidelines: Eight Domains of Care

Domain 1: Structure and processes of care
Domain 2: Physical aspects of care
Domain 3: Psychological and psychiatric aspects of care
Domain 4: Social aspects of care
Domain 5: Spiritual, religious, and existential aspects of care
Domain 6: Cultural aspects of care
Domain 7: Care of the patient nearing the end of life
Domain 8: Ethical and legal aspects of care

grown. Palliative care had become part of the national discussion of healthcare reform, making it necessary to assure concordance between the NCP *Clinical Practice Guideline* and the NQF *Framework and Preferred Practices*. Moreover, many stakeholders needed direction in implementing the conceptual ideas of the NCP *Clinical Practice Guidelines* into practice. As part of the commitment to have the guidelines reflect changes in palliative care, healthcare policy, and healthcare research, the guidelines were updated.

Within the review process, all 38 of the NQF preferred practices were reflected within the domains of palliative care. To broaden the scope of the document, there was appraisal and discussion within special interest focus groups related to palliative care (i.e., pediatrics, social work, oncology, geriatrics) to assure that the guidelines were representative of practice.[4] To ensure the inclusivity and expansiveness of the guidelines to all settings where palliative care is provided, clarifications were made and sections were further developed.[4] Finally, an updated palliative literature search was performed which yielded more articles specific to the American landscape.

From 2009 to 2013, significant maturation within the field of palliative care occurred. The numbers of hospice and palliative care programs across the nation with increased representation across healthcare systems and settings grew extensively. Although hospice and palliative nursing had been formally recognized as a specialty by the American Nurses Association for more than 20 years, palliative medicine was formally recognized by the American Board of Medical Specialties in 2008, establishing it as a distinct and well-defined subspecialty of care within healthcare. Palliative care research demonstrated that the presence of palliative care improved quality of life, decreased psychological symptoms, and perhaps increased survival. Healthcare reform included critical elements of palliative care and the establishment of a national palliative care quality measurement strategy within the United States through the Center for Medicare and Medicaid Services[5] (see Box 2.2).

National Consensus Project for Quality Palliative Care: Definitions and Tenets

In order to promote consistency, the NCP supports the palliative care definition developed by the Center for Medicare and Medicaid Services (CMS), which states:

> Palliative care means patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness involves addressing physical, intellectual, emotional, social, and spiritual needs and to facilitate patient autonomy, access to information, and choice.[6]

In addition, several underlying palliative care tenets are delineated by the NCP[7]:

1. Palliative care is patient- and family-centered care.
2. Palliative care is comprehensive, with continuity and access across health settings.
3. Early introduction of palliative care concepts should begin at diagnosis of a serious or life-threatening illness by the primary team. Specialist consultation may be offered as well.
4. Palliative care may be offered concurrently with or independent of curative or life-prolonging care. Patient and family hopes for peace and dignity are supported throughout the course of illness, during the dying process, and after death.
5. Palliative care is interdisciplinary and collaborative. Patients, families, palliative care specialists, and other healthcare providers collaborate and communicate about care needs.
6. Palliative care team members have clinical and communication expertise.
7. The goal of palliative care is the relief of physical, psychological, emotional, and spiritual suffering of patients and families.
8. Palliative care should focus on quality care.
9. There should be equitable access to quality palliative care services across geography, health settings, patient populations, and conditions.

At the outset, the mission of the NCP was to create clinical practice guidelines to ensure the quality of palliative care in the United States. The goal for the *Clinical Practice Guidelines for Quality Palliative Care* was to (1) to promote quality and reduce variation in new and existing programs, (2) develop and encourage continuity of care across settings, and (3) facilitate collaborative partnerships among palliative care programs, community hospices, and a wide range of other healthcare delivery settings.[8]

The development process was fourfold. First, there was a review of all international standards and guidelines. This included, most notably, those from Canada, Australia, Scotland, and Great Britain, where palliative care was established. From this, basic assumptions about palliative care were constructed. Second, a thorough review of the literature in hospice and palliative care was performed to support the guidelines. Since the Medicare Hospice Benefit is unique to the United States, it changes the dynamic of palliative care implementation. Because palliative care was in its infancy in the United States, there was little American literature specific to it, so evidence was borrowed from other countries and specialties. It was understood, however, that the guidelines would be changed with the evolution of the evidence base for palliative care, US healthcare reform, and professional practice. Third, a broad range of interdisciplinary experts across settings and populations was convened to develop consensus in quality palliative care delivery across the healthcare continuum. In considering quality, it was agreed that palliative care interdisciplinary team members would observe established professional and organizational codes of ethics. In addition, palliative care services would adhere to established standards and requirements for healthcare quality in safety, effective leadership, medical record keeping, and error reduction. Fourth, an inclusive writing process was created that role-modeled the collaborative process and underscored the importance of the project.[8] The NCP members reviewed the document line by line, with each sentence necessitating at least 80% agreement of task force members before inclusion.

An overall goal was that the guidelines would acknowledge specialty palliative care versus primary palliative care. Primary palliative care could be incorporated into any discipline in order to assure competency in symptom management and communication skills. Specific specialty palliative care qualifications would continue to be delineated by specialty organizations granting professional credentials and programmatic accreditation. A core assumption is that ongoing professional palliative care education (knowledge, attitudes, and skills) would occur to assure the delivery of quality palliative care across the domains established in the document.[8]

Thus, the *Clinical Practice Guidelines* are a framework for program development and a blueprint for existing programs to use to measure their quality. Rather than set minimally acceptable practices, the guidelines set ideal practices and goals that palliative care services should strive to attain. Upon the completion of each edition, a review process across healthcare and consumer organizations occurs. The result is both an assurance that the guidelines reflect the field and a formal endorsement process.

The Eight Domains of the *Clinical Practice Guidelines*

The NCP delineates eight domains of care and supports the goal of each domain with both available palliative care literature and other related literature from other specialties (see Box 2.2). Articles specific to each domain were published in a variety of journals (see Box 2.3).

Box 2.3 Domains and Articles Specific to the Domain

Domain 1: Structure and Processes of Care

Ferrell B. Overview of the domains of variables relevant to end-of-life care. *J Palliat Med*. 2005;8(S1):S22–S29.
Ferrell B, Connor S, Cordes A, et al. The national agenda for quality palliative care: the National Consensus Project and the National Quality Forum. *J Pain Symptom Manage.* 2007;33(6):737–744.

Domain 2: Physical Aspects of Care

Blouin G, Fowler B, Dahlin C. The National Agenda for Quality Palliative Care: promoting the National Consensus Project's domain of physical symptoms and the National Quality Forum's preferred practices for physical aspects of care. *J Pain Palliat Care Pharmacother.* 2008;23(3):1–7.
Dahlin C. Promoting culture within pain and palliative care: National Consensus Project guidelines and National Quality Forum preferred practices. *Am Acad Pain Manage/ Pain Practitioner.* 2007;17(2):7–9.

Domain 3: Psychological and Psychiatric Aspects of Care

Hultman T, Reder ER, Dahlin C. Improving psychological and psychiatric aspects of palliative care: the National Consensus Project and the National Quality Forum preferred practices for palliative and hospice care. *Omega.* 2008;57(4):323–339.

Domain 4: Social Aspects of Care

Altilio T, Otis-Green S, Dahlin C. Applying the National Quality Forum preferred practices for palliative and hospice care: a social work perspective. *J Soc Work End-of-Life.* 2008;4(1):3–16.

Domain 5: Spiritual, Religious, and Existential Aspects of Care

Scott K, Thiel M, Dahlin C. The national agenda for quality palliative care: the essential elements of spirituality in end-of-life care. *Chaplaincy Today.* 2008;24(2):15–21.

Accessed January 7, 2018.

Domain 6: Cultural Aspects of Care

Dahlin C. Promoting culture within pain and palliative care: National Consensus Project Guidelines and National Quality Forum preferred practices. *Am Acad Pain Manage/Pain Practitioner.* 2007;17(2):7–9.

Domain 7: Care of the Patient Nearing End of Life

Lynch M, Dahlin C. The National Consensus Project and National Quality Forum preferred practices in care of the imminently dying—implications for nursing. *J of Hosp Palliat Nurs.* 2007;9(6):316–322.

Domain 8: Ethical and Legal Aspects of Care

Colby WH, Dahlin C, Lantos J, Carney J, Christopher M. The National Consensus Project for quality palliative care Clinical Practice Guidelines Domain 8: ethical and legal aspects of care. *HEC Forum.* 2010;22(2):117–131.

Domain 1: Structure and Process of Care

This domain addresses the organization of specialty palliative care teams and the necessary processes and procedures for quality care delivery.[7] The criteria emphasize coordinated assessment and continuity of care across healthcare settings. In particular, there is a description of the interdisciplinary team composition, team member qualifications, and necessary education, training, and support. There is attention paid to and emphasis on interdisciplinary team engagement and collaboration with patients and families. Finally, the domain incorporates the new mandates for quality as established within healthcare reform, which will continue to evolve. Palliative nurses need to understand specialty palliative care delivery as defined by specialty palliative care nursing qualifications, including certification through the Hospice and Palliative Credentialing Center, educational requirements, and communication. Palliative care nurses also need to understand the essential aspects of interdisciplinary care delivery and collaborative team processes.

Domain 2: Physical Aspects of Care

This domain recognizes the multidimensional management of symptoms using pharmacological, interventional, behavioral, and complementary interventions. There is emphasis on the assessment and treatment of physical symptoms using appropriate, validated tools. Finally, there are recommendations for the use of explicit policies for the treatment of pain and symptom management, the use of multimodal strategies and safe prescribing, and safe storage and disposal of controlled medications.[7] Palliative nurses must be educated in the range of pharmacological and nonpharmacological guidelines to provide safe pain and symptom management, particularly within the current opioid misuse crisis.

Domain 3: Psychological and Psychiatric Aspects of Care

This domain acknowledges the psychological and psychiatric dimensions of palliative care. It reviews the collaborative assessment process of these diagnoses, similar to that for the multidimensional approach to physical aspects. It defines essential elements including patient–family communication on assessment, diagnosis, and treatment options in the context of patient and family goals of care. Again, multimodal strategies are encouraged. Most significantly, this domain includes required criteria for a bereavement program. Palliative nurses need to understand that psychological and psychiatric aspects of care are as important as the physical aspects. Moreover, nurses must consider a bereavement plan because care continues for the family after death through the provision of bereavement care.

Domain 4: Social Aspects of Care

This domain emphasizes interdisciplinary engagement and collaboration with patients and families to identify support within the organization and the community to capitalize on patient and family strengths. It defines essential elements of a palliative care social assessment. Notably, it includes the description of the role of the bachelor's- or master's-prepared social work professional. Palliative nurses need to focus on family systems to support person-centered and family-focused care. In addition, they need to collaborate with social work and integrate the expertise of their social work colleagues.

Domain 5: Spiritual, Religious, and Existential Aspects of Care

This domain has evolved to include a spirituality definition. While simultaneously stressing interdisciplinary responsibility and collaboration in assessment and management of spiritual issues and concerns, there is emphasis on the use of an appropriately trained chaplain. Requirements for staff training and education in spiritual care are described. Finally, the domain promotes spiritual and religious rituals and practices for comfort and relief.[7] Palliative nurses need to understand the range of the spiritual component, whether it is ritualized or not, and its impact on care. In addition, they need to collaborate with spiritual care providers and integrate the expertise of their chaplain and spiritual leader colleagues.

Domain 6: Cultural Aspects of Care

The development of this domain now includes a definition of required interdisciplinary team culture and cultural competence, highlighting culture as a source of resilience and strength for the patient and family. Cultural and linguistic competence with respect to language, literacy, and linguistically appropriate service delivery is stressed.[7] Palliative nurses need to understand the cultures of the communities they serve. Palliative nurses also need to consider the breadth of cultural competence outside their own worldview and embrace cultural care beyond the use of an interpreter service.

Domain 7: Care of the Patient Nearing End of Life

The title of this domain has changed from Care of the Imminently Dying to Care of the Patient at the End of Life to broaden care to advanced stages of illness through death. In particular, it emphasizes the social, spiritual, and cultural aspects of care throughout the dying trajectory for the patient. It underscores the importance of meticulous assessment and management of pain and other symptoms. The importance of communication, information, and documentation of the signs and symptoms of the dying process, inclusive of the patient, the family, and all other involved health providers, is underscored.[7] Palliative nurses need to promote this nursing expertise and assure quality care at this time.

Domain 8: Ethical and Legal Aspects of Care

This domain is separated into three sections: advance care planning, ethics, and the legal aspects of care. The responsibility of the palliative care team to promote ongoing goals of care discussions accompanied by completion and documentation of advance care planning is emphasized. Significant is the affirmation and acknowledgment of the frequency and complexity of palliative care ethical and legal issues. Consultation from ethics committees and legal counsel are stressed, as are team competencies in ethical principles and education regarding particular legal aspects of care. There is also emphasis on the understanding of the respective scopes of practice issues among team members.[7] The use of ethics and legal resources could help diminish moral distress for nurses as well as for all healthcare professionals. Palliative nurses need to understand the scope of their care and the boundaries of ethics, as well as the resources available to provide care in this important specialty.

Implementation of the *Clinical Practice Guidelines*

Since 2013, developments have occurred in the field that have spurred further refinement of the guidelines. In 2014, the IOM released its report, *Dying in America—Improving Quality and Honoring Individual Preferences Near End of Life*. It highlights five areas in which to assure quality palliative care:

- delivery of person-centered and family-focused palliative care,
- clinician–patient communication and advance care planning,
- professional education in palliative care,
- policies and payment for palliative care, and
- public education and engagement in palliative care.[9]

In terms of the delivery of patient-centered and family-focused palliative care, the *Clinical Practice Guidelines* domains have grounded care within various populations. Various professional organizations have delineated the role of palliative care, as in the care of patients with amyotrophic lateral sclerosis (ALS), heart disease, stroke, and dialysis.[10–12] This is particularly true in oncology care. The American Society of Clinical Oncology (ASCO) delineated quality standards using NCP guidelines within cancer care[13] (see Box 2.4). More recently, the guidelines have been applied to patients entering cancer clinical trials.[14] Other populations include those with pulmonary disease and cystic fibrosis, in which the guidelines grounded the role of palliative care.[15,16] The quest to develop quality perinatal palliative care resulted in the use of the NCP domains as the basis of a survey of perinatal programs across the United States and a tool for parents of infants in palliative care.[17,18]

Many clinician–patient communication and advance care planning initiatives have been grounded in the guidelines. The NCP guidelines also served as an important document to promote international and national consensus for the spiritual aspects of whole-person care.[19] And there have been several initiatives related to the NCP domain which focus on communication, including Comfort Communication,[20] Vital Talk,[21] and The Serious Illness Project.[22,23] An initiative related to the Ethical and Legal Aspects of Care domain, which focuses on advance care planning and engagement, is The Conversation Project.[24]

Professional education in palliative care has used the NCP framework to develop curriculum. This includes the End-of-Life Nursing Education Consortium (ELNEC) for nurses[25] and Education in Palliative and End-of-Life Care (EPEC) for physicians.[26] Professional organizations have used the guidelines for the creation of specialty practice. The National Association of Catholic Chaplains used them to create their certification program.[27] The Physicians Assistants Association is using them to create a palliative care specialty within its discipline.[28] The Society of Palliative Pharmacists used them to delineate the important role of pharmacists on the team.[29]

Box 2.4 Professional Organization with Palliative Care Guidelines

American Society of Clinical Oncology: Palliative care at cancer diagnosis
American Heart Association and American Stroke Association: Cardiovascular disease and stroke
American Academy of Neurology: Amyotrophic lateral sclerosis (ALS)
Renal Physicians Association and American Society of Nephrology: Initiation of and withdrawal of dialysis

A major body of work in palliative care has focused on the development of quality measures to demonstrate the value and effectiveness of palliative care. As was the intent of their creation, the NCP *Clinical Practice Guidelines* have served as the basis for the development of specific measures and a research agenda.[30–32] One program is Measuring What Matters, a joint initiative between the American Academy of Hospice and Palliative Medicine (AAHPM) and the Hospice and Palliative Nurses Association (HPNA), which reviewed the domains to create their profile of measures.[33] The PEACE measures that evaluate quality in hospices and palliative care also used the domains.[34]

In assuring quality of programs, The Joint Commission initiated Advanced Palliative Care Certification beginning in 2011 for hospitals, using the NCP *Clinical Practice Guidelines* as benchmarks to measure the breadth and depth of palliative programs.[35] In 2016, the Joint Commission added certification in palliative care for the community and offered a Community-Based Palliative Care Certification to home health agencies and hospice organizations, as well as hospitals.[36] In order to meet these standards and assure quality care delivery, many programs have made the case for including all essential team members, particularly from social work and chaplaincy, as integral members of specialty palliative care teams.

Although the guidelines have been applicable to all populations across all settings, over the past few years there has been a growing emphasis placed on care outside the hospital and in the community. To that end, there has been discussion in having guidelines that reflect the opportunities and challenges in the community. One study on guidelines in the community suggested that there could be more in the domains on social issues to reflect the experiences of patients as well of those of the caregiver.[37] Another study matched the guidelines to person-centered goals in serious illness.[38] Finally, the Connecticut Coalition to Improve End-of-Life Care used the guidelines to determine community proficiency in end-of-life (EOL) care.[39]

Given the rapidly changing healthcare landscape, palliative care is quickly expanding. A new revision of the guidelines is in process that includes a deliberate broadening of partnerships with constituents from clinical providers, community service providers, payers, and professional clinical and consumer organizations. A summit meeting was held in 2017, with 58 representatives from organizations across the country gathering to gain further input on the growing trend of care in the community.[17] Moreover, the next edition of the guidelines will be inclusive of both primary palliative care and specialty palliative care.[28]

National Consensus Project *Clinical Practice Guidelines*: Implications for Nursing

Nursing and palliative care are intertwined. Recognition of specialty palliative nursing expertise and assuring the quality of palliative nursing practice are essential to quality palliative care. Nurses practice in a variety of settings that may have palliative care programs. The NCP *Clinical Practice Guidelines* establish essential elements of specialist palliative care that promote quality, consistent clinical services. In particular, the guidelines assure clear expectations of high-quality nursing practice, including orientation, job descriptions, and peer review.

The 2011 IOM report *The Future of Nursing: Leading Change, Advancing Health* acknowledged the essential contributions of nursing at the bedside and in healthcare redesign in its four messages[40]:

1. Nurses should practice to the full extent of their education and training.
2. Nurses should achieve higher levels of education and training through an improved education system that promotes seamless academic progression.
3. Nurses should be full partners, with physicians and other healthcare professionals, in redesigning healthcare in the United States.
4. Effective workforce planning and policymaking require better data collection and information restructure.[22]

The NCP *Clinical Practice Guidelines* promote these messages and delineate quality in three areas particularly appropriate for nursing and consistent with the IOM report: professional development, education, and certification. The *Clinical Practice Guidelines* offer a framework to care, educational areas, and criteria for benchmarking nursing. The guidelines are a framework applicable to nurses across settings ranging from acute care, ambulatory care, rehabilitation facility, community, home care, and hospice programs, to long-term care facilities, accountable care organizations, and patient medical homes.

As a quality imperative, the NCP *Clinical Practice Guidelines* can result in improved patient outcomes and better compliance with state and federal regulations. Because appropriate resource utilization is a common concern, the emphasis on community assessment and communication across settings and specialties may provide a nursing benchmark. Moreover, the strict description of pain and symptom assessment, management, the use of assessment tools, and evidence-based practice is significant, particularly with regard to the opioid crisis. These criteria may promote safe nursing practices and improved patient and family satisfaction in pain and symptom control.

Domain 2, Physical Aspects of Care, and Domain 3, Psychological and Psychiatric Aspects of Care, may help organizations meet evidence requirements for the American Nurses Credentialing Center Magnet Status Recognition Program in the areas of Structural Empowerment, concerning nursing image and professional development; Exemplary Professional Practice, concerning consultation and resources, autonomy, and interdisciplinary relationships; New Knowledge, Innovation, and Improvements, concerning quality improvement; and Empirical Quality Results, concerning quality of care.[41] They can also facilitate accreditation by The Joint Commission in the areas of pain management, culturally competent care, and EOL care. Again, they may also help the nurse promote higher patient satisfaction and patient experience.

Domain 4, Social Aspects of Care; Domain 5, Spiritual, Religious, and Existential Aspects of Care; and Domain 6, Cultural Aspects of Care coach the nurse to deliver more effective and culturally competent care by focusing care on the patient and family system. This is particularly important in the landscape of rapidly changing population demographics. Domain 7, Care of the Patient Nearing End of Life, is an area of nurse expertise and helps nurses coach and mentor one another in this area. Domain 8, Ethical and Legal Aspects of Care, broadens the support system of the nurse by including both an ethics committee and a legal counsel in advocating for the patient and/or family.

The NCP *Clinical Practice Guidelines* have been used for many palliative nursing educational initiatives, particularly within the HPNA. First, in the *HPNA Standards for Clinical Education of Hospice and Palliative Nurses*, the *Clinical Practice Guidelines* serve as the basis for palliative nursing educational activities for nurses including observerships, practicums, preceptorships, residencies, fellowships, and immersion courses.[42] Second, HPNA has created a resource for both the registered nurse (RN) and the advanced practice registered nurse (APRN) that delineates the implementation of the guidelines.[43,44] Third, the HPNA created *Palliative Nursing Manuals* based on the NCP domains. In collaboration with Oxford University Press and using the *Oxford Textbook of Palliative Nursing*, eight *Palliative Nursing Manuals* promote quality practice and excellence in the domains.[45] Fourth, the NCP guidelines serve as the basis for the HPNA RN Pathway and APRN Pathway, which are currently in development and will be available in 2019. The pathways use the Benner Novice to Expert Framework for an RN or APRN to develop from a novice to an expert palliative nurse by grounding the education in the NCP guidelines.

Other essential nursing education courses use the NCP. The *Clinical Practice Guidelines* frame the ELNEC curricula in demonstrating best practices.[46,47] The guidelines serve as an underpinning to nurse-specific roles and skills. The American Association of Colleges of Nursing and the City of Hope utilized the NCP in the development of *CARES: Competencies and Recommendations for Educating Undergraduate Nursing Students: Preparing Nurses to Care for the Seriously Ill and Their Families*.[48] To accompany this, they have created an educational program based on these competencies for utilization within all undergraduate and pre-licensure nursing programs. In another project, the NCP domains serve as the structure for an intervention to improve nurses' skills in palliative care.[49] Lindley, Herr, and Norton use the NCP domains to describe the role of hospice and palliative care nurses in quality improvement.[50] Finally, in 2017, the American Nurses Association and the HPNA released *A Call For Action—Nurses Lead and Transform Palliative Care* in which the NCP guidelines ground palliative nursing in its fourth recommendation[51]:

> Advocate the use of the National Consensus Project for Quality Palliative Care *Clinical Practice Guidelines for Quality Palliative Care* in the development, implementation, and evaluation of specialty, evidence-based, palliative care services for all organizations.[51]

As an education tool, the guidelines offer content for specialty palliative nursing and promote more effective educational programs based on the evidence from research. Essential nursing education features include a focus on orientation, communication, pain and symptom assessment, social/cultural assessment, and spiritual assessment. The *Clinical Practice Guidelines* promote understanding of the domains (particularly bereavement and social, cultural, and spiritual care) and the essential nursing components in patient-centered care delivery. Just as important, the essential aspects of ethical foundations and legal regulations assist the nurse in scope-of-practice issues and mitigate moral distress by providing more clearly delineated processes for conflict resolution.

Conclusion

The NCP *Clinical Practice Guidelines for Quality Care* is a significant resource to facilitate collaborative care for patients with serious, debilitating, and life-limiting illnesses. It offers the palliative nurse a framework for comprehensive, quality, person-centered care across all settings within a community, ranging from home, assisted living, group homes, shelters, and nursing care facilities to adult and pediatric day care centers, community and senior centers, office and clinic practices, and acute hospital settings. It promotes care across all populations from neonates to children to adults and older adults; across the range of chronic progressive and serious life-threatening illnesses, injuries, and trauma; and across a range of vulnerable and underresourced populations (homeless individuals, immigrants, low-income individuals, oppressed racial and ethnic groups, veterans, prisoners, older adults, and individuals with mental illness).[21]

The NCP *Clinical Practice Guideline*s promote the growth and maturity of the field by facilitating the development and continuing improvement of clinical palliative care programs providing care to patients and families with serious illness; establishing uniformly accepted definitions of the essential elements in palliative care that promote quality, consistency, and reliability of these services; establishing national goals for access to quality palliative care; fostering performance measurement and quality improvement initiatives in palliative care services; and promoting continuity of palliative care across settings (i.e., home, residential care, skilled facility, long-term care setting, rehabilitation setting, hospital, and hospice).[7] They offer the foundation upon which nurses can create and develop quality palliative care and practice.

CHAPTER 3

Hospital-Based Palliative Care

Patricia Maani-Fogelman

Key Points

- Hospital-based palliative care (HBPC) teams provide both an interdisciplinary and multidisciplinary component to the care of patients with advanced illness.
- HBPC teams can provide structured and ongoing care throughout the course of patient hospitalization and across care settings, from intensive care to medical surgical floor settings and nursing homes.
- Data analytics and care metrics provide support for continued HBPC programmatic growth.
- Nurses at all levels are vital to the ongoing delivery, management, and supportive care of the patient with advanced illness.

Case Study

Mrs. K was an 82-year-old retired nurse with rheumatoid arthritis, severe right heart failure/pulmonary hypertension (Group 2 and 3 disease) and left heart failure, heart block with pacemaker placement, renal failure, kyphoscoliosis, and obstructive sleep apnea. In the past year, she has had six admissions for acute or chronic hypoxemic respiratory failure. Serial echocardiograms demonstrated progressive right- and left-sided heart failure with rising estimated pulmonary artery pressures. She was not a candidate for advanced pulmonary hypertension therapies. Her hypoxemia worsened, and she required around-the-clock oxygen at higher flow rates. During the last admission, she became dependent on bilevel positive airway pressure (BiPAP) for ventilatory support and could not be weaned off this support. In past discussions with her pulmonary-palliative medicine nurse practitioner, she had verbalized the desire not to be sustained on artificial means of life support, to have a comfortable death at home (if possible), but, most importantly, to have her family present. During this admission, it became clear that she would not be able to wean off BiPAP. The pulmonary-palliative nurse practitioner had ongoing discussions with Mrs. K during daily inpatient rounds as well as family meetings held with Mrs. K, her husband, and adult children. She did not want to continue BiPAP, and a discharge home was not possible due to medical acuity. The pulmonary-palliative nurse practitioner provided ongoing support. Goals of care were discussed, Mrs. K's wishes for end-of-life (EOL) care were carefully navigated, and a plan was developed to transition Mrs. K from BiPAP to nasal cannula with supportive medications to assure relief of any respiratory distress. It was agreed that she would be provided with inpatient palliative and EOL care to assure that her end-of-life goals were met. The chaplain provided Mrs. K with the Sacrament of the Sick and Last Rites in accordance with her Catholic religion. Additional family came to visit. All her grandchildren were able to have private visits with her, where she dispensed her best advice and aspirations for their success in both life and love. When Mrs. K was ready, the nurse practitioner premedicated her with opioid for respiratory distress and secretion management. Opioid medication and anxiolytics were administered as the patient requested. Over the next few hours she became less interactive and less able to be aroused. When her respiratory symptoms became more intense, an opioid infusion was started for optimized symptom management and Mrs. K became visibly more comfortable. Her family was reassured, and they verbalized satisfaction with her care. Surrounded by her family and in no distress, Mrs. K passed away later that night.

A Brief History

The history of hospital-based palliative care (HBPC) is a long and evolving story. In 1978, Senator Edward Kennedy said "Hospice is many things. Hospice is home care with inpatient back-up facilities. Hospice is pain control. Hospice is skilled nursing. Hospice is a doctor and a clergyman coming to your home. . . . But most of all, hospice is the humanization of our health care system."[1] The number of US hospitals offering palliative care services has been increasing rapidly for more than a decade, many times in response to patient needs as well as healthcare and medical/nursing education reform (see Box 3.1).

While there has been a national trend indicating growth, the Center to Advance Palliative Care's (CAPC) 2015 State-by-State Report Card gives the nation a grade of B: the 2015 Report Card shows a continued increase in the number of hospital palliative care teams in the United States, with 67% of US hospitals (>50 beds) reporting palliative care teams, an increase of 10% from the 53% of hospital reporting the same in 2008.[2] This evidence supports the reality that, even with continued growth, access to palliative care remains inadequate for millions of patients living with advancing, chronic disease. While there is still room for improvement nationally, it is gratifying to know that the number of states with A grades (defined as more than 80% of the state's

Box 3.1 Milestones in the Evolution from Home Hospice to Hospital-Based Palliative Care

1970s: Awareness of hospice philosophy transfers from Great Britain to the United States

1976: Karen Ann Quinlan case

1980s: Recognition of aging population, chronic disease demographics, growth of National Institute on Aging and the American Association of Retired Persons

Passage of Medicare Hospice Benefit

Recognition of AIDS

1990s: National recognition in the United States of the problem of end-of-life care

1990: Nancy Cruzan case

1990–1997: Kevorkian-assisted deaths

1991: Patient Self-Determination Act

1995: SUPPORT study findings of poor end-of-life care

1997: Legalization of assisted suicide in Oregon

1997: Institute of Medicine (IOM) Report: "Approaching Death: Improving Care at the End of Life"

1997: Institute for Health Care Improvement (IHI) End-of-Life Breakthrough Collaborative

1998: First palliative care APN programs (Ursuline College, New York University)

1999: Kevorkian convicted of first-degree murder and imprisoned

2000s: Baby boomers with aging parents achieve positions of leadership and authority (Project on Death in America [pdia] scholars/leaders) entering and legitimizing palliative medicine as a specialty field

2001: Institute of Medicine Report "Improving Palliative Care for Cancer"

Public Broadcasting System (PBS) Bill Moyers Special, "On Our Own Terms"

1995–2003: Robert Wood Johnson Foundation funds end-of-life activities

Faculty Scholars Program

2001: Disseminating End-of-Life Education to Cancer Centers (DELEtCC)

2002: Department of Veterans Affairs initiates multiple palliative/end-of-life programs

Mayday, Kornfeld sponsor mini-fellowships (Northwestern, Memorial Sloan Kettering, etc.)

Growth and development of specialty education and organizations

Shift of professional membership organizations from being homes of the isolated to active change agents in policy, education, and clinical change: HPNA, AAHPM

Center to Advance Palliative Care & Palliative Care Leadership Centers

NHPCO, AAHPM, HPNA—membership organizations

Palliative Medicine achieves ABMS specialty status

Advanced and NA specialty nursing certification

Expansion of Harvard course, EPEC, ELNEC, JPM

Development of (MD) fellowship programs

2004: National Consensus Project + 2008 NQF-Quality Guidelines

2005: Terry Schiavo case

2005: The American Heart Association and the American College of Cardiology release new guidelines about treating heart failure that includes recommendations that hospice care education be provided early in the course of an illness.

Research evidence to support palliative care emerging and developing new funding sources

NPCRC/ACS Junior Faculty & Pilot Project Awards

2008: The Joint Commission considers Palliative Care Certification process

2008–2014: California launches 5-year initiative "Spreading Palliative Care in Public Hospitals" to develop HBPC programs

2010: *New England Journal of Medicine* landmark study: "Early Palliative Care for Patients with Metastatic Non–Small-Cell Lung Cancer."

2010: NHPCO Standards of Practice for Pediatric Palliative Care and Hospice Receives American Academy of Pediatrics' Affirmation of Value.

2010: We Honor Veterans, a pioneering campaign to help improve the care Veterans receive from hospice and palliative care providers, is launched by NHPCO in collaboration with the Department of Veterans Affairs.

2010: A provision in The Patient Protection and Affordable Care Act will require state Medicaid programs to allow children with a life-limiting illness to receive both hospice care and curative treatment.

Box 3.1 Continued

2011: The Joint Commission launches Palliative Care Certification.

2011: NHPCO publishes report, Private Conversations and Public Discourse: The Importance of Consumer Engagement in End-of-Life Care.

2011: The Concurrent Care for Children: Implementation Toolkit is released by NHPCO and the District of Columbia Pediatric Palliative Care Collaboration.

2011: Campaign for the National Center for Care at the End of Life Launched by National Hospice Foundation.

2011: Ethical Marketing Practices position statement and commentary are released by NHPCO.

2011: The bicameral Wyden-Roberts HELP Hospice Act is introduced in Congress. The Concurrent Care for Children: Implementation Toolkit is released by NHPCO and the DC Pediatric Palliative Care Collaboration.

2012: LIVE—Without Pain, a new public awareness campaign from NHPCO's Caring Connections, dispels myths about pain and empowers consumers.

2012: An innovative, online advocacy resource, the Legislative Action Center, is created online by the Hospice Action Network. More than 1.5 million people are reached through the six-part online video series, Basics of Hospice.

2013: Research from Mount Sinai's Icahn School of Medicine demonstrates cost savings of hospice and NHPCO and Hospice Action Network work to take this research to legislators and the media.

2014: FHSSA expands its mission and is re-launched as Global Partners in Care.

2017: Palliative Care and Hospice Education and Training Act, PCHETA, would amend the Public Health Service Act to increase the number of permanent faculty in palliative care education programs. S. 693, H.R.1676 (www.nhpco.org/history-hospice-care)

hospitals reporting a palliative care team) has increased, from 3% in 2008 to 17% in 2015; perhaps most significantly, for the first time, no state has a grade of F (defined as less than 20% of a state's hospitals reporting a palliative care program).[1] However, deficits in care remain an ongoing issue, with one-third of US hospitals (>50 beds) reporting no palliative care services and one-third of the states receiving a grade of C or D.[2,3]

The Aging Population

More than one-third of Medicare patients with advanced, chronic illness experience four transitions in care during their last year of life.[2,3] This burden is significantly higher in the Medicare population than in the general population; in the aged, the majority of deaths are attributable to common diagnoses: congestive heart failure, chronic lung disease, cancer, coronary artery disease, renal failure, peripheral vascular disease, diabetes, chronic liver disease, and dementia.[2–4] Their disease trajectory is chronic and progressive in the setting of advancing, incurable disease that will eventually reach a point of maximal medical therapies providing little to no benefit and continued failure. Palliative care teams provide consultation services to help manage complicated patients in the acute, subacute, and chronic illness setting. The HBPC team maintains a focus on management of pain and symptom issues through the course of the hospital admission. Palliative care teams focus on strong communication with the patient/family, primary and specialty teams, and the interdisciplinary team (IDT).

In 1974, the Royal Victoria Hospital in Montreal, Canada, developed one of the first initiatives in North America to improve HBPC. They created a palliative care service to meet the needs of hospitalized patients who were terminally ill within the general hospital setting.[5] An integral part of the Royal Victoria Hospital, a 1,000-bed teaching hospital affiliated with McGill University, the palliative care service consisted of five complementary clinical components: (1) the palliative care unit (PCU), (2) the home care service, (3) the consultation team, (4) the palliative care clinic, and (5) the bereavement follow-up program. Members of an IDT were involved with the care of these patients, and the focus was on holistic care with pain control and symptom management. Decades later, these basic palliative care concepts are more prevalent throughout US hospitals and the nation, and several milestones over the past four decades have shaped the evolution of care of the seriously ill. In the 1970s, the concept of home-based hospice programs (often volunteer-only) seen in Europe and Canada began to appear in the United States, imported from Europe and Canada. Since that time, several professional, medical, societal, and academic endeavors have coalesced in the form of HBPC programs that adapt and "upstream" principles of hospice care into mainstream medicine. Although there is no requirement for all healthcare systems to have such a program, palliative care is gradually being recognized as a "standard of care." For organizations that still need convincing, Meier[6] and the National Consensus Project[7] make the case for implementation of and early involvement of hospital-based palliative care (1) to improve clinical quality of care for seriously ill patients; (2) to increase patient and family satisfaction with care; (3) to meet the demand of a growing, chronically ill, elderly demographic; (4) to serve as "classrooms" for the next generation of clinicians to provide better care to the seriously ill; and (5) to provide value-added, cost-effective care in the face of a national healthcare and economic crisis.[6,7] Recent palliative care studies present a compelling argument that, based on the amount of available evidence, HBPC is state-of-the-art care.

Although much of the data to support the evolution of HBPC are derived from care deficits identified in hospitalized patients at the very end of life,[1–4] the goal of HBPC is to improve the quality of life (QOL) of persons with life-limiting illness early in the illness and across all settings of healthcare.[6–8]

Defining Palliative Care

While there have been variations in defining "palliative care," the Center to Advance Palliative Care today offers the most clarified and structured definition: "*Palliative care, and the medical subspecialty of palliative medicine, is specialized medical care for people living with serious illness. It focuses on providing relief from the symptoms and stress of a serious illness. The goal is to improve quality* *of life for both the patient and the family. Palliative care is provided by a team of palliative care doctors, nurses, social workers and others who work together with a patient's other doctors to provide an extra layer of support. It is appropriate at any age and at any stage in a serious illness and can be provided along with curative treatment."* Palliative care utilizes a whole-person philosophy, seeking to examine factors beyond simply the person's diagnosis.[9]

The Center to Advance Palliative Care (CAPC) defines HBPC as "an interdisciplinary medical team focused on symptom management, intensive patient–physician–family communication, clarifying goals of treatment and coordination of care across health care settings." CAPC has identified a streamlined process to establish an HBPC program, which includes seeking expert guidance from validated sources (such as capc.org), establishing a planning committee with key stakeholders (hospital administrative leadership, providers from chronic disease programs, physicians, nurses, social workers, case management, spiritual care, and business/finance coordinators), collecting data that identify the needs of the patients at the institution (including deficiencies in care, transitions in care at end of life, analytics on pain/symptom management, length of stay, cost per day, and patient/family satisfaction), and reviewing the literature on palliative care impact, which can then be used to develop a business plan that can be integrated into action.[9]

In Temel and colleagues' (2010) landmark study, "Early Palliative Care for Patients with Metastatic Non–Small-Cell Lung Cancer," lung cancer patients who received palliative care along with conventional treatment survived 2.7 months longer than patients who received only standard oncological care. Published by the *New England Journal of Medicine*, this study clearly demonstrated the value, need, and importance of palliative medicine interventions for patients with advanced, life-limiting illness.[10]

Ever since the increased national awareness and ongoing analysis of the availability of HBPC programs in 2000, there has been continued growth (as already mentioned, 67% of hospitals with 50 or more total facility beds offer palliative care). And there is a definite set of institutional characteristics associated with the presence of a HBPC program—bigger facilities are more likely to offer palliative care than smaller centers: 90% of hospitals with 300 beds or more had HBPC versus 56% of hospitals with less than 300 beds. Tax status was also a significant predictor: not-for-profit hospitals and public hospitals were, respectively, 4.8 times and 7.1 times more likely to have a palliative care program as compared to for-profit hospitals. In terms of geographic distribution, HBPC prevalence was highest in the New England states (88%), Pacific states (77%), and mid-Atlantic states (77%), and lowest in the west south central (43%) and east south central states (42%). Therefore, while access to HBPC improved, a deficit remains due to factors such as regionality and tax status.[2,11]

Standardizing Palliative Care in Hospitals

To assure standardization in HBPC delivery, the National Consensus Project (NCP) released the first palliative care clinical practice guidelines in 2004; these were updated in 2009 and 2013, and a new edition is scheduled for release in Summer 2018. The NCP identified eight Domains of Care (structure and processes, physical aspects, psychological/psychiatric aspects, social aspects, spiritual/religious/existential aspects, cultural aspects, care of the patient at end of life, and ethical/legal aspects) to assure consistent care delivery reflective of changes in the national healthcare arena of reform, as well as new outcomes research that defines best-practice elements for high-quality palliative care.[12]

Chronic illness and longer life was the legacy of the twentieth century. However, the healthcare system did not keep pace with medical advances, and the hospital remains the common location for EOL care despite Americans' stated preference for death at home.[13–15] Hospitals were designed primarily to provide acute, episodic care to persons with acute illness rather than comfort and continuity to persons who were not expected to survive a disease or episode of illness. Therefore, fundamental system reform and redesign is warranted to improve (and possibly prevent) hospital care of persons with life-limiting illness.

This is a call to action, particularly for nurses, since nursing care is the primary service provided during hospital admission, and much of the care and the system that patients experience can be influenced by nurses at all organizational levels. The way nurses learn and share their knowledge will further direct the process of patient care.[15,16] HBPC programs have begun to change the quality and quantity of hospitalized deaths as nurses evolve into the servant-leader role, defining and directing multi-/interdisciplinary teams and modifying efforts at multiple levels of the hospital care system to improve the complex care process for persons with life–limiting illness.[3,14-17] Improved palliative care structure, standards for care processes, and measurement of outcomes have begun as a result of the development of HBPC programs.

Quality of Care Issues

In an ideal world, discussion of advance directives should take place with patients when they are not in crisis. The early introduction of palliative care specialists may help to clarify and document patients' goals of care and pain/symptom management preferences. The HBPC teams can facilitate medical and nursing staff education about advance directives, palliative care, and EOL issues. Establishing baseline competence levels and protocols and policies to support identification of patients' goals of care will hopefully minimize unnecessary patient and staff suffering.

Barriers

The well-known barriers that block access to palliative care include[17]:

1. Lack of resources
2. Lack of knowledge about existing resources or provider reluctance to refer
3. Misunderstandings and/or lack of clear, effective understanding of palliative care
4. Provider bias, which includes the overall common reluctance to refer
5. Patient and/or family barriers created by reluctance
6. Restrictive specialist palliative care service program eligibility criteria

The inclusion of palliative care in the hospital can help avoid putting patients through unnecessary and often undesired interventions; this results in overall cost savings when resources are spent where they have the greatest potential to yield the best outcomes.[18]

Models of Hospital-Based Palliative Care

HBPC can be primary, secondary, or tertiary, and its promotion requires a myriad of resources. Depending on the model of palliative care being introduced, the required resources can vary greatly. For example, some changes may require financial support via construction or the addition of staff, whereas other changes are less resource-intensive. Regardless of the healthcare system and the availability of resources, all healthcare practitioners could introduce palliative care concepts and use already established resources to develop or improve their palliative care services. Healthcare systems must consider their mission and level of palliative care delivery (e.g., primary, secondary, tertiary) as they do other medical specialties, and they must incorporate a model of palliative care resourcing in accordance with that level.[19,20] Institutions with limited resources may choose a primary model that focuses on enhancing existing services and clinician education, while secondary and tertiary palliative care programs may provide multiple services, including inpatient and/or outpatient consult teams, an inpatient palliative care/hospice unit, and a home care program, all under the jurisdiction of a single hospital system. A full-service approach can ease transitions among different levels of care and has the potential to provide optimal, seamless palliative care. The CAPC also offers various consensus guidelines for operational and inpatient unit metrics that hospitals can use to measure programs for quality, sustainability, and growth.[9,20]

Primary Palliative Care

Primary palliative care should be available at all hospitals. This level of care requires, at a minimum, clinician education in the basics of pain and symptom management. Primary palliative care refers to a level of care whereby basic skills and competencies are required of all physicians, nurses, and other healthcare practitioners who encounter persons with life-limiting illness. The NCP, the National Quality Forum (NQF), and the Joint Commission have each identified standards that should be addressed in all hospitals and other settings (see later discussion). All practitioners should be competent at this level: they gain the knowledge, attitudes, and skills needed to provide palliative care to their patients through basic palliative care training and clinical practice. There is a growing availability of continuing education, including established formal programs for all disciplines to improve their knowledge of basic palliative care principles. The End-of-Life Nursing Education Consortium (ELNEC) and Education for Physicians on End-of-Life Care (EPEC) are two comprehensive educational programs that can provide such information. Both educational programs are further described in Chapter 72.

Secondary Palliative Care

Secondary palliative care refers to a model in which all providers have a minimum level of competence, and specialists provide palliative care through an IDT, specialized unit, or both. The development and success of these specialized services come about because of strong leadership, marketing, and accessibility.[18–20] It is not necessary for an IDT or unit to evaluate every patient with palliative care needs who is admitted to the hospital, but these specially trained clinicians are available as a resource and guide for their colleagues.

Tertiary Palliative Care

Teaching hospitals and academic centers with teams of experts in palliative care are classified as tertiary organizations. A tertiary-level program may serve as a consultant to primary- and secondary-level practices in difficult clinical situations or as model programs to assist developing centers. These centers also serve as training programs for incoming palliative medicine providers, with fellowship programs ranging from 1 to 2 years for both physicians and nurses. Practitioners and institutions involved at the tertiary level of palliative care are also involved in educational and research activities.[19,20] Multidisciplinary training programs for nurses and physicians are an important function of a tertiary center (see later discussion). Tertiary centers also have an obligation to perform research to enhance the evidence base for palliative care.

It is the responsibility of all hospitals and healthcare organizations to be competent, at a minimum, at the primary level of palliative care. Organizations at different levels may choose among different components of care to incorporate into their model. Some components are less resource-intense (e.g., staff education, care pathways), while others may require additional allocations of budget and personnel. The latter resources include IDTs, specialized PCUs, outpatient/ambulatory palliative care clinics, and structured outreach or strong relationships with skilled nursing facilities and home-based hospice programs.

The Inpatient Interdisciplinary Consult Team

A growing literature summarizes the development of palliative care consultation teams within hospitals to offer specialized consultation and expertise to patients, families, and other healthcare providers.[19] Many US and European hospital-based teams have described their experiences.[21–23] Among the components of successful teams are an interdisciplinary approach, physician and nonphysician referral, rapid response to requested consultations, around-the-clock availability, and ability to follow patients through all care settings.

Interdisciplinary consultation teams can be effective in modeling behaviors that are supportive of appropriate HBPC, but they should also recommend infrastructure and organizational changes as part of their approach to consultation. Gathering demographic statistics about the location and nature of regular consultations may help to identify the need for institutional policies and procedures. For example, if a unit or care provider has difficulty managing patients with dyspnea on a regular basis, targeted educational approaches and treatment algorithms or standardized orders may help achieve consistent and long-lasting change. Theoretically, an IDT could "put itself out of business" with such an approach. Conversely, teams may become "stretched too thin" in their attempts to meet the needs of their organization. However, the news remains positive: teams to date have not reported the need to dissolve as an outcome of implementing system changes.

Studies have begun to examine the impact of IDTs on the overall care of hospitalized, seriously ill patients.[24,25] However, this is challenging research, and, as in any multicomponent intervention, it is difficult to identify exactly which components or processes of the team are responsible for the outcomes. Valid, reliable measures and multimethod research are likely to be needed to capture this information.[24,25] Maintaining an IDT can be costly; therefore, it is imperative to continue to evaluate programs and strengthen the evidence base to provide economic justification for many hospitals.

A consensus panel has recommended minimum data that should be collected by all consultation services.[26,27]

Inpatient Hospice and Palliative Care Units

Some hospitals, faced with the problem of providing high-quality palliative care, have found the development of a specialized unit to be the solution. When access to palliative care is limited due to lack of availability or awareness,[17,21,25] hospitals in the United States have begun opening specialized units for the care of patients with hospice or palliative care needs (albeit with varying degrees of experience).[27–30] An inpatient unit has some advantages and disadvantages. Advantages include:

- Patients requiring palliative care have a familiar place to go during the exacerbations and remissions that come with progressive disease.[28–30]
- Unit staff and policies are under the control and financing of experts trained as a team who are skillful at difficult care and communications.[31,32]
- Patients may receive palliative care earlier if other care teams see the advantages of this approach and trust that patients will receive good care.[28–33]

Providers who monitor their patients on these units (if allowed) can learn valuable lessons about palliative care that can be carried forward to future patients.[33] These future patients may not require admission to the PCU for some types of care. Some disadvantages of creating a PCU include:

- It can prevent others from learning valuable palliative care techniques if the PCU staff are "specialized" and are secluded in one area.[34]
- Care providers may come to rely on this expertise instead of learning palliative care techniques themselves.
- If PCU transfer includes a transfer of doctors to a palliative care specialist, patients and families may feel abandoned by their primary team in the final hours.
- Hospice providers fear loss of the hospice philosophy when a PCU exists in the context of the general hospital.

Interdisciplinary Education: A Key Component of Palliative Care

It is imperative that staff caring for patients with life-limiting illness have sufficient and appropriate palliative care knowledge and skills. Organizations with or without HBPC programs should encourage staff members to participate in conferences on EOL and palliative care and should support them through the continuing education process (e.g., becoming certified in a specialty). The value of improved education is not only in direct patient care, but also in the role modeling that takes place. Most students in medical, nursing, and other healthcare disciplines receive clinical training for practice in hospitals.[35] However, few hospitals provide role models for teaching palliative care practices[35–37]; witness the following comments made by family members about the insensitive way that the act of "pronouncing" the death of their loved one was handled by an inexperienced new medical intern[37]:

> I was holding his hand when he stopped breathing. I called the nurse, who called the doctor. He went over and looked at him lying in the bed, listened for a heartbeat with his stethoscope, and said, "He's dead," and walked out of the room. That's it—not "I'm sorry." No, "Is there anything we can do?" Just, "He's dead." It was painful and made us think that the staff didn't care.

A study by Ferris and colleagues[36] documented that medical schools devote little time to care of dying patients. A survey of medical interns revealed significant concern and fear about providing these services with little or no supervision. The traditional "See one, do one, teach one" supervisory principle of medical education was ineffective. One resident explained that the pronouncing experience was not one that was perceived as causing harm when performed by inexperienced staff. Another stated, "I felt really inadequate, I had absolutely no idea what to do when the nurse called me to pronounce this patient whom I had never met—my first night on call. I was never taught the steps—how long should I listen to the chest to be sure there was no heartbeat; what, if anything else, I should do; what should I say to the family. Thankfully, the death coordinator was there to help me fill out the paperwork." Conversely, in states where nurses can pronounce deaths, some course work exists to teach a process that gives attention to the family. For resident education, there is a comprehensive, multimedia program called "The Art of Compassionate Death Notification."[38] The program includes a facilitator's guide, manuals for learners, a pocket card of the process, and videos demonstrating communication skills. At our medical center, the residency program conducts real-world patient scenarios where residents are given random patient case scenarios (actors play the role of patients/family) and carry out their evaluation of the case. These scenarios are observed by staff reviewers (physicians, nurse practitioners, ethicists) who then provide feedback to the resident regarding communication technique, body language, and more. The focus of such teaching formats is to provide trainees with honest feedback on their ability to navigate real-life scenarios and bring attention to both the areas in which they excel and those in which they need assistance or improvement, such as communication/choice of words, body language, and self-awareness.

The lack of role models for students in the clinical setting is further compounded by the lack of palliative care content in student curricula and major textbooks. When major medical and nursing texts were analyzed, they were found to be sorely lacking in content that would inform students about the basics of palliative symptom management, decision-making, and critical communication skills.[39–42] On a positive note, however, there is evidence that this situation is changing: the growing awareness of and need for palliative care has triggered greater incorporation of palliative care–focused content in medical and nursing school curricula and textbooks. Teaching formats have also become more innovative: Ellison and Radecke[43] conducted an "Issues at the End of Life" course as a joint effort between the office of a university chaplain and a palliative medicine program for college students. This course earned multiple teaching awards for originality, creativity, and collaboration. "Issues at the End of Life" divided the class into sessions focused on religious, spiritual, and theological issues and included guest presenters from Geisinger Medical Center in Danville, Pennsylvania, including physicians, nurses, bioethicists, hospice and social workers, and counselors. The objectives were to demystify aging, illness, and death while enhancing empathy and compassion to promote improved communication skills that could be used across various difficult situations. The most unique element of this course was its service-learning project for the creation of a personal legacy: each student worked with a designated community member facing EOL issues (due to advanced age, terminal illness, or both) to create a lasting, meaningful record of the person's life. Projects included audio- and video-recorded life histories, memory books, and even a memory quilt made from symbolic garments such as wedding attire, outfits from special occasions, baby blankets, and baptismal gowns. The course was a brilliant recognition of the common human experience of life and death—highlighting the need for better awareness, recognition, and interventions that offer as much attention at the end of life as one receives throughout life.

Creative Ways to Actively Engage Learners in Palliative Care Education

- Arrange for clinician role models to provide lectures to students and faculty.
- Assist with curriculum review of current EOL care training.
- Change elective coursework and clinical work in hospice and palliative care to required status and include these subjects in other mandatory clinical assignments.
- Use texts that contain clinically relevant palliative care content.
- Include content on ambulatory-based symptom management and decision-making that defines patient preferences for care.
- Encourage students to describe evidence-based approaches to palliative care and to challenge their mentors about approaches and interventions that increase the burden of care without clear patient benefit.
- Encourage students to learn from staff role models the appropriate ways of communicating bad news and presenting options that respect patient preferences and values.
- Identify opportunities for undergraduate or graduate fellowships in palliative care.
- Encourage quality improvement teams to offer students opportunities to participate and to collect data from patients, charts, and staff.

Experienced healthcare providers also have needs for specialty palliative care educational experiences (see Chapter 72). Both the nursing and medical professions have embraced the concept of palliative care continuing education, advanced academic training, and certification.

ELNEC and EPEC are exemplary continuing education programs. The ELNEC program is a collaboration of the City of Hope Medical Center and the American Association of Colleges of Nursing, and the program has a variety of curricula for different audiences (undergraduate and graduate nursing faculty, nurses working in critical care, pediatrics, or geriatric settings, etc.). The American Medical Association (AMA) and EPEC programs address similar issues for physicians. Both curricula are widely available to educate practicing nursing and medical staff.

The Harvard Medical School Program in Palliative Care Education and Practice

Another example of palliative care continuing education is sponsored by the Harvard Medical School Center for Palliative Care. In response to the need for leaders in palliative care education in nursing and medicine, the Harvard program offers intensive learning experiences for physician and nurse educators who wish to become expert in the clinical practice and teaching of comprehensive, interdisciplinary palliative care, as well as to gain expertise in leading and managing improvements in palliative care education and practice at their own institutions. The program includes a special pediatric track. The course is delivered in two sections: Part 1 consists of 7 days of intensive learning, followed by a 6-month interim when participants work on an individual project and contribute to weekly e-mail discussions of problematic clinical, educational, and program development cases presented by other participants through e-mail exchanges. Part 2 is a second 7-day block that includes continued experiential learning and training focused on communication, teaching methods, teamwork, and leadership.

The curriculum features content on how to (1) teach the fundamentals of palliative care (assessment of physical causes of distress, psychosocial and spiritual assessment, ethical and cultural issues, palliative care in geriatric and pediatric populations, depression, and bereavement); (2) communicate at the end of life (understanding the experience of life-threatening illness, delivering bad news, communicating across cultural barriers, family meetings, providing feedback to learners); (3) manage challenges in palliative care education (principles of adult learning, understanding, learning styles, new teaching methodologies); and (4) develop and promote clinical and educational programs in palliative care (assessing institutional structure and culture, evaluating readiness to change, dealing with resistance, developing and financing palliative care programs, and fund-raising strategies).

The course faculty includes physicians, nurses, social workers, and educators from within the Harvard teaching hospitals as well as outside experts. Complete information can be accessed at http://www.hms.harvard.edu/cdi/pallcare/pcep.htm

Advanced Education and Certification in Palliative Care

As standards of care are increasingly applied to HBPC programs, advanced specialty training in palliative care will likely become a requirement. Academic opportunities for education and preparation as an advanced palliative care practitioner currently exist in several programs (see Chapter 72). Following these programs and other specialized training, nurses may take advanced certification in palliative care through the National Board for Certification of Hospice and Palliative Nurses (NBCHPN). Eligible nurse practitioners and clinical nurse specialists can acquire credentialing as an Advanced Certified Hospice and Palliative Nurse (ACHPN). Certification exams are also available for registered nurses, licensed vocational nurses, nursing assistants, and nurse administrators. Nationally, hundreds of nurses have become board certified as palliative care specialists since this certification's inception.

A major advance in the field came about in 2007, when the American Board of Medical Specialties (ABMS) voted to approve hospice and palliative medicine as a recognized medical subspecialty. The application to recognize the subspecialty had broad support and was cosponsored by 10 medical specialty boards. As a result, physicians in many specialties—including internal medicine, family medicine, pediatrics, psychiatry, neurology, surgery, emergency medicine, and obstetrics and gynecology—can seek this certification. Prior to that time, this certification exam was offered by the American Board of Hospice and Palliative Medicine (ABHPM). In the first decade of certification, more than 2,100 physicians obtained certification from ABHPM. The ABHPM was not recognized by the ABMS, but worked successfully over the course of the decade to persuade the ABMS to recognize hospice and palliative medicine as a medical subspecialty. Although voluntary, this recognition is used by the government, healthcare systems, and insurers as evidence of high standards. There are currently 24 Member Boards of the ABMS (see www. abms.org). These 24 Member Boards constitute the officially recognized allopathic specialties of medicine in the United States.

Developing Standards for Hospital-Based Palliative Care

Several organizations have worked together to develop standardized palliative care practices.

National Consensus Project

In April 2004, the NCP for Palliative Care released its *Clinical Practice Guidelines for Quality Palliative Care*. An updated third edition of the guidelines was published in 2013, and the fourth edition in October 2018.[12] The guidelines, which can be downloaded free of charge from http://www.nationalconsensusproject.org, represent a consensus of four major US palliative care organizations: the American Academy of Hospice and Palliative Medicine, the CAPC, the Hospice and Palliative Nurses Association (HPNA), and the National Hospice and Palliative Care Organization (NHPCO). The guidelines identify core precepts and structures of clinical palliative care programs. The domains were intended as a framework for HBPC programs to develop and evaluate their approaches to delivering comprehensive palliative care services. Although voluntary, one potential outcome for these guidelines is to provide a framework for certification or mandatory accreditation.[12]

National Quality Forum

In 2007, in response to a need for national quality standards, the NQF released a document listing “preferred practices.” The NQF collaborated with the NCP in developing these 38 “best practices” or performance measures, which are organized under the NCP’s eight domains of care. The practices are evidence-based or endorsed by expert consensus and apply to hospice and palliative care services across all care settings.

The NQF is a nonprofit, public–private partnership organization whose mission is to develop ways to improve the quality of US healthcare. The NQF has representation from national, state, regional, and local organizations representing consumers, public and private insurers, employers, professionals, health plans, accrediting bodies, labor unions, and other organizations representing healthcare research and quality improvement. They rely on or use consensus-building processes to develop national standards for the measurement and public reporting of healthcare performance that is safe, timely, beneficial, patient-centered, equitable, and efficient. These standards have served in other areas of care as a method to link performance with reimbursement.

Center to Advance Palliative Care

One of the major efforts to improve HBPC programs in the United States is led by the CAPC. Originally formed and funded by a 4-year grant from the Robert Wood Johnson Foundation in 2000, the national center was established at Mount Sinai School of Medicine in New York City. The Center has a mission to make available to hospitals and health systems nationwide information on how to establish high-quality palliative care services.

The CAPC assists hospitals with the planning, development, and implementation of HBPC programs. In addition to assisting hospitals and other health systems in program development, CAPC facilitates collaboration among hospitals, hospices, and nursing homes; promotes educational initiatives in palliative care; and encourages growth and development of new and innovative mechanisms for financing palliative care programs.[20,44,45] More recently, the CAPC has collaborated on the development of a strong evidence base and palliative care research with the National Palliative Care Research Center (NPCRC, described later in this chapter).

The CAPC has developed palliative care leadership centers (PCLCs) to assist organizations that wish to learn the practical aspects of developing a palliative care program.[44] Among the PCLCs are Fairview Health Services, Minneapolis, Minnesota; Massey Cancer Center of Virginia Commonwealth University Medical Center, Richmond; Medical College of Wisconsin, Milwaukee; Mount Carmel Health System, Columbus, Ohio; Palliative Care Center of the Bluegrass, Lexington, Kentucky; and University of California, San Francisco. Each represents a different type of healthcare system and palliative care delivery model. They serve as exemplary organizations offering site visits, hands-on training, and technical assistance to support development of palliative care programs nationwide. Further information regarding the PCLCs can be found on the CAPC website (http://www.capc.org).

The National Palliative Care Research Center

The mission of the NPCRC is to improve care for patients with serious illness and address the needs of their families by promoting palliative care research. In partnership with the CAPC, the NPCRC aims to rapidly translate these findings into clinical practice. The NPCRC uses three mechanisms to accomplish its aims:

- Establish priorities for palliative care research;
- Develop a new generation of researchers in palliative care;
- Coordinate and support studies focused on improving care for patients and families living with serious illness.

The NPCRC, located in New York City, receives direction and technical assistance from the Mount Sinai School of Medicine. Prior to the establishment of the NPCRC, there was no organizing force promoting and facilitating the conduct of palliative care research. Because departments or divisions of palliative medicine do not yet exist in most medical schools, palliative care research is conducted by a small number of highly successful investigators working in isolation at a limited number of universities and clinical settings in the United States.

The NPCRC provides an administrative home to promote intellectual exchange, sharing of resources (e.g., biostatisticians), and access to data from ongoing studies to plan and support new research. Furthermore, the Center takes a collaborative approach to establishing its funding priorities. It is a key force in the development of an evidence base from which standards of HBPC can be developed and measured. (For more information about its activities, see http://www.npcrc.org.)

The Joint Commission

The Joint Commission is one of the paramount accreditation organizations for hospitals and other healthcare organizations. Its purpose is to continuously improve the safety and quality of care provided to the public. The Joint Commission is an independent, not-for-profit organization, and perhaps its most important benefit is that Commission-accredited organizations make a commitment to continuous improvement in patient care. During an accreditation survey, the Joint Commission evaluates a group's performance by using a set of standards that cross eight functional areas: (1) rights, responsibilities, and ethics; (2) continuum of care; (3) education and communication; (4) health promotion and disease prevention; (5) leadership; (6) management of human resources; (7) management of information; and (8) improving network performance.[46,47]

In 2004, a specific palliative care focus was introduced within two standards: (1) rights, responsibilities, and ethics and (2) the provision of care, treatment, and services. The goal of the first standard is to improve outcomes by recognizing and respecting the rights of each patient and by working in an ethical manner. Care, treatment, and services are to be provided in ways that respect the person and foster dignity. The performance standard states that a patient's family should be involved in the care, treatment, and services, if the patient desires. Care, treatment, and services are provided through ongoing assessments of care; meeting the patient's needs; and either successfully discharging the patient or providing referral or transfer of the patient for continuing care. Institutions and providers are encouraged to seek and maintain advanced certification in palliative care delivery.[47] More detailed information is available by contacting the Joint Commission or visiting their website at http://www.jcrinc.com.

These standards incorporate a stronger emphasis on palliative care practices within organizations. Hence, organizations are being held accountable for the way they provide appropriate palliative care. It is in the public's best interest that the Commission requires organizations to adhere to these provisions for a successful accreditation. In 2008, a process to develop specific "Certification for Palliative Care Programs" was begun, and, in 2011, the Commission's Advanced Certification Program for Palliative Care[47] was launched: the standards for palliative care certification are built on the NCP's *Clinical Practice Guidelines for Quality Palliative Care* and the NQF's *National Framework and Preferred Practices for Palliative and Hospice Care Quality*. Standards and expectations were developed using experts in palliative care and key stakeholder organizations. The standards are published in the *Palliative Care Certification Manual*.

Chapters address the following issues:

- Program management
- Provision of care, treatment, and services
- Information management
- Performance improvement

To be eligible for Advanced Certification for Palliative Care, a palliative care program must:

- Be provided within a Joint Commission-accredited hospital. All types of hospitals are eligible, including children's hospitals and long-term and acute care hospitals. A dedicated unit or dedicated beds are not required.
- Provide the full range of palliative care services to hospitalized patients 24 hours per day, 7 days per week:
  - Programs must have team members available to answer phone calls nights/weekend and the ability to come to the hospital to see patients 24/7 when necessary to meet patient/family needs.
  - Programs must be able to provide the same level of palliative care services during nights/weekends as during normal weekday hours.
  - Programs are not required to have palliative care team members physically present in the hospital 24/7.
- Have served a minimum of 10 patients and have at least one active patient at the time of the initial Joint Commission on-site review. Hospice patients are eligible for inclusion in the minimum patient count only if they were receiving inpatient palliative care from the program prior to transitioning to hospice care. These patients may be selected for tracer activity during the on-site review, with the reviewer focusing on the episode of inpatient palliative care closest to the hospice transition.
- Use a standardized method of delivering clinical care based on clinical practice guidelines and/or evidence-based practice.
- Direct and coordinate the provision of palliative care, treatment, and services for the program patients (that is, write orders, direct or coordinate activities of the patient care team, and influence composition of the patient care team).
- Follow an organized approach supported by an IDT of health professionals.
- As of January 2017, all hospitals currently certified in the Advanced Palliative Care program, as well as those hospitals seeking initial certification, will be required to implement data collection for five standardized measures effective with discharges on and after January 1, 2017.
- Updates on the Joint Commission progress on standard development can be obtained from the Commission's website under "certification programs": http://www.jointcommission.org/certification/palliative_care.aspx.

Veterans' Health Administration Initiatives

Please see Chapter 44 for more information.

Professional Societies Contribute to Palliative Care Development

Multiple professional societies have made contributions to the development of HBPC generalized or specialty population-specific palliative care standards, guidelines, or consensus statements by raising professional and public awareness of the unique issues of palliative care. A few selected organizations and their initiatives are described in this section.

National Hospice and Palliative Care Organization

The NHPCO was founded in 1978 as the National Hospice Organization. The organization changed its name in February 2000 to include palliative care. Many hospice care programs have added palliative care to their names to reflect the range of care and services they provide because hospice and palliative care share the same core values and philosophies. According to its website, the NHPCO is the largest nonprofit membership organization representing hospice and palliative care programs and professionals in the United States. The NHPCO is committed to improving EOL care and expanding access to hospice care with the goal of profoundly enhancing QOL in America for the dying and their loved ones. The NHPCO advocates for the terminally ill and their families. It also develops public and professional educational programs and materials to enhance understanding and availability of hospice and palliative care, convenes frequent meetings and symposia on emerging issues, provides technical informational resources to its membership, conducts research, monitors congressional and regulatory activities, and works closely with other organizations that share an interest in EOL care.

Hospice and Palliative Nurses Association

The HPNA was incorporated in 1987 to establish a network and support for nurses in this specialty. In 1998, the organization formally added palliative care to its mission to recognize the needs of nurses working in palliative care settings separate from hospice. The HPNA has become the nationally recognized organization providing resources and support for advanced practice nurses, registered nurses, licensed practical nurses, and nursing assistants who care for people with life-limiting and terminal illness. To guide best practices, they have developed numerous position statements and standards that are available to members and nonmembers on a variety of topics.

Processes for Providing HBPC

While HBPC programs are increasing in number, many organizations are still at the stage of contemplating enhancing palliative resources or developing a program. Such an endeavor requires careful planning, as these programs are not "one size fits all." Patience, persistence, and consensus-building are vital to successful program development. As described earlier, the CAPC has taken a leadership role in assisting organizations of all types to build a successful program that is suited to their unique patient population, resources, and organizational culture.

Process of HBPC Program Development

Regardless of organizational type, the first step in developing a HBPC program is to perform a system assessment or "organizational scan" to identify existing organizational strengths, resources, potential partnerships, and collaborators.[5] A task force or team of interested clinicians, administrators, and possibly consumers might be a good start. Examples of possible existing resources include clinicians from all disciplines with interest and training in palliative care, existing relationships with hospice, case management, discharge planners, and hospital chaplaincy programs. The needs assessment should determine the hospital focus on length of stay, ventilator days and pharmacy/ancillary costs per day, palliative care leadership based on personal experience or professional interest, preexisting pain programs, and trustee/philanthropic interest in and support for palliative care. After the system assessment is performed, the second step is to identify areas of need within the organization to highlight where palliative care programs can make the greatest contribution. Many institutions have easy access to data that can help to "build the case" for palliative care. Selling the idea of palliative care to an institution or gaining institutional support is easier when benefits (such as cost savings, efficiency, and improved clinical care) can be shown. Common areas of need that have shown improvement because of HBPC programs include pain and symptom management, patient and family satisfaction, nurse retention and satisfaction, bed and intensive care unit (ICU) capacity, and length of stay. Other outcomes may include pharmacy costs, establishment and strengthening of hospice partnerships, and improving fragmented subspecialty care. To assist organizations with the complexities of the planning process, the CAPC provides a systems assessment tool and a needs assessment checklist, which can be found at https://www.capc.org/search/?q=system+assessment+tool.

The Process of Providing Palliative Care: Developing an Interdisciplinary Team

The holistic process of providing palliative care to patients and their families is rarely accomplished by one individual or discipline. The IDT is the foundation of the HBPC service and is uniquely different from the traditional delivery of medical care. The core IDT typically consists of specially trained palliative care professionals, including physicians, nurses at all levels of training (registered nurses, nursing assistants, and advanced practice registered nurses [APRNs]), social workers, pharmacists, spiritual care counselors, healing arts/complementary practitioners, hospice representatives, and volunteers.[60]

Identifying which team member(s) can best serve a patient's needs is a key part of the initial assessment. One clinician may be designated to receive initial consults and organize distribution of work for the day. A team may decide that all new consults are seen first by a medical provider: either the physician or the APRN. The physician also serves as the medical resource person for other team members and supervises physician learners. APRNs may work independently or collaboratively with the attending physician to conduct initial consultations. If resources allow, this may be done together; however, workload and resources may dictate that new consults are divided among the medical providers. In organizations that support learners, after a period of supervision and observation, it may be that the learner (e.g., fellow, resident, medical or nursing student) conducts an initial chart review and patient and/or family interview and then presents the patient to the physician or APRN, after which the pair will revisit the patient. At all times the team should be aware of the patient's energy level and the learner's level of expertise in deciding whether this format is appropriate. During the initial consult psycho/social/spiritual needs are identified and other team members are integrated into the plan of care.

A palliative care–certified physician and/or APRN may be responsible for the initial assessment and day-to-day medical care of most patients. However, depending on the patient's needs, another member of the team might take the lead in care. For example, if the patient's primary concern is physical, then a medical provider may direct the plan of care. If the patient's primary concern is existential in nature, the spiritual care provider may take the lead. Alternatively, if the patient's primary need is for family support, the social worker may be the most active care provider. Healing arts and complementary medicine practitioners and volunteers are also integral members of the IDT. Healing arts/complementary medicine practitioners are providers from a variety of backgrounds who can provide massage, energy work, or instruction in guided imagery or meditation. Palliative care volunteers are specifically trained to see palliative care patients and are overseen by a volunteer coordinator. They provide presence, active listening, and company for patients and families. Although some tasks are seemingly small, such as reading, playing cards, or running small errands, these are often essential aspects of care from the patient/family perspective. Pharmacists, healing arts/complementary therapy clinicians, hospice liaisons, and volunteers may or may not be part of the core team in some organizations. For example, even though medication needs may be complex, few teams have a dedicated pharmacist who can round daily with the team. Hence, it may be more realistic to have a pharmacist present during regularly scheduled IDT meetings. Similarly, local hospice liaisons, healing arts/complementary therapy practitioners, and others may only be available to meet with a team weekly. Nonclinical members of the team including administrative, financial, or practice managers and secretarial support are responsible for holding the IDT together by providing the supportive infrastructure within which the team can operate. These key team members may serve as representatives or liaisons on important institutional committees. Another important function of program administrators is the collection of data for clinical and fiscal evaluation for quality improvement, program justification to the institution, or research. The receptionist/secretarial support may be the first contact for patients and referring clinicians and can become the "face or voice of the program." Individuals selected for these positions should be skilled, patient, and caring to enable them to deal with the stress of people in crisis and the urgency of consultations. After an initial consultation, depending on the patients' needs, they may continue to be seen in follow-up throughout their hospitalization. Some patients may have acute needs (such as uncontrolled pain) that may require them to be seen more than once daily. Other patients may be seen several times a week or weekly or until the goal of the initial consultation is achieved. Some patients may be visited by the medical provider, the spiritual care provider, the healing arts provider, and a volunteer—all on the same day.

Processes to Support Interdisciplinary Team Communication

Communication may be the most challenging and crucial aspect of providing palliative care.[48–50] Intrateam communications that are regular and efficient will allow for seamless care to be delivered. Teams will likely explore a variety of mechanisms to achieve optimal communication about not only issues of patient care but also team function.[50] The purpose of regular patient care–related team meetings is to allow all disciplines to contribute to the development and implementation of comprehensive care plans that reflect the values, preferences, goals, and needs of each individual patient.[49] Practicing as a true IDT requires significant and ongoing intention and effort. Traditionally, the medical model has driven healthcare delivery and, to a large extent, still does. However, in a holistic care model of palliative care, the psycho/social/spiritual care providers should have equal authority and input; for many clinicians, this represents a change in practice. Teams should be mindful of tendencies to become "efficient" that can sometimes lead to a focus only on the medical or physical aspects of care. Minimally, a weekly face-to-face meeting in which all IDT members gather is considered an essential element of team function to provide high-quality, coordinated care. During the IDT meeting, active patients are presented, and all team members have an opportunity to contribute their expertise in the development of the plan of care.

Performing the Palliative Care Consult

A palliative care consult can be initiated in a variety of different ways. Some services (or reimbursement mechanisms) require that a physician initiate the consult, rather than a nurse or other care provider. If someone other than the attending physician requests a consult on a hospitalized patient, it is important to include the attending (or primary care) physician in the consult. Ideally, a provider-to-provider conversation prior to consultation would review and identify the priority issues. Most services do this before seeing the patient.

When Is a Consult Made?

Consultations should be initiated at any time a person with a life-limiting illness has physical, psychological, social, or spiritual needs.[26,32,51] Palliative care programs began for many reasons, but one of them was to meet the EOL care planning and symptomatic needs of patients who are not yet hospice-eligible, either because of life expectancy (greater than 6 months) or because they are receiving active, disease-modifying treatment. Palliative care referrals do not hinge on the "less than 6 months" life expectancy, as is often the case for hospice referrals. Referring patients with life-limiting illness early is one of the benefits of having a palliative care service. Some organizations have built-in consult triggers, protocols, or algorithms for specific life-limiting illnesses in which consults are recommended at diagnosis. "Automatic referrals" would be generated for all patients who are newly diagnosed with certain types of life-limiting cancers (e.g., pancreatic, brain, stage IIIB and greater lung, liver, etc.), or teams may simply rely on the utility of the "surprise" question,[54] a validated research tool commonly used in palliative care research to help identify those patients at higher risk for 1 year mortality and who would therefore likely benefit from palliative care. Figure 3.1 provides an example of a "trigger tool"; this tool was piloted in various settings, including the adult ICU, inpatient oncology, and general medical surgical floors. Noncancer patient populations that may be considered for automatic referrals are those with amyotrophic lateral sclerosis (ALS), heart failure, end-stage dialysis-dependent renal failure, and those who, regardless of diagnosis, experience frequent hospitalizations. These patient populations are typically highly in need of palliative care services. Careful planning and close collaboration with colleagues are necessary to establish a process for automatic referrals that ensures that those patients who are most in need of palliative care services have them "early and often." Some automatically scheduled palliative care consultations may occur in the outpatient setting or clinic, while some organizations have hospital "triggers" that may alert that primary team that a patient may benefit from these specialized services. Over time, in HBPC programs with high community visibility and/or marketing efforts, it may be common to have patients or family members self-refer.

What Is Included in the Initial Palliative Care Consultation?

The initial consult will lay the foundation for all further interactions with the patient and family. In addition to specialty expertise, the palliative care team may offer the unique resources of presence and time. Much has been written about the importance of sitting during the initial consult. Making sure there is adequate time to see the patient and family is crucial.[52] If time restrictions are unavoidable, state these constraints at the outset of the consultation. Sitting

Medical Record Number: _______________ **Age:** ___________ **Reason for Admission:** _____________________

To evaluate appropriateness of a PSMC, consider the following criteria:

		SCORING
1) ***Would you be surprised if this patient were alive in one year?***		
Yes – Score 3 points		
No – Score 0		
	TOTAL SECTION 1 (0 OR 3)	

2) ***Basic Disease Process***	Score 2 points each	
a. Cancer (metastatic/recurrent)		
b. Advanced COPD (requires home oxygen)		
c. Neurological disease (difficulty swallowing or incontinent)		
d. End stage renal disease (considering stopping dialysis)		
e. Advanced congestive heart failure (one-block DOE)		
f. >3 hospitalizations or ED visits for incurable disease in past year		
g. Other terminal or incurable disease causing significant symptoms		
TOTAL SECTION 2		

3) ***Uncontrollable Symptoms or Clinical Conditions***

Score 2 points each		Score 1 point each		Score 1 point each		
a. Pain		e. Anxiety		i. Prolonged vent support		
b. Dyspnea		f. Depression		j. Other _____________		
c. Nausea		g. Weight loss				
d. Bowel obstruction		h. Constipation				
				TOTAL SECTION 3		

4) ***Anticipated Functional Status of Patient at Time of Discharge*** Score as specified

Using ECOG Performance Status (Eastern Cooperative Oncology Group)

Grade	Scale	Score	
0–1	Fully active, able to carry on all pre-disease activities without restriction or restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature.	0	
2	Ambulatory and capable of most self-care but unable to carry out any work activities. Up and about more than 50% of waking hours.	1	
3–4	Capable of only limited self care; confined to bed or chair more than 50% of waking hours or worse.	3	
		TOTAL SECTION 4 (0, 1, OR 3)	

5) ***Psychosocial issues (patient or family)***	Score 2 points each	
a. Need to discuss end of life issues		
b. Need for evaluation for possible hospice referral		
c. Artificial hydration or nutrition requested or considered		
d. Unrealistic goals or expectations		
TOTAL SECTION 5		
TOTAL SCORE SECTIONS 1–5		

SCORING GUIDELINES:

TOTAL SCORE ≤ 8	Problem-directed consult, if desired
TOTAL SCORE = 9–11	Consider PSMC
TOTAL SCORE ≥ 12	Strongly consider PSMC

Form completed by: ____

PALLIATIVE AND SUPPORTIVE RAPID RESPONSE CONSULT
(Worksheet only. Not part of permanent medical record.)

Medical Record Number: ___________ **Age:** _______ **Reason for Admission:** ____________________

To evaluate appropriateness of a PMRRC consider the following criteria:

1. Palliative Medicine consult tool score>9 (see page 1)
2. Patient referred from SNF for PEG tube placement with underlying significant dementia or progressive metastatic cancer.
3. Patient older than 75 years old with significant medical problems and: 1. No advance directive and no surrogate decision maker 2. Advance directive that lists both do and do not selections 3. Progressive single or multi-system disease with anticipated survival of one year or less and limited therapies available for the underlying disease 4. Family or home caregivers with disparate goals for the patient 5. Patient is full code and has multi-system organ failure, metastatic cancer, or a progressive terminal disease despite treatment or no treatment is planned for the underlying disease
4. Patients or families that are requesting medical treatments for life prolongation or CPR that the primary service believes would be of little or no benefit to the patient.
5. Assistance with medication logistics and discussion of possible hospice referral or comfort care plans for SNF

Figure 3.1 Continued

down during the consultation and making sure everyone who is participating in the consult has a seat is important (see Chapter 5, "Communication in Palliative Care"). Depending on the resources available and the composition of the team, an initial consult can occur almost anywhere. For inpatient consults, it is often in the patient's room; for outpatient consults, it may be in the clinic exam room. If resources permit, consults can also be done at the patient's home or in local care facilities. The main concern is an environment that allows for privacy and quiet—often difficult to find in most acute care hospitals.

Patients are generally unfamiliar with the term "palliative care" and/or associate it with hospice care or death. Patients who are early in their disease process may wonder why a consult to this service has been initiated. Establishing the patient's level of understanding and explaining the role and focus of the palliative care team is an important starting point to the consultation. Often patients and families may need reassurance that they are not being "abandoned" by their primary team. Explaining that the palliative care team consults and provides expert guidance to the primary team but does not replace them is important. Providing a clear and confident explanation of services will help everyone know what to expect. Providing a brochure or some written information about what palliative care is and who the team members are can be helpful. Assessing patient/family knowledge and understanding their current situation is the next step. Healthcare providers often believe that they have done a complete and thorough job in explanations; however, patients are under stress and may need multiple explanations in very simple language before they fully understand their situation.[50,52] Next, a complete and thorough assessment is begun. This should include a review of symptoms and physical complaints as well as an assessment of psychological, emotional, social, and spiritual concerns. Eliciting a clear picture of the patient's social support structure and family relationships is essential as the contextual issues will often affect, if not drive, decision-making. Exploring what gives meaning to patients' lives and who they are as individuals will help direct care. Do not hesitate to humanize the medical encounter by taking the time to get to know the patient as an individual—their hobbies, passions in life, the meaning they attribute to work and family are all important aspects of learning about a new individual. Assessing and attending to cultural preferences will enhance communication and increase the effectiveness of interventions.

Other areas that are important to assess are goals of care, advance care planning wishes, and treatment decision-making style. Due to time constraints and sometimes lack of skill, these complex issues are often overlooked or only superficially explored by the primary team. Yet they are some of the most important pieces of the puzzle when constructing a plan of care. It is important to find out what the patient/family is hoping for from treatment interventions. This is where the role of nursing advocacy comes in: as the individuals spending the greatest amount of time at the bedside, nurses can often identify patient/family personal preferences and goals, ascertaining the answers to questions such as "What does getting better mean to you?" Often, this issue is ignored when, in fact, it needs more time and consideration. To the medical team, "getting better" may mean the patient is able to leave the hospital; to the patient, it may mean a full recovery or expectation of return to a higher level of functionality. The clinical implications of a new disease or advanced illness are not always clear to the patient or family, requiring further review and discussion. Exploring, on the first visit, whether the patient and family have ever considered and/or completed advance directives may elucidate this. Completing advance directives is a structured way of looking at goals of care and what is meaningful when making treatment decisions. Some programs have developed standardized templates that remind the team (and the referring provider) of the important and comprehensive domains of care and intervention that are included in the consultation.

Who Should Be Present at an Initial Consultation?

While there are times when it is appropriate to conduct a consult without the patient present (e.g., the patient is in a coma), in most cases, every effort is made to include the patient. The patient should decide which support members and/or family he or she wants to include. There may be one or more members of the palliative care team present. A member from the referring team may want to attend, but this is less common on initial consult. If a focused family meeting is arranged, it is imperative that the referring team be present, so all decision-makers are in the room together. Family meetings are a large part of palliative care interventions.[50,52] During the initial consult it may be clear that a family meeting is needed to proceed with discussion about care planning, and, on occasion, such a meeting may be simultaneously organized as a part of the initial consult. Direct inquiry with the patient will also identify key family/support members desired for any discussions, and efforts should be undertaken to include those identified whenever possible. Conducting a family meeting takes skill and planning—in today's hectic world, it is often difficult to coordinate multiple schedules or for family members to reach the hospital due to distance and other concerns. In these instances, the use of teleconferencing[53,54] has become especially helpful. Resources are available to assist inexperienced team members with the important process of organizing and conducting a family meeting.

Continuing the Care: Day-to-Day Operations

Patients with serious illness may follow many different paths: they may be typical in the current "care as usual" for a seriously ill patient compared with an "ideal" or expected pathway in a healthcare system with an HBPC program. Numerous institutions have studied their processes of care and have created clinical pathways that can help standardize procedures and reduce the variation of care experienced by terminally ill or symptomatic palliative care patients as they traverse the complex healthcare system. Usual components include attention to patient symptoms as well as family needs at system entry and throughout the course of stay until discharge. Assigning time frames to address needs helps in monitoring progress and tracking outcomes that have been met, as well as those that continue to need attention. Although published guidelines and standards may offer similar suggestions, the road map format of clinical pathways identifies practical and accountable mechanisms to keep patient care moving in the direction of specific identified outcomes. Some pathway forms allow for documentation of variation from the designated path. Analysis of several instances of variation might alert a care team about a potential system "defect" in need of improvement.

Many institutions have implemented standard orders or evidence-based algorithms to guide various aspects of care pertinent to EOL situations. Some of these include limitations of certain types of therapies such as cardiopulmonary resuscitation (CPR) and blood pressure medications. In addition, preprinted order sheets that outline management of symptoms and side effects such as nausea, constipation, and pain are making it easier for physicians and trainees to reproduce comprehensive plans that do not vary because of individual opinion. These order forms can be valuable teaching tools in a setting of regularly changing care providers. Nurses can advocate through development of hospital policy, education, and individual practice for aggressive comfort care. The healthcare team must ensure that a positive approach—focusing on what can be done for patients with life-limiting illness and their families—is implemented. At a macro level of cancer care, the National Comprehensive Cancer Network[55] has published detailed "care standards" in its *Palliative Care Clinical Guideline*. This booklet is produced as a professional and patient guide and is available from http://nccn.org.

Documenting Palliative Care Consultations

As in all aspects of healthcare delivery, documentation is the foundation for communicating with other providers, particularly across care settings. As a consultative service, including the primary care providers, the plan of care promotes collegiality and helps assure follow-through. Recommendations for symptom management; identification of goals of care, advanced illness planning, and resuscitation wishes; or emotional counseling and support are at the heart of the palliative care assessment and interventions. An electronic medical record (EMR) may provide an immediate way to share information with all members of the care team. Pertinent members with whom the consult should be shared include the primary referral service (if the patient is inpatient), the primary care provider, and other specialties consulting on the patient. Providing a copy of the consultation note, electronically in real time, can assist with the timely communication and implementation of recommendations.

Documentation can also be a vehicle for education that should not be overlooked. Including specifics in the plan of care can help other providers learn aspects of palliative care. For example, breakthrough dosing for pain medications is often underdosed by the primary team. When addressing pain management in the palliative plan of care, noting the total daily opioid use and writing the details of the calculation (10–20% of total daily need) in print can teach other providers how to prescribe adequate breakthrough medication in the future. Clear and concise communication helps every member of the team.

Finally, documenting goals of care, resuscitation wishes, and advance care planning in a way that is visible to everyone is a challenge. Patients often complain that they have provided documents or information, such as an advance directive, but, at the point of care, the information is not easily located. As a quality improvement initiative, our institution created a visible tab embedded in the EMR for advance directives. In this system, important documents (advance directives and Do Not Resuscitate orders) are scanned into the record and are readily available. This decision is also added to the patient's EMR-based problem list so that every provider accessing the chart can quickly determine if the patient has, for example, elected no code status, completed an advance directive, and the like. For patients who have verbally stated wishes but have not completed the official document, a clinician can complete a templated advance care planning note that carries the same force as an official form. This can be completed by any team member and can indicate the durable power of attorney as well as care wishes (resuscitation wishes, medically administered nutrition/hydration wishes, etc.). The templated notes and actual documents are all located in the same section of the EMR and are accessible to all providers (including in the Emergency Department and physician offices that are part of the medical center system).

Completing the Process: Transitions of Care and Continuity

The palliative care team must remember that they are the consultants and that, ultimately, most patients will remain under the guidance of the primary provider. While some referring providers welcome aggressive assistance in care, others may prefer to accept or decline palliative care team recommendations. Talking a case over with the primary team is always preferable to leaving a note in the record. Continuity is improved dramatically when there is an outpatient as well as an inpatient component of an HBPC.

For patients who do not return to the center, providing continuity is difficult. Sending the initial palliative care consult and pertinent notes to the receiving team (including the patient's primary care provider or skilled nursing facility, if applicable) is useful. Being open to phone calls or proactively placing a personal call to the receiving provider will help to build bridges to the community and encourage community providers to see the palliative care team as a resource.

Outcomes and Their Measurement: The Role of Quality Improvement and Research in Hospital-Based Palliative Care

Measurement of outcomes is vital to demonstrate quality and to maintain viability and growth of HBPC programs. Although the field is still developing, tools are beginning to emerge to measure care, assist with developing standards of care, and, most importantly, bring individual and organizational transparency and accountability to the care that is being delivered. Documentation of less than excellent outcomes may result in the organizational tension needed for change to occur. Such motivation can stimulate improvement and motivation for both administrators and clinicians.

As described earlier in this chapter, several organizations such as the CAPC, NQF, and NCP have urged all programs to collect standardized measures across settings. The CAPC has taken the lead in providing technical assistance in this regard. Resources for business, clinical, quality management, and strategic and financial planning are available on the CAPC website, with a link to the actual tools and instruments for measurement and planning of clinical care.

Several efforts have been initiated to advance the measurement of palliative care outcomes. In 2014, the Institute of Medicine (IOM) published *Dying in America*; the IOM committee believes a person-centered, family-oriented approach that honors individual preferences and promotes QOL through the end of life should be a national priority. *Dying in America* provides a comprehensive assessment of the knowledge gaps, structural problems, and financial disincentives that hamper delivery of optimal care, and it makes cross-sectoral recommendations to achieve compassionate, affordable, sustainable, and effective care for all Americans.

The American Society of Clinical Oncologists (ASCO), recognizing that oncologists had few reliable resources to assess and measure the quality of supportive care delivered in their practices, launched a health plan program developed by its Quality Oncology Practice Initiative (QOPI). Data are collected on a quarterly basis and, if desired, reported by ASCO to insurers. Measurement of data in this fashion not only impacts the quality of care delivered within an individual program but also promotes evidence-based practices and standardization across settings. In 2016, ASCO updated the "Integration of Palliative Care into Standard Oncology Care," a document which provides evidence-based recommendations to oncology clinicians, patients, family and friend caregivers, and palliative care specialists and is designed to update the 2012 ASCO provisional clinical opinion (PCO) on the integration of palliative care into standard oncology care for all patients diagnosed with cancer. This update is the most current evidence-based guideline, using nine randomized controlled trials (RCTs), one quasi-experimental trial, and five secondary analyses from RCTs in the 2012 PCO. In the 2016 update, ASCO recommended that inpatients and outpatients with advanced cancer should receive dedicated palliative care services early in their disease trajectory and that it should be concurrent with active treatment.[48] Details can be viewed directly at www.asco.org/palliative-care-guideline.

The CAPC website and a printed technical manual contain tools for measuring HBPC outcomes. When assisting an organization to establish a program, CAPC encourages the incorporation of clinical, financial, operational, and customer metrics.[27]

The CAPC convened a consensus panel to discuss which operational metrics should be measured as programs "strive for quality, sustainability and growth" and which metrics can be used to "compare service utilization across settings." The 12 domains of operational data that were agreed on may be used to compare service characteristics and impact within a program or between programs. The four categories of measurement to assure effectiveness and efficiency recommended by CAPC are (1) clinical (pain and symptom control) metrics, (2) program operational measures, (3) customer metrics (satisfaction surveys of patients, families, and providers), and (4) financial metrics (Table 3.1). Examples of actual tools to measure these characteristics are available on the CAPC website mentioned earlier.

Every program should have a plan to measure and monitor its effect on the quality of patient care, ideally from program inception. Some measures will be useful for internal planning for staffing, need for program growth, and productivity goals. These same measures could then be compared to other programs as external benchmarks, especially for newer programs under development. Ultimately, the data collected can be used to assure that high-quality palliative care is provided across organizations.[20,27] CAPC also collates national data on the prevalence of HBPC teams, which can be further evaluated by state at https://reportcard.capc.org/tables-charts/ (see Figure 3.2).

Table 3.1 Metric categories

Metric domain	Examples
Operational	Patient demographics (diagnosis, age, gender, ethnicity) referring clinician, disposition, hospital length of stay
Clinical	Symptom scores, psychosocial symptom assessment
Customer (patient, family, referring clinicians)	Patient, family, referring clinician satisfaction surveys
Financial	Costs (pre- and post-HBPC consultation), inpatient palliative unit, net loss/gain for inpatient deaths

Economic Issues

Palliative care has been demonstrated to lower costs for both hospitals and payers by reducing hospital lengths of stay as well as pharmacy and procedural costs. Cost savings (cost avoidance) were demonstrated when matching patients who had palliative care team involvement were compared with those patients who did not.[56] Although it is not the goal of palliative care to reduce costs, cost analysis of palliative care programs has demonstrated this to be the case.[56,57] Reduction in costs by palliative care intervention may occur in multiple ways. Patients and their families are often stressed and burdened by a serious illness. Many times, they are not clear about what to expect and may be experiencing the fragmentation of multiple specialty providers giving seemingly conflicting messages. Compounding this is the erroneous societal expectation that medicine can fix nearly any health challenge. It is no wonder that patients and families sometimes have unreasonable expectations and are unable to discern the larger picture when functional status is declining and treatment options offer fewer benefits to quality or quantity of life.

In HBPC, clinicians may be able to provide the family with "the big picture" of the illness situation. As an "objective" assessor, the palliative care provider is particularly skilled at summarizing all relevant information and assisting the patient to match treatments with his or her own personal values and preferences. In so doing, patients and families are better able to apply their personal wishes and goals to the care that is being offered. They may elect to decline certain diagnostics or invasive treatments in favor of those that will provide comfort. Some may choose to not escalate care or perhaps to discontinue treatments that were previously initiated. In the setting of a prolonged critical care stay where treatments are no longer resulting in positive progress, a palliative care consult may result in de-escalation of disease-modifying care in favor of increasing "low-tech" comfort care. Such changes in treatment can result in reducing suffering of the patient and family and, at times, can also result in significant cost avoidance.[58,59] In the less costly hospital care that occurs in the critical care unit, the palliative care team can assist patients and families to select medical treatments and care that are consistent with their values and preferences.[58] When patients and families have a clear understanding of their prognosis and realistic information about proposed procedures or treatments, they may wish to decline further hospital care and return home. In some situations when symptom relief procedures or family respite is indicated, palliative care involvement can facilitate timely occurrence of the needed procedures so that time in the hospital is minimized. Not only does this potentially reduce costs, but quality of care is also enhanced.[58,59] In settings of seemingly futile care or conflict among healthcare providers, patients, and families or among healthcare providers, involvement of palliative care in conjunction with an ethics committee consultation may help achieve more rapid conflict resolution. Cost savings can be accomplished in indirect ways as well.[59] When the palliative care team is involved, they can spend the time at the bedside necessary to manage pain and other symptoms. This is invaluable to an already overburdened primary treating team, who may be working with other patients who also have intensive care needs. Thus, QOL and satisfaction for the patient and family as well as professional colleagues is enhanced. The palliative care team may also be invaluable in assisting with complex plans for discharge, coordinating care across settings, and enhancing communication between the treating team and the patient and his or her family.

Influencing Institutional, State, and National Policy

It is not enough to provide excellent, comprehensive care to just those patients who are referred for consultation. The truly effective HBPC program must seek out ways to influence care for all patients with life-limiting illness by developing an awareness and ability to influence healthcare policy within its institution and at a state or national level.[60] The influence should begin within the larger organization in two main ways: (1) by developing policies, procedures, and practices that will guide the care of all persons with life-limiting illness within the agency and any affiliates and (2) by integrating palliative care education and competency standards into basic orientation and continuing (preferably mandatory) staff education. Examples of the former include development of consultation triggers, policies for advance care planning, limitations of life-sustaining treatments, "comfort measures," withdrawal of mechanical ventilation, and standardized pain and symptom assessment and management. This type of influence will likely necessitate regular or ad hoc participation or leadership on institutional practice or ethics committees. Staff orientation has grown in sophistication, such that "simulated" patients and learning labs are becoming standard mechanisms for learning basic care skills. Practicing skills of communicating bad news, holding family meetings, and discussing advance care planning are some possible activities that lend themselves to such environments. Similarly, most organizations hold staff accountable for mandatory CPR certification. It would seem reasonable to require mandatory "do not resuscitate" classes in which staff learns effective care to provide when patients are near death but will not be resuscitated. Other educational endeavors include annual presentations at other departments or affiliated agencies' grand rounds on palliative care topics. Also, holding annual regional palliative care conferences for professionals or the public can bring attention to the program. Acting locally at the state level in legislative or health policy forums can make a big difference in care of patients.[61] Some states have palliative care or EOL task forces that make policy and legislative recommendations that will enhance the care of the seriously ill. For example, the Palliative Care and Hospice Education and Training Act (PCHETA; HR 1676/S 693) was introduced in March 2017 as bipartisan legislation intended to address the growing need for palliative care in the United States: PCHETA was drafted to strengthen training for palliative care team providers and improve palliative care teaching and research. Additionally, its intent is to generate national education programs to enlighten medical professionals, patients, and families about the benefits of palliative care and hospice. It also directs the National Institutes of Health (NIH) to use existing funds and authority to expand palliative care research and create academic and career incentive awards by providing grants or contracts to health professionals who agree to teach or practice in the palliative care field for at least 5 years (see https://www.congress.gov/bill/115th-congress/house-bill/1676). Collaborating with local organizations also lends power to individual efforts. For example, the NHPCO, the American Cancer Society, nursing and medical associations, and professional organizations at local, state, or national levels often have lobbyists and resources to assist with legislative efforts. Chapter 74 contains a broader discussion on the nursing role in policy development. However, it is important for HBPC program staff and leaders to keep these initiatives in mind as they develop within a healthcare setting.

Future Directions

Despite a strong foothold within mainstream medicine, there is always the continued need for growth, improvement, and education to sustain and expand palliative care. Collaborating to build systems of compassionate care needs to be balanced with moral ideals as well as institutional realities. This will eventually lead us to, as Senator Ted Kennedy said, "the humanization of our healthcare system." Therefore, it is vital that we strive to be agents of change in both our practice as well as on the state and national levels, to help carve the granite of health policy to assure it is meeting the needs of all patients. Our forward movement must include a dedication to assure integrated palliative care across healthcare settings with proper reimbursement.

External agencies must require mandatory adherence to standards, and those agencies that meet established standards should be properly reimbursed for their performance. Funding for palliative care research, adequate reimbursement, and support for faculty development must become national priorities. The growing consumer demand for patient- and family-centered care may be the "tipping point" that will make palliative care services an integral part of every organization that touches the lives of persons with life-limiting illness and their families. As awareness for palliative medicine interventions for the advanced illness patient evolves, it is our moral imperative that provides the clearest rationale: "Be kind whenever possible. It is always possible" (Dalai Lama). In every action taken, let us endeavor to always practice with kindness, and let kindness be the driving force for changing the face of healthcare delivery.

Acknowledgments

CHAPTER 4

Principles of Patient and Family Assessment

John D. Chovan

Key Points

- Comprehensive assessment of the patient and family is essential to planning and implementing palliative nursing care.
- Assessment involves input from the patient, family, and all members of the interdisciplinary team with information shared verbally as well as in the patient's health records.
- Ongoing, detailed, and comprehensive assessment is needed to identify the complex and changing needs and goals of patients facing chronic or life-threatening illness and those of their families.

Introduction

An effective assessment is crucial to establishing an appropriate nursing care plan for the patient and family. The palliative care nursing assessment may vary little from a standard nursing assessment.[1,2] To assess effectively, nurses working at the generalist level and at the advanced level of practice and other members of the interdisciplinary healthcare team must maximize their listening skills and minimize making quick judgments. Clinicians must actively explore both their initial hunches and alternative hypotheses to minimize premature closure.[3] Nurses use the therapeutic use of self to engage patients and families during the assessment, including the tools of active listening and the appropriate use of silence.

The goals of the palliative care plan that evolve from the initial and ongoing nursing assessments focus on maximizing quality of life (QOL). The quality-of-life framework by Ferrell et al.[4] is used to organize the assessment. The four quality-of-life domains in this framework are physical, psychological, social, and spiritual well-being. For this chapter, the psychological and social domains are combined into one: the psychosocial domain.

Because the needs of patients and families may change throughout the course of a chronic or life-threatening illness, these quality-of-life assessments are examined here at four critical stages along the illness trajectory: (1) at the time of diagnosis; (2) during treatment, that is, initial treatments and subsequent planned or unplanned treatments focusing on cure; (3) after treatment, that is, when the planned course of treatment is completed or when the patient's goals shift away from curing the illness; and (4) during active dying.

Effective palliative care assessments are predicated on nurses understanding their thoughts, values, emotions, convictions, and experience with respect to issues commonly arising in palliative nursing care. Nursing leaders agree that self-awareness and understanding one's perspectives are essential to providing quality nursing care.[5] Self-awareness has been demonstrated not only to improve quality of care, but also to decrease stress on the part of nurses' patients and patients' families.[6] Box 4.1 comprises some of the issues that palliative care nurses might explore about themselves to enable their effective assessments.

Chronic and Life-Threatening Illnesses

The experiences of seriously ill patients are dynamic in terms of the continuous or episodic declines they face throughout the illness trajectory. These experiences are associated with the trajectory that is characteristic for the illness. For example, persons living with dementia experience a slow, gradual decline, frequently at home or in a memory unit of a long-term care facility. Persons living with chronic obstructive pulmonary disease (COPD), on the other hand, experience a gradual decline punctuated by exacerbations requiring hospitalization and treatment, oscillating between a quasi–steady-state of relatively stable symptoms and acute episodes of severe symptomatology. Also, persons with a cancer diagnosis may experience a cure and then be cancer-free for the rest of their lives, or they may experience a recurrence of their disease. Every illness has its distinctive trajectory, but every person's journey along that trajectory is unique.

The focus of care for palliative care patients is a frequently shifting balance between cure and palliation. At diagnosis, the focus is likely to be more curative, focusing on minimizing the impact of the disease process on the person, whereas managing symptoms and optimizing QOL are secondary foci. But, over time, as the illness progresses and the patient declines, the focus shifts and becomes increasingly more palliative; that is, reduction of symptoms and maximizing QOL become the primary foci while attempts to impact on the disease process are purely for the sake of comfort. Examples of these kinds of illnesses today include AIDS; cardiovascular, respiratory, gastrointestinal, hepatic, and renal diseases; diabetes; neurological disorders such as multiple sclerosis, cerebral palsy, amyotrophic lateral sclerosis, Parkinson's disease, and dementia; chronic and severe mental illnesses, such as schizophrenia and bipolar disorders; multiple types of cancer; and sickle cell disease. For some of these illnesses, the focus of disease management may include attempting to extend life through research with the hope of finding a cure.

Box 4.1 Questions for Self-Awareness Prior to Palliative Nursing Assessments

What do I believe about . . .?

- QOL
- suffering
- patient autonomy
- pain, treating pain, tolerance, and dependence
- death and dying
- advance directives
- code status
- organ donation
- funerals, burial, and cremation
- cultures other than my own
- the use of:
  - CPR
  - life support, ventilators, and tracheostomies
  - medically administered nutrition at end of life and feeding tubes (NG, OG, PEG)
  - medically administered hydration at end of life
  - medications that could hasten death

Could I authentically discuss . . .?

- QOL
- suffering
- patient autonomy
- pain, treating pain, tolerance, and dependence
- death and dying
- advance directives
- code status
- organ donation
- funerals, burial, and cremation
- cultures other than my own
- the use of:
  - CPR
  - life support, ventilators, and tracheostomies
  - medically administered nutrition at end of life, and feeding tubes (NG, OG, PEG)
  - medically administered hydration at end of life
  - medications that could hasten death

Would I feel comfortable . . .?

- including my last name when introducing myself to patients and families
- asking family members to leave the room if necessary
- asking others in the room to let the patient answer my questions without their help
- asking questions that are controversial
- asking questions that are personal
- talking with families of dying or dead patients
- touching patients who are dying or dead

Noncancer illness accounted for more than two-thirds (72.3%) of the admissions to hospice in 2016 as reported by the National Hospice and Palliative Care Organization,[7] the distribution of which is listed in Table 4.1.

Persons diagnosed with a chronic or life-threatening illness may repeatedly alter their expectations about the future. Words describing the status of the disease during a cancer illness, for example, include "no evidence of disease," "remission," "partial remission," "stable disease," "recurrence," "relapse," and "metastasis." Noncancer illnesses such as heart failure (HF) and COPD are described by words such as "exacerbation" and "recovery." Mental illnesses are often episodic with episodes of "stability" punctuated with episodes of "decompensation" or "relapse." Patients and families report experiencing a "roller-coaster ride" in which the hopeful points in better health are often followed by crises with relapse or disease progression. Patients may be told, more than once, that they are likely to die within a short period of time only to recover and do well for a period. As a result, the finality of death may be more difficult when it does occur because, up to this point in the patient's trajectory, the disease has always responded to treatment.

Case Study: Hibaaq

Hibaaq is a 65-year-old married female patient of Somali descent. She was raised Muslim and considers herself adherent to her faith, and she has just been diagnosed with COPD/chronic bronchitis. Although she and her husband Liban had no history of smoking, they had been working in a chemical factory since their arrival in the United States more than 40 years ago. Liban is considering retirement soon. They live with their three children: 30-year-old son Rooble, 28-year-old daughter Sagal, and 20-year-old daughter Ubex.

Table 4.1 Major diagnoses for hospice admissions in 2016

Diagnosis	% of all hospice admissions
Cardiac and circulatory	18.7%
Dementia	18.0%
Respiratory	11.0%
Stroke	9.5%
Other	15.6%

Source: *NHPCO Facts and Figures: Hospice Care in America*. Alexandria, VA: National Hospice and Palliative Care Organization; 2018. https://www.nhpco.org/sites/default/files/public/Statistics_Research/2017_Facts_Figures.pdf.

Patient and Family Assessment

Introduction to Physical Assessment

Nurses understand that QOL is based in part on the severity and impact of physical symptoms. Physical assessment not only provides a baseline of symptoms at one point in time, but also monitors their changes, the emergence of new symptoms, the effectiveness of their treatments, and changes in how they impact on the patient's QOL. Physical assessment can uncover symptomatology in the psychosocial and spiritual domains as nurses use the *therapeutic use of self* when assessing and caring for patients and their families.

Physical assessment focuses primarily on organ systems and symptoms related to their functioning. Historical information can come from the electronic health record (EHR) to understand documented details from previous assessments done by others on the interdisciplinary care team, including diagnostic lab results and imaging. Subjective information is collected by talking to the patient and developing a picture of how they view their health and health status. Data are also triangulated with caregivers, frequently family and friends. During the interview, the nurse reviews each organ system with the patient to collect data on symptoms. The nurse develops objective information by doing a physical examination. Observing a patient's facial expressions, the nurse may notice nonverbal signs of pain. Auscultating heart sounds can shape an understanding of circulation changes and, thus, ischemic pain. The abdomen can deliver information about bloating and constipation through auscultation and palpation. Percussing the lungs can provide data about respiratory status and, thus, dyspnea.

Physical assessment also includes a determination of functional status. Various scales have been shown to be predictive of survival in specific classes of palliative patients based on an assessment of

Table 4.2 A framework for psychosocial assessment

Types of loss		
Physical loss	**Psychosocial loss**	**Spiritual loss**
Body function	Alterations	Hope for the future
Body parts	Autonomy	Illusion of control
Energy	Body image	Illusion of immortality
Mobility	Lifestyle	Illusion of predictability/certainty
Pain	Money	Time
Sexuality	Relationship changes	
	Role function	
	Sense of mastery	
	Sexuality	
	Time	
	Work changes	
Types of responses to loss		
Observing emotional responses	**Identifying coping styles**	
Acceptance	*Functional:*	
Anger	Normal grief work	
Anxiety	Problem-solving	
Bargaining	Humor	
Denial	Practicing spiritual rituals	
Depression	*Dysfunctional:*	
Sadness	Addictive behaviors	
Shock	Aggression	
Withdrawal	Fantasy	
	Guilt	
	Minimization	
	Psychosis	
Personal needs associated with loss		
Assessing the need for information	**Assessing the need for control**	
Wants to know details	Very high	
Wants the overall picture	High	
Wants minimal information	Moderate/average	
Wants no information, but wants the family to know	Low	
	Absent, wants others to decide	

Table 4.3 Differentiating normal grief from depression

Parameter	Depression	Normal grief
Anger	No expression of anger	Open expression of anger
Course	Frequently not self-limited	Self-limiting but recurrent with each additional loss
Crying	Crying absent or persists uncontrollably	Crying is evident and provides some relief
Dreams	No memory of dreaming	Dreams may be vivid
Emotions	Consistent dysphoria or anhedonia (absence of pleasure)	Emotional states variable
Energy	Extreme lethargy, weight loss	Lack of energy, slight weight loss
Intervention	Adaptation requires professional treatment	Adaptation does not require professional intervention
Losses	May not identify loss or may deny it	Identifies loss
Preoccupation	Self-preoccupied, rumination	Preoccupied with loss
Sleep	Insomnia or hypersomnia	Episodic difficulties sleeping
Social interaction	Socially unresponsive, isolated	Socially responsive to others

their functional status. For example, the Palliative Performance Scale (PPS) allows the nurse to assign a number on a 10-point scale (0–100% in increments of 10%) of functional status based on five observed parameters: ambulation, activity and evidence of disease, self-care, intake, and level of consciousness.[8]

Introduction to Psychosocial Assessment

Persons diagnosed with a chronic or life-threatening illness experience many losses. Responses to illness, however, vary tremendously among individual patients and family members. In addition, the same person may respond differently at various times during an illness. How a patient copes depends on the severity of the illness, the patient's history of coping with stressful life events, and available supports. Some individuals develop coping styles that are more helpful than others when facing a life-threatening illness.

Tables 4.2, 4.3, and 4.4 provide a framework for three key elements of psychosocial assessment: (1) conducting the psychosocial assessment, (2) distinguishing nonpathological grief from depression, and (3) doing a general mental status assessment. Throughout the illness trajectory, nurses use these tools to monitor patient response to illness and treatment.

Nurses assess two very important parameters to assist patients and families to cope in the most functional way possible. These parameters are (1) the need for information and (2) the need for control in making decisions. Observers of exceptional patients—persons who have thrived despite their prognosis—have noted that patients who are proactive and assertive information seekers often appear to experience better outcomes than patients who are passive in making decisions.[9] Indicators of a person's need for control may include:

- An expressed need for information.
- Comfort in asking questions.
- A willingness to assert their own needs and wishes relative to the plan of care.
- Initiative taken to research print and Internet resources on the illness and treatment.

Table 4.4 General mental health assessment

Appearance
Hygiene
Grooming, makeup
Manner of dress (appropriate, inappropriate)
Posture
Body language

Mood and affect (congruence)
Interview behavior
Specific feelings expressed
Facial expressions

Intellectual ability
Attention (distractibility)
Concentration
Concrete/abstract thinking
Comprehension
Insight into situation, illness
Judgment
Educational level

Sensorium/level of consciousness
Alert
Drowsy
Somnolent
Obtunded
Stuporous
Unresponsive

Psychomotor behavior
Gait
Observable symptoms (tics, tremors, perseveration, pilling)
Movement (akathisias, dyskinesias)
Coordination
Compulsions
Energy

Speech
Pressured, slow, rapid
Goal-oriented, rambling, incoherent, fragmented, coherent
Relevant, irrelevant
Poverty of speech
Presence of latencies (delayed ability to respond when conversing)

Thought patterns
Loose, perseverating
Logical, illogical, confused
Oriented, disoriented
Poorly organized, well organized
Tangential, circumstantial
Preoccupied, obsessed
Paranoid ideas of reference
Delusions
Hallucinations
Blocking, flight of ideas
Neologisms (made-up words)
Word salad (meaningless word order)
Presence of suicidal or homicidal ideation, plan, access to means

Table 4.2 provides details for doing a psychosocial assessment. More detailed information on the psychosocial aspects of cancer patients can be found in Holland's *Psycho-Oncology*.[10]

Some patients with advanced disease have been able to integrate their losses in a meaningful way, managing to reconcile and transcend them. An example of such a person is Randy Pausch, a late computer science professor at MIT who reported in his *Last Lecture*[11] on making meaning of living with a terminal diagnosis of cancer. And, of course, while all this is going on with the patient, family members are also going through a myriad of their own responses, which often are at different rates and intensities within the same family unit. Randy Pausch's wife Jai Pausch recounts her journey in *Dream New Dreams*.[12] (For more information, see Chapter 32 of this volume, "Supporting Families and Family Caregivers in Palliative Care.")

Grief is a normal reaction to loss, especially a major loss such as one's health. Nurses understand that although persons may be experiencing normal grief, ineffective adaptations or coping can indeed lead to depression.[13] Criteria for depression in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5)[14] include grieving the loss of a loved one, *but only if other criteria for depression are met*. In chronic illness, grief is also likely to be recurrent as losses accumulate and the patient and family reexperience these losses. This does not make it pathological, but it does form the basis of the roller-coaster phenomenon that many patients describe, one that can lead to a more pathological depression.[15,16] Table 4.3 compares normal grief with depression.

In some cases, patients may appear to be having difficulties in coping, but the nurse cannot easily identify the specific problem. The nurse may need to make a more thorough mental health screening assessment to determine the most appropriate referral.[17] Key elements in such an assessment are found in Table 4.4. In such instances, a referral to a behavioral health professional may also be warranted. Additional information and tools used to assess for emotional distress can be found in Chapter 52, "Palliative Care Nursing in the Outpatient Setting."

Introduction to Spiritual Assessment

Although Chapter 34, "Spiritual Screening, History, and Assessment," provides additional information on collecting information on the spiritual domain, the following discussion illustrates the importance of including the spiritual domain as a component of a comprehensive nursing assessment.

Attempts to define spirituality can often result in feelings of dismay and inadequacy. It is like trying to capture the wind or grasp water. Assessing and addressing the spiritual needs of patients, therefore, can be a formidable challenge. Spirituality may include one's religious identity, beliefs, and practices, but it involves much more. The person without an identified religious affiliation is no less spiritual. Indeed, the desire to speak one's truth, to explore the meaning of one's life and illness, and to maintain hope are all fundamental human quests that reflect the depth of the spirit. Various definitions of spirituality have appeared in the literature over the past years. But spirituality is defined by consensus in the palliative care community as "a dynamic and intrinsic aspect of humanity through which persons seek ultimate meaning, purpose, and transcendence, and experience relationship to self, family, others, community, society, nature, and the significant or sacred. Spirituality is expressed through beliefs, values, traditions, and practices."[18 (p. 646)]

The spiritual issues that arise at the time of diagnosis of a serious or life-threatening illness are abundant and varied. As a person progresses through the phases of an illness, he or she is confronted with mortality, limitations, and loss. This frequently leads to questions such as "What is my life's purpose?," "What does all this mean?," "What is the point of my suffering?," "Why me?," and "Is there life after death?" Indeed, Viktor Frankl, in his classic work *Man's Search for Meaning*,[19] affirmed that the quest to find meaning is one of the most characteristically human endeavors. To find meaning in suffering enhances the human spirit and fosters survival.

According to Abraham Maslow's theory,[20] human needs can be placed on a hierarchy that prioritizes them from the most basic physical and survival needs to the more transcendent needs. Thus, a patient's ability and willingness to engage in dialogue about issues of meaning, to discuss successes and regrets, and to express his or her core values may occur only after more fundamental needs are addressed. This reality in no way diminishes the spiritual compared with the physical; rather, it supports the need for a interdisciplinary approach that provides holistic care of the entire person. For example, if a nurse relieves a young woman's cancer pain and a social worker secures transportation for her to treatments, the patient and her family may be more able to address the vital concerns of her soul. Religious or spiritual advisor consultation may be indicated.

Responding to the spiritual needs of patients and families is not solely the domain of the chaplain, clergy, or other officially designated professionals. All members of the healthcare team share the responsibility of identifying and being sensitive to spiritual concerns. The sensitivity of the nurse to a patient's spiritual concerns improves the quality of palliative care throughout the illness trajectory. When members of the interdisciplinary healthcare team serve as companions to a patient and family during their journey with an illness, they offer vital and life-affirming care.

A patient must not be viewed in isolation, but rather in the context of those who are affected by the illness. The focus of spiritual assessment, therefore, includes not only the patient, but members of the patient's family—however the patient defines his or her family—including people not related to the patient by blood, marriage, or adoption, such as friends, neighbors, their faith community, and unmarried partners, and in traditional and nontraditional configurations. This perspective affirms the power of a systems view, the view that places the patient at the center of care while still being integral to the interdependent and connected family. Spiritual support to family members not only assists them directly but also may contribute to patient comfort secondarily: comfort may increase as the patient sees his or her loved ones being cared for as well.

The purpose of a spiritual assessment is to increase the healthcare team's knowledge of the patient's and family's sources of strength and areas of concern to prepare for planning quality care that maximizes patient and family QOL. The methods of assessment include direct questioning, acquiring inferred information, and observing. As with the physical and psychosocial domains, this is most effectively accomplished when a basis of trust has been established. The interdisciplinary team best serves patients' and families' needs when they determine whether the patient is experiencing spiritual distress and desires specialized spiritual care. Some patients are connected to a spiritual community and, when experiencing spiritual distress, look to their established community and leadership, such as a minister, priest, rabbi, imam, or other religious figure, for support. Patients without an established

Box 4.2 Spiritual Screening Questions

- Is religion or spirituality important to you?
- If so, does your religion or spirituality give you comfort?
- If not, has there ever been a time when spirituality or religion was important to you?
- Would you like me to contact anyone in your faith community?
- Would you like a visit from your faith community leader?
- Would you like a visit from a chaplain?

connection to a spiritual community tend to fall into one of three groups: (1) those who may be experiencing spiritual struggle but are unlikely to request spiritual support, (2) those who would like spiritual support but may or may not request it and would be dissatisfied if they did not receive it, and (3) those for whom religion and spirituality is not important and who would not want a visit from a chaplain or any spiritual support person.

The nurse's role historically includes being able to support the patient's spiritual life and concerns. A body of knowledge and cultural practices prescribe and confer the specific role—such as minister, priest, rabbi, imam, or other religious figure—with certain privileges to function as a companion to those patients who are addressing religious and spiritual concerns. Linking the patient with these professionals based on a sensitive screening of needs will enhance the patient's healing and integrative process. The Rush Protocol[21] is a tool to discern among these groups of patients and to respond more effectively to their needs and preferences. Box 4.2 is a summary of the kinds of questions useful for the nurse to ask as part of a spiritual screening.

One of the fundamental principles underlying spiritual assessment (and spiritual care) is the commitment to the value of telling one's story.[22] Alcoholics' Anonymous,[23] a very successful program with spiritual tenets, acknowledges the power of story. This might be paraphrased as follows: in the hearing is the learning, but in the telling is the healing. Park[24] presents the concept of a person's global meaning, their internal mechanism of making sense of the world.

Simple, open-ended questions such as "How is this illness affecting you?" and "How is the illness affecting the way you relate to the world?" provide the opportunity for validation of the patient's global meaning and placing her or his response to the illness within it.

Cultural Competence

The Joint Commission defines cultural competence as "the ability of health care providers and health care organizations to understand and respond effectively to the cultural and language needs brought by the patient to the health care encounter."[25 (p. 1)] Expecting that healthcare professionals will know all the customs, beliefs, and practices of patients from every culture is unrealistic, of course, and to do so promulgates the notion of stereotypes. All providers, however, should strive for some degree of cultural competence by being aware of differences and being open to asking appropriate questions to relate back to plans of care. Reference sources are useful to nurses and other members of the interdisciplinary team in gaining background information for cultural competence.[26] But the transformational nurse will ask the questions appropriate to building the nursing database.

Nurses and other members of the interdisciplinary healthcare team assess in culturally competent ways when they:

- Are aware of one's own ethnicity, biases, and ethnocentrism, the unconscious tendency to assume that one's own worldview is everyone's worldview or is somehow superior. This is especially important with differences viewed by some as moral choices, such as persons of different religious views, sexual orientation, or nonconforming gender.[27]
- Convey respect.
- Solicit the patient and family as teachers and guides regarding cultural practices.
- Ask about the patient's personal preferences, such as food, spiritual beliefs, family relationships, music, communication preferences, and interpersonal customs.
- Avoid expectations for any individual to represent his or her whole culture.
- Assess the patient's and family's beliefs about illness and treatments.
- Respect cultural differences regarding personal space and touch: "Whom do I ask for permission to examine you?" and "May I touch you here?"
- Determine needs and desires regarding health-related information: "When I have information to tell you, how much detail do you want to know and to whom do I give it?"
- Note and affirm the use of complementary and integrative healthcare practices: "Do you ever consult a healer or a person who provides medicines to persons in your community?"
- Are sensitive to the need for interpreter services[28] (Box 4.3) and engage professional interpreters who maintain compliance with the Health Insurance Portability and Accountability Act (HIPAA) for relaying information, instead of relying on family members to interpret.[29]

Box 4.3 Meeting the Need for Interpreter Services

Overview

- Medical interpretation can occur with an onsite face-to-face translator, a telephone-based interpreter, or a video-based interpreter over the Internet.
- Skills of a medical interpreter are not just the ability to interpret quickly and exactly between two languages, but also the ability to provide a cultural interpretation and context.
- A child or family member should not be used as an interpreter for major explanations or decision-making about healthcare. Even adult children may feel uncomfortable speaking with their parents or grandparents about intimate topics. Furthermore, many lay people do not know or understand medical terms in their own language. Informed consent requires that the patient receive accurate information that he or she can understand before making a healthcare decision.

(*continued*)

Box 4.3 Continued

- Use the services of a certified medical interpreter, if possible. See the websites for the International Medical Interpreters Association (http://www.imiaweb.org/) and the National Board of Certification for Medical Interpreters (http://www.certifiedmedicalinterpreters.org/) for more information.

When Working with an Interpreter in Healthcare

- Speak directly to the patient, not the interpreter. The interpreter should divert their eyes away from the patient and you as a nod to their role as a nonparticipant.
- Use simple language and ask open-ended questions. Be patient for the answers.
- Observe nonverbal communication and inquire of the patient what these might mean.
- Ask that any educational information be repeated back to you from the patient.

Services

- Several telephone-based interpretation services are available. AT&T and Language Line provides translation services by subscription or on a pay-as-you-go basis (http://www.languageline.com). The partnership is also making interpretation services more accessible via smartphones and has a video-based interpreting service for 35 languages, including American Sign Language (ASL).
- RTT Mobile and Sprint have partnered to provide a device initially for use by emergency responders and hospitals to communicate with persons with limited English proficiency. Called ELSA, the device immediately connects the service provider with an interpreter in the requested language over the Sprint network, enabling instant communication (http://www.rttmobile.com/interpreters). It is now used by healthcare providers and other industries around the world.
- Many online, video-based interpretation services are available. Cloudbreak provides a service called My Accessible Real-Time Trusted Interpreter (MARTI). It is HIPAA-compliant and available 24/7, 365 days a year by subscription (http://www.marti.us).

Review of the Electronic Health Record

Before meeting a patient or family member, the nurse prepares for the face-to-face encounter. This is done by reviewing the patient's EHR and developing an understanding of the nature of the patient's journey thus far: the initial nursing database. With the advent of the EHR and its emergence in hospitals, clinics, and primary care offices, access to up-to-the-minute patient data supports thorough preparation prior to making face-to-face contact with patients and their families. Also, palliative care patients are often very ill and do not have the energy or patience for, or interest in, answering myriad questions—especially if the questions do not relate to their immediate needs. The nurse conducts individualized assessments based on prioritized symptoms for each patient, therefore, based on the initial review of the EHR.

Beginning with the database prior to the initial face-to-face encounter will assist the nurse to focus assessments and increase the effectiveness of the time spent with patients and their families. Frequently, for patients in hospitals and other facilities, the nurse will print portions of the EHR, particularly the face sheet and the most recent history and physical examination, and write on them while building the nursing database from the EHR and during the face-to-face assessment interview. With increasing experience and expertise, the nurse will be able to streamline the amount of data needed to be written down, but all relevant data are always reviewed.

Although the three domains are discussed separately in this chapter, the nurse understands that holistic, interdisciplinary care of patients and their families often leads to interweaving of the domains during not only the review of the EHR but also face-to-face assessment encounters.

The nursing review of the EHR should reflect an understanding of the following:

- *Demographic information*: Note the patient's name and identification number, age, date of birth, gender, ethnicity, primary language, and occupation. The patient's address and phone number may become important for discharge planning and if advance directives (see later discussion) must be completed. Among the demographic information to collect are the names and contact information of any other service providers who have participated in the patient's journey, such as healthcare professionals, home health agencies, and clergy. If in an inpatient context, also note the room number and bed number of the patient.
- *Referral information*: Note whether the patient was referred for palliative services from another healthcare provider and, if so, the date of the referral and the reason given by the referrer for the consult. This is often most important for billing, but also in developing rapport with the patient and others on the interdisciplinary team.
- *Next of kin and contact information*: Note any familial relationships, such as spouse, partner, significant other, children (adults and minors), parents, and anyone else documented in the record. The nurse may want to document these relationships in a genogram (see Figure 4.1) to facilitate sharing of sometimes complex family structures. Some of this information may be documented in the EHR by other contributors of the interdisciplinary team, such as social work, case management, and pastoral care. Although HIPAA requires protection of personal health information, some patients' identities and whereabouts are subject to an extra level of security, such as prisoners, abused persons, and public figures. This is noted in the nurse's database. Finally, if two patients on the census have similar names, such as Lucy Walls and Lucia Wells, the nurse notes it.
- *Primary point of contact*: Identifying one point of contact for the patient and the associated phone number will facilitate communication between the palliative care team and the family. This person—frequently a spouse, parent, nearest living relative, or eldest child—will often be the designated person for making the healthcare decisions that they know the patient would have made for him- or herself. This surrogate decision-maker will often be documented in the EHR as the "Healthcare Power of Attorney," "HCPOA," or "POA" (or sometimes "DPOA" for durable power of attorney). Should a person become unable to speak for him- or

herself without having a designated surrogate to speak for him or her, most state laws designate a hierarchy of persons who are called on to speak for the patient, such as a court-appointed guardian, then a legal spouse, followed by adult children (sometimes as a group), siblings, other family members, and then other interested nonrelated parties. Distinguishing between the person who holds legal authority (power of attorney) for fiscal decision-making and the person who holds legal authority (power of attorney) for healthcare decision-making is important. If it is the same person or if the distinction is not obvious, the nurse clarifies this during the interview. Sometimes, engaging others on the team is needed to facilitate this clarification, such as chaplaincy or social work.

- *Religious affiliation*: Note the patient's stated religious affiliation and clergy, if indicated. Refer to the spiritual assessment information in this chapter for detailed information.
- *Advance directives and code status*: The Patient Self-Determination Act of 1990 requires all inpatient facilities to ask patients on admission if they have advance directives and, if so, to request a copy of them. Laws regarding advance directives and orders for code status are specific to each state, so the nurse must be familiar with the local laws for advance directives and orders for code status. A national movement to provide a way for the wishes of a patient to be explicitly stated in a single order from a healthcare provider, the Physician Orders for Life-Sustaining Treatment (POLST) Paradigm,[30] is being implemented in various states and municipalities across the country. The presence or absence of advance directives and orders for life-sustaining treatment must be noted. The nurse reviews the documents and notes the patient's wishes as stated in them. If the documents are missing or incomplete, note that the missing data may be acquired during the assessment interview or referred to the resource persons (social worker or chaplain, for example) so designated at the nurse's institution. Also, note if the EHR indicates whether the patient is a registered organ donor.
- *Insurance coverage*: Patient care within the context of the US healthcare system is often delimited by the patient's resources. For example, Medicaid may have a restricted medication formulary. If the patient does not have adequate insurance coverage, consider a social work consult to help the patient access the necessary resources to obtain financial assistance.
- *Recent health trajectory*: Nurses may tap several sources of information in the EHR to develop an understanding of the patient's recent health trajectory and current health status. The most recent history and physical examination document (H&P) will describe the patient's diagnosis, history of the present illness, past medical and surgical history, and family and social history, all of which are pertinent to the provision of quality palliative care. It will also serve as a subjective and objective snapshot of the physiological state of the patient by organ system at the time the H&P was created as well as a summative impression of the health status of the patient at that time: the subjective review of systems, the functional assessment, and the objective physical examination. The functional assessment is particularly good at helping people not familiar with healthcare jargon to understand the changes in the patient across the illness trajectory and is typically reflected in the PPS score. The initial findings and plan of medical care are also included. The nurse continues to develop the picture of the patient's current state by reviewing the consultation notes by the other involved services and the recent progress notes, including other medical services and ancillary services, such as case management, dietary, respiratory therapy, physical and occupational therapy, and speech therapy. Note also the use and whereabouts of hearing aids, eyeglasses, and dentures, and the placement of ports, central lines, pacemakers, defibrillators, and implants.

- *Medications*: Review the patient's drug allergies and medications as listed in the EHR (home use and inpatient use), including over-the-counter and herbal preparations. Note if any newly ordered medications relate to the patient's comfort. Make note of medications that are or are not present for key symptoms including pain, dyspnea, anxiety, appetite, nausea, bowel function, and sleep, and for any symptoms mentioned in the H&P or indicated by the results of the diagnostic tests, such as lab results and reports from radiology and pathology. For example, patients with liver or kidney failure may have pruritus, and patients with a newly diagnosed chronic illness may have a depressed mood. Also note if any home medications can induce tolerance, such as some antidepressants and some pain medications. Stopping these medications abruptly could cause the patient to experience discontinuation or withdrawal symptoms. Persons who are stable on their home medications for hypertension, psychiatric issues, and other cardiac issues should not have their PO medications discontinued abruptly without additional input from care providers.
- *Diagnostic test results*: Objective information such as current vital signs and the results of diagnostic tests is important not only to understand the patient's current state but also to understand trends that inform the trajectory of the patient's illness and current symptoms. Trends in vital signs can indicate improving or declining status related to infections, oxygenation, and hemodynamic stability. Organ perfusion can be evaluated in part by indicators such as mental status changes, renal function tests, and liver function tests. In turn, functionality of these organs can affect the patient's plan of care. For example, the metabolites of morphine, a commonly used opioid analgesic, are excreted by the kidneys. When renal function is compromised (serum creatinine >2.0 mg/dL, or >1.5 mg/dL in older adults), the metabolites rapidly accumulate. Because they are neurotoxic, they can cause confusion. Drugs that are metabolized by the liver will lose their efficacy with compromised liver function, and the production of albumin—essential for functions such as drug transportation, wound healing, hemostasis, immune function, water and electrolyte balance, and muscle mass—and prealbumin (or transthyretin) can decline or cease. Levels of albumin (20-day half-life) are used to evaluate long-term nutritional status because they are thought to reflect the patient's nutritional status for the past few months. Prealbumin (2-day half-life) levels are thought to reflect nutritional status over the past few days, and, because absolute value of prealbumin may be influenced by other factors, trends in the prealbumin level are used to evaluate improvement during a clinical stay rather than specific values. Radiology and pathology reports may provide further information about symptoms and the severity and trajectory of the patient's illness, such as biopsy results, mass effects, and location of spinal compression fractures.
- *Complementary therapies*: Note the presence or absence of any complementary therapies the patient has used or those symptoms that may be amenable to available complementary therapies: creative/reactive modalities such as music therapy and art therapy; body energy work such as Reiki, Therapeutic Touch, and Healing Touch; introspective modalities such as guided imagery, meditation, and hypnotherapy; and interventional modalities such as massage therapy, aromatherapy, acupressure, and acupuncture.

At this point, the nurse will have a very good understanding of the data that are required to complete the assessment and the information that must be reconfirmed with the patient and family. The initial hypothesis of the holistic picture of the patient in all domains—physical, psychosocial, and spiritual—should begin to take shape.

Additional information is required to develop the most appropriate palliative plan of care for the patient and the family that can only be collected through a face-to-face interview.

The Initial Face-to-Face Encounter

The nurse is prepared to encounter the patient at any point in the trajectory of his or her illness because many people do not encounter palliative care services at diagnosis. Irrespective of when in the trajectory the nurse first meets the patient and family, the nurse establishes a relationship and begins to build trust with the patient and family—and other caregivers—as appropriate, at the first meeting and at every subsequent encounter.

Nurses and other members of the interdisciplinary healthcare team establish rapport and build trust when they:

- Find the nurse who is caring for the patient and ask about any issues the nurse might have become aware of during his or her care for the patient thus far. Note these issues in the database and add them to the list of items for further probing during the patient and family interview.
- Use hand sanitizer or wash their hands within view of the patient and family to demonstrate professionalism and concern for safety.
- Verify that this is the correct patient: check the armband, if applicable. If the patient is alert, begin the interview, "Good morning. What is your name?" If the patient is not alert, attempt to arouse the patient if possible. If the patient is not responsive, the EHR and/or the family may be the best source of information.
- Introduce themselves to the patient and others in the room with first and last name, role, and how the patient may address her or him: "My name is Jane Doe. I am a nurse practitioner on the palliative care team. Your attending physician Dr. Jones asked our service to see you, and I talked with your RN Josh this morning. You may call me Jane."
- Determine how the patient would like to be addressed: first name, last name, title, and/or nickname: "What may I call you?" Do not be surprised if a patient asks to be called something more formal than expected, such as "You may call me Mrs. Jackson," or by an unfamiliar name. Do not hesitate to ask how a name is spelled if in doubt.
- Identify the other persons in the room and their relationship with the patient: "Whom do we have in the room with us, Mrs. Jackson?" Sometimes the patient will introduce the individuals if he or she can, or the individuals in the room will introduce themselves. The nurse requests elaboration of the relationship between the patient and others in the room as appropriate. Modify the genogram as appropriate.
- Explain the purpose of the interaction and the approximate length of time expected that the nurse will spend with the patient: "Our team does several things including pain and symptom management, helping you to determine your goals, and keeping

you comfortable in the hospital. We will be spending about 20 minutes talking with you and examining you."

- Obtain the patient's permission to proceed with the assessment: "May I continue?," giving the patient an opportunity to get comfortable: "Do you need to use the restroom before we start?," and excusing others whom the patient does not wish to be present during the interview and examination: "Mrs. Jackson, do you want your visitors to stay here during our conversation or would you rather they step out of the room?" Some patients may want others to be present during the interview, to assist with recall—particularly patients with compromised memory—but not during the examination. The nurse modifies the assessment routine to accommodate the focused goals of the assessment and patient preferences.
- Take a seat near the patient, being respectful of the patient's cultural norms for physical closeness and eye contact, "Do you mind if I sit down next to you? So we can talk more comfortably?" Some patient rooms are very small, so the nurse is cognizant of his or her presence in the room and the most appropriate place to be seated to interact with the patient and family.

Completing the Nursing Database

Now that the nurse has begun to establish rapport and trust with the patient and the patient's family in the room, the nurse completes the nursing database using interview, observation, and assessment techniques drawn from all three domains. Nurses complete the nursing database when they:

- Invite the patient to describe how he or she learned of the illness: "So tell me, Mrs. Jackson, how you learned about your illness."
- Take care not to interrupt the patient too often; use communication techniques such as probing, reflecting, clarifying, responding empathetically, and asking open-ended questions to encourage greater detail if the patient's account is brief or sketchy.
- Proceed through the physical assessment, the psychosocial assessment, and the spiritual assessment (see later sections).
- Prepare to end the interview when appropriate, thus supporting patient-centered care: ask the patient and the family if they have any unanswered questions for which the nurse might assist with finding the answers and give them the opportunity to ask about something that is unclear or that they had not had the chance to ask earlier.
- Ask the patient and family if they can think of anything else that the nurse might do for them that would contribute to their comfort and close the initial interview by summarizing any action items.
- Bid everyone a professional goodbye as appropriate.

A growing issue that relates to family members' health is genetic testing for familial diseases. The nurse asks patients with diseases that could have a genetic origin whether they would be interested in receiving more information. Patients or family members who desire more facts will benefit from written materials and referral to an experienced genetic counselor. For a tool to support this assessment, refer to the American College of Preventive Medicine's Genetic Testing Time Tool.[31] The National Society of Genetic Counselors (http://www.nsgc.org) has an extensive listing of genetic counselors in the United States and around the world through the Find a Genetic Counselor tool (https://www.nsgc.org/p/cm/ld/fid=545).

Assessment at Diagnosis

The palliative care nursing assessment goals at the time of diagnosis are to:

- Determine the baseline health of the patient and family.
- Identify problems for which interventions can be planned with the patient and family that maximize their QOL.
- Uncover learning needs to guide teaching that promotes optimal self-care.
- Ascertain patient and family strengths to reinforce healthy habits and behaviors for maximizing well-being.
- Discern when the expertise of other healthcare professionals is needed, such as a social worker, registered dietitian, chaplain, or therapist.

Physical Assessment at Diagnosis

Nurses complete the physical assessment at diagnosis when they:

- Move through the review of systems to verify and update information in the nursing database.
- Avoid nursing jargon—terminology unfamiliar to the average person—such as the use of abbreviations, acronyms, and shortcut phrases (e.g., Q 4 HRS, PO, HS; UTI, CHF, and PEG; and tele, tachy, brady down, and Q-sign).
- Request permission to touch the patient: "Mrs. Jackson, now I would like to examine you. Is that OK?"
- Obtain data by inspection, auscultation, palpation, and percussion; observe and interview the patient as necessary during the examination; and explain each action in advance: "I'm going to listen to your lungs and heart, then your belly." The format, policies, procedures, and expectations of the healthcare agency in which the assessment occurs guide the specific details that are collected and documented. Box 4.4 shows cues to guide the review of systems, Box 4.5 shows cues to guide the functional assessment, and Box 4.6 shows cues to guide the head-to-toe physical assessment and PPS score.
- Assist with the discussion and decision-making about code status using language that does not confuse the patient and family. Such a discussion must be undertaken based on the goals established by the patient in conversation with the members of the healthcare team. The discussion should be in the context of the person's health status and an understanding of likely outcomes of an attempt to resuscitate. Possible negative outcomes of an attempt to resuscitate include pain and injuries, such as rib fractures, clavicular fractures, and tracheal bleeding from the trauma of chest compressions. If a patient's health is particularly compromised, include in the discussion the low likelihood that the patient would return to her or his current level of functioning should the resuscitation efforts be successful. If consistent with the patient's goals of care, one way to introduce the topic to the patient and/or family is, "We hope for the best, but try to prepare for the worst. I would like to ask you a few questions about your thoughts about care at the end of life. Have you thought about this? What would be important for you at the end of your

Box 4.4 Review of Systems

General

"In general, how have you been feeling?"

Weight changes

Changes in energy level

Changes in sleeping pattern

Fevers, chills, sweats

Pain: acute, chronic

P—Precipitates/Palliates: What happened when first noticed? What brings it on? What makes it better?

Q—Quality: Aching, burning, cramping, deep, stabbing, throbbing

R—Region/Radiation: Where is the locus of the pain? To where does the pain radiate?

S—Severity: Pain scale, 0 = no pain, 10 = worst ever

Acceptable level

Getting better, worse, or staying the same

T—Timing: Onset, constant or episodic, frequency, duration

U—Understanding: What do you think it means?

Head, eyes, ears, nose, throat (HEENT)

Head, neck

Head or neck pain—PQRSTU

Headache—PQRSTU

Eyes

How is your vision?

Changes, pain, discharge

Blurriness

Double vision

Photophobia

Redness

Excessive tearing

Tiredness

Ears

How is your hearing?

Changes, pain, discharge

Tinnitus

Vertigo

Nose, sinuses

How's your sense of smell?

Changes, pain, discharge

Postnasal drip

Congestion

Obstruction

Throat, mouth

Pain: Mouth, tongue, teeth, throat, swallowing—PQRSTU

Changes: Voice, swallowing, gums

Sores

Bleeding

Respiratory

How is your breathing?

Changes

Pain when breathing—PQRSTU

Dyspnea: At rest, on exertion, how far can you walk; tripoding

Cough: Productive, quantity, color

Wheezing: On inspiration, on expiration

Cyanosis: Lips, fingernails, toenails

Orthopnea: Sleep with pillows, how many

Sleep apnea, snoring

Paroxysmal nocturnal dyspnea

Cardiovascular

Chest pain (CP)—PQRSTU or pressure

Syncope: How often, for how long

Palpitations: Sense of rapid or irregular heartbeat, how often, for how long

Lower extremity edema

Leg pain with or without ambulation—PQRSTU

Wounds or ulcers in feet, slow healing

Gastrointestinal

Appetite

Difficulty swallowing

Heartburn—PQRSTU

Food intolerances

Nausea: How often, for how long, precipitates, palliates

Vomiting: Amount, color, how often, for how long, precipitates, palliates

Pain: Abdominal—PQRSTU

Abdominal swelling or distention

Flatulence

Bowel movements: Last BM, normal frequency (daily, Q2D, Q3D); incontinence

Stool changes: Form, frank blood, black and tarry

Constipation: How often, for how long, precipitates, palliates

Diarrhea: How often, for how long, precipitates, palliates

Hemorrhoids

Genitourinary

Pain—PQRSTU: Flank, suprapubic, dysuria

Frequency

Box 4.4 Continued

Urgency

Hesitancy

Strength of stream

Nocturia

Hematuria

Urinary incontinence

Incomplete emptying, still need to urinate when done

Hair changes: Pubic, axillary, other

Libido: Decrease, increase

Orgasm: Changes, anorgasmia

Fertility problems

Date of last breast self-exam

Breast, changes, pain—PQRSTU, discharge

For men:

Date of last genital self-exam

Penis: Changes, pain—PQRSTU, discharge

Scrotum: Changes, pain—PQRSTU

Arousal: Changes, ED, priapism, pain—PQRSTU

Intercourse: Changes, pain—PQRSTU, inability to complete to satisfaction

Ejaculation: Changes, delay, premature, pain—PQRSTU

Semen: Changes, amount, color, consistency

For women:

External: Changes, pain—PQRSTU, discharge

Menses: Changes, pain—PQRSTU

Intercourse: Changes, pain—PQRSTU, dryness, inability to complete to satisfaction

Musculoskeletal

Muscle ache—PQRSTU

Low back pain—PQRSTU

Pain, swelling, cracking, popping of joints

- Upper extremities: Shoulders, elbow, wrists, fingers
- Lower extremities: Hips, knees, ankles, toes

Bone pain—PQRSTU

Endocrine

Heat or cold intolerance

Polyuria, polydipsia, polyphagia

Changes in distribution of facial hair, body hair

Immune

Allergies: Respiratory, topical, food

Any unexplained inflammation

- Rubor—erythema
- Tumor—swelling
- Calor—warmth
- Dolor—pain—PQRSTU
- Functio laesa—loss of normal function

Hematology/oncology

Abnormal bleeding or bruising

New or growing lumps or bumps

Hypercoagulability

Skin and hair

Hair: Changes (color, texture), loss

Skin

Lesions: Changed size, shape, color

Eruptions, growths

Itching, pain—PQRSTU

Neurological

Tremors

Numbness

Weakness

Dizziness

Balance or coordination problems

Sudden loss of neurological function

Abrupt loss or change in level of consciousness

Witnessed seizure activity

Psychiatric

Mental status changes

Mood changes

New worry or anxiety

Changes in thought patterns

Memory changes

Perception of health

How do you define health?
How do you view your situation now?
What are your concerns?

life?" Depending on the patient's or family member's responses, further conversation may be required regarding details such as the desire for resuscitative efforts (including chest compressions, defibrillation, and intubation) and for artificial life support (including mechanical ventilation, and medically administered nutrition and hydration).

Psychosocial Assessment at Diagnosis

The primary psychosocial feature of a new diagnosis is anticipatory grief. Patient responses and those of their family members to receiving bad news range from shock, disbelief, and denial to anger and fatalism. Statements such as, "I can't believe this is happening to me" or "Why is this happening to us?" are signals to the nurse that the patient and family are grappling heavily with this threat to life as they know it to be. There is already a sense that life will be forever changed. A longing emerges to return to the way things were.

In response to these emotional states, nurses and other members of the interdisciplinary team are most helpful when they:

- Normalize the patient's and family's experiences: "Many people share similar reactions to this kind of news."
- Use active listening skills to facilitate grief work: "Of all that is happening to you right now, what is the hardest part to deal with?"
- Create a safe space for self-disclosure and build a trust relationship: "No matter what lies ahead, you will not face it alone."
- Develop a collaborative partnership to establish a mutual plan of care: "What would help you the most right now?"
- Respect the patient's or family's use of denial in the service of coping with harsh realities: "It must be hard to believe this is happening."
- Assess the patient's and family's coping styles: "When you have experienced difficult times in the past, how did you get through them?"
- Reinforce strengths. "It sounds like this has helped you before."
- Maximize a sense of control, autonomy, and choice. "It seems you really have a handle on this."
- Assess the patient's need for information: "What do you know about your illness?," "Are you the kind of person who likes to know as much as possible, or do you function on a need-to-know basis only?," "What would you like to know about your illness now?"
- Check the need for clarification: "What did you hear?" or "Summarize in your own words how you understand your situation now."
- Mentor patients and families who have had little experience with the healthcare system, and coach them on having effective conversations with other members of the healthcare team. Suggest that they write down questions and the answers they receive, and teach them ways to navigate the complexities of the healthcare system.

Nurses must always remember that although the patient is feeling strong emotions when he or she first learns of the diagnosis, the family is also experiencing intense feelings. Similar assessments of family members will help to mobilize resources at critical times. Family members experience their grief reactions at their individual rates throughout the course of the patient's illness. Each family member has his or her own coping style and need for information.

Box 4.6 Physical Examination and PPS Score

General: Observe for patient disposition, acute distress, arousability; manner of dress, posture, body language, diaphoresis.

Vital Signs: Temperature, heart rate, respiratory rate, SpO_2, O_2 rate, O_2 delivery device, vent parameters, SBP/DBP.

HEENT:

- Head: Observe for shape and evidence of trauma.
- Eyes: Observe pupils bilat for shape and reaction to light and accommodation, retinal fundi, sclera, icterus, discharge, tearing, glasses, contacts, reading glasses.
- Ears: Observe external ear, ear canal, tympanic membranes bilat, cerumen, discharge, hearing aids.
- Nose: Observe for inflammation, obstruction, discharge.
- Neck: Palpate cervical lymph nodes for stiffness.
- Throat: Observe for jugular vein distention (JVD), thyroid location; palpate sublingual lymph nodes, thyroid; observe oropharynx, dentition, dental hygiene, dry or cracked lips. Auscultate carotid pulses bilat.

Respiratory: Observe chest excursion, use of accessory muscles, effort; palpate for tenderness; auscultate breath sounds all lobes anterior/posterior, appreciate adventitious sounds, rales, rhonchi, wheezing; palpate fremitus, crepitus; percuss for dullness.

Cardiovascular: Observe posture, edema, cyanosis, cardiac assist devices; auscultate heart sounds; palpate peripheral pulses (radial, pedal) bilat.

Gastrointestinal: Observe for distention, abdominal ascites, ostomy, rectal tube, stool; auscultate bowel sounds in all four quadrants; palpate superficially and deep; observe for rebound tenderness; percuss for margins of abdominal organs.

Genitourinary: Observe for presence of urine, volume, color.

Musculoskeletal: Observe for spontaneous movements of extremities, muscle strength, spinal flexibility, temperature, deformities; L/R comparisons.

Neurological: Observe for level of consciousness, orientation, grossly intact cranial nerves II-XII, sensation in all extremities, full range of motion (ROM) in extremities, cerebellar reflexes, tremors, Romberg, gait.

Psychiatric: Observe for mood, affect, anxiety, disordered speech, language, delirium, hallucinations, capacity for decision-making, memory, attention span. An example tool for screening of cognition is the Saint Louis University Mental Status (SLUMS) Examination.[32]

Integumentary: Observe for rashes, bruising, wounds, discoloration, mottling, lesions, nevi (ABCD), venous access ports, complexion, makeup.

PPS: Determine the patient's current PPS score based on observations and collected data about the patient's ambulation, activity and evidence of disease, self-care, intake, and level of consciousness.

Family: Assess and document the overall health of family members. Identification of the major health problems, physical limitations, and physical strengths of family members serves as a basis for care planning. The physical capabilities and constraints of the caregivers available to assist and support the patient may affect the plan of care, especially in relation to the most appropriate setting for care. This information also provides direction for the types of referrals that may be needed to provide care.

See Chapter 32, "Supporting Families and Family Caregivers in Palliative Care," and Chapter 65, "Supporting Adolescents with a Parent in Hospice," for additional information.

Nurses and other members of the interdisciplinary healthcare team assess the psychosocial domain at diagnosis when they:

- Assist in the process of making initial treatment decisions, which can be an opportunity to begin a relationship that will continue to grow. Members of the healthcare team may ask questions such as, "What is most important to you in life?" and "Is QOL or quantity of life most meaningful?" Assisting the patient and family in identifying and expressing their values will guide them in subsequent decision-making.
- Observe changes in family members' roles and responsibilities. For example, one member of the household may decide to stay at home to care for the loved one and no longer work outside the home, thus eliminating one source of family income, or the adult child may become the caregiver when the parent can no longer take care of her- or himself.
- Identify external community support systems such as a faith community, volunteer organizations, and transportation services.
- Assist the patient and family to identify coping strategies to use while awaiting answers from results of diagnostic tests and procedures. Waiting for results is not only one of the most stressful times but also a stressful time that recurs throughout the illness.

Spiritual Assessment at Diagnosis

The diagnosis of a serious illness generally brings with it a sense of shock to the patient and family. It may threaten many of their assumptions about life, disrupt their sense of control, and cause them to ask "Why?" At diagnosis, an important nursing assessment is to learn any spiritual practices that might have an impact on the patient's and family's healthcare decisions, such as avoiding various foods, not receiving blood products, and not being touched by a person of the opposite gender. Spiritual goals at this phase are to normalize initial concerns, provide information that fosters positive coping, inform the healthcare team of any special spiritual needs, and encourage the patient and family to seek supportive spiritual resources.

Nurses and the other members of the interdisciplinary healthcare team assess the spiritual domain at diagnosis when they:

- Determine the patient's and family's level of hopefulness or optimism about the future: "What are you hoping for?" or "How do you see the future?"
- Inquire about how the patient and family have dealt with past crises of faith, meaning, or loss: "What helped you get through that?"
- Determine the patient's and family's comfort level in talking about the spiritual life: "Some people need or want to talk about these things; others don't. How is it for you?"
- Inquire about spiritual support persons available to the patient and family, such as a priest, pastor, rabbi, imam, counselor, or spiritual advisor: "Is there a spiritual support person available to you? Does he or she know you are here?"
- Determine the patient's or family's need or desire to speak with a spiritual support person: "Would you like me to contact that spiritual support person for you?"
- Ask about spiritual practices that inform the healthcare team about caring for the patient and family: "Are there any spiritual practices that we should be aware of to help us take better care of you?"
- Ask about spiritual self-care practices to promote healthy coping: "How are you taking care of yourself at this time?"
- Listen for comments from the patient and family regarding the importance of their religious traditions and practices: "Well, she reads the Bible every day, but don't ask her about the last time she went to church."

Case Study: Hibaaq at Diagnosis: COPD

Over the course of the past years, Hibaaq had frequent productive coughs and colds, which she attributed to the fumes at work. She was reluctant to be seen by a provider because she was raised to believe that going to a healthcare provider would make her sick. One winter, she was having increased trouble breathing and reluctantly agreed with her younger daughter to see her primary care provider, who referred her to a pulmonologist. After collecting a history of her symptoms, doing a physical examination, collecting data on various COPD tools,[33] completing spirometry testing, and reviewing her blood tests, the pulmonologist determined that Hibaaq had COPD. Recommended treatment at this point was a long-acting beta-adrenergic agonist, and she was referred to a community palliative care program.

The palliative care assessment goals for Hibaaq and her family at the time of diagnosis are to:

- Assess Hibaaq for knowledge about her plan of care and readiness to adhere to the medical plan of care, as well as any roadblocks to doing so.
- Assess Hibaaq and her family for their need for resources so they can learn about how to live and cope effectively with this lifelong, incurable illness.
- Determine Hibaaq's and her family's need for supportive encouragement and to screen for depression and challenging behaviors, as well as the need for therapy and antidepressants.
- Assess for available spiritual supports and the need for a chaplaincy referral.
- Assess for readiness to discuss advance directives and the need for appropriate forms.

Assessment during Treatment

Reassessments during treatment determine the changes that have occurred since the initial assessment. They occur regularly during scheduled interactions with patients and families, as well as during any emergent crisis.

The palliative care nursing assessment goals during treatment are to:

- Assess the patient's systems in all domains that have a history of, or are at risk for problems, considering both changes from the patient's baseline problems and any side effects of the treatments.
- Identify the current and potential problems to plan early interventions with the patient and family, particularly as they approach decision points regarding treatment.
- Ascertain the need for teaching to prevent, minimize, and manage problems with the goal of maximizing QOL.
- Identify patient and family strengths, healthy habits, and behaviors to reinforce for maximizing well-being.
- Determine the need for other healthcare professionals' expertise to make appropriate referrals; for example, a referral to a physical therapist or a pharmacist.

Physical Assessment during Treatment

Knowledge of the usual disease process and of the side effects of treatment assists the nurse in focusing reassessments on those body systems most likely to be affected. The nurse begins to build a strategy during the assessment of possible nursing interventions and therapies that might be used to address disease progression and symptoms before they occur or worsen.

In addition to the patient's physical assessment, the nurse makes periodic observations and inquiries about the health of other family members. Documenting any changes in their health problems or physical limitations and physical strengths that might have an impact on the patient's care and the family's overall QOL is important. The nurse determines the PPS score and also documents changes in PPS score from the last documented assessment. Changes in PPS score have been shown to be better predictors of mortality than simply PPS alone.[34]

Psychosocial Assessment during Treatment

Once a treatment plan has been initiated, patients often express relief that "something is finally being done." Acting frequently reduces anxiety. The most important psychosocial intervention at this stage is the amelioration of as many treatment side effects as possible. After basic needs for physical well-being are assessed and symptoms are controlled, the patient can explore and meet higher needs, including the needs for belonging, self-esteem, and self-actualization.[20] Patients who are preoccupied with pain and nausea or vomiting have no energy or ability to explore the significance of their illness or their feelings about it. Effective management of physical symptoms is mandatory before the patient can begin to work on integrating the illness experience into the tapestry of his or her life.

After several months or years of treatment, the effects of having a chronic illness may exhaust even the hardiest person. Patients may begin to weigh the benefits versus the burdens of continuing aggressive therapies. Initially, patients will endure almost anything if they believe a cure is possible. As time unfolds, their attitudes may change as they watch their QOL erode with little prospect of a more curative outcome. Patients may also reprioritize what is most important to them. For example, the Type A personality may find less satisfaction at the office, or the stay-at-home parent may experience a lower level of fulfillment from daily routines around the house. Change, transition, and existential questioning characterize this phase, particularly while preparing to transition to the next phase.

Nurses and other members of the interdisciplinary healthcare team assess the psychosocial domain during treatment when they:

- Inquire about the patient's newly emerging identity as a result of the illness: "What activities and which relationships bring you the most joy and meaning?" or "Have you been able to define a new purpose for yourself?"
- Assess for signs of anxiety and depression, which remain the two most common psychosocial problems associated with severe illness (Table 4.5); for more information contrasting anxiety and depression, consult Holland's *Psycho–Oncology*.[35-37]
- Screen for suicidal ideation in cases of depression: "Have you been feeling so bad that you've been thinking of a way to hurt yourself?," "Do you have a plan for how to do it?," and "Do you have access to what you would use to carry out your plan?"
- Determine the need for counseling and possible psychotropic medication to enhance positive coping and comfort.

Spiritual Assessment during Treatment

With the treatment of a serious illness comes the introduction of an additional stressor to the patient and family. It is important to assess how they incorporate the demands of treatment into their daily routine and how these changes have affected the meaning of their lives. The spiritual goals during treatment are to reinforce positive coping, mobilize existing spiritual resources, invite the patient and family to develop new skills for self-care, update documentation of patient wishes as they evolve, and continue disclosures in an atmosphere of trust.

Nurses and other members of the interdisciplinary healthcare team assess the spiritual domain during treatment when they:

- Assess how hope is shifting: "What are your hopes for the future?"
- Assess the level and quality of support they are receiving, for instance, from other family members, faith community, and neighbors: "What kinds of support do you need?" and "Who is helping you out?"
- Explore expressions of anxiety and fear: "What is concerning you the most at this time?"
- Assess how the patient and family are coping with the rigors of treatment: "What is the most challenging part of this for you?" and "What is helping you day by day?"
- Determine the need for referrals to a chaplain or faith community as needed.
- Inquire about the patient's and family's definitions of QOL and the impact of treatment on these aspects of their lives: "What is most important to you in life now?"
- Determine their use of spiritual practices such as meditation, relaxation, prayer, or burning incense, for example, and offer assistance in developing them: "What are you doing to take care of your spirit?"
- Ask how the patient or family members feel about their current practices: "Are these helpful or not?"
- Assess the need for changes in the patient's advance directives and in code status: "Have you thought any more about who you would want to make your healthcare decisions for you if you were not able to make them yourself?," "Have you talked with your family about whether or not you want to be put on a breathing machine if you cannot breathe on your own?," "Do you still want a feeding tube if you need one?," "If you require dialysis to stay alive, do you want it?"

Case Study: Hibaaq during Treatment

Hibaaq often felt dyspneic, and although her husband insisted that she wear an oxygen mask as therapy, she did not find it to be very helpful. At times, she felt on the verge of panic when she was short of

Table 4.5 Assessing for anxiety and depression

Depression	Anxiety
Anhedonia (absence of pleasure)	Anorexia or overeating
Diminished ability to concentrate, make decisions, or remember	Compulsions (repetitive ritualistic acts)
Fatigue, decreased energy	Excessive worry
Feelings of worthlessness or inappropriate guilt	Frequent crying spells, headaches, gastrointestinal upsets, palpitations, shortness of breath
Insomnia and hypersomnia	Irritability, muscle tension
Marked weight loss or weight gain	Obsessions (persistent painful ideas)
Psychomotor retardation	Restlessness, agitation
Recurrent thoughts of death, suicidal ideation (lethality assessed by expressed intent, presence of a plan and the means to carry it out, previous attempts, and provision for rescue)	Self-medication
Sad mood (refer as needed)	Thoughts interfere with normal activities of daily living
	Trouble falling or staying asleep
	Unrealistic fears (phobias)

breath, and it could get so bad that she had someone take her to the hospital. Hibaaq had difficulty understanding why her illness was not improving. Her pulmonologist added an inhaled corticosteroid to her therapeutic regimen. As the years progressed, her functional status continued to decline, and her exacerbations became more frequent, resulting in the addition of an oral phosphodiesterase 4 inhibitor as treatment. Over time, she began to question her treatment goals, and she looked to her family for advice to help her.

After a family meeting with the nurse on her community palliative care team to discuss the goals of care as the list of treatment options became exhausted, the nurse talked with her about "expecting the best but preparing for the worst." Hibaaq listened, but, when asked, she replied that she did not want to think about all of this.

The goals of the palliative care nursing assessment while Hibaaq is continuing treatment are to:

- Assess information needs for treatment decision-making.
- Assess the impact of her current symptoms on her QOL as well as Hibaaq's thoughts about what would make her most comfortable.
- Determine Hibaaq's adherence to her medical plan of care and identify roadblocks and possible remediation for those roadblocks.
- Identify Hibaaq's need for education about her treatment options.
- Address why she does not want to talk about her advance directives.
- Determine the need for a mental health consult for depression and anxiety.
- Assess the need for a chaplain referral to assist with emerging existential issues and threatened faith.

Assessment after Treatment

After treatment, the patient embarks on a journey leading to long-term survival, chronic illness, recurrence or exacerbations, or the terminal phases of the illness. The course of treatment for cancer patients is frequently chemotherapy and/or radiation. Once treatment is completed, the patient enters either remission, long-term survival, or a terminal trajectory. Patients with terminal cancer diagnoses and patients with terminal noncancer diagnoses may, of course, at any time decide to stop all attempts to cure the illness and to initiate a completely palliative plan of care, maximizing comfort and QOL. Sometimes, treatment of an illness during an exacerbation simply does not work. At this point, after treatment is over or the patient stops treatments, the nursing assessment continues to focus on QOL, including patient and family coping.

Patients in this part of their disease trajectory should be assessed frequently to determine if they would be appropriate for hospice; that is, do they meet criteria based on their illness.

The goals of the palliative care nursing assessment after treatment are to:

- Assess the benefits and burdens of all interventions to manage the symptoms remaining from the treatments and/or the disease process.
- Determine the current physical problems that are most distressing to the patient and family to prepare for possible palliative interventions.
- Assess functional status and disease process to determine when a hospice referral is appropriate.
- Assess learning needs about managing problems with the goal of maximizing QOL.
- Assess patient and family strengths, healthy habits, and behaviors to enhance well-being and to prevent problems.

"Survivors" are defined as those patients whose diseases are cured, who go into long remissions, who become chronically ill, or who recover from an exacerbation of a chronic illness. These individuals may require some degree of palliative care for the rest of their lives. Examples of survivors likely to require ongoing palliative care include (1) cancer survivors with graft-versus-host disease (GVHD), irreversible peripheral neuropathies, or structural alterations of the integumentary, gastrointestinal, and genitourinary systems, such as mastectomies, amputations, colostomies, ileostomies, and laryngectomies, and (2) persons with other chronic illnesses who have survived an acute episode and have returned to a chronic phase of their disease process.

Psychosocial issues for survivors include fear of recurrence or exacerbation as well as practical considerations such as insurance and job discrimination. Many patients make major life changes regarding work and relationships because of their illness experiences. These patients live with the ramifications of the disease and its treatment for the rest of their lives, even cancer patients who have met criteria for being cured.

Some patients begin to explore in new ways the spiritual foundations and assumptions of their lives. Often, patients relate that, despite the crisis of an illness and its treatment, the experience resulted in a deepened sense of meaning and gratitude for life.

Physical Assessment after Treatment

The patient is reassessed after treatment to determine the changes that have occurred since previous assessments. Although the focus is on the systems that have been affected and altered by the disease and treatments, assessing the patient from a holistic perspective is even more crucial. Thorough assessment of the residual problems and changes in the patient's body are critical to successful symptom management. Effective management of symptoms with palliative interventions achieves the goal of maximizing the patient's and family's QOL, whether in long-term survival or during the terminal phase. The PPS is a general scale that is widely applied to patients with life-threatening illnesses. Nurses also use functional assessment tools that are developed for patients living with specific chronic or life-threatening illnesses.

In addition to the patient's physical assessment, nurses continue to make periodic observations and inquiries about the health of other family members. Noting changes in family members' health, physical limitations, and physical strengths is important to ascertain any impact on the patient's care and the family's lifestyle.

Psychosocial Assessment after Treatment Ceases

For those patients who are free of disease, palliative care focuses on post-treatment–related symptoms and fears of recurrence. For others, disease progression or recurrence is most often signaled by the appearance of advancing physical symptoms. When this happens, the patient's worst nightmare has been realized. A recurrence or exacerbation is experienced differently than an initial diagnosis because the patient is now a veteran of the patient role and may understand all too well what the recurrence or exacerbation means.

Research suggests that a strong correlation exists between caregiver stress and morbidity.[38] This is especially true of caregiver stress that affects blood pressure and mental health stress responses such as chronic depression. For additional information, refer to Chapter 32, "Supporting Families and Family Caregivers in Palliative Care."

Nurses and other members of the interdisciplinary healthcare team assess the psychosocial domain after treatment when they:

- Revisit the quality versus quantity of life preferences as the patient and family weigh the benefits and burdens of further treatment. Beginning these conversations earlier rather than later in the illness helps to make them less threatening and creates an ongoing dialogue that will help the patient, family, and healthcare providers alike when further treatment becomes futile.
- Evaluate the patient's readiness to discuss a transition in emphasis from curative to comfort care only. The patient often signals his or her readiness by statements such as, "I'm getting tired of spending so much time at the hospital" or "I've had it with all of this." Ask: "What has your physician told you that you can expect now?" or "How do you see your future?"
- Explore readiness to set new goals of treatment: "I know you understand that your illness has not responded to the treatments as we had hoped. I'd like to reexamine your healthcare goals with you."
- Assess for family adaptation to stress and coping.
- Revisit the need for advance directives and changes in code status.
- Reevaluate the need for a discussion about hospice if the patient begins to question the efficacy of treatments and present hospice as the gold standard for end-of-life (EOL) care. A hospice referral should never be made as a gesture indicating that "There is nothing more that we can do for you." The benefits of increased availability of services, such as symptom management, respite opportunities, and bereavement care for the family, should be emphasized.

Spiritual Assessment after Treatment

The main spiritual goal of this phase of illness is to provide the patient and family with a "place to stand" to review the past and look toward the future. This encourages grieving past losses, creating a sense of meaning, and consolidating strengths for the days ahead.

Nurses and other members of the interdisciplinary healthcare team assess the spiritual domain after treatment when they:

- Determine the quality and focus of the patient's and family's hopes for the future. Listen for a transition from hoping for a cure to another kind of hope, such as hope for a remission, hope to live until a special family event occurs, and hope for continuing care for their family when the patient cannot care for them. Observe for any barriers to hope or evidence of hopelessness.[39]
- Listen for comments that suggest a crisis of belief and meaning. For example, at recurrence, a patient may feel abandoned or experience an assault on his or her faith. Questions such as "Why?" and "Where is God?" and "Why are my prayers not being answered?" are very common. Nurses respond to these questions by normalizing them and emphasizing that to question God or one's faith can indicate a vitality of faith, not its absence.
- Assess the patient's and family's use of spiritual practices: "What are you doing to feel calmer and more peaceful?" Determine the need for a chaplain referral if the patient or family are interested and open to such an intervention.
- Inquire about the desire for meaningful rituals, such as communion, special prayers, or anointing. Evaluate the need for consulting with the patient's or family's clergy or a chaplain on the healthcare team.
- Assess the level and quality of community supports: "Who is involved in supporting you and your family now?" and "Do you think you need any additional help?"
- Listen for indicators of spiritual suffering (such as language about unfinished business, regrets, diminished faith, and fears of abandonment) and evidence of relationship discord: "What do you find yourself thinking about now?" and "What are your chief concerns or worries?"
- Assess the need and desire of the patient and family to talk about the meaning of the illness, the patient's declining physical condition, and possible death: "Is there something you would like to talk with me about that you are not asking right now?" and "Would you rather talk somewhere away from your loved ones?"
- Assess the patient's and family's need to review critical life incidents, to allow grieving, and to explore beliefs regarding the afterlife: "What do you believe happens to a person at the time of death?"

Case Study: Hibaaq after Treatment

Hibaaq experienced exacerbations of increasing frequency, having been hospitalized about once per month over the past year. She was extremely fatigued and tired of these hospitalizations and understood her time was drawing short, but she wanted to be able to see the birth of her first grandchild, who was due to arrive in about 6 months. After talking with her family, she decided that she no longer wanted to come to the hospital and that she wanted to pursue a comfort-only plan of care, which comprised hospice care at home. She changed her code status to allow for a natural death at home, but she prayed daily that she would "remain on this Earth to enjoy my family and to meet my grandchild."

The goals of the palliative care nursing assessment after Hibaaq's treatment are to:

- Reevaluate adherence to activities that could maximize her QOL.
- Evaluate appropriateness of interventions that could prevent further crises arising from her COPD.
- Determine the need for relationship-building within the family system to reduce everyone's stress levels.
- Establish Hibaaq's wishes with respect to her advance directives and complete the forms.
- Assess for a referral to hospice.

Assessment during Active Dying

The goal of hospice is to support the terminally ill patient and family wherever they choose to be. Hospice teams provide palliative care in patients' homes, acute care settings, nursing homes, and specially designed inpatient hospice facilities. Unfortunately, many patients die without the support of hospice services.

The goals of a palliative care nursing assessment when the patient is actively dying are to:

- Observe for signs and symptoms of impending death that could be managed aggressively to promote comfort (Table 4.6).
- Determine the primary source of the patient's and family's suffering to plan interventions to provide relief.

Table 4.6 Common physical symptoms by persons who are actively dying

Symptom	Definition
Agitation	Nonpurposeful movements associated with increased anxiety
Anorexia	No interest in eating or drinking
Confusion	Disorientation and lack of orderly thought
Delirium	An acute change in consciousness, cognition, and perceptual disturbances that can fluctuate throughout the day
Dyspnea	Shortness of breath
Fatigue	Overwhelming tiredness
Incontinence	Bladder, bowel
Insomnia	Difficulty sleeping
Mottling	Changes in skin color and temperature due to decreasing circulation that progresses from distal to proximal during the last 2–3 hours of life
Pain	PQRSTU (see Box 4.4)
Restlessness	Uncontrollable increase in motor activity
Skin breakdown	Due to local ischemia secondary to immobility
Terminal secretions	Collection of saliva in the back of the throat that gurgles with each breath

- Identify the primary sources of strength for the patient and family members so that they can be used to provide support.
- Ascertain the patient's and family's need and readiness for teaching about the dying process.
- Look for ways to support the patient and family to enhance meaning during this intense experience.
- Determine whether the family members and friends who are important to the patient have had the opportunity to visit in person or on the telephone, as desired by the patient and family.
- Assess the family to anticipate family members' reactions to the patient's death.
- If not in hospice, assess for appropriateness for referral.

Physical Assessment during Active Dying

Physical assessment during the active dying process is highly focused and is limited to determining the cause of any suffering and identifying sources of comfort. Table 4.7 shows common areas to assess in the last few days of a person's life.

In addition to the patient's physical assessment, nurses monitor the health of other family members to prevent and minimize problems that could compromise their health during this very stressful time. Frequently, assessing the family's need to participate in making the patient comfortable can lead to interventions enabling them to do something to help the patient.

Psychosocial Assessment during Active Dying

Many people believe that the transition from life to death is as sacred as the transition experienced at birth. Keeping this in mind, nurses can help to create a safe environment in which patients and families are supported in their relationships and the creation of meaningful moments together. The patient may also still be reviewing his or her life. Common psychosocial characteristics of the person who is actively dying include social withdrawal, decreased attention span, and decreasing ability to concentrate, all culminating in a gradual loss of consciousness. Spiritual experiences such as visions and visitations from deceased relatives or spiritual/religious figures are often viewed as normal and transcendent at this stage of life in those with strong spiritual beliefs. Nurses avoid the tendency to medicalize transcendent experiences and view them as nonaberrant, positive, and an opportunity for making meaning.

During active dying, nurses and other members of the interdisciplinary healthcare team assess the psychosocial domain when they:

- Assess the patient's reports of seeing deceased loved ones or visions as normal and not as evidence of confusion or other mental health problems and determine the need for a behavioral health consult to distinguish such experiences from delirium.
- Evaluate for the need to support communication among the patient, family members, and close friends, and the need for reminiscing, story-telling, and other familiar ways of relating to each other—for example, through humor and singing.[40,41]
- Assess the patient's and family's need and readiness for continued education about death and dying, particularly children (Box 4.7).
- Evaluate for the need and readiness of family members to learn that continued touching and talking to the patient is appropriate, even if the patient is unconscious.
- Assess for need and readiness of the family members to learn to give permission to the patient to let go and to provide reassurance that the family will remain intact and will learn to deal effectively with the patient's absence.
- Observe family members for evidence of poor coping and for the need to make referrals for additional support. See Box 4.8 for risk factors for complicated bereavement in family members.
- Assess the family members for the need and readiness to learn about organizing visitation shifts that rotate in the face of lengthy and exhausting vigils at the bedside.
- Revisit any complementary and alternative therapies that the family might find effective.[42]

Spiritual Assessment during Active Dying

When the patient enters the phase of active dying, spiritual realities often increase in significance. Persons with life-threatening illnesses who participate in spiritual rituals experience feelings of higher existential well-being and less subsequent spiritual strain.[43] The goals of spiritual care during active dying are to:

- Facilitate any unfinished business among the patient and significant others, such as discussions with others to express love, regret, forgiveness, and gratitude.
- Promote the integrity of the dying person by honoring his or her life. One way to do this is by encouraging reminiscence at the bedside of the patient, recalling the "gifts" the patient bestowed on the family—that is, his or her legacy of values and qualities passed on to survivors.

Table 4.7 Assessment during active dying

General	*Location*	Is the home the best place for the patient to die? Has the family thought about their comfort in living in the house after their loved one dies there? Is the room too hot or too cold for the patient and for the family in the room?
	Symptoms	Are pain and other symptoms well controlled? Would massage, body energy work, or other complementary therapies add to patient's comfort?
	Family	Is everyone present who is supposed to be there? Are family members capable & comfortable with continuing to provide physical care for the patient? Are family members getting enough sleep and rest to maintain their own health? Are additional resources needed to support the family? Would the patient want the family pet in the room or on the bed?
	Spirit	Does the patient want a special member of the clergy present? Are they available to be here for the patient and the family? Are there any spiritual or cultural rituals to be done before or immediately after death?
	Help	Does the family know whom to call on a 24-hour basis for advice and support? Does the family know not to call for emergency medical services when the patient dies?
Head & neck	*Mind*	How important is level of alertness versus control of pain and anxiety which may cause sedation?
	Vision	What objects and people at the bedside provide comfort when seen by the patient? Family photos? Children's drawings? Special objects? Pets? Loved ones sitting nearby? What degree of lighting does the patient prefer? Does darkness increase anxiety? Would scented candles provide solace?
	Hearing	What sounds most comfort the patient? Music? Family chatting nearby? The TV or radio on in the background? Would music thanatology be of comfort? Someone reading to him or her? Silence?
	Smell	What scents does the patient enjoy? Would aromatic lotions be soothing? Are there clothes of a person whose scent would be of comfort? Does the patient have favorite colognes or perfumes? If on oxygen, would humidification be of comfort?
	Taste	What are the patient's favorite flavors? Would mouth care to relieve dryness be more acceptable with fruit punch, apple juice, beer, or coffee?
	Mouth	Does the family/caregiver understand how to provide good, frequent mouth and lip care, particularly if the patient is a mouth-breather?
	Face	Does the patient receive comfort from face and head massage or a facial with aromatic salves? Does a fan blowing on the face relieve feelings of air hunger?
Shoulders & arms	*Mechanics*	Do the caregivers understand good body alignment and several ways to position the patient comfortably? Are they following good body mechanics when repositioning the patient?
	Soothing	Would applying aromatic lotion to hands and arms comfort the patient and give family members something meaningful to do?
Chest, back, & spine	*Lungs*	Is the patient at high risk for death rales? Is there a scopolamine patch or other meds in the home for immediate use if noisy respirations begin? Would oxygen help the patient breathe easier? Or a fan pointed at the patient's face?
	Heart	If patient is at home, is the family prepared for the moment of death? For example, do they know NOT to call 911? Do they have a neighbor close by to come and be with them until a healthcare provider arrives?
	Back & spine	Are pain patches in place or do they need to be changed? Does the family know how to boost the patient back up in bed when they slide down? Does the family understand how and when to turn the patient for comfort? Does the family know how to make an occupied bed, using good body mechanics?
Legs & feet	*Circulation*	Are family members interested/concerned with learning the assessment technique of feeling the feet and limbs for coolness and examining for mottling as they progress slowly from the periphery to the center of the body during the last few hours of life?
	Soothing	Would applying aromatic lotion to feet and legs comfort the patient and give family members something meaningful to do?
Abdomen	*Bowels*	If the patient is incontinent of stool, are family members comfortable and know how to provide personal hygiene? Do family members know how to use protective pads, adult diapers, pull sheets to keep the patient clean? If stools are frequent, can antidiarrheals be given? Ostomy care?
	Skin	Are protective ointments needed to decrease skin breakdown if the incontinence is frequent? Are pressure points up off of the bed?
Pelvis	*Urine*	If incontinence is present, would inserting a Foley catheter prevent skin irritation and conserve the patient's and family's energies? Is the family comfortable doing this? Are others available to insert the catheter?

- ◆ Assist the patient and family in extracting meaning from the dying experience.
- ◆ Provide sensitive comfort by being present and listening, or determine the patient's and family's need for privacy.
- ◆ Provide information regarding hospice, bereavement support groups, or counseling if indicated.

During active dying, nurses and other members of the interdisciplinary healthcare team assess the spiritual domain when they:

- ◆ Determine the need for different or more frequent visits by the patient's or family's spiritual support person: "Is there anyone I can call to be with you now?" and "Are there any meaningful activities or rituals you want to do?"
- ◆ Inquire about dreams, visions, or unusual experiences such as seeing angels or persons who have died, reports of needing to go home, or awaiting the arrival of a bus or a train, to normalize these if they are disclosed. Ask if these experiences are sources of comfort or fear and encourage further discussion, if appropriate.
- ◆ Assess for ability to maintain hope by asking, "What are you hoping for now?" reassuring the patient and family that they can be hopeful and still acknowledge that death is imminent and that moving toward a transcendent hope is vital. Evaluate for the need to reinforce that although the focus of hope may have been on cure, remission, or an extension of time earlier in the disease trajectory, now hope may be focused on an afterlife, the relief of suffering, or the idea of living on in loved ones' memories.
- ◆ Listen for and solicit comments regarding the efficacy of spiritual practices. For instance, if the patient is a person who prays, ask, "Are your prayers bringing you comfort and peace?"
- ◆ Assess for expressions of fear, panic attacks, or an increase in physical symptoms such as restlessness, agitation, pain, or shortness of breath that may indicate intense spiritual distress. Evaluate for the need for a chaplain's intervention to provide spiritual comfort and to assist the patient in reaching peace, possibly reducing the need for medications.
- ◆ Determine the need and desire of the patient and family to engage in forgiveness, to express feelings to one another, and to say their good-byes. Assess the need to facilitate phone conversations if the family member or friend cannot be present physically and to educate the family to hold the phone up to the dying patient's ear to hear the voice at the other end, even if the patient cannot move or is comatose.
- ◆ Assess for a prolonged dying process that may indicate the patient is having difficulty letting go, perhaps due to some unfinished business, an unsaid good-bye, or fears related to dying. Explore with the patient and family what these issues might be and assess for the need for a chaplaincy referral.
- ◆ Assess for readiness of the family to celebrate the life of the loved one by acknowledging his or her contributions to family members, close friends, and the community.
- ◆ Explore the need and desire for additional comfort measures in the environment, such as soothing music, devotional readings, gazing out a window at nature, or increased quiet.

Box 4.7 Common Responses of Children to Serious Illness in the Family

- ◆ Magical thinking that results in feelings of guilt, for example, "I once told Mommy I wished she were dead."
- ◆ Fears of abandonment, especially in younger children.
- ◆ Fears of contracting the disease.
- ◆ Anger, withdrawal, being uncooperative, especially in adolescents.
- ◆ Acting-out behavior with lack of usual attention.
- ◆ Frustrations with an altered lifestyle because of decreased financial resources, less family fun activities because of the ill person's inability to participate, interruptions in schedule.
- ◆ Inability to concentrate and focus, especially regarding schoolwork.
- ◆ Identify family communication ground rules to seek to improve communication among family members: "Is it OK if we discuss this subject with you and your family?"
- ◆ Help the patient and family explore the benefits and burdens of various treatment options when making decisions about the plan of care.
- ◆ Assess parental readiness to assist children with their adaptation needs: "How do you plan to tell your children?"
- ◆ Assess the coping of children within the family by being aware of their fears and concerns.

Box 4.8 Risk Factors for Complicated Bereavement in Family Members

- ◆ Absence of helpful cultural and/or religious beliefs.
- ◆ Age of the patient and the surviving loved ones, developmental phases of the patient and family members.
- ◆ Anticipated situational stressors, such as loss of income, financial strain, lack of confidence in assuming some of the patient's usual responsibilities.
- ◆ Concurrent life crises.
- ◆ Determine the patient's and family's need and interest for education about death and dying.
- ◆ Extreme anger or anxiety.
- ◆ History of mental illness or substance abuse.
- ◆ History of other recent or difficult past losses.
- ◆ Illnesses among other family members.
- ◆ Limited support within the family's circle or community.
- ◆ Marked dependence on the patient.
- ◆ Special bereavement needs of children in the family.
- ◆ The patient's dying process is difficult, as can be indicated by poorly controlled symptoms of pain, shortness of breath, agitation, delirium, or anxiety.
- ◆ Unresolved grief from prior losses.

Box 4.9 Assessing for Funeral Plans and Preferences

- A consumer-oriented guide to funeral planning is available at http://www.funeral-help.com that includes funeral planning software for purchase.
- Assess for a referral to hospice for EOL care if the death of the patient might be anticipated within the year. Ask other members of the interdisciplinary healthcare team: "Would it surprise you if this person would die within the year?"
- Assess the patient's and the family's readiness to discuss funeral preferences and plans and desired disposition of the body.
- Determine the need and desire for reconciliation: "Are there people with whom you want or need to speak about anything?" and "Do you find yourself having any regrets?"
- Determine the patient's and family's readiness to talk about the most meaningful, celebratory occurrences in life to foster integrity, life review, and a sense of meaning: For example, "How did you meet your spouse?," "Were your children all born here?," and "Where did you and your other half like to vacation?"
- Does the patient want to make his or her wishes known regarding the type of service, or will the family decide these details? For example: clothes to be buried in, favorite songs to be sung or played, poems to be read, casket or urn selection, open or closed casket.
- Has the decision been made regarding a burial or disposition of the ashes? For example: the cemetery, the plot for burial or inurnment, the mausoleum crypt, the columbarium niche, or the location for scattering ashes.
- Has the patient and/or family decided about the disposition of the body? For example: organ, eye, and/or tissue donation; autopsy; in-earth burial (above ground or below ground); cremation; and/or total body donation to a medical school.
- Has the patient and/or family selected a funeral home or a funeral and memorial society?

- Ask the family about their anticipated needs and preferences at the time of death: "Is there anyone you will want us to call for you?," "What can the healthcare team do to be most supportive?," "Are there specific practices regarding the care of the body that you want the team to carry out?" See Box 4.9 for ways to assess for funeral plans and preferences.

Case Study: Hibaaq's Death

Granddaughter Shamsi arrived a bit later than Hibaaq expected. The tears in the new grandmother's eyes rained down across the mask that was helping Hibaaq breathe. As her breathing changed, Hibaaq's family kept vigil. The hospice nurse suggested that the family continue to talk to Hibaaq as death drew closer. Liban asked if the sounds in her throat were bothering her. The hospice nurse continued to treat Hibaaq's symptoms as she slipped away, having achieved her goal of meeting her granddaughter. The family wept when the hospice nurse reported to them that Hibaaq was gone.

The goals of the palliative care nursing assessment during Hibaaq's active dying phase are to:

- Evaluate Hibaaq and her family frequently for comfort including the need for extra chairs, the desire for coffee, and reminders to take breaks from time to time.
- Assess the environment for factors that are calm and soothing.
- Be vigilant for adherence to the patient's religious and cultural preferences in spite of the absence of written advance directives.
- Determine the need to resolve conflict about EOL care preferences and measures that could be implemented to improve patient and family outcomes.
- Discover the need to educate the family on the appropriate response to changes in a dying loved one's status.
- Inquire about the family's readiness to learn about the hospice's community grief program.
- Determine one's own needs and the staff need for support after caring for a patient for a long time and who has now died.

Conclusion: Principles of Patient and Family Assessment

A comprehensive palliative care nursing assessment of the patient and family occurs throughout the trajectory of the illness and is a holistic view that includes the physical, psychosocial, and spiritual domains. Patient and family assessment provides the foundation for mutual goal setting, devising a plan of care, implementing interventions, and evaluating the effectiveness of care. Reassessments are done throughout the patient's illness, looking for changes from previous assessments to ensure that QOL is maximized in all domains. Box 4.10 offers a best-practice tip for assessing symptoms.

Maximizing QOL for patients and families is a process. It is a journey that the nurse and all members of the interdisciplinary healthcare team travel alongside of the patient and family. The palliative care nurse understands that, above all and irrespective of the phase or focus of the assessment, two of the most important assessment questions that the nurse can ask the patient and family are "What is your greatest concern?" and "How can I be of help?"

Box 4.10 Best-Practice Tip

Clinicians may find the use of an abbreviated symptom assessment form helpful to track the efficacy of palliative care interventions. Whereas pain is usually plotted along the familiar 0–10 scale, other symptoms such as nausea, vomiting, diarrhea, constipation, fatigue, anxiety, and depression can be quickly evaluated on a flow sheet as mild, moderate, or severe or using a symptomatology scale. Also, the Palliative Performance Scale (PPS) can provide a numerical evaluation of functionality that is quick to record and compare. These kinds of tools assist in interdisciplinary evaluation of symptoms and patient status without requiring paging through lengthy progress notes. In this way, treatment can be highly individualized and evidence-based.

CHAPTER 5

Communication in Palliative Care

An Essential Competency for Nurses

Constance M. Dahlin and Elaine Wittenberg

Key Points

- The foundation of quality palliative care is effective communication that assures an individualized, respectful approach to care, from diagnosis to death, with regard to values, preferences, and beliefs.
- The art of nursing communication involves the therapeutic use of self, presence, silence, and listening to facilitate a patient- and family-centered process.
- The science of communication is a learned skill that establishes the nurse–patient relationship, comprised of 20% verbal and 80% nonverbal characteristics.
- Essential nursing communication includes gathering and imparting information and providing support and reassurance, as dictated by the individual needs of patients and families.
- Nurses have an essential role in advance care planning (ACP). Other roles include delivery of bad news and poor prognosis or discussing the transition to hospice and palliative care.

Introduction

The art and science of palliative nursing is founded on communication.[1] Nurses have an important role in patient care, particularly in palliative care communication.[2] As the most trusted member of the healthcare team,[3] they play an essential nursing role in advocating for and implementing the patient's wishes and preferences and communicating these to family members and other healthcare providers. Often, a nurse is the patient's first healthcare contact and spends the most time with the patient at the bedside. Nurses are essential to team work in promoting optimal communication among the team, patient, and family.

The American Nurses Association (ANA) *Nursing Scope and Standards of Practice* communication standard states that the nurse "communicates effectively in all areas of practice."[4 (p.71)] To do so, the nurse assesses his or her own communication skills and effectiveness that demonstrate caring, respect, deep listening, authenticity, and trust. This also includes the nurse's responsibility to assess communication ability, utilize alternate strategies for difficulties, convey accurate information, maintain interprofessional team communication, and demonstrate continuous improvement of communication skills.[4]

The ANA *Code of Ethics* delineates the nurse's obligation to promote patient self-determination through the assessment of patient understanding of information and the implications of all potential decisions. Nurses support patient autonomy through patient decision-making, particularly around difficult decisions.[5] In particular, they assist patients to define their goals and wishes as well as to express their cultural and religious practices and preferences.

Case Study: Marita

Marita worked as a registered nurse on a psychiatric floor. She had many patients with depression as well as congestive heart failure, pulmonary disease, diabetes, cancer, and renal failure. She enjoyed her work as she felt her expertise was working with patients and families to decide on goals of care as patients are discharged from the floor. One patient frequently admitted was Frances Leary, a 51-year-old woman with depression, diabetes, heart failure, renal failure, and hepatitis C. At first, Frances was very stoic about her care and told everyone she was fine. Marita was consistent in providing therapeutic presence during each admission, treating Ms. Leary with respect. One day, while helping Ms. Leary with dressing, she asked, "Ms. Leary, how do you feel about being in the hospital?" Ms. Leary stated that she did not like to be in the hospital, but felt she needed to fight for her family. When Marita asked her about what she would prefer to do, Ms. Leary stated she wanted care at home so she did not have to come back. Marita learned she was separated from her husband and had a daughter and a son. However, all of the family members were involved with her care.

Overview

Although communication seems fairly straightforward, it is actually a complex, continual transactional process that occurs between persons by which information, feelings, and meaning are conveyed through verbal and nonverbal messages. As viewed by multiple goals theory, communication interaction is seen as the exchange of ideas around a task, as well as the exchange of ideas around a relationship. In essence, multiple goals theory describes every message as possessing two levels of meaning: the content level and the relationship level.

In professional contexts, these can be referred to as the *task* and *relationship* levels.[6,7] Message content generally concerns the *tasks* of communication—for example, instructing, diagnosing, managing, directing, encouraging, supporting, and so forth. *Relationship* refers both to how people interpret the content of messages and how they understand their shared connection. For example, if a nurse asks a patient, "What is your pain level today?" the content is obviously an inquiry designed to obtain information about the patient's pain. Still, the relationship level of meaning is determined by how these words are spoken. If the nurse is glancing at paperwork or working with medical equipment while she asks this question and no eye contact is made, or if she is standing in the hallway rather than at the bedside, the patient will likely interpret this as a matter of routine communication rather than a genuine inquiry. As a result, no relational components are developed within the exchange.

While the content level of a message is conveyed by the words themselves, the relational level generally is manifested by nonverbal communication. *Nonverbal communication* includes physical appearance and grooming, both of which influence perception. *Artifacts*, the presence of physical objects and the environmental setting, can be barriers to developing relationships with patients and families. These objects include bedrails, bedside tables, and other medical equipment that reduce the emotional connection during conversation. A nurse sitting for a short time at the bedside versus standing at a distance and separated by bedrails can greatly impact communication. *Vocalics*, the variety of ways that words are spoken, including volume, pitch, accent, rate of speech, use of pauses, and tone, also are part of nonverbal communication. The way the voice is used communicates loudly on a relational level. For example, speaking loudly to an elderly patient who has good hearing can be condescending and can distance the nurse from the patient. *Proxemics*, the way space and distance is used during communication, and whether or not it is respected and acknowledged during nursing work, can impact relational communication. Finally, *haptics*, or the use of touch, can be task-related but can also convey relational messages of warmth and caring.

Within undergraduate nursing education, there is little education specific to communication, let alone in palliative care. Yet nurses rank communication as the most important competency.[8] Although nurses are now exposed to care along the disease trajectory, this phenomenon continues today as nurses still feel unprepared in communication skills.[9] Nurses fear saying the wrong thing, causing emotional distress or sadness that they feel unequipped to manage, showing emotion with patients and families, or not having permission from the clinical team to discuss serious matters.[10–13]

Nursing communication is focused on the patient as the person who experiences the illness or condition, as well as being focused on the family.[14–16] Opportunities for communication exist throughout nursing care delivery, such as during patient care including task-related care, personal care, illness education, bad news delivery, assessment of spiritual and religious concerns, in response to physical and psychological distress, and within interdisciplinary collaboration.[11,17] There are a myriad of settings beyond the home or the hospital, including wherever care occurs: rehabilitation facilities, office-based clinics, long-term care facilities, veterans' facilities, correctional facilities, homeless shelters, group homes, and mental health settings. Without effective communication, the patient's experience of suffering is unknown, and effective symptom control is impossible.[18,19]

Box 5.1 Communication Behaviors Valued by Patients and Families

- Being present and being silent
- Being in the moment
- Knowing and being comfortable with oneself
- Knowing the other person
- Connecting
- Affirming and valuing
- Acknowledging vulnerability
- Utilizing intuition
- Empathizing and willing to be vulnerable
- Providing serenity and silence

Effective Communication

Communication is a central aspect of patient- and family-centered care whereby the needs of the patient and family dictate care.[20] Communication promotes many critical aspects of care: information sharing; active listening; identification of values, goals, and health care preferences; and decision-making, and it facilitates support and collaboration.[21] Effective communication, as viewed by seriously ill patients and their families, primarily consists of providing accurate information in a sensitive, simple, and straightforward manner using plain language.

Good communication allows for optimal palliative care because it is the basis of the relationship.[1] Communication provides a basis for a strong nurse–patient relationship and a therapeutic basis for the care.[2] Specific nursing behaviors focus on the promotion of information-sharing, disclosure, reassurance, presence, facilitation, and dignity.[22–24] Indeed, emotional intelligence may promote more effective communication. Specific abilities include (1) the correct identification of emotions in oneself and others, (2) the use of emotions to facilitate reasoning, (3) understanding emotions, and (4) managing emotions.[25]

Nurse interactions have been described within the following categories: supporting, caring, collaborating, reassuring, fostering hope, and advocating for the patient.[23] Research speaks to the various aspects of communication: active listening, presence, eliciting preferences, and facilitating communication choices.[26] The establishment of trust, continuity, and understanding fosters good relationships[26]; and creating a patient-centered approach facilitates more effective communication.[27] Box 5.1 reviews valued communication behaviors.

The Role of the Nurse in Palliative Care

Nurses are often the first health provider to meet with and identify issues for patients with life-threatening illness. They create a therapeutic relationship and accompany the patient through the illness journey with their constant presence, and they may be best situated to learn the patient's hopes, worries, dreams, regrets, and fears of being a burden.[1,28,29] Moreover, they can advocate for the patient's values, preferences, and wishes.[30] To be effective, nurses need education and empowerment to initiate these discussions.

Honesty and hope conveyed by healthcare providers has been revealed within the literature to be important to patients and families. Focusing on quality of life (QOL) offers hope and meaning to the patient, leaving open the possibility of "miracles" while simultaneously assisting the patient to prepare for losses.[31] Honesty can be achieved through open dialogue and determining patient readiness to discuss serious illness, death, and/or dying.[32] Additionally, discussing outcomes other than cure, such as improved functional status or independence in care needs, assists in focusing the care on the current situation.

With the relief of suffering as the basis of nursing, all nurses practice some aspects of palliative care.[4,33,34] Various communication modalities promote relief of physical, emotional, spiritual, and psychological distress: availability, presence, empathy, respect, listening and talking, eye contact, smile, warm voice tone, and words of comfort, caring, encouragement, and even humor, as well as the use of touch.[35] The heart of this is therapeutic presence: attending to suffering, affirming the patient's self-worth and dignity, decreasing isolation, facilitating identification and clarification of treatment goals, embracing advocacy, and enhancing holistic care.[36]

Nurse characteristics preferred by patients and family and delineated in research cross both verbal and nonverbal realms. One study described satisfactory patient communication as compassionate, responsive, and dedicated, while unsatisfactory patient communication was described as sparse, conflicted, contradictory, and increasing only when things were close to the end.[37] Overall, it appears that patients and families want consistent and routine communication with a compassionate presence.[37] Required communication skills include effective listening, appropriate nonverbal communication, counseling skills, empathy, and supportiveness.[38] The most beneficial nurse behaviors for families are (1) keeping family informed, (2) providing assurance, (3) being a compassionate presence, (4) facilitating final acts, and (5) honoring dignity.[26] Another study categorized nurses' communication encompassing skills that explore patient concerns, the provision of support, enhancing disclosure, educational preparation, and referral for further counselling, as necessary.[22] Essentially, facilitative styles that reflect the therapeutic use of self and patient-centered care are more beneficial than directive styles.[27]

Communication with patients has several aspects. The first is day-to-day interactions focusing on nursing tasks. This occurs in simple communication such as small talk or in providing information on basic treatment issues, medication schedules, activities of daily living, or personal care. Another component includes the nursing process and assessment of treatments. The nurse approaches the patient in an open manner to assess the physical, psychological, spiritual, and emotional aspects of care and treatment. Within this process, the nurses allow the patient to determine treatment effectiveness. The third and most complex component of communication occurs in the existential realm. This is attending to the patient's deepest sense of self. Communication at this level is sensitive and often nuanced because the existential aspects of end of life include disclosure, searching for meaning, and suffering.[19] Exploration at this level can help a patient live with a life-threatening illness, achieving both better QOL and psychological healing.[39]

Across the palliative care spectrum, communication occurs at critical junctures. Depending on the diagnosis or condition of the patient, such communication may occur over a long or a short period of time. Since 80–90% of patients who die have a chronic illness, there are usually many opportunities for communication to occur.[40] Within the nurse–patient relationship, Perrin speaks about three stages: introductory, middle, and termination (see Table 5.1).[41] The introductory phase of communication occurs when the nurse and the patient learn about each other's styles. The middle phase involves establishing a working relationship in which the work of nursing is done, such as pain and symptom management, and discussions are held about the meaning of life, along with discussions of legacy and family closure. The third and final phase is termination, in which the nurse and the patient say goodbye to each other either because the patient or nurse is leaving the system or the patient is dying.

The initial communication or introductory phase starts at diagnosis with the introduction of the nurse as a member of the care team. During this period, the nurse assesses the patient's learning styles and information needs, and the patient determines the nurse's style.[41] The tasks for the nurse include exploring the patient's understanding of his or her illness, eliciting personality and coping styles, and identifying existing documents related to the delegation of surrogate decision-makers, advance directives, or out-of-hospital medical orders for life-sustaining treatments. Assessing learning style includes discerning the patient's ability to learn and understand the seriousness of the illness. These abilities vary according

Table 5.1 Stages of the nurse–patient relationship

Stage[41]	**Initial or Introductory Phase**	**Working Phase**	**Termination Phase**
Nurse Tasks	1. Exploring patient/family understanding of illness. 2. Determining personality, coping and learning styles. 3. Eliciting presence of advance care planning.	1. Monitoring patient response to illness. 2. Providing clinical care. 3. Delivering treatment. 4. Offering illness/treatment	1. Saying goodbye. 2. Telling the patient what he/she meant to them or taught them. 3. Assisting with the transition.
Patient Tasks	Establishing trust and understanding with the nurse.	1. Establishing care plan in collaboration with team. 2. Participating in care. 3. Providing information on response to therapy.	1. Saying goodbye. 2. Showing appreciation to nurse and other staff. 3. Articulating needs with transition.

Table 5.2 Translation of medical language to lay language

Concept	Medical Language	Lay Language
Surrogate decision maker	You assign a durable power of attorney	You would assign someone
Articulate values and preferences	You may state your values and preferences	You may want to tell us what you want
Resuscitation	We would perform chest compressions and intubation	Your chest would be squeezed and a tube would be inserted into your throat.

to the age and cognitive development of the patient, as well as literacy, numeracy (capacity for numerical thought and expression), and native language. For children and some older adults, the family or support unit is primarily involved in both the information gathering process and ongoing communication with the health team.

The next phase is the working phase, which often extends over the course of the illness. Supportive care focuses on lifestyle adaptation to a serious, life-threatening illness, including providing information on the condition, treatment, and management (pharmacological, nonpharmacological, and interventional).[39] The patient and family establish trust with the nurse, who provides presence, emotional support, and reassurance.[39,41] The nurse has insight into patient and family coping and articulates their concerns or perceptions of care. At this time, according to Pierce, the nurse fulfils three critical communication tasks in end-of-life (EOL) care: (1) creating an environment conducive to communication, (2) easing interactions between physician and patient, and (3) facilitating interaction between family and patient.[42] Therefore, difficult discussions of bad news require nursing presence; the nurse is able to offer his or her perspectives of care and facilitate follow-up using language and shared information that was similar to that used in initial discussions.

As the patient enters the stage of advanced illness, the termination phase commences. It should be noted that termination may also occur if the patient changes practice settings or the nurse transitions to another position. At this time, the nurse offers continued presence and reassurance in monitoring comfort and providing intensive caring to both the patient and family.[43] Communication between the nurse and the patient and family focuses on support of decision-making, assurance of comfort, relief from pain and symptoms, information about the dying process, and solace in anticipatory grieving. The family caregiver's burden is often overlooked, but it is a major aspect of the illness experience.[44] It is hoped that the nurse and the patient are able to come to some closure as the patient dies. Immediately following the death, the nurse has a critical role in providing family support with the goal of promoting a healthy grief and bereavement process as much as possible.

Communication Barriers

Communication barriers exist for the patient, the family, and the nurse. For the patient, psychological barriers such as anger, fear, sadness, and helplessness prevent communication. Patients may feel that any discussion will cause too much distress for themselves and/or their families. For some patients, communication is not an area of comfort or value, so they may have little interest in processing feelings or information. Communication difficulties are common when patients are culturally and linguistically diverse from the health team.[45] Educational level and health literacy prevent comprehensive communication, particularly when medical language and jargon are used. See Table 5.2 for translations of common palliative care medical terms into lay language. Depending on socioeconomic status, patients may be overwhelmed with insurance issues, appointments, tests, procedures, treatments, and their cost implications. Patients may engage in a bit of "magical thinking"—that is, the fear that talking about something about their health may make it happen. The physical surroundings of the care environment have been noted to be potential communication barriers.[46] This includes noise, distractions, and lack of privacy, appropriate lighting, and seating. Finally, physical limitations such as cognitive, vision, hearing, and speech impairments, as well as pain or exhaustion, may limit communication.[47]

Families or caregivers share many of these same barriers.[48] They face dilemmas when talking about the patient's life-limiting illness, and this often inhibits information exchange.[49] Families may not understand the full extent of illness and may not know what to discuss. Moreover, families may find it too painful to talk about the advanced state of their loved one's illness because such discussion triggers anticipatory grief and loss. In order to maintain hope, families tend to overestimate the possibility of cure. They also fear future regrets if they do not pursue or demand further curative treatment. Last, it is not uncommon for family members to have little knowledge of the patient's preferences for types of care. Therefore, their ability to fully participate in decision-making in the context of the patient's preferences is limited.[50] Nurses must attend to the family caregivers to assure quality care of the patient.[51]

Circumstantial barriers exist as well.[52] Time is always an issue, in terms of attending to a patient or the time available to deeply discuss an issue. The scheduling of patients using layered appointments and tests may allow for little reflective time or time for meaningful discussion.[46] Changes in the patient's condition may prevent full discussion of details, considerations, or future treatment. Barriers to goals-of-care discussions include family members' or patients' difficulty in accepting a poor prognosis, difficulty understanding the limitations and complications of treatments, disagreement among family members, and patients' incapacity to make decisions.[53] All of this may be affected by lack of privacy in care settings such as open treatment suites for chemotherapy, renal care, heart failure, or in urgent care settings. Families may be uninformed and receiving mixed messages. Additionally, situations where information exchange must occur by telephone prevent the nurse from "reading" the family's nonverbal communication.

Nursing communication barriers include personal, professional, and legal concerns. Nurses may have difficulty or discomfort with communication due to personality, cultural norms, struggles of unresolved grief, fear of their own mortality, or fear of being emotional in front of a patient.[13,54,55] A lack of education and training, difficulty in prognostication, and perceived reluctance of patient or family all contribute to nurse communication barriers.[56,57] New nurses worry that bringing up issues related to death and dying will cause too much emotional distress to the patient and family.[54,55,57]Alternatively, they may worry about their scope of practice or authority to initiate such conversations. Some nurses are concerned that talking about palliative issues will result in patient and family conflict.[58] Finally, even though communication and information-sharing is part of the scope of practice and advocacy for both registered nurses (RNs) and advanced practice registered nurses (APRNs), many nurses feel discomfort with EOL communication and focus on maintaining hope instead of talking about prognosis.[59]

Consequently, nurses may employ avoidance behaviors regarding communication. A nurse may focus more on the biomedical aspects, particularly using technical medical jargon, and thereby avoid any elicitation of or response to a patient's thoughts and feelings.[23] Or a nurse may focus only on the present time, preventing the patient from expressing previous concerns. For example, rather than listening to the patient share concerns, the nurse may stop the conversation by providing false reassurance such as, "It will be okay now," or dismissing the emotion with a sentence such as, "Don't worry about that, it will just make you more anxious." Another way of avoiding discussion is to change the focus or the subject. For example, if the patient says, "I am worried about my family," the nurse may divert the conversation by saying, "So, how is your nausea?" Sometimes the nurse may interrupt the conversation by offering advice: "Of course, you will get over this in time. It won't last for too long." Another avoidance technique is responding to a patient's expressed difficulties by stating, "Clearly, you need to talk to the social worker about your issues."[60] Or, "it is not my role to discuss this." Finally, nurses and physicians may collude with patients in avoiding any discussions of death and dying, thus preventing information-sharing with the patient.[57,61,62]

The COMFORT Model: A Model for Effective Communication

A novel communication training curriculum named COMFORT, an acronym that identifies the basic principles of nurse communication, is offered as a communication framework.[52,63] Built from evidence-based research in hospice and palliative care settings, the COMFORT curriculum teaches nurses to focus concomitantly on task and relational communication as a way of improving communication and resolving communication challenges. COMFORT is an acronym that stands for the seven basic principles of palliative care communication (C-Communication, O-Orientation and options, M-Mindful communication, F-Family caregivers, O-Openings, R-Relating, T-Team). The curriculum teaches nurses how to provide life-altering news, assess patient/family health literacy needs, practice mindful communication, acknowledge family caregivers, and address communication openings and goals. COMFORT is designed to assist nurses with the practice of biopsychosocial and patient-centered communication. The framework is not a linear guide, an algorithm, a protocol, or a rubric for sequential implementation by nurses but rather a set of holistic principles that can be used concurrently and reflectively in the care of patients/families with life-limiting illness.

Information Needs of Patients and Families

To best provide supportive care to patients and families, it is necessary to understand their information and communication needs. Patients require information about treatment options, management of symptoms, support from family and friends, fulfilment of family or cultural expectations, attaining meaning, and maintaining dignity and control. Correspondingly, the communication needs for the patient include disease specifics, rationale for care, being listened to, and the opportunity to participate in important discussions. The role of the nurse is to assess the patient's knowledge and concerns in these areas, offer reinforcement of health information, and facilitate information exchange with the rest of the care team. The nurse also guides the patient in understanding the care plan, clarifies team responsibility for specific aspects of care, and provides support in the process.[64,65]

In order for full participation in the patient's care, family communication is essential. The communication needs of the family and other caregivers depend on their role in the family system, age, decision-making ability, and other rules within and specific to the family. Family caregivers/members are not always aware of the information they might need, may avoid relevant information, and may not express their information needs.[66] The most frequently reported information need among patients and families receiving palliative care is about pain management. Families also need to understand how the interdisciplinary team works, including the individual team members involved in care, their roles in the plan of care, what influences the plan of care, and the site of care.[67]

Nurses are information providers and communication facilitators, educating patient and family about illness and procedures, challenging family members to consider the consequences of treatment, and encouraging awareness about a patient's decline over time.[68] As an information provider and communication facilitator, the nurse provides reassurance of the patient's comfort, support in coping with the patient's condition, explanations of the evolving care plan, and delineation of the current aspect of clinical care. Moreover, families may be very involved in care but have multiple home and work obligations. Therefore, it may be a challenge for family members to participate directly in meetings at the bedside, which may necessitate frequent nursing updates about care. Finally, families may experience a high level of stress because of their need for constant updates of information.[69] The nurse has a major role in acknowledging and validating the family's stress and emotions. Families who are able to talk about the disease are able to support a patient's preferences for care, navigate the practical demands of care, and come to terms with difficult issues.[49]

Conflict in palliative care arises from mismatched expectations and suboptimal communication.[70] When family members begin to have concerns about the patient's quality of care, this is an indication that they are insufficiently prepared for the patient's death and/or are having difficulty understanding and accepting the prognosis.[70] A common circumstance occurs when either the family member or the patient requests that the other party not be informed about the extent of the seriousness of the situation. If the family is protecting the patient, the nurse should explore the family's reason for withholding information. Such requests may include spiritual beliefs, cultural issues, fear of death, fear that the patient will lose hope and give up, or discomfort with any such discussions. Each concern requires a different approach. If there is a spiritual or cultural issue, the nurse must explore the family's spiritual dimension and cultural mores.[71–73] If the family states they are fearful, the nurse can explain that most patients want to know their diagnosis so that they can participate in life closure activities and determine how to spend their final days. Most importantly, the nurse must assess the patient and determine whether he or she wants to know health information and how much health information he or she wants to know. Finally, in this situation, the nurse must attend to his or her own integrity. The response to the family who requests topics be avoided should include that the nurse won't bring up such topics, but if the patient brings up any difficult topics, the nurse will be honest in his or her responses and in the conversation.

When the patient is trying to protect the family, the principles of autonomy and confidentiality are paramount. In this situation, the nurse should explore the reasons why the patient is withholding information from the family. Often, there may be a past personal history or event rooted in shame, guilt, or lack of acceptance of a lifestyle. The nurse can first provide therapeutic presence in allowing the patient to process this. Additional social work and/or spiritual care support may be necessary. If appropriate, the nurse should explain that if family is to be involved in caregiving, it is helpful for them to have a full understanding of the patient's illness and comorbid conditions. The patient ultimately has the right to allow or limit information, and the nurse must honor this.

Another challenge is family dynamics. Serious illness results in either effective coping, where the family comes together, or ineffective coping, where the family falls apart. Assessment of both the patient and family reveals consistency in perspectives of family coping. Patient support may be suboptimal if there is inconsistent structure to support the ill person, or if family members are overburdened by care. Often, there are conflicted relationships due to psychological, physical, and sexual abuse; neglect; substance abuse; and past violence. Or relationships may be strained by divorce or separation. These situations are fraught with drama and divert the focus away from the patient. The nurse must understand that he or she cannot fix these problems and focus instead on the tangible health issues at hand. In addition, these situations necessitate interdisciplinary collaboration, including assistance from social work, mental health specialists, and/or addictions specialists.

The Role of Anxiety in Communication

An important phenomenon affecting nurse–patient–family communication is anxiety. Anxiety occurs in both the patient and the nurse, affecting how communication is delivered by the nurse and how it is received by the patient. The Institute of Medicine Report, *Delivering High-Quality Cancer Care: Charting a New Course for System in Crisis,* describes the role of anxiety in receiving communication.[74] Anxiety is a necessary element in everyday life. Indeed, mild anxiety helps most people do their work by being alert to issues, identifying problems, and facilitating creative solutions. Therefore, some patients may be mildly anxious and able to process information and, in fact, be quite creative. Other patients, however, may be mildly anxious and unable to process simple, basic information. It is important for the nurse to assess the patient's anxiety level and his or her ability to process each interaction.

As health issues become more serious, in particular regarding disease progression, anxiety increases to a moderate level. A patient's ability to process information becomes selective. At that point, the patient has a heightened awareness and may be thinking of possible bad outcomes including worsening disease. In this case, the nurse supports the patient by allowing him or her to voice fears and concerns and by reiterating information that the team has provided. It may be necessary to provide this information in small, easily understandable amounts.

The highest level is severe anxiety and panic resulting in total impairment of a patient's ability to process information.[75] This severe anxiety and panic often occurs in the patient when it is revealed that there are no further curative treatment options or that that the disease has progressed or advanced, resulting in a short prognosis or a terminal diagnosis. In this situation, once the clinician gives the difficult news, the patient may go into shock or panic about the news. He or she may be unable to process any further information. Understanding the patient's anxiety level is critical here. At this point, the nurse offers acknowledgment of the difficult news the patient has heard, validating reactions and discussing emotions. Nonverbal communication includes therapeutic presence. At this point, the team should refrain from any further information-sharing until the patient has had time to process the bad news.

Core Elements of Nurse Communication

Imparting Information

A primary role of the nurse is to impart information about the illness, medications, and treatments. By the nature of their scope of practice, APRNs may also offer diagnosis, prognosis, and treatment options. The task of imparting information is complex because providing information alone is not enough. Rather, information must be provided within the context of educational level, developmental level, literacy level, numeracy level, and primary language, along with psychological state and other social determinants of care.[76] When health literacy needs are not met, patients report a lack of understanding about their disease, difficulty making decisions, fears of dying, lack of understanding about unexpected symptoms, and a reliance on less credible online resources to fill gaps in understanding.[31] Low overall literacy, health literacy, and lack of English competency negatively impact clinical interactions, self-care, and caregiver support.[77]

In palliative care, patients' and families' learning needs span the continuum of care. The ability to recognize low health literacy in patients and family members is an important part of imparting information. Barriers to health literacy include the patient's physical and emotional state, prior healthcare experiences, and fear of asking questions.[78] There are many tools that can be utilized to ensure that nurses communicate effectively and meet patients' health literacy needs.[78–80] A technique called *chunking* (provide small amounts of information) and *checking* (assess for understanding) is one recommended communication strategy to addressing health literacy needs.[78] Another strategy is the *teach-back method* which involves asking patients to share their understanding of instructions or information discussed in a teaching session. Finally, using analogies and culturally appropriate metaphors can address low health literacy barriers. Given that many palliative care discussions are based on "what may happen," it is essential for nurses to tailor their communication to the individual health literacy level of patients and families to promote understanding.[77]

Most nurses do not feel comfortable or confident using health literacy strategies. The patient's educational level and understanding of medical language affects his or her information processing. If a patient hasn't completed high school, he or she may not understand complex words. It is important to use one to two syllable words. If English is a second language, attention must be paid to medical terminology and translating terminology into simple words. In one study, only 6.7% of nurses often or very frequently addressed a patient's need for easy-to-understand sources.[81] Nurses have a desire to communicate with patients with limited English proficiency to better understand their needs, yet they struggle to connect with these patients due to time management pressures.[82] In order to better care for non–English speaking patients, nurses increase their awareness of patient needs, culture, and personal growth in terms of attitude and self-awareness and the appropriate use of medical interpreters.[73,83]

Developmentally appropriate language refers to the age of the patient and his or her ability to reason. Younger children do not have complex reasoning abilities, whereas adolescents do. Information for pediatric patients and families must meet their particular needs, with modifications to make the language simpler and more concrete. The same is true for those patients with developmental delays or cognitive deficits. The stress of being in a healthcare setting impairs a person's ability to process information. Therefore, imparting information usually means providing information incrementally, at a fifth- or sixth-grade education level, to allow patients and families to best hear and process what is being said. Most words should be of one syllable, which then makes sentences simpler and easily understood.

Case Study Continued: Imparting Information

Marita met with Ms. Leary and her daughter, Patricia. She asked them what they understood of Ms. Leary's health. Ms. Leary stated that she understood her heart was bad and she had diabetes. Patricia stated that she knew her mother had many illnesses, that her kidneys were not working and her heart was failing. Marita asked if they understood what that meant. When they said no, Marita explained what heart failure was and how it was worse with her diabetes. Both Ms. Leary and Patricia had a new understanding that these conditions would not be reversed. They were appreciative of the time Marita spent with them.

In a transactional approach to communication, both nurse and patient/family contribute to and negotiate the meaning of verbal and nonverbal messages.[84] Both parties are influenced by one another as they attach meaning to messages. Environmental, social, and personal factors influence how messages are interpreted.[6] In this approach, communication is considered a collaborative ongoing process that allows for recognition of misunderstanding and finding ways to mutually honor diversity.[6] Patient-centeredness describes shared opportunities for communicating among all involved parties.

Information-Gathering

The next role of the nurse is to gather information. The most effective tool in gathering information from patients and families is the use of *open-ended questions*. Open-ended questions promote both the opportunity and richness to listen to the patient's narrative and observe nonverbal communication. The nurse benefits from the expression of values, priorities of care, coping, life priorities, and spiritual concerns. *Closed-ended questions* include "yes-or-no" questions or limited response questions and leading questions. The use of closed-ended questions, which usually focus on physical symptoms or history questions, limits the patient's response, thereby inhibiting elaboration, explanations, and clarifications of various topics.[28] Within the time constraints of clinical care, a nurse may not have enough time for a long conversation. However, a few key questions set a tone of a caring relationship. Box 5.2 offers a list of potential questions to use to start conversations.

Box 5.2 Useful Open-Ended Questions to Initiate Discussions

How are things going for you?
How are you coping with your illness?
What concerns you about your illness?
What concerns do you have about your illness?
How is treatment going for you?
What concerns you about your treatment?
What worries do you have about your illness or treatment?
What are your hopes in terms of your illness and treatment?
Who are the important people to you?
What relationships are the most important to you?
Who are the people who provide you support?
What gives you meaning in your life?
What gives you joy in your life?
What provides you with the strength to live or cope with each day?
Is there any important or unfinished business you need to attend to?

Source: Adapted from References 1, 18.

Often, important questions are asked but, as the patient starts to answer, the nurse moves the conversation on. When the nurse asks an open-ended question, it is essential to listen to the answer. Otherwise, distraction, unresponsiveness, or lack of acknowledgment is invalidating to the patient and/or family. Resentment may also result if the patient has shared something intimate without receiving acknowledgment of its significance.

Case Study Continued: Gathering Information

Marita inquired about Ms. Leary's QOL. Ms. Leary stated that it was poor as her functional status and mobility were poor, which affected her depression. Marita asked if it would be helpful to gather the family together to discuss a discharge plan with more supports to avoid rehospitalization. Ms. Leary said "yes," as she wanted to know her options. It was determined that her son Peter lived nearby and should be involved, as well as her ex-husband, if they could find him. With her permission, Marita arranged for a family meeting with the palliative team and Ms. Leary, Patricia, and Peter. They reviewed Ms. Leary's goals of care and her QOL. They asked about the changes in her health over the past few years. It was determined that, in the last year, she had declined the most. The palliative team asked about her priorities in life and her values. She said she wanted to be independent, but if this was not possible, she wanted no further treatment. Her family struggled with this. The palliative care team discussed the options and said they would talk later. Marita reviewed the discussion with Ms. Leary and her family after the meeting. They felt relief in being offered choices about her care.

Interdisciplinary collaboration is the backbone of palliative nursing, as holistic care plans can only emerge from working with other team members. Collaboration consists of interdependence and flexibility, wherein team members must work together to accomplish goals. In this case, the team elicits Ms. Leary's goals and priorities. It is important that family members receive the same message from team members. Collaboration promotes patient- and family-focused care.

Listening

Listening is an active process that requires concentrated presence and attention. Focused listening allows understanding of the patient's journey within the disease trajectory and of how the patient is processing information. During the listening process, the nurse focuses on the patient's story attentively, without interrupting, noting his or her specific word choices and concerns. One helpful technique is to begin the discussion by asking an open-ended question such as "What brought you to the hospital?" or "Tell me about what has been going on?" Specifically, the nurse observes both the spoken verbal content in the patient's responses, focusing on both what is said and what is left unsaid. In addition, the nurse notes speech patterns, tone, rapidity, and coherency. Concurrently, the nurse observes nonverbal expressions including emotion and accompanying physical movement. All of these observations will determine distress in the physical, psychological, spiritual, and emotional dimensions of care as well as which areas are a priority to address.

The nurse's use of silence is paramount. It allows the nurse to be fully present in the moment rather than mentally preparing answers or replies. Correspondingly, the nurse uses reflection to convey empathy. The nurse clarifies what has been heard by such comments as "Hmm" or "Tell me more." By acknowledging the patient's responses and exploring his or her meaning in a compassionate and supportive way, the nurse encourages the patient to explain difficult issues and concerns.[57] There may be times when the patient is silent. In this circumstance, it is appropriate for the nurse to just sit quietly, letting the patient reflect on the moment and the current situation. It is after these moments of silence that a patient may reveal sensitive information, concerns, thoughts, or past history (trauma, abuse, or illicit behaviors). The patient's revelation of information may be at a deeper level because he or she has been given the opportunity and permission to reveal such information.

There are several strategy models for palliative nursing communication.[10] One model of listening and attending is Ask-Tell-Ask. In this model, the nurse asks a question. The patient then responds with both statements and questions. The nurse then responds to the content of the discussion. The nurse closes by asking a final question to determine patient understanding.[10] A second model is the SPIKES model. In this model, *S* represents listening skills, *P* represents patient perception of the current situation, *I* represents an invitation to provide information, *K* represents offering knowledge or the facts, *E* represents emotional exploration and empathy, and *S* represents summary.[11] Another model is SOLER, where the nurse sits *S*quarely opposite the patient, with an *O*pen body posture, *L*eaning in to demonstrate empathy, using *E*ye contact as appropriate and with *R*elaxed positioning.[11] Finally, there is the NURSE model, where the nurse *N*ames the emotions, *U*nderstands the patients, offers *R*espect to the patient, provides *S*upport, and *E*xplores the patient's concerns through the use of I statements.[11] Any of these strategies is effective, and each depends on the communication style of the nurse.

Eliciting Sensitive Aspects of Care: Culture, Religion, Ethics

Sensitivity, another term for *cultural competence*, includes issues pertaining to religious, spiritual, cultural, ethnic, racial, gender, and language issues. Communication norms differ among various cultures, resulting in diverse cultural communication customs. These may include deference to healthcare providers, preference for the gender of care providers, or the appropriateness of discussion surrounding certain topics. Attending to culture is a very important aspect of communication, necessitating an appreciation of verbal cues and the interpretation of nonverbal cues. In many situations, beneficence takes precedence over autonomy. Disclosure and nondisclosure must be viewed within the context of the patient and the family, with understanding of and respect for their values and beliefs.

In order to be culturally sensitive, a nurse must be "self-aware of his or her own culture, cultural biases, and assumptions. Palliative care staff members cultivate cultural self-awareness and recognize how their own cultural values, beliefs, biases, and practices inform their perceptions of patients, families, and colleagues." [40] Understanding one's own background serves as a starting point for the nurse. This includes reflection and examination of one's ethical values and beliefs by reflecting on ethnicity and its effect on health, illness, and death; religion and its role in death, dying, and afterlife beliefs; and individual communication patterns.

Eliciting health information and understanding of illness is essential to care. In some cultures there are social norms about whether or not the patient should know health information, especially if the patient is seriously ill. Therefore, it is critical for the nurse to assess the patient's and family's religion and culture and how it affects healthcare. This includes how much, if any, information a patient wants to know. It also includes what and how much information is conveyed as dictated by culture and ethnicity. A patient may state that she wants direct communication, or she may defer to family members who would then inform her. Next, the nurse asks the patient to identify others whom she wishes to be told about her medical issues and whom she wants to make healthcare and treatment decisions on her behalf. Finally, it is important for the healthcare team to understand any religious or cultural practices that will affect health decisions.[71] Some religions do not allow surgical removal of organs or blood transfusions; others may not allow pain medications. Box 5.3 offers questions to promote the discussion of cultural and religious concerns.

If English is not the first language of the patient and family, it is obligatory to use a professional interpreter, as delineated in the National Consensus Project for Quality Palliative Care (NCP) *Clinical Practice Guidelines* Domain 5, Cultural Aspects of Care (see also Chapter 2).[40] Some hospitals offer interpreter services; some offer telephonic interpretation. Interpreters are invaluable to assist the nurse in phrasing questions and comments to be culturally sensitive and appropriate. Too often, family members are asked to interpret from English to another language, placing the family member in a double bind. Although they may be acting as translators, culturally, they must also act within their family roles. This is even more troublesome if children are translating for parents. Consequently, family translators may need to protect the patient from information, withhold information, or leave out pertinent facts. In these cases, it may be very unclear what the patient has actually been told.[85]

Box 5.3 Useful Cultural Assessment Questions

Where were you born?

Where were you raised?

How does this affect you about health and illness?

Are there any cultural considerations important to your care?

Are there other beliefs that are important to your healthcare?

Are you spiritual or religious?

How should spirituality or religion be addressed in your healthcare?

Are there any important rituals that are important to your healthcare?

How do you describe your medical condition/illness?

What do you know about your medical condition/illness?

What do you want to know about your medical condition/illness?

What do you fear most about your condition and its treatment?

How have you treated your medical condition/illness?

Who else, if anyone, do you want to know about your medical condition/illness?

Who else, if anyone, should we talk to about your medical condition/illness, treatment options, and the disease process?

Who is responsible for making healthcare decisions for you?

Are there other important people in your community involved in your healthcare?

Are there other people in your community whom we should include in your healthcare?

Source: References 1, 40.

Case Study Continued: Eliciting Sensitive Aspects of Care: Culture, Religion, and Ethics

Marita worked with the team on a discharge plan. She asked Ms. Leary about her frequent symptoms at home. Ms. Leary admitted to shortness of breath and chest pain. She stated that she didn't want strong medications due to fear of addiction. She was also afraid she would lose her independence; if she took the medications, she would need to be placed in a nursing home as the medications would make her dopey. Marita asked about her history with medications. Ms. Leary became teary and stated she was brought up to be stoic about pain. She felt like her Catholic faith dictated she should suffer for her sins. She felt guilty about her relationship with her ex-husband who had a substance use disorder from whom she contracted hepatitis C. She stated it was a bad time with him as he was abusive. A couple of times, she injected heroin, but realized this would not help her relationship. This was an unresolved issue because her children did not know about this or the whole story about her ex-husband.

Marita has been offered many openings through which to explore Ms. Leary's faith, her coping style, and her fears. Gently exploring these areas will foster trust and offer potential comfort in allowing Ms. Leary to unburden herself.

Communication Approaches

The context of communication influences the process and outcomes of interactions. Because of the rapidly changing complexity of healthcare, different methods of communication may be utilized. Of course, timing is always the first consideration and may dictate the communication method. Quill and colleagues defined "urgent" situations that necessitate immediate communication.[86] These include (1) the patient is facing imminent death; (2) the patient is talking about wanting to die; (3) the patient or family is inquiring about hospice; (4) the patient has recently been hospitalized for severe, progressive illness; and (5) the patient is experiencing severe suffering and a short prognosis. Less urgent situations include (1) the discussion of prognosis, particularly if life expectancy is thought to be between 6 and 12 months; (2) the discussion of potential treatment options with low probability of success; and (3) the discussion of hopes and fears. More "routine" palliative communication includes circumstances when stability or recovery is predicted.[86]

In-person or face-to-face meetings are most preferred as everyone is in the same room, hearing the same information, and it is easier to "read" nonverbal and verbal cues. However, with the changing work environment and scattered families, this may not be possible. Therefore, telephone, video technology, protected website, and e-mail communications all provide both benefits and downsides for the patient and family and the healthcare team.

Using technology, inclusive meetings can occur in novel ways and can cross geographic barriers. The most basic form is teleconference. A phone can be put on speaker mode to allow the family to listen to and join the conversation. Missing here is nonverbal communication, for both participants in the conference room or the family member on the other end of the telephone line. Moreover, it is important to remember that participants in the conference room need to attend to the absent family member who is listening on the phone. First, this requires removing extraneous background noises by closing doors to avoid overhead pages or shutting windows to avoid street noise because these impact the ability to hear conversations. Second, the attendees need to avoid side conversations; attend to extraneous noises such as heavy breathing near the microphone, and reduce the noise of clicking pens, shuffling feet, or the like. Third, there should be frequent check-ins to assure that listeners are hearing the conversation and understand what is being said because telephone lines can be inconsistent or there can be a time delay. Finally, all participants need to identify themselves before they speak, so the listener can follow who is saying what. At the end of the call, the summary is especially important to ensure that everyone heard the same plan.

Other more novel meetings can occur via video conferencing on mobile phones, tablets, or computer using Facetime, Google Chat, Skype, or Zoom. Of course, organizational guidelines must be followed in terms of privacy and confidentiality. This allows for full involvement by all participants because both verbal and nonverbal communication are accessible. Introductions are important to allow each participant to be viewed by the person on the computer, tablet, or cell phone. All participants must be patient with the process because of time delays occurring between when something is said on one end of the computer to when it is received on the other end. The meeting's pace may need to be slowed to accommodate this. Again, like telephones, sometimes there are bad connections that make for static or other disruption. Thus, various parts of the conversation may need to be repeated. Similar to telephone conversations, efforts to reduce background noise should be made. Overall, families appreciate the effort taken to include them in discussions, and healthcare providers are happy to have family hear consistent conversations.

E-mail and Web Technology

Many patients request the use of e-mail or social media communication, thus creating both opportunities and challenges. Opportunities include the ability for a rapid response and time-saving in gathering family and decision-makers quickly. Challenges include assuring that these modalities meet state and federal compliance with confidentiality regulations. It is vital that written communication be tailored to the health literacy level of the patient and that medical terminology be explained within the text.[87] Health literacy level can also be reflective of the patient's/family's linguistic abilities, engagement, and state of their own health.[87] E-mail communication between patient/family and nurse primarily concern the patient's physical needs or address unmet communication needs following a clinical encounter. Written responses require a balance of evidence-informed content with understanding and compassion.[88]

It is important to set guidelines for the use of these methods of communication. These methods, if done incorrectly, can compromise confidentiality. Any health information should be discussed through appropriate organizational guidelines and policies, which usually require the use of institutional secure web portals and secure correspondence. Nonetheless, only routine communication should occur this way. Expectations should be set for appropriate overall use of e-mail or phone contact. Moreover, there should be one person designated to communicate with the team in addition to the patient, thereby discouraging multiple e-mails by different family members to the healthcare provider. Patients and families should be given guidelines about not using this method when the clinician is off-service or on vacation.

The clinician should delineate the types of communication that are appropriate for e-mail or Web-based requests. It is important that patients understand that clinical assessment is difficult to accomplish via e-mail. Clear explanation should cover the principle that e-mail does not substitute for in-person visits and that complex e-mails usually necessitate a face-to-face visit. Usual e-mail or Web-based correspondence includes nonurgent medication requests or refills, durable medical equipment requests, home service requests, follow-up of a stable response to a new treatment, referral information, and scheduling of follow-up appointments or routine check-ins.

The response time for such communication should be considered. Patients need to be informed of expectations in response times. Because clinicians cannot monitor these sites during their clinical duty hours, there may be a lag of several hours in response time. All health facilities have protocols for urgent and emergent issues to be attended to, and any patient emergencies or urgent issues should be directed to 911 or the office triage service. All clinical assessments should occur by phone and go through the triage system.

Patient and Family Meetings

Patient and family meetings are a wonderful but underutilized tool. These meetings promote respectful and sensitive delivery of information in a timely, thorough, current, comprehensive, and accurate fashion. The patient may or may not attend depending on his or her condition, decision-making capacity, and preference for involvement. It can be helpful to hear consistent messages. For the family, it is a time to meet the various team members and understand their roles. Family meetings help the family understand the disease process and options of care while providing reassurance that a plan is in place and that everyone is working toward a consistent goal.[89,90] The family meeting also provides clinicians an opportunity to collaboratively formulate a plan of care that is consistent with the goals and wishes of the patient and family.

There are several types of meetings that occur within the context of palliative care: information meetings, ACP meetings, bad news discussions, and code status discussions.[90] The first meeting type is a straightforward information meeting. These meetings help form a working relationship between the patient and family and the care team. There may be no particular agenda other than to convey information about the patient's current status or the nature of the illness and its symptoms. There may be no decisions to be made and no future planning. Other topics include predictions about the course of illness and treatment options. There may be a discussion of home care, symptom management, medications, and nursing support.

No matter the reason for a family meeting, there are guidelines for holding a meeting. Before calling a family meeting, it is important to maximize the effective use of time by clarifying the meetings' goal. A pre-meeting should be held to clarify the messages to be conveyed and determine who should lead the meeting; the leader may not necessarily be the physician.[90] The nurse may facilitate the initial conversation by serving as a focal point for continuity of care. Organizational culture may dictate who may lead family meetings. For more complex or contentious families, having a team meeting specifically to plan strategies to deal with a difficult family is time well spent. Consideration should be given to the attendance of essential healthcare providers.

The actual steps for a family meeting are fairly straightforward and based on common sense. There are eight steps: (1) finding an appropriately private space for the meeting; (2) introducing all the participants at the meeting; (3) using open-ended questions to establish what the patient (and family) knows; (4) determining how the patient wishes the information to be presented; (5) presenting information in a straightforward manner, using understandable language, in small quantities, and with pauses for processing and questions to assess understanding; (6) responding to emotions; (7) clarifying goals of care and treatment priorities; and (8) establishing a plan.[91] Box 5.4 reviews the process of a family meeting for sharing information, delivering bad news, or clarifying life-sustaining treatments.

Because of their perceived formality, scheduled meetings tend to take on more importance than informal meetings. Several steps are important to their success. After introductions have been done, the goals of the meeting can be stated. Then, using open-ended questions, the patient can be asked about his or her understanding of the medical condition and situation. This is followed by ascertaining the patient's worries and fears, how much information the patient wants to know, and which other people the patient wants to be informed concerning clinical issues or involved in his or her care.[92] This includes determining patient and family understanding of the illness and their values, preferences, and beliefs, along with their informational needs for the decision-making patient who is hesitant to express emotional concerns and who may need prompting or an invitation to speak. The designated

Box 5.4 The Family Meeting

Pre-meeting planning

1. Conduct clinician pre-meeting to assure consistency of message and process.
2. Clarify goals of meeting with patient and family as well as staff.
3. Decide on the essential people to attend the meeting—patient, family, and healthcare providers.

The family meeting encounter

4. Arrange appropriate setting.
5. Introduce all participants in room and his or her relationship to patient's care.
6. Review goal of meeting.
7. Elicit patient/family understanding of care to date.
8. Review current medical condition.
9. Attend to questions.
10. Review options for care.
11. Elicit response from patient if decisional.
12. Elicit response from family in terms of what patient would choose for himself or herself, if he or she could.

Summary

13. Review plan. If agreement—then decision. If no agreement—what follow-up is planned?
14. Document meeting—who attended, what was discussed, and plan.

Source: References 1, 92.

meeting leader offers a summary of the planned care. The next part of the meeting addresses questions and issues that require clarification. After this discussion, the leader summarizes the issues and develops a plan of care in collaboration with the patient and family. One of the most important yet often neglected tasks after the meeting is documentation.[90] The names and titles of the people who attended, the issues discussed, and the decisions made should be recorded in the medical record.

Scheduled Meetings and the Role of the Nurse

Scheduled meeting times are critical in allowing the patient to prepare emotionally and psychologically for any potential news. This includes allowing for the presence of the patient's support network to hear and validate information conveyed. Nurses play a vital role in these meetings because they are often responsible for organizing the meeting. Before the meeting, the nurse may assess the patient's physical, emotional, and psychological concerns to be conveyed in a meeting. This information can assist the team in planning discussion points at the scheduled meeting. After the meeting, the nurse can follow-up and reinforce information communicated.

Nursing presence at any discussions—particularly when important information is conveyed—cannot be overemphasized. The team may need education regarding nursing's pivotal role in patient advocacy, particularly in supporting the patient after difficult conversations.[93] If a primary nurse is not able to participate in important discussions, a nursing colleague may participate to offer a nursing perspective. If this is not possible, it is essential that the team review the specifics about the conversation with the nurse—in particular, the news delivered, the phrasing used, and the patient's response. This allows the nurse to provide collaborative follow-up support. Sometimes the nurse may be reticent and wait to be invited rather than being proactive in participating and facilitating discussions. This reticence can cause the nurse to feel uninformed and undervalued, ultimately leading to ineffective care.

The nurse may facilitate the initial conversation by serving as a reference point for the patient and family in conveying important concerns or worries gleaned from previous interactions. Often this occurs at the beginning of the meeting and personalizes the discussions to the specific needs of the patient and family. In addition, the nurse may act as a translator between the medical team and the patient, facilitating information-sharing, interpreting information and medical jargon in language the patient understands, and also ensuring that the members of the care team understand the patient's words and language. If the patient/family agrees to the plan, the meeting can end with a synopsis of the meeting and the decisions made. If the family disagrees, another meeting can be suggested. Box 5.5 offers questions to promote conversation about coping. Difficult or overbearing families may shift the conversation to their own needs and concerns. If overbearing or difficult patients or families obstruct meetings with anger, blame, and criticism, it is important to reinforce the goals of the meeting and to restate that the focus of care is on the patient.[94] It may be necessary to set ground rules about appropriate behavior. After the completion of such a meeting, these family members may be offered resources and referrals to help with their own individual grief and coping.

Box 5.5 Questions to Address Patients' and Families' Coping

How have you/your family coped with crises or difficult situations in the past?

Have you/your family been through something like this before?

How did you/your family react/cope?

Can you identify/anticipate any potential areas of concern for you and your family?

Have you told your family what you would want in terms of life-prolonging treatments?

Did the patient ever tell you what they wanted for themselves in terms of life-prolonging treatments?

Is there anyone you need to see? Is there anyone you think the patient would like to see?

Who is supporting you now? Is there anyone you'd like us to call?

Who could you call if things became more serious, difficult, or you needed emotional support?

Advance Care Planning

ACP is essential to palliative care; it serves as a valuable guide to inform the healthcare team about the patient's care goals. The NCP's *Clinical Practice Guidelines for Quality Palliative Care* (3rd edition) describes how "person-centered goals, preference, and choices form the basis for the plan of care."[40] ACP is a social process based on the ethical principle of autonomy of the patient. ACP is a process that promotes patient control of his or her health. It prepares for lack of capacity in decision-making and relieves the burden of decision-making on others. These comprehensive discussions promote the determination of the patient's values, goals, fears, and concerns while also developing the core topics for patient education, including the right to high-quality pain control and symptom management.

There are three discrete elements of ACP: designation of a healthcare durable power of attorney, completion of an advance directive, and out-of-hospital resuscitation orders. A *healthcare durable power of attorney* defines the person whom the patient designates to make decisions if or when he or she is unable to do so.[63] This is otherwise known as the *surrogate decision-maker*. It is beneficial for the nurse to help describe this role as well as to educate both the patient and the surrogate decision-maker on the role and when it is invoked.[2] Moreover, the nurse can facilitate discussion between the patient and the surrogate decision-maker about the patient's wishes.[2] The designation of a healthcare durable power of attorney can take place on its own or within an advance directive document such as a living will. There are several popular and easily accessible documents available for free, for example *Five Wishes for Adults* or *My Wishes for Teenagers* from Aging with Dignity and *Advance Health Care Directive Fact Sheet* from the Coalition for Compassionate Care of California and *Honoring Choices*.[95–97]

Because the process of ACP involves setting goals of therapy, developing care directives, and making decisions about specific forms of medical therapy, it is more effective if anchored in personal experience. For instance, if a patient has had a family member or friend with chronic illness, poor health, and/or a terminal illness, they may be able to reflect on the actual aspects of care. For chronically ill, debilitated, and terminally ill patients, planning topics include decisions about life-sustaining therapies (code status), medically administered feeding and hydration, and palliative and hospice care. Box 5.6 offers questions to initiate ACP conversations.

It is essential that culture, health literacy, and linguistic literacy are considered within the process of ACP.[40] Discussions need to consider and respect the education level of the patient in order for the patient to make meaningful choices. The use of interpreters is paramount to reflect the nuances of culture and language differences. In some cultures, any conversation related to death, dying, or planning at end of life is inappropriate discussion. In other cultures, the use of death and dying terminology may not be used, and euphemisms may be used instead (e.g., "passing on"). Additionally, discussions about limiting the use of life-sustaining technology may be seen as akin to hastening death. These viewpoints must be respected and supported, even if the healthcare team disagrees with them.

Ideally, ACP and completion of advance directives should begin within preventive or primary care settings. These discussions are best completed over time, which normalizes them. This allows opportunity for reflection and discussion with family and friends about possible scenarios, which in itself may prepare the patient for the course of disease. However, if not initiated early, then

Box 5.6 Initiating Advance Directive Conversations

Normalizing comments/questions:

I'd like to discuss a topic I bring up with all my patients.
I wonder if you have ever imagined being really sick and what treatments you would and would not want.
I'd like to talk with you about possible health decisions in the future, if you became really ill.
I often like to make sure I understand my patients' preferences and wishes for aggressive care if there were a serious change in condition.
I would like to discuss your feelings about going to the emergency room, the intensive care unit, and being on life support.
In order to best support you, I wonder how you define quality of life and what is important to you?

Inquiries of patient's understanding of illness:

What do you know/understand about your current health situation?
What do you know/understand from what the doctors have told you?
What more do you want to know/understand about the current situation?

Inquiries to elicit hopes and expectations:

What do you hope for in the future?
What do you expect from your condition in the future?
Have you ever thought about if things don't go the way you hope?
How can we help you live in the best way possible for you?
How do you wish to spend whatever time you have left?
What activities or experiences are most important for you to do to maximize the quality of your life?

Inquiries to elicit thoughts regarding cardiopulmonary resuscitation:

Have you ever thought about life support or life-prolonging treatment measures?
If you should stop breathing or your heart stops beating, would you want us to use "heroic measures" to bring you back?
Have you ever thought about if anything were to happen to you and you could not breathe on your own or your heart could not work on its own, what would you want?
Have you given any thought to what kinds of treatment you would want or not want if you become unable to speak for yourself in the future?

For the family:

Did your loved one (name of person) ever tell you what he or she wanted for himself or herself?
Did he or she (name of person) ever talk about life-prolonging therapies?
Did he or she (name of person) witness other family members or friends undergoing treatment and comment on his or her own preferences for care?
Did he or she (name of person) ever talk about the care of another family member and state whether he or she would have wanted the same type of treatment?

Source: Revised from Reference 1.

discussions should occur before acute, disabling events and, hopefully, before the end stage of a terminal illness. Otherwise, they are laden with greater emotional burden. Unfortunately, there are a number of reasons that these conversations do not occur, including reluctance to initiate such discussions due to time constraints, lack of comfort with such discussions, lack of skills in such communications, and fear of upsetting the patient even though she or he may wish to have the conversation.[2]

There seems to be agreement on the importance of (1) naming a surrogate decision-maker, (2) documenting care preferences, (3) promoting illness understanding through education, (4) exhibiting a willingness to discuss death and dying, and (5) completing personal finances and business affairs. Patients differ in the extent to which they wish to participate in treatment decisions; therefore, it is essential to determine this. Being provided with adequate information and direction in realistic healthcare choices is critical. Without any structure or context, the weight of these decisions can cause patients and families to feel a sense of self-blame or loss of confidence in the team. This is because the burden of stopping care is heavy, and patients and family may feel that this is the same as "giving up."

To promote consistency of care preferences in the community, out-of-hospital or community resuscitation medical order sets are appropriate. These orders usually consist of do-not-resuscitate orders because the default in our health system is full resuscitation. However, they may be known as Comfort Care Orders, Allow Natural Death Orders, Physician/Provider Orders for Life Sustaining Treatment (POLST), or Medical Orders for Life Sustaining Treatment (MOLST). As stated on the POLST website, "The POLST Form is a set of medical orders, similar to the do-not-resuscitate (allow natural death) order. POLST is not an advance directive and does not substitute for naming a health care agent or durable power of attorney for health care."[98]

Survival estimates affect patient decision-making, thereby necessitating accurate prognostic information. However, there are several barriers to this. First, physicians are poor at estimating and reporting accurate survival times to patients.[99] Second, patients often receive conflicting information from various team members. Unsubstantiated information on the Internet adds furthers disparity to prognosis. Patients appear to want honesty, along with optimism and hope.[99] Nurses can promote the consistency of such information by being present when such information is delivered. Given their knowledge and working relationships with professional colleagues, nurses may also temper overly optimistic survival times.

A change in focus from future cure-oriented treatments to current functional status can facilitate realistic, authentic conversations. For instance, if the patient is talking about more treatment, but he or she is essentially bed-bound, the opportunity is presented to discuss the reality of actually participating in such treatment. Having the patient consider potential situations may be helpful. One such statement may be, "There may come a time when you need help breathing with a ventilator. But we may not be able to get you off the machine. What should we do then?" Such a scenario may offer understanding of the seriousness of the illness, realistic options for therapy, and potential circumstances of death. The result is that the patient may share his or her values and express preferences for care. The result may be a sense of control, a sense of trust with healthcare providers, and a sense of resolution in certain aspects of one's life.

Advance Care Planning and the Role of the Nurse

A central communicative role of the palliative nurse is to identify opportunities to engage patients and families about ACP. Discussions of ACP are identified as essential task-focused communication to be accomplished during the first visit or to be shared during interdisciplinary team meetings when reviewing patient plans of care.[100] The goal of ACP discussions is to impart information to help the patient and family understand the entire situation of the patient's illness; this requires the use of clear explanations, a review of options, and a formal clarification of the difference between hospice and palliative care.[2,31] Common barriers to discussions about ACP include patient or family unwillingness to listen, noncommunicative patients, nurse discomfort, and perceived physician hesitance to discuss the topic.[31] Importantly, discussions about ACP need to be reviewed during interdisciplinary team meetings to ensure that all team members are aware of the patient's preferences.[101] Nurses are encouraged to engage in relationally focused communication as part of these discussions and address psychosocial and spiritual concerns.[2,102] Nurses may often serve as a translator as well. Although families and patients have questions about their healthcare, many of them may not understand or be familiar with the medical terms often used by nurses and other clinicians.

Ongoing Discussions of Goals of Care

The patient's priorities and needs shift, resulting in a changing and evolving care plan. Many palliative care specialists have emphasized the importance of systematic meetings to discuss the patient's concerns. In particular, the early introduction of such conversations in the disease process promotes better outcomes.[61,91] These outcomes include more informed choices, better palliation of symptoms, and more opportunity for resolution of important issues.

Nurses may be particularly helpful in advocating for patients when they are unable to speak for themselves. In these cases, the nurse may assist the surrogate decision-maker to convey the patient's wishes by inquiring more about the patient's personal history. Asking the patient such questions as "Are there things that would be left undone if you were to die sooner rather than later?" that stimulate thought and discussion about dying and important life closure issues, such as healing broken relationships and completing financial transactions. However, a nurse may ask this in a different way, such as, "Are there things you need to do in case things do not go as well as we hope?" Encouraging patients to hope for the best outcome while preparing for the possibility that treatment may not work—"hope for the best, prepare for the worst"—is helpful in guiding the patient.[103] Again, the advocacy role facilitates the provision of all essential information the patient needs to make choices. This includes managing care at home and support structures for family caregivers. Box 5.7 offers questions for ongoing care.

As patients decline, they may wish to defer to family or surrogates. If the surrogate decision-maker is unsure about the patient's wishes or if no advance directive is available, the nurse can pose questions to prompt clarification on the values and preferences of a patient. These include, "What type of person was the patient?," "What did he or she value?," "Did she or he ever comment on another person's health situation in terms of what they would want or not want?," and "What stories or memories can you recall from his or her life that illustrate his or her values?" In addition to helping to clarify

Box 5.7 Questions for Discussion About Ongoing Care

How do you spend your days?

What is an average day like for you?

If you were not ill, how would you like to spend your time?

How has your condition/disease interfered with your daily activities?

What practical problems/issues have occurred as a result of your illness?

Which symptoms bother you the most?

How are things with family and friends?

Have you been feeling worried, sad, or frightened about your illness?

Do you have a preference for where you spend your time, at home, in the hospital, or at health appointments?

Source: Revised from Reference 21.

a patient's wishes, addressing these questions may also serve as a healing review of the person's life and help identify what has brought them meaning.

Case Study Continued: Care Planning

With Marita's assistance, Ms. Leary was discharged home with a palliative care team to enable her to stay at home. Chaplaincy spent time with her discussing her faith and her need for forgiveness. Social work met with her to allow her to consider her legacy and whether she wanted to tell her children her long-kept secret. Ms. Leary was admitted several times for symptoms and appreciated the continuity of care in having Marita as her nurse. When she was at the end of her life, she moved to a hospice facility.

Bad News Discussions

In palliative care, bad news includes a poor disease diagnosis, recurrence, disease progression, lack of further curative treatments, lack of any treatments to stabilize disease, transition to comfort care, and a terminal prognosis. Bad or unfavorable medical news may be defined as "any news that drastically and negatively alters the patient's view of her or his future."[18]

Nurses often convey a variety of bad news to patients and families such as cancellations or delays in treatments, confirmation of a serious or life-threatening illness, decrease in QOL, and care-setting options.[104] Nurses working in inpatient care settings, especially critical care nurses, are particularly prone to bad news disclosures, as they develop relationships with patients and families in a constantly changing environment.[105] Deciding who delivers the bad news may depend on multiple factors: the relationship of the patient with the team, the clinician the patient most trusts, and, sometimes, institutional culture or practice guidelines.

Bad news disclosures are emotionally charged events for both patient and family and for the nurse and require continuous assessment of patient understanding, fears, and information preferences.[104,105] Coyle and Sculco beautifully describe the emotional setting of giving bad news for the clinician and the patient[106]:

> Is it possible for any news, transmitted by a doctor [or nurse] to a patient, to be "good news" in the face of advancing disease that is not responsive to chemotherapy? The doctor [or nurse] is in a position of having to give information that the patient does not want to hear, and yet the patient needs to have the information in order to make necessary life decisions. Does it matter how the information is given when medical information itself can remove hope for continued existence? In a way, both parties—the doctor and the patient—are engaged in a communication dance of vulnerability. The physician is vulnerable because he/she must deliver the facts, whatever they may be, and the patient is vulnerable because he/she doesn't want to hear any more bad news.[106]

Physicians and nurses are part of this communication dance. Patients with advanced disease generally want to have this information. Paradoxically, however, although patients may want information, clinicians may be reluctant to initiate such a discussion.[107] Physicians may avoid telling the patient too much because they want to avoid feelings of failure. While the principle of delivering bad news in the context of the patient's and family's understanding is essential, a large underlying factor is the relationship of the caregiver with the patient and family and their understanding of the condition and its trajectory. Nurses, particularly APRNs, along with their physician colleagues, communicate a wide range of bad news to patients. However, registered nurses may feel uncomfortable in meaningful conversations because they may perceive lack of permission, authority, or scope of practice within their organization. They may also lack communication skills, communication education, or role modeling in effective communication.

Behaviors for effective presentation of bad news may be grouped into four domains: (1) preparation, (2) message or content delivery, (3) responding to the patient (and family), and (4) closing the encounter.[103,108] Essential within the preparation of giving bad news is attention to the healthcare provider's own emotional stress. There may be a range of possible feelings: guilt, lack of control, failure, loss, fear, or resentment.[85] Awareness of these feelings allows for clarity in ownership of issues and a more objective encounter. Nurses, in particular, may also need to deal with their own emotions either from a long-term relationship with the patient or family or from a connection in which there was a personality match.[104]

Devastating news can come in many forms for patients and families, and nurses cannot expect to anticipate with accuracy what news will be considered bad. When information is bad, as interpreted by patient and family, a nurse's compassionate presence does not mean having the right answers or all the answers, but rather just "being there" for patients. Mindful presence in bad news disclosures can attend to the spiritual, religious, and existential aspects of care. Nurses are often charged with regularly exploring and assessing patient fears, beliefs, preferences, and desires. Simply providing therapeutic presence and talking about these concerns is noted as very meaningful to patients and families.[109]

Recommended steps for family meetings about bad news focus on the following: (1) ensuring privacy and adequate time, (2) assessing patients' understanding, (3) providing information about diagnosis and prognosis simply and honestly, (4) avoiding the use of euphemisms, (5) encouraging expression of feelings, (6) being empathetic, (7) giving a broad but realistic time frame regarding

Box 5.8 Delivering Bad News

1. Prepare for the meeting:

   Determine with the patient whom they want present.

   Determine with the team which health care providers should be present.
2. Create a comfortable, quiet setting with seating for all participants and free of interruptions. Obtain interpreter as needed.
3. Clarify and clearly state your and the patient's goals for the meeting.
4. Determine what the patient and family know about the patient's condition and what they have been told.
5. Provide the foundation of a brief overview of the patient's course and condition for understanding of the entire group.
6. Give a warning of the news to come:

   "Unfortunately, I have some bad/difficult news to share with you." "I wish I had better news." "This isn't the information I expected."
7. Pause.
8. Give the bad news.
9. Sit quietly and allow the patient and family to absorb the information.
10. Wait for the patient to respond.
11. After being silent, check in with the patient such as by saying, "I have just told you some difficult news. Do you feel comfortable sharing your thoughts about this?" This may help the patient verbalize concerns.[18]
12. Listen carefully and acknowledge the patient's and family's emotions, such as by reflecting on both the meaning and the effect of their responses. Give an opportunity for questions and comments.
13. Provide a summary and give description of follow-up.

Source: Revised from Reference 1.

prognosis, and (8) arranging review or follow-up.[91] Other points are summarized in Box 5.8.

Often, in response to bad news, patients may ask difficult questions such as, "Why me?" Rather than feeling the need to answer, the nurse might offer therapeutic presence. Acknowledgments, such as "That is a tough question," allows the nurse to comment and explore further. This can be followed-up by, "Can you tell me what you are thinking right now?" Or, another statement could be, "That was difficult news, how was it to hear?" By acknowledging and normalizing the patient's feelings, the nurse invites the patient to voice his or her thoughts, feelings, and concerns. By sharing the patient's distress, the nurse may reduce the patient's sense of isolation and suffering. After listening to the patient's and family members' fears and concerns, it is essential to provide accurate, hopeful information. When the patient asks whether he or she can partake in some activity that may or may not be in a realistic time frame, the nurse can respond, "I wish that were possible, but I am worried it won't happen." Or, "I hope that you can do that, too, but if you can't, here is what we can do in the meantime." The issue of abandonment should be deliberately addressed. This can be achieved with such words as, "I wish things were different. But no matter what, I will be there to support you in your decisions and promote your quality of life." This allays fear that even though the patient can no longer tolerate treatment, providers will continue caring for them.

Prognosis

Another common and difficult question is the patient's response to such news with the question, "How long do I have to live?" Responding to and acknowledging such a question normalizes the discussion around death and dying. The nurse may choose to answer in several ways, depending on his or her comfort in these discussions. One response is, "Are you asking for a specific timeline?" Here, the nurse is trying to ascertain whether the patient is asking about dying or is thinking of a certain event that he or she wishes to live to experience. Another response is, "How long do you think you have to live?" This allows patients to voice concerns about time and offer their own impression of their remaining time. The patient may say, "Not long, but I wanted to see how long you thought," thus comparing input from different members of the team. A third response may be along the lines of, "Why are you asking that question now?," "What makes you ask that question now?," or "Why do you ask?" This invites the patient to share his or her fears and concerns about dying. The nurse may also reflect on difficult information with, "I imagine it is very frightening not knowing what will happen and when. Do you have particular fears and concerns?" Finally, if the anticipated survival time is short or the nurse is uncomfortable, he or she may reply, "What has the team told you?" In this case, the patient may state that the team has given a certain estimate of time, or the patient may be seeking validation of the prediction.

When it is appropriate to offer a timeline, it is helpful to give a range of time rather than exact times. Instead of the specific time of 2 weeks or 6 months, it is more helpful to say, "weeks to months." This prevents the patient or family from making a calendar and ticking off the days until death. In those cases, if the patient surpasses the exact time, there is often anger about the countdown. However, when death is imminent, it is helpful to say "hours to days." It is also useful to explain what supports that timeline, such as significant changes, signs and symptoms of dying, or rapid disease progression. This allows the patient and family to prepare for their final time together.

Discussion of Life-Sustaining Treatments

Often when patients are critically ill and have advanced disease, the healthcare team seeks clarification on the use or continuation of life-sustaining measures. Life-sustaining measures may include vasopressors to help the heart pump more efficiently and effectively, dialysis for kidney failure, antibiotics for infections, and medically administered nutrition and hydration. "Code status" is commonly defined as the use, or limitation of use, of life-sustaining therapy in the event of clinical deterioration of respiratory function and/or cardiac arrest. Major life-sustaining measures within cardiopulmonary resuscitation (CPR) include invasive ventilator support consisting of nasotracheal or endotracheal intubation, noninvasive ventilator support (CPAP, BiPAP), and defibrillation (cardiac electroshock). The use, continuation, or discontinuation of life-sustaining measures are all necessary aspects to these discussions.

Currently, when a patient in any setting experiences a cardiac arrest and/or respiratory failure, the default is full resuscitation. Thus, CPR is performed unless the patient or the patient's surrogate has indicated do not resuscitate (DNR) and/or not to be intubated and supported with mechanical ventilation—do not intubate (DNI). The public has little understanding of the reality of implementing CPR. Only 6–10% of people survive CPR outside of hospitals, while inpatient rates are around 24%.[110] These statistics decline in patients with serious life-threatening illness. Additionally, patients and families need to be informed that returning to previous function and QOL is unlikely. Rather, if the patient survives, functional status often diminishes along with QOL. To dispel concerns of abandonment, it is particularly important to reassure the patient, family, and surrogate that even though CPR will not be performed, all beneficial care will be actively provided. The team should offer recommendations because patients and families cannot make responsible decisions without survival rates, prognosis, and resultant QOL following CPR.

The process is similar to other patient and family meetings. The recommended steps include (1) establishing an appropriate setting; (2) inquiring of patient and family what they understand of the patient's condition; (3) finding out what the patient expects for the future; (4) discussing resuscitation within the context of the patient's condition; (5) eliciting the patient's understanding of present condition and thoughts of the future, including the context in which resuscitation would be considered; (6) responding to concerns and emotions; and (7) developing a plan.

There are several important concepts around code status discussions. Use of medical vernacular, such as "full code" or "no code" and "Do you want everything done?" is ambiguous at best. These terms simply indicate whether or not to perform a procedure, offering little insight into the patient's goals of care. Instead, code status that includes definition of QOL, preferences, values, or beliefs guides care decisions. Box 5.9 offers some exploratory questions on QOL.

Box 5.9 Questions to Facilitate Quality-of-Life Discussions

How is your quality of life? How would you describe quality of life?

What would not be quality of life? What would be an unacceptable life?

Is this how you thought disease-focused treatment or advanced illness would be?

What would make this time especially meaningful for you?

What makes life worth living for you?

How have your religious or spiritual beliefs been affected by your illness?

Source: Revised from Reference 1.

The focus of discussion on the use of life-sustaining technology is to review the anticipated benefits and burdens of interventions. The challenge is that patients need to understand that CPR statistics are related to people without a life-threatening illness. A possible statement could be, "With all the treatments we have done, you still have a serious illness that is incurable. Full code will mean returning to the intensive care unit. This would cause further weakness and debility and keep you away from your family." Or another statement could be, "We know that resuscitation is not without pain from chest compressions and discomfort of ventilator tubes. You have stated you did not want to be in restrained in any way." However, the process of determining the use of life-sustaining treatment is incomplete without documentation. Both the plan and the context of the conversation must be documented in the record and accessible to other healthcare professionals. Ideally, it should be accompanied by a completed state-recognized comfort care/DNR order forms.

According to the position statement *Nursing Care and Do Not Resuscitate (DNR) and Allow Natural Death (AND) Decisions,*[111] "Nurses must advocate for and play an active role in initiating discussions about DNR with patients, families, and members of the health care team." The team can offer the patient and family a plan that focuses on aggressive pain and symptom management, psychological support, and better QOL. They can then ask for agreement from the patient and family, thereby allowing the patient and family to assent to a plan. Assent means the family agrees to the plan without having to take on the burden of choosing a specific option. Consent means the family is offered a range of options, and they choose which option. By assenting, the burden of the decision is removed from the family and placed on the care team. For many families, this feels like less of a burden because the team makes the difficult decision. It may still be the same plan, but the team has allowed the patient and family to "unshoulder" the burden or weight of the decision.

Nurses are often ideally positioned to contribute to conversations about EOL care and decisions, including maintaining a focus on patients' preferences, and to establish mechanisms to respect the patient's autonomy.[112] There are often circumstances when the patient and family convey their overwhelming sense of pressure or responsibility about the decisions they are being asked to make. When this occurs, often the responsibility of making such a decision is too great for patients and families. They may feel that by making a choice to refuse resuscitation, they are "pulling the plug." In these situations, nurses can take an active role in creating an interdisciplinary care plan as described by ANA's Position Statement *Registered Nurses' Roles and Responsibilities in Providing Care and Support at the End of Life*. "Nurses are obligated to provide care that includes the promotion of comfort, relief of pain and other symptoms, and support for patients, families, and others close to the patient."

Discussions of Life-Sustaining Treatments and the Role of the Nurse

Nurses are heavily invested in clarifying code status. This arises from the wish to avoid inflicting further suffering on patients with serious and life-limiting illness. Nurses fear situations in which the primary physician is unavailable and they must deal with a covering physician unfamiliar with the patient and his or her goals of care. Therefore, most nurses want to quickly establish the code status with providers familiar with the patient's medical condition.

It is essential that nurses understand the use of life-sustaining treatments among a variety of patient populations. Explaining the benefits and risks of such treatments to patients and families requires nurses to be familiar with both the appropriate and inappropriate use of life-sustaining treatments.[113] Incorporating clinical ethics in decision-making about life-sustaining treatments is a key component in discussions with family.[114] There are several important communication points regarding life-sustaining measures. First and foremost is that the nurse remains present and open to the patient's and family's rationale about these difficult issues. Second is that discussion with the patient and/or the patient's surrogate includes (1) perception of the benefits and burdens of life-sustaining treatments and the suffering with or without these interventions; (2) any values, beliefs, and cultural issues of the patient and family that affect the decision or need for such interventions; (3) the available data regarding the benefits and burdens of the interventions; and (4) collaborative decision-making about these interventions to meet the patient's goals.

The significant role of nurses in providing information and family guidance during challenging decision-making about life-sustaining measures cannot be overemphasized. When the patient is dependent on a ventilator, the nurse must assess the patient's literacy level and understanding along with any visual or auditory impairments in order to teach family members how to communicate with the patient.[115] Teaching the patient and family how to use communication tools such as picture/letter boards and to understand nonverbal cues (e.g., head nods, mouthing words) and creating an appropriate environment (visual and proximal positioning) to facilitate patient–family communication are the responsibility of the nurse.[116]

Because of 24-hour presence with the patient, the nurse may be the one to whom the patient and family turn for explanations, recommendations, reassurance, validation, and support. Questions to the nurse may focus on the meaning of medical jargon such as "CPR/DNR/DNI," presser support, ventilators, and so forth. This is usually followed by patient and family questions such as, "What do you think?" or "What should I do?" The nurse must first define these terms and their intended effect. By educating the patient about the actual intervention and likely outcome, a nurse may be able to reassure the patient.[68] The nurse can offer the facts and reflect back the patient's values and preferences such as, "Mr. X, you told me you want to be comfortable and not return to the hospital. We can get support at home to keep you comfortable and aggressively treat any symptoms." Reassurance and support for the appropriateness of preferences and decisions develops from questions such as, "Do you feel I made the right decision?" or "What would you do?" Patients may need reassurance that the nurses will continue to provide care. The nurse may respond with, "I support your decision."

Conversations About Medically Administered Hydration and Nutrition

Numerous cultures place great social and cultural importance on drinking and eating. When patients are not able to take food or fluid by mouth, medically administered hydration and nutrition may be provided through the gastrointestinal tract using a nasogastric or gastric tube or may be administered intravenously. Finally, for some cultures, intravenous fluids and nutrition may be necessary to prevent any sense of hastening death. Many people believe that not eating and drinking causes great physical suffering. Medically administered hydration and nutrition may alleviate any guilt felt by patients and family arising out of the feeling that they had not "tried everything." Therefore, it is necessary to discuss the potential benefits and burdens of both instituting and withholding medically administered hydration and nutrition. The rationale for and against these procedures is discussed in Chapter 70, "Ethical Considerations in Palliative Care."

Conversations About the Transition to Palliative Care or Hospice

The transition in care away from curative-directed therapies is often an emotional time for patients, families, and clinicians alike. Patients may feel a sense of sadness, anger, denial, and loss of control to the disease. Families may finally come to terms with the reality of the situation or the serious nature of the illness. Physicians may feel a sense of failure for not curing the disease and frustration with the lack of any further medical options. Nurses may feel grief from the impending termination of the patient and family relationship. The focus of care shifts from curing the disease; from physical cure to emotional and psychological healing.

A direct nursing approach is helpful, stating, "We are no longer able to cure or control your disease. We would like to optimize your quality of life, manage pain and symptoms to avoid suffering, and promote optimal functioning. We have expert nurses who care for patients with life-threatening illness, helping you avoid the hospital. We will work with them to care for you at home." This allows the patient and family to understand that they will continue to be cared for and not feel abandoned. Such discussions lend themselves to completing legal and financial business. This allows for life closure in preparation for death and legacy work. Usually, this also includes attending to psycho-emotional-spiritual work. For the family, such discussions promote preparation and planning for a home death and strategies for sustainability in caregiving.

The nurse has a central role to empower the patient at this time. This is accomplished by a continued dialogue about hopes, preferences, and QOL. Each situation is individual and cannot be determined by an algorithm or recipe approach; personalizing the experience promotes emotional healing. Guidelines for initiating conversations during the last phase of life include (1) focusing on the patient's unique illness experience, (2) discussing issues of closure, (3) promoting discussions about pain and symptom management at the end of life, (4) addressing and planning for the preferred site of death and who will provide care for them, (5) facilitating home health and hospice arrangements, and (6) promoting a respectful death. Box 5.10 offers questions to open exploration of changing goals. Nurses offer information to patients and families about resources and transitions of care. This includes hospice, home health, and other community-based healthcare resources, when such resources are consistent with the patient's and family's values, beliefs, preferences, and goals of care.[3] The nurse is then responsible for the coordination and communication of the plan. He or she promotes continuity of care and continued support in the home. The hospice, palliative, or home care nurse must educate the patient and family about necessary caregiving skills concerning medications, equipment, and personal care.

Box 5.10 Questions for Changing Goals of Care

What do you understand about your disease and current condition?

What do you understand about further treatment?

What are some of the concerns you have at this time?

What, if anything, are you worried about or afraid of?

Given the severity of your illness, what is most important for you to achieve?

Have you given any thought to what kinds of treatment you would want (and not want) if you become unable to speak for yourself in the future?

We want to focus on maximal comfort and optimal functioning with as much support as possible. Is that okay?

How is your family handling your illness and its change?

How is your family coping with your changing condition?

Are there topics you need help in discussing with them?

Would it be helpful to have us talk to them with you about changes in goals?

Transition to Death

When curing is no longer viable, there is the potential for physical comfort and psychological healing instead of cure. Simple presence, listening, and attending to the basic humanity of the dying patient may be one of the nurse's most powerful contributions. Nurses may reduce anxiety and help prepare patients and families just by describing the dying process. As appropriate, the explanation includes the actual physiological and biological process of dying in simple language. The alleviation of pain and symptoms is based on a patient's previously stated preferences regarding desired level of alertness. This may include discussion about the withdrawal of ineffective and/or burdensome medical treatments, including preferences concerning medically administered hydration and nutrition.

Often, a patient considers the meaning of his or her life or performs a life review. This facilitates healing in recognition of personal purpose and meaning, resolution of past conflicts, attaining forgiveness and reconciliation, and achievement of personal integration and inner peace. Additional strategies to help relieve emotional and spiritual suffering include guided imagery, music, reading, and art that focuses on healing.[87] All this may include the collaboration of social work, volunteers, and chaplain colleagues.

The nurse's therapeutic presence with the patient in his or her state of vulnerability and decline can be profound. Here, the nurse consciously and nonjudgmentally listens and bears witness to the patient, encouraging any expression of emotion, doubts, or regrets. The simple acts of visitation, presence, and attention can be potent healing affirmations—a sacramental gesture received by the dying person who may be feeling helpless, diminished, and fearful that he or she has little to offer others. The willingness to demonstrate concern to the patient far outweighs any technique or expertise in the art of listening.

During the dying process, the nurse guides care while promoting healthy bereavement within the family. One critical nursing task is role-modeling for families. Specifically, the nurse demonstrates the art of being present to the dying person. Simply encouraging the family to engage in loving, physical contact, such as holding hands, embracing, or lying next to the patient can be healing. It may help the patient in his or her transition and may help the survivors in their anticipatory grief. For families who want to be present at the time of death, explaining that patients often wait until they are alone to die may prevent the family from feeling a sense of guilt if they are not present at the time of death. Allowing the family to be with the patient after death may help the surviving family members grieve the loss of their loved one.

After death, the nurse offers continued presence, support, and information. The nurse informs the family of the process of certifying death and may assist the family in informing others about the death. Awareness of anticipatory grief and bereavement guides care at this time. Bereaved families are often in most need of having someone to listen to them. Such activities, including telling the story of the loved one's illness, including details of the days and weeks around the death of their loved one, and sharing memories of the loved one, are therapeutic. The nurse may offer information for burial or funeral services as well as grief services. When the family is ready to leave their loved one, the nurse assures respect for the body and explains the process of postmortem care.

Team Communication and Collaboration

Collaboration within an interdisciplinary team is a vital force in working with patients with serious, life-threatening illness. Hanson and Carter describe collaboration as a "dynamic interpersonal process in which two or more individuals make a commitment to each other to interact authentically and constructively to solve problems and to learn from one another to accomplish identified goals, purposes, or outcomes. The individuals recognize and articulate the shared values that make this commitment possible."[117] Good communication ensures better collaboration, ensures comprehensive care, and assures safety and quality.[118] Collaboration enables the sustainability of the team.

However, teams are social systems and have their own dynamics, just as a family does. In effect, the team can be a "work family." With good leadership, role delineation, and flexibility, interdisciplinary teams have the capacity to work well, creating a synergy that promotes positive outcomes.[119] If working effectively, the team identity as a palliative care team supersedes each individual member's discipline. There are necessary qualities to promote effective collaborative teams. First, the participation of all members is essential; the degree of involvement may depend on the issues of the patient and family. Each member's role should be well-defined and respected. Good communication and negotiation are necessary to delineate roles. Second, each team member should have a voice in team processes. Third, the team's mission and goals should be periodically reviewed to assure that all members are working on the same premise. Team members share information and work both independently and together to develop goals. Each team member should be committed to quality care. Fourth, each team member should understand his or her role in patient care and maintain the process of the group. Leadership is shared among team members depending on the task at hand. This means that there must be respect for different styles, trust in clinical competence, and compassion for each other.[117,120] Periodic review of these guidelines will ensure the team's effectiveness and efficiency as a team.

Effective teams promote collaboration through good team communication, team organization and coordination, and competency. This teamwork will be characterized by different environmental and organizational cultures, which dictate the nature of the teamwork as collaborative, deferential, or hierarchical. It is also variable depending on a nurse's role and level of practice. Part of teamwork is the development of working relationships and understanding differing communication styles. This necessitates:

- Recognition of individual team member contributions.
- Respect for and acknowledgment of the competence and expertise of team members.
- Clear definition of roles, responsibilities, and tasks.
- Well-defined reporting structures for both work functions and practice.
- Scheduled communication among team members and meeting times.
- Skilled leadership to manage nurses who are novices, intermediate practitioners, and experts.
- Evaluation processes for quality of care and team effectiveness.
- Psychological and spiritual support for team.
- Ethical and legal resources for the team.
- Respect for patients as individuals.

There is a negative process to teamwork as well. Barriers to effective teamwork include lack of training, hierarchical team structures, organizational rules, and reimbursement issues that cause inherent authority issues.[121,122] Ineffective leadership results in lack of mission and vision. Moreover, team attitude can have an effect on care. There has been an emerging arrogance among palliative care team members that "they know best, are the most caring, effective, and ethical." This can cause negative feelings among other healthcare colleagues, who may feel they are just as caring and committed to patient care.

Poor communication results in poor care, negative outcomes, conflicts, and, ultimately, team demoralization.[118,123] If roles and responsibilities have not been clearly delineated, nurses may feel restrained to broach and discuss certain topics with patients and families, defaulting to the physician who may prefer that these discussions occur at the nursing level. Consequently, a lack of clear roles between nurse and physician can leave patients and families with no communication about their illness, treatment, or prognosis. Ongoing discussions between physician and nurse occur more as a task-focused discussion about patient assessment and response to treatment.[114] Nurses also play an important role in mediating communication between physician and patient and family.[123,124]

Much has been written about how conflict among team members results in bad practices. Eight problematic team behaviors include (1) overwhelming the patient, (2) making the patient part of the team, (3) squelching the voice of individual team members, (4) lack of accountability, (5) team process trumping client outcome, (6) orthodoxy and groupthink, (7) overemphasis on health and safety goals, and (8) squandering of resources. All of these issues can occur at various times within the palliative care team and necessitate good communication and conflict resolution. Examples of these problems include the following:

1. *Overwhelming the patient and family*[125]: This occurs in several ways in terms of timing, information, and presence. One is overwhelming the patient with too much information. An example is when patient and family have just heard difficult news. Then the palliative care or hospice teams enter to "fix" everything, before the patient and family have had time to absorb and integrate the information. Another overwhelming experience is a high ratio of healthcare providers in family meetings. The patient or family may feel outnumbered and disempowered to raise individual issues or concerns.
2. *Making the patient part of the team*[118]: Patients are told that they are part of the decision-making team and are asked for input. The boundaries about what decisions they can or cannot make are ambiguous, especially if they disagree. Moreover, as the patient declines, he or she may not really be able to participate in decision-making.
3. *Squelching the voice of individual team members*: The team may explicitly express that everyone's input is equal when, implicitly, that is not the case. Nonphysician voices may be dismissed, minimized, marginalized, or overturned by physicians when there is disagreement. Another example occurs when, in trying to advocate for a certain unpopular perspective, a team member's opinion may be discounted as "not really understanding the situation," being "no longer objective," or "too close to the situation."
4. *Lack of accountability*: This is often a challenge when there are too many healthcare consultants working with the primary team. Sometimes, with everyone on the palliative care team working on the same issues, no one takes responsibility for the overall care of the patient. In addition, there may be cases where a primary team is detached but asks for input from the palliative care team, but nothing is implemented. Or there may be too many consultants, and the patient receives many mixed opinions with no clear advocate.
5. *Team process having higher value than client outcome*: Healthcare providers often have certain ideas or feelings about what is right or wrong and how things are done. The challenge is to allow an open process to occur and not to limit it to one particular pathway simply because that is the way it is always done. Patients and families are unique in their needs and don't always follow algorithms.
6. *Orthodoxy and groupthink*: A group can become insular and not incorporate new ideas.[126] The team becomes unable to assess itself, and obvious problems are overlooked. In EOL situations, this often happens in relation to the dying process. A nurse may understand that the patient is dying, but other health professionals look for a specific symptom and treat it. The team may think the nurse is "giving up," rather than admit the patient is dying.
7. *Overemphasis on health and safety goals*: This occurs when the care plan itself takes precedence over the patient's needs or choices. This is often seen in the discharge process when the healthcare team disagrees with the patient's lifestyle choices. So, the team resorts to making a plan based on their "safety agenda" rather than a patient's choice.
8. *Squandering of resources*: The needs of patients are missed, especially in the dying phase, resulting in implementation of high-cost interventions with low impact on the patient's overall care.

Teamwork and the Role of the Nurse

Among the team, nurses work the most closely with physicians, either implementing medical orders or following care plans. However, nurses and physicians differ in their communication styles. Nurses tend to be more narrative or qualitative and to emphasize more process and reflection. Physicians tend to be more quantitative and want facts and numbers. Neither style is better than the other; rather, both styles are essential in patient- and family-centered care. Nurses become frustrated with physician communication when physicians seem inattentive or are unwilling to discuss goals of care. On the other hand, physicians report frustration when nurses share disorganized information, include extraneous or irrelevant information, or delay in getting to the point.[127]

The goal of a communication interaction between the nurse and the physician dictates whether reflection or facts are needed. If the contact is about information-sharing, the nurse may need to present details, albeit short and brief. If a treatment change is warranted, the nurse provides supporting evidence. For example, if calling about pain and symptoms, the nurse should know the medications the patient is taking, when they were last taken, and the patient's pain scores, and the nurse should offer a suggested plan. Or, if calling about a patient's change in code status or goals of care, it is critical the nurse offer the rich narrative of the context of the conversation so that the physician may have an effective follow-up conversation.

Quality communication between physician and nurse includes delineating communication roles, reviewing topics to be discussed with the patient and family and by whom, fostering an active communicative role for nurses rather than blindly following physicians' requests, and limiting their own communication with others.[117] When nurses receive authorization or permission from physicians to communicate with patients and families about designated topics or to participate in breaking bad news disclosures, it removes a barrier to nurse communication, which promotes better patient outcomes and patient safety.[118]

Conflict Resolution

Conflict is a situation in which two or more people or parties disagree. This can occur due to different perspectives of care, different patient goals, different values, different ethics, or different role expectations. *Task communication* for teams involves gathering information from each other about clinical care of the patient and family, while *relational team communication* emerges from the general support that team members share regarding workplace stress, coping, and burnout.

Nurses on the front line deal with conflict all the time. This may occur between a patient and a nurse, between a nurse and a doctor, between an advanced practice nurse and a registered nurse, or between two healthcare teams. Conflict is inevitable and healthy for palliative teams, secondary to different perspectives, different experience, length of time in palliative care, and the sense of urgency to alleviate symptoms. If managed well, it helps people look at different perspectives and can allow for creativity and positive movement. If dismissed or ignored, it can breed demoralization and negativity.

Nurses deal with conflict differently depending on their level of practice, practice site, and experience. Often, nurses avoid conflict if they constantly have difficulty in dealing with a team member who will not talk about disagreements. However, in palliative care, the goal should be collaboration in which all problems are discussed and mutual solutions are reached.

Box 5.11 Effective Conflict Negotiation

1. Reflection of the conflict

A. Identify the conflict—the facts

Review:
What happened? Objective data.
What emotions contributed to conflict? Subjective data.
Consider:
What impact has the situation had on you?
How did you contribute to the problem?

B. Identify the goal of conflict resolution

Clarify:
What do you hope to accomplish?
What is the best way to address the issue?
What is at stake for you?

2. Negotiation of the conflict

A. Address the conflict with the other person.

Consider:
When and how is the best way to raise the issue?
How is the best way to achieve the purpose of resolution?

B. Identify each individual's purpose to conflict resolution—the feelings

Review:
Where do you and the other person share purposes?
Where do you and the other person's interests differ?

C. Exploration of the conflict

Discuss:

What is the other person's perspective? Listen to the other individual and explore the story.

What are the other person's feelings? Acknowledge feelings behind story and paraphrase them.

Does the other person understand your perspective? Ask other individual to "listen to you as you share your version of the events and your intentions."

D. Problem solve, with patient's best interest as goal

Invent options to meet each side's most important concerns and interests.

Decide tack of resolution: Avoidance, collaborate, compromise.

Use objective criteria or palliative care standards (NCP *Clinical Practice Guidelines*) for what should happen.

Determine approach for future communication.

Source: Revised Reference 1.

Several methods are available to resolve conflict: negotiation, accommodation, and collaboration. What differentiates these approaches are the perceived power differences. Conflict resolution occurs through a process, see Box 5.11. This involves looking at the facts of a conflict, the feelings of a conflict, and the identity in the conflict.[128] First, the nurse identifies the source of the conflict, reviewing the facts of what happened and what the impact was.

Second, the nurse reflects on the emotional aspect of the conflict—these are the feelings. Then, the nurse addresses the goal of conflict resolution in terms of what she or he hopes to accomplish as it relates to the patient and/or family. Sometimes, this may require looking at the role each provider has at stake and then thinking what is best for the patient.

There are several steps in meeting with a team member about a conflict. Be curious about your colleague's perspective by learning his or her story. In doing so, the two parties share their common purposes and differing interests. Express your views, including statements of feelings, and take the time to listen. This leads to exploration of the conflict and letting each party tell his or her perspective while acknowledging feelings and each party's version of the events. Among the hardest things to learn to say are "I am sorry," "I was wrong," and "You could be right." It is not necessary for the nurse to feel pressured to agree instantly. Rather, it is important to discuss the range of the issues. Problem-solve together, with the common goal being the patient's well-being, and decide on a tack of resolution.

Conclusion

Communication in palliative nursing is the essential tool by which nurses deliver care. Effective communication sets the foundation on which the care plan is established and guides the care. Nurses need to seek education and practice communication skills in situations specific to patients with serious illness.[129] The art of nursing communication is based on the use of physical presence, listening, silence, and therapeutic presence. This is enhanced through emotional intelligence. The science of nursing communication involves skills in verbal and nonverbal communication and the application of communication strategies to promote effective, quality care. Patient- and family-centered care necessitates effective nurse communication to impart communication, gather information, and provide a therapeutic presence. Communication is essential in team collaboration and resolving conflict. Nurses have a direct role in difficult conversations ranging from information-sharing about diagnosis and treatment, counseling about EOL choices, determining values and preferences, supporting patients and families in bad news conversations, and facilitating transitions to palliative and hospice care.

CHAPTER 6

Advance Care Planning

Shigeko Izumi

Key Points

- Advances in medical technology have made extension of life possible and various end-of-life (EOL) treatment options available. However, patients frequently lack decision-making capacity at the time when they need to make EOL decisions for themselves.
- Family members and healthcare providers often do not know what EOL care patients want and experience psychological distress during and after making EOL decisions for the patient.
- Advance care planning (ACP) is a process that facilitates patients making plans for EOL care for the time when they are not capable of making their own decisions. The plan is intended to be shared with family members, significant others, and healthcare providers to guide EOL decision-making that honors the patient's values, goals, and preferences of care.
- ACP is a central tenet of person-centered care. Building systems to assist all patients with ACP and honor their values as standard practice is urgently needed.

Introduction

The goal of healthcare is to provide the care patients want to receive.[1] However, providing the care that patients want is difficult if the care team does not know what the patient's preferences are. Advance care planning (ACP) is a process to plan for future healthcare decision-making so that family members, surrogate decision-makers, and healthcare providers can know and honor persons' preferences when they become unable to make their own decisions or express their preferences. While ACP is increasingly recognized as an essential component to provide patient-centered and high-quality end-of-life (EOL) care, how to facilitate and use ACP to guide better EOL care remains challenging.[2] This chapter provides a contextual background for ACP, definitions and processes of ACP, and the nurse's role in ACP.[3]

Background

Advances in medical technology have made extension of life possible and various EOL treatment options available.[2] To date, when patients face life-threatening illness or injury, several treatment options may be available including cardiopulmonary resuscitation (CPR), ventilators, or medically administered nutrition to extend life; experimental treatments aimed at achieving a cure; and palliative care focusing on comfort and improving quality of life. A large national survey of Medicare beneficiaries shows that 86% of people prefer to spend their last days at home rather than in a hospital and that they do not want life-prolonging treatments that make them feel worse.[3,4] Although the proportion of people who die in hospitals has gradually declined and the use of hospice services has increased in recent decades,[5] more than one-third of decedents still died in a hospital in 2015, indicating a gap between what EOL care people want to receive and what they actually received.

Studies also show increases in intensive care unit (ICU) use in the last 30 days of life and increases in the number of healthcare transitions in the last few months of life.[6] Multiple healthcare transitions, including in and out of the ICU during the end stage of their lives, imply that patients' health status fluctuates during this time, and they have to make multiple healthcare decisions as to where and what kind of care they receive through the last few months of their lives. A typical course of care transitions in EOL care is that a patient is admitted to an acute care setting for exacerbation of illness; is transferred to ICU for intensive treatments as his/her condition worsens, where s/he potentially faces limited treatment options or becomes too ill to endure treatment, thus changing the focus of care; and is discharged to home or a similar environment to receive comfort care.[7] Transitions in treatments and sites of care as their condition changes is common and appropriate if each decision reflects the patient's preferences and goals at that time. However, because the default medical treatment for seriously ill patients is "do everything to save a life," some of the transitions that happen in the last few months, weeks, or days of their lives may be driven by this default and may not reflect these patients' true preferences based on well-informed decision-making.[7,8] To choose treatments that may be different from the default treatments that healthcare providers assume, patients have to actively engage in the decision-making and express specific preference for the chosen treatment. Unfortunately, approximately 70% of patients needing to make EOL care decisions are unable to participate in the discussion and lack the decision-making capacity or ability to express their preferences.[9,10]

Therefore, it is important that family members and healthcare providers know what is important for patients and what EOL care they want to receive while the patients are still capable of expressing their preferences. Unfortunately, family members who are expected to assume the surrogate decision-maker role infrequently have prior conversations with the patients and know their preferences or values. When family members make decisions for critically ill patients without prior conversations, they often struggle and experience strong emotions such as guilt and regret during and after rendering a decision, which contributes to long-lasting psychological suffering.[11–13] Having ACP conversations with patients prior to decision-making is shown to be associated with less decisional conflict and less psychological burden for surrogate decision-makers.[14]

For patients to have an opportunity to express their preferences for EOL care while they are capable of decision-making, the Patient Self-Determination Act (PSDA) was passed in 1990. The PSDA requires hospitals, nursing homes, and other healthcare institutions to ask all patients whether they have advance directives and to provide information about advance directives upon their admission to the facility.[15] Although the PSDA was intended to educate patients about healthcare decision-making rights and encourage them to make the decision and document it in a legal form, advance directive completion rates actually hover between 20% and 50%,[16–18] and completion of advance directives does not necessarily promote better care at the end of life.[19,20]

Patients might have advance directives, but often no one knows that an advance directive exists or it cannot be located when needed.[21] Some advance directives are written using legal terms and are difficult to understand, particularly for persons with low health literacy, with a different primary language, or in poor health.[22,23] Treatment preferences that are based on hypothetical scenarios may not reflect what the person wants in the actual situation.[20] Broad value statements such as "maintain dignity" can be too general to guide concrete treatment decisions in specific situations.[24] Despite the well-intentioned enactment of the PSDA, situations where family members and healthcare providers have to make difficult EOL care decisions without knowing the patient's preferences continue to exist.

The Institute of Medicine (IOM) report *Dying in America*[2] examined the issues in EOL care in the current healthcare system and identified a lack of clear communication about death and dying and candid discussions to learn about a patient's values and preferences as a barrier for quality EOL care. Their recommendations include improved clinician–patient communication and ACP as essential components to improve EOL care.

Definitions of Advance Care Planning

The IOM report defines ACP as "a process of discussion of EOL care, clarification of related values and goals, and embodiment of preferences through written documents and medical orders. This process can start at any time and be revisited periodically, but it becomes more focused as health status changes" (pp. 122). More recently, consensus definitions of ACP were developed by multidisciplinary international ACP experts[25,26] (see Box 6.1). Key points common to these definitions include:

1. ACP is a process, not a one-time event.
2. ACP includes discussions to understand and share values, goals, and preferences of the person for future medical care.
3. ACP can start at any age or stage of health.

The concept of ACP has been evolving. Sudore et al. observed a shift in definition of ACP in the past few decades, and disagreements about what ACP should entail exist among ACP experts.[25] The observed disagreements include whether to focus on conversations versus a written document, treatment preferences versus a patient's values, and who should be included in the process.

Box 6.1 Consensus Definition of Advance Care Planning

Advance care planning (ACP) is a process that supports adults at any age or stage of health in understanding and sharing their personal values, life goals, and preferences regarding future medical care. The goal of ACP is to help ensure that people receive medical care that is consistent with their values, goals, and preferences during serious and chronic illness.

Sudore RL, Lum HD, You JJ, et al. Defining advance care planning for adults: A consensus definition from a multidisciplinary Delphi panel. *J Pain Symptom Manage.* 2017;53:821–831.

Advance care planning enables individuals to define goals and preferences for future medical treatment and care, to discuss these goals and preferences with family and healthcare providers, and to record and review these preferences if appropriate.

Rietjens JAC, Sudore RL, Connolly M, et al. Definition and recommendations for advance care planning: an international consensus supported by the European Association for Palliative Care. *Lancet Oncol.* 2017;18(9):e543–e551.

Conversation Versus Documentation

In the consensus definition (Box 6.1), conversations are highlighted as a critical part of ACP to understand the patient's values and preferences, while documentation of the patient's values and preferences (e.g., advance directives) is an important strategy or a tool to ensure that the patient's preferences are clearly communicated to family members, providers, and across settings. Patients having conversations with their family members and significant others create a space where patients can reflect and let others know and understand what is important for them. In conversations, others can ask the patient to clarify what he or she means, and then family members are left with a deeper understanding of what and why certain choices are important for the patient. Such dialogue could guide decision-making in a situation where documentation is lacking or where such decisions were not anticipated.

Documentation of the ACP conversations in the patient's health record to provide the context of patients' decisions is recommended. Documentation of patient's values and preferences with or without conversations is also possible. Some programs encourage patients to write a letter or create a video letter to their healthcare providers and loved ones and add it to the patient health record; this is another way to communicate preferences to others (see https://med.stanford.edu/letter.html). While conversations and letters are powerful ways to communicate values and preferences, formal documentation of patient's instructions for EOL care, such as advance directives, also should be encouraged. Despite some deficiencies in legal documents, having a standardized form that concisely communicates a patient's preferences in emergency situations is valuable. Healthcare providers seeing the patient when EOL care decisions need to be made are often not the same providers who know the patient and were involved in the ACP conversations. Having a formal document outlining a patient's preferences and identifying key decision-makers assists healthcare providers who may be unfamiliar with the particular patient. The providers can then contact and involve the right persons in the decision-making and will be more likely to reach the right decisions for the patient.

Treatment Preferences Versus Patient's Values

Another area of disagreement is knowing and focusing on patients' preferences for specific medical treatments or their life goals and values. While patients' expressed preferences for specific treatments (e.g., CPR, tube feedings) are helpful, their preference for the treatment may be different in a hypothetical scenario when compared to the actual situation. In a specific context where a decision needs to be made, available treatment options may vary. Experts recommend that ACP conversations should start with overall personal life goals and values, such as what is important for them; then these values should be translated into more specific discussions about medical treatments as their stage of illness progresses and more specific treatment decisions need to be made.[25,27]

Who Should Have Advance Care Planning?

There are discussions about whether ACP should include healthy adults or only seriously ill patients. Concern exists in some experts that a healthy person with no experience with serious illness may have little perspective from which to make ACP decisions. Therefore, they suggest that healthcare providers should focus their ACP efforts on patients with serious illness only. Yet identifying patients with serious illness who should have ACP is often difficult and unreliable.[28] One of the reasons that many patients admitted to ICU have never had prior ACP conversations despite their serious illness is that clinicians often do not recognize the seriousness of the illness and the need for ACP until it is too late. Furthermore, even healthy persons could suddenly face EOL decision-making due to accident or acute illness and could benefit from having a plan. The goal of ACP is not to make definitive decisions about EOL care at the moment, but to learn about patients' values and preferences so that the conversations and/or documents could guide future decision-making when an unfortunate event happens. The current definition of ACP has broadened to encompass engagement with people for future decision-making regardless of their age or stage of illness.

Another issue regarding ACP's target population is whether ACP should focus on patients or surrogate decision-makers. A goal of ACP is that a person with decision-making capacity reflects on his or her life values and goals and makes a plan for their EOL care. Because patients are often not able to make their own decisions at the end of life,[9] ACP should include identifying a surrogate decision-maker, communicating the plan to that person, and preparing them to make the necessary decisions. Even when patients retain their decision-making capacity at the end of life, those who have had opportunities to reflect on their life values and discuss them with their loved ones are better prepared to clarify care preferences as they face important decisions. Therefore, the focus of ACP is preparing both patients and surrogate decision-makers through engagement in ACP and communicating the values and preferences that will guide the decisions.

The last area of consideration is who should facilitate ACP. In the past, ACP conversations were mostly limited to those patients with life-threatening illnesses, and conversations often included the delivery of poor prognosis related to the patient's illness. Therefore, physicians historically assumed the role. With recent ACP definitions that have broadened the process to include healthy persons or those with chronic illness and to focus more on personal goals and values rather than medical treatments, there are opportunities for other healthcare team members to facilitate continuous ACP conversations across the illness trajectory. Primary care providers who see patients at their wellness visits; nurses consulting for chronic illness management; and nurses, social workers, or chaplains who are admitting and caring for patients across acute care settings can all facilitate these conversations and elicit what is important for patients and help them communicate these values to their families and healthcare providers. Currently, licensed independent providers (LIPs) are able to bill for ACP conversations using a billing code for the Center for Medicare and Medicaid Services.[29] Although non-LIP professionals' time for ACP facilitation is not billable, there is no restriction on or statement about who can and cannot have ACP conversations with patients.

Process, Tools, and Strategies for ACP

The ACP conversation should start well before the time of actual EOL decision-making and be revisited as the person's health and life values change. As the person becomes seriously ill and gets closer to the EOL stage, the focus of ACP conversations could be narrowed and specific. Because these conversations happen over time, on multiple occasions, it is rare for individual clinicians to participate in the evolution of ACP over several years of the person's life. Figure 6.1 is a model describing the continuum of ACP along with changes in health status.[30] The model illustrates ACP activities across a continuum from health to illness to end of life and the topics that clinicians could address with the person depending on the stage of his or her health. In the following section, the process of ACP along with the continuum of the ACP model is described with Case Studies illustrating issues.

Case Study 1: Healthcare Professionals Did Not Know Who Would Be the Surrogate Decision-Maker

A twenty-four-year-old obstetric patient was admitted to a hospital for elective caesarean section. During the procedure, she experienced massive blood loss necessitating an emergent decision about hysterectomy. Because the patient was unconscious and a decision needed to be made, the physicians consulted with the woman's mother who was present in the waiting area and was listed as her "emergency contact" in the electronic health record. The mother consented for the hysterectomy, and the procedure was completed.

After the surgery, the patient was upset because she wanted her fiancé, with whom she is going to make future family plans, to make the decision, not her mother. Asking patients about their surrogate decision-makers was not a requirement before a procedure in this hospital, and the surrogate decision-maker section in the health record was left empty. According to the state law and the hospital's policy, if patients do not name the surrogate decision-maker, a default surrogate decision-maker is determined in order of (1) spouse, (2) adult child, (3) parent, or (4) siblings. In this case, the patient did not have a spouse or adult child, and her mother was the legally correct surrogate decision-maker.

Naming the Surrogate Decision-Maker

Because acute illness or injury could happen to anybody, it is recommended that healthcare providers ask all patients to name and document a surrogate in the patient's health record. Even healthy patients admitted to a hospital for elective surgery may need someone to make decisions for them while they are under anesthesia. Case Study 1 is not about EOL decision making, but it is an example of how not knowing the patient's surrogate decision-maker could result in less than optimal decisions that were not concordant with the patient's preferences. Assisting persons in appointing a surrogate decision-maker becomes especially important with a diagnosis of life-limiting or chronic illness that is expected to cause declining mental health. Alzheimer's disease is an example of a chronic illness where an individual may lose the ability to make informed decisions. It is important to have conversations to name a surrogate as soon as possible, while the person can participate in the conversation.[31]

A surrogate decision-maker is someone patients trust to make healthcare decisions and to speak for them in the event they are unable to. A surrogate decision-maker is sometimes called a *healthcare proxy*, a *durable power of attorney (DPoA) for healthcare*, a *healthcare agent*, or *healthcare representative*. Most of the states and many healthcare organizations have policies about the surrogate decision-makers for incapacitated patients. If a patient does not appoint a surrogate before he or she loses capacity, decision-making falls to the patient's next of kin according to state law, usually in the following order: spouse, adult children, parents, adult siblings, adult grandchildren, or close friends. Patients can name their surrogate decision-makers out of order of the state law or name someone other than next of kin, but this needs to be documented in a legal form, such as an advance directive or healthcare proxy, to be valid. In Case Study 1, the patient's mother was not only the emergency contact person and present in the waiting area, but she was also the legally valid next of kin to be the surrogate decision-maker. Because the patient was not asked and did not name her fiancé as her surrogate decision-maker in a legal document, her fiancé was not contacted when the decision had to be made. Today's family structure and personal relationships are diverse and complex. If the surrogate decision-maker a patient trusts is not the conventional next of kin, it is important to advise the patient to complete his or her advance directives in order to legally name the surrogate decision-maker.

A surrogate decision-maker is the person who will speak and make decisions for the patient when he or she is unable to speak for him- or herself. Speaking up and making healthcare and life-support decisions in a high-stress situation is very difficult; it is beneficial to guide patients on how to choose the right surrogate decision-maker. The surrogate decision-maker should be someone who:

- You can trust to speak for you
- You can talk to and who knows about your values, goals, and preferences
- Is willing to accept the role
- Is able to follow your wishes
- Is able to speak up on your behalf
- Is able to make decisions in stressful situations

Brochures and other materials guiding the selection of the right surrogate decision-makers are available at the Conversation Project website (https://theconversationproject.org/wp-content/uploads/2017/03/ConversationProject-ProxyKit-English.pdf); the next section provides more information on the Conversation Project.

Complete Advance Directives

Advance directives are written documents that describe a person's treatment preferences in EOL care and identify a surrogate decision-maker. Advance directives are legal documents in most states. In some states, surrogate decision-makers are appointed using a special form (e.g., healthcare proxy, healthcare power of attorney) separate from an advance directive form. The section for treatment preferences in an advance directive is sometimes called a "living will," where persons express what life-sustaining treatment (for example, CPR, tube feeding) they would or would not want in terminal conditions. It is recommended that all adults who have decision-making capacity complete an advance directive for the time when they may become unable to make decisions.

Unfortunately, completion of an advance directive is difficult for many people because it is written in ambiguous and nonspecific medical and legal terms. In addition to the difficulty posed by the high literacy level of advance directive forms, thinking and making decisions about future EOL care can be an overwhelming task. Although completion of an advance directive does not require involvement of healthcare professionals, many persons find assistance or guidance from healthcare professionals helpful. Resources are available to guide the public in having these conversations and formulating advance directives. The Conversation Project started as a grassroots movement to promote EOL care conversations at the kitchen table so that individuals could let their loved ones know about their values and preferences. In collaboration with the Institute for Healthcare Improvement (IHI), the Conversation Project provides various materials to support these conversations among loved ones (https://theconversationproject.org/). Another good online resource is *PREPARE for Your Care,* a web-based guide that helps people plan for and make decisions about their future care. *PREPARE* is based on behavior change theory and is designed to engage older adults and persons with diverse cultural background and low-literacy levels in ACP.[32] Step-by-step video instructions and an easy-to-read advance directive are provided at this website. The organizers of the site document significant increases in the number of people accessing ACP and its documentation online[33]; see https://prepareforyourcare.org/welcome.

It is not only important to complete an advance directive, but it is also essential to document where the advance directive can be found when needed. Keeping advance directives in a safety vault or lawyer's office without telling anybody does not serve the purpose. Persons who have completed advance directives should be advised (1) to give copies to their surrogate decision-makers and healthcare providers, (2) inform their families and close friends about their surrogate decision-maker and wishes, (3) keep a copy of the advance directive where it can be easily found, and (4) take a copy with them if they go to a hospital or nursing home. ACP is an ongoing conversation, and completing an advance directive is not a one-time event. People change their minds as their health and life circumstances change. The advance directive should be revisited and revised as life goals and values change.

Having a Goals-of-Care Conversation

When patients become ill, more focused conversations between patients and healthcare professionals need to occur. The aim of such conversations is for healthcare providers to understand patients' goals and values and align medical treatments with them. Prior reflection, conversations with families, and completion of advance directives would be helpful to prepare for these conversations. Yet thinking about hypothetical EOL situations and planning for immediate or near future decision-making about medical treatment carry different weights and require different approaches.

There are two similar and overlapping yet slightly different types of conversations at this stage. One is a conversation that leads to shared decision-making to select the right treatment at any stage of illness. This conversation does not need to be about EOL care. It could occur when a patient and healthcare providers discuss and decide what treatment option is appropriate for the patient who is newly diagnosed with early-stage cancer or for heart failure that is gradually progressing. The underlying tenet is that patients should receive care that is consistent with their goals and values at all times. Thus, each treatment decision should be made based on candid discussions that ensure that the goals of treatment align with the patient's goals and values at the moment.

Another type of conversation is one with seriously ill patients, for whom a poor prognosis is looming and revisiting the alignment of current treatment goals and the patient's goals is needed. This is comparable to the conversation traditionally called ACP, goals-of-care conversation, delivering bad news, or EOL conversation. This conversation is usually triggered by clinicians when they see a patient approaching end of life and have concerns that current treatment may or may not align with that patient's quality of life. A limitation of this approach in preparing patients for better EOL care is its reliance on clinician judgment to identify the need and take action. Clinicians so focused on treating disease may not recognize a patient's overall decline. They may be aware of the need for a conversation, but they may be afraid to talk about death and dying and therefore avoid the conversation.[34–37] Because of these reasons, the conversation may occur too late, when patients are in crisis or unable to participate in the discussion.[38,39]

There are growing efforts to train healthcare providers to have earlier goals-of-care conversations with their patients. Vital Talk (vitaltalk.org) and the Serious Illness Care Program (https://www.aradnelabs.org/areas-of-work/serious-illness-care/) are examples of programs that provide evidence-based conversation skill training and guides for healthcare providers. A key issue in goals-of-care conversations that meaningfully contribute to planning for quality EOL care is knowing patients' goals, values, and wishes and aligning treatments to meet these personal values. Healthcare providers are trained to make judgments about the best treatment in the situation and provide those treatments, but they sometimes fall short in ensuring that the medically appropriate treatment matches the patient's values. Vital Talk and the Serious Illness Conversation Guide provide framework, strategies, and some useful language to elicit a patient's values and goals and to make shared decisions for treatments that align with a patient's values, particularly when the patient is seriously ill and has a limited prognosis. Although many of these training programs have been targeting licensed independent providers (e.g., physicians, nurse practitioners, physician assistants) whose scope of practice includes prognostication and medical treatment decisions, there is an increasing interest to expand this training to clinician groups that have the skills to assist patients and facilitate the conversations.

The healthcare system is transitioning from a traditional biomedical model where healthcare providers make healthcare decisions from a position of authority to a patient-centered care model where care providers and patients jointly make treatment decisions. When the shared decision-making becomes the norm for any treatment decision beginning in the early stage of illness, the serious illness conversation may become a mere extension of prior conversations and be less threatening for both patients and clinicians.

Medical Order for Life-Sustaining Treatment

The aim of this step is to translate patients' preferences about life-sustaining treatments into a standing medical order. When people reach a critical stage in their illness such that healthcare providers would not be surprised if they die within a year, it is helpful to have a standing medical order that instructs other healthcare professionals about what treatment should be provided in an emergency or outside-of-hospital settings. The Physicians Order for Life Sustaining Treatment (POLST) (also called Medical Order for Life Sustaining Treatment [MOLST] in some states) is a portable medical order form that prescribes life-sustaining treatments that patients would want during a medical crisis and helps to avoid the provision of treatments that patients would not want (http://polst.org/about-the-national-polst-paradigm/what-is-polst/). The POLST should be portable and stay with patients. If patients live in their home, the POLST should be posted in a visible location (e.g., refrigerator door). If patients are transported to a nursing home, emergency department, or hospital, the POLST should go with the patient.

A POLST paradigm is adopted in many states. Although details may vary slightly by state, the POLST form usually includes preferences for CPR, different levels of medical interventions (comfort measures only, limited treatment, or full treatment), and signature by ordering healthcare provider. The POLST form should be completed based on informed, shared decision-making between patients and healthcare providers. The POLST form must be signed by a healthcare provider who is accountable for the medical orders. State law identifies which healthcare providers are authorized to sign medical orders. In Oregon, where POLST was first developed, there is a state-wide POLST registry where all POLST forms are sent. Through this registry, healthcare staff can access a patient's POLST online in an emergency.

Table 6.1 Differences between advance directives and Physicians Order for Life-Sustaining Treatment (POLST)

Advance directive	POLST
For anyone 18 years or older	Most appropriate for those who are frail or seriously ill
Legal document completed by patient with instructions for end-of-life treatments	Medical orders for life-sustaining treatments based on discussions between a patient and a healthcare provider
Does not guide emergency personnel because it is NOT a medical order	Provides medical orders to emergency medical personnel
No need for healthcare provider's signature	Needs healthcare provider's signature
Appoints a surrogate decision-maker Needs patient's and surrogate decision-maker's signature	Does not identify surrogate decision-maker Patient's and surrogate decision-maker's signature is recommended but not required
No registry available Patients and/or family members need to produce it when needed	POLST registry may be available POLST stays with patient

Because it is a medical order, POLST should be followed by emergency medical personnel outside of hospitals as well as any healthcare professionals in other settings. Both advance directives and POLST are useful tools to communicate and document patients' values and preferences for EOL care. Yet there is some confusion between the two. Table 6.1 summarizes the differences between advance directives and POLST.

Use of Advance Care Planning in EOL Decision-Making

The purpose of the ACP is to ensure that a patient and his or her loved ones know what is important for the patient and what treatment he or she wants to receive at the end of their life. When the person becomes not able to make his or her own decisions, those present (family, friends, and the healthcare team) feel prepared to make the best decision honoring the person's values and preferences. All prior conversations between the person and his or her family and healthcare teams—and any documentation of these conversations, such as naming surrogates, advance directives, goals-of-care conversations, and POLST—will guide persons, family members, and healthcare providers to make EOL care decisions. The last stage of ACP (the bottom apex of the continuum of the ACP model in Figure 6.1) is not planning, but using the plan developed through the process. When healthcare professionals see a patient who is seriously ill, the automatic response is to save the patient's life. But if that is not what the patient wants, doing everything to save the patient's life may not be quality care for that patient. Some healthcare providers equate providing life-extending treatment that does not match with a patient's wishes to medical error. In order to provide the care that patients want to receive, healthcare professionals need to inquire as to whether the patient has ACP and elicit the patient's wishes instead of assuming the patient wants to live longer. The healthcare professional's role is to work with patients and surrogate decision-makers to make the best decision that honors a patient's values in a given situation.

Roles and Responsibilities of Nurses in Advance Care Planning

The American Nurses Association's position statement[1] asserts that nurses are responsible for facilitating the process of informed healthcare decision-making for patients. ACP is a central tenet of person-centered care, and it provides a way to facilitate informed, shared decision-making for EOL care by assisting patients to reflect and communicate their values.

Case Study 2: Advance Care Planning at Hospital Admission Make a Difference

Nurses in a bone marrow transplant (BMT) unit in an academic medical center were conducting a quality improvement project that asked all patients to name a surrogate decision-maker and encouraged them to have advance directives completed within 48 hours of admission to their unit. On admission, a patient with a new diagnosis of blood cancer told the nurse that she wanted her two best friends to be her surrogate decision-makers instead of her family. She explained that her ex-husband was the primary support but not the decision-maker, and her daughter was using substances and was unreliable. The nurse involved a social worker to assist this patient to complete an advance directive appointing her friends as surrogate decision-makers.

Two weeks later, this patient was dying unexpectedly in the ICU. At her bedside were only her ex-husband and her daughter who wanted "to do everything." ICU nurses saw the advance directive and contacted the social worker in the BMT unit, and the social worker spoke with the patient's surrogate decision-maker friends by phone. The surrogate decision-makers had previous conversations with the patient about the EOL care she wanted to have and did not want to have. The decision was made to not intubate and not continue aggressive life support treatments. The patient's ex-husband and daughter were upset that they were not named as decision-makers, but the patient's wishes were honored at the end of life because she had talked about these issues and had the directive in place. This patient died 5 minutes after aggressive treatment was stopped, and she was comfortable as she died with her daughter holding her hand.

As described in prior sections, ACP should happen across the various stages of a patient's health, and all patients that nurses encounter in their practice should have the opportunity to plan and prepare for future health situations. In Case Study 2, the patient was not expected to die during this hospital stay, but nurses asked who the patient trusted to be her surrogate decision-makers and encouraged her to have conversations with her chosen surrogates. The BMT unit nurse's early ACP conversation with the patient to plan for EOL decision-making enabled the ICU care team to provide the care the patient wanted. Nurses are responsible for educating their patients about the importance of ACP and assisting them in making a plan that is appropriate for them. Nurses working in primary care settings should educate patients who come in for annual wellness visits about the importance of identifying surrogate decision-makers and encourage them to start these conversations with their families in case of an unpredictable event, such as an accident. Reviewing ACP can be a routine health maintenance process, one similar to immunizations. Nurses seeing patients with chronic illness can assist them in thinking about what is important for them and encourage them to have conversations with healthcare providers to make informed shared decisions about treatments that are consistent with their values.

When patients are making a plan for future treatment by completing advance directives or POLST, nurses can explain what the potential implications of CPR or tube feedings are and assist them in having meaningful conversations with healthcare providers and in making well-informed decisions. When a patient and his or her family are in a situation where EOL care decisions need to be made, nurses should advocate for the patient by directing the healthcare team's attention to the patient's values, goals, and preferences and ensuring that the patient receives the care he or she wants.[40]

In addition to their responsibilities as registered nurses, advance practice nurses need to be familiar with the process of ACP that is appropriate to their specialty role and patient population. The specialty role may include communication, documentation of information and forms, and possibly how to bill for the ACP conversation to make the ACP facilitation practice sustainable in their practice. Additional training to facilitate serious illness conversations, including prognosis and treatment decisions, may be needed. Models describing the process of ACP and tools introduced in prior sections could be used to plan and implement ACP in the advance practice nurse's role as well.

Conclusion

ACP is gaining recognition as an essential component to provide quality EOL care, and both the public and healthcare professionals are increasingly aware of its importance. While the concept of ACP is broadly accepted as good practice, implementation of ACP in routine practice in many care settings remains challenging. In addition, evidence showing what and how ACP improves the quality of care that patients receive is still limited.

Essential components of ACP such as knowing a person's values, goals, and preferences; facilitating conversations with patients, families, and healthcare providers for informed shared decision-making; and advocating for provision of care that is consistent with a patient's values are core principles of nursing. Nurses, particularly palliative nurses who have expertise in these areas, take a leading role in ACP by educating patients, families, and other healthcare professionals and advocating for its implementation in everyday practice.

SECTION II

Symptom Assessment and Management

CHAPTER 7

Interdisciplinary Palliative Care Teams

Specialists in Delivering Palliative Care

Polly Mazanec, Rebekah Reimer,
Jessica Bullington, Patrick J. Coyne,
Herman Harris, II, Mary Catherine Dubois,
Catherine Rogers, and Jennifer Aron

Key Points

- Palliative care attends to the physical, psychological, social, and spiritual domains of quality of life, providing specialty care for patients with serious illness and their families.
- Palliative care is provided by an interdisciplinary team (IDT) whose members are palliative care specialists able to meet the complex, multidimensional needs of patients and families facing serious illness.
- The roles of the palliative care team members are unique within their specialty; however, there are many instances in which team roles may overlap.
- Four major models of team-based palliative care—inpatient consult teams, ambulatory care teams, community-based palliative care teams, and hospice teams—provide interdisciplinary expertise in the delivery of quality palliative care across the disease trajectory of serious illness.
- A highly functioning palliative care team requires that its members share the team's mission and vision, share leadership and accountability, and trust and respect each other.

Introduction

Palliative care is interdisciplinary care (nursing, medicine, social work, chaplaincy, and other specialties as appropriate) that specializes in assessment and management of physical, psychological, social, and spiritual needs of patients and families dealing with serious illness.[1] It focuses on improving the quality of life (QOL) of patients and families and is initiated ideally at the time of a serious illness diagnosis and provided concurrently with disease-oriented treatment, across the disease trajectory.[1,2] Members of the palliative care team work not as individual disciplines, but as a team, as a whole, with a shared vision and mission to improve patient and family QOL.[3]

Over the past two decades, the United States has witnessed a remarkable growth in palliative care services with the expansion of four major care-delivery models.[1,4,5] The most frequently utilized model of palliative care was initiated in the early 1990s in acute care settings as a consult service for those hospitalized with serious illness. This inpatient consult service provided specialty care in the hospital setting, with or without a palliative care unit.[6] In the mid-2000s, research began to demonstrate that patients benefit from having specialty palliative care services available in ambulatory care units, and this emerged as a second model for palliative care.[7,8] These outpatient services were started in oncology clinics across the country.[7,8] Now, many more specialty outpatient departments, such as cardiovascular clinics and neuromuscular clinics for diseases such as Parkinson's disease and amyotrophic lateral sclerosis (ALS), are collaborating with ambulatory palliative care to provide outpatient services. Most recently, a third model of palliative care delivery, community-based palliative care teams, has arisen out of a need to focus on the delivery of palliative care to those in the home, including assisted living and long-term care facilities.[9] Community-based palliative care can be delivered in person or via telehealth in areas of limited access.

The fourth model of palliative care delivery is hospice care.[10] Hospice care is the initial model of team-based palliative care, one that began in the United States in the late 1970s in response to a need to improve care to patients at end of life and their families. It is regulated by federal programs (i.e., Medicare, Medicaid, and Veterans Affairs) in the United States, as a separate system of care for those with a life-expectancy of 6 months or less who choose to forgo disease-focused treatments.[1,11] Hospice always delivers palliative care; however, palliative care is not the equivalent of hospice care. The confusion between these two services has made it challenging to educate patients, families, and other healthcare providers on the differences (Table 7.1).[1]

Table 7.1 Models of palliative care

	Inpatient consult service	Ambulatory palliative care	Community-based palliative care	Hospice care
Team	Interdisciplinary team: physician, nurse; access to social work (SW) and chaplaincy as available and as needed	Interdisciplinary team: Physician, nurse; access to outpatient SW, chaplaincy as available and as needed	APRN or physician: Requests are made for additional team members, if available	IDT including physicians, nurses, SW, chaplain, volunteers, nursing assistants, and bereavement coordinators
Eligibility	From diagnosis of serious illness across disease trajectory	From diagnosis of serious illness across disease trajectory	From diagnosis of serious illness across disease trajectory	Patients of all ages who have a prognosis of survival of 6 months or less if the disease follows its usual course; must forgo Medicare coverage for curative treatment related to the terminal illness
Delivery site	Consult services go to patients and families in the ICU, ER, and hospital units	Outpatient clinic setting; can be imbedded in specialty clinics (heart failure) or in a designated palliative care clinic; ideally, space is allocated for conferencing with patients and families	In patient's home, including assisted living, long-term care facilities; may also use telehealth resources	Most hospice care is delivered in the patient's home; other sites include assisted living, long-term care facilities, residential hospice facilities, inpatient hospice units or hospice-contracted inpatient beds
Reimbursement	Physician and APRN bill insurance or Medicare Part B for inpatient care	Physician and APRN bill for outpatient specialty visit	Physician and APRN bill insurance for specialty provider care	Team care is bundled and covered by Medicare hospice benefit or commercial insurance hospice benefit, modeled after Medicare; Medicaid coverage varies by state

APRN, advanced practice registered nurse; ER, emergency room; ICU, intensive care unit.

The focus of this chapter is on the interdisciplinary team (IDT) that provides specialty palliative care regardless of the model of care delivery. The chapter emphasizes each team member's essential role in the provision of quality palliative care and how the team as a whole collaborates with the patient and family to ensure that the patient's goals of care are respected and honored. A complex case study will demonstrate the roles of the team and their unique contributions to quality palliative care for a patient with ALS and her family. This chapter will also discuss the four major models of palliative care in more depth and the current benefits and challenges of each. An introduction into the development of a palliative care team and the importance of maintaining a healthy, functional team will be presented at the end of the chapter.

The Interdisciplinary Palliative Care Team

According to the National Consensus Project (NCP) guidelines,[9] palliative care "provides relief from pain and other symptoms, supports quality of life, and is focused on patients with serious advanced illness and their families. Palliative care may begin early in the course of treatment for a serious illness and may be delivered in a number of ways across the continuum of health care settings, including in the home, nursing homes, long-term acute care facilities, acute care hospitals, and outpatient clinics. Palliative care encompasses hospice and specialty palliative care, as well as basic palliative care."[9]

Within Domain 1 of the NCP *Guidelines for Quality Palliative Care*, Structure and Processes of Care, there are ten guidelines, each with its own criteria, that relate directly to the palliative care delivery model and the IDT.[9] These guidelines are important not only for the development of the palliative care team, but also for sustaining the IDT by evaluating their ability to meet these criteria on a regular basis and revise processes as necessary. Quality structure and processes of care are critical to the sustainability of the palliative care IDT. Communication and collaboration within the team is essential. It is not unusual for there to be some overlap in the roles of these IDT members, but collaboration and communication among team members ensures a well-functioning team and improves the overall patient and family outcomes.

Role of the Team Members

Chaplain

According to Domain 5 of the NCP *Guidelines for Quality Palliative Care*,[9] spiritual care is an essential component of a palliative care team. Unfortunately, less than half of the teams listed in the 2015 National Palliative Care Registry had a complete core of team members, including chaplains.[12]

Spirituality is "recognized as a fundamental aspect of compassionate, patient and family-centered palliative care. It is a dynamic and intrinsic aspect of humanity through which individuals seek meaning, purpose, and transcendence and experience relationship to self, family, others, community, society, and the significant or sacred. Spirituality is expressed through beliefs, values, traditions, and practices."[9] Although it is the responsibility of all IDT members to recognize spiritual distress and attend to the patient's and the family's spiritual needs within their scope of practice, the palliative care chaplain is able to complete a comprehensive spiritual assessment and initiate appropriate interventions for those needing spiritual support.[2,9,13]

The primary role of the chaplain on a palliative care team is to support and/or accommodate the spiritual and religious needs of patients, families, and staff. Chaplains provide support across cultures and faiths by offering a nonjudgmental presence. Chaplains can be called simply to talk, using religious or nonreligious language, or they can be called to address specific religious needs, such as providing sacraments or other rituals that provide existential comfort. The goal of the chaplain is to aid in restoring identity, meaning, and/or connection to those who invite a chaplain's care. The palliative care chaplain builds on the traditional hospital chaplaincy role by assisting the team in symptom assessment, especially existential distress, eliciting goals of care, advance care planning, and supportive complex decision-making.[14]

Palliative Care Nurse

It is not unusual for a large palliative care team to include both registered nurses (RNs) and advanced practice registered nurses (APRNs). Nurses are educated to focus on the holistic needs of the person, providing supportive care to the physical, psychological, social, and spiritual needs of patients and families, and advocating for their needs. The specialty-trained palliative care nurses build on this nursing foundation by adding expert communication skills, knowledge of pain and symptom assessment and management, expertise in coordination of care, and skill in educating patients, families, and other healthcare professionals about palliative care concepts. Board certification in this nursing specialty is offered through the nursing organization, the Hospice and Palliative Certification Corporation.

Specialty palliative care nurses (PCNs) use expert communication skills,[15] listening to patients and their families and exploring what the patient's values, goals for care, and communication preferences are. The PCN on the team also contributes to pain and symptom assessment and management, is skilled in pharmacological and nonpharmacological approaches to pain and symptoms, and has expertise in equianalgesia. The PCN collaborates with the team to develop a plan to aggressively treat pain and symptoms, to reassess interventions, and to evaluate and report the efficacy to the other healthcare providers involved in the patient's care.

Another key role of the PCN is education for patients and families experiencing serious illness and other healthcare professionals unfamiliar with palliative care.[16] It is often the PCN who initiates and leads debriefing of the staff who have faced challenges in caring for a patient, discussing what went well, what could have been done differently, and lessons learned for the future.

The PCN has a major role in coordinating care among all healthcare providers involved in the patient's care. The nurse collaborates with the IDT to identify which team members should be involved in the patient's care based on the patient's acuity (physical, psychological, social, and/or spiritual needs) and with the patient's other healthcare providers across clinical settings (inpatient, ambulatory care, and hospice) to keep them informed of the plan of care and to ensure that the patient's values and wishes are honored.

Advanced Practice Registered Nurse

Specialty trained and board-certified master's or doctorate-prepared APRNs are valuable members of the palliative care team.[17] As nurses, they are able to fulfill the role described for the specialty PCN; however, they are also licensed providers and can determine and order appropriate diagnostic testing and pharmacologic interventions for patients with serious illness. They receive additional training in communication and advance care planning, and many play a leadership role on the palliative care team. Detailed information on the role of the APRN can be found in Chapter 68 "The Advanced Practice Registered Nurse."

Physician

The palliative care physician brings to the palliative care team the clinical expertise of medical diagnosis, knowledge of the disease course, prognostication, expertise in goals-of-care conversations, and medical management, including pain and symptom management. The American Academy of Hospice and Palliative Medicine recognizes the specialty of palliative medicine and offers board certification for physicians completing a fellowship in Hospice and Palliative Medicine.[18]

In addition to specialty medical management, the palliative care physician is helpful in addressing issues and concerns that the primary team may have, clarifying information, and respecting and advocating for the patient's goals and wishes. The physician can assist the team with discharge planning. Assessing the appropriateness of nursing home placement, a rehabilitation facility, a transitional care facility, or hospice (both home and inpatient hospice care) are part of the scope of practice for the palliative care physician.

Social Worker

Social workers are educated to understand complex family dynamics and are skilled at integrating cultural considerations into care, communicating with patients and families, and advocating for patient preferences.[19] A major aspect of their role in caring for patients with serious illness is to assess the needs, strengths, and resources of the patient and family, build on their strengths, enhance their connections to their resources and supports, and connect them with new resources to meet emotional, legal, and financial needs.[20] While the palliative care social worker (PCSW) will follow the patient and family throughout the illness, various primary social workers may also be involved in other clinic visits or hospitalizations. Clear communication between the other social workers involved and the nurse case managers is crucial to ensure the continuity of care and avoid duplication of effort.[21]

Palliative Care Bereavement Coordinator

The role of bereavement coordinator is not a part of every palliative care program, although bereavement care is part of quality palliative care.[4,9] Bereavement coordinators help to identify and follow-up with families at risk for complicated grief. They send cards and resources to bereaved families and make regular calls to those at risk for or exhibiting signs of complicated grief. Often, they coordinate memorial/celebration of life services for family and staff. Many palliative care teams ask that their social worker or chaplain assist in this role.

Volunteers

Some palliative care programs utilize volunteers to offer additional support and services to patients, the families, and the team, as recommended in Domain 1 of the NCP *Guidelines for Quality Palliative Care*.[9] Volunteers require supplementary palliative care training to meet the unique needs of patients with serious illness and their families.

In order for any volunteer program to thrive, particularly a specialized one, someone must be dedicated to training, guiding, and supporting these volunteers. Volunteer coordinators are an important addition to palliative care teams. Most hospitals have a central volunteer program that recruits, selects, and orients hospital volunteers. A palliative care volunteer coordinator works with this central program to identify volunteers who have the interest and skills that match the needs of patients and families cared for by the team. Furthermore, coordinators provide support to these volunteers who give the gift of their time and presence to patients and families during extremely difficult times.[22] Palliative care volunteers should always have access to the coordinator for debriefing and, if possible, to the chaplain or social worker for loss, grief, and bereavement support and as well as moral distress.[23]

Ancillary Disciplines/Consultants

According to the NCP *Guidelines for Quality Palliative Care*,[9] other disciplines may be included on the patient's team, as needed. These ancillary disciplines are consulted for their expertise in areas of need that have been identified by the palliative care team.

Examples of these therapeutic disciplines include, "child-life specialists, nursing assistants, nutritionists, occupational therapists, recreational therapists, respiratory therapists, pharmacists, physical therapists, massage, art, and music therapists, psychologists, and speech and language pathologists."[9] In addition, complementary and alternative therapies such as acupuncture or Reiki, if available, may be utilized to address pain and symptoms management.[24]

Case Study: Demonstrating the Unique Contributions of IDT Members

Jane Smith, a 40-year-old married woman with two young children was diagnosed with a rapidly progressing neurodegenerative disease, amyotrophic lateral sclerosis (ALS). Jane and her husband, Robert, were both working parents at the time of her diagnosis. She and her family were given the devastating news that her life expectancy was 1–5 years and that her ability to live as she had would change dramatically as her disease progressed. Jane worried how her husband would manage caring for their children, John and Sarah, as well as her elderly mother. Early in her diagnosis, the palliative care team was introduced to Jane and her family. Jane learned that this team would help provide support to her and her family across the disease trajectory, as well as manage any symptoms she developed along the way.

Six months post-diagnosis, Jane developed a pneumonia that resulted in respiratory distress, intubation, and admission to an intensive care unit (ICU). She was weaned from the ventilator after a few weeks and moved to an acute medical unit for further recovery. Unfortunately, her disease began to progress more rapidly, affecting her ability to walk and care for herself independently. Due to the financial burden of her 24/7 care needs, she was transferred to a long-term care unit within the hospital. She remained on this unit another 4 months until her death.

Throughout Jane's hospitalization, the inpatient palliative care team continued to care for her. They provided consistency and care coordination as she changed from one unit to the next. The team was able to assess her changing goals as her illness advanced. Following her intubation in the ICU, Jane stated that she did not wish to go back on a ventilator ever again. She felt very strongly about this decision, even though her husband was hesitant to relinquish this potentially life-prolonging intervention. As her illness advanced, Jane's decisions centered around prolonging her time with her family but stopped short of wanting aggressive resuscitative measures. In this case study, you will see how the palliative care team helped Jane by advocating for her goals of care and framed her decisions with her family and staff in the context of her desired QOL.

The following paragraphs detail how the role of each team member improved patient and family QOL.

Palliative Care Chaplain

The chaplain became acquainted with Jane while participating in morning rounds as a member of the palliative care team. He reviewed her pertinent background information in the medical record and also consulted with the bedside RN to gain insight into the patient's mood, recent medical events, and any observed interactions with family before going to her room.

On first meeting, the chaplain identified himself and inquired whether or not Jane desired a chaplain visit. She welcomed a visit but immediately in the conversation identified herself as "not religious." The chaplain offered affirmation of Jane's experiences with structured religion and invited further broadening of the discussion as to the things that she felt gave her life meaning and connection. Jane stated that she found greatest meaning when she was engaged in her children's lives and, therefore, was experiencing anxiety due to loss of involvement with them because of her current hospitalization. She also stated that she was struggling with loss of autonomy, as she was now dependent on others for her care.

The chaplain employed active listening in an effort to assist the patient in identifying and celebrating ways that her influence continues to play a role in her children's development, exploring ways she could feel less isolated, and allowing emotional space for the patient to safely express her fears and frustrations. At the conclusion of the visit, Jane expressed that she felt less anxious and thanked the chaplain for the opportunity to give voice to her existential struggles. She also indicated that she was open to follow-up visits and invited the chaplain to return when her husband was present so that he could also feel supported. Immediately after the visit, the chaplain documented a detailed spiritual assessment in the patient's medical record and a follow-up plan and consulted with the other members of the palliative care team.

Palliative Care Nurse

The PCN became actively involved in Jane's care during her intensive care unit (ICU) admission. The palliative care nurse completed a thorough physical assessment, paying close attention to Jane's pain and other distressing symptoms. The PCN then gathered information from the ICU team regarding Jane's condition, sharing changes, concerns regarding progression of disease, and treatment options with the rest of the palliative care team. From there, the PCN coordinated a formal family meeting with Jane, her family, and the palliative care team to discuss concerns, changes in condition, and goals of care, and to provide emotional support to Jane and her family. After Jane was successfully extubated, the nurse ensured that all members of the IDT and other healthcare providers were aware that Jane did not want to be re-intubated, documenting the patient's wishes in the electronic medical record.

Knowing that care preferences can change over time, the PCN continued to check in with Jane and her family. The PCN provided a mindful presence to allow Jane and her family to process difficult information and concerns. Although Jane's husband did not agree with her decision not to be re-intubated, the PCN allowed Jane's husband to express his distress and assisted him in reframing expectations for Jane's care through her eyes.

Throughout the trajectory of Jane's hospitalization, the PCN assisted in assessing, planning, intervening, and reassessing Jane's pain and symptoms. Recognizing that Jane's distress was not only physical, but also spiritual and emotional pain, the palliative care nurse collaborated with the chaplain and social workers to ensure that Jane's needs were being addressed. As Jane's disease progressed, she expressed that she did not want to die at home and was aware that it would be too difficult for the family to provide the level of nursing care she needed, 24/7. Although hospice services were offered, she preferred to die in the hospital's long-term care unit, with the palliative care team she knew well.

Palliative Care Physician

The palliative care physician met Jane for the first time at the time of diagnosis, in the neurology clinic and then again as an inpatient when she was admitted to the hospital. In both instances, it was critical to assess her understanding of her disease and its progressive, life-limiting nature; treatment options; and symptoms, as well as her need for psychological, social, and spiritual support.

Management of her dyspnea and pain were critical during her hospitalization. The physician worked with the palliative care team and respiratory therapy to develop a plan to keep Jane as comfortable as possible. Specific conversations with Jane and her husband during her hospital admission included a discussion about the eventual respiratory failure that results from this disease and the treatment options available when that time comes. A discussion of re-intubation and tracheostomy, the risks and benefits, as well as expectations that accompany each option were presented during her hospitalization. QOL and patient values were at the center of these conversations.

During Jane's stay in the long-term care unit, the physician, along with the palliative care team, continued the conversation about goals of care and began to discuss end-of-life planning. That conversation included a discussion of eating for pleasure, despite its aspiration risks. For her, the comfort and pleasure associated with eating was always worth the risk. Jane preferred to die in the long-term care unit rather than at home or in a hospice facility. She requested the palliative care team continue to care for her and her family.

Palliative Care Social Worker

The PCSW, along with the palliative care team physician, met Jane, Robert, and Jane's mother at the neurology clinic shortly after diagnosis to provide emotional support to them for the trauma of Jane's being diagnosed with such a devastating life-limiting illness. The PCSW acknowledged that the grieving of the loss of their life together had already begun and offered support groups locally and online that could help the family, as well as tips on communicating and supporting the children as Jane's disease progressed.

Through the psychosocial assessment, it became clear that the family's support system of friends, neighbors, and faith community had offered to help with whatever was needed, but Jane and Robert were uncomfortable accepting help and were so overwhelmed that they didn't know what help to ask for. The PCSW gave them a free online resource with which to create a care calendar where their needs could be listed and friends could sign up to help; the PCSW helped them identify a neighbor who could manage the website.

When the PCSW met with Jane in the hospital, she was nearing the end of her sick leave from work, which meant the end of her health insurance. The PCSW gave them directions on how to apply for Social Security Disability and took this opportunity to suggest that Jane complete a Healthcare Power of Attorney and a Last Will and Testament.

When Jane was admitted to the ICU with an aspiration event, the PCSW met with Robert and Jane's mother for support, and connected Robert with the Child Life Therapist who guided Robert in how to prepare the children to visit Jane in the ICU and to answer their questions about when Jane would be able to talk to them again. After Jane's continued decline in the transitional care unit left her unable to feed herself, but wanting to eat in spite of risk of aspiration pneumonia, the PCSW had discussions with Robert respecting her wishes, including no re-intubation.

As Jane's death became imminent, the PCSW reconnected Robert with the Child Life therapist for help in telling the children that Jane was dying. Robert was given Grief Recovery books for the children to read after their mother's death and a list of grief resources (counselors, groups, camps, websites, and a book list) for Robert and the children. The chaplain and the PCSW made certain that Jane's room was peaceful and provided support to the family throughout Jane's last day.

The palliative care team, led by the PCSW and chaplain, held a debriefing session for staff the week after her death. They, too, were grieving the loss of this vibrant woman whose independence they grew to admire despite their moral distress that it could hasten her death. Nine months later, at the Hospital's Bereavement Service, which Jane's entire family attended, Robert shared with the PCSW that the bereavement cards he received quarterly from the palliative care team helped him realize that others were still thinking of Jane. He had the children enrolled in a grief camp in the coming months, and the family grief recovery group they attended at their church helped the entire family know they were not alone in their grief.

Volunteers

The Smith family benefited from the presence of palliative care volunteers throughout the course of Jane's hospitalization. When Jane was initially admitted to the ICU, palliative care volunteers provided supportive visits to her family and brought the children coloring books and other activities to use while visiting at the hospital. As Jane improved and was no longer intubated, volunteers were able to communicate with her directly and provide supportive visits when her family members were at school and at work.

The palliative care volunteers continued this supportive relationship as Jane transferred to other units within the hospital. Their continued visitation furnished a consistent, nonclinical relationship based on providing compassionate presence, active listening, and comfort. Over time, the volunteers provided many services to both Jane and her family, including helping her with journaling and assisting her with composing letters and cards for her children after she was gone. As Jane's illness progressed and her family struggled to cope with their inevitable loss, a volunteer assisted with legacy work for her children, making memory stones with Jane's fingerprint. Jane's children were able to carry these stones with her fingerprint in their pockets wherever they went, feeling their mom's presence.

Ancillary Disciplines Consulted

Ethics consultation. After Jane's transfer to a long-term care unit within the hospital, staff grew concerned about her ability to swallow food and drink. Both her family and staff worried she might aspirate again and questioned whether they should continue to provide comfort feeding. Jane made it clear to everyone that eating was an important aspect of her life and she did not want life support if she aspirated. Due to the distress of family and the staff taking care of Jane, an ethics consult was called to help clarify the situation. Through the ethics consultation, it was determined that because her wishes were well-known and documented in her advance directive, there was no conflict with feeding her.

Respiratory therapy. Respiratory therapy was involved throughout Jane's hospitalization from intubation in the ICU to her final hours of life. Respiratory therapists worked with Jane on maintaining her lung function and airway clearance for as long as possible and tailored their interventions to support her wishes of no re-intubation.

Physical and occupational therapy. Physical and occupational therapy were involved in Jane's care plan from her time of diagnosis to help preserve her functional status, safety, and ability to perform activities of daily living (ADLs) independently for as long as possible.

Speech language pathology. Speech language pathologists (SLPs) worked to prolong Jane's ability to speak, eat, and drink by teaching her exercises and compensatory strategies as the disease progressed. Understanding her desire to continue eating and not be re-intubated, they worked to educate Jane, her family, and the staff on foods and techniques to reduce the risk of aspiration events.

Registered dietitian/nutritionist (RDN). As Jane grew weaker, the RDN was consulted for supplemental nutrition via percutaneous endoscopic gastrostomy (PEG) tube. Although Jane did not desire most forms of life support, receiving supplemental nutrition via a PEG tube supported her goal to have as much quality time with her family as possible. The RDN recommended nocturnal feedings with comfort meals during the day. In Jane's final days, the RDN worked with the palliative care team to reassure her husband that supplemental nutrition was no longer necessary and that feedings at this juncture would actually do her harm.

Child life specialists (CLSs). Child life specialists have training in the emotional and developmental needs of children facing illness and expertise in pediatric bereavement and coping strategies. CLSs supported Jane's children during the ICU experience and helped both parents prepare the children for Jane's decline and impending death.

Palliative care bereavement coordinator. The bereavement coordinator followed-up with Jane's family through telephone calls and cards for 12 months following her death. The bereavement coordinator provided resources to help the children, such as bereavement camps and support groups designed for children, as well as resources for Jane's husband. In addition, the bereavement coordinator provided staff debriefings to promote staff grieving and coping. At the yearly remembrance ceremony, Jane's family and staff were reconnected.

Case Study Summary

By having access to a palliative care team that addressed physical, psychological, social, and spiritual needs, and coordinated all necessary services, Jane had the opportunity for the best possible outcomes in the face of her illness. But what made her wishes a potential reality was the communication between her palliative care team and her other healthcare providers. Without assessment, reassessment, and collaboration between disciplines and services, it would not have been possible to tailor her care based upon what was most important to Jane and her family. A strong palliative care team, comprising a physician, nurse, social worker, and chaplain, can support a patient like Jane by honoring her wishes, providing aggressive pain and symptom management, and offering support and grief counseling and spiritual care for existential distress.

Palliative Care Delivery Models

Inpatient Palliative Care Consult Team

Inpatient consult services have grown in number by more than 180%[1] and are now available in 96% of all academic medical centers.[4] Most consult services usually include a basic team of board-certified palliative care physicians and nurses, including advance practice registered nurses. Ideally, a PCSW and chaplain are also on the team, but, in some institutions, the palliative care team must use the institution's social workers and hospital chaplaincy for support. Providers on the palliative care team (physicians and advanced practice registered nurses) are to be compensated for their consulting services, similar to other specialty consult services.[4] Research has demonstrated that inpatient palliative care services decrease hospital costs, ICU admissions, and emergency room visits as well as improve patient satisfaction, alleviate symptom burden, improve hospice utilization, and improve QOL.[1,4,25]

The majority of patients with advanced illness die in acute care settings or in long-term acute care facilities, despite the fact that most people prefer to die at home.[4,10] For patients who are newly diagnosed with a serious illness, the palliative care team assists in providing information regarding the illness trajectory and treatment options and serves as a conduit of communication between the patient and family, healthcare providers, therapy services, and community resources (i.e., home health, Veterans Benefits, ambulatory palliative care, or hospice services). For inpatient consults that arise later in the disease process, the palliative care team often is needed for advance care planning conversations, including hospice care. Patients may not want more diagnostic tests, procedures, or disease-modifying treatments, all of which increase their time spent in observation units or in inpatient settings. It is imperative that the inpatient palliative care team addresses what is most important to the patient so that goals of care are reflective of the patient's values and preferences.

For patients who are actively dying in inpatient settings, a consult to the palliative care team helps identify the patient's goals and preferences for end-of-life care. The palliative care team's role is to not only support and uphold the patient's goals of care, but also to provide support to the family and the primary team. If the inpatient facility has a palliative care unit, transfer to that unit, which has skilled PCNs providing 24/7 care, can provide the best possible care for the patient and family who are unable or uncomfortable returning home with hospice care.

For patients who are discharged from the hospital and wish to continue with life-prolonging treatments, ambulatory palliative care, if available, can assist the patient with pain and symptom management and continue conversations regarding goals of care. Outpatient palliative care usually occurs in ambulatory care centers or specialty clinics.

Ambulatory Palliative Care Teams

The landmark study by Temel et al.[7] demonstrated that outpatient palliative care not only improves QOL for patients with advanced lung cancer, but also improves length of life. Ambulatory palliative care teams have been shown to improve patient and family satisfaction and ensure that care is consistent with patient wishes.[2,8] In addition, this outpatient care improves early access to palliative care, improves symptom management, and has decreased the utilization of hospital resources, especially emergency room visits.[2] During an outpatient palliative care visit, patients can be assessed by many members of the IDT in a single setting and, depending on patient and family need, during one visit.[26]

Community-Based Palliative Care Teams

Although palliative care is predominantly practiced in the inpatient setting, community-based palliative care (CBPC) is rapidly growing and providing services in the place where patients spend most of their time—outside of the hospital.[9,27] CBPC is provided in the patient's home or wherever the patient resides, such as assisted living or skilled nursing facilities. The team's ability to go where the patient is decreases the burden and stress associated with transportation to the ambulatory clinic or physician's office. When the patient is not eligible for hospice care or does not elect hospice services, CBPC fills a gap that had previously existed in the healthcare system.

When palliative care becomes involved earlier in the trajectory of illness and within the patient's home, trusting relationships can be built and difficult conversations regarding goals of care can be done earlier.[28] Research has shown that patients receiving CBPC tend to be referred to hospice earlier and have an increased median and total length of stay on hospice care.[27,28] The team is able to offer support in the home, help establish clear goals of care with the patient and family, and provide expertise in pain and symptom management.[29] This model of palliative care delivery is decreasing unwanted hospital, ICU, and emergency room admissions.[1] However, access to CBPC currently is limited in many areas of the country.

The Hospice Team

Hospice care is palliative care for patients and families in the last 6 months of life who choose to forego disease-modifying treatment.[10] The overall focus of hospice is to provide comfort and improve all domains of QOL: physical, psychological, social, and spiritual. Hospice care is provided by a palliative care IDT including physicians, nurses, social workers, chaplains, hospice aides, volunteers, and other disciplines as needed.

The Medicare Hospice Benefit[11] defines patient's hospice eligibility based on prognostication: when two doctors certify that there is a prognosis equal to or less than 6 months to live, assuming the disease takes its natural course, the patient becomes hospice-eligible.[11] The Medicare hospice benefit, or other insurance hospice benefit, covers the cost for all hospice team services as well as any medical equipment and all medications related to the patient's serious illness at no additional cost. If a patient does not have insurance but is eligible for and desires hospice care, a Medicare-certified hospice must provide care, regardless of ability to pay.[11]

The hospice team delivers care wherever the patient is living, in the home, assisted living, hospital, or long-term care nursing facility. Hospices provide 24/7 coverage as well as short-term general inpatient hospice (GIP) care for patients whose symptoms are difficult to control, as well as short-term respite care for exhausted caregivers caring for the patient in the home.[10] It is important that patients who qualify for hospice-level care and their families are educated about the benefits of hospice care. Many are misinformed, thinking that hospice is a place, rather than a palliative care delivery model, or that hospice care is only for the final days or weeks of life. Early intervention with hospice care provides the best quality care, rather than crisis intervention, for all who are eligible for this care.[30] Additional information about hospice and palliative care is found in Chapter 1.

Building a Palliative Care Team

When considering starting a palliative care team or enhancing a team, many things need to be taken into consideration. It is critical to identify the vision of what the goal of the team is and how it will meet the needs of the institution. This will vary from institution to institution based on resources, mission and size of the institution, administrative priorities, educational requirements, demographics of the patient population, and the plan to include learners, as well as the overall value that palliative care has as an institutional core value. The palliative care members included on the team will vary greatly based on institutional requirements/resources as well as on the team's mission (i.e., whether it is a consult service, an outpatient service, a clinic, or an inpatient unit).[4,5] The leadership within the palliative care team must ensure that all members of the palliative care team share the same vision so that there is no miscommunication about the role which palliative care may fill as it evolves.

Convincing the administration of the importance of palliative care for the institution requires understanding the values that palliative care brings to a healthcare system. The vision/mission of palliative care must coincide with that of the institution. Improved patient and family satisfaction scores as well as substantial cost savings to the institution, including decreased 30-day readmission rates, are data that must be tracked.[31]

Resources for developing a palliative care team are readily available.[4] For the palliative care team to be successful, there must be a business plan that includes exploring the financial impact of the program as well as looking at the basic needs of the evolving program. These needs may include financial support from the institution, a plan to increase the workforce when the program census grows, and monitoring data on the impact of quality improvement, such as improved pain scores or lower readmission numbers.[4] In addition, a plan for recruitment and retention of palliative care clinicians is important to consider at the time of development.

Palliative care teams require leadership and structure so that each member is aware of the defined expectations of his or her role. Much of this work can be accomplished with clear policies and procedures and a strong orientation program. However, the most effective way to build and grow a team is with ongoing, effective team communication.[30] Detailed information on how to start and maintain a strong palliative care team is beyond the purview of this chapter but is available from the Center to Advance Palliative Care.[4]

Sustaining a Healthy, Functioning Palliative Care Team

A healthy team is one in which the members respect and appreciate their team members as individuals and the team as a whole unit. Team members must all share the same team values, mission, and vision. Team members need clearly delineated roles but must understand that there are many aspects of palliative care that are shared by each discipline.[3] There needs to be shared accountability for quality patient and family care, and work and productivity expectations must be transparent.[32]

According to Guideline 1.8 of the NCP *Guidelines for Quality Palliative Care*,[9] the palliative care program must recognize the emotional impact that caring for those with serious illness has on team members. Processes need to be in place to provide support for sustainability. Burnout and compassion fatigue in hospice and palliative care professionals are significant and are on the rise, making retention a problem for some teams. Clinician burnout has been reported to be as high as 62%.[33] Proactive team activities for individual and team self-care, resilience strategies, and healthy work environment are critical to success. Many palliative care teams have adopted personal and team wellness programs; regularly scheduled debriefing sessions to vent frustrations, anger, and concerns; and a plan for crisis debriefing.

Whenever a team comprises more than one individual, conflict is inevitable. It is important that team members are aware of symptoms of stress and conflict and are comfortable discussing them openly. Poorly functioning teams suffer from rivalry, mistrust, and role ambiguity, all of which are toxic to team health. Team building activities that encourage trust and mutual respect will help to prevent these challenges from arising. Most importantly, the team needs to keep its focus on its agreed upon mission and values: care that is in the best interest of the patient and family.[3]

Palliative care requires the expertise of a strong interdisciplinary team to meet the unique and challenging needs of the patients and families that are cared for on a daily basis. Although working as a team adds a layer of challenges, including conflicting work schedules, role overlap, differing opinions, and, on occasion, conflict, team collaboration allows the palliative team to offer a higher level of service for patients and families while supporting the needs of its individual team members.

Conclusion

Palliative care is best delivered by an IDT that attends to the physical, psychological, social, and spiritual well-being of patients with serious illness and their families.

The NCP *Guidelines for Quality Palliative Care* [9]give direction for the structure and processes of developing and sustaining palliative care teams. Interdisciplinary professionals bring their unique individual discipline's expertise to the patient's plan of care and then collaborate as a team to achieve the best possible patient and family outcomes. The models of palliative care delivery vary in their settings, reimbursement, and eligibility; however, the mission and vision for all models of palliative care are focused on the patient and family goals of care and QOL. A team that works collaboratively and addresses individual and team wellness will be resilient and sustainable, despite team challenges and changing dynamics of the healthcare system. Most importantly, the team will be rewarded with the professional satisfaction of delivering quality palliative care to all those in their care.

CHAPTER 8

Pain Assessment

Regina M. Fink, Rose A. Gates,
and Kate D. Jeffers

Key Points

- Pain is a multidimensional experience.
- There are multiple, persistent barriers to pain assessment.
- Patient's self-report of pain is the gold standard, even for those who are nonverbal or cognitively impaired.
- Patients or residents should be screened for pain on admission to a hospital, clinic, long-term care facility, hospice, or home care setting.
- If pain is reported, a comprehensive pain assessment should be performed at regular intervals, whenever there is a change in the pain, and after any modifications in the pain management plan.
- A comfort/function goal describes how much pain can occur without interfering with function, quality of life, and is the level of pain that will enable function and comfort.
- Dosing analgesics based only on a pain intensity score is not recommended as it disregards the relevance of other vital pain assessment elements (e.g., pain interference on function) and may contribute to untoward patient outcomes.
- Risk factors for and presence of substance use disorders should be assessed in all patients.
- Pain assessment instruments should be evidence-based, valid, and reliable, and culturally tailored based on the patient's age, cognition, and language.
- Healthcare providers need to examine their personal biases and attitudes toward patients with different ethnic backgrounds.
- Patients or residents unable to speak for themselves should be assessed by observation of pain behaviors and family caregiver proxy or surrogate reporting.

Introduction

Unrelieved pain is one of the most frequent reasons for palliative care consultation.[1] Evidence demonstrates that pain is prevalent and undertreated in the palliative care setting, contributing significantly to patient discomfort and suffering at the end of life.[2,3] Among hospitalized patients, multiple distressing symptoms, including pain, worsen during a patient's final admission, and approximately 40% suffer from uncontrolled pain within the last few days of life.[4,5] Even in the care-oriented culture of hospice and palliative care, pain is one of the most bothersome symptoms requiring more intensive management and sedation during the last weeks of life.[6,7] A nationally representative longitudinal survey of US community-dwelling residents found pain to be prevalent in the last year of life, ranging from 54–61%, with a solid upward trend from 1998 through 2010.[8]

Pain is also a concern in patients with cancer throughout the illness trajectory. According to a systematic review/meta-analysis of 122 articles published since 2005, cancer pain prevalence rates are 39% post curative treatment; 55% during anticancer therapy; 66% in advanced, metastatic, or terminal disease; and 51% among all cancer stages.[9] Approximately 40% of cancer patients report moderate to severe pain (defined as ≥5 on a 0–10 numeric rating scale).[9] Regarding pain experience by cancer type, 70% of patients with head and neck cancer experienced the most pain, followed by patients with gynecologic malignancies (60%), those with gastrointestinal (colon, esophageal, pancreatic) cancers (59%), with lung cancer (55%), with breast cancer (54%), and with urogenital (prostate, bladder) cancer (52%).[9]

Pain relief in long-term care (LTC) varies widely, with 45–80% of residents having substantial pain with suboptimal pain treatment.[10] Pain continues to be poorly assessed, with more than one-third of LTC residents having no formal or regularly scheduled pain assessment, despite implementation of pain assessment documentation required by the Minimum Data Set (MDS) 3.0.[11] Even with an intensive educational initiative and support provided to nursing staff in 27 nursing homes, researchers found no statistically significant difference in adherence to clinical guideline practice pain recommendations, with pain continuing to be prevalent in LTC residents.[12]

This chapter reviews various pain types, barriers to pain assessment, and guidelines for pain assessment in the palliative care setting. A multidimensional model for pain assessment is described, and multiple instruments that can be used to assess pain in verbal, nonverbal, and cognitively impaired patients are appraised. Two case studies are presented for discussion.

Pain Types

According to the International Association for the Study of Pain (IASP), pain is defined as "an unpleasant sensory or emotional experience associated with actual or potential tissue damage, or described in terms of such damage. The inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment."[13] Pain has also been clinically defined as "whatever the experiencing person says it is, existing whenever the experiencing person says it does."[14]

Pain is commonly described in terms of categorization along a continuum of duration. An understanding of the characteristics, severity, and nature of the pain is essential to providing appropriate treatment. *Acute pain* is usually of brief duration: hours, days, weeks, or a few months and associated with tissue damage, inflammation, or a surgical procedure. Acute pain serves as a warning that something is wrong and is generally viewed as a time-limited experience. In contrast, *persistent* or *chronic pain* worsens and intensifies with the passage of time, lasts for an extended period (months, years, or a lifetime), and adversely affects the patient's function or well-being. The term "persistent" is favored as it is not associated with the negative stereotype often associated with a chronic pain patient label.[9] Approximately 15% of adults in United States have pain lasting longer than 3 months.[15] Persistent pain may accompany a disease process such as acquired immune deficiency syndrome (AIDS), arthritis or degenerative joint disease, chronic obstructive pulmonary disease (COPD), heart failure, neurological disorders (e.g., multiple sclerosis, cerebrovascular disease, Parkinson's disease), fibromyalgia, sickle cell disease, cystic fibrosis, and diabetes. It may also be associated with an injury that has not resolved within an expected period of time, such as low back pain, trauma, spinal cord injury, complex regional pain syndrome, postherpetic neuralgia, or phantom limb pain. The terms "cancer pain" or "cancer-related pain" have been used to distinguish pain in patients with a malignancy from those without a malignancy (nonmalignant pain). Cancer-related pain can present as acute or persistent pain, related to primary or metastatic disease, the result of treatment (surgery, chemotherapy, biotherapy, radiation therapy, or procedures), side effects of treatment, or infection.[16]

There are two predominant pathophysiologies of pain, nociceptive or neuropathic, although pain can also present with a mixed picture. Nociceptive pain arises from actual or threatened damage to non-neural tissues due to the activation of nociceptors. Nociceptive pain can be further divided into visceral or somatic pain.[13] In contrast, neuropathic pain is caused by injury to the peripheral or central nervous system.[16]

Case Study 1: Pain in a Patient with Rectal Cancer

Mrs. Amelia G. is a 30-year-old Hispanic woman with rectal cancer and lung metastases. She is married, with two children, ages 3 and 7 years. Her husband is rarely at home due to traveling with his job. Her mother lives with her to help care for the children. Three years ago, after delivering her baby, she developed bleeding from hemorrhoids. Subsequently, she began to have abdominal pain and marked constipation accompanied by an approximate 50-pound weight loss. She had insurance issues and was unable to see a primary care physician for 6 months. Physical exam revealed an anorectal mass and colonoscopy showed a large, obstructing, fungating mass in the rectum. No metastatic disease was present on computed tomography (CT) chest, abdomen, and pelvis. She underwent a resection and diverting colostomy; biopsies showed well to moderately differentiated invasive adenocarcinoma. Positron emission tomography (PET) and CT scan suggested increased metabolic activity in lymph nodes adjacent to the rectal mass and left perihilar region and a right lower lung nodule consistent with metastatic disease. She underwent video-assisted thoracoscopic surgery (VATS); the right lung nodule was positive for metastatic disease. Approximately 4 weeks postoperative, she started chemotherapy with the FOLFOX regimen (5 FU, leucovorin, oxaliplatin) every 14 days. Bevacizumab (Avastin) and Neupogen were added with the third cycle. PET/CT after 2 months of chemotherapy showed no evidence of active disease. She completed her chemotherapy concurrently with radiation therapy. A restaging PET scan showed no progressive disease. She was then scheduled for a low anterior resection and possible ostomy reversal, which revealed residual rectal adenocarcinoma, minimal treatment effect, and perineural invasion. She continued with chemotherapy, and 6 months later a CT scan showed enlarging pulmonary nodules consistent with disseminated cancer recurrence in her lungs. She also developed left hip pain and was found to have a sacral fracture. A month later, a PET/CT showed more extensive bilateral pulmonary metastatic disease with mediastinal and hilar adenopathy. She was recommended to start a different chemotherapy regimen, but delayed initiation of chemotherapy for a number of months to get stronger. She received FOLFIRI chemotherapy at reduced doses with a plan to add panitumumab when she tolerates the current treatment.

Her symptoms included anorexia, fatigue, neuropathy in her feet related to prior oxaliplatin, cough with occasional hemoptysis, anxiety, intermittent diarrhea, and persistent and breakthrough pain in her abdomen and back. She took oxycodone 10 mg every 3 to 4 hours as needed for pain and alprazolam for anxiety. She was evaluated and counseled by her dietician. She verbalized understanding that her cancer is "serious," but remained hopeful to live as long as she can so she can care for her children. After much encouragement, she agreed to a palliative care referral for symptom management and to provide support for her family.

Discussion Questions

1. What are the types of pain that Amelia experienced?
2. What are appropriate ways of assessing her pain?
3. Based on the patient's condition and pain experience, what pharmacological approaches might you suggest for pain control? What, if any, adjuvants might be helpful to include? What long-acting opioid might you suggest?
4. What nonpharmacological strategies would you incorporate into the pain management plan of care?
5. What other symptoms or side effects might you be concerned about? How will you address these? In particular, how would you manage opioid-induced constipation?
6. How does the patient's prognosis affect the intensity of her pain?
7. Describe how the patient's ethnicity may affect her expression of pain, her response to analgesics, and the provider's management of her pain?

Barriers to Optimal Pain Assessment

Over the past five decades, a plethora of research has generated knowledge about pain and its management. However, problems continue in the misuse of information or unwillingness of healthcare professionals to appropriately apply knowledge from research and advances in technology. Furthermore, clinicians fail to adequately evaluate or assess the nature of pain or the totality of a patient's problems. The current opioid crisis has also introduced new barriers to the adequate and timely control of pain in patients with chronic conditions, as well as in those in palliative care settings. Review Box 8.1 for multiple barriers to optimal pain assessment.[17–21]

Box 8.1 Barriers to Optimal Pain Assessment

Healthcare Professional Barriers

Lack of identification of pain assessment and relief as a priority in patient care

Inadequate knowledge about pain assessment

Perceived lack of time to conduct and document a pain assessment and reassessment

Failure to use valid and reliable pain measurement instruments

Inability of clinician to empathize or establish rapport with patient

Fear of patient or family caregiver opioid misuse

Lack of care continuity

Lack of communication among the healthcare professional team

Prejudice or bias in dealing with patients

Failure to accept the patient's pain reports

Healthcare System Barriers

A system that fails to hold healthcare professionals accountable for pain assessment

Shorter lengths of stay, early discharge without adequate time to assess pain and evaluate newly prescribed pain management regimens

Lack of criteria or availability of culturally tailored instruments for pain assessment in certain settings

Lack of institutional policies for performance and documentation of pain assessment by electronic health record

Lack of time to talk with patients about pain

Lack of access to a pain management specialist

Restrictive opioid prescription policies

Patient, Family, Societal Barriers

The highly subjective and personal nature of the pain experience

Lack of patient communication with healthcare professionals about pain:

- Lack of a common language to describe pain
- Compromised communication skills, such as sensory or cognitive impairment
- Patient fears or beliefs (addiction, not being believed, not wanting to bother staff, age-related stoicism, doesn't report pain because "nothing helps," curative therapy may be curtailed due to pain)
- Patient inability to pay for medications or self-care strategies
- Marginal patient involvement in pain plan of care
- Negative public image of opioids

Source: Adapted from References 17–21.

Pain Assessment Guidelines and Standards

Recognition of the widespread inadequacy of pain assessment and management has prompted corrective efforts within many healthcare disciplines, including nursing, medicine, pharmacy, and pain management organizations to develop clinical practice guidelines and quality assurance recommendations for the assessment and management of acute, cancer, and end-of-life pain.[10,16,21–30] In addition, the Centers for Disease Control (CDC) Guideline for Prescribing Opioids for Chronic Pain[15] focuses on three main areas: (1) determining when to initiate or continue opioids in patients with chronic pain, (2) opioid selection, and (3) assessing risk and addressing harms of opioid use in all patients. Although the guidelines are not aimed at cancer patients receiving active treatment and patients receiving palliative or end-of-life care, they have the potential to influence pain assessment and use of opioids in these populations and settings.

Despite the availability of effective medications and clinical guidelines for pain management, pain control is suboptimal in a sizeable proportion of patients with cancer pain. The National Comprehensive Cancer Network Guidelines for Cancer Pain recommend a comprehensive and multimodal pain management approach.[16] Changes in standards and pain management guidelines are continually evolving as more data are discovered about the effectiveness of assessment tools in relationship to prescribing patterns of analgesics. For example, the American Society of Pain Management Nurses (ASPMN)[31] published a position paper on not prescribing and dosing opioid analgesics based solely on a patient's pain intensity as it disregards the relevance of other vital elements of an assessment and may contribute to untoward patient outcomes. Additionally, the Joint Commission[32] has announced new pain assessment and management standards that include the following:

- Identifying a leadership team responsible for safe opioid pain management
- Involving patients in their treatment plan, setting realistic goals and expectations
- Promoting safe opioid use by identifying and monitoring high-risk patients
- Facilitating clinician access to prescription drug-monitoring databases
- Conducting performance improvement activities focusing on pain assessment and management to increase quality and safety for patients

In particular, each accredited hospital must have defined criteria to screen, assess, and reassess pain consistent with the patient's age, condition, and ability to understand. This underscores the need for culturally sensitive, age-appropriate pain rating scale availability to assist with assessment activities.

Patient-centered care requires that healthcare professionals seek opportunities to empower patients and family caregivers in decision-making about their care, taking into account their personal preferences and values. It also includes evaluation of the patient's knowledge, beliefs, concerns, and misconceptions about pain and its management.[33,34] Table 8.1 reviews various barriers that may play a role in pain assessment, function, and response to treatment.[33,34] Patients may be reluctant to tell the nurse and other healthcare providers when they have pain. They may attempt to

Table 8.1 Patient and family caregiver beliefs, concerns, and misconceptions about pain and its management

Disease-related	◆ If the pain is worse, it must mean I am getting worse or my cancer is spreading. ◆ Pain is inevitable. I just need to bear it. ◆ If I tell about my pain it may lead to more tests and treatments.
Sociocultural or spiritual-related	◆ Admitting pain is a sign of weakness. ◆ I don't want to worry my family. ◆ If I talk about my pain it may lead to a loss of independence. ◆ Good patients avoid talking about pain. ◆ It's OK to suffer; that's part of life and a way to eternal life. ◆ I don't want to bother the nurse or doctor; they're busy with other patients.
Medication-related	◆ I better wait to take my pain medication until I really need it or else it won't work later. ◆ My family thinks the pain medication makes me "spacey"; I'd better hold back. ◆ If it's morphine, I must be getting close to the end. ◆ If I take opioids regularly, I will get addicted. ◆ If I take my pain medication before I hurt, I will end up taking too much. It's better to "hang in there and tough it out." ◆ I'd rather have a good bowel movement than take pain medication and get constipated. ◆ If I take too much pain medication, I could die.
Family caregiver beliefs, concerns, misconceptions	◆ My loved one will experience too many side effects ('knocked out', drowsy, or constipated). ◆ Pain treatments may not work. ◆ I worry about overdose. ◆ I am concerned about tolerance. ◆ I am concerned about my loved one becoming addicted. ◆ My loved one does not want to be viewed as weak.

Source: Adapted from References 33, 34.

minimize its severity, may not know they can expect pain relief, and may be concerned about taking pain medications for fear of deleterious effects. Involving patients and family caregivers in the pain assessment process is integral to improving pain management with the desired outcome of decreased pain for patients.

Pain Assessment

Accurate pain assessment is the cornerstone to optimal pain management; it is a continuous process that encompasses multidimensional factors. In formulating a pain management plan of care, a comprehensive pain assessment is crucial and includes a detailed history, a comprehensive physical examination, and patient self-report of pain.

History

It is important to take a detailed history incorporating a review of events leading up to the present illness, key medical comorbidities (including medication use), symptoms, substance abuse disorder (including aberrancy and medication diversion), genetics, and psychological and sociocultural issues that may contribute to pain and/or impact pain management and response to treatment. In the future, genetics could play a significant role in pain assessment and treatment. Research findings have now substantiated the role of pharmacogenomics in affecting individual variability in drug responses.[35] Pharmacogenomics is the study of the effects of genetic factors or genome on drug responses. Soon, healthcare providers may be able to predict an individual's response to particular analgesics based upon pharmacogenetic test results. Increased availability and decreased costs may lead to greater provider utilization of pharmacogenetic testing to determine the best drug to prescribe for an individual patient with various conditions.

Physical Examination

A comprehensive physical examination includes inspection of affected painful areas and common referred pain locations and evaluation of musculoskeletal and neurological systems, especially if neuropathic pain is suspected. In frail or terminally ill patients, physical examination maneuvers and diagnostic tests should be performed only if the findings will potentially change or facilitate the treatment plan. As pain is often accompanied with depression in more than one-third of patients, a psychological exam or psychosocial assessment may be warranted.[36] The burden and potential discomfort of any diagnostic test must be weighed against the potential benefit of the information obtained.

Patient Self-Report

A patient's self-report of pain is most valuable in directing pain management. Pain mnemonics (displayed in Table 8.2) can assist nurses and other healthcare providers in querying patients about key pain assessment components.[37–40] The WILDA approach begins with an open-ended question, "Tell me about your pain," facilitating the patient's story and including the most problematic aspects of the pain experience.[40]

- ***Words***: Ask the patient to describe his pain or discomfort using descriptors. Table 8.3 summarizes pain types, etiological factors, descriptors, and potential interventions based on pain type.[41]

Table 8.2 Pain mnemonics

Mnemonic	Assessment parameters
OLDCART	◆ **O**nset: When did the pain start? ◆ **L**ocation: Where is the pain located? ◆ **D**uration: How often does the pain occur? How long does the pain last? ◆ **C**haracteristics: How does the pain feel (intensity)? What words would you use to describe the pain? ◆ **A**ggravating Factors: What makes your pain worse? ◆ **R**elieving Factors: What makes your pain better? ◆ **T**reatment: What treatments have you tried to control the pain? How are they working? How do the treatments affect the pain intensity?
PEG	◆ **P**ain on average ◆ **E**njoyment: Interference with enjoyment of life ◆ **G**eneral activity: Interference with general activity
PQRST(A)	◆ **P**rovocation/Palliation: What caused it? What relieves it? ◆ **Q**uality: What does it feel like? ◆ **R**egion/**R**adiation: Where is the pain located? Does the pain radiate? ◆ **S**everity: How severe is the pain on a 0 to 10 scale? ◆ **T**iming: Constant or intermittent? ◆ **A**djuvants : What has made it better? What makes the pain worse?
WILDA	◆ **W**ords used to describe the pain ◆ **I**ntensity: On a scale of 0–10, what is your pain now, at rest, with movement, worst pain possible in the past 24 hours? What is your comfort/function goal? ◆ **L**ocation: Where is your pain? ◆ **D**uration: Is the pain constant? Does the pain come and go? Source: Adapted from References 37–40.

Screening tools are available to enhance and refine neuropathic pain assessment and management.[42–44] For example, the 11-item neuropathic pain scale quantifies neuropathic pain severity and response to treatment.[45]

- ***Intensity***: Using the 0–10 numeric rating scale (0 = no pain and 10 = worst pain possible), ask the patient:
  - What is your pain now, at rest, with movement, and after a pain-relieving intervention?
  - In the past 24 hours, what was your least, worst, average pain?
  - What is your comfort/function goal?
- Three levels of pain intensity are mild (1–3), moderate (4–6), and severe (7–10).[16] The comfort/function goal describes how much pain can occur without interfering with function or quality of life and is the level of pain that will enable function and comfort. Pain intensity can also be quantitatively measured with a verbal descriptor scale, faces scale, or pain thermometer (scales are discussed later in this chapter). The nurse must consider the practicality, ease, and acceptability of the instrument's use by the palliative care patient. While an assessment of intensity captures only one aspect of the pain experience, it is the most frequently used parameter in clinical practice.
- ***Location***: Ask the patient, "Where is your pain? Do you have pain in more than one area?" Encourage the patient to point or place a finger on the area involved. The majority of cancer patients have pain in two or more sites[16]; therefore, it is crucial to ask questions about pain location. Separate pain histories should be acquired for each major pain complaint because their causes may differ and the treatment plan must be tailored to the particular pain type. For example, neuropathic pain may radiate and follow a dermatomal path; pain that is deep in the abdomen may be visceral; and when a patient points to an area that is well-localized and nonradiating, the pain may be somatic, possibly indicating bone metastasis.
- ***Duration***: Ask the patient, "Is your pain always there (persistent)? Does it come and go (intermittent)? Or do you have both types of pain?" Patients may experience "breakthrough" pain (BTP), an intermittent, transitory flare of pain, with several subtypes described—incidental, spontaneous, or end-of-dose failure pain.[46] Patients with progressive diseases such as cancer and AIDS can experience persistent pain that has an ill-defined onset and unknown duration. Asking about pain duration can determine if controlled-release and/or immediate-release opioids are appropriate.
- ***Aggravating and Alleviating Factors***: Ask the patient, "What makes the pain worse or better?" Pain interference with functional status can be measured by determining the pain's effects on activity, function (walking or repositioning in bed), energy, falling and/or staying asleep, relationships, mood, and/or appetite. Pain interference with functional status is highly correlated with pain intensity scores; a pain intensity score of 4 or higher has been shown to significantly interfere with daily

Table 8.3 Pain descriptors

Pain type	Etiological factors	Descriptors	Potential interventions
Neuropathic	Peripheral or central nervous system injury ◆ Nerve involvement by tumor ◆ Spinal cord compression ◆ Neuralgia (trigeminal, post herpetic) ◆ Peripheral neuropathies (microtubule inhibitors, viral or antiretroviral therapies, diabetes) ◆ Post stroke pain ◆ Phantom pain ◆ Radiation plexopathy	Burning Electrical Numb "Pins and needles" Radiating Shooting Tingling	Anticonvulsants Antidepressants Local anesthetics Corticosteroids Nerve blocks ±opioids (e.g., tramadol, methadone)
Somatic	Nociceptor activation or injury to superficial cutaneous and deep musculoskeletal structures ◆ Bone or spine metastasis ◆ Fractures ◆ Arthritis ◆ Osteoporosis ◆ Immobility	Aching Dull Sore Throbbing	Nonsteroidal anti-inflammatory drugs (NSAIDs) Corticosteroids Muscle relaxants Bisphosphonates Radiation therapy (bone metastasis) ±opioids
Visceral	◆ Bowel obstruction ◆ Venous occlusion or ischemia ◆ Liver metastasis ◆ Ascites ◆ Post abdominal or thoracic surgery ◆ Pancreatitis ◆ Cancers in the abdomen and chest	Bloated Crampy Deep Pressure Squeezing Stretching	NSAIDs Opioids (use with caution in patients with bowel obstruction) Spinal analgesia
Psychological	Psychological disorders	Hurts everywhere	Psychiatric treatment, support, nonpharmacologic strategies

Source: Adapted from Reference 41.

functioning.[47] Analgesics or nonpharmacologic interventions should be administered at least an hour before activity to decrease discomfort.

Ongoing and subsequent evaluations are necessary to determine the effectiveness of pain relief measures and to identify any new pain. Patients should be asked whether they have pain (screened for pain) on admission to a hospital, clinic, long-term care facility, hospice, or home care agency. If pain or discomfort is reported, a comprehensive pain assessment should be performed at regular intervals, whenever there is a change in the pain, and after any pain management plan modifications. Reassessment of pain intensity should occur after each pain management intervention, once sufficient time has elapsed for the treatment to reach peak effect (e.g., 15–30 minutes after a parenteral medication and within 1 hour of administration of oral medication or other nonpharmacologic intervention).[16] Pain assessment and reassessment should be individualized and documented so that interdisciplinary team members have an understanding of the pain problem. Information about the patient's pain can be obtained from multiple sources: verbal self-report, observations, interviews with the patient and family caregiver, review of healthcare data, and feedback from other healthcare providers.

Pain is uniquely personal and subjective. The quality and usefulness of any assessment is only as good as the ability of the assessor to be thoroughly patient-focused. This means listening empathetically, maintaining open communication, and validating or legitimizing the concerns of the patient and family caregivers. A clinician's understanding of the patient's pain and accompanying symptoms confirms that there is genuine personal interest in facilitating a positive pain management outcome.

Finally, pain does not occur in isolation. Other symptoms and concerns experienced by the patient compound the suffering associated with pain. *Total pain* has been described as the sum of the following interactions: physical, psychological, social, and spiritual.[48] At times, patients describe their whole life as painful. The provision of palliative care to relieve pain and suffering is based on the conceptual model of the whole person experiencing "total pain."

Case Study 2: Pain in a Patient with COPD

Mr. Joe M is a 72-year-old man with a 7-year history of COPD related to cigarette smoking, construction work, and asbestos remediation. He began smoking at a very young age and developed a 2-pack per day habit. At the age of 58, he was finally able to quit smoking but had decreased pulmonary function with symptoms of chronic cough, sputum, and shortness of breath on exertion such as walking on a steep incline or stairs. Other secondary diagnoses include coronary artery disease, stable angina, osteoporosis with mild kyphosis of the upper spine, diabetes mellitus controlled with oral medication, and gastroesophageal reflux disease (GERD). He was previously diagnosed with anxiety and depression and moderately consumed alcohol. He has slowly and steadily declined and has had difficulties performing activities of daily living. He was not able to do the things he enjoys and just does "some things around the house."

Last week, just prior to attending church, he had persistent coughing and developed sudden severe shortness of breath and left-sided chest pain. His family thought he might be having a heart attack and took him to the local hospital's Emergency Department. He was found to have a spontaneous pneumothorax. A chest tube was placed emergently, which expanded his lung. However, he had a persistent air leak and developed a hospital-acquired pneumonia. After 1 week, he was finally able to have the chest tube removed. Two days later, he went home, on oxygen therapy (2 L, nasal prongs). Once home, he began questioning the worth of continued treatment and asked his wife, "Would it be a sin to stop?"

Mr. M was referred to your palliative care clinic because of difficult to manage pain, dyspnea, depression, anxiety, and a significant loss of functional status after this recent hospitalization. He was discharged from the hospital with hydrocodone 5 mg/APAP 325 mg PRN for "post-procedural pain" and told that he should not need this for more than a few days to a week. His primary care physician was aware of the recently released CDC opioid guidelines for chronic pain, which has made him uncomfortable prescribing opioids for Mr. M. His physician was hopeful that an adjuvant medication may work for his pain and agreed to a trial of a long-acting opioid only if the patient and family were amenable and the palliative care interdisciplinary team agreed to do the prescribing and monitoring.

Mr. M said, "I can't seem to 'bounce back.'" His wife Kay and daughter Abby accompanied him to the palliative care clinic appointment. They expressed concern about this referral, thinking palliative care means hospice, but decided to come since they are worried about his increasing pain. They were also anxious about him becoming addicted to pain medication. Pain limited his activity and plans for home physical therapy. His pain was a 6/10 in his chest and back.

Mr. M, a stoic man, had been relatively active in his Roman Catholic congregation, although lately he did not attend Mass due to pain and fatigue. He never wanted to be a "bother" to his family. He continued to question ongoing treatment and was afraid to raise this issue with his priest or church friends out of fear that he would not be supported in his wishes.

Discussion Questions

1. Based on what you have learned about Mr. M's condition, comorbidities, and complications of COPD, what type(s) of pain might he be experiencing?
2. How would you assess Mr. M's pain? What instruments might be helpful in understanding his pain experience?
3. What potential barriers exist that may impact his ability to receive optimal pain management? How would you address these with Mr. M and his family?
4. Based on Mr. M's condition and pain experience, what pharmacological approaches might you suggest for pain control? What, if any, adjuvants might be helpful to include? What long-acting opioid might you suggest?
5. What nonpharmacological strategies would you incorporate into the pain management plan of care?
6. What other symptoms or side effects might you be concerned about? How will you address these? In particular, how would you manage opioid-induced constipation?

Three months later, Mr. M decided to forego additional therapy and enrolled in hospice. His pain was well managed at home. Over the last week of his life, he became unresponsive yet he still seemed to have pain and discomfort.

Discussion Questions

7. What pain assessment instruments can be used to assess his pain?
8. How would you incorporate his family caregivers in the assessment process?

Multidimensional Model for Pain Assessment

An individual's pain is unique; it is actualized by the multidimensionality of the experience and the interaction among factors both within the individual and in interaction with others.[49–53] Pain is determined by the interaction of three components: the sensory/discriminative (selection and modulation of pain sensations), the motivational/affective (affective reactions to pain via the brain's reticular formation and limbic system), and the cognitive (past or present experiences of pain).[49] Evidence supports the usefulness of a multidimensional model for pain by describing theoretical components of the pain experience: physiologic, sensory, affective, cognitive, behavioral, and sociocultural.[50,51] The sociocultural dimension, comprising a broad range of ethnocultural, social, demographic, and spiritual/religious factors, influences an individual's perception of and responses to pain and its management. Environmental conditions or stimuli such as excessive noise, lighting, or extreme temperatures may be sources of stress for individuals in pain and may negatively affect the pain experience.[53] Creating a peaceful environment may assist in alleviating the patient's pain.

The multidimensional approach to pain assessment provides the foundation to improve palliative care outcomes and to positively impact a patient's quality of life. Questions guiding a multidimensional pain assessment are reviewed in Table 8.4. We will further examine the various components of the sociocultural dimension.

Sociocultural Dimension

The sociocultural dimension encompasses all of the demographic variables (e.g., age, gender, ethnicity, spirituality, marital status, social support) of the patient experiencing pain. Although many studies have examined these factors in regards to pain assessment, treatment, and outcomes, few have concentrated on their highly interactive nature. Ultimately, all of these factors can influence pain assessment.

Age

Much of the pain literature has called attention to the problem of inadequate pain assessment and management in the elderly in a palliative care setting. Elderly patients suffer disproportionately from chronic painful conditions and have multiple diagnoses with complex problems and accompanying pain. Elders have physical, psychological, and social needs distinct from those of younger and middle-aged adults.

Pain assessment may be more problematic in elderly patients because their reporting of pain may differ from that of younger patients due to their increased stoicism. Elderly people often present with failures in memory, depression, and sensory impairments that may

Table 8.4 Multidimensional pain assessment

Dimension	Question
Physiological/Sensory	What is the cause of the patient's pain? How does the patient describe pain?
Psychological/Affective	How does the patient's emotional state affect report of pain? How does the pain influence the patient's mood or affect?
Cognitive	How do patient's/family caregiver's knowledge, attitudes, and beliefs affect the pain experience? What is the meaning of pain to the patient/family caregiver? What is the patient's past experience with pain and its management and how does this impact the pain experience?
Behavioral	How can you tell the patient is experiencing pain? What pain behaviors or nonverbal cues inform you that the patient may be experiencing pain? What strategies have the patient/family caregiver tried to decrease pain?
Sociocultural	What social support systems does the patient have in place to assist in the pain management care plan? How does the patient's cultural background affect the pain experience, expression, coping, and management? How does the patient's spirituality/religion affect the pain experience, expression, coping, and management?
Environmental	How does the environment affect patient's pain expression or experience?

hinder history-taking. They may also underreport pain because they believe pain is a part of aging. Moreover, dependent elderly people may not report pain because they do not want to bother the nurse or doctor and are concerned that they will cause more distress in their family caregivers.[34] It is important to pay particular attention to pain assessment in the elderly so that the chance of inadequate analgesia is decreased. Dementia, cognitive and sensory impairments, and disabilities can make pain assessment and management more difficult and will be discussed later in this chapter. Loss of hearing and visual acuity may impede communication, as well as dementia and memory loss. Despite these challenges, clinicians should recognize that self-assessment pain scales can often be used reliably in older patients with mild to moderate dementia and even in some with severe dementia. Behavioral scales can detect possible pain and should only be used in patients who cannot complete a self-report.

Gender

Gender differences may affect sensitivity to pain, tolerance, distress, willingness to report pain, exaggeration of pain, and nonverbal expression. Research has demonstrated that men show more stoicism than women, women exhibit lower pain thresholds and less tolerance to noxious stimuli than men, women become more upset when pain prevents them from doing things they enjoy, women seek care of pain sooner, and responses to analgesics and pain prevalence in various conditions may vary according to gender.[54,55] It is important to note that gender differences in pain response for patients with chronic pain are not universal and do not exert a large effect.[56] Explanations that require further investigation include molecular and genetic mechanisms, hormonal influences, and sociocultural and psychological effects. Nurses and other healthcare professionals need to be mindful of possible gender differences when assessing pain and planning individualized care for persons in pain. However, until there are more definitive data, men and women should receive similar pain care based upon individualized assessments.

Ethnicity

Significant racial and ethnic disparities exist throughout healthcare settings suggesting both inequitable treatment and disparate pain care outcomes.[57] To avoid disparities in pain treatment, providers must assess the effects of ethnicity on pain expression and perception. The term "ethnicity" refers to differences among groups of people according to their common language, traditions, shared origins, social backgrounds, culture, and physical characteristics. Bates's biocultural model proposed that culturally accepted patterns of ethnic meanings of pain may influence the neurophysiological processing of nociceptive information that is responsible for pain threshold, pain tolerance, pain behavior, and expression.[52] Research studies have documented that ethnic differences in pain perception exist in a variety of clinical pain conditions, and neurobiological factors may contribute to these differences.[58]

Ethnic minorities are not appropriately assessed for pain and are at risk for undertreatment.[58–61] Pain has been underestimated in Latinos and African Americans and has been associated with inadequate pain management.[58–61] Differences in cultural backgrounds among patient and healthcare providers may result in false beliefs, misinterpretations, lack of trust, and decreased communication about pain.[61] Minority patients, in particular those who speak English as a second language, may be at increased risk due to lack of clear communication and other biases. While pain assessment instruments are accessible in various languages, the translations may not capture cultural nuances or meanings.[60] When caring for a person experiencing pain, the healthcare provider must avoid cultural stereotyping and provide culturally sensitive assessment and educational materials, enlisting the support of an interpreter or navigator who speaks the patient's language when needed.[61] A crucial element of any initiative on pain must focus on improving pain care for racial and ethnic minorities, the poor, and other vulnerable populations.[57]

Marital Status and Social Support

While there is scant literature related to the influence of marital status, family, and social support on the patient's pain experience, it is important to understand and assess the type of support patients receive from family caregivers as it may influence pain expression, meaning, and the ability to comply with therapeutic recommendations.

Spirituality

The spiritual dimension may influence a person's pain response, expression, and experience. Whereas pain refers to a physical sensation, suffering refers to the quest for meaning, purpose, and fulfillment. Unrelieved physical pain may cause emotional or spiritual suffering, yet suffering may occur in the absence of pain. Many patients believe that pain and suffering are meaningful signs of the presence of a higher being and must be endured; others are outraged by the pain and suffering they must endure and demand alleviation. Healthcare providers should give patients the chance to verbalize their personal points of view. Assessing a patient's existential view of pain, suffering, and spiritual pain is important as it may impact healing and dying processes. Suggestions for clinical implications include nurses' and providers' examination of their own spirituality and how that could affect their communication with patients, exploring respectful communication with patients about spirituality and its effects on pain, inclusion of spirituality in education and support programs for both patients and healthcare providers, incorporation of spiritual preferences in comfort strategies where appropriate, and referral to spiritual care providers.

Financial Status

When assessing pain, it is also important to consider the patient's financial status. Insurance companies may require a patient to take a tiered approach to pain medications, require the use of certain opioids over others, or set quantity limits on the amount of medication allowed in a given time frame. Regardless of how thorough pain assessment is, treatment will not be effective if patients cannot obtain the medication. It is essential that providers and nurses be aware of the changing landscape and provide sufficient support for patients.

Past Experiences

Patients should be asked about their prior experiences with pain. For example, many patients have listed allergies to medications that are actually potential side effects, such as "nausea" or "constipation." These are predictable, nonallergic reactions based on the properties of the drugs. Assessing which medications a patient has tried before and his or her response or perceived response to those treatments can help to guide recommendations for treatment.

Substance Abuse

The increased focus on opioid abuse and the opioid crisis in the United States adds an additional challenge or layer to the assessment of a patient's pain. Patients with a history of addiction are another high-risk population for undertreatment of pain and for misuse of opioid analgesics. Providers may be opiophobic, may lack trust, and may have inadequate knowledge about addiction and how to manage pain in those with a history of or current substance use; all interfere with optimal management.[62] Caring for palliative care patients with active substance abuse is difficult as providers attempt to manage pain without contributing to addiction.

In addition to conducting a pain assessment as previously described, providers must assess for addiction risk by using one of many opioid-specific screening tools (e.g., Opioid Risk Tool, SOAPP-R).[63] These instruments provide scoring for risk stratification based on multiple factors (age, gender, personal or family history of substance abuse, history of psychiatric illness or preadolescent sexual abuse). The Opioid-Related Behaviours in Treatment (ORBIT) scale, designed to be brief (10-items), identifies behaviors indicative of problems relating to opioid therapy such as nonadherence, diversion, and hazardous use or misuse. It also facilitates measurement of change over time; however, additional validation of the tool is required.[64]

Relevant outcomes of opioid therapy in patients with a history of addiction should include assessment of the five A's (analgesia, activities of daily living, adverse events, aberrant activities, and adjuvant use) prior to opioid initiation and regularly throughout a treatment course (refer to Table 8.5).[62,65] Ongoing communication

Table 8.5 The 5 A's

5 A's goals	Definition	Assessment
Analgesia	Level of comfort	◆ Decrease in pain intensity ◆ Effectiveness of the intervention on the pain
Activities of daily living and affect	Functional status	◆ Increased physical activity ◆ Ability to cope with illness and symptoms ◆ Improved psychological affect ◆ Family/social relationships intact ◆ Appropriate medication and healthcare utilization
Adverse events or effects	Side effects related to treatment	◆ Constipation ◆ Mental status or cognitive changes • Sedation • Euphoria • Confusion ◆ Respiratory depression ◆ Other physical and psychological effects
Aberrant activities	Behaviors that warn of potential substance misuse, abuse, or addiction	◆ Behaviors that suggest concern, e.g., loss of medications, early requests for prescriptions, lack of approval for dose escalation, concurrent illicit drug use, using an unsanctioned route of administration, and repeated resistance to the recommended treatment plan
Adjuvants	Adjuvant medication use	◆ Use of adjuvants should be maximized and titrated upward to decrease opioid requirements ◆ Include nonpharmacologic interventions

Source: Adapted from References 62, 65.

and assessment are keys to maintaining comfort while preventing misuse, abuse, and diversion. For additional information about managing pain in patients with substance use disorder, please refer to Chapter 42 for greater detail.

Pain Intensity Assessment Scales

Pain is a subjective, self-reported experience; the ability to quantify the intensity of pain is essential to monitoring a patient's responsiveness to analgesia. The most commonly used pain intensity scales, the numeric rating scale (NRS), verbal descriptor scale (VDS), Wong–Baker FACES pain scale, Faces Pain Scale-Revised (FPS-R), vertical pain thermometer, and visual analogue scale (VAS), are illustrated in Figure 8.1[66,67] and reviewed in Table 8.6.[67–74] These are effective, reproducible means of measuring pain, can be universally implemented, and are regularly applied in palliative care settings.

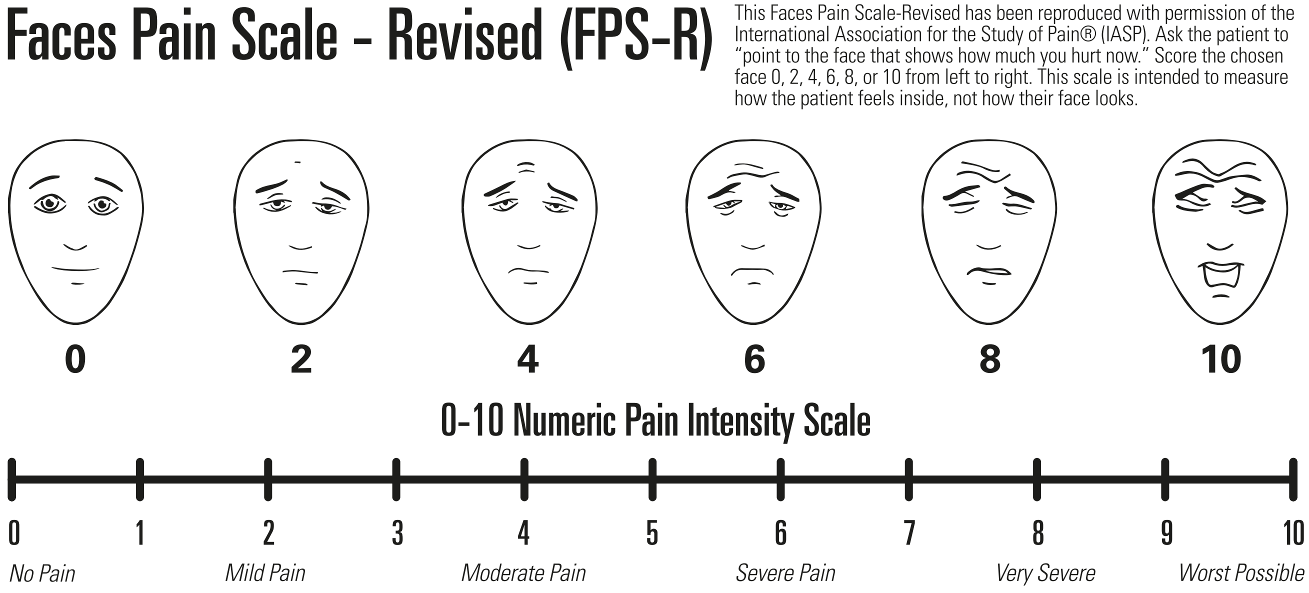
Although no one scale is appropriate or suitable for all patients, universal adoption of a 0–10 scale for clinical assessment of pain intensity in adult patients is recommended.[68,75] Standardization promotes collaboration and consistency in evaluation among caregivers across multiple settings (i.e., inpatient, ambulatory, home care/hospice or long-term care environments). Standardization also facilitates pain research through the collection of comparative data, allowing for simplification of data analyses. Detailed explanation of how to use a pain scale is necessary before patient use in any clinical care area.

Healthcare providers inconsistently use the word anchors on pain intensity scales. The intention behind the use of a word anchor to discriminate pain intensity is to provide a common endpoint. Some of the common word anchors that have been used are "worst possible pain," "pain as bad as it can be," "worst pain imaginable," "worst pain you have ever had," "most severe pain imaginable," and "most intense pain imaginable." Inconsistent or different word anchors may yield different pain reports. Therefore, it is important for healthcare professionals to achieve consensus about consistent use of word anchors in a particular setting.

Comparison of Pain Intensity Scales

Several studies have been systematically reviewed, and, although many are limited in sample size and population, a positive correlation has been demonstrated among the NRS, VDS, Wong–Baker FACES scale, and FPS-R.[29] Each of these commonly used pain rating scales appears to be adequately valid and reliable as a measure of pain intensity in cancer patients, elders, and patients with mild to moderate degrees of cognitive impairment.[29]

The use of a faces pain scale to measure pain intensity avoids language barriers and may cross cultural differences. Several faces pain scales have been used to assess pain in both pediatric and adult populations. A systematic review of commonly used faces scale for self-report of pain intensity in children recommended that the FPS-R be used in research studies[73]; however, there were no recommendations for using one faces scale over another in clinical use, and there is no consensus as to the type of faces scale to use in the palliative care setting. The literature regarding pain scale choice among ethnic groups is equivocal. Elderly long-term care residents of various ethnicities were asked to choose which of three pain intensity scales (NRS, VDS, and FPS) they preferred to use to rate their pain. Of those able to choose, the VDS was the most commonly selected (52%), more men than women and those residents with moderate to severe pain preferred the NRS; a higher percentage of minority (Latino) residents preferred the FPS.[76] Participants clearly agreed that the FPS represented pain but also agreed that the FPS may represent other constructs, such as sadness or anger, depending on how they were cued; this may suggest that the FPS may be measuring pain affect, not just intensity. Ware et al. recommend consideration of the FPS-R when repeat assessments are indicated in older cognitively impaired minority adults.[77] While the FPS-R is generally favored for *both* cognitively intact and cognitively impaired older adults, it should be noted that the FPS-R may not clearly represent pain intensity only but may also represent a broader construct "pain affect."[77] In addition, Ware et al. found that Latino patients preferred the FPS-R over the vertical pain thermometer and other instruments used to measure pain intensity.[77]



Faces Pain Scale - Revised (FPS-R)

This Faces Pain Scale-Revised has been reproduced with permission of the International Association for the Study of Pain® (IASP). Ask the patient to "point to the face that shows how much you hurt now." Score the chosen face 0, 2, 4, 6, 8, or 10 from left to right. This scale is intended to measure how the patient feels inside, not how their face looks.

Pain Assessment Guide

Tell Me About Your Pain

W Words to describe pain (discomfort)

Somatic	*Visceral*	*Neuropathic*
aching	crampy	numb
dull	gnawing	burning
throbbing	deep	radiating
sharp	squeezing	shooting
stabbing	pressure	electrical
sore	stretching	tingling
penetrating	bloated	pins & needles

Pain in Other Languages

Japanese - itami
Chinese - tong
Vietnamese - dau
Spanish - dolor
French - douleur
Russian - bolno
Croatian-Bosnian - bol
Arabic - ألَم
Ethiopian - amonyal

I Intensity (0-10)

If 0 is no pain and 10 is the worst pain possible, what is your pain now?
….at rest? …..with movement? …
In the last 24 hours what was your least pain? …worst? ... average?
What is your comfort-function goal?

L Location

Where is your pain?

D Duration

Is the pain constant? …intermittent? …..both types?

A Aggravating and Alleviating Factors

What makes the pain worse? …better?

How does the pain affect:

activity
function
energy
sleep
relationships
mood
appetite

Are you experiencing medication side effects?

nausea/vomiting
sleepiness
drowsiness
constipation
itching
confusion
urinary retention
dizziness

Things to Check

vital signs, response to past medication/treatment, substance abuse history
use of nonpharmacologic techniques, chronic pain history

Figure 8.1 Continued

In summary, a variety of scales have been used to assess pain in varied patient populations. Each has been widely used in clinical research and practice. Little research has been done on the appropriateness of pain scales in the palliative care setting. Intellectual understanding and language skills are prerequisites for pain assessment scales such as the VDS. These scales may be too abstract or too difficult for palliative care patients. Because most dying patients are elderly, simple pain scales, such as the NRS or a faces scale, may be more advantageous.

Multidimensional Pain Instruments

Several multidimensional pain measurement instruments are used in clinical and research settings to standardize pain assessment and incorporate patient demographic factors, pain severity scales, pain descriptors, pain influence on function, and other questions related to pain. Five key instruments are briefly reviewed here.

Short Form-McGill Pain Questionnaire-2 (SF-MPQ-2)[78,79] The newest version of the SF-MPQ-2 (previous versions MPQ, MPQ-SF) is reliable, valid in older and younger people with cancer pain, and available in multiple languages. It includes 22 words to describe pain (each word or phrase is rated on an NRS [0 = none, 10 = worst possible pain]) with two additional pain measures: the Present Pain Intensity Index (PPI) and overall intensity of total pain experience (no pain – mild – discomforting – distressing – horrible – excruciating).

Brief Pain Inventory-Short Form (BPI-SF) [80] This is a 9-item self-administered survey used to evaluate the severity of a patient's

Table 8.6 Pain intensity scales

Scale	Description	Comments
Numeric rating scale (NRS)	Number provided on a 0–10 scale represents pain intensity 0=no pain 10=worst possible pain	◆ Gold standard for adult patients able to self-report ◆ May be used in children age 7 years or older ◆ Verbal administration enables visually impaired or those by phone to quantify pain intensity
Verbal descriptor scale (VDS)	Adjectives reflecting pain extremes are ranked in order of severity ◆ No pain ◆ Mild pain ◆ Moderate pain ◆ Severe pain ◆ Very severe pain ◆ Worst possible pain	◆ Easily comprehended by the elderly ◆ Each descriptor may correlate with a number to constitute pain intensity ◆ May be translated into multiple languages ◆ Less reliable in those who are illiterate and have limited English vocabulary
Faces pain scale-revised (FPS-R)	Six oval faces range from neutral (no pain) to a grimacing face (worst pain)	◆ Ease of use ◆ Oval-shaped faces without tears are adult-like in appearance and more acceptable by adults ◆ Facial expressions may be difficult to discern by those with visual difficulties ◆ Note: May measure other constructs instead of pain (e.g., depression, anger, distress)
Wong-Baker FACES scale (FACES)	Six cartoon-type faces range from a widely smiling face (no pain) to a face with tears (most pain)	◆ Easily visualized ◆ Ease of use by children ◆ Presence of tears on the most pain face may introduce bias when used with cultures not sanctioning crying.
Vertical pain thermometer (VPT)	Modified verbal descriptor scale that looks like a thermometer	◆ Increased sensitivity in elderly ◆ Ease of use is those with moderate to severe cognitive deficits
Visual analogue scale (VAS)	0–10 cm line 0–100 mm line	◆ Primarily used in research ◆ Reliable and valid ◆ Difficult to use in elderly, those with physical or visual disability ◆ Paper and pencil required ◆ Scoring is time-consuming

Source: Adapted from References 68–74.

pain and its impact on daily functioning. The patient is asked to rate his or her worst, least, average, and current pain intensity; list current treatments and their perceived relief; and rate the degree to which pain interferes with general activity, mood, walking ability, work, enjoyment of life, relations with other persons, and sleep on a 0–10 NRS. The BPI-SF is a modification of the Brief Pain Inventory–Long Form (32-items) and is available in multiple languages.

Memorial Pain Assessment Card (MPAC)[81] The MPAC is simple, valid, and consists of three VASs (pain intensity, pain relief, and mood), and a VDS with eight pain descriptors. It can be completed in less than 20 seconds and distinguishes between pain intensity, relief, and psychological distress.

American Pain Society Patient Outcomes Questionnaire-Revised (APS-POQ-R)[82] This 23-item, two-page survey was designed for quality improvement purposes. The questionnaire takes 10 minutes to complete, has established reliability and validity in adult hospitalized medical-surgical patients, and measures six aspects of quality: (1) pain severity and relief; (2) impact of pain on activity, sleep, and negative emotions; (3) side effects of treatment; (4) helpfulness of information about pain treatment; (5) ability to participate in pain treatment decisions; and (6) use of nonpharmacologic strategies. The use of this tool in palliative care populations has not been established.

***Edmonton Symptom Assessment System-revised* (ESAS-r)**[83] Since palliative care patients may experience concomitant symptoms, it is impossible to limit an assessment to the report of pain. Complications or symptoms related to the disease process, such as fatigue and anxiety, may exacerbate pain, or interventions to alleviate pain may cause side effects that result in new or worsening symptoms, such as constipation or nausea. The ESAS-r was developed to assist in the assessment of nine symptoms that are common in the palliative care setting: pain, tiredness, drowsiness, nausea, lack of appetite, depression, anxiety, shortness of breath, and well-being. There is also a blank scale for patient-specific symptoms. The ESAS was originally trialed in palliative care inpatients, and 83% of symptom assessments were completed by nurses or patients' family caregivers.[84] Tested in cognitively intact palliative care patients, the modified version, ESAS-r, is clearer in format; easier to understand with accompanying definitions describing the various symptoms, including pain; and specifies a timeframe of "now."[83] If patients are unable to complete the form or are unresponsive and incapable of self-report (final days of life), observer judgments become necessary and a space is provided for the person completing the assessment.

Nonverbal or Cognitively Impaired Patients

Patient's self-report, the gold standard for pain assessment, is not always feasible in those unable to verbalize pain and for patients with cognitive impairment (e.g., dementia and delirium). Impaired cognition and sensory losses are serious problems for the elderly, many patients with life-threatening illness, and for the majority of palliative care patients who may be imminently dying. These patients are all at increased risk for pain due to underassessment and undertreatment.[28,29] Patients who are nonverbal or cognitively impaired are often excluded from pain studies; thus, pain assessment and treatment in these groups are poorly understood.

Pain Behaviors

As noted by the IASP, "the inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment."[13] No single objective assessment strategy, such as interpretation of behaviors, determination of pathology, or estimates of pain by others, is sufficient by itself.[28] Nonverbal pain expression may complement, contradict, or replace the verbal complaint of pain. Pain behaviors may be a means of expressing or coping with pain. Behavioral cues can include anxiety, sleeplessness, inability to concentrate, and restlessness. Unfortunately, some of these behaviors or cues may relate to etiologies or symptoms other than pain. For example, insomnia caused by depression may complicate pain assessment.

It is not reasonable and is even inaccurate to assess pain by reliance on involuntary physiological bodily reactions, such as increases in blood pressure, pulse, or respiratory rate and depth. Elevated vital signs may occur with sudden, severe pain, but they usually do not occur with persistent pain after the body reaches physiological equilibrium.[34] The absence of behavioral or involuntary cues does not negate the presence of pain. Assessment of behavior for signs of pain during rest and movement may provide a potentially valid and reliable alternative to verbal and physiological indices of pain. Examples of pain behaviors in cognitively impaired or nonverbal patients or residents are displayed in Table 8.7.[10,24]

The *ASPMN Position Statement on Pain Assessment in the Patient Unable to Self-Report*[28] provides recommendations for assessing pain in special populations including nonverbal older adults with dementia and those who are intubated and/or unconscious.

Pain assessment and management can be guided by this hierarchy of pain assessment framework presented in Box 8.2.[21,28,29,34]

Assessing Pain in Dementia

The inability of patients with dementia to verbally communicate their pain makes them a vulnerable patient group, dependent on their caregivers. Knowing the life story of the patient, professional experience, teamwork based on good communication, and use of a pain assessment tool has been reported to improve pain relief at the end of life for patients with dementia.[85]

It has been proposed that the white matter lesions produced by vascular dementia may cause an increase in pain experience via central neuropathic pain mechanisms.[86] In addition, pain behaviors in individuals with dementia may be different from those of patients/residents who are cognitively intact. The relationship between pain and aggressive behavioral symptoms varies according to the communicative status of residents and disproportionately affects those who cannot articulate their pain. Strategies for enhancing pain management in these residents are needed to adequately treat pain and reduce aggression.[87] It has also been shown that patients/residents with increased levels of cognitive impairment may report less severe pain and patients with progressive dementia may have fewer pain complaints, which may be related to a diminished capacity or difficulty in communicating pain.[88] There is no consistent evidence to indicate that persons with dementia experience less pain sensation. Instead of being less sensitive to pain, older adults with dementia may not interpret sensations as painful.

Pain indicators in elderly demented patients identified by nursing home staff members include specific physical repetitive movements, facial expressions, vocal repetitions, physical signs of pain, and behavioral changes from the norm for that person. Observations of facial expressions may not be valid in patients with some types of dementia in which facial expressions are muted or in conditions that result in distorted facial expressions, such as Parkinson's disease or stroke.[88] A descriptive study examined ethnic differences in the presentation and intensity of nonverbal pain behaviors among African American, Caucasian, and Hispanic older adults with dementia when screened for pain by certified nursing assistants and found no significant differences in overall

Table 8.7 Pain behaviors

Behavior	Manifestation
Verbalizations	Saying common phrases: "Help me," "Ouch," "Don't touch me," "Stop hurting me," "Leave me alone" during activity such as positioning, movement, or bathing
Vocalizations	Moaning, groaning, crying, oohing, aahing, calling out, screaming, shouting, sighing, breathing heavily
Facial expressions	Grimace, frown, wince, frightened or sad look, closed eyes or rapid blinking, wrinkled or furrowed brow, tight jaw, clenched teeth
Changes in activity or movement	Posturing, splinting, bracing, guarding a body part, rubbing a painful area, pacing, rocking, withdrawing, lying still in bed, constant or intermittent shifting of position, resisting care
Mental status changes	Restless, agitated, jittery, distress, confusion

Box 8.2 Hierarchy of Pain Assessment and Treatment in the Nonverbal or Cognitively Impaired

1. Use the hierarchy of pain assessment techniques:
    a. Obtain self-report, if possible.
    b. Search for potential causes of pain or other pathologies that could cause pain.
    c. Observe patient behaviors that are indicative of pain.
    d. Obtain proxy reporting (family members, parents, caregivers) of pain and behavior/activity changes.
    e. Attempt an analgesic trial to assess a reduction in possible pain behaviors.
2. Establish a procedure for pain assessment.
3. Use behavioral pain assessment tools, as appropriate.
4. Minimize emphasis on physiologic indicators such as vital signs.
5. Reassess and document.

Source: Adapted from References 21, 28, 29, 34.

Box 8.3 Checklist: Pain Assessment and Management in the Nonverbal or Cognitively Impaired Patient or Resident

- Is there a reason for the patient to be experiencing pain? Review the patient's diagnoses and investigate reason for any new pain.
- Was the patient previously treated for pain? If so, what regimen was effective (include pharmacologic and nonpharmacologic interventions)?
- How does the patient usually act when he/she is in pain? (Note: the nurse may need to ask family/significant others or other healthcare professionals.)
- What is the family caregiver's interpretation of the patient's behavior? Does he or she think the patient is in pain? Why does he or she feel this way?
- Try to obtain feedback from the patient; for example, ask patient to nod head, squeeze hand, move eyes up or down, raise legs, or hold up fingers to signal presence of pain.
- If appropriate, offer writing materials or pain intensity charts that patient can use.
- If there is a possible reason for or sign of acute pain, treat with analgesics or other pain-relief measures.
- If a pharmacologic or nonpharmacologic intervention results in modifying pain behavior, continue with treatment.
- If pain behavior persists, rule out potential causes of the behavior (delirium, side effect of treatment, symptom of disease process); try appropriate intervention for behavior cause.
- Explain interventions to patient and family caregiver.

pain intensity noted across ethnic groups. These findings are the first to examine ethnic differences in nonverbal pain behaviors for older adults with dementia.[89]

Behavior or responses caused by noxious stimuli in individuals with dementia may not necessarily reflect classic or typical pain behaviors. There is considerable variability and uniqueness in behavior expressions of pain in nonverbal older adults with dementia.[88] For example, pain may be exhibited by withdrawn behavior, aggressive behavior, or verbally abusive behavior. In a study of 26 patients with painful conditions from a nursing home Alzheimer's unit, Marzinski[90] reported diverse responses to pain that were not typical of conventional pain behaviors. For example, a patient who normally moaned and rocked became quiet and withdrawn when experiencing pain; pain in another nonverbal patient caused rapid blinking. Other patients who normally exhibited disjointed verbalizations could, when experiencing pain, give accurate descriptions of their pain. A checklist (refer to Box 8.3) can be used as a template for assessment and treatment of pain in the nonverbal or cognitively impaired patient/resident.

Instruments to Assess Pain in Nonverbal or Cognitively Impaired Patients

Pain Behavioral Scales

Assessing pain in patients/residents who are nonverbal or cognitively impaired and are unable to verbally self-report pain presents a particular challenge to clinicians. An instrument that could detect the presence of or a reduction in pain behaviors could facilitate effective pain management plans. However, because pain is not just a set of pain behaviors, the absence of certain behaviors does not necessarily mean that the patient is pain free. As evident from several excellent reviews of pain tools,[28,29,91] many healthcare providers and researchers have attempted to develop easy-to-use, valid, and reliable instruments for the assessment of pain in this vulnerable population. Currently, there is no one specific tool based on nonverbal pain behaviors that can be recommended for general applicability in clinical practice, special populations, and palliative care settings. A basic summary of common instruments used to assess pain in populations unable to self-report is found in Table 8.8.[92–100] Herr and colleagues[28] have performed an extensive and critical evaluation of many of these existing tools (conceptualization, subject/setting, reliability and validity data based on research, administration/scoring methods, strengths/weaknesses) with the intent of providing up-to-date information to clinicians and researchers as it becomes available. These detailed reviews can be accessed at http://prc.coh.org/pain_assessment.asp.

Proxy Pain Assessment in the Nonverbal or Cognitively Impaired

Just as the experience of pain is subjective, observing and interpreting a patient's/resident's pain is a subjective experience. Without verbal validation from the patient, the clinician must rely not only on behavioral observations but also on intuition and personal judgment. It is also particularly important to elicit the opinions of those individuals closest to the patient, which are also subjective.

Nurses and other healthcare providers reflect the difficulty of accurately assessing pain in nonverbal or cognitively impaired patients in studies that show low concurrence between patients' self-ratings of pain and clinicians' ratings.[101] Other findings are equivocal, with some studies suggesting that family caregivers or significant

Table 8.8 Pain instruments for populations unable to self-report

Instrument	Population	Description
Behavioral Pain Scale (BPS)	Critically ill, intubated patients	Each of 3 dimensions scored (1–4) for a total score (3 = no pain to 12 = maximum pain) Facial expression 1. Relaxed 2. Partially tightened 3. Fully tightened 4. Grimacing Upper limb movements 1. No movement 2. Partially bent 3. Fully bent 4. Permanently retracted Compliance with mechanical ventilation 1. Tolerating movement 2. Coughing but tolerating ventilation most of the time 3. Fighting ventilator 4. Unable to control ventilation
Critical Care Pain Observation Tool (CPOT)	Critical care patients	Each of 4 domains scored from 0–2 for total score (0–8) ◆ Facial expression ◆ Body movements ◆ Patient compliance with the ventilator (intubated) or vocalization (extubated) ◆ Muscle tension Pain is suspected when score >2 or increases by 2 or more.
Checklist of Nonverbal Pain Indicators (CNPI)	Cognitively impaired elders	Rate absence (0) or presence (1 or 2) of 6 behaviors at rest and on movement for total score (0–12) ◆ Nonverbal vocalizations ◆ Facial grimace/wince ◆ Bracing ◆ Rubbing ◆ Restlessness ◆ Verbalization
FLACC-revised (FLACC-r)	Postoperative children, critical care patients, cognitively impaired adults	Each of 5 items scored from 0–2 for total score (0–10) ◆ Face ◆ Legs ◆ Activity ◆ Cry ◆ Consolability
Multi-dimensional Objective Pain Assessment Tool (MOPAT)	Non-communicative hospice patients	Behavioral dimension: 4 items scored (0 = none to 3 = severe) ◆ Restless ◆ Tense muscles ◆ Frowning/grimacing ◆ Patient sounds Physiologic dimension: scored no change from usual (0) or change from usual (1) ◆ Blood pressure ◆ Heart rate ◆ Respirations ◆ Diaphoresis Both dimensions summed for total pain score (0–16)

(continued)

Table 8.8 Continued

Instrument	Population	Description
Pain Assessment behavioral Scale (PABS)	Nonverbal hospitalized critically ill patients	Each of 5 items scored from 0–2 for a total score (0–10) ◆ Face ◆ Restlessness ◆ Muscle tone ◆ Vocalization ◆ Consolability Patient is observed at rest and with movement. Two scores are generated; higher score is documented.
Pain Assessment in Advanced Dementia (PAINAD)	Advanced dementia patients	Each of 5 items scored from 0–2 for a total score (0–10) ◆ Breathing (independent of vocalization) ◆ Negative vocalization ◆ Facial expression ◆ Body language ◆ Consolability

Source: Adapted from References 92–100.

others had difficulty assessing pain in their loved one[102] or accurately estimating the amount of pain cancer patients experience and others proposing that family caregivers overestimate patients' pain. Bruera and colleagues[103] studied relatives and nurses who cared for 60 unresponsive, dying patients. Both were asked to rate a patient's discomfort level using six observed behaviors (grimacing, groaning, shouting, touching or rubbing an area, purposeless movement, labored breathing) and the suspected reason for the discomfort. Although the mean levels of perceived discomfort were similar, relatives reported significantly more observed behaviors and more often indicated pain as a reason for discomfort than did the nurse caregivers. According to Cohen-Mansfield,[104] relatives of cognitively impaired nursing home residents are better able to interpret facial expressions and other pain behaviors if they visit their loved ones at least once a week and have a close relationship. To detect pain in cognitively impaired nursing home residents, it is essential for family members and certified nursing assistants to know the resident's usual behavior and patterns to be able to detect pain.

Implications for Treatment

Although pain assessment in the nonverbal or cognitively impaired patient or resident presents a challenge to clinicians, it should not pose a barrier to optimal pain management. If patients are no longer able to verbally communicate whether they are in pain or not, the best approach is to assume that their underlying disease is still painful and to continue pain interventions based on analgesic history.[30] A collaborative interdisciplinary palliative care team can optimize patient care and develop a plan of care.[105]

Nonverbal patients should be empirically treated for pain if there is preexisting pain or evidence that any individual in a similar condition would experience pain. Likewise, palliative measures should be considered in nonverbal patients with behavior changes potentially related to pain.

Conclusion

Multiple factors should be incorporated into the assessment of the pain experience. The case studies include some of the pain assessment techniques discussed in this chapter. A review of these cases may prove beneficial when nurses and other healthcare providers apply this content.

CHAPTER 9

Pain Management

Judith A. Paice

Key Points

- Pain is highly prevalent in palliative care, yet the majority of individuals can obtain good relief with available treatment options.
- An awareness of barriers to adequate pain care allows palliative care nurses to assess for and to plan interventions to overcome these obstacles when caring for patients. Advocacy is a critical role of the palliative care nurse.
- Assessment of pain, including a thorough history and comprehensive physical exam, guides the development of the pharmacological and nonpharmacological treatment plan.
- Pharmacological therapies include nonopioids, opioids, adjuvant analgesics, nonpharmacological and integrative therapies, cancer treatment, and, in some cases, interventional techniques.
- Intractable pain and symptoms, although not common, must be treated aggressively. In some cases, palliative sedation may be warranted.

Introduction

Of the many symptoms experienced by those at the end of life, pain is one of the most common and most feared. However, this fear is largely unfounded because the majority of patients with terminal illness can obtain relief. Nurses are critical members of the palliative care team, particularly in providing pain management. The nurse's role begins with assessment and continues through the development of a plan of care and its implementation. During this process, the nurse provides education and counseling to the patient, family, and other team members. Nurses also are critical for developing institutional policies and monitoring outcomes that ensure good pain management for all patients within their palliative care program. To provide optimal pain control, all healthcare professionals must understand the frequency of pain at the end of life, the barriers that prevent good management, the assessment of this syndrome, and the treatments used to provide relief. Effective pain control and alleviation of suffering is highly dependent upon the strength of clinician, patient, and family communication and relationship. These are key strengths of nursing at all phases of palliative care.

Prevalence of Pain

The prevalence of pain in the terminally ill varies by diagnosis and other factors. Approximately one-third of persons who are actively receiving treatment for cancer and two-thirds of those with advanced malignant disease experience pain.[1] Individuals at particular risk for undertreatment include the elderly, minorities, and women. Almost three-quarters of patients with advanced cancer admitted to the hospital experience pain upon admission. In other studies of patients admitted to palliative care units, pain often is the dominant symptom, along with fatigue and dyspnea. Children dying of cancer also are at risk for pain and suffering.[2]

Unfortunately, there has been little characterization of the pain prevalence and experience of patients with other life-threatening disorders. However, those working in palliative care are well aware that pain frequently accompanies many serious illnesses, such as human immunodeficiency virus (HIV), multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), and end-stage renal disease (ESRD).[3–6] Furthermore, many patients in hospice and palliative care are elderly and more likely to have existing chronic pain syndromes, such as osteoarthritis or low back pain.[7]

Additional research is needed to fully characterize the frequency of pain and the type of pain syndromes seen in patients at the end of life. This information will lead to improved detection, assessment, and, ultimately, treatment. Unfortunately, pain continues to be undertreated even when prevalence rates and syndromes are well understood. The undertreatment is largely due to barriers related to healthcare professionals, the system, and patients and their families.[8]

Barriers to Pain Relief

Barriers to good pain relief are numerous and pervasive. Often, because of lack of education, misconceptions, or attitudinal issues, these barriers contribute to the significant numbers of patients who do not get adequate pain relief.[9] Careful examination of these barriers provides a guide for changing individual practice, as well as building an institutional plan within the palliative care program to improve pain relief (Box 9.1). Most studies address the barriers associated with cancer pain. Therefore, barriers facing individuals with other disorders commonly seen in palliative care are not well characterized. One might suggest that these individuals are affected to an even greater extent, as biases may be more pronounced in those with noncancer diagnoses.

Healthcare Providers

Fears related to opioids held by professionals lead to underuse of these analgesics, and this concern has been exacerbated by the exploding opioid misuse epidemic.[10] Numerous surveys have revealed that physicians, nurses, and pharmacists express concerns about addiction, tolerance, and side effects of morphine and related compounds.[11,12] This concern has increased as rates of misuse and

Box 9.1 Barriers to Cancer Pain Management

Problems related to healthcare professionals

Inadequate knowledge of pain management

Poor assessment of pain

Concern about regulation of controlled substances

Fear of patient addiction

Concern about side effects of analgesics

Concern about patients' becoming tolerant to analgesics

Problems related to the healthcare system

Low priority given to cancer pain treatment

Restrictive regulation of controlled substances

Problems of availability of treatment or access to it:

- Inadequate reimbursement
- Shortages of medications
- Limited availability of palliative care and pain specialists
- Limited access to addiction specialists for patients with substance use disorder
- Insufficient time

Problems related to patients

Reluctance to report pain

Concern about distracting physicians from treatment of underlying disease

Fear that pain means disease is worse

Concern about not being a "good" patient

Poor health literacy/challenges to adherence to analgesic regimen

Reluctance to take pain medications

Fear of addiction or of being thought of as an addict

Worries about unmanageable side effects

Concern about becoming tolerant to pain medications

Source: Adapted from References 9, 12.

even deaths due to recreational opioid use have increased in the community.[13] Inevitability of pain is also expressed, despite evidence to the contrary. Not surprisingly, lack of attention to pain and its treatment during basic education is frequently cited. Those providing care at the end of life must evaluate their own knowledge and beliefs, including cultural biases, and strive to educate themselves and their colleagues.

Healthcare Settings

Lack of availability of opioids is pervasive, affecting not only sparsely populated rural settings but also inner-city pharmacies reluctant to carry these medications.[14,15] Pain management continues to be a low priority in some healthcare settings, reimbursement for these services is poor, and, as a result, some settings lack qualified professionals with expertise in pain management.[16] All of this is complicated by the cost of analgesic treatments and lack of reimbursement by third-party payers.[17]

Patients and Families

Understanding these barriers will lead the professional to better educate and better counsel patients and their families. Since these fears are insidious, patients and family members or support persons should be asked if they are concerned about addiction and tolerance (often described as becoming "immune" to the drug by laypersons). Studies have suggested that these fears lead to undermedication and increased intensity of pain.[18] Concerns about being a "good" patient or belief in the inevitability of cancer pain lead patients to hesitate in reporting pain. In these studies, less educated and older patients were more likely to express these beliefs. Patients seeking active treatment may believe that admitting to pain or other symptoms may reduce their eligibility for clinical trials. Lack of adherence to the medication regimen, complicated by limited understanding, can lead to unrelieved pain.[19,20] Some patients and family members delay taking opioids, believing they are only for the dying.

At the end of life, patients may need to rely on family members or other support persons to dispense medications. Each person's concerns must be addressed or provision of medication may be inadequate. Studies suggest that little concordance exists between patients' and family members' beliefs regarding analgesics. The interdisciplinary team is essential here, with nurses, social workers, chaplains, physicians, volunteers, and others exploring the meaning of pain and possible barriers to good relief. Education, counseling, reframing, and spiritual support are imperative. Nurses are particularly well-trained to offer the education and "coaching" that has been shown to provide improved relief. Strategies to provide education and support have included print materials, Internet-based programs, telehealth programs, and videoconferencing to educate patients, particularly those in rural areas. Overall, patient education has resulted in modest improvements in pain outcomes.[21]

Effects of Unrelieved Pain

Although many professionals and laypersons fear that opioid analgesics lead to shortened life, there is significant evidence to the contrary. A large cohort study revealed that individuals experiencing chronic pain had a 10-year increased mortality.[22] It is likely that inadequate pain relief hastens death by increasing physiological stress, potentially diminishing immunocompetence, decreasing mobility, worsening proclivities toward pneumonia and thromboembolism, and increasing the work of breathing and myocardial oxygen requirements. For example, studies of men with prostate cancer reveal a significant association between pain interference scores and risk of death.[23,24] Furthermore, pain may lead to spiritual death as the individual's quality of life is impaired. Therefore, it is the professional and ethical responsibility of clinicians to focus on and attend to adequate pain relief for their patients and to properly educate patients and their caregivers about all analgesic therapies, including opioids.

Assessment and Common Pain Syndromes

Comprehensive assessment of pain is imperative. This must be conducted initially, regularly throughout the treatment, and during any changes in the patient's pain state. For a complete discussion of pain assessment, see Chapter 8.

Pharmacological Management of Pain in Advanced Disease

A sound understanding of pharmacotherapy in the treatment of pain is of great importance in palliative care nursing. First, this knowledge allows the nurse to contribute to and fully understand the comprehensive plan of care. Thorough understanding also allows the nurse to recognize and assess medication-related adverse effects, to understand drug–drug and drug–disease interactions, and to educate patients and caregivers regarding appropriate medication usage. This will assure a comfortable process of dying, both for the well-being of the patient and for the sake of those in attendance.

This section provides an overview of the most commonly used agents and some of the newer pharmaceutical agents available in the United States for the treatment of unremitting and recurrent pain associated with advanced disease. The intent of this section is to arm the reader with a fundamental and practical understanding of the medications that are (or should be) available in most contemporary care settings, emphasizing those therapies for which there is clear and convincing evidence of efficacy.

Since patients or family members are not always aware of the names of their medications, or they may bring pills to the hospital or clinic that are not in their original bottles, many web-based resources provide pictures that can assist the nurse in identifying the current analgesic regimen. These can be found at http://www.drugs.com/pill_identification.html or http://www.webmd.com/pill-identification/default.htm. Some of these programs are available as applications for mobile phones and tablets.

Nonopioid Analgesics

Acetaminophen

Acetaminophen has been determined to be one of the safest analgesics for long-term use in the management of mild pain or as a supplement in the management of more intense pain syndromes, yet questions regarding its analgesic efficacy have been raised. Acetaminophen (also abbreviated as APAP and referred to as paracetamol outside of North America) may be considered an adjunct to any chronic pain regimen. A recent Cochrane review of oral acetaminophen found no high-quality evidence to support or refute its use alone or in combination with opioids for cancer pain.[25,26] Reduced doses or avoidance of acetaminophen is recommended in the face of renal insufficiency or liver dysfunction.[27] A complete review of both prescribed as well as over-the-counter (OTC) medications taken by the patient is indicated.[28] Many OTCs contain acetaminophen, and patients may not be aware of the risk of overdose. An intravenous formulation of acetaminophen is currently available and has been studied in a variety of perioperative, postoperative, and acute care settings. A Cochrane review found that approximately 36% of patients experienced approximately 4 hours of effective analgesia.[29] Intravenous acetaminophen has also been used to treat fever in pediatric oncology.[30] Cost issues and lack of clear benefit over oral administration may preclude its use in palliative care.[31]

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) affect analgesia by reducing the biosynthesis of prostaglandins, thereby inhibiting the cascade of inflammatory events that cause, amplify, or maintain nociception. These agents also appear to reduce pain by influences on the peripheral or central nervous system independent of their anti-inflammatory mechanism of action. This secondary mode of analgesic efficacy is poorly understood. The "classic" NSAIDs (e.g., aspirin or ibuprofen) are relatively nonselective in their inhibitory effects on the enzymes that convert arachidonic acid to prostaglandins. As a result, gastrointestinal (GI) ulceration, renal dysfunction, and impaired platelet aggregation are common.[32,33] The cyclooxygenase-2 (COX-2) enzymatic pathway is induced by tissue injury or other inflammation-inducing conditions. It is for this reason that there appears to be less risk of GI bleeding with use of the COX-2 selective NSAID celecoxib, at least during initial months of treatment[34] (Table 9.1).

The NSAIDs, as a class, are very useful in the treatment of many pain conditions mediated by inflammation, including those caused by cancer. The NSAIDs offer the potential advantage of causing minimal nausea, constipation, sedation, or other effects on mental functioning. Therefore, depending on the cause of pain, NSAIDs may be useful for moderate to severe pain control, either alone or as an adjunct to opioid analgesic therapy. The addition of NSAIDs to opioids has the benefit of potentially allowing the reduction of the opioid dose when sedation, confusion, dizziness, or other central nervous system effects of opioid analgesic therapy alone become burdensome.

Decreased renal function and liver failure are relative contraindications for NSAID use. Similarly, platelet dysfunction or other potential bleeding disorders contraindicate use of the nonselective NSAIDs due to their inhibitory effects on platelet aggregation, with resultant prolonged bleeding time. Cardiovascular risk associated with NSAIDs, including myocardial infarction and stroke, has been identified and appears to be higher in those with preexisting risk factors.[35,36] Cardiovascular risk appears to be dependent upon duration of use, with celecoxib risk associated with 30 days or more of continuous use, while with other NSAIDs, such as ibuprofen, the risk increases within 7 days of use.[37,38] Studies suggest that patients are often unaware of the adverse effects associated with these drugs and may use NSAIDs in a way that increases risk.[39]

Opioid Analgesics

As a pharmacological class, the opioid analgesics represent the most useful agents for the treatment of pain associated with advanced disease (Box 9.2). The opioids are nonspecific insofar as they decrease pain signal transmission and perception throughout the nervous system, regardless of the pathophysiology of the pain. Moderate to severe pain is the main clinical indication for the opioid analgesics.[9,40] Despite past beliefs that opioids were ineffective for neuropathic pain, these agents have been found to be useful in the treatment of this complex pain syndrome; however, higher doses are usually warranted. Other indications for opioid use include the treatment of dyspnea, reduction in diarrhea, use as an anesthetic adjunct, and as a form of prophylactic therapy in the treatment of opioid use disorder (OUD) (e.g., methadone or buprenorphine for those with a history of misuse of opioids).

Table 9.1 Acetaminophen and selected nonsteroidal anti-inflammatory drugs

Drug	Dose if patient > 50 kg	Dose if patient < 50 kg
Acetaminophen[a,b]	500–1,000 mg q4–6h oral; maximum 4,000 mg/24 hr (2,000–3,000 mg if used chronically) 1,000 mg q6h IV (given over 15-minute infusion); maximum 4,000 mg/24 hr	10–15 mg/kg q4h (oral) 15 mg/kg q6h; maximum 75 mg (IV) 15–20 mg/kg q4h (rectal)
Aspirin[a,b]	4,000 mg/24 hr maximum, given q4–6h	10–15 mg/kg q4h (oral)
		15–20 mg/kg q4h (rectal)
Ibuprofen[a,b]	2,400 mg/24 hr maximum, given q6–8h	10 mg/kg q6–8h (oral)
Naproxen[a,b]	1,000 mg/24 hr maximum, given q8–12h	5 mg/kg q8h (oral/rectal)
Choline magnesium trisalicylate[a,d]	2,000–3,000 mg/24 hr maximum, given q8–12h	25 mg/kg q8h (oral)
Indomethacin[b]	75–150 mg/24 hr maximum, given q8–12h	0.5–1 mg/kg q8–12h (oral/rectal)
Ketorolac[c]	30–60 mg IM/IV initially, then 15–30 mg q6h bolus IV/IM or continuous IV/SQ infusion; short-term use only (3–5 days)	0.25–1 mg/kg q6h short-term use only (3–5 days)
Celecoxib[d,e]	100–200 mg PO up to bid	No data available

[a] Commercially available in a liquid form.

[b] Commercially available in a suppository form.

[c] Potent anti-inflammatory (short-term use only due to gastrointestinal side effects).

[d] Minimal platelet dysfunction.

[e] Cyclooxygenase-2-selective nonsteroidal anti-inflammatory drug.

Box 9.2 Guidelines for the Use of Opioids

Clinical studies and experience suggest that adherence to some basic precepts will help optimize care of patients who require opioid analgesic therapy for pain control:

- Oral administration of opioids is preferred in most cases. Intramuscular administration is highly discouraged. Subcutaneous or intravenous delivery is an alternative.
- Noninvasive drug delivery systems that "bypass" the enteral route (e.g., the transdermal [fentanyl or buprenorphine] and the oral transmucosal routes for delivery of fentanyl for treatment of continuous pain and breakthrough pain) may obviate the necessity to use parenteral routes for pain control in some patients who cannot take medications orally or rectally.
- Anticipation, prevention, and treatment of sedation, constipation, nausea, psychotomimetic effects, and myoclonus should be part of every care plan for patients being treated with opioid analgesics.
- Changing from one opioid to another or one route to another is often necessary, so facility with this process is an absolute necessity. Remember the following points:
    - Incomplete cross-tolerance occurs, leading to decreased requirements of a newly prescribed opioid.
    - Use morphine milligram equivalents (MME) as a "common denominator" for all dose conversions in order to avoid errors.

Source: References 9, 40.

The only absolute contraindication to the use of an opioid is a history of a hypersensitivity reaction (rash, wheezing, and edema). In the rare event that a patient describes a true allergic reaction, one might begin therapy with a low dose of a short-acting synthetic opioid (e.g., intravenous fentanyl) or try an intradermal injection as a test dose. The rationale for using a synthetic opioid (preferably one without dyes or preservatives since these can cause allergic reactions) is that the prevalence of allergic reactions is much lower.

It is also critically important for clinicians who are involved in patient care to be aware that titration of opioid analgesics to affect pain relief is rarely associated with induced respiratory depression and iatrogenic death.[41,42] In fact, the most compelling evidence suggests that inadequate pain relief hastens death by increasing physiological stress, decreasing immunocompetence, diminishing mobility, increasing the potential for thromboembolism, worsening inspiration and thus placing the patient at risk for pneumonia, and increasing myocardial oxygen requirements. Furthermore, in several systematic reviews, there was no relationship between opioid use and survival.[43,44]

There is significant inter- and intraindividual variation in clinical responses to the various opioids, so, in most cases, a dose-titration approach should be viewed as the best means of optimizing care.[45] This implies that close follow-up is required to determine when clinical endpoints have been reached. Furthermore, idiosyncratic responses may require trials of different agents to determine the most effective drug and route of delivery for any given patient. Table 9.2 lists more specific suggestions regarding optimal use of opioids.

Another factor that needs to be considered with opioid analgesics is the potential to accumulate toxic metabolites, especially in the face of decreasing drug clearance and elimination

Table 9.2 Approximate equianalgesic doses of most commonly used opioid analgesics[a]

Drug	Parenteral route	Enteral route
Morphine[b]	10 mg	30 mg
Codeine	130 mg	200 mg (not recommended)
Fentanyl[c]	100 mcg	TIRF[c]
Hydrocodone[b]	Not available	30 mg
Hydromorphone[d]	1.5 mg	7.5 mg
Levorphanol[e]	2 mg acute, 1 chronic	4 mg acute, 1 chronic
Methadone[e]	See text	See text
Oxycodone[f]	Not available	20 mg

TIRF, transmucosal immediate-release fentanyl.

[a] Dose conversion should be closely monitored since incomplete cross-tolerance may occur.

[b] Available in continuous and sustained-release pills and capsules, formulated to last 12 or 24 hours

[c] Also available in transdermal and TIRF, see package insert materials for dose recommendations. TIRF = transmucosal immediate release fentanyl.

[d] Available as a continuous-release formulation lasting 24 hours.

[d] These drugs have long half-lives, so accumulation can occur; close monitoring during first few days of therapy is very important.

[f] Available in several continuous-release doses, formulated to last 12 hours.

Source: References 9, 40.

as disease progresses and organ function deteriorates. Due to its neurotoxic metabolite, normeperidine, meperidine use is specifically discouraged for chronic pain management. As well, the mixed agonist–antagonist agents, typified by butorphanol, nalbuphine, and pentazocine, are not recommended for the treatment of chronic pain. They have limited efficacy, and their use may cause an acute abstinence syndrome in patients who are otherwise using pure agonist opioid analgesics.

Morphine

Morphine is most often considered the "gold standard" of opioid analgesics and is used as a measure for dose equivalence (Table 9.2).[9,40] Although some patients cannot tolerate morphine due to itching, headache, dysphoria, or other adverse effects, common initial dosing effects such as sedation and nausea often resolve within a few days. In fact, one should anticipate these adverse effects, especially constipation, nausea, and sedation, and prevent or treat appropriately (see later discussion). Metabolites of morphine and hydromorphone, morphine-3-glucuronide (M3G) and hydromorphone-3-glucuronide (H3G), respectively, may contribute to myoclonus, seizures, and hyperalgesia (increasing pain), particularly when patients cannot clear these metabolites due to renal impairment.[46,47] However, in a small study of hospice patients, increased levels of either M3G or H3G were not correlated with the presence of myoclonus.[48] If adverse effects exceed the analgesic benefit of the drug, convert to an equianalgesic dose of a different opioid. Because cross-tolerance is incomplete, reduce the calculated dose by one-third to one-half and titrate upward based on the patient's report of relief and/or improved level of function.[9]

Morphine's bitter taste may be prohibitive, especially if "immediate-release" tablets are left in the mouth to dissolve. When patients have dysphagia, several options are available. The 24-hour, long-acting morphine capsule can be broken open and the "sprinkles" placed in applesauce or other soft food. Oral morphine solution can be swallowed, or small volumes (0.5–1 mL) of a concentrated solution (e.g., 20 mg/mL) can be placed in the mouth of patients whose voluntary swallowing capabilities are more significantly limited. Buccal uptake of morphine is slow, unpredictable, and insufficient to produce analgesia due to its hydrophilic nature.[49] Furthermore, again due to the hydrophilic nature of morphine, creams, gels, and patches that contain morphine do not cross the skin and therefore do not provide systemic analgesia.[50] Commercially prepared suppositories, compounded suppositories, or microenemas can be used to deliver the drug into the rectum. Sustained-release morphine tablets have been used rectally, with resultant delayed time to peak plasma level and approximately 90% of the bioavailability achieved by oral administration.[51]

Fentanyl

Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally (buccal, sublingual, and nasal), and by nebulizer for the management of dyspnea. Because of its potency, dosing is usually conducted in micrograms.

Transdermal Fentanyl

Transdermal fentanyl, often called the fentanyl patch, is particularly useful when patients cannot swallow, do not remember to take medications, or have adverse effects to other opioids. Two primary systems are currently available—a reservoir-based patch and a matrix type patch. These systems exhibit quite similar effects in intact skin, although differences may result when exposed to heat (greater drug permeation at 72 hours in the reservoir system) or to compromised skin (greater permeation seen in the matrix patch).[52] Although the package insert states that transdermal patches should not be used in opioid-naive patients, a small study suggests that the 12 mcg/hr patch can be safely used in this population.[53] Fever, diaphoresis, cachexia, morbid obesity, liver function, ascites, and the concomitant use of 3A4 inducers may have an impact on the absorption, predictability of blood levels, and clinical effects of transdermal fentanyl.[54] One study comparing cachectic with normal weight patients found reduced serum fentanyl levels in those with reduced weight.[55] Despite these lower levels, clinical experience reveals that transdermal fentanyl can be effective even in those patients with few fat stores. Higher doses may be indicated. There is some suggestion that transdermal fentanyl may produce less constipation when compared to long-acting morphine.[56] At lower doses, transdermal fentanyl has limited effect on the sphincter of Oddi, suggesting that this may be a safe and effective therapy for patients with pancreatitis.[57]

Some patients experience decreased analgesic effects after only 48 hours of applying a new patch; a more frequent (q48h) patch change should be scheduled. As with all long-acting preparations, breakthrough pain medications should be made available to patients using continuous-release opioids such as the fentanyl patch.

Transmucosal Immediate Release Fentanyl Products

Several formulations of transmucosal immediate-release fentanyl (TIRF) products are available, including oral transmucosal fentanyl citrate (OTFC), buccal tablets, and soluble film, as well as oral and nasal spray.[58] Adults should start with the lowest dose and monitor efficacy, advancing to higher dose units as needed. Clinicians must be aware that, unlike other breakthrough pain drugs, the around-the-clock dose of opioid does not predict the effective dose of OTFC. Fentanyl nasal spray has the most rapid onset of the TIRF products, with significantly improved pain intensity scores as early as 5 minutes after administration, along with minimal adverse effects.[59]

Oxycodone

Oxycodone is a synthetic opioid available in a long-acting formulation, as well as in immediate-release tablets (alone or with acetaminophen, aspirin, or ibuprofen) and liquid. It is approximately as lipid soluble as morphine but has better oral absorption. The equianalgesic ratio is approximately 20 mg to 30 mg of oral morphine. Side effects appear to be similar to those experienced with morphine.[60] Substances that inhibit CYP3A4, such as the highly active antiretroviral agent ritonavir, the antiviral voriconazole, and even grapefruit juice, have been found to increase oxycodone concentrations.[61] Lower doses of oxycodone may be warranted when CYP3A4 inhibitors are administered.

Methadone

Methadone has several characteristics that make it useful in the management of severe, chronic pain. The half-life of 24–60 hours or longer allows prolonged dosing intervals, although for pain control, dosing every 8–12 hours is recommended. Methadone may also bind as an antagonist to the *N*-methyl-D-aspartate (NMDA) receptor, believed to be of particular benefit in neuropathic pain and in preventing hyperalgesia. Additionally, methadone can be given orally, parenterally, and sublingually. Furthermore, methadone is much less costly than comparable doses of proprietary continuous-release formulations, making it potentially more available for patients without sufficient financial resources for more costly drugs.[62]

Despite these advantages, much is unknown about the appropriate dosing ratio between methadone and morphine, as well as the safest and most effective time course for conversion from another opioid to methadone (Table 9.2). As a result, recommendations suggest that patients be started on no more than 30–40 mg of methadone per day with very slow upward titration. Methadone should not be used for breakthrough pain dosing or on an as-needed basis.[63] Furthermore, although the long half-life is an advantage, it also increases the potential for drug accumulation before achieving steady-state blood levels, putting patients at risk for oversedation and respiratory depression. For example, it would take 12 days to reach steady state when the half-life is 60 hours. Close monitoring of these potentially adverse or even life-threatening effects is required, and most experts suggest that methadone only be prescribed by experienced clinicians.[63,64] Myoclonus has been reported with parenteral methadone use.[65] Of concern for some patients is the prolongation of QT wave (also called torsade de pointes) that can occur with methadone administration.[66]

Methadone is metabolized by CYP3A4, CYP2D6, and other enzymes. As a result, drugs that induce CYP enzymes accelerate the metabolism of methadone, resulting in reduced serum levels of the drug (Table 9.3). This may be demonstrated clinically by shortened analgesic periods or reduced overall pain relief. Examples of these drugs often used in palliative care include several antiretroviral agents, dexamethasone, carbamazepine, phenytoin, and barbiturates.[67] Drugs that inhibit CYP enzymes slow methadone metabolism, potentially leading to sedation and respiratory depression. These include ketoconazole, omeprazole, and selective serotonin reuptake inhibitor (SSRI) antidepressants such as fluoxetine, paroxetine, and sertraline.

Table 9.3 Selected medications that increase or decrease methadone serum levels

CYP3A4 inducers that decrease methadone	CYP3A4 inhibitors that increase methadone
Barbiturates	Cimetidine
Carbamazepine	Ciprofloxacin
Dexamethasone	Diazepam
Phenytoin	Haloperidol
Rifampin	Ketoconazole
Spironolactone	Omeprazole
	Verapamil

Patients currently receiving methadone as part of a maintenance program for addictive disease will have developed cross-tolerance to the opioids and, as a result, require higher doses than naive patients. Prescribing methadone for substitution therapy in addictive disease requires a special license in the United States.

Hydromorphone

Hydromorphone is a useful alternative when synthetic opioids provide an advantage. It is available in oral tablets, liquids, suppositories, parenteral formulations, and a long-acting formulation.[68] Although hydromorphone-3-glucuronide may accumulate in renal disease, this metabolite is removed when patients are receiving dialysis, providing evidence for the safety of this drug in these patients.[69]

Oxymorphone

Oxymorphone is a semi-synthetic opioid that has been available in a parenteral formulation for almost 50 years and had been available in oral immediate-release and extended-release formulations since 2006.[70] The safety and efficacy profile in people with cancer is similar to other opioids, such as morphine and oxycodone.[71] An outbreak of oxymorphone injection that led to multiple new diagnoses of HIV infection within a small town in Indiana raised concerns regarding misuse of the opioid; the manufacturer voluntarily withdrew the extended-release formulation from the market.[72]

Other Opioids

Buprenorphine, codeine, hydrocodone, levorphanol, tramadol, and tapentadol are other opioids available in the United States for treatment of pain. Their equianalgesic comparisons are shown in Table 9.2. Buprenorphine, a partial agonist, is typically used as part of an opioid maintenance program instead of methadone. A 7-day buprenorphine patch approved for moderate to severe pain is now available in the United States.[73] Codeine is limited by pharmacogenetics; as a prodrug, it must be broken down by the enzyme CYP2D6 to provide analgesia, yet approximately 10% of Caucasians in the United States are poor metabolizers.[74]

Conversely, some patients are ultrarapid metabolizers, which can lead to overdose.[75] Hydrocodone is only available in combination products in its immediate-release form, thus limiting dose escalation in palliative care due to concerns regarding excess acetaminophen or other agents. There are single-agent, long-acting hydrocodone products that are administered daily or every 12 hours.[76] Levorphanol has similarities to methadone, including a longer half-life; it is difficult to obtain in the United States.[77] Tramadol is a weak opioid and has serotonin and norepinephrine reuptake inhibition properties. It is available in immediate- and extended-release formulations. Although effective for mild, nonmalignant, neuropathic pain, a systematic review found insufficient data to support its use for cancer pain.[78] Dose escalation is limited due to potential lowering of the seizure threshold, and clinicians must be alert to the risk of serotonin syndrome. Tapentadol is available in immediate- and extended-release formulations, and reports suggest it may be useful in some palliative care settings, particularly in the relief of neuropathic pain.[70,79]

Alternative Routes of Administration for Opioid Analgesics

Many routes of administration are available when patients can no longer swallow or when other dynamics preclude the oral route or favor other routes. These include transdermal, transmucosal (buccal, sublingual or nasal), rectal, enteral, vaginal, epidural, and intrathecal. In a study of cancer patients at 4 weeks, 1 week, and 24 hours before death, the oral route of opioid administration was continued in 62%, 43%, and 20% of patients, respectively. More than half of these patients required more than one route of opioid administration. As patients approached death and oral use diminished, the use of intermittent subcutaneous injections and intravenous or subcutaneous infusions increased.

Thus, in the palliative care setting, nonoral routes of administration must often be available. Enteral feeding tubes can be used to access the gut when patients can no longer swallow. The size of the tube should be considered when administering long-acting morphine or oxycodone "sprinkles" to avoid obstruction of the tube. The rectum, stoma, or vagina can be used to deliver medication. Thrombocytopenia, neutropenia, or painful lesions may preclude the use of these routes. Additionally, delivering medications via these routes can be difficult for family members, especially when the patient is obtunded or unable to assist. As previously discussed, transdermal, transmucosal, or buccal fentanyl are useful alternatives to these techniques.

Parenteral administration includes subcutaneous and intravenous delivery (intramuscular opioid delivery is inappropriate in the palliative care setting). The intravenous route provides rapid drug delivery but requires vascular access, placing the patient at risk for infection and potentially complicating the care provided by family or other loved ones. Subcutaneous boluses have a slower onset and lower peak effect when compared with intravenous boluses. Subcutaneous infusions may total up to 10 mL/hr (although most patients absorb 2–3 mL/hr with least difficulty). Volumes greater than 10 mL/hr are poorly absorbed. Hyaluronidase has been reported to speed absorption of subcutaneously administered drugs.

Intraspinal routes, including epidural or intrathecal delivery, may allow administration of drugs, such as opioids, local anesthetics, α-adrenergic agonists, or ziconitide.[80] One randomized controlled trial demonstrated benefit for cancer patients experiencing pain.[81] However, the equipment used to deliver these medications is complex, requiring specialized knowledge for healthcare professionals and potentially greater caregiver burden. Risk of infection is also of concern. Furthermore, cost is a significant concern related to high-technology procedures.

Preventing and Treating Adverse Effects of Opioid Analgesics

- *Constipation*. Patients in palliative care frequently experience constipation, in part due to opioid therapy.[82] Always begin a prophylactic bowel regimen when commencing opioid analgesic therapy.[40] Most clinicians recommend a laxative/softener combination, although a randomized controlled trial found that senna plus placebo was more effective than senna and docusate.[83] Avoid bulking agents (e.g., psyllium) since these tend to cause a larger, bulkier stool, increasing desiccation time in the large bowel. Furthermore, debilitated patients can rarely take in sufficient fluid to facilitate the action of bulking agents. Fluid intake should be encouraged whenever feasible. Senna tea and fruits may be of use. Several agents have been approved to address opioid-induced constipation (OIC). Several peripherally acting mu-opioid receptor antagonists (PAMORAs) are available, including subcutaneous and oral formulations (namely methylnaltrexone and naloxegal).[84,85] Lubiprostone, an oral agent that works on chloride channels in the intestine, was approved for use in opioid-induced constipation in noncancer patients.[86] For a more comprehensive review of bowel management, refer to Chapter 14.
- *Sedation*. Excessive sedation may occur with the initial exposure to opioids.[87] If sedation persists after 24–48 hours and other correctable causes have been identified and treated if possible, opioid rotation or the addition of psychostimulants may be beneficial. Psychostimulants include dextroamphetamine 2.5–5 mg orally every morning and midday or methylphenidate 5–10 mg orally every morning and 2.5–5 mg midday (although higher doses are frequently used). Adjust both the dose and timing to prevent nocturnal insomnia and monitor for undesirable psychotomimetic effects (such as agitation, hallucinations, and irritability). Little research is available to guide the use of these agents. Modafinil, an agent approved to manage narcolepsy, has been reported to relieve opioid-induced sedation with once-daily dosing. However, a randomized controlled trial found no effect on cancer-related fatigue compared with placebo.[88] Because of the lack of data regarding these agents, selection of drug and dosing are empirical.
- *Respiratory depression*. Respiratory depression is rarely a clinically significant problem for opioid-tolerant patients in pain. When respiratory depression occurs in a patient with advanced disease, the cause is usually multifactorial. Therefore, other factors beyond opioids need to be assessed, although opioids are frequently blamed for the reduced respirations. When undesired, depressed consciousness occurs along with a respiratory rate of less than 8/min or hypoxemia (O_2 saturation <90%) associated with opioid use, cautious and slow titration of naloxone, which reverses the effects of the opioids, should be instituted.[40] Excessive administration may cause abrupt opioid reversal with pain and autonomic crisis. Dilute 1 ampule of naloxone (0.4 mg/mL) in 10 mL of injectable saline (final concentration 40 mcg/mL) and inject 1 mL every 2–3 minutes

while closely monitoring the level of consciousness and respiratory rate.[40] Because the duration of effect of naloxone is approximately 30 minutes, the depressant effects of the opioid will recur at 30 minutes and persist until the plasma levels decline (often 4 or more hours) or until the next dose of naloxone is administered.

- *Nausea and vomiting*. Nausea and vomiting are common with opioids due to activation of the chemoreceptor trigger zone in the medulla, vestibular sensitivity, and delayed gastric emptying, but habituation occurs in most cases within several days.[87] Assess for other treatable causes. In severe cases or when nausea and vomiting are not self-limited, pharmacotherapy is indicated. See Chapter 12 for a thorough discussion of the assessment and treatment of nausea and vomiting.
- *Myoclonus*. Myoclonic jerking occurs more commonly with high-dose opioid therapy, although it has also been reported with lower dosing.[65,89] A lower relative dose of the substituted drug may be possible due to incomplete cross-tolerance, which might result in decreased myoclonus. Clonazepam 0.5–1 mg orally every 6–8 hours, to be increased as needed and tolerated, may be useful in treating myoclonus in patients who are still alert, able to communicate, and take oral preparations. Lorazepam can be given sublingually, if the patient is unable to swallow. Otherwise, parenteral administration of a benzodiazepine, such as midazolam, is indicated if symptoms are distressing.
- *Pruritus*. Pruritus appears to be most common with morphine, in part due to histamine release, but can occur with most opioids. Fentanyl and oxymorphone may be less likely to cause histamine release. Most antipruritic therapies cause sedation, so this side effect must be viewed by the patient as an acceptable tradeoff. Antihistamines (such as diphenhydramine) are the most common first-line approach to this opioid-induced symptom when treatment is indicated.[90] Ondansetron has been reported to be effective in relieving opioid-induced pruritus, but no randomized controlled studies exist.[91] See Chapter 20 for more information regarding pruritus.

Adjuvant Analgesics

A wide variety of nonopioid medications from several pharmacological classes have been demonstrated to reduce pain caused by various pathological conditions (Table 9.4). As a group, these drugs have been called analgesic "adjuvants," but this is something of a misnomer since they often reduce pain when used alone. However, under most circumstances, when these drugs are indicated for the treatment of severe neuropathic pain or bone pain, opioid analgesics are used concomitantly to provide adequate pain relief.

Antidepressants

The mechanism of the analgesic effect of tricyclic antidepressants appears to be related to inhibition of norepinephrine and serotonin.[92] The tricyclic antidepressants are generally believed to provide relief from neuropathic pain.[93] Side effects often limit the use of these agents in palliative care. Cardiac arrhythmias, conduction abnormalities, narrow-angle glaucoma, and clinically significant prostatic hyperplasia are relative contraindications to the tricyclic antidepressants. The delay in onset of pain relief, from days to weeks, may preclude the use of these agents for pain relief in end-of-life care. However, their sleep-enhancing and mood-elevating effects may be of benefit.

Both older antidepressants and newer atypical agents have been shown to be effective in relieving neuropathic pain, although there remains little support for the analgesic effect of SSRIs. Atypical antidepressants venlafaxine and duloxetine have been shown to reduce neuropathy associated with chemotherapy-induced neuropathy.[94]

Antiepilepsy Drugs

The older antiepilepsy or anticonvulsant drugs, such as carbamazepine and clonazepam, relieve pain by blocking sodium channels. Previously referred to as membrane stabilizers, these compounds are useful in the treatment of neuropathic pain, especially in those with episodic, lancinating qualities. Gabapentin and pregabalin act at the alpha-2 delta subunit of the voltage-gated calcium channel.[92] Additional evidence supports the use of these agents in neuropathic pain syndromes seen in palliative care, such as thalamic pain, pain due to spinal cord injury, and cancer pain, along with restless leg syndrome.[93] In a study comparing amitriptyline, gabapentin, and pregabalin in cancer patients with neuropathic pain, no significant differences were found in analgesic effect, although pregabalin had a greater morphine sparing effect.[95] Both gabapentin and pregabalin require dose reduction in ESRD.[96] Other anticonvulsants have been used with success in treating neuropathies, including lamotrigine, levetiracetam, tiagabine, topiramate, and zonisamide, yet no randomized controlled clinical trials are currently available.

Corticosteroids

Corticosteroids inhibit prostaglandin synthesis and reduce edema surrounding neural tissues. Dexamethasone has been found to reduce postoperative pain and nausea and is particularly useful for relieving painful neuropathic syndromes, including plexopathies, as well as pain associated with stretching of the liver capsule due to metastases.[97,98] Corticosteroids are also highly effective for treating bone pain due to their anti-inflammatory effects, as well as pain flair after radiation treatment of bone metastases.[99] Dexamethasone has been found to be useful in relieving symptoms associated with malignant intestinal obstruction.[100] Dexamethasone produces the least amount of mineralocorticoid effect, leading to reduced potential for Cushing's syndrome. Dexamethasone is available in oral, intravenous, subcutaneous, and epidural formulations. The standard dose is 2 to 24 mg/day and can be administered once daily due to the long half-life of this drug. Dexamethasone doses as high as 100 mg may be given with severe pain crises. Intravenous bolus doses should be pushed slowly, to prevent uncomfortable perineal burning and itching. An additional benefit of steroid use was revealed by a recent clinical trial in cancer patients that supported the use of dexamethasone in the relief of fatigue.[101]

Local Anesthetics

Local anesthetics work in a manner similar to the older anticonvulsants—by inhibiting the movement of ions across the neural membrane. They are useful for relieving neuropathic pain. Local anesthetics can be given orally, topically, intravenously, subcutaneously, or spinally. Mexiletine has been reported to be useful when anticonvulsants and other adjuvant therapies have failed, although high-quality studies are lacking. Local anesthetic gels and patches have been used to prevent the pain associated with needle

Table 9.4 Adjuvant analgesics

Drug class	Daily adult starting dose[a] (range)	Routes of administration	Adverse effects	Indications
Antidepressants	Nortriptyline 10–25 mg	PO	Anticholinergic effects	Neuropathic pain
	Desipramine 10–25 mg	PO		
	Venlafaxine 37.5 mg bid	PO	Nausea, dizziness	
	Duloxetine 30 mg	PO	Nausea	
Anticonvulsants	Clonazepam 0.5–1 mg HS, bid or tid	PO	Sedation	Neuropathic pain
	Carbamazepine 100 mg qday or tid	PO	Sedation, Aplastic anemia (rare)	
	Gabapentin 100–300 mg tid	PO	Sedation, dizziness	
	Pregabalin 50 mg bid or tid		Sedation, dizziness	
Corticosteroids	Dexamethasone 2–24 mg qday; may give up to 100 mg IV bolus for pain crises	PO/IV/SQ	"Steroid psychosis," dyspepsia	Cerebral edema, spinal cord compression, bone pain, neuropathic pain, visceral pain
	Prednisone 15–30 mg tid	PO		
Local anesthetics	Lidocaine 1–5 mg/kg hourly	IV or SQ infusion	Lightheadedness, arrhythmias	Neuropathic pain
N-Methyl-D-aspartate antagonists	Dextromethorphan, effective dose unknown	PO	Confusion	Neuropathic pain
	Ketamine (see Pain Crises)	IV		
Calcitonin	25 IU/day	SQ/nasal	Hypersensitivity reaction, nausea	Neuropathic pain, bone pain
Capsaicin	0.025–0.075% cream 8% patch	Topical	Burning	Neuropathic pain
Baclofen	10 mg qday or tid	PO	Muscle weakness, cognitive changes	
Calcium channel blockers	Nifedipine 10 mg tid	PO	Bradycardia, hypotension	Ischemic pain, neuropathic pain, smooth muscle spasms with pain

[a] Pediatric doses for pain control not well established.

Source: References 9, 40.

stick and other minor procedures. Both gel and patch versions of lidocaine have been shown to reduce the pain of postherpetic neuropathy. Intravenous or subcutaneous lidocaine at 1–5 mg/kg (maximum 500 mg) administered over 1 hour, followed by a continuous infusion of 1–2 mg/kg/hr has been reported to reduce intractable neuropathic pain in patients in inpatient palliative care and home hospice settings in adults and children.[102–104]

N-Methyl-D-Aspartate Antagonists: Ketamine

Antagonists to NMDA are believed to block the binding of excitatory amino acids, such as glutamate, in the spinal cord. Ketamine, a dissociative anesthetic, is believed to relieve severe neuropathic pain by blocking NMDA receptors. Case reports and small studies suggest that intravenous or oral ketamine can be used in adults and children for their relief of neuropathic pain or to reduce opioid doses.[105] A Cochrane review found insufficient trials conducted to determine safety and efficacy when used in combination with morphine in cancer pain.[106] However, a systematic review concluded that although limitations in the data exist, ketamine may be an option for refractory cancer pain.[107]

Ketamine is commercially available in the United States only in a parenteral formulation. If the oral route is indicated, a palatable solution can be compounded or the parenteral solution ingested, usually mixed with juice or other liquids to mask the bitter taste. Because the opioid-sparing effect is so pronounced, the opioid dose should be reduced by 25–50% when initiating ketamine (Box 9.3). Routine use often is limited by cognitive changes, hallucinations, and other adverse effects, although small studies suggest that gradual upward titration may prevent these effects in adults and children.[108,109] Topical ketamine, usually in combination with amitriptyline and baclofen, may be useful for neuropathic conditions due to cancer treatment such as chemotherapy-induced peripheral neuropathy.[110] More research is needed regarding the efficacy of and adverse effects associated with the use of ketamine for intractable pain in the palliative care population.

Bisphosphonates

Bisphosphonates, such as pamidronate, zoledronic acid, and ibandronate, inhibit osteoclast-mediated bone resorption.

Bisphosphonates treat hypercalcemia and prevent pain related to skeletal events such as metastatic bone disease and multiple myeloma.[111] Denosumab, a RANKL inhibitor, prevents the development of osteoclasts and has been shown to reduce skeletal related events associated with solid tumors, which would reduce pain associated with fractures. A recent review questions the analgesic efficacy of these agents and concludes that bisphosphonates and denosumab appear to be beneficial in preventing pain by delaying the onset of skeletal events.[112] A Cochrane review of these agents used to treat bone metastases of breast cancer found some evidence to support pain relief,[111] yet a review of their use in prostate cancer found no benefit in reducing pain.[113] Toxicities include renal dysfunction and osteonecrosis of the jaw. Clodronate and sodium etidronate appear to provide little or no analgesia.

Calcitonin

Subcutaneous calcitonin may be effective in the relief of bone pain, although studies are inconclusive.[114] The nasal form of this drug may be more acceptable in end-of-life care when other therapies are ineffective. Usual doses are 100–200 IU/day subcutaneously or nasally.

Radiation Therapy and Radiopharmaceuticals

Radiotherapy can be enormously beneficial in relieving pain due to bone metastases or other lesions.[115] In many cases, single-fraction external beam therapy can be used to facilitate treatment in debilitated patients.[116] Goals of treatment should be clearly articulated, so that patients and family members understand the role of this therapy. Targeted therapies, also referred to as cyberknife or gamma knife radiosurgery, can be effective in selected situations.[117] Radiolabeled agents, also described as radiopharmaceuticals, such as strontium-89 and samarium-153, have been shown to be effective at reducing metastatic bone pain.[118] Thrombocytopenia and leukopenia are relative contraindications since strontium-89 can cause thrombocytopenia in as many as 33% of those treated and leukopenia in up to 10%. Because of the delayed onset and timing of peak effect, only those patients with a projected life span of greater than 3 months should be considered for treatment. Patients should be advised that a transitory pain flare can occur after either external beam therapy or radiolabeled agents; additional analgesics should be provided in anticipation.

Chemotherapy

Palliative chemotherapy is the use of antitumor therapy to relieve symptoms associated with malignancy. Patient goals, performance status, sensitivity of the tumor, and potential toxicities must be considered. Examples of symptoms that may improve with chemotherapy include hormonal therapy in breast cancer to relieve chest wall pain due to tumor ulceration, or chemotherapy in lung cancer to relieve dyspnea. However, in a study of patients with stage IV cancers, 69% of those with lung and 81% of those with colorectal cancers did not understand the chemotherapy was not curative.[119] A prospective trial of palliative chemotherapy given 4 months before death revealed an increased risk of undergoing cardiopulmonary resuscitation, mechanical ventilation, or dying in an intensive care unit.[120] Clear discussions regarding the goals of therapy are warranted.

Other Adjunct Analgesics

Topical *capsaicin* is believed to relieve pain by inhibiting the release of substance P. This compound has been shown to be useful in relieving pain associated with post-mastectomy syndrome, postherpetic neuralgia, and postsurgical neuropathic pain in cancer. A burning sensation experienced by patients is a common reason for discontinuing therapy. A Cochrane review of low-dose topical capsaicin found this therapy unlikely to have meaningful effect, but that the high concentration (8%) topical capsaicin patch has been found to be effective in treating HIV-associated and other painful neuropathies.[121]

Patients often ask about *cannabinoids* for the relief of pain particularly as many states have legalized medical marijuana. Major advances, such as the characterization of the cannabinoid receptors (CB1 and CB2), have increased our understanding of the role of these receptors in pain.[122] Review of existing literature evaluating the role of cannabinoids supports some benefit for relief of neuropathic pain with adverse effects that include short-term cognitive impairment.[123,124] Questions regarding the long-term safety and regulatory implications remain.[125] Of importance to prescribers is that although a state may have legalized marijuana, its possession, sale, and use remain a federal offense. The greater insight into cannabinoid receptors has allowed the development of more selective agents that might provide analgesia without the central nervous system depressant effects seen with tetrahydrocannabinol (THC). Nabiximols, an oral cannabinoid spray shown to be effective in advanced cancer pain poorly responsive to opioids, has been approved in Canada and several countries in Europe for the relief of neuropathic pain.[126,127]

Baclofen is useful in the relief of spasm-associated pain. Doses usually begin at 10 mg/day, increasing every few days. A generalized feeling of weakness and confusion or hallucinations often occurs with doses above 60 mg/day. A small retrospective chart review of patients with neuropathic cancer pain suggested benefit from oral baclofen.[128]

Dexmedetomidine is an alpha-2 adrenergic agonist used primarily within intensive care or during invasive procedures. Early case reports suggest it may provide relief in intractable pain, although cost and hypotension may limit its use.[129]

Interventional Therapies

In addition to previously discussed spinal administration of analgesics, interventional therapies to relieve pain at end of life can be beneficial, including nerve blocks, vertebroplasty, kyphoplasty, radiofrequency or cryoablation of painful metastases, procedures to drain painful effusions, and other techniques.[130–132] Few of these procedures have undergone controlled clinical studies. One technique, the celiac plexus block, has been shown to be superior to morphine alone in patients with pain due to unresectable pancreatic cancer, although persistent diarrhea is a potential risk.[133,134] *Botulinum toxin* (sometimes referred to as Botox) can be injected into areas of muscle spasticity, with reductions in tightness and pain. This has been used extensively in migraine treatment and chronic pain conditions and has been found to be of benefit in peripheral neuropathic pain.[135,136]

A complete review of interventional procedures can be found in a variety of sources. The choice of one of these techniques depends on the availability of experts in this area who understand the special

Box 9.3 Palliative Care Program Guideline: Ketamine Utilization for Palliative Care

This is a guideline only. Due to patient variability and nuance, clinical decisions may deviate from this document.

Purpose: Ketamine is an adjunct medication often considered for opioid-refractory pain or intractable side effects from opioids, particularly if the pain is neuropathic in nature or if a high degree of morphine tolerance is suspected.

Definition: Ketamine is an N-methyl-D-aspartate receptor (NMDA) agent which may be opioid sparing.

Consultation and recommendations by the Pain Service and/or Palliative Care Service are required to ensure that all other pain management measures have been considered and for guidance in the process.

Protocol:

A. Oral Dosing

1. The typical starting dose is 10–15 mg orally every 6 hours. Reversal of morphine tolerance may occur at low doses such as this, while management of neuropathic pain is likely to require higher doses.
    a. There is no commercially available oral product. The injectable product may be diluted from its standard concentration of 50 mg/mL or 100 mg/mL with cherry syrup or cola to mask the bitter taste when given orally.
    b. Consider decreasing long-acting opioid by 25–50%.
2. Dosing may be increased daily by 10 mg every 6 hours until pain is relieved or side effects occur. Do not increase doses more frequently than every 24 hours.
    a. Major side effects include dizziness, a dream-like feeling, and auditory or visual hallucinations. If intolerable side effects occur, ketamine should be decreased to the previous dose or discontinued. Resolution may not occur for 24 hours.
    b. Oral doses as high as 1,000 mg/day have been reported in the neuropathic pain literature with average oral doses of 200 mg/day in divided doses required for pain relief.

B. Parenteral Dosing (palliative care provider will be present for initial dose)

1. Ketamine may be given intravenously or subcutaneously if the oral route is not available. A trial bolus of 5–10 mg IV can also be considered, which may be repeated once after 15–30 minutes.
    a. The starting infusion dose is 2–3 mcg/kg/min, which may then be increased by 1 mcg/kg/min every 1 hour up to a maximum of 6 mcg/kg/min.
    b. Consider decreasing long-acting opioid by 25–50%.
    c. The injectable solution is irritating and may require the subcutaneous needle to be changed daily.

- In case of adverse psychiatric reaction, have haloperidol 1 mg every 10 minutes as needed available; may increase as needed to achieve control.

needs of palliative care patients, the patient's ability to undergo the procedure, and the patient's and family's goals of care.

Nonpharmacological Therapies

Nondrug therapies, including cognitive–behavioral techniques and physical measures, can serve as adjuncts to analgesics in the palliative care setting. This is not to suggest that when these therapies work, the pain is of psychological origin. The patient's and caregivers' abilities to participate must be considered when selecting one of these therapies, including their fatigue level, interest, cognitive level, and other factors.[137,138]

Cognitive–behavioral therapy often includes strategies to improve coping and relaxation, such as relaxation, guided imagery, music, prayer, and reframing.[139] These strategies have been found to be useful in reducing pain and anxiety and improving sleep in those with advanced disease as well as reducing endocrine symptoms in women being treated for breast cancer. Physical measures such as massage, reflexology, heat, chiropractic, and other techniques have also been shown to produce relaxation and relieve pain.[140]

Integrative therapies include acupuncture, aromatherapy, herbal therapies, and many other techniques formerly called *complementary and integrative therapies*. See Chapter 28 for information about these approaches to pain and symptom management. More rigorous research is needed in the palliative care setting regarding all of the nondrug therapies that might enhance pain relief.

Principles of Pain Management

Pain is a biopsychosocial and spiritual phenomenon, and this is particularly true in those with life-threatening illnesses. Therefore, multimodal therapies, incorporating pharmacologic, nonpharmacologic, and integrative therapies, are indicated for the relief of pain in this population. When applied carefully, these treatments provide relief for the majority of patients (Box 9.4).

Pain Crisis and Refractory Pain at the End of Life

Most pain seen in palliative care is controllable with appropriate use of pharmacologic, nonpharmacologic, and integrative therapies. Some neuropathic pains, such as invasive and compressive neuropathies, plexopathies, and myelopathies, may be poorly responsive to conventional analgesic therapies short of inducing a nearly comatose state. Widespread bone metastases or end-stage pathological fractures may present similar challenges. When confronted by a pain crisis, the following considerations will be helpful:

- Differentiate terminal agitation or anxiety from "physically" based pain, if possible. Terminal symptoms unresponsive to rapid upward titration of an opioid may respond to benzodiazepines (e.g., lorazepam, midazolam).
- Make sure that drugs are getting absorbed. The only route guaranteed to be absorbed is the intravenous route. Although invasive routes of drug delivery are to be avoided unless necessary, if there is any question about oral, enteral, or transdermal absorption of analgesics or other necessary palliative drugs, parenteral access should be established.
- Preterminal pain crises that respond poorly to basic approaches to analgesic therapy merit consultation with a pain management consultant as quickly as possible. Radiotherapeutic, anesthetic, or neuroablative procedures may be indicated.

Box 9.4 Guidelines for Pain Management in Palliative Care

- Sustained-release formulations and around-the-clock dosing should be used for continuous pain syndromes.
- Immediate-release formulations should be made available for breakthrough pain. Each breakthrough dose is usually 10–20% of the 24-hour dose of the sustained-release formulation. Thus, as the sustained-release dose increases, so does the immediate-release dose.
- Cost, convenience, and availability of medications (and other identified issues influencing compliance) are highly practical and important matters that should be taken into account with every prescription.
- Anticipate, prevent, and treat predictable side effects and adverse drug effects.
- Titrate analgesics based on patient goals, requirements for supplemental analgesics, pain intensity, severity of undesirable or adverse drug effects, measures of functionality, sleep, emotional state, and patients'/caregivers' reports of impact of pain on quality of life.
- Monitor patient status frequently during dose titration.
- Be aware of potential drug–drug and drug–disease interactions.
- Incorporate nonpharmacologic and integrative therapies.
- Recommend expert pain management and/or palliative care specialty consultation if pain is not adequately relieved within a reasonable amount of time after applying standard analgesic guidelines and interventions.
- Know the qualifications, experience, skills, and availability of pain management experts (consultants) within the patient's community before they may be needed.

These basic guidelines and considerations will optimize the pharmacologic management of all patients with pain, particularly those in the palliative care setting.[9,40]

Management of Refractory Symptoms at the End of Life

Sedation at the end of life is an important option for patients at home or in the hospital with intractable pain, delirium, dyspnea, or other symptoms. The most commonly employed agents include benzodiazepines, including midazolam or lorazepam, barbiturates, and in some cases, propofol.[141] Palliative sedation is best delivered under the guidance of experts in palliative care and is usually reserved for those patients who are expected to die within hours to days.[142] Light sedation may first be attempted to allow communication with loved ones, although in some circumstances this may be insufficient to relieve the intractable symptoms. In a survey of loved ones of patients who had died, some having received sedation while others had not, the use of sedation had no negative effect on the relatives' perception of the quality of dying or of their own well-being.[143] See Chapter 27 for extensive discussion regarding palliative sedation.

Pain Control in People with Substance Abuse Disorders

The numbers of patients entering palliative care with a current or past history of substance abuse disorders are unknown yet thought to be significant and increasing in concert with the exploding opioid misuse epidemic. The use of universal precautions and risk mitigation strategies is essential when assessing all individuals in pain to reduce risk associated with the use of opioids and other controlled substances.[144] Important principles and practical considerations guide the care of those individuals with previous or current substance use disorder who require treatment of pain in the palliative care setting (see Chapter 42 for a complete discussion of care for the addicted patient at the end of life).

Case Study

Sylvia Johnson was a 45-year-old woman with metastatic colorectal cancer. She had been receiving chemotherapy with the goal to reduce tumor burden and relieve symptoms, including pain, yet she now had extension of the tumor into the pelvis, along with liver metastases. She lived alone but had family support in the community and she continued to work throughout the course of treatment. Her goal was to continue chemotherapy, have the ostomy reversed, and work full-time; she strongly declined any conversations regarding prognosis. She reported severe throbbing and burning pain in the rectal region with radiation down the left leg; she was taking hydrocodone/acetaminophen 10/325 mg 2 tablets every 3 hours without adequate relief. Because of the frequent requests for refills, the oncology team was concerned about misuse of the drug and consulted palliative care.

The palliative care team conducted a thorough pain assessment and screened for risk for opioid misuse. She had no obvious risk factors. Due to concerns regarding acetaminophen intake, the team added morphine extended-release 60 mg every 12 hours and continued hydrocodone/acetaminophen 10/325 mg 1 tablet every 3 hours as needed. She was also started on gabapentin for the neuropathic component of pain. She was educated about safe use and storage of the medication.

After a few weeks of treatment with this regimen, the team was contacted by a physician from an outside hospital; Ms. Johnson was in the ICU with a hemoglobin of 5.4 gm/dL (normal 11.6–15.4 mg/dL) and a creatinine 6.0 mg/dL (normal 0.51–7.17 mg/dL). Apparently she had been supplementing the analgesic regimen with large doses of OTC NSAIDs and acetaminophen and developed a gastrointestinal bleed along with acute kidney and hepatic injury. Several transfusions of packed red blood cells and fluid resuscitation, along with clipping of the ulcer under upper GI endoscopy, helped restore normal values. She was switched to fentanyl patch 50 mcg and oxycodone immediate-release 15 mg prior to discharge; gabapentin was held until complete resolution of kidney and hepatic injury.

Despite aggressive therapy, the disease advanced along with pain, anxiety, and sleep disorders. The fentanyl patch was gradually titrated to 100 mcg every 48 hours, as she reported increased pain on day 3 of application. She was using oxycodone immediate release 30 mg, 1–2 tablets every 3 hours for breakthrough pain, and the gabapentin had been restarted and titrated to 900 mg three times a day. Clonazepam was added at night and in reduced doses during the daytime to address anxiety. There was an episode when she requested a refill of oxycodone early; review of the state prescription drug monitoring program data revealed that she received only 40 tablets at the last refill, although 150 tablets had been ordered. A call to the pharmacy revealed they had only a limited supply and had to provide a partial fill.

Although initially reluctant to discuss advance directives or goals, she now began to accept and seek support, including hospice care. Her family provided support to allow her to remain at home, and she died comfortably with limited pain or symptom burden.

Ms. Johnson's case illustrates several important points about pain management in palliative care, particularly highlighting the need for assessment as the patient's condition changes over time. Other key concepts:

- Evaluate acetaminophen and NSAID intake when using combination products; this can be exacerbated by use of OTC agents. Serious adverse effects can occur.
- Neuropathic pain requires multimodal therapy, including adjuvant analgesics.
- Use of alternate routes of drug delivery is common at end of life; use equianalgesic principles when converting from one opioid to another or from one route to another.
- Frequent requests for refills do not always indicate issues related to misuse; inadequate numbers of pills may be ordered, and, at times, pharmacies may partially fill a prescription due to drug shortages. Further investigation is warranted. Screening for risk factors associated with substance abuse is crucial for all patients so these issues can be adequately addressed.
- Patients and caregivers need to understand that opioids are not to be used to treat sleep, anxiety, or mood disorders. Although use of opioids may initially be sedating, tolerance will develop and high doses will be needed to obtain the original effect. Careful assessment is needed, and appropriate pharmacologic and nonpharmacologic therapies of these comorbid conditions (sleep, anxiety, and sadness/depression) are necessary.
- Safe storage principles of controlled substances should be taught and implemented in the home.

Conclusion

Pain control in the palliative care setting is feasible in the majority of patients. Understanding the barriers that limit relief will lead to improved education and other strategies to address these obstacles. Ongoing, skilled assessment captures changes in pain and other symptoms as the patient's condition evolves. Developing comfort and skill with the use of pharmacological and nonpharmacological therapies will enhance pain relief. Together, these efforts will reduce suffering, relieve pain, and enhance the quality of life of those at the end of life.

CHAPTER 10

Fatigue

Edith O'Neil-Page, Grace E. Dean,
and Paula R. Anderson

Key Points

- Fatigue is the most common chronic symptom associated with cancer and other chronic progressive diseases.
- Thorough assessment of all patient comorbidities and symptoms is critical to accurately diagnose and treat disease-related fatigue.
- Education interventions in fatigue directed at healthcare providers, patients, and families provide an important opportunity for consistent integration of current guidelines into practice.
- Ongoing research has provided lines of evidence for improved patient outcomes through both pharmacological and nonpharmacological measures.

Introduction

Fatigue is identified as a "common phenomenon in modern society" yet has no widely accepted definition and affects populations differently.[1–4] Commonly, it is a symptom exhibited following a stressor, activity, disease, and or treatment. Fatigue can be a natural and healthy defense against physical or emotional stress, where symptoms are largely relieved following natural rest. However, in the presence of neoplastic and chronic disease, fatigue is typically not relieved by rest and consequently has a detrimental impact on quality of life (QOL) for patients and their families, thus presenting a significant management challenge for healthcare providers.[4–6]

Cancer-related fatigue (CRF) is one of the most common, devastating, and multidimensional symptoms associated with cancer diagnosis and treatment.[3,2] Fatigue associated with disease commonly occurs with groups of debilitating symptoms or side effects such as nausea, vomiting, and/or diarrhea. These symptoms occurring together are often referred to as *symptom clusters*.[7] They may vary with diagnosis, stage, and/or treatment severity. The resultant fatigue involves the entire person, touching every facet of daily life. It can progressively interfere with common, daily physical and/or social activity with varying impact on QOL and emotional stability.[1,6] Fatigue may have the greatest potential to interfere with quality at the end of life.[8,9]

Chronically ill patients often do not have the energy or forethought to communicate to healthcare professionals about what may be perceived as a nonurgent symptom.[3] Some may find it difficult to convey the extent of their exhaustion to healthcare providers as a result of lack of understanding and a general acceptance of the disease process, treatment, and side effects. Healthcare providers and other professional staff may consider the stress of fatigue or other symptoms as "expected side effects" of disease and treatment and acknowledge symptoms through "normalization" or acceptance. As such, the psychosocial-emotional impact of fatigue or other symptoms such as loss of appetite and the inability to maintain adequate nutrition and hydration may have significant financial and psychosocial impacts on family interactions as well as on clinical issues and inability to maintain clinical treatment plans.[10]

Definitions of Fatigue

Fatigue is a complex phenomenon, one studied by many disciplines, yet it has no widely accepted definition.[3] Even within different nursing specialties there has been little agreement on a definition of fatigue. CRF is "primarily a subjective, complex whole body experience"[4] and is described as a lack of energy or exhaustion that interferes with normal activities and function.[10]

Fatigue is commonly associated with cancer but is not a stranger to other chronic and accelerating disease processes such as chronic obstructive pulmonary disease (COPD),[11] irreversible cardiomyopathies,[12] chronic renal failure,[13,14] HIV/AIDS,[15] and multiple sclerosis.[16,17] The manifestation of fatigue in any disease process may differ with each diagnosis and treatment. In oncology, for example, patients may perceive fatigue differently depending on when fatigue occurs in the disease trajectory.[1] Often, it is the recognition of fatigue symptoms that initiates pursuit of diagnosis or disease discovery and implementation of medical treatment.[1] Once diagnosed, the cancer patient may experience fatigue as a side effect of treatment, as well as the emotional consequence of a critical disease. The presence of fatigue across various stages of the disease process as a pervasive side effect of treatment often continues well into recovery.[10]

Fatigue is consistently noted to be one of the most prevalent, severe, and distressing symptoms of malignancy and other chronic diseases.[18] Descriptors of fatigue range from a single focus of tiredness to the broad, multifocal, and overwhelming multidimensional syndrome of exhaustion that differs from the anticipated feelings of tiredness that are often felt in healthy individuals and are relieved by adequate rest.[19]

In recovery from disease treatment, the level of energy that returns is commonly less than expected; this is referred to as a "new normal" and then becomes reality.[1] Fatigue is often perceived differently by those living the experience of disease, treatment, and recovery from those who observe the process, including healthcare providers and family. This difference in perception may continue to be observed differently throughout the course of disease or treatment.

Fatigue is often identified by patients as experiential, with descriptors such as "I feel as if I have been run over by a truck." Or, "I can't believe this is me." Differentiating the sensation of fatigue from "tiredness or sleepiness" and assessing its impact on daily life and the patient's ability to function is often difficult for patients but also challenging for healthcare providers, friends, and family.[20,21] In cancer recurrence, fatigue becomes as much an enemy as the diagnosis. As the disease progresses to advanced stages, there is a resultant loss of dignity associated with demoralization and existential distress.[22] Fatigue at the end of life may be experienced as the end of a very long struggle, a natural stage of the dying process, and it may protect against elements of suffering.[22]

The National Comprehensive Cancer Network (NCCN)[3] Fatigue Practice Guidelines Panel, charged with synthesizing research on fatigue to develop recommendations for care, defines fatigue as "a distressing, persistent, and subjective sense of physical, emotional, cognitive tiredness, or exhaustion related to cancer or cancer treatment, that is not proportional to recent activity and interferes with usual functioning."[3]

The American Cancer Society defines CRF as "feeling tired—physically, mentally, and emotionally" and "having less energy to do the things you normally do or want to do."[23] This definition is similar to that used by multiple sclerosis patients, who defined fatigue as one of the most frequent and most disabling symptoms—a subjective lack of physical and/or mental energy that interferes with usual and desired activities.[24,25] Sufferers of other nonmalignant diseases such as stroke and end-stage heart failure define fatigue as being "physically tired and mentally exhausted" and perceive it as one of their worst symptoms, yet one that often receives little attention.[26]

While other definitions have been proposed, two key elements are dominant in most definitions of fatigue: (1) a subjective perception with physical, emotional, and cognitive features and (2) interference with an ability to function, often negatively impacting QOL.[6]

Prevalence

Fatigue is currently reported to be the most common symptom linked to the clinical course of cancer and other chronic diseases.[2,3] Estimates of prevalence are between 50% and 90% depending on the diagnostic category, length of disease, course of treatment, complications, physical state, and a myriad of psychosocial factors.[17,18] Despite the significant prevalence of disabling and distressing symptoms, fatigue remains underdiagnosed and undermanaged. Fatigue has been indicated as the most prevalent, disabling, and continuous phenomenon in patients receiving various treatments for cancer.[10] Fatigue cuts across all diagnoses, ages, genders, stages of disease, and treatment modalities.[8] Both chemotherapy and radiation therapy result in fatigue, while fatigue following combined chemoradiation therapy continues to be underestimated and profoundly affects QOL. Furthermore, "fatigue may persist for months or years" following curative treatment.[27,28]

Cancer is only one of many diseases in which fatigue is a common symptom. Prevalence rates for CRF and other chronic diseases are identified in Box 10.1, including cardiac disease,[9] COPD,[11] renal disease,[14] HIV/AIDS,[15,29] and multiple sclerosis.[16]

While symptoms rarely occur in isolation, there is growing evidence to support the occurrence of multiple symptom "clusters" along with the concept of symptom burden.[7,30] The increase in symptom cluster conditions is expanding. For example, when cancer was a comorbid condition in rheumatoid arthritis, 60% of subjects reported fatigue.[31] Other studies suggest a correlation between fatigue, physical function, systemic inflammatory response, and psychological distress in advanced cancer.[28]

Box 10.1 Prevalence of Fatigue and Populations at Risk

Cancer

Prevalence rates of cancer-related fatigue (CRF) vary depending on cancer type and stage, as well as the diagnostic criteria. One study indicated that more than 80% of patients receiving radiotherapy experience fatigue, as did up to 90% of incurable cancer patients. Fatigue is also the most common and distressing symptom experienced by pediatric cancer patients. In some cancer survivors, fatigue persists months or even years after treatment.[1,3,19]

Cardiac

Research suggests the widespread presence of fatigue in patients with chronic heart failure. One such study of these patients indicated that 99% of the sample reported fatigue.[9]

Chronic Obstructive Pulmonary Disease

Second only to breathlessness in its prevalence, fatigue is experienced by 96% of those with COPD.[11]

Renal Disease

In renal disease, the prevalence of fatigue varies depending on the method of treatment employed. Of those treated by hemodialysis, 82% report fatigue, notably physical fatigue and reduced activity. Fatigue prevalence in those treated by peritoneal dialysis was greater than 88%.[14]

HIV/AIDS

The diagnosis of HIV/AIDS is now more consistently addressed as a chronic disease rather than as a terminal illness as a result of antiviral therapy. However, as the disease becomes more chronic, fatigue is now recognized as an ongoing, chronic symptom and needs to be recognized and treated as such.[15,29]

The prevalence of fatigue in HIV-positive patients, according to one study, was 69%. While fatigue was not the most common symptom in AIDS patients, it was nonetheless widespread, affecting at least 42% of patients.

Multiple Sclerosis

Fatigue is the most prevalent and potentially debilitating symptom of multiple sclerosis. It is experienced by 75–95% of multiple sclerosis patients, more than half of whom name fatigue as one of their most distressing symptoms. Much of the treatment for multiple sclerosis–related fatigue involves eliminating secondary causes of fatigue (depression, sleep problems, medications) and using energy more efficiently. The FDA has not approved any drugs to specifically treat multiple sclerosis; however, medications such as amantadine, modafinil, or methylphenidate are sometimes used.[16,25]

Pathophysiology

Causes of fatigue are associated with multifactorial issues including anemia, chemotherapy or other related treatments, and comorbid symptoms such as pain, depression, and anxiety.[27] Anemia can result in severe fatigue and significantly impair QOL. It has a profound impact on patients, with additional complications that include dyspnea, palpitations, dizziness, and decreased cognitive function.[32] These symptoms can be common in patients with advanced disease or who are receiving aggressive therapy. Use of hematopoietic growth factors or erythropoietin-stimulating agents (ESAs) are known to relieve symptomatology and have been utilized to alleviate some degree of fatigue. However, recent research clearly indicates an increased risk of thromboembolic events with use of ESAs.[32,33]

Some evidence suggests that dysregulation of pro-inflammatory cytokines may play a mechanistic role in the symptom of fatigue as a common biological mechanism.[23] Pro-inflammatory cytokines may be released as part of the host response to infection, tumor, tissue damage from injury, or depletion of immune cells associated with treatments. These inflammatory stimuli can signal the central nervous system to generate fatigue as well as changes in sleep, appetite, reproduction, and social behavior.[4,34,35]

Fatigue, like pain, is not only explained by physiological mechanisms, but must be understood as a multicausal, multidimensional phenomenon that includes physical, psychological, social, and spiritual aspects.[19,34,36]

Factors Influencing Fatigue

Many characteristics that may predispose patients with other advanced diseases to develop similar fatigue syndromes have not been studied comprehensively. However, the increase of fatigue prevalence has stimulated oncology research to identify and quantify patient characteristics in treatment-related fatigue for clinical identification and development of treatment modalities.[37] Box 10.2 provides a list of factors that have been identified.

Box 10.2 Risk Factors Associated with Fatigue

Personal Factors

- Age
- Marital status
- Menopausal status
- Income/insurance

Psychosocial Factors

- Mental and emotional state (depression, fear, anxiety, distress, conflicts)
- Culture/ethnicity
- Living situation

Care-Related Factors

- Number/cohesiveness of caregivers
- Responsiveness of healthcare providers

Disease-Related Factors

- Stage and extent of disease
- Comorbidities
- Anemia
- Pain
- Dyspnea
- Nutritional changes (weight loss, cachexia, and electrolyte imbalance)
- Continence
- Sleep patterns/interruptions

Treatment-Related Factors

- Any treatment-related effect from surgery, chemotherapy, or radiation (skin reaction, temporary altered energy level, urinary/bowel changes, pain)
- Medication issues (side effects, polypharmacy, taste changes, over-the-counter medications)
- Permanent physiological changes

Patients with cancer, when compared with others with nonmalignant disease, express more fatigue, have worse sleep quality, more disrupted circadian rhythms, worse QOL, and lower activity levels.[38] The more advanced the cancer, the greater the occurrence of fatigue.[38]

The most frequent and problematic issue following an acute myocardial infarction is fatigue, which is often expressed in the same terminology used by those experiencing CRF.[26] Symptoms are similar in that they are poorly defined and often underidentified. Many of the experiences parallel that of patients with malignancy. Participants in one study identified interference with daily functional status and described symptoms related to depression.[39,40]

Similarly, patients with end-stage renal disease on chronic dialysis complain of high levels of pain and fatigue associated with other symptoms. Other associated symptoms, headaches, cramps, itching, dyspnea, nausea and vomiting, and sleep disruption often identify severe fatigue and symptom distress as significant.[14]

In one study, 100 patients with rheumatoid arthritis (RA) were asked to identify factors that contributed to their fatigue. Results indicated that the rheumatoid disease process itself was the primary cause of fatigue; joint pain was specifically mentioned.[31] Disturbed sleep was the second most frequent factor, and physical effort to accomplish daily tasks ranked third.[31] Patients with RA indicated that they had to exert twice the effort and energy to accomplish the same amount of work. In another study, women with RA reported more fatigue than men; the authors explained this variance as a result of female patients' higher degrees of pain and poor quality of sleep.[41]

Many characteristics that may predispose patients with other advanced diseases to develop similar fatigue syndromes have not been studied comprehensively. However, depression and fatigue are two related concepts often linked to cancer patients.[42] Fatigue is part of the diagnostic criteria for depression, and depression may develop as a result of being fatigued. While depression is reported less frequently, feelings of depression are common in patients with cancer. Research indicates that women who are fatigued score twice as high on the depression scale as those who were not fatigued and that depression is the strongest predictor of fatigue.[42]

Depression and fatigue may coexist with cancer without having a causal relationship since each can originate from the same pathology.[42] Fatigue in patients undergoing cancer treatment has been closely linked with other distressing symptoms, such as pain, dyspnea, anorexia, constipation, sleep disruption, depression, anxiety, and other mood states impacting patient QOL.[42]

Rather than focusing on specific individual symptoms, an earlier, more consistent, and thorough nursing assessment allows the identification in patients of symptom clusters associated with disease related fatigue.[43] Early recognition and intervention and management may improve patient outcomes. As CRF may be apparent before, during, and after treatment, nursing practice is called to continue the exploration of symptom relationships and identify opportunities for interdisciplinary collaboration to improve support for vulnerable populations.[44,45]

Assessment of Fatigue

Assessment of the whole person, physical, psychosocial, and emotional, of the mind and spirit as well as the body, is as essential in the recognition of fatigue as it is in pain. Fatigue, like pain, is also a subjective interpretation of various stimuli determined by the person who is experiencing the sensation. Caregiver or staff perceptions may differ from those articulated by the person experiencing fatigue.

The NCCN guidelines[3] for CRF clearly delineate steps and processes to put the assessment and recognition of fatigue on the same level as pain and calls for caregivers "to screen every patient for fatigue as a vital sign at regular intervals" using an age-related severity scale and, based on those findings, to implement a program of patient education and strategies to manage fatigue.[3] The guidelines also include a step-by-step diagram from a "focused history" to specific interventions of nonpharmacological and pharmacological treatment, from the evaluation phase through active treatment, post treatment, and the end of life.

There are numerous methods of assessing and diagnosing fatigue. Recognizing the importance of CRF, the diagnosis has been proposed for inclusion in the International Classification of Diseases (Box 10.3). However, some researchers suggest that the diagnostic criteria are too stringent, and the strict exclusion of those with possible "mood disorders" is of concern and may underestimate fatigue occurrence.

Box 10.3 Criteria for Diagnosing and Evaluating Fatigue

Criteria for diagnosing and evaluating fatigue include the presence, frequency (sporadic or constant), duration, and degree of interference with activities of daily living (ADLs).

1. Complaints of generalized weakness or limb heaviness
2. Diminished concentration or attention
3. Decreased motivation or interest in engaging in usual activities
4. Insomnia or hypersomnia
5. Sleep is unrefreshing or nonrestorative
6. Perceived need to struggle to overcome inactivity
7. Marked emotional reactivity to feeling fatigued (sadness, frustration, irritability)
8. Difficulty in completing daily tasks attributed to feeling fatigued
9. Perceived problems with short-term memory
10. Postexertional malaise lasting several hours

Fatigue, as with any symptom, is not static. Changes take place daily and sometimes hourly in the patient with an advanced illness. As such, fatigue bears repeated evaluation on the part of the healthcare provider. An example of a thorough assessment of the symptom of fatigue is found in Box 10.3, which uses both a subjective and an objective framework to ascertain patient fatigue and possible underlying physiological events that may exacerbate the fatigue. Important areas to explore are patient and family beliefs and expectations related to the fatigue experience and awareness of changes in energy levels, exacerbation and remission of symptoms, and what improves the level of fatigue.[27]

Many scales have been developed to measure fatigue in the adult with varying levels of validity and reliability. Examples of fatigue measurement tools include the Multidimensional Assessment of Fatigue, the Symptom Distress Scale, the Fatigue Scale, the Fatigue Observation Checklist, and a Visual Analog Scale for Fatigue.[46] These scales are available for use in research and may be used in the clinical arena. A comprehensive review by Piper and colleagues[47] describes the advantages and disadvantages of the single-item as well as multi-item, multidimensional CRF measures currently in use. The European Association for Palliative Care compiled a list of assessment instruments that have been used in research for fatigue in the palliative care group.[48] One scale that has been used extensively in the oncology population is the Piper Fatigue Scale. This questionnaire has 22 items that measure four dimensions of fatigue: affective meaning, behavioral/severity, cognitive/mood, and sensory. This scale measures perception, performance, motivation, and change in physical and mental activities.[49]

As symptoms are identified, caregivers must be aware of the presence of other clinically significant distress or impairment in social, occupational, or other important areas of functioning and report these to the medical team. Other important considerations include evidence from the history, physical examination, or laboratory findings that symptoms are a consequence of disease-directed therapy or determination that symptoms are not primarily a consequence of a comorbid psychiatric disorder (e.g., major depression, somatization disorder, somatoform disorder, or delirium).

The perception of fatigue is most efficiently assessed when a self-report scale is offered to patients, similar to the evaluation of pain. It allows a quantification of patient fatigue using a visual analog scale (VAS) where 0 equals no fatigue and 10 equals severe fatigue that interferes with some function.[6] As with the use of any measurement tool, consistency of utilization over time is essential to understanding the measurement by both patient and professional staff.

Management and Treatment of Fatigue

Fatigue may be identified and treated in the absence of an absolute cause through recognition of contributing factors such as anemia, deconditioning, depression, dehydration, hypoxia, metabolic and endocrine disorders, insomnia, pain, malnutrition, infection, or other comorbidities. Identifiable goals are to alleviate recognizable factors contributing to fatigue in general and provide support systems to develop or improve patients' and families' coping mechanisms. Often the acknowledgment of the potential of fatigue in any chronic disease assists with understanding the phenomena. It is beneficial for family members to understand the potential exhaustion of illness and its treatment. Frequently, patient and family both are under the impression that once treatment is complete, fatigue, like the disease, will "disappear."[19]

When considering palliative care, the management of fatigue is extremely challenging. By its very definition, palliative care may encompass a prolonged period ranging from early in the course of a disease when a person may be physically and socially active to a few weeks before death, when all activity may diminish considerably. With fatigue interventions, the wishes of the patient and family are paramount. Effective management takes into consideration the extent of the disease, other symptoms, whether or not palliative treatment is still in process, and the age, developmental and emotional status, and the physical location of the patient.[49] Intervention and treatment for fatigue are suggested to occur at two levels: management of symptoms that contribute to fatigue and prevention of additional or secondary fatigue by maintaining a balance between restorative rest and restorative activity. Fatigue interventions have been grouped into two broad categories: pharmacological and nonpharmacological related to associated causes and symptoms. Treatment may include both of these modalities and may be adjusted to meet the changes in status.

Pharmacological and Herbal Interventions

Pharmacological approaches to treat fatigue in patients with cancer and chronic progressive diseases include both Food and Drug Administration (FDA)-approved medications and herbal therapies. More frequently used pharmacological therapies include corticosteroids and psychostimulants and, to a lesser degree, antidepressants, tumor necrosis factor alpha, micronutrients, and various other classes of drugs. Corticosteroids such as dexamethasone are commonly used to counteract fatigue, poor appetite, and nausea.[50] However, side effects may include insomnia, mood swings, elevation of blood glucose, and increased occurrence of *Candida* infection. A large study was conducted with the psychostimulant methylphenidate to identify its effects on depression and cognition associated with CRF.[51] Analysis demonstrated limited evidence to support treatment and did identify some adverse events of vertigo, anxiety, anorexia, and nausea. When compared to modafinil, other research reported improved results using this drug.[52] One study reported the addition of a central nervous system stimulant that might counteract the somnolence of opioid use and, as a result, might enhance the effects of pain medication and increase patient activity levels.[53]

Although treatment results suggest that erythropoietin reduces the need for red blood cell transfusion, it may in fact "increase the risk of thromboembolic events."[32] Other drugs have been used to combat chronic disease-related fatigue. Clinical trials of tumor necrosis factor alpha (etanercept) have had some effects on fatigue for patients experiencing rheumatoid arthritis.[54]

One study reviewed the treatment of fatigue with modafinil to evaluate efficacy and tolerability in non–small cell lung cancer (NSCLC) patients in a treatment versus placebo trial. The results indicated no difference between the two groups and reported that modafinil had no effect on CRF and should not be prescribed outside a clinical trial setting.[55] Another study explored the use of modafinil in hepatitis C and HIV/AIDS patients, in whom it appeared to be effective.[56]

The benefit of herbal therapy was clearly demonstrated with a trial for treatment of CRF with the use of American ginseng 2,000 mg/day with no associated toxicities.[57] Continued exploration with positive results for multiuse pharmaceuticals and alternative medicines are very encouraging for patients with chronic progressive disease and associated fatigue.

Nonpharmacological Interventions

Interventions for fatigue encompass several disciplines. Historically, nurse clinicians and researchers have been the trailblazers in assessing and managing fatigue in the clinical setting. Research has been conducted on all of the fatigue management strategies listed in Table 10.1. Included are patient and staff educational interventions, studies on disrupted sleep patterns, nutritional deficits and their effect on patient QOL, symptom management, and physical and attentional fatigue. Sample sizes have often been small and groups homogeneous, but the studies highlight the contribution of nurse researchers.

Fatigue may demonstrate a response to exercise programs.[27,44] In palliative care, a group exercise program was piloted for those with incurable cancer and a short life expectancy.[58] Outcomes indicated that physical fatigue was reduced. Toward the end of life, the NCCN guidelines recommend general strategies for fatigue management that begin with energy conservation techniques, prioritizing activities, delegating, taking rest periods, and using labor-saving devices. They also recommend optimizing patient activity levels with the consideration of a referral to both physical and occupational therapy. Increased caution was emphasized for those with bone metastases and immunosuppression.

Attentional fatigue has been noted to be disturbing and burdensome to many cancer patients.[59] Many cancer survivors continue to suffer from acute, chronic, and late side effects of treatment, with one of the most onerous side effects being cognitive impairment. Early research indicates that exercise may be an effective intervention for improving the severity of side effects of cognitive impairment, sleep problems, depression, pain, anxiety, and physical dysfunction.

Nutritional consultation for patients has been shown to be key to managing physiological deficiencies from cachexia, nausea, and anorexia. Adequate hydration and the replacement of lost electrolytes enable the fatigue sufferer to have the best opportunity to control fatigue symptoms that are physiologically based.[60]

Sleep disruption is a common problem encountered by patients with advanced chronic progressive disease. Sleep cycles may be negatively affected by innumerable internal and external factors. The disturbances may be actual or perceived, but either results in daytime impairment. Common sleep disturbances resulting in fatigue include insomnia, breathing disorders, and movement disorders.[61] Fatigue interferes with activities of daily living, affects QOL, and may be offered as a reason to discontinue treatment. Sleep disturbances are often reported together with fatigue. One study examined the relationship between fatigue and sleep parameters in women undergoing chemotherapy.[42] The investigators found that fatigue worsened and sleep quality remained poor throughout the course of chemotherapy, although total time of sleep increased over the course of treatment. Additionally, one study of multiple

Table 10.1 Interventions to relieve fatigue

Problem	Intervention	Rationale
Lack of information or lack of preparation	Explain complex nature of fatigue and importance of communication of fatigue level with healthcare providers. Explain causes of fatigue in advanced cancer and chronic progressive diseases and evaluate fatigue level with each visit. ◆ Fatigue can increase in advanced disease. ◆ Cancer cells can compete with body for essential nutrients. ◆ Palliative treatments, infection, and fever increase the body's need for energy. ◆ Anxiety, depression, and tension can contribute to fatigue. ◆ Changes in daily schedules or interrupted sleep schedules contribute to fatigue development. Prepare patient for planned ADL and daily events (eating, moving, visitors, healthcare provider appointments).	Preparatory sensory information reduces anxiety and fatigue. Realistic expectations decrease distress and fatigue.
Disrupted rest/sleep patterns	Evaluate/establish sleep routine: ◆ Usual sleep pattern, length of uninterrupted sleep, temperature in room, activity prior to sleep. ◆ Eating habits prior to sleep, medications, exercise. ◆ Establish/continue regular, routine bedtime and awakening. ◆ Obtain as long sleep sequences as possible, plan uninterrupted time. ◆ Take short rest periods/naps that do not interfere with night sleep. ◆ Use light sources to cue the body into a consistent sleep rhythm. ◆ Pharmacologic management of insomnia should be used when behavioral and cognitive approaches have been exhausted.	Minimizing time in bed helps patients feel refreshed, avoids fragmented sleep, and strengthens circadian rhythm.
Deficient nutritional status	Recommend to patient: ◆ High-protein, nutrient-dense food to "make every mouthful count." ◆ Use protein supplements to augment diet. ◆ Suggest small, frequent meals. ◆ Coordinate time up in chair with meal arrival time. ◆ Socialization may increase oral intake. ◆ Encourage adequate intake of fluids, 8 glasses/day or whatever is tolerated, unless contraindicated. ◆ Consider requesting an appetite stimulant like medroxyprogesterone acetate (Megace).	Increased nutrition will raise energy level. Less energy is needed for digestion with small, frequent meals.
Multi-symptom occurrence	Assess and control symptoms contributing to or coexisting with fatigue such as: pain, sleeplessness, depression, nausea, diarrhea, constipation, electrolyte imbalances, dyspnea, dehydration, infection. Assess for symptoms of anemia and evaluate for the possibility of pharmacologic intervention or transfusion.	Multiple distressing symptoms drain energy and will contribute to marked physical/mental fatigue.
Decreased energy reserves	Plan/schedule activities: ◆ Identify a person to be in charge (fielding questions, answering the phone, organizing meals). ◆ Adjust method/pace of care and move slowly when providing care. ◆ Prioritize and save energy for the most important events. ◆ Eliminate or postpone noncritical activities. ◆ Learn to listen to body; if fatigued, rest. Obtain physical therapy consult: ◆ Mild physical therapy may help joint flexibility and prevent pain. ◆ Engage in individually tailored, team approved exercise/yoga program. Use distraction/restoration: ◆ Encourage activities to restore energy: spending time in natural environment, gardening, listening to music, praying, meditating, engaging in hobbies (art, reading, journaling). ◆ Spend time with family/friends, joining in passive activities (riding in car, watching meal preparation).	Energy conservation helps to reduce fatigue burden and efficiently use energy available. Pleasant activities may reduce/relieve mental (attentional) fatigue.

myeloma patients utilizing a prescribed individualized exercise program revealed significant improvement in fatigue levels.[62]

Psychosocial techniques are the last broad category of fatigue intervention. A meta-analysis of CRF research aimed at evaluating both physical and psychosocial interventions (cognitive-behavioral therapy and counseling) as well as behavioral treatments (massage, yoga) and their effect on fatigue provided evidence that psychosocial interventions, restorative approaches, and counseling therapies have a moderate to strong effect in reducing fatigue.[63]

One of the identified barriers to fatigue management is lack of patient, nursing, and provider knowledge and understanding of the relationship between physical activity and inactivity as it relates to fatigue. Patient, provider, and caregiver education enhances the opportunity for successful fatigue management. Education should include information on such topics as changes in disease status, progression, additional procedure or treatment needs, or medication side effects. Nurse-initiated and -planned educational sessions with the patient and family may provide a forum in which to respond to forgotten questions, reinforce nutritional information, and together manage symptoms to improve QOL.[47]

As the practice guidelines and standards for fatigue management in palliative care continue to evolve, the NCCN fatigue guidelines provide a framework for adults, children, and adolescents suffering from fatigue.[3] It is recommended that quality management be ongoing and implemented as continuous quality improvement projects. Finally, the guidelines suggest that medical care contracts include reimbursement for fatigue-related treatments and that disability insurance address coverage for long-lasting fatigue.[6]

Conclusion

This chapter provides an overview of fatigue as it spans the illness trajectory and end-of-life experience for patients with chronic progressive disease. While fatigue is a complex phenomenon that has been widely studied, it still has no universally accepted definition. Individuals with cancer and many other chronic, progressive diseases continue to experience fatigue, and the costs associated with it—not only in the economic sense but also in its physical, emotional, and psychological impact on life—need to be understood. Many factors, including age, psychological state, social support, access to care, disease type and status, pharmaceutical issues, cognitive impairment, and comorbid conditions influence fatigue. CRF is a serious problem that interferes with physical, psychological, emotional, social, and economic function. The need for healthcare providers to recognize and identify symptoms and explore management strategies is crucial to the lessening of human suffering. Professional nurses are in a unique position to recognize, identify, and explore the needs of patients who may prematurely decline further treatment as a consequence of their fatigue.

CHAPTER 11

Anorexia and Cachexia

Elizabeth E. Schack and Dorothy Wholihan

Key Points

- Anorexia and cachexia are distressing symptoms of advanced and chronic illnesses.
- They are distinct syndromes but clinically difficult to differentiate.
- Metabolic alterations are the primary cause of anorexia/cachexia syndrome.
- Assessment and treatment of anorexia and cachexia include determining whether exogenous etiologies such as nausea and pain are involved and undertaking vigorous treatment of any such etiologies if present.

Introduction

Management of anorexia/cachexia syndrome (ACS) requires a multimodal, interdisciplinary approach utilizing pharmacological, nonpharmacological, and psychosocial interventions. Anorexia is defined as the reduction or loss of desire to eat[1] and is a symptom that accompanies many common illnesses. In acute events, anorexia usually resolves with resolution of the illness, and any weight lost may be replaced with nutritional supplements or increased intake. Unchecked, anorexia leads to insufficient caloric intake and protein-calorie malnutrition. Weight loss from this starvation phenomenon usually involves loss of fat, rather than muscle tissue.[2] Anorexia is common among patients with advanced cancer and advanced acquired immune deficiency syndrome (AIDS) but also characterizes the clinical course of patients with other chronic progressive diseases, such as chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), and end–stage renal disease.[3–6]

Anorexia and cachexia are two distinct clinical syndromes but are often intertwined in chronic progressive disease. Cachexia is a complex syndrome that usually involves anorexia along with significant weight loss, loss of muscle mass with or without fat wasting, and generalized weakness associated with increased protein catabolism and inflammatory response.[7] The word "cachexia" is derived from the Greek *kakos*, meaning bad, and *hexis*, meaning condition or appearance; throughout medical history, cachexia has been associated with the gravely ill.[7,8] The first clinical definition can be traced to Hippocrates earlier than 400 BC: "The flesh is consumed and becomes water . . . the abdomen fills with water, the feet and legs swell, the shoulders, clavicles, chest and thighs melt away . . . the illness is fatal."[7] It is important to differentiate the cachexia syndrome from simple anorexia or starvation. Anorexia resulting in decreased intake is usually a component of both phenomena, but cachexia can still be found in the absence of decreased appetite.[9] Anorexia alone does not account for the magnitude of weight loss seen in diseases like cancer, and nutritional supplementation does not restore the lean body mass of cancer ACS.[9] Two separate international groups came together in 2008[10] and 2011[11] to develop operational definitions of cachexia, diagnostic criteria, and classification in the hopes of advancing future clinical practice and outcome measures for future clinical trials. In 2011, Fearon and colleagues provided this definition of cachexia:

> Multifactorial syndrome characterized by an ongoing loss of skeletal mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. The pathophysiology is characterized by a negative protein and energy balance driven by a variable combination of reduced food intake and abnormal metabolism.[11]

Cachexia is a devastating multifactorial syndrome that occurs in more than 80% of patients with cancer before death and is the main cause of death in more than 20% of such patients.[7,8,12] In contrast to the starvation seen in anorexia, in cachexia there is approximately equal loss of fat and muscle, significant loss of bone mineral content, and no response to nutritional supplements or increased intake.[8]

Weight loss, regardless of etiology, has a decidedly negative effect on survival, and loss of lean body mass has an especially deleterious effect.[10,13] Evidence-based reviews about prognosis reveal a significant correlation between anorexia/cachexia and survival in newly diagnosed cancer patients and in patients with advanced disease.[6,13] Weight loss is also linked to decreased survival in CHF, COPD, end-stage renal disease, and AIDS.[4,12,14–17] The term "anorexia/cachexia syndrome" has been used mostly in reference to patients with cancer, and thus the condition is sometimes termed "cancer-related anorexia/cachexia" (C-ACS).[9,12] A classification system for cancer cachexia has been developed with three stages of clinical relevance: pre-cachexia, cachexia, and refractory cachexia[11,18,19] with the hope that it will improve ease of cachexia recognition by clinicians through objective and standardized criteria. Varied terminology has been used to describe the syndrome in other disease states: for instance, HIV wasting syndrome, cardiac cachexia, pulmonary cachexia syndrome, and, in patients with advanced renal disease, malnutrition-inflammation-cachexia syndrome (MICS).[20] Table 11.1 lists the various terms used to describe anorexia-cachexia and estimated prevalence in different disease states. The pathophysiology and clinical presentation of ACS overlap in these various diseases even though the underlying metabolic and neurohormonal imbalances may differ.

Table 11.1 Anorexia/cachexia syndrome in various disease states

Disease	Terminology	Estimated prevalence: highest in advanced disease
Cancer	Cancer-related ACS	Up to 86%
CHF	Cardiac cachexia	16–36%
COPD	Pulmonary cachexia syndrome	30–70%
HIV disease	HIV wasting syndrome	10–35%
Renal disease	MIC: malnutrition-inflammation cachexia syndrome	30–60%

Source: References 6, 7, 12, 15, 16, 17, 30.

The basic issue of underlying chronic inflammation can be seen in them all.[7,10,21] For the purposes of this chapter, the term ACS refers to all chronic, advanced disease–related anorexia/cachexia syndromes.

The ACS of all diseases is characterized by a variety of signs and symptoms that represent interference with energy intake (decreased appetite, early satiety, taste changes, etc.) and nutritional status that include increased metabolic rate, weight loss, hormonal alterations, muscle and adipose tissue wasting, fatigue, and decreased performance status.[9,22] Whatever the specific disease, the development of ACS poses a significant clinical problem. It is a grave prognostic sign but also has a detrimental effect on quality of life (QOL), as documented by studies of all the preceding major diagnoses. This syndrome leads to serious physical and functional deficits and can be devastating to self-image, social and family relationships, and spiritual well-being.

Pathophysiology of Anorexia/Cachexia Syndrome

The basic etiologies of ACS are (1) decreased food intake, (2) metabolic abnormalities, (3) the actions of pro-inflammatory cytokines, (4) systemic inflammation, (5) neurohormonal dysregulation, (6) tumor by-products, and (7) the catabolic state.[23,24] These result in derangement of function with negative effects on survival and QOL. There is within some of these mechanisms a mutually reinforcing aspect; for example, anorexia leads to fatigue, fatigue increases anorexia, anorexia increases fatigue, and so on.[24] Table 11.2 summarizes the mechanisms and effects of ACS.

Table 11.2 Mechanisms and effects of anorexia/cachexia syndrome

Mechanisms	Effect
Loss of appetite	Generalized host tissue wasting, nausea or "sick feeling," loss of socialization and pleasure at meals
Reduced voluntary motor activity (fatigue)	Skeletal muscle wasting and inanition (fatigue)
Reduced rate of muscle protein synthesis	Skeletal muscle wasting and asthenia (weakness)
Decreased immune response	Increased susceptibility to infections
Decreased response to therapy or treatment intolerability	Earlier demise and increased complications of illness

Source: References 2, 22, 24, 46.

The ACS is categorized as primary or secondary, depending on its etiology. *Primary* ACS results from endogenous metabolic abnormalities such as cytokine production, which stimulates chronic inflammation and resulting catabolism. The syndrome is called *secondary* if it results from exogenous etiologies caused by symptoms that interfere with the intake or absorption of nutrients. Examples of such interfering symptoms are pain, nausea, intestinal obstruction, or psychosocial distress.[21]

Primary Anorexia/Cachexia Syndrome

The pathogenesis of primary ACS is multifactorial, complex, and incompletely understood. Accumulating evidence suggests that chronic illness disrupts the homeostatic function of the central nervous system, leading to profound metabolic changes. Peripheral input causes the awareness of threats such as a growing tumor or cardiac or renal failure, and this promotes a catabolic effect which results in increased energy expenditure, reduced intake, increased muscle breakdown, and loss of adipose tissue.[1,21,25,26]

Metabolic Alterations

Metabolic alterations are common in cancer and other diseases and are thought to be due in large part to the systemic inflammatory response and stimulation of cytokine production (principally tumor necrosis factor alpha [TNF-α], prostaglandins [PG], interleukin-1 [IL-1], interleukin-2 [IL-2], interleukin-6 [IL-6], interferon α [IFN-α], and interferon β [IFN-β]). Other catabolic tumor-derived factors thought to play a role in cachexia include proteolysis-inducing factor (PIF) and lipid-mobilizing factor (LMF).[1,8,27] Major metabolic alterations include glucose intolerance, insulin resistance, increased lipolysis, increased skeletal muscle catabolism, negative nitrogen balance, and, in some patients, increased basal energy expenditure.[28]

A number of different theories regarding the pathophysiology of ACS continue to be studied. The maladaptive activation of oxidative processes that may be seen in chronic illness are also thought to be partially responsible for the cachexia syndrome.[27,29] Recent advances in genomics suggest that specific genetic polymorphisms contribute to the prominent inflammatory component of this problem.[29] The melanocortin system of the hypothalamus, which coordinates appetite and feeding, is influenced by peptide hormones such as leptin and ghrelin.[8,27] Disturbances in these hormonally regulated feedback loops appear to play a role in ACS. Other potential mediators of ACS include testosterone, insulin-like growth factor-1, myostatin, and adrenal hormones.[27] In sum, the underlying pathophysiological processes of ACS are complex and not yet fully understood. Researchers postulate that the preceding mechanisms play different roles of varying importance in different diseases.[1,8,28] The relative importance of these factors and the interplay among them remains unclear. However, irrespective of the underlying mechanism or specific medical illness, patients experience progressive worsening of their clinical condition and, ultimately, shorter survival soon after the development of cachexia.[19]

Secondary Anorexia/Cachexia Syndrome

Secondary causes of ACS include exogenous factors that can frequently lead to weight loss, anorexia, fatigue, or other symptoms associated with this wasting syndrome.

Physical Symptoms

A number of physical symptoms of advanced disease may contribute to or cause anorexia, including pain, dysgeusia (abnormalities in taste, especially aversion to meat), ageusia (loss of taste), hyperosmia (increased sensitivity to odor), hyposmia (decreased sensitivity to odor), anosmia (absence of sense of smell), stomatitis, dysphagia, odynophagia, dyspnea, hepatomegaly, splenomegaly, gastric compression, delayed emptying, malabsorption, intestinal obstruction, nausea, vomiting, diarrhea, constipation, inanition, asthenia, various infections (see later discussion), and early satiety.[8,9] Alcoholism or other substance dependence may also contribute to or cause anorexia. Primary or metastatic disease sites have an effect on appetite, with cancers such as gastric and pancreatic having direct effects on organs of alimentation.[2,12,28]

In general, people who are seriously ill and/or suffering distressing symptoms have poor appetites. In addition, in cancer, metabolic paraneoplastic syndromes such as hypercalcemia or hyponatremia (syndrome of inappropriate antidiuretic hormone secretion) may also cause anorexia or symptoms such as fatigue that contribute to anorexia. Patients with HIV disease may also develop primary muscle disease, leading to weight loss.[30] Many treatments for chronic diseases have deleterious effects on appetite or result in side effects leading to anorexia and/or weight loss.[31] Each of these should be ruled out as a contributing cause of anorexia and, if present, treated as discussed elsewhere in this textbook.

Treatment Side Effects

Many interventions used to treat advanced chronic disease have adverse effects on nutritional status. The many medications used to treat HIV/AIDS and its sequela are an excellent example. Despite the success of highly active antiretroviral therapy (or HAART) in curbing ACS in many patients, the myriad medications involved in the prevention and treatment of AIDS complications often lead to anorexia and malabsorption themselves, and HIV wasting remains a problem for many.[30] Cytotoxic drugs can be emetogenic, cause taste changes, or precipitate other gastrointestinal (GI) side effects such as oral stomatitis and diarrhea.[23] Radiotherapy can also lead to significant side effects, including nausea, vomiting, diarrhea, xerostomia, and severe fatigue.[9] Among patients with advanced renal disease on dialysis, there is a high prevalence of protein-energy malnutrition.[4,20]

Psychological and/or Spiritual Distress

Psychological and spiritual distresses are often overlooked causes of anorexia. The physical effects of the illness and/or treatment coupled with psychological responses (especially anxiety and depression) and spiritual distress may result in little enthusiasm or energy for preparing or eating food. As weight is lost and energy decreases, changes in self-image occur. Appetite and the ability to eat are key determinants of physical and psychological QOL.[32,33] Cultural influences must always be considered. For many patients, the net result of ACS and weight loss constitute a negative-feedback loop of ever-increasing magnitude and suffering in multiple dimensions.[34] Clinicians evaluating patients with anorexia are encouraged to review basic principles for the assessment and management of depression, as covered in detail in Chapter 22. Treatment of underlying depression can improve appetite considerably.

Oral Issues

Special attention should be directed toward the oral cavity of patients with advanced disease. The fit of dentures may change with weight loss, or already poorly fitting dentures may not be as well tolerated in advanced disease. Dental pain may be overlooked in the context of terminal illness. Oral and esophageal infections and complications increase with disease progression and immunocompromise. Xerostomia and worsening of tooth decay can occur with radiation therapy to the head and neck region. Basic oral hygiene can often be neglected in the setting of advanced illness. Aphthous ulcers, mucositis, candidiasis, aspergillosis, herpes simplex, and bacterial infections cause oral or esophageal pain and, thus, anorexia.[22]

Assessment

Anorexia and weight loss may begin insidiously with only decreased appetite and slight weight loss, which can accompany virtually any illness. As the disease progresses and comorbid conditions increase in number and severity, anorexia and malnutrition increase, and a mutually reinforcing process may emerge. Cachexia has long been considered a part of advanced disease and end of life. However, skeletal muscle loss may be present earlier in the disease trajectory, and the early stages may be missed in patients with underlying obesity.[12,21] Early identification is optimal, but further research is needed to more clearly define the benefits of early assessment and intervention on patient outcomes.[21,35]

With ACS common and in many cases inevitable among patients with advanced or terminal illness, identifying specific causes is an extremely challenging task. Several international workgroups have proposed guidelines for the definition and classification of anorexia and cachexia.[10,11] More specifically, an international consensus exists on the framework for the definition of cachexia, diagnostic criteria, and classification of cancer cachexia. Future validation of these frameworks should ultimately aid in future study trials, leading to universally accepted guidelines and routine clinical management.[11,21] There have been standardized tools for the general assessment of nutrition status, but none specific to ACS for palliative care.[36] Nevertheless, anorexia from some etiologies is treatable; hence, assessment of the possible presence of etiologies noted previously is integral to quality palliative care. Assessment parameters are used according to the patient's ability to tolerate and benefit from the assessment.

Assessment parameters should include appetite, nutritional intake, and basic nutritional status.[21] Appetite is a component of several well-validated tools of global symptom assessment, such as the Edmonton Symptom Assessment Scale,[37] the Memorial Symptom Assessment Scale,[38] or the visual analog scale (VAS).[39] In addition, simple assessment questions about change in appetite can be transformed into a numerical assessment scale. Intake can be measured retrospectively by recall or prospectively by calorie count. Detailed exploration with appropriate physical examination can identify associated factors (i.e., dysphagia, nausea, oral issues, or pain). Open-ended questions can be helpful in eliciting specific characteristics of the eating problem.

A variety of methods can be used to assess nutritional status, from basic tools such as the Subjective Global Assessment for Nutrition (SGA)[36,40] and its modified patient-generated subjective global assessment (PG-SGA)[41,42] to sophisticated anthropometric and laboratory testing.[6] Common lab values may reveal decreased serum albumin, a prognostic indicator of increased morbidity and mortality, as well as changes in several electrolyte and mineral levels.[6] Other patient-rated tools like Functional Assessment of Anorexia/Cachexia Therapy (FAACT) or its Anorexia/Cachexia Subscale (A/CS) have been developed for clinical trials for orexigenic (appetite-stimulating) agents for cancer- or HIV-related anorexia and are too cumbersome for routine patient evaluation.[6]

Perhaps the most important component of assessment in ACS involves the patient's goals of care. Since palliative care encompasses the entire disease continuum, stage of illness and goals of care should be clearly determined before detailed assessment and intervention are planned or initiated. It is imperative to evaluate the degree of suffering or distress experienced as a result of the ACS. A cost–benefit analysis should be undertaken to determine whether a diagnostic workup is valuable in light of the effort, cost, or discomfort it may incur. At some point in the illness, even basic assessments, such as weight, serve only to decrease the patient's QOL. Assessment parameters are summarized in Box 11.1.

Assessment also includes a psychosocial evaluation, particularly concerning food, determining usual intake patterns, food likes and dislikes, and the meaning of food or eating to the patient and family. Too often, a family member attaches huge significance to nutritional intake and exerts pressure on the patient to increase intake: "If he would just get enough to eat." Giving sustenance is a fundamental means of caring and nurturing, and it is no surprise that the presence of devastating illness often evokes an almost primitive urge to give food. Assessment should also include an evaluation of the patient and family health literacy level, as well as their desire and preferred means of receiving health information.[43]

Box 11.1 Assessment Parameters in Anorexia and Cachexia

The patient is likely to report anorexia and/or early satiety.

Weakness (asthenia) and fatigue are present.

Mental status declines, with decreased attention span and ability to concentrate. Depression may increase concurrently.

Inspection/observation may show progressive muscle wasting, loss of strength, and decreased fat. There often is increased total body water, and edema may thus mask some wasting.

Weight may decrease. Weight may reflect nutritional status or fluid accumulation or loss.

Increased weight in the presence of heart disease suggests heart failure.

Triceps skinfold thickness decreases with protein calorie malnutrition (PCM; skinfold thickness and midarm circumference vary with hydration status).

Midarm muscle circumference decreases with PCM.

Serum albumin concentrations decrease as nutritional status declines. Albumin has a half-life of 20 days; hence, it is less affected by current intake than other measures.

Other lab values associated with ACS include anemia, increased triglycerides, decreased nitrogen balance, and glucose intolerance.

Source: References 8, 17, 34, 42.

In some cases the patient is less troubled than the family by poor nutritional intake. Clinicians should explore the meaning of feeding in the context of the family's cultural and religious background and help identify other ways in which the family can participate in caring for the patient.[43]

Interventions

The palliative approach to care of the patient with ACS focuses on improving patient comfort and minimizing distress caused by the anorexia and weight loss. Assisting patients and families to adapt to progressive symptoms and alleviating symptoms that may be exacerbating the problem are two foci of interventions. Interventions may combine a variety of approaches, including treatment of secondary (exogenous) causes of anorexia, nutritional support, enteral and parenteral nutrition, pharmacological management, and psychosocial support.[44]

Exogenous/Secondary Symptom Management

The presence of symptoms that may cause or exacerbate secondary anorexia and weight loss should be evaluated and treated as possible. If anorexia is due to an identifiable problem, such as pain, nausea, fatigue, depression, or taste disorder, appropriate interventions as discussed elsewhere in this book should be instituted. The goal here is to identify and manage potentially correctible problems that contribute to low dietary intake.[8]

Nutritional Support

Oral nutritional support, in an attempt to increase intake or to maximize nutritional content, may be helpful especially early in the disease process or in specific disease states. For example, there is evidence that nutritional supplementation can be effective in patients with COPD.[45] However, C-ACS studies have been disappointing. The current evidence continues to reveal that, despite best efforts of improving the quantity and quality of nutrition through conventional nutritional support, it does not improve lean body mass in patients with cancer.[9,46] Unfortunately, there is no conclusive evidence that dietary counseling or other conventional nutritional support has increased survival, significant weight gain, or improved QOL with cancer patients, but the overall risks are low and patients and families tend to value this support.[26,33]

Helping family members understand nutritional needs and limitations in terminal situations is essential.[47,48] Consultation with a nutritionist is usually warranted for the purpose of education and recommendation of appropriate supplements. General guidelines for nutritional interventions include the following[22,33,34,49]:

- The nutritional quality of intake should be evaluated and appropriately modified to improve the quality. Patients who are not moribund may benefit emotionally from supplementary sources of protein and calories. Clinicians should determine the meaning to the patient and family of giving, taking, and refusing food. Strong and even unconscious beliefs about food are difficult to modify, and many families require education and frequent support in the face of helplessness and frustration related to ever-diminishing intake.

- Culturally appropriate or favored foods should be encouraged. Preserving cultural or social traditions around meals may also be helpful. Families should be encouraged to share mealtime with patients or continue habits such as a glass of wine with meals, if medically appropriate.
- Small meals, on the patient's schedule and according to the taste and whims of the patient, are helpful, at least emotionally, and should be instituted early in the illness so that eating does not become burdensome.
- Foods with different tastes, textures, temperatures, seasonings, degrees of spiciness, degrees of moisture, and colors should be tried, but the family should be cautioned against overwhelming the patient with a constant parade of foods to try. Room temperature and less spicy foods are preferred by many patients.
- Different liquids should also be tried. Cold, clear liquids are usually well tolerated and enjoyed, though cultural constraints may exist. For example, patients with illnesses that are classified as "cold" by some Southeast Asians and Latinos are thought to be harmed by taking drinks or foods that are either cold in temperature or thought to have "cold" properties.
- Measures as basic as timing intake may also be instituted. Patients who experience early satiety, for example, should take the most nutritious part of the meal first. Filling fluids without nutritional value (such as carbonated soda) should be avoided at mealtime. Oral care must be considered an integral part of nutritional support. Hygiene and management of any oral pain are essential in nutritional support. Procedures, treatments, psychological upsets (negative or positive), or other stresses or activities should be limited prior to meals.

Enteral and Parenteral Nutrition

Enteral feeding (via nasoenteric tube, gastrostomy, or jejunostomy) may be indicated in a small subset of terminally ill patients. Many clinicians postulate that there exist certain patients with a good functional status and relevant secondary (exogenous) component to their ACS who may benefit from invasive nutritional interventions. Examples include patients with head and neck cancer with severe dysphagia who are undergoing radiation therapy, patients with slow-growing tumors causing bowel obstruction, patients undergoing certain surgeries for upper gastrointestinal tract (UGI) malignancies, or those undergoing bone marrow transplant.[50,51] However, the evidence remains insufficient to recommend precise guidelines for specific populations.[50] In general, guidelines recommend against enteral feedings for cancer patients undergoing routine radiotherapy, chemotherapy, or bone marrow transplantation.[8] Furthermore, despite the common practice of placing percutaneous endoscopic gastrostomy (PEG) tubes in patients with head and neck cancer, insufficient evidence exists that prophylactic PEG placement improves clinical outcomes.[50]

The clinical indications for enteral nutrition in noncancer diagnoses remain controversial, perhaps no more so than in the case of dementia. Although more than 30% of patients with dementia in nursing homes have PEGs, the best available data suggest that tube feeding does not improve QOL, reduce pressure ulcer formation or healing, limit aspiration risk, enhance functional capacity, or increase survival.[52] In these patients, careful hand feeding has been recommended as an alternative. Two nonmalignant conditions warrant consideration of enteral feeding. These include patients with stroke who otherwise have good QOL and patients with early amyotrophic lateral sclerosis (ALS).[53,54] In general, patients with poor performance status and poor prognosis are at high risk for mortality from gastrostomy.[50,55] In these patients, comfort feeding should be the primary focus in maintaining QOL.

The use of parenteral nutrition in ACS has been controversial within the palliative care field, and, in nearly all cases, if the patient has a functioning gut, enteral nutrition is preferred over parenteral nutrition because of the latter's very limited benefit and because the former is associated with lower cost and fewer complications.[26,56] In palliative care settings, long-term use of parenteral nutrition should be considered only if aligned with goals of care and in those with good underlying functional status, a prognosis of 2–3 months, and in whom enteral feeding is not possible.[56,57]

Pharmacological Interventions

A plethora of pharmacological studies have targeted C-ACS,[12,21] and recent work includes other chronic advanced disease.[2] The most frequently prescribed and most studied drug is megestrol acetate (MA), a synthetic progesterone agent that acts to increase appetite and weight gain.[58] Although the mechanisms by which MA operate are not well understood, most hypotheses suggest that the medication acts on cytokines, inhibiting TNF, and it may also increase release of neuropeptide Y (NYP) in the hypothalamus, resulting in stimulation of the neurons involved in the satiety mechanism.[8,58] The most recent Cochrane review discussed trials that evaluated the efficacy, effectiveness, and safety of MA in palliating ACS in patients with cancer, AIDS, and other underlying pathologies.[59] The review found that MA improves appetite but has a small effect on weight gain. The review shows that it does not improve QOL and suggests that side effects are more frequent in patients treated with MA.[59] Side effects of MA include hypoadrenalism, hypogonadism, and, most concerning, thrombosis and deep vein thrombosis (DVT).[9,58] Limited data are available regarding the safety of using MA, especially in the long term.[59]

Glucocorticoids are widely used in the palliative care setting to address a number of symptoms, including pain, dyspnea, and nausea.[3] In cancer patients, steroids have been shown to have a limited positive effect on appetite, nutritional intake, and sense of well-being, but no demonstrable effect on weight.[21] The varying use of corticosteroids (dexamethasone, methylprednisolone, or betamethasone), dose quantity, treatment duration, and attrition rates in studies make it difficult to draw firm conclusions on which corticosteroid and dosing is safest to use.[3] The wide range of side effects, especially with longer duration of use, including adrenal suppression, hyperglycemia, and peptic ulceration, may preclude their use in some patients. However, some suggest that corticosteroids may be more suitable for patients with shorter life expectancy, especially if they have other symptoms that may be alleviated by this drug, as just suggested.[21]

Cannabinoids have shown similar positive effects: improved appetite and mood but without weight gain.[1,8] At least two of the US Food and Drug Administration (FDA)-approved cannabinoids are available in the United States: dronabinol (approved for treatment of anorexia associated with weight loss in patients with HIV/AIDS and for treatment of refractory chemotherapy-induced nausea and vomiting) and nabilone (approved only for treatment of refractory

Table 11.3 Medications commonly used in anorexia/cachexia syndrome

Medication effects and common dosing	Indications	Side effects and considerations
Progestational agents esp: Megestrol acetate 160–800 mg/day	Improves appetite, weight gain, and sense of well-being	Thromboembolic events, glucocorticoid effects, GI upset/problems, heart failure, menstrual abnormalities, tumor flare
Corticosteroids e.g.: Dexamethasone 3–6 mg/day (considered preferable due to its lower mineralocorticoid effect) Prednisone 20–30 mg/day	Improves appetite and sense of well-being	Immunosuppression, masks infection, HTN, myopathy, GI disturbances, dermal atrophy, increased ICP, electrolyte imbalances, anxiety, avoid abrupt cessation
Cannabinoids: Dronabinol 5–20 mg/day	Increases appetite and decreases anxiety	Somnolence, confusion, dysphoria, especially in elderly
Metoclopramide 10 mg before meals	Improves gastric emptying, decreases early satiety, improves appetite	Diarrhea, restlessness, fatigue, drowsiness, extrapyramidal side effects

HTN, hypertension; ICP, intracranial pressure.

Source: Reference 6, 8, 58, 60, 63.

nausea and vomiting associated with chemotherapy).[6] However, the central nervous system side effects and difficulty in dosing limits the use of this medication.[26] Commonly used pharmacological options with indications and notable side effects are presented in Table 11.3.[60]

Since June 2017, 29 US states and the District of Columbia have medical marijuana programs, although marijuana remains illegal under federal law.[61] As of yet, there are no controlled clinical studies to support marijuana's efficacy for symptom management in conditions such as ACS.[6] Additionally, there can be distressing central nervous system side effects, particularly for older populations.[9,61] Based on the medical and legal concerns, the use of medical marijuana is not included in any domestic treatment guidelines.

Future directions in pharmacological management target various pathways implicated in ACS. Neurohormonal manipulation, cytokine inhibition, and anti-inflammatory interventions all show some promise in clinical trials.[9,31,46]

The peptide hormone ghrelin is a circulating mediator of appetite and has been implicated in ACS. Early trials that supplement ghrelin in various illnesses have shown short-term increases in caloric intake in patients with cancer and renal failure[9] and improved lean body mass and exercise capacity in those with COPD and CHF.[62] An oral ghrelin mimic, anamorelin, seems to have shown the best progress toward approval after early-phase trials showed increased food intake, appetite, and lean body mass in patients with cancer.[21,63] In preliminary studies, selective androgen receptor modulators and ghrelin mimetics have an overall positive effect on lean body mass but not on function. As a result, they have not been approved for clinical use.[64]

Thalidomide is a controversial medication of interest to ACS researchers. Previously withdrawn from the market due to its teratogenic side effects, thalidomide is now under study in advanced disease due to its potent antiemetic and TNF and IL-6 inhibitor activity.[8] Although its safety profile remains a concern, this medication may be a useful option and is under study.[9] Other medications under study include melanocortin (thought to decrease circulating TNF); various anabolic steroids, such as growth factor, insulin like growth factor, and testosterone derivatives; omega-3 polyunsaturated fatty acids (as found in fish oils); the antidepressant mirtazapine; the atypical antipsychotic olanzapine; beta-adrenergic agonists; and anti-inflammatory medications (i.e., COX-2 inhibitors).[1,6,8,9,24,56] While further research continues, these agents have shown some benefit in lab and in limited clinical studies. There is also increasing evidence that, given the multifactorial process involved in ACS, treatments involving combinations of agents may show promise.[21,31]

Psychosocial Support

Anorexia and cachexia can have a profound impact on the QOL of patients, not only heralding physical decline but also leading to significant emotional and social distress.[8,49,65] Weight loss negatively affects patient self-esteem but can cause even more distress and anxiety among family and partners. In a descriptive study by Reid and colleagues,[65] patients viewed wasting as a social stigma and an ominous prognostic sign. However, family held on to beliefs that weight loss was a result of decreased appetite alone. Conflict over food was a common consequence of such dissenting views. Lack of education and a strong symbolic attachment to food increased distress.[26,65] Nurses can play a critical role in assessing patients and family and providing sensitive and culturally appropriate education and support.[66]

Multimodal Approach

The devastating psychosocial consequences, pathophysiological complexities, and treatment resistance of ACS lead inevitably to consideration of a multimodal approach.[2,34,43,45] A summary of what should be included in this approach is summarized in Box 11.2.

Case Study: Some Issues Commonly Associated with Anorexia/Cachexia Syndrome

Mr. G is a 58-year-old man with stage 4 bladder cancer (metastatic to peritoneum and liver) who was recently admitted to the

Box 11.2 Components of a Multimodal Approach to Anorexia/Cachexia Syndrome

1. Early and ongoing determination of goals of care
2. Optimal treatment of underlying disease according to goals of care
3. Prevention, recognition, and prompt treatment of exogenous causes
4. Guidance from nutrition specialists
5. Appropriate pharmacological interventions
6. Resistance exercise as appropriate
7. Compassionate counseling to patient, family, and significant caregivers with clear, consistent, and empathetic dialogue

hospital from home with decreased oral intake, vomiting, nausea, and new onset abdominal pain. He received his most recent palliative chemotherapy 1 month ago and was tolerating the treatment well. Over the past several weeks, he was spending most of his day in bed since the onset of his symptoms and reported that his husband was struggling to care for him at home. Mr. G reports that he has not had stool output from his colostomy in more than 1 week, and he has not been able to tolerate food or liquids without vomiting over the past 2 days. He reports that he has had a poor appetite for many months, and he has lost 10 pounds since his last chemotherapy. Low-dose intravenous morphine was initiated to treat his abdominal pain, as was conservative medical management of his partial small bowel obstruction (SBO) related to tumor burden diagnosed on admission. His partial SBO resolved, and he was able to tolerate small, more frequent liquid nutritional supplements, but reports that he is “forcing myself to eat.” He also reported that he continues to have some underlying nausea that interferes with his eating. After a nutrition evaluation, Mr. G was determined to have severe malnutrition, and he had a workup for a potential enteral feeding tube placement to assist with nutritional support. After many past debulking and other abdominal surgeries, his anatomy would not permit an enteral feeding tube, and it was determined he was not a candidate for parenteral feeding. The primary, oncology, and palliative care teams worked closely with Mr. G and his husband to determine his goals and assess his needs moving forward, uncovering educational gaps and promoting management options and support. Mr. G decided that he wanted to trial a short stay at a skilled nursing facility (SNF) to allow a chance to “regain some of my strength with the goal of going home.” He reports that home hospice is something he has thought about and will continue to consider moving forward. The palliative care team initiated low-dose dexamethasone 4 mg/day orally with some slight improvement of patient’s appetite but significant relief of his underlying nausea. Mr. G also reported some improvement of his appetite with dronabinol in the past, so twice-daily dosing of dronabinol 2.5 mg/day orally was also initiated with significant improvement in his appetite. Prior to Mr. G’s discharge to an SNF, he was stabilized and his symptoms were controlled with a clear plan in place.

Conclusion

Increasingly, ACS is recognized as a serious aspect of advanced or terminal illness and as an area requiring further research, especially with respect to (1) the pathophysiology of cachexia and (2) increasing treatment options.

The management of ACS is complicated by numerous obstacles, including lack of clear definitions and guidelines, inconsistency in assessment and management strategies, and knowledge deficits about this complex clinical syndrome in health professionals and caregiving families. The challenge is compounded by the interwoven emotional symbolism of food and nurturance. As palliative care providers, we should strive to support, understand, and translate the developing evidence that guides our care. The complex and potentially devastating impact of this problem demands a holistic response. Palliative care nurses are optimally situated to coordinate and drive the necessary multidisciplinary approach to address anorexia and cachexia in advanced, progressive disease.

Current understanding of ACS includes the following:

- Anorexia and cachexia are distinct syndromes but clinically difficult to differentiate.
- Anorexia is characterized by decreased appetite that may result from a variety of causes (including unmanaged symptoms such as nausea and pain). It results primarily in loss of fat tissue, and resultant weight loss is reversible.
- Cachexia is a complex metabolic syndrome thought to result from the production of pro-inflammatory cytokines such as TNF and IL-1. In cachexia, there is approximately equal loss of fat and muscle and significant loss of bone mineral content. Weight loss from cachexia does not respond to nutritional interventions.
- In 2011, an international consensus defined cachexia as a multifactorial syndrome characterized by an ongoing loss of skeletal mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. The pathophysiology is characterized by a negative protein and energy balance driven by a variable combination of reduced food intake and abnormal metabolism.[11]
- Assessment and treatment of ACS include determination of whether exogenous etiologies such as nausea or pain are involved, the vigorous treatment of any such etiologies, and nutritional and psychosocial support if indicated.
- Treatment of cachexia is unsatisfactory, and no single pharmacologic agent successfully treats it, so a multimodal approach as discussed earlier is recommended.

CHAPTER 12

Nausea and Vomiting

David Collett and Kimberly Chow

Key Points

- Nausea and vomiting are symptoms commonly experienced in advanced disease although the majority of available research continues to focus on the cancer population.
- The cause of nausea and vomiting is often multifactorial and requires a thorough assessment and understanding of the emetic pathway and neurotransmitters involved in order to aid treatment decisions.
- Pharmacological and nonpharmacological interventions should be considered when managing the distressful symptoms of nausea and vomiting, with treatment tailored to the individual needs and goals of each patient.
- Nurses play a vital role in helping patients and family members manage and cope with nausea and vomiting.

Introduction

Nausea and vomiting are symptoms commonly experienced by patients with chronic and advanced illness. These highly distressing symptoms may be directly or indirectly related to disease and can have a significant impact on both the physiological and psychological well-being of patients.[1] Physiological repercussions of poorly controlled nausea and vomiting include metabolic disturbances, malnutrition, electrolyte imbalances, and impairment of functional ability as well as unnecessary hospitalizations, emergency room visits, and interruptions in disease-related treatments.[2–4] Psychologically, nausea and vomiting, whether experienced together or separately, can cause distress, anxiety, and fear, leading to the erosion of one's quality of life (QOL) in multiple domains, and they may also cause strain on caregivers.[1]

To date, the majority of research on nausea and vomiting focuses on the oncology population, with an emphasis on treatment-induced symptoms in patients receiving disease-directed therapy for either curative or palliative purposes. Despite advances in antiemetic therapies over the past three decades, nausea and vomiting continue to be some of the most feared and distressing symptoms reported by patients.[1,5] Larger organizations including the National Comprehensive Cancer Network (NCCN), American Society of Clinical Oncology (ASCO), and the American Nurses Association (ANA) have embraced palliative care as part of comprehensive cancer care starting at diagnosis to improve patient outcomes and QOL throughout treatment.[2,6,7] As such, palliative care clinicians must work alongside primary disease management teams to ensure the proper palliation of these bothersome symptoms. Doing so can improve QOL and allow patients to more comfortably continue on with appropriate life-saving or life-prolonging therapies if this is in line with their goals of care.

Unfortunately, the literature on the prevalence, assessment, and management of nausea and vomiting in the noncancer population is lacking. Advances in healthcare and technology have led to increased survival across various disease populations, with patients now living longer with chronic illness and the potential for high symptom burden. More research is needed to better understand the prevalence and etiology of noncancer nausea and vomiting to develop treatment regimens that are disease- and patient-specific.

Given the available evidence, this chapter will use advanced cancer patients as a model for assessment and treatment of nausea and vomiting, which can then be extrapolated for use in other patients with noncancer diseases. Understanding the emetic pathway and main neurotransmitters involved in this process may be one place to start.[8] Methods for proper symptom management, including screening, preventing, assessing, treating, and follow-up, will be explored, and nursing interventions and patient and family education will be highlighted.

Epidemiology of Nausea and Vomiting in Palliative Care

The extent of patient suffering with any serious illness is largely determined by the presence and intensity of disease-related symptoms. An understanding of symptom prevalence in different diseases will allow clinicians to anticipate problems for the patient, develop plans of care, and educate clinical staff.

The prevalence and severity of nausea and vomiting specifically in the palliative care population have been difficult to capture for various reasons including lack of standardized tools to measure symptoms and the common misconception that nausea and vomiting occur as a single entity when they are, in fact, two individual symptoms.[8] While they should be viewed as symptoms independent of each other, it is common for nausea and vomiting to form a highly distressful symptom cluster. Symptom clusters have been described as a stable group of two or more interrelated symptoms that often occur together, and studies have looked at their effects on QOL and treatment approaches.[9–11] Gastrointestinal (GI)-specific clusters may include nausea, vomiting, appetite loss, taste change, and/or constipation. In one study looking at patients with bone metastases receiving radiation therapy, nausea was found to cluster with shortness of breath and poor appetite.[1,12] Understanding the pathophysiology of these clusters may lead to a better and more effective approach to symptom management that targets multiple rather than individual symptoms.[10,13]

Cancer Population

Prevalence of nausea and vomiting in patients with advanced cancer has been reported between 20% and 70% and is described by patients as one of the most dreaded side effects of cancer treatment.[3,14,15] Research on nausea and vomiting over the past three decades has led to steady improvements in the control of chemotherapy-induced nausea and vomiting (CINV), with the development of 5-hydroxytryptamine3 (5HT3) receptor antagonists in the 1990s being one of the most significant advances in symptom management for patients receiving chemotherapy.[14,16]

Despite these advances, approximately 30–50% of patients' post-chemotherapy administration will experience nausea, vomiting, or both.[1,2,17] Oncology patients may experience these symptoms because of disease and/or treatment. The incidence, prevalence, and severity is related to the emetic potential of the chosen treatment regimen and specific patient variables, with some studies suggesting that female gender and younger age are predisposing factors for CINV.[2,3,8,18]

The data on the prevalence of nausea and vomiting at end of life in cancer patients are mixed and have been reported as high as 70% in the last weeks of life.[8,16,18,19] The severity of symptoms is related to cancer type, whether the patient is still receiving disease-targeted therapies, and acute issues that may occur as the disease progresses. One acute complication of some cancers is malignant bowel obstruction (MBO), which is a common cause of morbidity and death in patients with advanced GI and gynecological malignancies. Prevalence of MBO ranges from 25% to 50% in colon cancer, 16% to 29% in ovarian cancer, and 6% to 19% in the gastric cancer population.[20] Common clinical signs and symptoms of MBO include nausea, vomiting, lack of stool or flatus, and abdominal pain. Severity of symptoms is usually associated with the degree of obstruction.[21]

Noncancer Population

Nausea and vomiting for patients with noncancer serious illness has received less attention, and available research provides conflicting information. Similar to the cancer population, drawing firm conclusions regarding the epidemiology of nausea and vomiting in the noncancer population is complicated by methodological difficulties and the lack of standardized symptom definition and reporting.[8,22,23]

One large retrospective cohort analysis of patients receiving community-based palliative care, 90% with noncancer diagnoses, found that lower palliative performance status (PPS) was associated with higher scores of pain, depression, nausea, and constipation.[24] Other studies suggest that nausea and/or vomiting are experienced by people with advanced illness, such as AIDS, congestive heart failure, chronic liver disease, and chronic kidney failure, but not as commonly as pain, breathlessness, or fatigue.[8,23]

In the heart failure population, particularly at end of life, the prevalence of nausea ranges from 11.2% to 48%, with more than half reporting only partial or no relief of this distressing symptom.[25,26] For patients with chronic renal failure, prevalence of nausea ranges from 30% to 44% during the various stages of illness and shifts toward 13% to 34% at the end of life after discontinuation of dialysis. During the end stages of renal disease, nausea has been known to cluster with other symptoms related to uremia such as lack of appetite, dizziness, shortness of breath, and chest pain.[25,27,28] Patients with cirrhosis who are not candidates for liver transplantation have high symptom burden and palliative care needs, with the presence of nausea documented as high as 58%.[29]

An important population of patients with both cancer and noncancer diagnoses to consider are those residing in long-term care facilities. Nearly one of every four deaths in the United States occurs in these settings, with numbers expected to increase to as high as 40% in 2040 as the population ages.[30] Some of the challenges to appropriate symptom management in long-term care facilities are the lack of palliative care–trained staff, high staff turnover rates, and the lack of physician or advanced practice provider presence. The residents at these facilities often have high rates of serious comorbid conditions including cancer, progressive neurodegenerative conditions, and other diseases that impair functional status and the ability to communicate.

In this setting, nausea seemed to occur less frequently than pain, dyspnea, or constipation. Symptoms may also be underreported and undertreated especially for these patients who often have multiple comorbidities.[22,30] In one study looking at the palliative care needs of 49,172 deceased nursing home residents during the final week of life, 11.1% reported nausea compared to 58.7% reporting pain, the most prevalent symptom.[22] Although research has been conducted on assessing and managing pain in these settings, further studies on nonpain symptoms are necessary.

Conceptual Concerns Related to Nausea and Vomiting

The terms "nausea" and "vomiting," often clinically associated, are in fact distinct concepts that are many times mistakenly used interchangeably or imprecisely, impacting the ability to assess and measure prevalence and burden.[8] *Nausea* is an unpleasant feeling of the need to vomit experienced in the back of the throat and epigastrium. The patient often describes the sensation as feeling "queasy" or "sick to my stomach" or may have a difficult time describing the unpleasant sensations experienced.[3,8,31,32] *Vomiting* is a physical event that results in the forceful expulsion of gastric contents from the stomach through a complex reflex involving the GI tract, diaphragm, and abdominal muscles. This may be described as "barfing," "upchucking," or "puking."[3,32] The two should always be assessed separately. *Retching* is similar to vomiting without the actual expulsion of material.[3] Patients often describe this as "gagging" or "dry heaves."

While there are multiple etiologies for nausea and vomiting in advanced cancer, CINV is one of the most common and can continue even near death as many patients remain on systemic therapy in the late stages of their disease. Three distinct types of CINV have been described. The acute phase can occur within minutes of administration and commonly resolves within 24 hours, with the greatest symptom intensity after 5–6 hours. The delayed phase usually occurs 24 hours following treatment, with peak intensity between 48 and 72 hours. Anticipatory nausea and vomiting differs from the other two; it is a response to conditioned stimuli developed from significant nausea and vomiting during previous chemotherapy treatments and occurs even before treatment is administered.[2,5]

Physiological Mechanisms of Nausea and Vomiting

Understanding the pathophysiology of nausea and vomiting is important for optimal management of a patient with these symptoms. Having knowledge of the mechanisms allows for a rational selection of pharmacological and nonpharmacological therapies or interventions to address the cause.

Vomiting occurs when the vomiting center, located in the medulla oblongata, is activated by peripheral and central afferent pathways. Peripherally, afferent nerves from the GI tract activate the vomiting center when there is pathology such as mucosal irritation, bowel wall invasion by neoplasm, or activation of stretch receptors. Stretching of the bowel lumen, as well as stretching of the capsule on visceral organs, can activate the afferent neural circuit. The gag reflex occurs when the glossopharyngeal nerve (cranial nerve IX) is stimulated in the pharynx by coughing or other mechanical irritation.[33] Central neural circuits that induce vomiting include the chemoreceptor zone and the cortex. The chemoreceptor trigger zone (CTZ) is a vascular region in the area postrema of the fourth ventricle and is outside of the blood–brain barrier.[34]

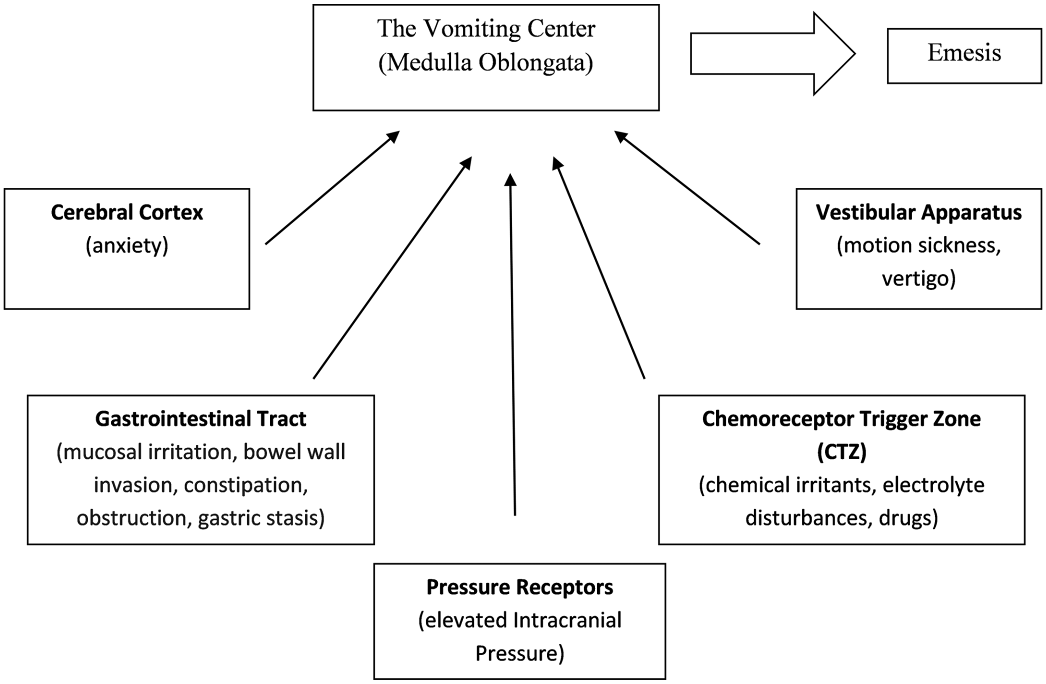
Chemical irritants (e.g., medications), electrolyte disturbances (e.g., hypercalcemia), and infections stimulate the CTZ. Vomiting that occurs when our senses of smell, taste, sight, or hearing are stimulated or vomiting associated with fear or anxiety, is cortical. The nausea and vomiting that occurs with motion sickness or vertigo is mediated by the vestibulocochlear nerve. Vomiting that is prominent in the morning can be associated with increased intracranial pressure (ICP).[35] The neural pathway for nausea and vomiting associated with increased ICP is less understood than other neural pathways to the vomiting center. Figure 12.1 is a conceptual illustration of the described pathways that lead to nausea and vomiting.

The afferent pathways and the vomiting center rely on specific neurotransmitters that result in nausea and emesis when there is an appropriate stimulus. For example, enterochromaffin cells in the gut release serotonin when there is mucosal irritation from chemotherapeutic agents. The released serotonin binds to its receptor and this afferent signal is transmitted to the vomiting center. Previously, it was believed that chemotherapy caused nausea and vomiting primarily by triggering the CTZ. Now it is understood that irritation of the gut and resultant serotonin activation of the peripheral afferent pathway from the gut are important causes, along with central afferent CTZ activation. The neurotransmitters involved in activation of the CTZ are dopamine and serotonin. The vestibular system depends on activation of histamine and acetylcholine to transmit afferent signals to the vomiting center. The vomiting center is rich in serotonin, histamine, and acetylcholine receptors.[8,34,36]

Pharmacological therapies often target these ligand–receptor actions to prevent nausea and vomiting. Serotonin receptor antagonists, such as ondansetron, are particularly helpful for CINV because they block the activation of the GI afferent loop to the vomiting center, as well as inhibit serotonin action in the CTZ and the vomiting center. Neurokinin-1 (NK1) receptor antagonists, like aprepitant, target the neurokinin receptor NK1 that was more recently discovered to be involved in vomiting. The vomiting center is rich in NK1 receptors, and when the usual ligand, substance P, is attached to the receptor, vomiting is induced. [37]

Causes of Nausea and Vomiting

There are numerous potential causes of nausea and vomiting in cancer patients, especially in those with advanced disease. It is helpful to have a thorough understanding of the common causes, which can be subdivided into six clinical



The Vomiting Center
(Medulla Oblongata)
Emesis
Cerebral Cortex
(anxiety)
Vestibular Apparatus
(motion sickness, vertigo)
Gastrointestinal Tract
(mucosal irritation, bowel wall invasion, constipation, obstruction, gastric stasis)
Chemoreceptor Trigger Zone (CTZ)
(chemical irritants, electrolyte disturbances, drugs)
Pressure Receptors
(elevated Intracranial Pressure)

Figure 12.1 Emetic pathways.

syndromes: biochemically/drug-induced, gastric stasis, GI obstruction/irritation, increased ICP, vestibular, and psychological. It is important to remember that common causes may overlap (e.g., drug-induced and psychological causes). These clinical syndromes are presented in Box 12.1.[3,8,15,35,38]

Box 12.1 Common Syndromes Involving Nausea and Vomiting in the Palliative Care Population

Biochemically/Drug-Induced

Fluid and electrolyte imbalances (e.g., hypercalcemia, hyponatremia)

Organ failure (e.g., liver, renal)

Chemotherapy

Medications (e.g., opioids, antibiotics, anticonvulsants, antidepressants)

Gastric Stasis

Carcinoma of stomach

Ascites

Opioid-related

Anticholinergic drugs

Peptic ulcers

Gastrointestinal Obstruction/Irritation

Cancer-related

Esophagitis

Peptic ulcers

Gastric distension or compression

Delayed gastric emptying

Bowel obstruction

Constipation

Biliary obstruction

Intraabdominal spread (e.g., peritoneal disease)

Adhesions

Treatment related (e.g., chemotherapy, radiation)

Infection (e.g., cryptosporidiosis)

Medication (e.g., aspirin, NSAIDs)

Increased Intracranial Pressure

Cerebral edema

Intracranial tumor

Intracranial bleeding

Meningeal disease

Vestibular

Opioid-induced

Cerebral metastases

Motion sickness

Psychological

Fear

Anxiety

Anticipatory

NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors

Although the potential causes of nausea and vomiting are extensive and the frailty of the palliative care patient often precludes invasive diagnostic testing, studies have shown that it is possible to determine the underlying cause or causes for targeted therapy.[3] Approach to treatment relies heavily on identifying the symptoms present and any patterns, grasping the physiological mechanisms involved, and determining the underlying etiology, keeping in mind that causes are often multifactorial.[15,31] The skilled clinician will use her or his assessment to quickly identify any reasonably reversible causes that remain in line with the patient's and family's goals of care.

Assessment of Nausea and Vomiting

Among the principles of emesis control for the cancer patient is, first and foremost, to prevent nausea and vomiting.[2] When this goal is not achieved, recommendations advocate for a structured approach to assessing and treating these symptoms.[15,34] Assessment is an important process and the foundation of all treatment-related decisions. It should be an ongoing process that begins with the initial patient contact.

The palliative care specialists' approach to symptom assessment and treatment requires understanding of symptom pathophysiology and possible etiologies, which can be obtained from the patient's history, physical exam, and diagnostic test results.[32] It is rare that patients present with nausea and vomiting as a first sign of advanced cancer. Generally, patients who complain of this symptom complex have a well-documented history of their disease, including diagnosis, prior treatment, and sites of metastases. Regardless, a focused exam is needed to narrow down the list of differential diagnoses while paying special attention to causes that may be reversible.[15]

The history of present illness and review of systems should include questions regarding the pattern of symptoms (e.g., time of onset, duration, volume of vomitus), whether the symptoms occur in tandem or in proximity with other symptoms (e.g., epigastric pain, dysphagia, hiccups, heartburn, or constipation), possible triggers (e.g., medications, radiation therapy, meals, position, smells), and previous remedies attempted (e.g., over-the-counter or prescription medications). The clinician should also consider the functional status of the patient and his or her overall prognosis as this can help guide treatment decisions.[15]

A physical exam should be comprehensive to assess for possible etiologies. The oral cavity should be assessed for thrush or mucositis. The abdomen should be visually inspected, auscultated, and palpated to assess for physical signs such as abdominal distension or masses, presence or absence of bowel sounds, and organ enlargement or ascites.[38] A rectal examination should be performed if there is suspicion of impaction. A neurological exam is also recommended, assessing for increased ICP or other neurological

Box 12.2 Rhodes and McDaniel Recommended Criteria for Choosing Instruments to Measure Nausea, Vomiting, and Retching

- Use self-report tools rather than observational assessment whenever possible.
- Check reliability and validity.
- Look for clarity, precision, cultural sensitivity, and understandable wording.
- Instrument should be in an easy-to-read format.
- Determine and describe the symptoms and components.
- Determine a time frame for recall of the symptom experienced.
- Consider the purpose of the tool, the target population, and whether it is for acute, delayed, or anticipatory nausea and vomiting or for patients with advanced cancer.
- Consider the ease of scoring and type of score.

Source: Rhodes & McDaniel (2001), reference 34.

etiologies. Laboratory studies may help rule out organ dysfunction, infection, and electrolyte imbalances; imaging diagnostics should be ordered if indicated to guide treatment decisions.[32,38] Ultrasound, computed tomography (CT) scan, and magnetic resonance imaging (MRI) are all imaging modalities that can be useful to further diagnose etiologies (e.g., small bowel obstruction, intracranial causes).[38]

Information obtained by questionnaires or self-report tools such as diaries or logs is crucial for the identification and management of this symptom complex and for improving the patient's QOL. Rhodes and McDaniel provide clear criteria when trying to choose the appropriate assessment tool for individual patients, summarized in Box 12.2.[34]

There are several measurement tools that may be used to assess one or more of the components of nausea and vomiting. Some tools provide a global measure while others measure a single component of the nausea and vomiting. Instruments may involve checklists, visual analog scales, patient interviews, or Likert scales, and almost all involve self-report by the patient.[1,39,40] The most commonly used tools with reliability and validity reproducible in research studies are shown in Table 12.1.[34,39,41,42]

Nurses working in all settings and with all age ranges of patients need to use skillful observation along with effective data collection techniques for a complete and comprehensive assessment. This is especially applicable in populations that may have difficulty communicating symptoms, such as in pediatric populations, long-term care populations, or with patients with limited abilities to communicate (e.g., cognitive impairment, intubated). Research has shown that caregiver symptom reports can be helpful when making these assessments.[43] Keep in mind that patients with different levels of cognitive or communication ability may still be able to make their needs known and communicate pain and other distressful symptoms. For all patients, early recognition and assessment of symptoms must be tailored to individuals.

Case Study: A 69-Year-Old Man with Multiple Myeloma

Mr. M is a 69-year-old man with refractory multiple myeloma who presented to the emergency department with fatigue, left hip pain, and severe nausea without vomiting. An abdominal and pelvic CT scan showed a left femur fracture, worsening myeloma lesions, and no evidence of bowel obstruction. Blood work revealed an elevated serum creatinine level of 2.1 mg/dL.

Mr. M reported being "stuck in bed" for a week due to left hip pain. He was prescribed oxycodone by his oncologist, which he took 5 mg every 4 hours around-the-clock with minimal relief. In between, he took ibuprofen 800 mg every 6 hours for additional pain control. He reported no bowel movement for 4 days. He was started on intravenous fluids and rotated to fentanyl via intravenous patient controlled analgesia (PCA) pump.

He was taken to the operating room for fracture, and, after an uncomplicated recovery, he was transferred to the floor with the fentanyl intravenous PCA. He continued to rate his nausea as moderate to severe. When assessed at bedside, he became tearful, stating he just found out from his oncologist that his multiple myeloma was unusually aggressive and that he likely only had 3 to 4 months to live—he had thought he had years. He stated he felt "sick to his stomach" when thinking about dying.

He described his nausea as wave-like and stated that he vomited once earlier in the day. He felt like when he used a rescue dose of the PCA, his nausea worsened. He also found that nausea increased with food. The medication administration record showed that he had received two prn doses of ondansetron 8 mg intravenously during the previous shift, which were not helpful. He had a bowel

Table 12.1 Tools to measure nausea and vomiting

Instrument	Type	Reliability/Validity

movement earlier, which improved his constipation. On physical exam, he was mildly cachectic, with diminished lung sounds, normoactive bowel sounds, and his surgical site was dressed clean, dry, and intact.

During interdisciplinary rounds, it was decided his nausea was likely multifactorial and exacerbated by his progressive disease, elevated creatinine levels, opioids, and anxiety. The team decided on a stepwise approach, starting oral olanzapine 2.5 mg nightly and intravenous metoclopramide 10 mg every 6 hours, which Mr. M felt was helpful in controlling his nausea. Though the fentanyl could have been contributing, Mr. M found the PCA most effective for his pain and finally felt like he could have some QOL. No changes were made to the analgesic regimen, with plans to reassess. Additionally, Mr. M was amenable to a chaplaincy consult and to receiving acupuncture.

Substance P antagonists (NK1 receptor antagonists)

Treatment of Nausea and Vomiting

Management of nausea and vomiting requires a combination of both pharmacological and nonpharmacological approaches. Understanding the cause(s) of nausea and vomiting is crucial as it allows proper selection of treatment regimens. Often the cause is multifactorial, requiring multiple interventions used concurrently. Investigations to rule out potentially reversible or treatable causes such as dehydration, electrolyte imbalances, and constipation should be considered.

Pharmacological Management of Nausea and Vomiting

It is essential for the nurse to know the clinical pharmacology of the large and increasing number of antiemetics available for use. This includes an understanding of nonoral routes of delivery. Medication delivery that does not require intravenous access is also frequently employed because patients with advanced illness may require control of severe symptoms in nonhospital settings.

Similar to the management of chronic pain, patients with chronic nausea will need around-the-clock medications for baseline symptom control, supplemented with rescue dosing. Guidelines for the pharmacological treatment of these symptoms in the palliative care population rely primarily on basic pharmacology and consensus guidelines, as multiple review articles have found the evidence base supporting pharmacological treatment of nausea and vomiting in advanced illness to be suffering from a lack of strong studies.[8,32,38]

Two approaches to pharmacological treatment have been described, a mechanistic approach and an empirical approach.[8,15,32] The mechanistic approach to treatment involves the selection of medications expected to block the relevant receptors in the emetic pathway as inferred from the patient's clinical presentation. For example, a prokinetic agent such as metoclopramide is chosen when a patient's nausea is related to gastric stasis. Once an appropriate medication is selected, it is titrated until the symptom is relieved, maximum doses are reached, or the patient experiences dose-limiting side effects. Classes of antiemetics are listed in Box 12.3. If the nausea is not relieved with the first agent, a second medication from another class should be added and similarly titrated.[15] Mechanism-based treatment is limited by pharmacologic and physiologic factors. Pharmacologically, the presence of similar receptors at multiple sites of the emetic pathway and the activity of single medications at multiple receptors prevent simple targeting of treatment. Physiologically, the etiology of chronic nausea and vomiting in advanced disease is often multifactorial or not known.[8]

The empirical approach for nausea and vomiting has been described as drug selection based on prescriber preference, or starting with one drug and adding or rotating to another if the first choice is unsuccessful.[15] Mechanistic and empirical approaches have resulted in similar response rates. Although the two methods have not been directly compared, both rely on a thorough understanding of the clinical pharmacology of the medications to be used.

Prokinetic Agents

Prokinetic agents include metoclopramide, domperidone, cisapride, and macrolide antibiotics. Domperidone and cisapride are recognized as effective prokinetic medications, but neither are available for use in the United States due to QTc prolongation and risk of serious cardiac toxicity.[8]

Prokinetic medications alleviate nausea and vomiting by stimulating motility of the upper GI tract. Four potential mechanisms for this effect have been proposed: stimulation of serotonin (5HT4) receptors in the gut wall, antagonism of 5HT3 receptors in the CTZ and gut, activation of motilin receptors, and release of the "dopaminergic brake" on gastric emptying. At higher doses, metoclopramide has antiemetic activity due to dopamine (D_2) receptor antagonism in the CTZ. Metoclopramide's activity at the 5HT4 receptor requires acetylcholine as a mediator at the myenteric plexus, thus, in theory, anticholinergic medications can antagonize its effect.[3,44]

Metoclopramide is widely used across palliative care settings and is often favored as first-line treatment of nausea and vomiting.[15,32] This prokinetic agent is specifically indicated in the setting of gastric stasis and is typically administered before meals. The central dopamine blockade in the CTZ results in a side-effect profile similar to antipsychotic medications, including extrapyramidal symptoms (EPS). Other adverse effects include akathisia, serotonin syndrome, and tardive dyskinesia. Due to the risk of tardive dyskinesia, a potentially irreversible condition, the US Food and Drug Administration (FDA) issued a black box warning. Risk is increased with use for greater than 12 weeks.[45] Reduced doses are recommended for patients with renal impairment and the elderly. Metoclopramide is contraindicated in the presence of complete bowel obstruction, GI hemorrhage or perforation, and immediately postoperatively.[38,45]

The macrolide antibiotic erythromycin has also been identified as a prokinetic medication due to its motilin receptor stimulation, and it has been shown to be effective in treating diabetic gastroparesis. Side effects include hepatotoxicity and QTc prolongation.[44]

Dopamine Receptor Antagonists: Butyrophenones, Phenothiazines, Atypical Antipsychotics

Butyrophenones

Droperidol and haloperidol are drugs in the butyrophenone class, acting primarily as dopamine antagonists. They achieve their antiemetic effect by binding to the D_2 receptors in the CTZ. There is mixed evidence regarding the use of haloperidol or droperidol for treatment of nausea and vomiting. To date, there have not been any randomized control trials (RCT) evaluating the effectiveness of these two drugs.[15]

Common side effects of this medication class include sedation, hypotension, anticholinergic effects, dystonias, EPS, QTc prolongation, and, rarely, neuroleptic malignant syndrome.[8,15,46] Haloperidol is less sedating than antipsychotics of the phenothiazine class. Because of its direct antidopaminergic activity, haloperidol should not be given to patients with Parkinson's disease. Additionally, it should be used cautiously with olanzapine as there is an increased risk for EPS.[2] The FDA has issued black box warnings for both drugs due to concerns related to prolonged QTc.

Citing its ability to treat nausea as well as delirium and hallucinations, researchers identified haloperidol as one of four essential drugs needed for quality care of the dying in an international survey of palliative care clinicians.[47] The sedating effect may be considered beneficial when caring for patients close to death. Dose reduction and caution with elderly patients is recommended for all dopamine antagonists.

Phenothiazines

Phenothiazines include prochlorperazine, chlorpromazine, and levomepromazine. Levomepromazine is not registered for use in the United States. These medications possess a broader spectrum of activity compared to haloperidol, blocking histaminic, muscarinic, serotonergic, and/or alpha-adrenergic receptors in addition to dopamine blockade.[48] No RCTs examining the use of levomepromazine to treat nausea and vomiting in palliative care were identified in a recent review.[49]

Their broad spectrum of activity is reflected in their numerous side effects including sedation, hypotension, anticholinergic effects, dystonias, EPS, QTc prolongation, leukopenia, and lowered seizure thresholds.[8,45] The availability of oral, rectal suppository, parenteral, and sustained-release formulations offers flexibility of administration in the outpatient setting, an important consideration in the palliative care population.

Atypical Antipsychotics

Olanzapine is an atypical antipsychotic that blocks dopaminergic, serotonergic, histaminic, and muscarinic receptors. Coverage of multiple receptors allows olanzapine to address nausea and vomiting that is caused by cancer or medications.[50] Consensus has shown that it has been used as a second-line antiemetic for patients with refractory nausea, with efficacy shown in small uncontrolled studies.[15,48,51] It has been used with advanced cancer patients in multicenter trials.[52] In small case reports, olanzapine was effective in treating nausea refractory to other treatments,[53,54] and reviews have identified RCTs showing its effectiveness for preventing and addressing breakthrough CINV.[55] Some authors have recommended olanzapine as a first-line monotherapy for nausea and vomiting in palliative care, though it can be included as part of multidrug regimens as well.[50]

Because advanced cancer patients may have multiple causes of nausea and vomiting (i.e., opioids, chemotherapy, disease burden), olanzapine is well suited for palliative care settings. Olanzapine causes fewer EPS than other antipsychotics and does not usually cause QTc prolongation. Its low cost and once-daily dosing schedule are additional benefits that can reduce financial and medication burden.[50]

Antihistaminic Agents

Antihistaminic agents include promethazine, cyclizine, meclizine, hydroxyzine, and diphenhydramine. Currently, cyclizine is not available for use in the United States. The first generation of piperazine antihistamines have recognized antiemetic properties related to H_1 receptor blockade in the vomiting center, CTZ, and vestibular nuclei.[3] Due to their action in the inner ear, antihistamines are specifically indicated for nausea and vomiting associated with movement, dizziness, or vertigo. Evidence supports antihistamines as a class likely to be beneficial for the treatment of nausea and vomiting in noncancer chronic diseases as well as postoperative nausea and vomiting, with less support for its use in CINV.[45] Diphenhydramine is often used in combination protocols to minimize the development of EPS when dopamine antagonists are used.[3,38]

Cyclizine is an H_1-antihistaminic anticholinergic medication. It achieves its antiemetic effect by decreasing excitability in the inner ear labyrinth, blocking conduction in the vestibular-cerebellar pathways, and directly inhibiting the H_1 receptor in the vomiting center. It is recommended for use when nausea or vomiting is caused by elevated ICP, motion sickness, pharyngeal stimulation, or mechanical bowel obstruction, and it is less sedating than promethazine.[3]

Antihistamines also have some anticholinergic activity, which can be beneficial when treating bowel obstruction. Cyclizine has greater anticholinergic activity than promethazine and is less sedating than scopolamine. Clinicians should be mindful that this same anticholinergic activity may reverse the effect of prokinetic drugs such as metoclopramide, and concurrent use should be limited. Other adverse effects include sedation, dizziness, headache, and lowered seizure threshold.[8,32]

Selective 5HT3 Receptor Antagonists

Serotonin antagonists include ondansetron, granisetron, tropisetron, dolasetron, and palonosetron and achieve their antiemetic effect by antagonizing 5HT3 receptors centrally in the CTZ and vomiting center and peripherally in the gut wall. There is strong evidence to support their use in the prevention of chemotherapy- and radiation-induced nausea and vomiting. Their effect is enhanced by the addition of dexamethasone and recommended by consensus guidelines.[2]

Consensus guidelines recommend their use for chemical causes of nausea and vomiting, vomiting refractory to dopamine antagonists, or when nausea is thought to result from massive release of serotonin from enterochromaffin cells, as seen in bowel obstruction and renal failure.[48] Due to their narrow mechanism of action compared with other antiemetics, the serotonin antagonists have a milder and more predictable side-effect profile, with constipation being the most common and significant side effect.[56]

Corticosteroids

Though the mechanism of action that produces the antiemetic effect is not well understood, there is strong evidence to support the use of corticosteroids, such as dexamethasone, in multidrug prophylactic antiemetic treatment during chemotherapy and radiation therapy.[45] Corticosteroids may be used to treat nausea stemming from increased ICP related to intracranial tumors, hypercalcemia of malignancy, or malignant bowel obstruction. Dexamethasone is thought to enhance the efficacy of 5HT3 receptor blockers, NK-1 blockers, and metoclopramide in the prevention of CINV.[45,48,57] Side effects are well documented, with significant adverse effects on nearly all organ systems, especially with long-term use. Short-term adverse effects include hyperglycemia, insomnia, and psychosis.[45]

Benzodiazepines

Benzodiazepines, such as lorazepam or alprazolam, act on the gamma-aminobutyric acid (GABA) receptors of the cerebral cortex and are often used to treat anticipatory nausea. Lorazepam may be used alone when the intent is to treat anticipatory nausea, due to its temporary amnestic effect, or when anxiety is a contributing factor to nausea or vomiting.[58–60] Sedation, confusion, and dizziness are possible common side effects. Benzodiazepines have been shown to be effective to treat anticipatory nausea in adult patients in combination with psychological techniques.[48,58–60]

Anticholinergic Agents

Anticholinergic medications include scopolamine, atropine, and hyoscyamine. Scopolamine (hyoscine) is the most commonly used anticholinergic medication for antiemesis and is a naturally occurring muscarinic antagonist. It achieves its antiemetic effect by blocking the muscarinic receptors in the vestibular nucleus and the vomiting center. A report of three cases of cancer-related nausea and vomiting found scopolamine to be effective when selected in a mechanism-based treatment plan.[61]

Anticholinergic medications are specifically indicated for nausea and vomiting associated with movement or dizziness and with treatment of bowel obstruction if the obstruction cannot be resolved.[61] These medications can cause the full range of anticholinergic side effects, including sedation, constipation, urinary retention, blurry vision, xerostomia, and delirium. Elderly patients are particularly sensitive to these side effects.[45] In the setting of imminent death, these anticholinergic properties are used advantageously to treat excessive respiratory secretions.[47] Anticholinergic medications are available in multiple formulations, including transdermal patches, ophthalmic drops that can be administered sublingually, and intravenous and subcutaneous injections, thus offering flexibility of administration in nonhospital settings.[45]

Somatostatin Analogues

Octreotide acetate is a long-acting somatostatin analog (vs. an antiemetic) that inhibits gastric, pancreatic, and intestinal secretions and reduces GI motility. Studies have shown octreotide may be helpful for nausea and vomiting associated with intestinal obstruction, where it is recommended to be used in conjunction with an antiemetic like haloperidol.[16] Additionally, it may be useful in cases where there is high-volume emesis.[62] Adverse effects may include diarrhea, abdominal pain, and nausea. Due to the cost of administration, somatostatin analogues are recommended only after a patient has tried standard treatments.[21] There are long-acting, depot forms of octreotide available for patients who would benefit from monthly dosing.

Cannabinoids

Marijuana is the best-known cannabinoid, and dronabinol is the plant extract preparation available for prescription use. The semisynthetic agents are nabilone and levonantradol. Cannabinoids are proposed to exert an antiemetic effect by binding to specific cannabinoid receptors in the brainstem and to the opioid mu receptor.[48,63] In one systematic review, nabilone was found to be superior to placebo, domperidone, and prochlorperazine for management of CINV, but not superior to metoclopramide or chlorpromazine. Another systematic review found oral nabilone, oral dronabinol, and intramuscular levonantradol were more effective treatments for CINV than dopamine antagonists, but were associated with significantly greater side effects.[48,63] Patients enrolled in various studies reported dizziness, dysphoria, euphoria, “feeling high,” and sedation as side effects to therapy.[64]

In recent years, there has been much attention focused on the medical use of cannabinoids, particularly for cancer symptom management.[63–65] Rigorous systematic reviews conclude that, based on limited evidence, cannabis-based medications may play a role in the management of CINV; however, ASCO, NCCN, and the Multinational Association for Supportive Care in Cancer and European Society for Medical Oncology (MASCC/ESMO) have not yet endorsed its use in standard guidelines.[5,63,64]

The evidence to support the use of cannabinoids in advanced cancer is weaker, and recommendations support the ongoing use of metoclopramide or haloperidol as first-line therapy, followed by 5HT3 receptor antagonists or olanzapine as second-line therapy.[63] With the approved use of cannabis-based medications for medical purposes, including cancer-related symptom management, more rigorous studies are needed to support its place in standard guidelines and to determine the risk–benefit ratio.

Substance P Antagonists (NK-1 Receptor Antagonists)

NK-1 receptor antagonists, such as aprepitant and fosaprepitant, prevent the binding of substance P to NK-1 receptors. Aprepitant is an oral drug that acts as an NK-1 antagonist, and its use in preventing and treating CINV has been strongly supported by national guidelines.[2,15,45,57] Aprepitant is particularly effective when combined with a 5HT3 receptor antagonist, such as ondansetron, and dexamethasone to prevent acute and delayed CINV.[5,57] Fosaprepitant is an FDA-approved, intravenously available NK-1 receptor antagonist that is converted to aprepitant within 30 minutes of administration. Studies comparing a single dose of fosaprepitant and a 3-day regimen of aprepitant showed similar outcomes in the prevention of CINV.[5]

NK-1 receptor antagonists are currently indicated for acute not chronic use, thus limiting their use for patients with advanced cancer who may not be receiving further disease-directed therapies.[45] Aprepitant is generally well tolerated, with some reports of nausea, diarrhea, and anorexia. Patients have reported pain at the injection site with fosaprepitant, as well as fatigue and hiccups.[45]

Combination Protocols

The use of multidrug regimens for the management of CINV is supported by a strong base of evidence including multiple RCTs and clinical practice guidelines. Regimens are stratified based on the emetic potential of the chemotherapeutic medications used and differ based on treatment of acute or delayed emesis.[2,5] The reader is encouraged to refer to current guidelines from NCCN,[2] ASCO,[66] and MASCC/ESMO.[16] Despite the availability of effective means of controlling CINV, nausea as an adverse event is not reliably assessed, nauseated patients often do not receive treatment, and adherence to guidelines is often compromised by the omission of dexamethasone.[53,67,68]

Home Hospice Approach to Selecting Antiemetics

In home hospice settings, routes of administration are an important consideration. Patients may or may not be able to take oral medications due to clinical decline or severity of nausea and vomiting. In these cases, sublingual medications may be a sound alternative. Other routes of administration, including rectal suppositories or subcutaneous injections, are more practical in home settings but require caregivers to be comfortable with administering medications via these routes. In the past, it was thought that topical combination gels of antiemetics, like ABR gel (Ativan, Benadryl, Reglan), had benefit in patients who could not take oral medications. However, studies have shown that these topical combinations lack evidence of efficacy, are not absorbed in any therapeutic manner, and are not recommended.[15,69,70]

Though the home hospice setting offers challenges for the management of nausea, vomiting, and other symptoms, consistent evaluation, intervention, and reevaluation will help address symptoms as disease progresses. The home setting may also be appropriate for inclusion of integrative modalities, like aromatherapy, massage, or acupressure.

Nonpharmacological Approach to Nausea and Vomiting

Despite the wide selection of pharmacological interventions with varying mechanisms of action, nausea and vomiting continues to be among some of the most distressing symptoms.[1,5] Although prophylactic antiemetic regimens have lowered the incidence of chemotherapy-induced vomiting from 90% to approximately 30% in patients receiving highly emetogenic regimens, nausea has been harder to control.[57] Additionally, anticipatory nausea and vomiting does not typically respond to commonly used antiemetic regimens.[59,60] Uncontrolled symptoms, whether treatment- or disease-related, possibly interfere with a patient's QOL and willingness to continue with treatments. Understanding nonpharmacological approaches to symptom management and integrating them into usual care is appropriate to minimize the physiological effects of uncontrolled symptoms and their potentially negative effects on QOL.

Nonpharmacological management of nausea and vomiting in addition to antiemetics has been tested over many years.[71] Treatments range from simple self-management techniques, integrative therapies, and, in some instances, palliative interventions to improve symptom management throughout disease treatment and at end of life. The use of certain nonpharmacological modalities has more recently been adopted into antiemetic guidelines, particularly for the treatment of anticipatory nausea and vomiting. Their use is based on a lower level of evidence, but with uniform consensus that the interventions are appropriate.[2,59,71]

Self-Management Techniques

Self-management emphasizes patient autonomy in their own care and encourages patients and families to assume the responsibility of managing their condition.[72] Self-management theories acknowledge the complexity of living with chronic conditions and the importance of managing these complexities in the context of one's everyday life rather than expecting patients to adhere to a series of prescribed orders that can be generalized across populations. These techniques start with evidence to guide treatment recommendations and are then tailored to meet the individual needs of patients and their families.[72,73]

There are a variety of potentially useful self-management strategies including psychological, cognitive, and behavioral modifications (Box 12.4[8,73,74]), and these should take into account individual factors, health status, and their environment when developing a plan of care.[74] While many of these interventions are not currently backed by strong evidence, they are associated with little harm and should be considered when treating nausea and vomiting in early and advanced disease.

Box 12.4 Self-Management Strategies for Management of Nausea and Vomiting

Dietary Modifications

Eat smaller, more frequent meals.

Reduce food aromas and other strong food odors.

Avoid spicy, fatty, and highly salty foods.

Premedicate with antiemetics prior to meals.

Give clear liquids.

Environmental Modifications

Avoid the sight and smell of food when not hungry.

Provide fresh air.

Avoid strong or unpleasant odors.

Minimize sights, sounds, or smells that can initiate nausea.

Psychological Strategies

Use relaxation and meditation.

Practice deep breathing.

Use cognitive distraction.

Other Strategies

Exercise.

Take medications as prescribed.

Source: References 8, 73, 74.

Integrative Medicine

There has been growing interest in the use of integrative medicine alongside curative and palliative treatments, with 38.3% of the US population estimated to use some form or combination of these techniques. This type of medicine refers to a wide variety of therapies that can be categorized into biological and nonbiological or behavioral interventions.[60,74–76] Recommendations are supported by limited data and suggest a role for integrative therapies for symptomatic relief of disease-related symptoms.[3,74,77,78]

There is enough evidence in the literature to support the implementation of certain techniques for prevention and treatment of nausea and vomiting; however, there is no convincing evidence favoring one method over another. Instead, the effectiveness of these techniques appears to depend on individual preference. RCTs are limited in number and sample size, stressing the urgent need for well-designed studies to test the effectiveness of particular interventions for managing adverse effects of chemotherapy and disease-related symptoms.[3,78,79] Patients should be educated to exercise caution before initiating certain herbal therapies due to the risk of drug interaction and adverse effects. The primary practitioner treating the patient's disease should be made aware of all conventional or integrative modalities of treatment.

Biological Therapies

Integrative biological therapies include nutritional supplements such as vitamins, minerals, botanicals, probiotics, and antioxidants as well as herbal medicines derived from natural sources. There have been few studies performed on these specific therapies for nausea and vomiting in advanced disease.[75,80]

An herbal remedy worth mentioning is ginger (*Zingiber officinale*), which is a spice best known for its role as a flavoring agent. Ginger has been used in Ayurvedic and traditional Chinese medicine to treat GI symptoms such as nausea and excessive flatulence since the sixteenth century. Studies have suggested ginger's efficacy in treating postoperative nausea, motion sickness, and pregnancy-associated nausea and vomiting through a combination of 5HT3, anti-inflammatory, and antispasmodic activities.[81,82] Newer studies have demonstrated the potential benefits of ginger in acute and delayed CINV in both the pediatric and adult populations, although findings and efficacy remain mixed.[81–84]

Reported adverse effects include grade two heartburn, bruising, flushing, and rash.[82] Potential adverse effects and herb–drug interactions must be understood before recommending ginger for symptom relief because the herb has been associated with increased risk of bleeding and hypoglycemia, and it is contraindicated with the use of tacrolimus, nonsteroidal anti-inflammatory drugs, blood thinners, and glucose-lowering medications.[85]

Nonbiological Therapies

Behavioral treatments that have specifically been recommended in guidelines for the treatment of anticipatory nausea and vomiting include progressive muscle relaxation, systematic desensitization, and hypnosis.[2,59] More detail will be paid to these particular interventions, as well as to acupuncture and acupressure later in the chapter. Other nonbiological integrative therapies are listed in Table 12.2.[74,86–91]

Acupuncture and Acupressure

Acupuncture is practiced in at least 78 countries, and its use, along with acupressure, for nausea and vomiting in the palliative care setting has been more widely explored when compared to other integrative therapies. Results have been mixed and integration into standards of care are limited by the lack of quality trials.[78,79]

Table 12.2 Nonbiological integrative therapies

Technique	Description	Comments
Music Therapy	Performed by credentialed professionals Incorporated at any phase of illness Addresses multiple dimensions of QOL First introduced in hospice population in 1980s	Likely to be effective Associated with significant reduction in severity and duration of CINV Perceived effects on autonomic nervous system Less time and energy to implement for patients No side effects
Aromatherapy	Therapeutic use of essential oils primarily via inhalation of its vapors	Oils such as peppermint and ginger have potential benefit of alleviating nausea and vomiting in postoperative and oncology patients Studies limited by design, small sample size, varied doses and methods
Massage	Soft tissue manipulation using touch and movement Reduces stress and anxiety while promoting relaxation which may lead to decreased heart rate, blood pressure, and respiratory rate	Effectiveness not established Variability in episodes of CINV and retching in breast cancer patients
Exercise	Any planned, structured, and repetitive bodily movement Incorporates cardiovascular, strength, and/or flexibility	Effectiveness not established in a study looking at female breast cancer patients receiving chemotherapy
Cognitive Distraction	Studied in adults and children Learn to divert attention away from a threatening situation and toward relaxing sensations Uses videos, games, puzzles, counting objects, deep breathing	No side effects Associated with decreased ANV and post chemotherapy distress

ANV, anticipatory nausea and vomiting; CINV, chemotherapy-induced nausea and vomiting; QOL, quality of life.

Source: References 74, 87–92.

Acupuncture is performed by trained specialists who insert fine needles or "studs" into acupoints along a specific meridian on the body. Acupressure can be performed independent of a practitioner and differs from acupuncture in that it involves applying digital pressure or acustimulation bands, rather than needles, on designated points on the body. These techniques are thought to work by stimulating or easing energy flow. More specifically in regards to nausea and vomiting, both acupuncture and acupressure use the P6 acupoint, which is most commonly used to alleviate symptoms and is located on the anterior surface of the forearm, approximately three finger-widths away from the wrist crease.[60,92]

Acupuncture and acupressure are nonpharmacological modalities that have been evaluated as "likely to be effective" for the prevention, management, and treatment of CINV when used in conjunction with pharmacological interventions.[60,79,92] A review of the current available literature favors the use of acupuncture in the different stages of CINV; however, some studies have shown no statistical difference when comparing acupressure to sham and control groups.[71,78] Despite the suggested benefits of acupuncture, the limited competency of practitioners to perform these techniques and limited availability of such practitioners has prevented increased use.[79] Acupressure offers a less invasive method to symptom management that may be effective and inexpensive.[92] The decision to integrate either or both interventions into the management of symptoms should be based on a holistic assessment of the patient's needs and goals.

Progressive Muscle Relaxation

Progressive muscle relaxation (PMR) allows individuals to respond to a stimulus that produces tension or anxiety by instead focusing on and isolating various muscle groups progressively up and down the body to induce relaxation.[60,74] This relaxation technique seems to be most effective in reducing the severity of nausea and vomiting after the administration of chemotherapy. PMR is not as effective with anticipatory nausea and vomiting unless used in conjunction with systematic desensitization or guided imagery.[60] In one study, the incidence of acute and delayed CINV was statistically lower for patients receiving PMR during the first 4 days following treatment, although no difference in severity of symptoms between groups was found.[74]

Systematic Desensitization

Commonly used to treat fears and phobias, systematic desensitization has proved particularly effective for treating anticipatory nausea and vomiting, as phobias may similarly develop through a learned-response or conditioning. The intervention works by teaching the patient how to counter a conditioned stimulus (e.g., entering the clinic, seeing the nurse) that normally elicits a maladaptive response (e.g., nausea and vomiting) with a response that is incompatible with feelings of nausea (e.g., PMR). Treatment has been documented as effective in more than half of treated patients.[60]

Hypnosis

While hypnosis was the first psychological technique used to treat and control anticipatory nausea and vomiting, very few controlled studies have been performed.[67] Hypnosis is a behavioral intervention that teaches patients to focus their attention on thoughts or images unrelated to the actual source of distress, often using passive types of muscle relaxation and distraction. Similar to systematic desensitization, patients learn to invoke a physiological state incompatible with nausea and vomiting. This technique has been effective mostly with children and adolescents because they may be more readily hypnotized. Overall, studies using hypnosis for anticipatory nausea and vomiting support the benefits of this intervention as it has no undesirable side effects and requires little training.[59,60,76]

Nursing Interventions

By definition, palliative care focuses on improving QOL and provides relief from distressing symptoms—which include nausea and vomiting.[93] The NCCN palliative care guidelines recommend aggressive symptom management, clarification of the intent of treatments, anticipation of the needs of patients and their families, and involvement of caregivers in the treatment process when appropriate.[2] Nurses have an essential role—whether it is doing an abdominal assessment at the bedside, providing antiemetic guidance over the phone, or asking about the pattern of a patient's nausea during an outpatient assessment. The palliative care nurse is instrumental in promoting a collaborative approach among team members. Nurses in various treatment settings should understand the standards of palliative care, advances in the management of nausea and vomiting, changes to relevant treatment guidelines, and potential side effects of treatments being administered.[94–96]

Just as vital are the roles that the patient and caregivers play in managing nausea and vomiting from disease or treatment. Oncology patients have reported high information needs regarding self-management of adverse effects.[74] As active participants in their care, they must be provided with the tools needed to practice symptom management and self-care. Personalized education plans and diaries with additional resources can help patients understand how to follow their plan at home and keep track of their symptoms—which can provide the healthcare provider with an understanding of symptom burden.[97,98] Education must include when and why to take certain antiemetic medications because patients may be given multiple agents, when to escalate symptom reporting to providers, and timelines for follow-up assessment.[99]

For CINV, acute phases are usually assessed and managed in the inpatient or outpatient setting; however, many patients are left to independently manage delayed nausea and vomiting, which can last up to 5 days post-treatment. Patients may be prevented from taking prescribed medications due to financial concerns, disbelief in treatment effectiveness, and perceived side effects, such as constipation or sedation. Likewise, certain patients may not report uncontrolled symptoms due to fear of being a "bad patient," communication issues with providers, or perceptions that symptoms are a normal part of cancer treatment.[50,97,100]

Sitting down with the patient to address his or her overall environment, fears, and concerns is crucial to ensure the steps to adequately control nausea and vomiting are achieved. Referring patients to other providers, such as palliative care specialists, should occur when symptoms cannot be controlled, or if additional support is needed.[99] Earlier involvement of palliative care resources can decrease symptom burden.

Conclusion

A major goal of palliative care is to improve QOL by addressing suffering in all its dimensions. It is important to remember that the most significant cost of inadequately controlled nausea and vomiting is patient suffering.[100] It can be difficult for nurses to meet the challenge of providing high-quality palliative care when there is a limited evidence base for interventions used routinely. Multiple studies and reviews have highlighted the need for more rigorous research on the management of nausea and vomiting, particularly in patients at the end of life and within the noncancer population. Nonetheless, vigilant assessment, appropriate use and evaluation of pharmacological and nonpharmacological interventions, and appropriate patient and family education and support may avert the need for unnecessary interventions at end of life and allow for QOL throughout the disease trajectory up until death and through bereavement. Nausea and vomiting profoundly affect all aspects of a person's well-being. Adequately managing these symptoms, especially at end of life, is essential.

CHAPTER 13

Dysphagia, Hiccups, and Other Oral Symptoms

Rachel Klinedinst, Audrey Kurash Cohen, and Constance M. Dahlin

Key Points

- Swallowing problems commonly occur in many advanced disease processes and can cause significant distress and burden on both the patient and the caregiver.
- Management of swallowing difficulties and oral complications in patients with serious illness focuses on preventing functional decline, maximizing quality of life and comfort, and supporting the patient's wishes.
- Oral symptoms and complications often occur concurrently and can impact patients' safety and comfort, as well as their ability to sustain nutrition and hydration and to manage oral medications.
- A multidisciplinary team approach will promote successful treatment with better outcomes and improved relief of symptoms.

Case Study: A Patient with Amyotrophic Lateral Sclerosis (ALS)

Mr. R was a 55-year-old man diagnosed with ALS. Two years prior, he developed weakness, twitching, and tingling sensation in his arms. He reported interval worsening in swallowing, speech, dyspnea on exertion and orthopnea, and loss of functional movements in his arms or hands. Mr. R received some relief from noninvasive ventilation consisting of BiPAP (bi-level positive airway pressure) several hours a day, although he struggled at night due to bouts of claustrophobia. Additional complications included worsening sialorrhea, laryngospasm, weak voice, poor cough strength, and fatigue with eating resulting in a 20-pound weight loss. He was given a home cough assist device and suction machine, and he was prescribed medications for anxiety and sialorrhea management. A videofluoroscopic swallow study with the speech-language pathologist (SLP) demonstrated that shakes and smoothies were the safest and most efficient consistency for his oral intake. The ALS team informed him that his clinical decline precluded him from feeding tube placement. Further family and team meetings were planned to assist the patient and family with decision-making.

Introduction

Food is a central aspect of life and also symbolizes love and community. Participating in the sharing of food and drink is a ritual that adds texture to life through socialization, communication, and enjoyment. Dysphagia, hiccups, and other oral symptoms such as sialorrhea, xerostomia, and dysgeusia are commonly experienced in patients with serious illnesses. These symptoms often occur concurrently, impacting not only a patient's safety and ability to sustain adequate nutrition and hydration, but also physical comfort, social well-being, and quality of life (QOL). The care and management of dysphagia and oral symptoms focuses on the specific disease process and trajectory while also encompassing the individual's preferences and goals.

Dysphagia

Definition

Dysphagia is defined as difficulty swallowing food or liquid. Swallowing impairments can threaten the safety and efficiency with which oral nutrition and hydration are maintained and patients' ability to manage oral medications. Chronic difficulty swallowing can be both frustrating and frightening for patients and their families. Because nutrition is compromised, generalized weakness, diminished appetite, weight loss, or malnutrition may ensue. Aspiration can occur, causing pneumonia, fevers, malaise, shortness of breath, and death.[1–3]

The psychological impact of dysphagia cannot be overstated. Its development may be pivotal in redirecting care from sustaining life to a palliative focus.[1] Swallowing difficulties and withdrawal from daily activities such as eating and drinking may become increasingly prevalent and alter social encounters.[2] Managing tube feedings, care of a gastrostomy stoma, or changing diet textures may become a significant burden. The challenge in managing dysphagia in patients with serious illness is to advocate for alignment with patient's goals of care, reduction in symptom burden, and maximization of QOL, even at the risk of optimal nutrition and hydration.

Physiology and Pathophysiology of Swallowing

Understanding the physiology of normal and aberrant swallowing is critical to meeting the challenge of caring for the patient with dysphagia. Swallowing, an extremely complex physiological act, involves the passage of food or liquid from the oral cavity through the esophagus and into the stomach, where the process of digestion begins.[3,4] Swallowing requires exquisite timing and coordination of more than 30 pairs of muscles under both voluntary and involuntary nervous system control within the brainstem as well as feedback from sensory receptors. Because humans swallow hundreds of times per day and are largely unaware of the activity, it is remarkable that difficulties do not occur more frequently.

The act of swallowing takes less than 20 seconds from the moment of propulsion of the bolus from the mouth into the pharynx until the bolus reaches the stomach. For purposes of discussion, the act of swallowing is divided into three stages: the oral stage, the pharyngeal stage, and the esophageal stage (Figure 13.1). In reality, these stages do not occur discretely; rather, there is melding and overlapping of events. Difficulty swallowing can occur anywhere along the swallowing continuum depending on the underlying disease.[5]

The first stage of swallowing (see Figure 13.1), the oral stage, is responsible for readying the bolus (ball of food or liquid) for swallowing.[6,7] Bolus preparation is under voluntary control and can be halted or changed at any point depending on the consistency and size of the food bolus. It is also during this stage that one takes pleasure from the flavor and texture of food through the chemoreceptors of the tongue and palate. During the oral stage, the bolus is partitioned into smaller portions. Sensory receptors assist in mediating saliva production, which is critical to moisten the bolus and assist with forming an optimal consistency.[3]

The tongue gathers all the food particles, and once the bolus is formed it is propelled backward into the pharynx by contraction of the tongue and floor of mouth muscles. Inefficient bolus flow may result from weakness in the tongue-driving force on the bolus from surgical tongue resection. Loss of control, reduced oral or lingual sensation, or impaired movement results in the bolus entering the airway while it is open, trouble containing the bolus in the oral cavity, and/or pocketed food remaining in the oral cavity.

The soft palate elevates to prevent material from entering the nasal passage. If the velopharynx is not sealed, nasal regurgitation of liquids and particles of solids occurs, such as in palate cancer where treatment involves resection and in patients with progressive neuromuscular disease.

The second stage of swallowing, the pharyngeal stage (see Figure 13.1), lasts approximately 1 second. This stage is the most complex, requiring precise timing and coordination between respiration, airway protection, bolus propulsion, and opening of the cervical esophagus. A carefully sequenced pattern of events is controlled by the central swallowing center in the medulla. Sensory feedback continually modulates and fine-tunes the motor response. If this sensory feedback loop is disrupted, the onset of the pharyngeal swallow may be delayed or, in severe cases, absent.[4,6,7]

The bolus is moved through the pharynx by pressure generated from the base of the tongue contacting the pharyngeal walls via pharyngeal muscles that progressively contract and relax and by

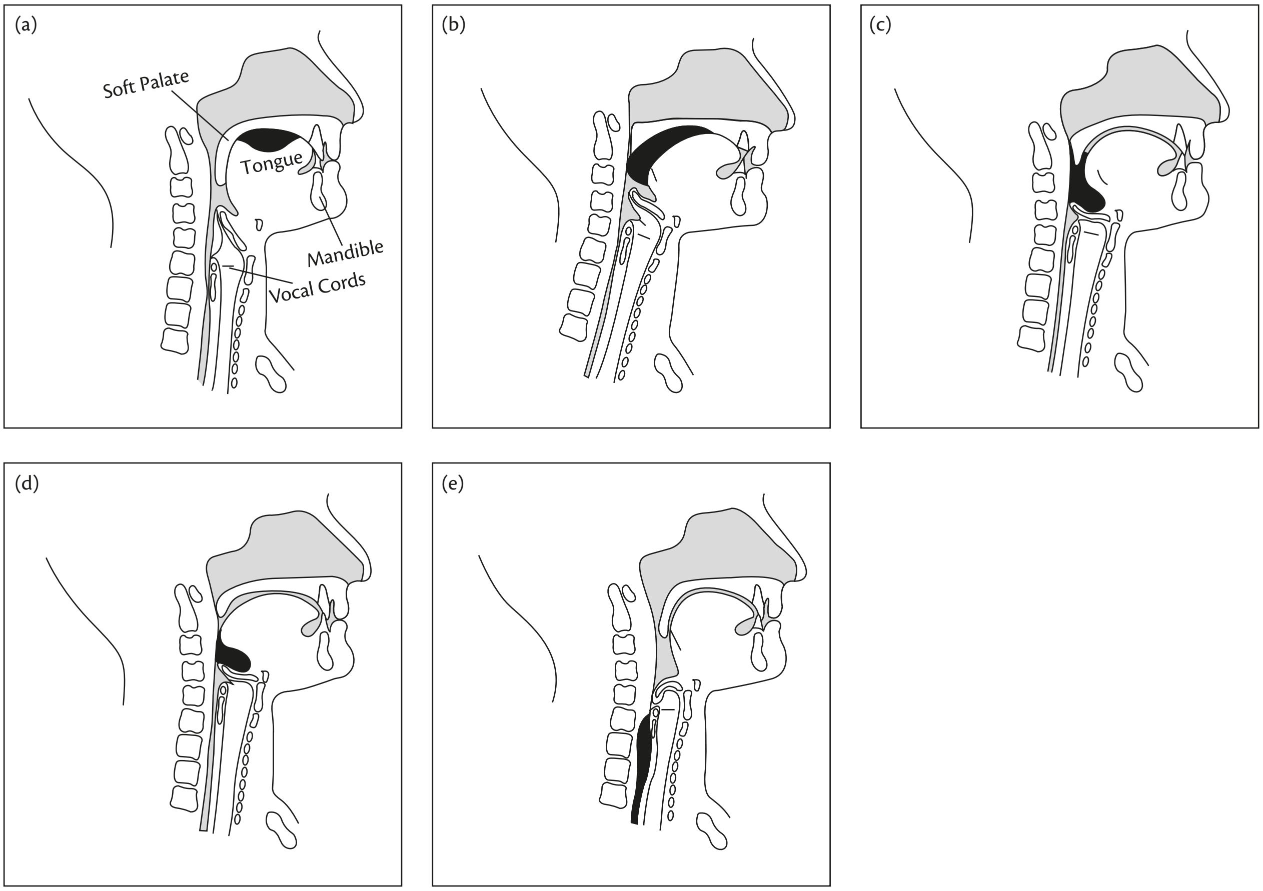

Figure 13.1 Stages of swallowing, beginning with voluntary initiation of the swallow by the tongue (A), oral transit (B), pharyngeal swallowing with airway protection (C) and (D), and esophageal stage (E).

relaxation of the upper esophageal sphincter. Weakness in pharyngeal muscles, obstruction from a mass, surgical alterations, or fibrotic tissue can all result in impaired propulsion of material through the pharynx and into the esophagus.

The upper esophageal sphincter (UES) separates the pharynx from the esophagus and is closed at rest. It prevents air from entering the esophagus and prevents esophageal contents from re-entering back up into the pharynx.[8] The UES opening creates a negative pressure in the esophagus, helping to propel the bolus through the pharynx and toward the esophagus.[8,9] Incomplete relaxation of the UES results in residue in the pharynx and, if abundant, material may spill over into the unprotected larynx and trachea.[9]

The process of airway protection, or closure of the larynx, is critical to prevent aspiration not only during oropharyngeal swallowing but also during periods of gastroesophageal reflux, regurgitation, or emesis. Breathing momentarily ceases during swallowing, and laryngeal closure expels any material that may have entered the laryngeal vestibule and prevents further material from entering the airway.[3] The bolus must fully clear the pharynx before the airway reopens or else this material may fall into the open airway and be aspirated.[3,4,6] Incomplete or delayed laryngeal closure due to mistiming or muscular incompetence may result in aspiration. Reduced sensory function and weakened laryngeal musculature may impair airway protection if the cough mechanism is weak and ineffective.

The esophageal stage of swallowing (see Figure 13.1) is the longest phase and involves transport of the bolus from the upper esophageal segment, through the lower esophageal segment, and into the stomach.[4,10] Like the pharyngeal phase of swallowing, the esophageal stage is under involuntary neuromuscular control. However, the speed of propagation of the bolus is much slower, with a rate of 3–4 cm/sec compared to 12 cm/sec in the pharynx.[11]

As the bolus reaches the esophagus, contractile waves carry the bolus through to the lower esophageal sphincter and into the stomach.[6,8,9] The lower esophageal sphincter contracts to its resting, closed state to contain the gastric contents within the stomach.[10,11] Dysfunction in the esophagus may result from reduced propulsion, and irregular or absent contractions. Narrowing of the esophagus from strictures or obstruction from a mass, as may occur in esophageal cancer, can limit the passage of the bolus through the esophagus and into the stomach.

Case Study: A Patient with Dementia and Strokes

Ms. T is an 85-year-old woman with a history of late dementia. She was admitted to the hospital with an acute stroke that affected her right side and her ability to walk, communicate, and swallow. During a swallowing assessment, Ms. T displayed inconsistent periods of wakefulness, oral and lingual weakness, and a weak cough. A swallowing trial revealed inability to clear the bolus from her mouth, latent onset of a swallow response, and a wet cough. She was deemed at increased risk for aspiration, pneumonia, dehydration, and malnutrition. A family meeting was convened to discuss the best treatment plan consistent with her goals of care.

Ms. T's advance directive stated, "no extraordinary or life-prolonging measures such as a breathing machine or stomach tubes." The family agreed to focus on comfort and forego any other aggressive medical care, including medically administered nutrition and hydration. A decision was made to move forward with oral feedings, small amounts of soft food items, and sips of liquid during periods of wakefulness and interest in eating. The family acknowledged the inherent risks of pulmonary infection, dehydration, and malnutrition. Prior to Ms. T's discharge home with hospice, the SLP, the nurse, and the dietician collaborated with the family and discussed the safest feeding techniques, strategies to improve the taste and texture of food, and oral care.

Etiology of Dysphagia

Dysphagia is a common symptom in patients receiving palliative care. Swallowing difficulties may be the presenting clinical feature or a sign of disease progression or advancing illness. Understanding the physiological impact of the illness is critical in evaluation of the swallowing disorder and the method of management. Some commonly encountered etiological categories in palliative care are discussed here.

Neoplasms

Brain Tumors

Although not often a presenting symptom, swallowing problems can develop directly or indirectly as a brain tumor increases in size and compresses surrounding structures. When extrinsic tumors are located around the brainstem or in the skull base, compressing or invading the lower medulla, the swallowing center may be directly affected. Other neoplasms can directly invade cranial nerves that innervate the swallowing structures. In addition to direct tumor effects, swallowing may be affected by surgical resection, chemotherapy or radiation side effects, depressed levels of consciousness, reduced awareness, fatigue, depression, seizures, and overall functional decline in 85% of patients.[12–14] High-grade tumors result in greater symptom burden such as seizures, altered consciousness, progressive cognitive deficits, and difficulty swallowing in the end-of-life phase.[15] Dysphagia may impact the patient's ability to take essential oral medications, including antiseizure or corticosteroid medications for tumor edema.

Head and Neck Cancer

Cancers of the head and neck arise in the oral cavity, tongue, oropharynx, larynx, nasopharynx, and sinuses. A high percentage of patients experience dysphagia, if not in the acute stage of the disease and its treatment, then as a late radiation therapy toxicity. The prevalence of aspiration and aspiration pneumonia in this population is substantial.[16]

Treatment approaches include surgery and chemoradiotherapy, depending on the cell type, location, tumor size, and presence of neck metastases. Complex surgical resections irrevocably alter the normal biomechanics of oropharyngeal swallow physiology, such as in the case of a glossectomy or mandibulectomy.[17] Laryngectomy, or removal of the voice box, offered to patients with advanced laryngeal cancer, results in a permanent stoma in the neck, altering the normal mechanism of swallowing, voice, and breathing.

Over the past twenty-five years, "organ preservation" using chemoradiation therapy has been the primary approach for treating cancers of the pharynx and larynx with the goal of sparing the organs involved in speech and swallowing. Unfortunately, "organ preservation" is not synonymous with "functional preservation." In spite of advances in radiotherapy methods aimed at sparing normal tissue and the use of targeted chemotherapy agents, patients suffer from significant acute treatment toxicities including pulmonary aspiration, mucositis, edema, xerostomia, and trismus (restricted jaw opening). Late radiation effects, occurring years after treatment, may include cranial neuropathies and fibrosis which can impair airway protection, pharyngeal contraction and bolus drive, and opening of the upper esophagus, resulting in chronic, progressive dysphagia and silent aspiration.[18–21] Some patients require feeding tubes years after treatment because of recurrent pneumonias and weight loss.[22]

Malignant Esophageal Tumors

Esophageal carcinoma can arise either from squamous cells of the mucosa or as adenocarcinomas of the columnar lining of Barrett's epithelium. Tumors of the squamous cell type are generally located in the upper or mid-esophagus, with smoking and alcohol consumption as high-risk factors, while tumors of the adenocarcinoma type are located more distally and occur in those with gastroesophageal reflux and obesity.[23]

If diagnosed early, endoscopic treatments such as radiofrequency ablation or endoscopic mucosal resection (EMR) or surgical esophagectomy may be the recommended treatment. Chemotherapy and radiation therapy may also be used either following surgery or as a concomitant treatment.[24] In cases of advanced disease, symptomatic relief of dysphagia and pain is typically the focus and may be best accomplished with least complications by brachytherapy or placement of a wire mesh self-expanding stent to open the lumen of the esophagus.[23,25] Treatments such as external beam radiotherapy and chemotherapy are associated with considerable side effects resulting in painful, difficult swallowing and in esophagitis, mucositis, xerostomia, loss of taste, and lymphedema.

Non–Head and Neck Cancer

Oncology patients often develop transient or persistent oropharyngeal dysphagia in a wide variety of cancers due to tumor location, side effects of radiation, cytotoxic effects of chemotherapy, cancer-related weakness and fatigue, and neurologic or respiratory compromise.[26,27] Chemotherapy and radiation therapy to the thoracic region may cause toxicity to the oral, pharyngeal, and/or esophageal mucosa, such as esophagitis and/or mucositis.[18,20,21] This results in altered taste, pain, reduced appetite, nausea, mucosal bleeding, and formation of lesions such as herpes simplex virus or varicella zoster.[28] Although the prevention of weight loss is of utmost importance for improved QOL and improved outcomes, this is not always possible especially if the patient is experiencing dysphagia.[29]

Progressive Neuromuscular Diseases

Motor Neuron Disease

Motor neuron disease (MND), of which the most common disease is Amyotrophic Lateral Sclerosis (ALS), is encountered with unfortunate regularity in patients receiving palliative care. ALS begins in the central nervous system (CNS), and rapidly progressive symptoms involve the upper and lower motor neurons.[30,31] One-quarter of ALS patients initially present with swallowing difficulty, with many displaying distal weakness that travels proximally to involve the bulbar musculature. Respiratory failure is the usual cause of death in patients with ALS because of weakness in diaphragmatic, laryngeal, and lingual function.[30,31]

As patients experience lingual, oral, pharyngeal, and respiratory muscle weakness, they develop increasing difficulty and fatigue with eating. Frequent choking may occur, and weight loss has a significant impact on QOL. Many patients reach a point where the burden of eating outweighs the pleasure, and alternative non-oral nutrition should be discussed early in treatment. An important prognostic factor is forced vital capacity (FVC), or the amount of air one can exhale after taking a maximal inhalation, which should ideally be greater than 50% at the time of PEG insertion for optimal benefit.

New pharmacological agents are being introduced to slow progression of the disease, treat symptoms, and prolong life as much as possible, including riluzole, a glutamate antagonist.[30,32–34] In 2010, the US Food and Drug Administration (FDA) approved dextromethorphan and quinidine (Nuedexta). Originally prescribed to alleviate pseudobulbar symptoms, it was found to palliate other bulbar symptoms including speech, swallowing, and saliva management. At the time of this writing, more extensive studies, including a phase III trial, are needed to confirm results and determine the duration of the treatment effect and impact on disease progression.[35] Edaravone (Radicava) is another medication for patients with ALS, approved by the FDA in 2017.[36]

Parkinson's Disease and Parkinsonian Syndromes

Parkinson's disease (PD) is a relatively common, slowly progressive disease of the CNS marked by an inability to execute learned motor skills automatically and resulting in resting tremor, bradykinesia (slowness of movement) and rigidity, gait dysfunction, autonomic disturbances, sleep problems, mood disorders, and cognitive dysfunction.[37] Dysphagia in PD may occur from changes in striated muscles under dopaminergic control and in smooth muscles under autonomic control.[31] Delayed swallow response, rigidity of musculature (lingual, laryngeal), reduced muscle strength, and incomplete opening of the upper esophageal sphincter can be present and contribute to aspiration.[31,38] Dysphagia and resultant pneumonia is one of the most prevalent causes of death in patients with Parkinson's disease.[33,38,39]

There is a paucity of research on clinical practices for dysphagia in patients with PD, although several reviews have demonstrated little positive effect of medical and surgical treatments on swallowing physiology.[39] Early identification, treatment focused on specific physiologic impairments and exercise-based therapies (see later section on swallowing exercises), and changing bolus characteristics may have a positive impact on swallowing function.[39]

Two other progressive neuromuscular diseases associated with dysphagia include progressive supranuclear palsy (PSP) and multiple system atrophy (MSA). Patients with PSP do not respond as well as patients with PD to pharmacological treatment. Instead, they display earlier clinical symptoms of dysphagia, and thus their dysphagia may be more aggressive and more life-threatening. One study correlated the initial development of pneumonia with a survival time of within 2.3 years. Dysphagia-related death accounted for 91% of deaths in studied patients with PSP.[40]

Although not nearly as common as PD, MSA is a rapidly progressive neurodegenerative disorder characterized by parkinsonism, ataxia, pyramidal signs such as spasticity, and autonomic failure such as urinary dysfunction and orthostatic hypotension, with a median duration from onset to death of almost 10 years.[41] There are two subtypes based on predominant clinical features: cerebellar (MSA-C) and parkinsonism (MSA-P). Dysphagia onset occurs within 5 years after diagnosis with MSA-P (the parkinsonian subtype).[41]

Myopathies

Myopathy is a neuromuscular disorder that results in muscle weakness and can be either inherited or acquired. Muscle disorders, or muscular dystrophy, are chronic and progressive, resulting in weakness of oral, pharyngeal, and esophageal muscles as well as in the muscles involved in breathing and walking.[42] Oculopharyngeal muscular dystrophy (OPMD) is an autosomal dominant muscle disorder with hallmark features of a slowly progressive ptosis and dysphagia, proximal limb and facial weakness, and abnormal gait, with onset generally occurring after age 40.[42]

Other chronic muscle diseases that are often associated with dysphagia include inclusion body myositis (IBM) and advanced Duchenne muscular dystrophy (DMD). Muscle wasting and loss of tongue and oromotor strength is a common feature that leads to oropharyngeal dysphagia, including smaller bolus size, reduced swallowing efficiency, nasal regurgitation, and reduced upper esophageal opening.[43] Laryngeal dysfunction, reduced cough strength, and impaired muscles of respiration are also factors that predispose these patients to reduced airway clearance and aspiration.[43] There is currently a lack of evidence from randomized controlled studies on best interventions for dysphagia in muscle disease.[43]

Multiple Sclerosis

Multiple sclerosis (MS) is characterized by scattered, multifocal plaques of demyelination within the CNS that result in varying combinations of motor, sensory, and cognitive deficits. Symptoms that affect QOL include fatigue, spasticity, paroxysmal symptoms, pain, ataxia, bladder and bowel dysfunction, depression, cognitive problems, and dysphagia.[44] Swallowing dysfunction largely depends on the location of the lesions. Dysphagia occurs in more than one-third of MS patients, typically at the end stage, and appears to be more common in those with brainstem or cerebellar involvement and in those with greater neurologic impairment.[44] Sclerosed plaques can be found in the cortex and the brainstem and can affect cranial nerves, affecting coordination of the swallowing sequence and/or sensation. Disease-modifying medications may slow the progression of disability by reducing inflammation in the CNS, the frequency and severity of MS attacks, and symptom burden. Thus, early initiation of drug treatment and ongoing medication management is recommended.[45]

Dementia

Dementia encompasses many etiologies; however, the most common form is Alzheimer's disease. Symptoms of dementia include progressive memory loss, poor awareness, loss of language abilities, inactivity, agitation, and confusion.[46] The different types of dementia and their varying trajectories result in an unspecific dysphagia. However, common attributes include the inability to independently self-feed and an inability to focus for the duration of meal times. With disease progression, patients may not engage in the task of eating and swallowing at all. They may hold food in their mouth for prolonged periods without mastication or bolus formation, especially with uniformly textured foods such as pureed items or bland foods. This often occurs when a swallowing dyspraxia makes it hard to plan and coordinate motor movements. Decreased consciousness and sedation predispose patients to both food and liquid aspiration. Additionally, sensory impairments and lack of attention reduce the ability to control the bolus in the mouth, resulting in aspiration from premature spillage before the pharyngeal swallow has been elicited. Moreover, behaviors such as distraction or agitation may prolong feeding time and hence reduce the amount of nutrition and hydration received.[47]

One study revealed that the most common clinical complications in patients at the end-stage of Alzheimer's disease were eating problems (86%), febrile episodes (53%), and pneumonia (41%), and these are associated with poor prognosis and high mortality rates.[46] Swallowing and feeding difficulties that arise in the late stages of dementia are irreversible, although treating concomitant infections, metabolic disarray, and/or dehydration may result in improved functioning.[47–49]

There is growing consensus that in cases of advanced and late-stage dementia, a palliative care approach focusing on maximizing oral intake and reducing treatment burden is appropriate. Studies indicate that hand-feeding is at least as good as tube-feeding for the outcomes of death, aspiration pneumonia, functional status, and patient comfort, while tube-feeding is associated with agitation, increased use of physical and chemical restraints, and worsening pressure ulcers.[48] The American Academy of Hospice and Palliative Medicine's *Choosing Wisely* campaign states that feeding tubes in patients with advanced dementia are not recommended and emphasizes assisted feeding by hand for comfort and human interaction.[50]

Aging, Chronic Illness, and Frailty

Aging, sarcopenia (muscle loss associated with aging), and multisystemic chronic illnesses can result in extreme muscle wasting and poor functioning. These diseases include end-stage chronic obstructive pulmonary disease, coronary artery disease, heart failure, and chronic renal failure.[51,52] Frailty, a state of increased vulnerability resulting from aging-associated decline in reserve and function across multiple physiologic systems, can contribute to sarcopenia and low physiologic reserve. Sarcopenic dysphagia, or difficulty swallowing due to the loss of muscle mass and strength of skeletal muscles, can impair tissue elasticity in the tongue and pharynx.[53–55] Additionally, aging affects the larynx; specifically, the vocal folds may not close sufficiently or timely enough to protect the airway.[55–57] Sensorimotor changes may occur that impact salivary production, taste, and smell. Swallowing efficiency in elderly adults is also affected by delayed swallow response.[55–57] The reduction in functional reserve leaves older individuals highly vulnerable to insults to the swallowing system for which they may be unable to compensate. Oropharyngeal dysphagia in the elderly has been estimated at 30–40% in community dwellers, rising to as much as 60% in institutionalized older adults.[51]

Hospitalized medical patients with cachexia, loss of muscle mass, significantly compromised pulmonary systems, and general weakness and deconditioning due to lengthy hospitalizations often develop dysphagia.[53,58] In a fragile and immunocompromised condition, there is a higher risk of pulmonary infections, poor outcomes from aspiration, and fatigue, all of which impact the ability to sustain appropriate nutrition. Moreover, this population is prone to negative outcomes from dysphagia, including increased length of hospital stay and greater risk of mortality.[58] Difficulty in completing oral care due to a low level of consciousness and/or the presence of an endotracheal tube can promote colonization of oral bacteria in the hospitalized patient. If aspiration of colonized oropharyngeal contents occurs (secretions, vomitus, food/liquid mixed with colonized secretions), it can result in aspiration pneumonia.[59] General immobility further impairs spontaneous pulmonary clearance, resulting in an inability to expectorate aspirated material.

Dysphagia as a Side Effect of Medications

There are 160 known medications with dysphagia specified as a potential adverse effect. Medications should be reviewed to determine if they produce dysphagia either as a possible side effect or through other mechanisms, including direct action on the CNS; as a by-product of reduced levels of consciousness, oral dryness, or taste disturbances; through reduced coordination or motor function; and/or when there is direct insult to esophageal mucosa and tissue injury that affects gastrointestinal (GI) motility.[26,60–62] (See Table 13.1.)

Table 13.1 Dysphagia as a side effect from medications

Drugs that affect the smooth and striated muscles of the esophagus	Anticholinergics, antimuscarine agents
Drugs that cause dry mouth/xerostomia	Antipsychotics, angiotensin-converting enzyme (ACE) inhibitors, antiemetics, antihistamines, diuretics, antidepressants, anticholinergics
Drugs that induce CNS depression	Benzodiazepines, opioids, antiepileptics, muscle relaxants, anticonvulsants
Drugs that cause esophageal mucosal injury	Bronchodilators, nonsteroidal anti-inflammatory meds, anticholinergics, antibiotics

Role of the Speech-Language Pathologist

Speech-language pathologists (SLP) are expert specialists in the assessment and management of oropharyngeal dysphagia. SLP involvement has been shown to have a positive effect in both prevention and treatment of oropharyngeal dysphagia.[63] An SLP skilled in palliative care can provide education about the swallowing process and the impact of disease progression, evaluate empirical data to determine swallowing potential and trajectory, assist in decision-making, and guide families and caregivers in safe feeding methods.[1] The SLP must carefully weigh the benefits of any intervention with its burden, attend to the individual spiritual and emotional issues, display skills and knowledge in biomedical ethics and legal issues, and remain highly sensitive to the psychosocial and family ramifications of treatment recommendations.[64,65] (See Chapter 56 for further discussion of the role of physical and occupational therapy in palliative care decision-making.)

Assessment of Dysphagia

For the patient with a serious and life-limiting illness, the goals of the swallowing evaluation are to (1) identify the underlying physiological nature of the disorder, (2) determine reversible conditions that may be a causative or contributing factor,[66] (3) determine interventions that can best alleviate the dysphagia and concomitant distress, and (4) collaborate with the patient, family, and caregivers on the safest and most efficacious method of nutrition and hydration. There are numerous tests and procedures that can be undertaken to evaluate swallowing function. The correct evaluation is driven by the specific patient complaints and concerns and goals of care.

Clinical Examination of Swallowing

Eliciting a description of the patient's complaints about swallowing, current eating habits, appetite, and diet is critical to understanding the physiological basis of the problem. Details of disease progression and prognosis and consideration of a patient's level of alertness, positioning, breathing, and ability to follow directions are also considered when determining the aggressiveness of a swallowing work-up and its treatment.

Direct observation of the patient eating, drinking, or taking medications by a perceptive clinician can yield valuable information about the underlying disorder. The SLP is vigilant for indications of chewing inefficiencies, aspiration, difficulties managing secretions, or obstruction. Typically, the SLP assesses the patient's oral-motor and sensory function as well as level of arousal, cognitive communicative abilities, and respiratory status while observing the partaking of a variety of liquid and solid foods (e.g., semi-solid, soft solid, and, where appropriate, food requiring mastication). Speech and voice are analyzed to assist in understanding the underlying physiology of the swallowing disorder. Functional airway protection is a critical predictor of safe swallowing and thus an important element of the swallowing evaluation. Although this cannot be definitively discerned from clinical observation alone, patients who have weak voices and decreased respiratory force for coughing and pulmonary clearance are at risk for pulmonary compromise.

Since aspiration may be silent in up to 40% of patients with dysphagia (e.g., present with no overt sign or symptom that material has entered into the airway, such as a cough or throat clear),[67] close attention is paid to occult signs of aspiration, including wet vocal quality, frequent throat clearing, delayed coughing, and changes in breathing.[4] Silent aspiration can only be confirmed definitively with an instrumental examination.

Screening of Swallowing Function

Given the causes for dysphagia and its impact on patients' overall health, outcomes, hospital length of stay, and cost of care,[58] early identification of swallowing dysfunction in high-risk hospitalized patients is paramount.[67,68] Dysphagia screening has been formally recognized in the care of stroke patients for more than a decade.[69] The use of a formal, validated screening protocol to identify potential aspiration risk can be completed by the nurse or a member of the healthcare team who undergoes appropriate training to assist in determining if a patient is safe to start eating and drinking. Screening programs have been shown to improve patient outcomes, including a 55% reduction in cases of pneumonia and a shorter hospital length of stay in many hospitalized patient populations.[58]

Specific clinical predictors (e.g., abnormal volitional cough, dysphonia, slurred speech),[70] subjective dysphagia symptoms, and patient reports[71] have been shown to accurately predict the increased risk of swallowing dysfunction and aspiration that warrants further instrumental swallowing evaluation (see Box 13.1).

Instrumental Evaluation

An instrumental swallow evaluation may be clinically indicated to delineate swallowing physiology and can provide valuable information for management, assess for integrity of the swallowing anatomy and mucosa, determine effectiveness of swallowing strategies, and clarify or confirm aspiration risk. Instrumental or objective evaluations take many forms (see Table 13.2) and are driven by the patient's complaints and suspected etiology.[72,73]

Box 13.1 Indications of a Swallowing Disorder

Reduced alertness or cognitive impairment

Coma, heavy sedation, dementia, delirium
Inattention during eating
Residual food in the oral cavity after eating
Impulsivity with regard to eating
Playing with food

Signs of oral-pharyngeal dysfunction

Dysarthria or slurred, imprecise speech
Wet sounding voice
Inability to manage secretions
Drooling or leaking from the lips
Frequent throat clearing, coughing or choking during or immediately after meals
Voice changes after swallowing
Laborious chewing, multiple swallows per small bites
Residual food in the oral cavity after eating
Nasal regurgitation
Recurrent aspiration pneumonias
Food or fluid noted in tracheotomy tube
Changes in posture or head movements during eating

Signs of esophageal dysfunction

Regurgitation or emesis after swallowing
Sour taste in mouth after eating
Solids caught in the chest region
Burping during/after eating
Pain on swallowing

Specific patient complaints (adapted from the EAT-10)

Sensation of food caught in the throat
Coughing and choking while eating
Painful or effortful swallowing
Alterations in attitudes toward eating
Swallowing problem interferes with pleasure when eating or socializing
Shortness of breath while chewing or after meals
Weight loss
Protracted meal times or inability to complete a meal
Avoidance of particular foods or fluids
Refusal to eat in the presence of others

Management of Dysphagia

The physiologic information obtained from clinical and instrumental swallowing assessment facilitates determination of intervention strategies aimed at increasing swallowing safety and efficiency and/or maximizing residual abilities. Often, treatment uses a variety of approaches and techniques simultaneously. Management strategies are individualized and only effective when targeting specific impairments in the biomechanics of swallowing as determined by an objective swallowing evaluation. Consideration of any swallowing intervention should be aligned closely with overall goals of care and treatment plan. When the disease process shifts to the terminal stage, and/or when swallowing function declines, swallowing interventions and recommendations shift as well to focus on maintaining comfort, minimizing symptoms, and upholding the patient's wishes.

Exercise-Based Therapy

Swallowing interventions may include active strengthening exercises and rehabilitation aimed at directly improving or maintaining swallowing function and the biomechanics of swallowing. Exercises may target increasing tongue strength or movement,[4,75] pharyngeal contraction, airway and vocal fold closure, hyolaryngeal excursion, and opening of the UES. Respiratory muscle strength training (RMST), although not a direct swallowing exercise, targets inspiratory and expiratory muscles for improved cough, voice, and swallow function.[76] Using a small handheld device, resistance training can be incorporated into the SLP dysphagia management program and has been shown to be effective for patients with ALS, Parkinson's, and stroke.[76]

Like any other strengthening program, exercises are only beneficial in certain instances, such as when muscle strength is impaired and can be improved; must be individualized to the specific dysfunction; and must consider principles of exercise physiology to determine appropriateness. The effectiveness and appropriateness of direct swallowing intervention in a patient with a degenerative process, such as dementia-related cognitive impairment, or with advanced stages of disease may be questionable.[31] Therefore, it is imperative to determine the realistic impact and the appropriate implementation of a course of swallowing exercises.

Compensatory Swallowing Strategies

Alterations in head and neck posture, modifications in food and liquid texture, techniques to improve airway closure, and external cueing to increase sensory awareness and feeding behaviors are considered compensatory in nature. Their effectiveness may be limited in patients with altered cognition, pulmonary complications, or who do not have available a caregiver who can assist them. Other modifications, such as altering food/liquid consistency, may significantly impact patient's pleasure with eating.

Postural Modifications

Postural changes during swallowing often have the effect of diverting the food or liquid to prevent aspiration or obstruction but do not change the swallowing physiology.[3,4] These strategies may be used in isolation or in combination, depending on the nature of the underlying swallowing pathophysiology (see Table 13.3).

Table 13.2 Instrumental Swallowing Evaluation Methods

Instrumental Evaluation	Primary Anatomic Focus	Description	Clinical Indications/Role
Videofluoroscopic Swallowing Study (VFSS) or Modified Barium Swallow (MBS)	Oropharynx; upper esophageal screen	A dynamic radiographic study Completed by a speech-language pathologist and radiologist Patient positioned upright while ingesting a variety of consistencies of barium-coated liquids and foods (pureed, semisolids, and solids) in controlled volumes	Assess oropharyngeal swallowing anatomy and physiology Screen the proximal esophagus Determine the nature of swallowing impairment Evaluate the integrity of airway protection Identify the presence and etiology of aspiration Assess the effectiveness of behavioral maneuvers and bolus texture modifications that may decrease the risk of aspiration and increase swallowing efficiency
Fiberoptic Endoscopic Evaluation of Swallowing (FEES)	Oropharynx and larynx	Endoscopic evaluation A thin, flexible nasoendoscope with a small distal camera is passed transnasally and into the pharynx Patient swallows saliva, food, and liquid dyed with food coloring Performed at the bedside or in a clinic setting	Determine the presence of laryngeal penetration, aspiration, and pharyngeal retention View laryngeal and pharyngeal anatomy Assess sensory integrity of the pharynx and /or larynx Evaluate effectiveness of compensatory swallowing strategies such as postural modifications or swallowing maneuvers Provide visual feedback to the patient during treatment
Barium Swallow and Upper GI Study	Esophagus, stomach, duodenum	Conducted under radiography Patient positioned upright and in the supine position Patient ingests liquid barium, and in some cases, a barium tablet and baking soda crystals	Identify mucosal and anatomical abnormalities, such as esophageal strictures, tumors, hiatal hernias Assess esophageal motility
Esophagogastroduodenoscopy (EGD)	Entire upper GI tract	Endoscopic evaluation using a thin, flexible tube passed intraorally through the esophagus and into the stomach Completed by a gastroenterologist	View the lining of the esophagus, stomach, and upper small intestine (duodenum) Confirm the presence of strictures and mucosal anomalies, hiatal hernias, tumors, or bleeding Obtain tissue biopsy Perform interventional procedures such as dilation and/or stenting of the esophagus, banding of varices, and removal of foreign bodies
High resolution manometry (HRM)	Pharynx, UES, esophagus through to the LES	A thin catheter with pressure monitors is introduced through the nostril into the throat, esophagus and stomach May include dry swallows (without food/liquid), small water bolus, and food substance such as pudding Completed by a gastroenterologist or speech pathologist (pharyngeal manometry)	Assess motility of the esophagus and the function and relaxation of the lower esophageal sphincter (LES); hallmark features of achalasia Can be used to assess pharyngeal contraction and relaxation of UES peristalsis Obtain pressure readings to measure the strength (“vigor”) and pattern of muscle contractions and intrabolus pressure
pH Probe	Esophagus	Ambulatory 24-hour pH probe A small tube with a pH sensor at the tip is passed through the nose into the esophagus Collects data on a portable or wireless monitor	Determine the presence and amount of reflux disease, or GERD and heartburn Measure acid exposure in the esophagus and compares results to “normal” Considered the gold standard test for acid reflux

Source: References 4, 40, 72, 73, 74.

Changes in Texture and Consistency of Food

Changes in food texture and liquid consistency may play a vital role when managing dysphagia and may be the best option to ensure a patient’s comfort or improve safety or efficiency of oral intake (see Table 13.4). However, these alterations can be unappealing and may necessitate emotional adjustment and support for patients. Typically, this management strategy is reserved for patients who are unable to follow directions to use postural changes or for whom other compensatory strategies or exercises are not feasible.[4] Enhancing the bolus characteristics to include more texture can

Table 13.3 Postural modifications

Postural Strategy	Rationale
Chin tuck	Closes larynx, pushes tongue closer to posterior pharyngeal wall, and promotes epiglottic deflection
Head back	Promotes bolus movement through the oral cavity with assistance of gravity
Head tilt to stronger side	Directs bolus down stronger side with assistance of gravity
Head turned to weaker side	Diverts bolus away from weaker side of pharynx, promotes opening of upper esophagus
Head tilt plus chin tuck	Directs bolus down stronger side while increasing closure of larynx
Head rotation plus chin tuck	Diverts bolus away from weaker side while facilitating closure of laryngeal vestibule and vocal folds

Source: Adapted from References 3, 4.

sometimes induce mastication and bolus formation more readily than a bolus that is both flavorless and homogenous in texture. This is particularly evident in patients with advanced dementia. (See Box 13.2 for suggestions for oral feeding.)

Specialized commercial agents derived from modified food starch or gum-based ingredients (xanthan, guar, cellulose) can be used to thicken liquids. Gum-based thickeners are preferred due to their better taste and improved performance over starch-based thickeners in terms of stability over time and at varying temperatures.[77] Thickened liquids release the fluid in the gastrointestinal tract and do not alter the body's absorption rate of fluids, although they may promote dehydration.[78] This can stem from patients lacking motivation to drink thickened fluids and thickened fluids providing the sensation of being full, as well as the increased fiber content of gum-based thickeners impacting early satiety.[78]

In an attempt to standardize the terminology surrounding stages of food and liquid consistency, the International Dysphagia Diet Standardisation Initiative convened a task force in 2015 with a goal to improve patient safety and improve cooperation and collaboration among healthcare professionals.[79] The classification system uses 7 levels of thickness, from 0 for thin liquids up to 7 for regular solid foods, and it measures thickness by either a fork-drip test or a syringe flow test for the viscosity of liquids.[79] At the time of this writing, this classification scale has not yet been widely adopted.

A close partnership and collaboration with the registered dietician will ensure the best outcome.[80–81] Nutritionists can provide individualized suggestions for calorie-dense foods or high-calorie nutritional supplements, depending on the patient's metabolic status. Food preparation in a manner that increases caloric and nutritional value and maximizes hydration is helpful, such as using cream, oil, and butter; adding sauces to foods, and increasing high-calorie healthy items such as hummus and avocado. Additionally, some nutritional supplement drinks are thicker liquids and calorically fortified, providing a safer alternative to more solid consistencies, while others come in a pudding format. Listed in Box 13.3 are cookbooks specific for patients with swallowing problems.

Airway Clearance Techniques

The ability to effectively cough to clear secretions and aspirated material is essential to reduce pulmonary infections and respiratory difficulties. Supportive airway clearance techniques may be

Table 13.4 Diet modifications for patients with dysphagia

Diet	Definition	Example	Indication - IDDSI
Liquid: Nectar consistency (Level 2)	Mildly thickened liquid.	Similar in viscosity to tomato juice; less thick than honey consistency	Reduced liquid bolus control Delayed swallow initiation and airway closure
Liquid: Honey consistency (Level 3)	Moderately thickened liquid.	Similar in viscosity to honey; available in ready-to-serve packaging or use thickening agent	Reduced oral or lingual control of liquid bolus Delayed swallow initiation and airway closure
Pureed diet (Level 4)	Blenderized food with added liquid to form smooth homogenous consistency. No chewing necessary.	Applesauce, yogurt, moist mashed potatoes, puddings	Significantly reduced chewing Reduced alertness or awareness of oral bolus Impaired pharyngeal contraction, esophageal stricture
Minced diet (Level 5)	Ground, finely chopped or diced foods that easily form a cohesive bolus with minimal chewing.	Pasta, soft scrambled eggs, cottage cheese, ground meats	Some limited chewing possible; may be protracted or laborious
Soft, moist, bite-sized diet (Level 6)	Naturally soft foods requiring some chewing. Food is cut in small pieces; serve with gravy to moisten.	Soft meats, canned fruits, baked fish Avoid raw vegetables, bread, nuts, and tough meats	Reduced endurance for prolonged meal Reduced attention span Tongue/lip weakness

Box 13.2 Suggestions for Oral Feeding

1. *Remove distractions at mealtime*. This can help patients focus on swallowing and using compensatory swallowing strategies.
2. *Emphasize heightened awareness of sensory and taste cues*. Using a larger bolus size, increased downward pressure of the spoon on the tongue, and cold or sour foods may alert the patient that food is in the mouth and improve oral sensation and awareness.
3. *Provide feeding utensils*. Patients with hand tremors or weakness that impact self-feeding may be aided with devices such as weighted cuffs or built-up utensils.
4. *Optimize the position of the patient*. Sitting as upright as possible when eating, drinking, or taking medications is typically deemed safest. Reduce the tendency to slump forward or to the side, or head extension, which can make the patient more vulnerable to aspiration.
5. *Schedule meal times*. Time meals to coincide with increased function and reduced fatigue or sedation from medications.
6. *Consider more frequent, smaller meals with high-calorie supplements*. Increased frequency of small meals may help patients who do not have sufficient efficiency or endurance to complete an entire meal at one time.
7. *Encourage the maximal number of calories for the least amount of effort*. Make every bite count with increased caloric and nutritional value by using cream, oils, and butter; adding sauces, and avoiding calorie-free beverages or foods unless otherwise indicated.
8. *Consider hand-feeding when appropriate*. Hand-feeding allows for continued intimate contact between patient and caregiver.

Box 13.3 Cookbooks for Altered Food Consistency Diets

- *Safe Swallowing with Dysphagia: A Puree Cookbook for Dysphagia-Related Lifestyles*. Sharon Lynn Mercer and Andrew Grachuk. CreateSpace Independent Publishing Platform, 2015.
- *Gourmet Puree Recipes: The Ultimate Collection*. Daniel Tyler. Encore Publishing, 2013
- *Down Easy: A Cookbook for Those with Swallowing Difficulties*. Judith M. Best. Judy Best Cookx. 2012.
- *Soft Foods for Easier Eating*. Sandra Woodruff, MS, RD, LDN and Leah Gilbert-Henderson, PhD, LDN. Square One Publishers, 2010.
- *Eat Well-Stay Nourished: A Recipe and Resources Guide for Coping with Eating Challenges. Vol 2*. SPOHNC: Support for People with Oral and Head and Neck Cancer, 2013.
- *Easy-to-Swallow, Easy-to-Chew Cookbook: Over 150 Tasty and Nutritious Recipes for People Who Have Difficulty Swallowing*. Donna Weihoffen, JoAnne Robbins, Paula Sullivan. John Wiley & Sons, Inc., 2002.
- *The Dysphagia Cookbook*. Elayne Achilles. Cumberland House Publishing, 2004
- *The I-Can't-Chew Cookbook*. J. Randy Wilson and Mark A. Piper. Hunter House, Inc. Publishers, 2003.

recommended to improve oxygenation and cough function, mobilize secretions in order to combat pulmonary infection, improve swallowing, and strengthen airway clearance. These techniques have been found to reduce length of time on a ventilator, reduce intensive care unit (ICU) stays, resolve atelectasis/consolidation, and/or improve respiratory mechanics.[82] These supportive treatments can be beneficial as part of the armamentarium of dysphagia management in patients with aspiration risk and/or poor secretion management.

A mechanical insufflator-exsufflator (MIE), or cough assist machine, provides positive pressure to maximally inflate the lungs, followed by an abrupt switch to negative pressure. The rapid change from positive to negative pressure simulates a cough, thereby assisting sputum clearance, and this can prevent pneumonia and other complications associated with secretion retention.[82,83] The device can be used with an oral mouthpiece as well as via tracheostomy tube.

Mucus clearance devices such as an Acapella or flutter valve are small handheld devices that are simple and inexpensive and that create the resistive features of positive expiratory pressure (PEP) and vibrations to help mobilize secretions. They allow more air to enter the airways, thus increasing the pressure behind secretions in order to move them toward the larger airways where they can be more easily expelled.[84] As the patient breathes out, mucus is loosened so that it is easier to cough up, promoting healthier lungs and airways. These devices may be an alternative to chest physiotherapy, suctioning alone, and manual cough assist. A therapist skilled in these techniques, typically a respiratory therapist or physical therapist, can assess the patient to determine the best technique. The American Association for Respiratory Care (AARC) offers a clinical guideline for the selection of an appropriate device.[82]

Medically Administered Hydration and Nutrition

For patients with a disease process that results in dysphagia and an inability to swallow, a decision often needs to be made regarding the best route to provide alimentation with consideration of medically administered hydration and nutrition. (See Chapter 15 for further discussion of medically administered hydration and nutrition.) While aspiration of food or liquid could realistically evolve into a life-threatening respiratory illness, paradoxically, committing a patient to non-oral feeding (also known as "non per os [NPO]")[7] is also fraught with complications and ethical dilemmas, especially in a patient with a life-limiting disease process. Real or perceived medical benefits, such as improved nutrition and hydration, easier administration of medications, and diminished pain and suffering are weighed against adverse side effects and impact on QOL. Irrespective of the scenario, the following should be considered:

1. Families and patients should be informed about the risks and consequences of developing aspiration pneumonia and malnutrition and the benefits and risks of non-oral and oral feeding options in order to make fully informed decisions and to guide decisions.[48,85]
2. A growing body of literature shows that, overall, there are limited medical benefits of medically administered hydration and nutrition in improving survival rates, reducing aspiration risk, and improving functional status and that the expected benefits may exceed actual outcomes.[86–88]
3. The presence of a feeding tube does not inherently imply NPO, or nothing by mouth. Some patients may continue to take food or liquid for their pleasure and comfort.

Medication Administration for Patients with Dysphagia

Oral medications can present enormous challenges to patients with swallowing difficulties. One study focusing on patients with chronic dysphagia found that more than 60% of subjects had difficulty swallowing tablets.[89] The physiologic difficulties they experienced included multiple swallows to clear the pill, residue in the pharynx after swallowing, increased time needed to swallow pills, use of liquid to assist in washing the pill down, and airway compromise.[89] Difficulty swallowing may impact adherence to medication regimens, result in missed medications or medication errors,[90] and alter the effectiveness of medical treatment, necessitating alternative modes of administration and modifications. A pharmacist's review of medications and formulations is essential[91] and suggestions may include:

1. Discontinue medications that are nonessential or no longer indicated.
2. Seek alternative routes of administration (transdermal, buccal, rectal, or intravenous).
3. Change to a liquid form when possible. Crush or cut pills, open capsules, or bury the tablets and pills whole in a semi-solid food such as applesauce, pudding, yogurt, or ice cream to create a uniform consistency. Crushing, opening, or chewing a medicine can alter pharmacologic properties, impact safety or efficacy (such as with opioid analgesics), and may result in a potentially toxic and lethal dose.[90,91]
4. Try compounding, performed by a pharmacist, to create an alternative form such as a powder, nebulized substances, liquid, lozenge, or suppository tailored to the specialized needs of an individual patient.[91]
5. Orally disintegrating medication (ODT) technology has been used to formulate medications that rapidly disintegrate in the oral cavity once placed on or under the tongue. Healthcare providers and patients should refer to the FDA for guidance found at their website.[92]

Hiccups

Case Study: A Woman with End-Stage Liver Disease and Hiccups

AL is a 55-year-old woman with cirrhotic liver failure, admitted to the hospital with worsening abdominal discomfort and ascites. The medical team informed her that, due to multiple comorbidities, transplant was not an option. The same day, AL developed hiccups that affected her ability to talk, eat, and sleep. A thorough examination was performed to determine the etiology. AL was prescribed metoclopramide to decrease abdominal distention and lactulose to relieve constipation. Paracentesis was performed to remove four liters of fluid from AL's abdomen, but the hiccups persisted. She was later prescribed baclofen 10 mg three times daily, which reduced the severity of the hiccups. However, as AL's ascites returned, the hiccups became more severe. The medical team recommended placement of a peritoneal drain to provide ongoing relief of ascites and better manage the distention causing AL's hiccups. Following drain placement, AL was discharged with home hospice services.

Definition and Impact

Hiccup, or singultus, is defined as sudden, involuntary contractions of the diaphragm and intercostal muscles, terminated by an abrupt closure of the glottis, producing a characteristic sound of "hic." Hiccup frequency is between 4 and 60 times per minute.[93] Although seemingly insignificant, hiccups can negatively impact QOL.[93,94] Prolonged hiccups may cause fatigue, insomnia, anxiety, depression, and weight loss.[93,95] While there are little data regarding the incidence of hiccups in the overall population, estimated prevalence in cancer patients is 3.9–4.8%.[96]

Pathophysiology of Hiccups

Hiccups arise from a synchronous spasmodic contraction of the diaphragm and the intercostal muscles, which results in sudden inspiration and prompt closure of the glottis, causing the hiccup sound. Anatomically, hiccups are generated by a reflex arc, which is made up of an afferent limb, a reflex center, and an efferent limb that stimulates muscular contraction.[93,97] Afferent impulses travel to the reflex center via the vagal and phrenic nerves, as well as T6–T12 sympathetic fibers. The reflex center, although not fully identified, is believed to include parts of the hypothalamus, the brainstem, and the cervical spinal cord. Efferent impulses leaving the reflex center utilize the vagal and phrenic nerves to stimulate areas of the diaphragm, intercostal muscles, and glottis, thereby producing the contractions known as a hiccup.

The precise physiologic function of hiccups is not well understood. There are several proposed theories, including the possibility that hiccups are a primitive intrauterine reflex to prevent fetal aspiration of amniotic fluid, a remnant of gill ventilation from a prior phase of human evolution, or—because hiccups are frequent during fetal development—a mechanism to prepare for independent respiration outside the womb.[97] There appears to be an inverse relationship between partial pressure of carbon dioxide (pCO_2) and hiccups; that is, an increased pCO_2 decreases the frequency of hiccups and a decreased pCO_2 increases frequency of hiccups.[93,97] Hiccups have a minimal effect on ventilation and are likely not a respiratory reflex.[97] Still, frequent or intense hiccups may cause significant fatigue and the sensation of labored breathing.

Hiccups are divided into three categories: benign, persistent, and intractable. Benign, self-limiting hiccups occur frequently, with episodes lasting from several minutes to 2 days. Gastric distention is the primary etiology. Other causes include spicy foods, alcohol ingestion, excess smoking, and psychogenic factors, particularly if they cause excitement or hyperventilation.[98] Persistent, or chronic, hiccups continue for more than 48 hours but less than 1 month. Hiccups continuing for longer than a month are considered intractable.[93,95] In palliative care, the duration of hiccups may not be as important as their perceived impact on the particular patient population. For instance, an obtunded patient with advanced liver disease may not be bothered by hiccups, while a patient with chronic obstructive pulmonary disease (COPD) may experience greater distress due to overall weakness and breathing that is already impaired at baseline.

There are more than 100 documented potential causes of intractable hiccups, although many have little supporting evidence outside of individual case reports.[93,98] Etiologies may be structural, metabolic, inflammatory, or infectious disorders. Structural causes affect the peripheral branches of the phrenic and vagal nerves, as in abdominal or mediastinal tumor compression, as well as in CNS disorders such as stroke, brain tumors, and neurologic diseases.[97,98] Other common causes of hiccups in terminal illness include sepsis and metabolic imbalances; pericarditis, myocardial infarction, pneumonia, or pleuritis; and gastrointestinal conditions such as esophagitis, gastric distension, gastritis, pancreatitis, and hepatitis.[93]

Many medications may trigger hiccups, including steroids, chemotherapeutic agents, dopamine antagonists, megestrol, methyldopa, opioids, benzodiazepines, and muscle relaxants.[98] Dexamethasone, frequently used as a palliative medication for cancer patients, has been shown to cause hiccups.[95,99] Substances such as alcohol, nicotine, and recreational drugs are other common causes.

Assessment of Hiccups

In palliative care, extensive workup for hiccups is impractical, uncomfortable, and rarely useful in determining etiology or delineating treatment. There is little evidence that laboratory tests are helpful in determining optimal management.[99] Thus, assessment includes a subjective review of the distress induced by the hiccups. Patients may experience secondary symptoms such as anorexia due to impaired swallowing, shortness of breath from the inability to take deep breaths, fatigue as a result of excess energy use, insomnia from hiccuping all night, heartburn from acid reflux produced by hiccups, and depression as well as the worry that hiccups are untreatable.[93]

Objective assessment includes the history and duration of the hiccups, previous episodes, and interference with rest, eating, or daily routines. Inquiry into possible triggers may be helpful, including patterns during the day and activities preceding the hiccups such as eating, drinking, or positioning. A review of recent trauma, surgery, procedures, and acute illness may reveal underlying causes for the hiccups. Finally, a thorough medication history may be useful in identifying pharmacologic triggers.

The presence of hiccups themselves is quite apparent. Further physical exam may assist in ruling out other underlying health conditions or signs of a septic process. Oral inspection may reveal swelling or obstruction. Any wounds or infections should be examined, and a thorough respiratory assessment should be performed.[93] More specifically, evaluate for temporal artery tenderness, foreign bodies in the ear, throat infection, goiter, pneumonia or pericarditis, abdominal distention or ascites, and signs of stroke or delirium.[93,98,99]

When supported by a patient's goals of care, specific testing may be warranted to eliminate other causes of hiccups. Chest x-ray may rule out pulmonary or mediastinal processes as well as phrenic/vagal irritation from peri-tumor edema in the abdominal area.[93,97] Blood work, including a complete blood count and metabolic panel, may exclude infection, electrolyte imbalances, and renal failure.[93,97] A computerized tomography (CT) scan of the abdomen or head may be done to preclude abnormalities or hemorrhage.[93,97]

Management of Hiccups

The absence of larger randomized controlled trials has resulted in lack of consensus around treatment,[99] leading to specialty-specific treatment modalities that favor familiar medications. Consequently, management is based on previous individual successes rather than a systematic, evidence-based approach. Treatment for hiccups should focus on the underlying disease. Both nonpharmacological and pharmacological interventions may be used. Therapies include physical maneuvers, medications, and other procedures that interfere with the hiccup arc.[99]

Nonpharmacological Interventions

Nonpharmacological treatments are divided into seven categories and include respiratory measures, nasal and pharyngeal stimulation, vagal stimulation, psychiatric treatments, gastric distention relief, phrenic nerve disruption, and other miscellaneous treatments. They are outlined in Box 13.4.

Box 13.4 Nonpharmacological Interventions for Hiccups

Respiratory measures

Breath holding
Rebreathing in a paper bag
Diaphragm compression
Ice application in mouth
Induction of sneeze or cough with spices or inhalants

Nasal and pharyngeal stimulation

Nose pressure
Stimulant inhalation
Tongue traction
Drinking from far side of glass
Swallowing sugar
Eating soft bread
Soft touch to palate with cotton-tipped applicator
Lemon wedge with bitters

Vagal stimulation

Ocular compression
Digital rectal massage
Carotid massage

Psychiatric treatments

Behavioral techniques
Distraction

Gastric distention relief

Fasting
Nasogastric tube to relieve abdominal distention
Lavage
Induction of vomiting

Phrenic nerve disruption

Anesthetic block
Phrenic block
Suboccipital release traction and posterior neck pressure

Miscellaneous treatments

Bilateral radial artery compression
Peppermint water to relax lower esophagus
Acupuncture

Source: References 93, 108.

Pharmacological Interventions

Initial pharmacologic therapy should attempt to decrease gastric distention, the common cause in 95% of cases. Additional measures include hastening gastric emptying and relaxing the diaphragm with simethicone and metoclopramide. If ineffective, second-line therapy should focus on suppression of the hiccup reflex.[93,97,98] Common pharmacological interventions are listed in Table 13.5. However, there is little evidence as to which interventions are most effective.

Table 13.5 Suggested pharmacological interventions for hiccups

Agent	Effect
Agents to decrease gastric distention	
Simethicone 4–125 mg PO q6h	Promotes gastric emptying
Metoclopramide 10–20 mg PO/IV q4–6h	Promotes gastric emptying
Muscle relaxants	
Baclofen 5–10 mg PO tid	Acts at synaptic level
Midazolam 5–10 mg liquid PO q4h	Reduces muscles spasm
Anticonvulsants	
Gabapentin 300–600 mg PO tid	Inhibits calcium channels that control neurotransmitter release in the brain and spinal cord
Pregabalin 25 mg bid	Same mechanism as above
Carbamazepine 600–1,200 mg PO bid-tid	Reduces muscle spasm
Valproic acid 15 mg/kg/day PO in one to three divided doses. May increase by 250 mg/wk until hiccups stop	Reduces muscle spasm
Phenytoin 200 mg IV × 1, then 100 mg PO qid	Reduces muscle spasm
Antidepressants	
Amitriptyline 10–50 mg/day PO	Acts at central nervous system
Sertraline 50–150 mg/day PO	Acts at central nervous system
Corticosteroids	
Dexamethasone 40 mg/day PO	Reduces inflammation
Dopamine agonists	
Haloperidol 2–10 mg PO/IV/SQ q4–12h	Reduces muscle spasm
Chlorpromazine 5–50 mg PO/IM/IV q4–8h or 25–50 mg IV in 1 L 0.9% normal saline	Blocks dopamine and alpha adrenergic receptors
Calcium channel blockers	
Lidocaine 1 mg/kg IV loading dose followed by infusion of 2 mg/min	Blocks sodium channels
Nifedipine 10–80 mg/day PO	Causes vasodilation to suppress spasm
Other medications	
Ketamine 0.4 mg/kg	Acts on cortex and limbic system
Amitriptyline 25–90 mg/day PO	Inhibits serotonin and norepinephrine uptake

Nursing Interventions for Hiccups

Although hiccups appear to be a simple reflex, their specific mechanism of action is often unclear. Many patients express frustration that the discomfort and disruption caused by hiccups is not taken seriously. Nursing interventions should focus on providing information about the broad range of strategies used to eliminate hiccups.

The extent of treatment for hiccups will depend on the degree of distress and the impact that hiccups have on the patient's daily routine, sleep, and nutrition. Nonpharmacological interventions should be considered first, including respiratory maneuvers, nasal and pharyngeal stimulation, distraction, and peppermint water. If these measures fail to eradicate the hiccups, pharmacologic interventions should be suggested. While any single agent may be ineffective, combined therapies target several regions that trigger hiccups and are more likely to produce relief.

If medications fail to relieve hiccups, the nurse should suggest a referral to a pain management specialist in order to explore interventional treatment options. These may include phrenic or cervical nerve blocks[93,97] or radiofrequency ablation.[97]As always, discussion with the patient should include prognosis and the benefits and burdens of any procedure. If hiccups become extremely burdensome and other therapies have failed, sedation may be considered. For further discussion of palliative sedation, the reader is referred to Chapter 27.

Other Oral Symptoms

Case Study: A Patient with Oral Symptoms

Mr. T is a 50-year-old man with newly diagnosed oropharyngeal cancer. He was treated with a 6-week course of concurrent chemoradiation. Prior to his treatment, he underwent a videofluoroscopic study to assess swallowing function and was provided with prophylactic exercises to maintain his baseline swallowing ability. Following treatment week 2, Mr. T began to experience mucositis/oral inflammation, resulting in thick mucus that was difficult to clear because of worsening dysphagia. A strategy of expectorating secretions and using a portable suction device was implemented. Further oral symptoms included odynophagia (oral pain), xerostomia (dry mouth), and dysgeusia (altered taste). Pain management consisted of opioids, topical lidocaine, and soothing mouthwash. In an effort to combat dry mouth and taste alterations, Mr. T used sugar-free hard candies, artificial saliva spray, and regular tooth brushing prior to meals. Despite these interventions, Mr. T's appetite was very poor, and he began to lose weight, so a feeding tube was placed. He continued to swallow small amounts of liquids as able. Although chemoradiation therapy ended at 6 weeks, the treatment-related toxicities continued to escalate for several more weeks before slowly subsiding.

Oral Symptoms in Serious Illness

Oral symptoms are common in palliative care patients. The overall condition of teeth, lips, gums, and oral mucosa directly affects a patient's ability to swallow, manage secretions, eat, drink, and communicate. Oral symptoms may restrict or inhibit these functional abilities, thereby negatively impacting QOL.[100] Symptoms such as sialorrhea (excess saliva production), xerostomia (dry mouth), and dysgeusia (altered sense of taste) are common oral symptoms and often occur together as part of a symptom cluster.[101]

Oral symptoms may be a direct result of physiologic changes to the oral mucosa known as *oral mucositis*. These changes are strongly associated with chemotherapy and radiation treatments and may include erythema, ulcerations, and soft tissue damage, as well as sensory disturbances in the mouth.[102] Long-term sequelae of mucositis include tissue fibrosis, salivary gland dysfunction, and increased susceptibility to mucosal infections, dental caries, and periodontal disease—all of which are risk factors for oral symptoms.[100,102] Beyond the oncology population, oral symptoms are common in end-stage cardiac, renal, and pulmonary disease, HIV/AIDS, and any other process affecting the salivary glands or saliva production.[100]

Pathophysiology of Saliva Production

The average amount of saliva generated by a healthy adult is between 800 and 1,500 milliliters daily,[103] which is produced primarily by three pairs of salivary glands in the oropharynx. The parotid, submandibular, and sublingual glands manufacture the majority of saliva; the remainder is released by thousands of minor glands in the epithelial lining of the mouth and the tongue. Parotid glands, located below and in front of each ear, produce watery, serous saliva.[103,104] Submandibular glands, located in the lower jaw, secrete mostly serous saliva with some mucinous elements.[103,104] Sublingual glands manufacture purely mucinous saliva.[103,104]

The salivary glands are activated by the parasympathetic nervous system. When gustatory nerves are stimulated, they release acetylcholine, which binds to muscarinic receptors on the salivary glands.[103] This facilitates an exchange of calcium, sodium, and chloride ions that pulls fluid from the cells and releases it through the salivary ducts via an osmotic gradient.[103] Within only a few seconds, the smell, sight, or taste of food triggers salivary production.

Saliva is 99% water. It also contains substances called mucins, which provide lubrication and protect the teeth and oral mucosa.[103,105] Mucins also aid in gustation and provide moisture for food-bolus formation. Saliva contains hundreds of solutes such as salts, proteins, minerals, enzymes such as ptyalin, antibodies, and other antimicrobial agents.[103] Solutes maintain a stable pH in the mouth, thus optimizing the sense of taste and inhibiting dental caries.[100] Antibodies and antimicrobial agents in saliva break down bacteria, viruses, and fungi, offering immunoprotection for the oral mucosa and dental structures.[103–105]

Oral Assessment and Examination

Any alterations in the normal process of saliva production may lead to oral symptoms. Thus, a complete oral assessment is fundamental to identification of oral symptoms. Thoroughly inspect the mouth and oral mucosa for signs of infection, gum disease, or dental caries. In particular, assess for ulcers or mucositis, as well as candidiasis. Examine the tongue for erythema or the presence of fissures, which may indicate a dry mouth. Salivary glands should be checked for swelling, a sign of obstruction. Oral appliances and dentures should be noted and their fit and condition assessed. Extraoral examination should observe for cracked lips, angular cheilitis (lip inflammation), or candida at the corners of the mouth. Note the presence of any oral symptoms such as dry mouth, altered taste sensations, or excess secretions.

If patients endorse the presence of oral symptoms, they may also report functional impairments with mastication, swallowing, and speech, as well as difficulties with dentures. Since oral complications frequently occur as part of a symptom cluster, assessment should include screening for related symptoms such as nausea, vomiting, oral pain, dysphagia, anorexia, weight loss, insomnia, and depression.[106,107] A thorough history should explore these problem areas, as well as evaluating subjective distress and reviewing current medications.[106,108] Finally, any recent sinus or upper respiratory infections, dental procedures, or ear, nose, and throat surgeries should be noted.

Nursing Interventions for Oral Symptoms

Oral health is often compromised in those who are seriously ill, and oral hygiene may be neglected. Illness-related changes in oral flora increase the risk of bacterial pneumonia as a result of aspiration of contaminated secretions.[109] Thus, a clean and moist oral cavity is not only important for patient comfort, but also may reduce infections and other complications. Mouth care, ideally with a toothbrush twice daily, is important for reducing oral debris.[110]

Other nursing interventions should include frequent oral assessments, suctioning of secretions as indicated, and providing moisture to the lips and oral mucosa.[111] It is important to carefully inspect and assess the condition of the entire oral cavity, using a flashlight if necessary. Extraneous secretions should be cleared regularly using mouth swabs, tongue scrapers, toothbrushes, and oral suction.

In hospitalized patients, humidification via a shovel mask or face tent may help to loosen secretions, moisten the oropharyngeal mucosa, and maximize comfort. Chlorhexidine, a broad-spectrum antibacterial agent, can be highly effective in reducing the risk of nosocomial respiratory infections and ventilator-associated pneumonia in critically ill patients[109,110] Oral care is particularly challenging to perform in patients with impaired cognition. Special considerations for the cognitively impaired patient include regular reminders and enlistment of family or care providers.[112]

Sialorrhea (Excess Oral Secretions) and Secretion Management

Definition

Sialorrhea, or excessive salivation and drooling, is typically due to the inability to control oral secretions and reduced swallowing function rather than a true salivary gland hyperfunction or hypersalivation.[113]

Impact

Sialorrhea can contribute to skin irritation, poor oral health, and dehydration and can increase the risk of aspiration pneumonia.[114] Furthermore, excessive drooling is embarrassing, isolating, and socially disabling.[114] Its presence can also impact mastication and speech intelligibility. In patients with impaired breathing and swallowing, the sense of choking and inability to clear saliva can be frightening and anxiety provoking.[114] Successful management of sialorrhea improves tolerance to noninvasive ventilation, a supportive treatment shown to increase life expectancy for patients with motor neuron disease.[113,114]

Incidence

Sialorrhea is common in patients with neurological conditions such as motor neuron disease/ALS, Parkinson's disease, and Alzheimer's dementia. It is estimated that up to 80% of patients with Parkinson's disease and 50% of patients with motor neuron disease experience sialorrhea, of which approximately 20% have moderate to severe symptoms.[113,115]

Etiology

Reduced frequency of swallowing, reduced oropharyngeal or laryngeal strength and/or sensation, inability to close the oral cavity, a weak cough with poor clearance of secretions,[114,115] and poor head posture are common causes of sialorrhea. Sensory dysfunction and/or lack of awareness of saliva build-up is also seen in some patients with neurologic disease, resulting in poor ability to recognize drooling.[116] Hypersecretion of saliva may also occur in the setting of oral or dental infection, as a side effect of medication (e.g., anticonvulsants, anticholinesterase, or lithium), or as a complication of gastroesophageal reflux.[116] Typically, when there is hypersalivation, the person is able to compensate by increased swallowing unless a concomitant dysphagia exists. Regardless of etiology, saliva pools in the mouth. In a patient with delayed or weak swallowing function or reduced oromotor strength, the pooled saliva either spills out anteriorly (e.g., drooling) and/or falls posteriorly into the pharynx and open airway, causing risk of choking and aspiration.

Assessment

Accurate assessment of the etiology, severity, and chronicity of sialorrhea is imperative to guide intervention decisions. Assessment should include gathering the history and timing of the secretions, understanding the burden of the secretion problem, reviewing other possible causes, and evaluating the type and frequency of secretions[115,116] (see Box 13.5). There are several objective rating scales in the literature that can be used to document the extent of sialorrhea, guide clinical decisions, and measure treatment effects (see Box 13.6).

Management

If evaluation reveals any reversible causes, these should be immediately addressed (e.g., treatment of oral infection, elimination of precipitating medications if possible, improved hydration, etc.). In the early stages, first-line management includes less invasive, nonpharmacological, behavioral, compensatory, and/or strengthening exercises via speech-language therapy, which may be helpful to improve oromotor function, sensation, and tongue control; self-management of saliva; triggers/reminders to swallow; and physical therapy and/or supportive neck collars for correction of body and head posture.[116,119]

Pharmacologic therapy is second-line therapy and aimed at saliva flow reduction. Anticholinergic medications block the parasympathetic stimulation to the salivary glands and thus reduce saliva production.[114,116,119] These medications include amitriptyline, benztropine, scopolamine patch, butylscopolamine, and sublingual atropine drops. Short-term use of glycopyrrolate bromide may be effective due to fewer anticholinergic side effects.

Anticholinergic side effects should be closely watched and monitored, including thickened/dried secretions which can be more difficult to expectorate, excessive dry mouth, urinary retention, drowsiness, confusion, and blurred vision, among others.[114,116,119] These side effects may be intolerable to the patient, leading to thickened secretions that are more likely to induce mucus plugging and resulting in poor oral hygiene.[119] Patients with sialorrhea who experience difficulty expectorating secretions may also find relief from a home/portable suction device and cough assist device.[116]

Botulinum toxin type A (BTx-A) and type B (BTx-B) are alternative options to treat sialorrhea in motor neuron disease and Parkinson's disease due to their reduced side-effect profiles. Botulinum toxin is injected subcutaneously under ultrasound guidance into the submandibular and parotid glands. Benefits are demonstrated at the first week after injection and last up to 3 months. The dosing should be controlled so that it does not induce excessive dry mouth and worsen dysphagia and difficulty chewing from diffusion of the toxin into nearby bulbar muscles.[113,114,116,119]

Radiation therapy to the parotid glands and submandibular glands is another alternative treatment for refractory sialorrhea or for those patients who cannot tolerate Botox injection or who still

Box 13.5 Guided Assessment of Sialorrhea

History: Timing during the day, chronicity, provocations

Medication review: Assess drug therapy for medications known to cause hypersalivation (neostigmine, clozapine, lithium, etc.)

Physical and oromotor exam: Sores on lips/chin, dental problems, health status of teeth, gums, oral mucosa, head posture, lip/tongue strength and sensation

Swallowing assessment

Imaging to rule out local abscess

Objective assessment of severity

Evaluation of type of secretions: Consistency, tenacious vs thin; frequency and quantification

Source: Adapted from References 113, 115.

Box 13.6 Sialorrhea (Secretion) Rating Scales

Oral Secretion Scale (OSS)

Targeted Population: Patients with amyotrophic lateral sclerosis (ALS) and Parkinson's disease (PD)

Measures: Saliva retention and swallowing

Scale design: Five grades of severity from very severe (0) to normal (4)

Sialorrhea Scoring Scale (SSS)

Targeted population: Patients with PD and children with developmental disabilities

Measures: Extent of drooling and location of wetness

Scale design: Nine grades of severity from least severe (1) to most severe (9)

Clinical Saliva Scale for Motor Neuron Disease (CSS-MND)

Targeted population: Patients with MND

Measures: Saliva burden and severity, effect of saliva on speech, use of NIV, social interactions

Scale design: Eight-item questionnaire, each rated from no problem (0) to severe problems (3)

Source: References 117, 118.

have not achieved adequate reduction.[113,114,116] Treatment duration is up to 9 months, often necessitating repeat therapy. Access to radiation treatment is limited by location, procedure, and cost.[114] Radiotoxicity can occur resulting in excessive dry mouth, facial pain and erythema, dental caries, and nausea.[119]

Last, surgical resection of either the parasympathetic neural pathway or of the submandibular and salivary glands or submandibular duct rerouting for severe cases can be performed.[114,116,119] Although effective, surgical intervention is invasive and the benefits and burdens of treatment must be considered.

Xerostomia (Dry Mouth)

Definition

Xerostomia is the sensation of oral dryness, which may or may not be accompanied by a decrease in salivary secretions (hyposalivation). True xerostomia results from dysfunction of the salivary glands themselves.[120] However, even with normal salivary gland function and saliva production, many patients report oral dryness, known as "symptomatic" or "pseudo" xerostomia.[120] It is often difficult to identify the exact underlying cause and/or contributing factors for this bothersome symptom.[103,120]

Impact

Decreased saliva and prolonged xerostomia cause significant symptoms in the oral cavity, including dental caries; oral pain and burning; lesions of the tongue, lips, gums, and oral mucosa; mouth infections such as candidiasis; taste changes; and bad breath.[103,112,120,121] In the esophageal region, problems include swallowing difficulties, along with alterations in speech formation and voice function.[103,112,121] Eating may be impaired due to chapped lips, difficulty chewing, and the need for frequent sips of liquid to mobilize food.[112,120,121]

Xerostomia negatively impacts QOL and may cause physical discomfort as well as emotional suffering and a retreat from socializing.[122] Social rituals, particularly meals, are a time to communicate, laugh, smile, and eat. Unfortunately, poorly controlled xerostomia may prevent patients from performing these functional activities. Adequate treatment offers not only increased comfort, improved nutrition, and better dental health, but also the benefit of a social structure that promotes effective coping.[122]

Incidence

Studies suggest that between 5.5% and 46% of patients experience xerostomia.[123] In palliative care, dry mouth may affect as many as 30% of patients.[124] Although well-described in the literature as a cancer-related symptom, xerostomia is also common in the later stages of diabetes, renal failure, cardiac disease, and liver disease, as well as in autoimmune diseases such as AIDS and Sjögren's syndrome.[120,121] The risk of xerostomia escalates with age and number of medical problems, in part because the symptom can be triggered by a wide array of medications.[123]

Etiology

The cause of xerostomia is reduced salivary secretions, which may result from infection, dehydration, endocrine and autoimmune processes, or age-related changes.[120,121] Medications are also notorious culprits of dry mouth, particularly those routinely used in palliative care, including sedatives, tranquilizers, antihistamines, antiparkinsonian medications, antiseizure medications, skeletal muscle relaxants, tricyclic antidepressants, and anticholinergics.[103,120,121,123] In general, the number of comorbidities with resultant complex pharmacotherapy increases the risk of xerostomia.[103,120]

Buccal erosion is another common cause of xerostomia. It frequently occurs as a result of cancer-directed therapies, particularly radiation treatment for head and neck cancers.[103,120,125] Although dose and duration of radiation exposure affect the degree of xerostomia,[126] reversible dysfunction of salivary glands may begin with doses as low as 10 Gy.[120] Irreversible gland degeneration and resulting decrease in saliva production typically occur at doses of 60 Gy or greater.[103] In up to 60% of patients, xerostomia develops within the first few days of irradiation.[127] In addition, many chemotherapeutic and cytotoxic agents used to treat malignancies produce mucosal alterations that may result in a dry mouth.[125]

Xerostomia may contribute to or exacerbate existing mental health issues such as depression and anxiety, thus leading to greater symptom burden and impaired coping.[120,122] Due to diurnal saliva production, xerostomia may worsen at night, resulting in sleep interruptions or insomnia. Finally, dry mouth may render the management of plaque and gums difficult, particularly in older adults or those with significant fatigue.[125,128] Patients undergoing cancer treatment or other immunosuppressive therapies may be unable to tolerate dental procedures.[125] Thus, patients may experience discomfort not only from their underlying illness but also from subsequent oral complications.

Assessment

Assessment should include patient rating in eight aspects of xerostomia, including overall mouth and lip dryness, speech, chewing, sleeping, dry mouth with eating and swallowing, resting, and the frequency of sipping liquids for eating and during the rest of the day.[106,107] Sample questions appear in Box 13.7.

Box 13.7 Xerostomia Assessment Questions

Do you experience dry mouth? How frequently?
Does dry mouth bother you?
Do you have dry lips?
Do you have dry nasal passages?
Do your gums bleed when you brush your teeth?
Is your tongue red and raw?

Do you find there are times you need to drink more fluids? When?
Do you experience difficulty speaking due to a dry or sticky mouth?
Do you have difficulty chewing? What types of foods?
Do you have difficulty swallowing? Solids or liquids?

Do you need extra fluid to help you swallow food? All foods or solids or semi-solids?
Do you use hard candies or gum for your dry mouth?
Do you find your sleep is disrupted by a dry mouth? How often do you wake up at night because of a dry mouth?
Have you experienced altered taste sensations? What types of tastes? Any types of foods?

Do you use tobacco? How often?
Do you drink alcohol? How often?
Do you drink caffeine? In what drinks? In what foods?
Are you taking any prescription medications, over the counter medications or preparations?

Source: References 106–108.

Diagnostic tests for xerostomia incorporate dry mouth evaluation and saliva measurement. One standard bedside evaluation is conducted by giving the patient a dry cracker or biscuit. Xerostomia is present if the patient cannot eat the cracker without taking extra fluids.[129] An alternate test is performed at the conclusion of mouth inspection by placing a tongue blade or dental mouth mirror directly on the tongue. Since dry mouth creates a ropey, pasty saliva, the object will stick to the tongue of a patient with xerostomia.[120,121] Another more precise option is sialometry, or the actual measurement of saliva flow through collection in a container or on a cotton swab.[120,121] However, for most palliative care patients, this is burdensome and unnecessary.

Documentation of the extent of xerostomia is essential. There are many rating scales specifically designed for this purpose. Several rating scales described in Box 13.8 are based on the appearance of oral mucosa.

Management

Much of xerostomia management focuses on interventions to alleviate rather than to eradicate or to prevent the symptom. A stepwise approach should guide management and treatment, as described in Box 13.9. Pharmacological interventions are outlined in Table 13.6.

Nonpharmacological interventions (see Table 13.7) should be tried first, as they may be less expensive and pose a lower side effect profile. Acupuncture is one promising nonpharmacologic approach for the prevention and relief of dry mouth, particularly among patients receiving radiation therapy. A recent randomized controlled trial for patients with radiation-induced xerostomia revealed fewer reports of dry mouth after 8 weeks of acupuncture treatments when compared to standard oral therapies.[133] In an earlier study utilizing acupuncture concurrently with radiation, patients with nasopharyngeal cancer reported decreased incidence and severity of xerostomia and improved QOL.[134]

Box 13.8 Dry Mouth Rating Scales

American Dental Hygienists Association

Tissue changes (tongue and mucosal color)
Oral disease (bad breath, cavities, infection)
Saliva, glands and function

American Cancer Society Radiation Side Effects-Dry Mouth

Decreased saliva
Thick saliva
No saliva

Oncology Nursing Society Xerostomia

0 No dry mouth
1 Mild dryness, slightly thickened saliva; little change in taste
2 Moderate dryness, thick and sticky saliva, markedly altered taste
3 Complete dryness of mouth
4 Salivary necrosis

Box 13.9 Stepwise Process for Managing Xerostomia

1. Treat underlying oral infections.
2. Review current medications, eliminating any that promote dry mouth. If elimination is not possible, consider decreasing the dose or modifying the schedule so that the peak effect does not coincide with diurnal decrease in salivary production.[123]
3. Stimulate salivary flow using either nonpharmacological or pharmacological interventions.
4. Replace lost secretions with spray saliva substitutes.
5. Protect teeth. Continue meticulous mouth care. Promote use of fluoride rinses.
6. Rehydrate. Encourage plenty of liquids.
7. Modify diet to avoid mouth pain from acids or hard foods.

Dysgeusia

Definition and Impact

Dysgeusia is an alteration or distortion in the perception of taste, usually described as being unpleasant. Patients with dysgeusia may report taste sensations that are abnormally bitter, salty, or metallic.[136] Dysgeusia may be experienced along with decreased sensitivity to taste (known as hypogeusia) or even absence of the sense of taste (known as ageusia).[137] Taste alterations may result in poor appetite, food aversions, decreased oral intake, and subsequent weight loss and malnutrition.[136–139] Furthermore, the associated inability to enjoy food and the social aspect of mealtimes may negatively impact overall QOL for patients with dysgeusia.[135,137,138]

Incidence

Dysgeusia occurs frequently among cancer patients who are undergoing chemotherapy and/or radiation treatments; as a result, much of the literature focuses on these populations. In one systematic review, dysgeusia was endorsed by 56.3% of cancer patients receiving chemotherapy only, 66.5% of patients receiving radiation therapy only, and 76% of patients treated with both chemotherapy and radiation.[139] Patients with head and neck cancer are among those most at risk for dysgeusia.[137]

Etiology

Among cancer patients, taste alterations may be the result of specific treatment modalities. While the precise mechanism of dysgeusia is not fully understood, it is generally accepted that damage to sensory receptor cells is the underlying cause of the symptom. The turnover rate of taste bud receptor cells is only about 10 days, rendering them particularly susceptible to chemotherapeutic agents and radiation, both of which destroy large numbers of cells with high turnover rates.[136,139] In addition, radiation may alter the anatomical structure of taste buds, thus reducing the ability of receptor cells to interact with the flavor molecules in food.[139] Finally, exposure to chemotherapy may cause alterations in neuronal cells as well, thus producing specific taste sensations even without the presence of receptor cell stimulation by flavor molecules.[139]

Table 13.6 Pharmacological interventions

Medication	Description	Dose	Drug Information
Pilocarpine	Nonselective muscarinic agonist and parasympathetic agent. Increases exocrine gland secretion and stimulates tissue in damaged salivary glands. Increases saliva production. Recent studies have shown that pilocarpine given before and during radiotherapy can reduce xerostomia.	5 mg tid	Response varies and depends on presence of functional salivary gland tissue. Optimal effect may require 2–3 months of use. Use cautiously in patients on beta-blockers, with cardiovascular or pulmonary disease, gastric ulcers, or glaucoma. Side effects include vision changes, sweating, nausea, diarrhea, urinary frequency, rhinitis, bradycardia, and bronchoconstriction.
Bethanechol	M3 muscarinic agonist. Resistant to cholinesterase. Also used to relieve anticholinergic side effects of tricyclic antidepressants.	25 mg tid	Side effects include nausea and diarrhea.
Yohimbine	Blocks alpha-2 adrenoreceptors.	14 mg/day	Side effects include drowsiness and confusion.
Cevimeline	Muscarinic agonist. Stimulates M1 and M3 receptors in lacrimal and salivary glands. Acts to increase saliva by inhibiting acetylcholinesterase.	30 mg tid	Less effective than pilocarpine. Use cautiously in patients on beta-blockers, with cardiovascular or pulmonary disease, or gastric ulcers. May cause dyspepsia. Overall fewer side effects compared to pilocarpine as it does not act on M_2 receptors. Less risk of bradycardia.
Antifungals	Used to treat xerostomia resulting from oral candidal infections.		First-line treatment is nystatin (suspension or troches, depending on swallowing ability), which may be expensive. Second-line treatment includes fluconazole, first dose 200 mg PO/IV. Fungal infections of the lips may require miconazole, clotrimazole, or ketoconazole.

Source: References 108, 120–124.

Table 13.7 Nonpharmacological interventions for xerostomia management

Intervention	Role/Effect	Comment
Preventative Measures		
Oral care	Reduces xerostomia severity. Promotes well-being.	Frequent soft brushing, water jet, denture cleaning, fluoride rinses, mouthwash, and flossing can stimulate salivation. Can help prevent candidiasis, since dentures can harbor infections.
Lip protectants	Prevents cracked lips and moistens skin. Includes use of lip barriers such as balms or ointments.	Avoid products containing alcohol, since these can be irritating. For angular cheilitis at the corners of the mouth, protect with lanolin and KY Jelly.
Dentifrices	Uses a paste or powder to clean teeth.	Several products contain antimicrobial enzymes to reduce oral infections and enhance mouth wetting. Examples are Biotene, Oral Balance, and Oasis.
Mouthwashes (non–alcohol containing)	Helps rinse debris from mouth.	Includes homemade mouthwashes made from saline, sodium bicarbonate, glycerin.
Diet modifications		
	Allows patient to eat.	Suggest soft-textured foods, as they are better tolerated (soup, pudding, mashed potatoes, and shakes). Instruct patient to take fluids with all meals. Add gravies and juices to food to aid swallowing. Apply olive oil to the gums and mucosa to act as a lubricant while eating. Educate patient regarding the avoidance of sugars and spicy foods. Carbonated drinks (ginger ale) or citrus juices (lemonade, pineapple, papaya) may be refreshing; however, citrus may be too irritating for patients with oral ulcerations.
Nonpharmacological		
Peppermint water	For mucous saliva.	Inexpensive.
Vitamin C	Disrupts salivary mucin and reduces viscosity of saliva.	Use in lozenges or other forms as preferred. May be irritating to the mouth, particularly if the patient has mouth sores. Can erode dental enamel.

(*continued*)

Table 13.7 Continued

Intervention	Role/Effect	Comment
Citric acid/sweets	For mucous saliva.	May cause burning sensation in mouth In sweets, can cause dental caries.
Chewing gum, mints	For watery saliva. Acts on chemoreceptors and mechanical receptors to stimulate saliva. May create a buffer system to compensate for dietary acids.	Chewing gum is more effective than mints. Recommend sugar-free gum/mints to prevent dental caries. Consider the social acceptance of gum chewing, particularly in older populations. Side effect of diarrhea from sorbitol if too much gum or mints ingested.
Rehydration	Replenishes lost moisture.	Encourage oral hydration by sipping water and other fluids. Includes adding humidity to oxygen systems or using vaporizers to combat the drying effects of indoor heating and air conditioning. Instituting these measures at night may promote sleep.
Saliva Replacement		
Water sprays or sip	Reduces oral pain and increases saliva.	Short-acting. Accessible. Use warm versus cold water based on patient preference.
Artificial saliva	Provides saliva substitute to lubricate oral mucosa.	Comes in gel or spray formula. Dose 2 mL every 3–4 hours. Contains carboxy-methylcellulose or mucin, which are animal products. Consider patient's religious beliefs and dietary preferences when recommending. Products with a mucin base may be better tolerated than those derived from carboxy-methylcellulose.
Procedures		
Laser treatment	Stimulates saliva production.	Longer lasting, expensive. Administered to salivary glands in an office setting.
Electrostimulation	Stimulates saliva production.	Longer lasting, less expensive than laser treatment. Delivered to the glands and tongue via a battery-operated process.
Acupuncture	Increases saliva production.	Weekly or regular intervals. Variable cost, can be expensive.

Source: References 105, 108, 112, 128, 135 (http://www.nidcr.nih.gov).

Taste disturbances are a common side effect in neurologic diseases such as Parkinson's disease, ALS, multiple sclerosis, and Alzheimer's dementia.[136] Other serious illnesses associated with dysgeusia include diabetes, hypothyroidism, and liver disease. More benign factors such as poor dental hygiene, periodontal disease, mucosal infection, tobacco use, and diet are also frequent contributors and should be considered in patients with serious illness.[136,139] Upper respiratory disease and sinus infections may interfere with olfaction and produce foul-tasting mucous that alters taste sensations.[136]

Medications also cause dysgeusia. Chemotherapeutic agents may produce a bitter or metallic taste in the mouth, which occurs when compounds in the drugs enter the oral mucosa.[136] Certain chemotherapy-containing antimetabolites combined with platinum derivatives (used for colon cancer) or with cytotoxic antibiotics, anthracyclines, or vinca alkaloids (used for lymphomas) are more likely to induce dysgeusia.[138] Taxane-based chemotherapy used in the treatment of breast cancer is also associated with increased risk of dysgeusia.[138,140] Other medications associated with dysgeusia are outlined in Table 13.8.

Table 13.8 Medications associated with dysgeusia

Category	Medications
Antibiotics	Ampicillin, macrolides, quinolones, sulfamethoxazole, trimethoprim, tetracycline, metronidazole
Neurologic medications	Migraine medications, anti-parkinsonian medications, muscle relaxants
Cardiac medications	Antihypertensives, antiarrhythmics, statins, diuretics
Psychotropics	Tricyclic antidepressants (TCAs), antipsychotics, anxiolytics, mood stabilizers
Other	Antihistamines, bronchodilators

Source: References 141, 142.

Assessment

Patient self-report is considered the gold standard in assessing taste disturbances. Clinical tests to evaluate taste function do exist and utilize various techniques to apply concentrated flavor solutions to the mouth and tongue in order to test thresholds for taste identification.[136,137,143] However, these tests are complex, costly, and not generally useful in the palliative care population.

Management

Pharmacological Interventions

Research exploring pharmacologic interventions for dysgeusia is limited. Zinc supplementation as a potential treatment for taste disturbances has been studied. Among patients with head and neck cancer, the value of zinc supplementation was inconclusive, with two studies supporting its role and two demonstrating no benefit.[143] In noncancer patients, a recent meta-analysis evaluating zinc supplementation found only low- to moderate-quality evidence to improve taste perception or health-related QOL, with the best results occurring among patients who had known zinc deficiencies.[144]

A variety of other medications for managing dysgeusia appear in the literature, yet they also lack the support of robust research. In a small trial for patients with idiopathic dysgeusia, alpha lipoic acid produced complete resolution of the symptom in 46% of patients and mild to moderate improvement in up to 91% of patients as compared to a control group.[140] In another isolated study of low-dose dronabinol administration, 55% of participants reported that the drug "made food taste better" compared to 10% of the placebo group.[145] Finally, a trial of the fruit *Synsepalum dulcificum* (miracle fruit) tested the food's ability to mask unpleasant flavors in patients with dysgeusia. Participants who consumed the fruit prior to meals reported positive taste changes and increased food intake.[143] Additional pharmacologic interventions for dysgeusia with little or no supporting evidence include amifostine, glutamine, and gingko biloba.[143,144]

Nonpharmacological Interventions

Little evidence supports nonpharmacological interventions for dysgeusia. One qualitative study of breast cancer patients who experienced dysgeusia while receiving taxane-based chemotherapy identified a range of strategies, including trying recipes that differed from their usual choices, eating strongly flavored foods, honoring specific food cravings, eating sugar-free candy before meals, cutting food with lemon, drinking sweetened beverages, using plastic cutlery, drinking from a straw, brushing one's teeth and tongue before meals, and using baking soda and salt wash or antibacterial mouthwash.[146] In another study of patients undergoing chemotherapy, an educational initiative provided a checklist of suggested dietary modifications. Among the most helpful interventions were avoidance of strong-smelling or strong-tasting foods, consumption of bland foods, drinking more water with foods, oral care prior to eating, and eating smaller, more frequent meals.[147] While dietary interventions may provide some benefit, more research is necessary to determine the most effective interventions.

Conclusion

Dysphagia, hiccups, and other oral symptoms commonly occur in advanced disease processes and can cause significant burden for both the patient and the caregiver. Swallowing difficulties may not only impede adequate nutrition and hydration but also impact QOL and social interactions. Symptoms such as hiccups, sialorrhea, xerostomia, and dysgeusia may seem inconsequential and are often overlooked by clinicians. However, these conditions are a visible aspect of a person's well-being. Whether experienced individually or as a symptom cluster, oral symptoms often considerably impact QOL for palliative care patients.

Management of dysphagia, hiccups, and oral symptoms in patients with serious illness focuses on preventing functional decline, maximizing comfort and QOL, and supporting the patient's wishes. Working with an interdisciplinary team to find solutions will offer optimal relief to patients and their families. Nurses may be the first to identify the presence of these symptoms and to understand their negative impact on QOL. Oral care is an essential intervention for dysphagia, sialorrhea, xerostomia, and dysgeusia. Nurses should address continued oral care as a vital aspect of promoting dignity, comfort, and QOL for patients with troublesome oral symptoms.

CHAPTER 14

Bowel Management

Constipation, Obstruction, Diarrhea, and Ascites

Stefanie N. Mooney, Purvi Patel,
and Sorin Buga

Key Points

- Constipation and diarrhea are common symptoms in the palliative care population and should be monitored closely with treatment based on cause.
- Malignant bowel obstruction and ascites can severely impact patient quality of life and require diligent assessment and active management.
- Palliative care involves providing patients with realistic expectations in addition to attentive management of symptoms affecting quality of life.

Constipation

Case Study 1: A Patient with Lung Cancer

Mr. B is a 78-year-old man with advanced non–small cell lung cancer, currently receiving paclitaxel and cisplatin therapy. Recently, his pain increased, and his opioid regimen was escalated accordingly. During his clinic visit, he mentions that he has not had a bowel movement in 5 days and feels uncomfortable. He has tried increasing fluids and taking over-the-counter stool softeners without relief.

Prevalence and Impact

Fourteen percent of the general population suffers from constipation, and 30–100% of patients with palliative needs are affected.[1,2] This broad range is primarily due to lack of consensus on the definition of constipation. In one study of a palliative population by Erichsen et al., 7% of patients had medical constipation (defined as fewer than three bowel movements per week), 19% had “perceived” constipation, and 15% had both medical and perceived constipation. Of those with constipation, 71% reported severe symptoms.[3]

Given the high prevalence, it is not surprising that constipation results in increased healthcare utilization. More importantly, constipation is associated with impairment of physical activity and decreased work productivity and may also contribute to symptoms of anxiety and depression, all of which lower health-related quality of life (QOL).[4–6] Up to a third of patients taking opioids for pain will decrease or discontinue their opioids due to opioid-induced constipation, choosing inadequate pain relief over this common side effect.[5,7] Additionally, patients may develop “catastrophic” thinking, wherein they associate constipation with rapidly declining health.[5]

Definitions

There is no widely agreed upon definition for constipation, and it is often interpreted subjectively. Common descriptions include decreased frequency of bowel movements, hard and/or small stools, straining or difficulty with evacuation of stool, and a sensation of bloating or fullness. The Rome I criteria were established in 1994 to more objectively define clinical constipation, and in 2016, the revised Rome IV criteria were published (see Box 14.1).[8–11]

Clark et al. suggest that, in defining constipation, four domains are considered: (1) any long-standing history of bowel dysfunction as determined using the Rome criteria, (2) evaluation of physical dysfunction that may contribute to normal defecation, (3) the patient’s subjective report of constipation based on straining and feelings of bloating or incomplete evacuation, and (4) objective measures such as stool frequency and consistency.[12]

Pathophysiology and Risk Factors

The normal gastrointestinal (GI) physiology is complicated and involves a combination of fluid regulation and intrinsic and extrinsic neurologic factors. Transit time is between 2 and 5 hours in the small intestine,[13] and 10–59 hours in the large intestine,[14] but these times can be altered by anything that affects the fluid balance or motility of the gut.

The causes of constipation can be broken down into primary and secondary causes. Primary causes include reduced fluid and fiber intake,[15] as well as decreased activity and mobility. Additional risk factors for constipation are female sex, increased age, and a lack of privacy or routine, as occurs with a hospitalized patient.[1,16] Requiring a bedpan or commode can be physically uncomfortable, adding to the challenge of defecation.

Box 14.1 Rome IV Criteria for Diagnosis of Clinical Constipation

Two or more of the following are present over the past 3 months, with initial onset at least 6 months prior:

- Straining more than 25% of the time.
- Lumpy/hard stool more than 25% of the time.
- Sensation of incomplete evacuation more than 25% of the time.
- Sensation of anorectal obstruction/blockage more than 25% of the time.
- Manual maneuvers (e.g., digital disimpaction) needed to stimulate more than 25% of bowel movements.
- Fewer than three spontaneous bowel movements per week.

Additionally, loose stools rarely occur without use of laxatives, and the patient meets insufficient criteria for irritable bowel syndrome.

Secondary causes of constipation are numerous and include structural, metabolic, neurologic, psychologic, and iatrogenic factors.

Structural Factors

Structurally, anything that impedes passage within the gut can contribute to constipation. This includes primary tumors of the pelvis or abdomen (e.g., cancer of the colon, pancreas, uterus, ovaries, and cervix) or metastases, as well as partial bowel obstruction from malignant or other causes. Patients with prior abdominal or pelvic surgeries may have surgical interruption of the GI tract or postsurgical adhesions that slow gut motility.[16] Abdominal muscle weakness also contributes to constipation by making it difficult to develop the necessary intraabdominal pressure required to have a bowel movement. Similarly, pelvic floor dysfunction can cause difficulty coordinating the act of defecation. External hemorrhoids and anal fissures result in discomfort during defecation and may discourage the patient from having bowel movements in a timely manner, further leading to irregular stooling.[17]

Metabolic Factors

Electrolyte abnormalities affect gut motility, thus contributing to constipation. Hypercalcemia, which is common in patients with multiple myeloma, other malignancies, or hyperparathyroidism, is often associated with constipation, as are hyponatremia and hypokalemia. Prolonged hyperglycemia can result in diabetic autonomic neuropathy, which increases the transit time of the gut. Hypothyroidism and the uremia associated with renal failure are other metabolic risk factors for constipation.

Neurologic Factors

Any neurologic condition that affects the autonomic, somatic, or enteric nervous systems may lead to constipation. Injury or compression of the lumbosacral spinal cord, cauda equina syndrome, paraplegia, and stroke with resultant paresis all affect a patient's ability to coordinate bowel movements. Patients with Parkinson's disease have a high risk for constipation. Other neurologic conditions, such as cerebral tumors and paraneoplastic autonomic neuropathy, are also associated with constipation.[16]

Psychologic Factors

Psychologic and psychosomatic factors also play a role in constipation, including depression. Painful past experiences or cultural beliefs relating to privacy may affect someone's comfort level in successfully having a bowel movement.[5]

Iatrogenic Factors

Some of the most common causes of constipation are iatrogenic in nature, resulting from medications. Opioids in particular contribute significantly to constipation in the palliative population. Up to 47% of patients taking opioid medications in general and 72% of those specifically taking oral morphine suffer from opioid-induced constipation (OIC). Higher doses and longer duration of use further increase the risk.[5,18] The analgesic effect of opioids occurs through binding of mu receptors within the central nervous system. OIC, on the other hand, occurs when these agents bind to opioid receptors within the myenteric plexus of the GI tract, resulting in decreased bowel transit times, increased fluid reabsorption, decreased GI chloride secretion, and stimulation and decreased relaxation of the pyloric and internal anal sphincters.[18,19] Unfortunately, while most opioid side effects improve over time, tolerance does not occur with constipation.[20]

Other medications that commonly contribute to constipation are listed in Box 14.2.

Box 14.2 Medications Commonly Associated with Constipation

- *Chemotherapy*: Any agent that results in autonomic nervous system dysfunction[16,21]
  - Vinca alkaloids
  - Taxanes
  - Oxaliplatin
  - Temozolomide
  - Thalidomide
  - Bortezomib
- *Anticholinergic medications*: decrease GI motility and fluid secretion[16]
  - Antihistamines
  - Antidepressants (tricyclic antidepressants in particular)
  - Antispasmodics (e.g., dicyclomine)
  - Anti-parkinsonian medications
- Diuretics: May cause dehydration, leading to increased risk of constipation (e.g., furosemide)
- Anticonvulsants (e.g., gabapentin, pregabalin, phenytoin)
- Neuroleptics (e.g., haloperidol, chlorpromazine)
- Supplements (e.g., calcium, iron)
- 5-HT3 antagonist antiemetics (e.g., ondansetron)
- Muscle relaxants (e.g., cyclobenzaprine)
- Calcium channel blockers (e.g., amlodipine)

Assessment

History

A good evaluation always starts with review of past medical and surgical history, medication use, and an assessment for any of the risk factors discussed in the pathophysiology section. Because there is a range of normal bowel function, the patient's previous bowel habits should be ascertained and symptoms discussed in regards to deviation from baseline. Although noting a recent change in fluid and oral intake is helpful information, it is important to note that bowel movements are still expected even in the absence of good oral intake, since not only food, but also sloughed cells of the GI tract and bacteria contribute to stool content.

Patients with constipation may report bloating, early satiety, abdominal pain, nausea, vomiting, and malaise. However, some studies suggest a patient's self-report of "yes" or "no" when asked if they have constipation may not be useful for clinical practice given the low correlation of their response with clinical criteria. Rhondali et al. suggest that, in the advanced cancer population, a simple scale from 0 to 10 may be more helpful than an answer of "yes" or "no." A positive screen constitutes a score equal to or greater than 3 as this resulted in 84% sensitivity and 62% specificity.[22] It is additionally important to assess for "red flags" that could indicate a serious issue, such as bloody or melenic stools, severe and intractable nausea or abdominal pain, significant weight loss, concurrent anemia, or family history of GI malignancy.[20]

Many scales have been proposed to better understand a patient's symptoms. The Constipation Assessment Scale and the Bowel Function Index are two commonly used screens that are reliable and validated, and these are discussed further in Table 14.1.[21]

Physical Examination

A thorough abdominal exam is an important component of evaluating constipation and should include visual inspection for surgical scars, distension, or skin changes. Auscultation can provide information on whether the bowels are moving, and percussion may be dull over colon filled with stool versus tympanic over areas filled with gas. A clinician should palpate for masses or ascites to assess for risk factors for constipation and may at times actually be able to palpate a fecal mass in the descending colon, with an associated "crepitus" sensation due to entrapped gas.[17]

A rectal exam should be performed (except in cases of thrombocytopenia or neutropenia, which increase the risk of bleeding and infection, respectively). This can exclude fecal impaction or diagnose external hemorrhoids, fissures, or ulcerations, all of which can be associated with constipation. In some cases, evidence of rectal prolapse or masses may be evident and require further evaluation.[17] Presence of bloody stool may be suggestive of hemorrhoids, colitis, or tumor.

A neurologic examination may assist in ruling out central nervous system or spinal cord abnormalities that could predispose a patient to constipation.[1]

Diagnostic Studies

While imaging studies are not generally indicated in the evaluation of constipation,[23] a plain abdominal radiograph or computed tomography (CT) scan may be considered in high-risk patients to exclude bowel obstruction.

When clinically indicated, calcium, sodium, potassium, and glucose levels may assist in assessment of metabolic risk factors, and a complete blood count can be helpful in excluding associated anemia, thrombocytopenia, and neutropenia.[1] Thyroid-stimulating hormone may also be considered if there is suspicion for hypothyroidism contributing to constipation.

Management

Nursing Interventions and Supportive Care

Patient education is a key component of constipation management and includes an awareness of risk factors as well as advice on how oral intake and behavior affect symptoms. Patients should

Table 14.1 Scales to assess constipation

Constipation Assessment Scale [21]	Bowel Function Index[18]
Self-administered	Clinician-administered
Relates to last 7 days	Relates to last 7 days
Rate presence and severity of symptoms: 0 = " no problem" 1 = "some problem" 2 = "severe problem"	Rate following items:
◆ Abdominal distension or bloating ◆ Change in amount of gas passed rectally ◆ Less frequent bowel movements ◆ Oozing liquid stool ◆ Rectal fullness or pressure ◆ Rectal pain with bowel movement ◆ Small volume of stool ◆ Unable to pass stool	◆ Ease of defecation (0 = easy/no difficulty; 100 = severe difficulty) ◆ Feeling of incomplete evacuation (0 = not at all; 100 = very strong) ◆ Patient's judgment of constipation (0 = not at all; 100 = very strong)
Total score of 0 = "no constipation" Total score of 16 = "severe constipation"	Patients already on first line interventions scoring 30 or more should be considered for prescription medications.
	Commonly used in OIC studies for patients already on prophylactic or first line interventions. Recommended by the American Academy of Pain Medicine.

Box 14.3 Suggested Algorithm for Management of Constipation

Stage 1

- Provide education on increasing fluids, dietary fiber, and exercise, if able.
- Assess for risk factors, including new constipating medications.
- Patients on opioids should be started on prophylactic bowel regimen unless otherwise contraindicated: stimulant laxative:
  - Sennosides 8.6 mg, 2 tablets at bedtime

Stage 2

- Titrate sennosides up to 4 tablets twice a day as needed, and/or:
- Add one of the following
  - Polyethylene glycol 17 g in an 8-ounce beverage once a day
  - Milk of magnesia 10 mL orally 2–4 times per day (limit use in patients at risk of electrolyte abnormality or renal dysfunction)

Stage 3

- Perform digital rectal exam to rule out impaction (excluding patients with neutropenia, thrombocytopenia)
  - If impacted and soft, manually disimpact
  - If impacted and hard, consider mineral oil or milk and molasses enema
  - Consider short-acting analgesic and/or anxiolytic prior to disimpaction
- If not impacted, consider use of lactulose 15–30 mL orally 3–4 times a day or bisacodyl suppository daily as needed
- Consider abdominal imaging if concern for obstruction or high impaction
- Consider bowel management consult

Source: Adapted in part from References 16, 39.

be given a goal, such as aiming for one unforced bowel movement per day (Box 14.3).

Even though many palliative patients have poor oral intake, they should be informed to still expect some stool output, even if it is less than usual. There is limited evidence that increasing oral fluids helps with constipation except for those with dehydration[4]; however, many clinicians recommend a daily goal of eight 8-ounce glasses of fluid unless otherwise contraindicated. From a nutritional viewpoint, increasing dietary fiber to 20–35 g/day (including high-fiber foods like prunes, apples, and pitted fruits, as well as green, leafy vegetables, whole grains, and bran) is recommended,[4,16] except for those at high risk of bowel obstruction. Other dietary recommendations include avoidance of constipating foods, like dairy products (e.g., cheese, ice cream), red meat, and processed foods.

There is limited evidence that exercise helps constipation, and exercise may be technically challenging for the palliative population to perform; however, expert opinion suggests activity be increased if the patient is able.[4] Allowing for privacy, easy access to facilities or commode, and routine (colonic motility is highest in the morning) are straightforward interventions that can help prevent and improve constipation.[4] There is some evidence that clockwise abdominal massage increases intraabdominal pressure with resultant improved bowel function[5] and can be easily performed by nursing staff or a family member. Using a footstool, squatting, or leaning forward during defecation relaxes the puborectalis muscle, allowing for easier passage of stool.[24]

When indicated, manual fecal disimpaction is a nursing intervention that can provide significant relief to the constipated patient. Appropriate analgesia and/or anxiolytics should be considered beforehand. Disimpaction should be avoided in patients with thrombocytopenia or neutropenia.

Pharmacologic Management

An initial pharmacologic approach includes avoidance of constipating medications when possible (e.g., considering an antiemetic other than ondansetron). Increasing the use of nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and adjunctive pain medications may decrease a patient's risk of OIC by decreasing opioid requirements.[25] Oral morphine has been shown to result in higher laxative utilization and increased constipation compared to transdermal fentanyl, so opioid selection may also be relevant.[26] In patients taking opioids, a prophylactic bowel regimen is recommended unless otherwise contraindicated,[17,25] and as opioid doses increase, the bowel regimen should be adjusted accordingly.

Oral laxatives are generally utilized as first-line pharmacologic treatment of constipation.[17] However, there are minimal data on the safety and efficacy of laxatives in the palliative population.[17] A 2015 Cochrane review of palliative patients with constipation suggested similar efficacy between multiple laxatives; however, many common laxatives were not included, and the overall quality and amount of included studies was low.[27] Though there is not a specific, widely agreed upon protocol for laxative use, the European Consensus Group on Constipation in Palliative Care recommends a combination of osmotic and stimulant laxatives in the palliative population,[17] and many clinicians will take a similar approach. There are many types of laxatives available, which are discussed in more detail below.

Bulk Laxatives

Bulk laxatives are indicated for patients with mild constipation and irritable bowel syndrome. These are typically not effective as sole agents in patients with OIC[16] and should be avoided in those with significantly reduced physical activity and poor fluid intake due to increased risk of bowel obstruction, which limits the utility in the palliative population.[5] The mechanism of action includes increased GI fluid retention, leading to larger and softer stools.[5] Common adverse effects include abdominal distension and flatulence; less commonly, fluid retention and hyperglycemia may occur. Onset of action is typically 12–24 hours, though this may be 72 hours or more.[5] Bulk laxatives should be taken with two 8-ounce glasses of water. Some examples of bulk laxatives include:

- Psyllium 4–6 g/day
- Methylcellulose 4–6 g/day
- Barley malt extract before meals and at bedtime

Surfactant (Detergent, Emollient, Softener) Laxatives

Surfactant laxatives are most effective when stools are hard, and these can be considered in patients who should not be straining (e.g., recent surgery, hypertension). In many cases, a surfactant is not sufficient as monotherapy, and while some use it in conjunction with a stimulant laxative, a 2015 Cochrane review of palliative patients with constipation did not demonstrate any difference in efficacy between the surfactant docusate in combination with the stimulant sennosides, as compared to placebo plus sennosides.[27,28] Surfactants work by decreasing the surface tension of stool, allowing for increased water and fat absorption, which in turn leads to softer stools. Onset may take up to 3 days, but while stool may become softer, surfactants do not induce laxation. Advantages include a low side-effect profile, though fecal soiling may occur. Examples of surfactant laxatives include:

- *Docusate sodium*: 50–300 mg 2 times a day with a full glass of water
- *Docusate calcium*: 240 mg/day
- *Castor oil*: In general, not recommended in the palliative population due to common side effects of nausea and vomiting[29]

Osmotic Laxatives

Osmotic laxatives are indicated for moderate to severe constipation and are additionally used as bowel preparation for colonoscopy. These laxatives are nonabsorbable sugars that have an osmotic effect in the intestines, pulling fluid into the lumen and resulting in softened stool, bowel distension, and increased peristalsis.[29] Osmotic laxatives should be avoided in patients with suspected or known partial or complete bowel obstruction. Adverse effects are common and include abdominal cramping from increased peristalsis. Fluid and electrolyte abnormalities may also result, and laxatives containing magnesium should be avoided in patients with renal dysfunction, while laxatives with sodium should be avoided in patients with congestive heart failure, hypertension, and edema.[29] Some examples of osmotic laxatives include:

- *Polyethylene glycol (PEG)*: 17 g once to twice daily mixed with 4–8 ounces of liquid, with onset of action in 1–4 days. PEG has been shown to be superior to lactulose and safe when used up to 12 months.[29] PEG is a preferred option in palliative care, given that it is not absorbed systemically or metabolized by gut bacteria, resulting in fewer adverse effects.[29] Additionally, studies suggest superiority in stool frequency over lactulose for patients with chronic constipation.[29]
- *Lactulose*: 15–30 mL up to every 6 hours, maximum of 60 mL/day. This is a hyperosmotic laxative with frequent side effects of flatulence, nausea, and abdominal pain. The sweet taste may make it intolerable to some patients, and it can result in rebound diarrhea. Onset is typically within 24–48 hours. Although this may be considered in the palliative population, it is not first-line, and additional studies for the safety and efficacy in this population are needed. Use with caution in diabetics due to risk of hyperglycemia.
- *Sorbitol*: 30–45 mL of 70% solution once a day. This is another hyperosmotic laxative that is less expensive and less emetogenic than lactulose. Use with caution in patients with diabetes, cardiopulmonary issues, or renal disease due to risk of hyperglycemia and fluid or electrolyte imbalance.[29] As with lactulose, there is minimal evidence regarding sorbitol use in the palliative population.
- *Magnesium*: Magnesium is a component of many saline laxatives, which are sometimes used for acute evacuation due to rapid onset, typically within 1–6 hours. Use should be limited due to increased risk of electrolyte abnormality. Examples include magnesium citrate 150–300 mL, magnesium hydroxide (milk of magnesia) 15–30 mL, and magnesium sulfate 15 g dissolved in water.
- *Sodium phosphate*: 4–8 g dissolved in water. Electrolyte abnormality is again a risk, limiting its use in the palliative population.

Stimulant Laxatives

Stimulant laxatives are commonly used in moderate to severe constipation and in OIC. They function by stimulating the submucosal and myenteric plexuses and causing mucosal irritation, both of which increase peristalsis and fluid secretion into the gut.[30] Due to strong peristaltic activity, abdominal cramping is a common side effect. Lower doses given more frequently may help prevent this.[30] Although there is hypothetical risk of disrupting normal bowel function with frequent use, the evidence for this is limited and may be irrelevant in the palliative population.[25] Some examples of stimulant laxatives include:

- *Bisacodyl*: 5–15 mg/day, taken with food to avoid gastric irritation. Bisacodyl is part of the diphenylmethane family and acts on the small and large intestines with time of onset typically 6–12 hours.[30] Should not be taken within one hour of consuming antacids or dairy products, which can affect absorption. Bisacodyl suppositories will be discussed later.
- *Sennosides (senna)*: 8.6 mg, 2 tablets at bedtime to start; may titrate up to 4 tabs twice a day. Derived from a plant, and part of the anthraquinone family, with action on the large bowel only.[30] Time of onset is 6–12 hours.[30] Of note, a 2015 Cochrane review did not demonstrate any difference in efficacy between lactulose and sennosides,[27] with sennosides being better tolerated and less expensive.

Lubricant Laxatives

These laxatives lubricate and soften stool for easier passage. They are sometimes used to prevent straining in certain populations (e.g., recent surgery, hypertension). Mineral oil 5–30 mL at bedtime on an empty stomach is one example, with onset of action in 2–3 days. However, lubricant laxatives are generally not recommended in the palliative population due to their significant side-effect profiles, including perineal irritation and pruritus, fecal soiling, possibility of malabsorption (especially oil-soluble vitamins and medications), and risk of aspiration lipid pneumonitis, especially in geriatric patients.[29]

Rectal Suppositories

Suppositories act as a lubricant and cause local irritation, which helps stimulate laxation. Due to patient and caregiver discomfort, these are not used first-line, but may be considered in patients without bowel movement for more than 3 days. They should be avoided in patients with neutropenia and thrombocytopenia due to risk of infection and bleeding.[16] Examples include:

- *Bisacodyl*: 10 mg/day, retain 15–20 minutes. Onset for suppository is faster than when used orally, typically 20 minutes to 3 hours, with average of 1 hour.[30]
- *Glycerin*: 2 g daily, retain 15–60 minutes. May induce bowel movement within 15–60 minutes, and side effects are rare.

Enemas

As with suppositories, enemas should be avoided in patients with neutropenia and thrombocytopenia, and use is otherwise limited due to patient and caregiver discomfort. Many examples exist:

- *Warm tap water enema*: 200 mL retained rectally. May lead to bowel movement within 30 minutes. Often considered the safest enema option.

- *Milk and molasses enema*: Combine 6 ounces warm water with 3 ounces powdered milk, then add 4.5 ounces of molasses; place in enema bag and administer rectally, retaining as long as possible. Use up to 4 per day for severe constipation. Do not use in patients with lactose intolerance.[31]
- *Mineral oil enema*: 1 bottle daily as needed.
- *Soapsuds enema*: 200 mL retained rectally. May lead to bowel movement within 30 minutes. Generally not recommended due to risk of mucosal damage and infection.[29]
- *Sodium phosphate enema*: Not recommended in the palliative population; use extreme caution in patients with renal insufficiency due to risk of causing electrolyte abnormality.

Peripherally Acting Mu Opioid Receptor Antagonists

Peripherally acting mu opioid receptor antagonists (PAMORAs) represent a newer class of medication and function by blocking mu opioid receptors in the GI tract, leading to improved peristalsis. These are typically only used when other medications have failed or in severe OIC. Cost is a limiting factor. Common examples include[7,16]:

- *Methylnaltrexone*: 0.15 mg/kg administered subcutaneously. A fixed dose of 8 mg for patients weighing 38–62 kg and 12 mg for patients weighing more than 62 kg may improve ease of dosing.[19] Thirty percent of patients will have laxation within 30 minutes of injection, with 50% of patients having laxation by 4 hours. Up to 50% may not respond by 24 hours after the first dose, in which case a second dose may be given; otherwise, it is recommended every 48 hours as needed.[25] Methylnaltrexone is utilized particularly in patients with OIC with advanced illness who have failed first-line treatment and is superior to placebo in inducing laxation without increasing pain from central opioid withdrawal,[17] with a number needed to treat of 3.[7] Side effects include dizziness, nausea, abdominal pain, flatulence, and diarrhea. Although data are limited, it is avoided in patients with bowel obstruction due to risk of bowel perforation.[5] An oral version has also been approved, dosed as 450 mg once daily.[32]
- *Naloxegol*: 12.5–25 mg orally once daily, 1 hour prior or 2 hours after a meal. Naloxegol is oral naloxone that has been pegylated, which decreases passage across the blood–brain barrier in order to avoid centrally mediated opioid withdrawal while still antagonizing mu receptors in the gut.[20,33–35] Although a recent study for its use in patients with cancer-related pain was ended due to low enrollment, it is generally well-tolerated, with primarily mild GI side effects, and so may be considered in some palliative patients.[34] Naloxegol is contraindicated in patients with bowel obstruction and additionally in patients on vascular endothelial growth factor (VEGF) inhibitors.[35] May interact with medications that have strong CYP4503A4 inhibition activity.
- *Combination naloxone/oxycodone*: 40/20 mg, 60/30 mg, or 80/40 mg. There is evidence of improved bowel function without reversal of analgesia.[5]
- *Sustained-release naloxone*: Acts like a PAMORA through modification of the GI release mechanism of naloxone, resulting in reduced systemic concentrations. In healthy volunteers, GI transit after codeine was shortened after sustained-release naloxone compared to placebo. There are not currently any studies in the palliative population.[33]
- *Alvimopan*: 6–12 mg orally twice daily up to 7 days. Onset of action is 1 day, with number needed to treat of 5.[7] Alvimopan is currently only available through a special program for short-term use in patients hospitalized following bowel surgery and is not yet approved for OIC.[33] A single study showed a higher rate of myocardial infarction in the treatment group and has resulted in a black box warning, though this result has not been replicated in other studies.[33]
- *Naldemedine*: 0.2 mg/day by mouth. Recently approved for OIC in patients with chronic noncancer pain.[32]

Chloride Channel Activators

This family of medications functions by activating chloride channels in the gut, leading to increased fluid secretion and motility, which subsequently leads to softer stools and decreased GI transit time.[29] Indications include OIC, chronic idiopathic constipation, and irritable bowel syndrome. A common example is lubiprostone, which has been shown in randomized controlled trials to improve straining, abdominal bloating and discomfort, and severity of constipation compared to placebo, though without superiority in regards to dependence on rescue laxatives.[33] Typical dosing is 8–24 mcg orally twice daily with food, with time of onset 12–24 hours. Adverse effects include headache, diarrhea, and nausea. It is contraindicated in bowel obstruction[20] and is not recommended for patients on methadone, which interferes with chloride channel activation.[35] Although a promising option, there are currently no studies specific to the palliative or cancer population, and its cost may be prohibitive given that it is still under patent.[33]

Guanylate Cyclase-C Receptor Agonists

These medications also stimulate chloride channels, increasing fluid secretion into the gut lumen. They additionally decrease visceral hypersensitivity and so may have analgesic function.[20] Linaclotide is the first medication in this class and is approved for chronic idiopathic constipation and irritable bowel syndrome. Standard dosing is 145–290 mcg orally once daily 30 minutes before breakfast. It is well tolerated, with a number needed to treat of 5–8.[20] Plecanatide was also recently approved for chronic idiopathic constipation. In a randomized controlled trial of patients receiving 3 mg/day of plecanatide versus placebo, the treatment group was more likely to have improved frequency and consistency of stools, as well as less straining.[36] Both of these medications are contraindicated in bowel obstruction, and studies are still needed in the palliative population.

Serotonin Type 4 Receptor Agonists

There is evidence that the selective serotonin reuptake inhibitors (SSRIs) fluoxetine and citalopram improve straining, sensation of incomplete evacuation, and global symptoms in patients with irritable bowel syndrome. Although there are no studies specific to the palliative population, these might be considered for a patient with depression who is prone to constipation. Another serotonin agonist, prucalopride, is a prokinetic agent[20] that has been evaluated in OIC and chronic constipation, although it is not currently approved by the US Food and Drug Administration (FDA).[18] One advantage is a low potential for drug interactions,[20] although adverse effects include headache, abdominal pain, nausea, and diarrhea.[20]

Metoclopramide

Metoclopramide is a dopamine antagonist that at high doses also antagonizes serotonin[37] in the chemoreceptor trigger zone of the central nervous system, leading to its utility in treating nausea in patients on emetogenic chemotherapy. This medication also sensitizes tissues of the upper GI tract to acetylcholine, leading to a prokinetic effect that explains its use in gastroparesis, as well as the adverse effect of diarrhea. Because of this prokinetic effect, there are some clinicians who might consider using metoclopramide in treatment of constipation. While there is minimal evidence to support the use of metoclopramide specifically for treatment of constipation, in a patient with nausea prone to constipation, it would not be unreasonable to consider metoclopramide in lieu of more constipating HT-3 antagonists. Extrapyramidal side effects are a possibility, especially in older patients,[38] and the patient should be maintained on the lowest effective dose for the shortest time possible. It should be avoided in patients with complete bowel obstruction due to risk for abdominal cramping and bowel perforation.

Probiotics

Probiotics are substances that benefit a host by altering the balance of helpful to harmful microorganisms. There is evidence that administering lactobacillus in the nursing home population improves constipation, though there is no evidence for its use as prophylaxis or in lieu of standard laxatives.[29] In another study, patients with chronic idiopathic constipation had lower levels of Bifidobacterium and lactobacillus in the intestinal microbiome, and treatment with 5×10^8 and 9.7×10^{10} colonies, respectively, resulted in decreased stool transit time.[20] Probiotics might be considered for certain palliative patients, especially since side effects are similar to placebo; however, there is a lack of head-to-head trials with laxatives, and the ideal dosing and bacterial composition has yet to be determined.[20] Additionally, cost may be a limiting factor.

Case Study 1 (continued)

Mr. B has multiple risk factors for constipation, including advanced age, use of chemotherapy associated with constipation (paclitaxel), and increased opioid requirements. Exam shows mild abdominal distension but is otherwise benign. Two tablets of sennosides are initiated routinely at bedtime, in addition to polyethylene glycol daily as needed. One week later he is having daily bowel movements.

Malignant Bowel Obstruction

Case Study 2: A Patient with Ovarian Cancer

Ms. S is a 46-year-old woman with advanced ovarian cancer and multiple prior abdominal surgeries. She is currently on palliative chemotherapy, and unfortunately has developed acute-onset nausea, bilious emesis, and abdominal pain. She had a small, watery bowel movement last night. She has not been able to keep down any food or liquids for 3 days.

Definition and Prevalence

Malignant bowel obstruction (MBO) occurs when the flow of GI contents is interrupted due to involvement of malignancy. Approximately 3–15% of all patients with cancer will develop MBO.[40] It is most common in patients with gynecologic and GI cancers, with 25–40% of MBO cases arising from colon cancer, 16–29% from ovarian cancer, and 6–19% from gastric cancer.[41] To a lesser degree, obstruction can also develop in patients with metastatic breast, lung, melanoma, and pancreatic cancers. At times, MBO may be the presenting symptom of intraabdominal malignancy; for other patients, it may be the first sign of tumor recurrence.

Pathophysiology and Risk Factors

MBO occurs when intestinal intraluminal pressure is increased and a cycle of distension-secretion-distension develops.[42] This can occur as a result of functional obstruction related to nerve involvement (e.g., paraneoplastic neuropathy or tumor invasion of the myenteric plexus) or iatrogenic reasons (including medications like opioids and anticholinergics, which slow the gut). Mechanical obstruction is more common than functional obstruction and is caused by both intrinsic compression of the intestines (e.g., from intraluminal or intramural tumor growth) and extrinsic compression (e.g., from postsurgical adhesions, tumor mass, carcinomatosis, and radiation or chemotherapy-induced fibrosis). Obstruction may be partial or complete, unifocal or involving multiple areas of intestine. About 61% of MBO cases start in the small intestine, 33% in the large intestine, and 20% in both simultaneously.[40] Advanced age, male sex, multiple comorbidities, and weight loss are all risk factors for increased mortality.[41]

Assessment

History

History should begin with a review of the risk factors previously discussed, including use of medications that slow the gut (e.g., opioids and anticholinergics), as well as presence of prior intraabdominal surgery, radiation, or chemotherapy. A history of previous obstruction is important information as studies have shown that more than half of patients with resolved MBO later develop recurrent obstruction.[40]

History should also include a careful discussion of symptoms. The symptoms described may provide information on the location of the obstruction. For instance, in small bowel obstruction (SBO), abdominal pain is typically an early symptom in the peri-umbilical region. On the other hand, abdominal pain in large bowel obstruction (LBO) is often localized, intermittent, colicky, and occurs later in the obstructive process.[43] Nausea tends to be more prominent in SBO, with abundant, bilious emesis; nausea occurs less often in LBO, though when present, emesis may be foul-smelling and occur as a late symptom.[40,43] Abdominal distension occurs more often with distal obstruction and is less likely when obstruction is proximal or when tumor encases the bowel. Anorexia and dehydration are often present and occur more frequently in SBO due to nausea with emesis.[43] In many cases, patients with MBO have not had a bowel movement in the last 72 hours, though loose stools may continue to occur if obstruction is only partial. A patient may continue to have stools even 12–24 hours after complete obstruction occurs due to decompression of the distal bowel.[40]

Physical Examination

Abdominal examination is key in the evaluation of MBO and should include inspection for surgical scars and hernias, which indicate higher risk for obstruction. Extent of abdominal distension should be assessed, as well as the presence and location of tenderness. Percussion should be performed, with a tympanic sound more indicative of air, while a dull sound is more suggestive of other causes, such as ascites or stool. Upon auscultation of bowel sounds, a hyperactive "tinkling" sound or borborygmi may be present; or, in the case of paralytic ileus, bowel sounds may be absent completely.[44] Presence of palpable masses on abdominal exam, in addition to the presence of ascites and cachexia, are often indicative of inoperable MBO.

Rectal exam to exclude fecal impaction should be performed except when the patient has neutropenia or thrombocytopenia. The rectum may need to be first emptied with a suppository or enema prior to confirming a diagnosis of MBO.

Bowel perforation from MBO should be considered in a patient who appears clinically ill on exam with abnormal vital signs and evidence of sepsis.

Diagnostic Studies

Abdominal CT is the gold standard for diagnosing MBO, with high sensitivity and a specificity of greater than 90%.[40,45,46] In addition to confirming the diagnosis, CT provides information on the location of the obstruction by revealing a transition zone between flat and distended bowel. CT can demonstrate if obstruction is partial or complete and whether risk factors like carcinomatosis or adhesions are present. It can also rule out surgical emergencies like bowel perforation, volvulus, or strangulation.

Although CT is the gold standard, many clinicians will still obtain an abdominal x-ray as the first imaging study as it is quick and inexpensive. X-rays are often sufficient to exclude MBO in a lower risk patient, with a sensitivity of 50% and specificity of 75%.[40,45,46] MBO is suggested on abdominal x-ray by the presence of dilated loops of bowel and air–fluid levels.

Management

While numerous studies exist on the topic of MBO, they are often poor quality, with small participation and multiple confounding factors. As a result, there is a paucity of widely accepted guidelines on the management of MBO, and many clinicians will either follow locally established guidelines or no guidelines at all.[42] However, several common themes exist and are discussed below (Box 14.4).

Nursing Interventions and Supportive Care

Providing education and managing expectations is a critical part of any patient's care. Given the high morbidity and mortality associated with obstruction (patients with inoperable MBO typically have a prognosis in the span of weeks to months at most),[40] nursing and other clinical staff may consider the diagnosis of MBO as a "checkpoint" in a patient's progression of illness and an opportunity to reassess a patient's values and overall goals of care.[47] It is reasonable at this time to consider a discussion on the risks and benefits of hospice care, which focuses on QOL and does not preclude a patient with MBO from receiving supportive and pharmacologic management of symptoms. Providing information on the reasons for each intervention recommended and an honest discussion of the expected outcomes can help reassure patients they are receiving appropriate care and help them decide when the risks of an intervention are too high. Patients and families should also be informed that even when obstruction does resolve, there is unfortunately a high rate of recurrent obstruction.[48–50]

Patients who present with MBO are often placed *nil per os* (NPO) to help manage nausea, since anything taken orally will have no place to go. A small subset of patients with partial MBO may be able to tolerate sips of liquid, and good oral care can help relieve the sensation of thirst. Intravenous hydration is often initiated to correct dehydration, and electrolyte replacement, such as correction of hypokalemia, may help improve bowel motility.

Box 14.4 Suggested Algorithm for Management of Malignant Bowel Obstruction

Stage 1

- Place patient NPO
- Nasogastric tube to low intermittent suction (as indicated)
- Parenteral rehydration +/− electrolyte repletion
- Surgical and/or interventional consultation
- Antiemetic: Dexamethasone 8 mg IV/SQ daily plus haloperidol 1 mg IV/SC every 8 hours
- Antisecretory: Scopolamine 1.5 mg TD patch or glycopyrrolate 0.1 mg IV/SC every 6 hours
- Analgesia: Opioids as per WHO ladder, given IV/SC with or without PCA

Stage 2 (for inoperable patient, after 5 days of treatment)

- If obstruction is resolved: Stop corticosteroids and antisecretory medications
- If obstruction is not resolved: Reduce corticosteroids and antisecretory medications and start octreotide 200 mcg every 8 hours IV/SC for 3 days

Stage 3 (after 3 more days of treatment)

- If vomiting has stopped: Find lowest effective dose of octreotide
- If vomiting continues: Stop octreotide and consider endoscopic venting gastrostomy

Source: Adapted in part from Reference 68.

Nasogastric tube (NGT) decompression is a common early intervention in MBO and is most helpful for patients with SBO who suffer from abdominal distension with intractable nausea and vomiting. The NGT is placed to suction and removes gastric contents, resulting in improved symptoms. Sometimes, bowel rest and gastric decompression alone may result in resolution of obstruction without further intervention. When gastric output is less than 100 mL/day, the NGT can be clamped on a trial basis, then removed if symptoms remain stable. Expert consensus says that NGT should not be removed if output is more than 1 L/day.[51] At times, patients may be adamant that they do not want an NGT, and indeed these tubes can be uncomfortable while also increasing the risk of nostril and esophageal erosion, pharyngitis, sinusitis, and aspiration.[47] Allowing flexibility in treatment options is warranted for these patients who already have minimal control of their situation. For instance, some patients prefer dealing with nausea to having a NGT, while others prefer to utilize a NGT so they can continue to drink for gratification, with fluids subsequently removed through the NGT via suction.

It is worth noting that total parenteral nutrition (TPN) is sometimes offered to patients with MBO in hopes of improving nutritional status. In a very select population with preserved functional status, the possibility of response to chemotherapy, or those with a specific goal (e.g., make it to a daughter's wedding), this may be appropriate.[47] However, in general, TPN is not recommended for MBO patients with concomitant terminal cachexia and may actually worsen symptoms by contributing to ascites, worsening pleural effusions, increasing GI secretions, and causing metabolic abnormalities.[52]

Surgical Management

All patients with MBO warrant surgical consultation. The primary goal of surgery is reestablishing function of the GI tract, but up to 50% of patients with MBO are poor surgical candidates.[42] Rarely, surgery is required on an emergent basis for bowel perforation or ischemia, but in nonurgent situations, initial nonoperative management is often appropriate. There is no well-defined criteria for surgical candidacy in MBO, and surgeon comfort level and the patient's ultimate goals play a large role in decision to proceed. However, some general principles in determining poor candidacy for surgery include a less than 2-month prognosis, advanced age,[49] poor performance status and nutritional level, presence of ascites or adhesions, and carcinomatosis or multifocal obstruction.[46]

Surgical intervention can take many forms in a patient with MBO. When obstruction is related to adhesions, these can be lysed surgically. Tumor debulking may help minimize external compression on the intestines, and, in cases where there are minimal sites of obstruction, bowel resection with reanastomosis is often the best option for return of GI function. In other situations, intestinal bypass or creation of an ostomy can circumvent the site of obstruction. The morbidity of surgical intervention in MBO is 42%, and mortality ranges from 5% to 32%, with lower rates for ostomies and higher rates for small bowel resection.[48,49] Up to 50% of patients who undergo surgical intervention may later reobstruct,[48,49] which is important for patients to consider before undergoing a risky surgery. However, when successful, studies have shown that surgical intervention results in 32–100% palliation of symptoms, 45–75% chance of resuming a diet, and 34–87% chance of being discharged home from the hospital.[48,49] Surgical patients have been shown to have higher QOL and longer median survival following surgery (8–34 weeks) compared to those who receive conservative treatment (4–5 weeks),[46] though it is difficult to tell if these findings result from the effects of surgery itself or are related to the fact that patients who are surgical candidates are often healthier to begin with.

Before a patient agrees to surgery, he or she should have a clear understanding of the expected outcome. While some return to a regular diet, as previously mentioned, others, such as those with gastrostomy, may require a soft or liquid diet to facilitate drainage. Even for patients who are able to take food orally following surgery, they should be aware that surgical treatment of MBO is not expected to reverse weight loss and anorexia due to concurrent widespread metastatic disease.

Procedural Management

Procedural interventions can be considered for patients who either decline surgery or are not candidates. These patients typically have a prognosis in the range of 2–6 months. One of the most common procedures performed for patients with MBO is placement of a venting gastrostomy, which can be performed by surgeons, gastroenterologists, or interventional radiologists. In this situation, the patient's gastrostomy is typically placed to low intermittent suction, taking the place of NGT decompression. Venting gastrostomy is indicated for nonsurgical patients who have received significant symptomatic benefit from NGT decompression.[53–55] Complications include leakage around the insertion site, skin irritation and infection, gastric bleeding, peritonitis, and tube blockage, which may necessitate multiple visits to the emergency room. In spite of this, many patients find a gastrostomy less intrusive and more comfortable than a NGT. Portal hypertension, ascites, and carcinomatosis are relative contraindications for placement of gastrostomy due to risk of poor healing; patients with high bleeding risk may also be excluded.[53–55] It is important to educate the patient, family, and even other staff involved in the patient's care that, in this situation, the purpose of the gastrostomy is for gastric decompression to relieve symptoms and is not intended for enteral nutrition or expected to improve nutritional status. However, for patients who desire food for oral gratification, venting gastrostomy may allow the opportunity to enjoy the taste of food, modified for elimination by the tube.

Self-expanding stents are another procedural intervention that can benefit patients with unifocal obstruction, especially in the esophagus, duodenum, or colon. Technical success rate is high, and obstruction is relieved 83–100% of the time.[56,57] Complications include stent migration (8.5–12.4%), as well as intestinal perforation (0.5–4%), for which patients on anti-angiogenic medications or concurrent radiation are at higher risk.[56,57] As with surgical interventions, patients should be aware that their diets following stent placement may not return to normal, but instead they may require low-residue or liquid diets. Additionally, stents take several days to fully expand and may cause significant discomfort as they place pressure against tumor mass. Some patients needing upper endoscopy for stent placement require general anesthesia and intubation, and, in patients with poor performance status, it should be realized that extubation following the procedure may be challenging. Stenting of the lower GI tract tends to be more straightforward, and studies have shown improved QOL for patients who received stenting for colorectal obstruction as compared to similar patients who received surgery.[58]

Pharmacologic Management

Pharmacologic management is important to consider for patients with MBO unable to benefit from surgical or procedural interventions, and is the recommended approach for patients with prognosis of days to weeks or weeks to months according to NCCN guidelines.[47] Inoperable MBO may resolve in more than a third of patients receiving supportive and pharmacologic management alone.[40] Oral administration of medications is typically avoided in MBO due to risk of worsening nausea and poor absorption, so the intravenous (IV), subcutaneous (SC), intramuscular (IM), transdermal (TD), sublingual (SL), and rectal (PR) routes may play a role. Due to the overall poor quality of data available for pharmacologic management of patients with MBO, many of the medications are utilized off-label. Pharmacologic management can be summarized into three goals: reduce nausea, reduce intestinal secretions, and provide adequate pain relief.

Antiemetics

No studies exist that demonstrate benefit of one antiemetic over another in the treatment of obstruction. Steroids, neuroleptics, and serotonin (5-HT3) antagonists are examples of commonly used antiemetics in this situation.

- *Steroids*: There is conflicting evidence regarding the benefit of steroids in patients with MBO. Studies have suggested a trend toward resolution of bowel obstruction for patients receiving 6–16 mg of dexamethasone, with a low rate of side effects, although there is no evidence of survival benefit.[42] In general it has been difficult to compare steroid studies due to multiple confounding factors, including whether or not carcinomatosis was present, the level of obstruction, and if the patient was on chemotherapy. Additionally, most studies have been small and involve the use of multiple medications simultaneously. In spite of the limited evidence, many experts recommend a trial of steroids given the low steroid-related morbidity when used short term.[42,51] The theoretical mechanism involves reduction in bowel edema and inflammation, leading to decreased intrinsic and extrinsic pressure on the intestines, which in turn decreases distension and has an indirect analgesic effect.[59] Dexamethasone is typically the steroid of choice given lower mineralocorticoid activity, leading to less fluid retention. A dose of 6–16 mg IV/SC can be given once a day for a 3- to 5-day trial; expert consensus suggests using no longer than 10 days.[42] Another option is methylprednisolone 1–4 mg/kg/day.
- *Neuroleptics*: This family of medications decreases nausea by acting as central dopamine antagonists.[60] Many experts consider haloperidol a first-line option due to a lower rate of sedation and lower anticholinergic side effects compared to chlorpromazine.[51] Suggested initial dosing is 0.5–2 mg IV/SC every 8 hours as needed, with option to titrate up to 15 mg/day. For a patient at home, a trial of haloperidol liquid concentrate may be attempted sublingually. Although there is a risk of tardive dyskinesia and cardiac QT prolongation from haloperidol, this risk may be less relevant in the palliative population. A second neuroleptic is chlorpromazine 10–25 mg IV every 4–6 hours as needed. Metoclopramide 5–10 mg IV/SC every 8 hours, with titration up to 20 mg every 8 hours if needed, can also be considered, but with a caveat. While haloperidol and chlorpromazine affect central dopamine-2 receptors only, metoclopramide also affects peripheral dopamine-2 receptors, leading to a prokinetic effect.[59,61] For this reason, metoclopramide can be considered in patients with partial MBO without cramping, but in a patient with complete obstruction, it may paradoxically worsen abdominal pain and nausea, along with increasing risk for bowel perforation.[51]
- *5-HT3 antagonists*: Some studies have suggested that this family of medications may help control emesis when used in combination with dexamethasone.[62] They function by antagonizing 5-HT3 receptors centrally in the chemoreceptor trigger zone, as well as peripherally at the vagus nerve. Because constipation is a common side effect, these are generally not considered first-line in patients with ileus. However, they are otherwise well tolerated, though with headache being one of the more common side effects. One example is granisetron 1–3 mg/day IV. A second example is ondansetron 4–8 mg IV every 4–8 hours as needed, up to 24 mg/day. Patients in the home setting may benefit from a trial of ondansetron oral disintegrating tablet given sublingually due to ease of administration.

Antisecretory Agents

Medications that decrease GI secretions to assist in resolving MBO include anticholinergic medications, proton pump inhibitors (PPIs), histamine-2 (H_2) blockers, and somatostatin analogues.

- *Anticholinergics*: This is a large group of medications that have antiemetic effects on the vestibular center, as well as antispasmodic and antisecretory effects. This leads to reduced volume of GI secretions compared to placebo. Common side effects are dry mouth and urinary retention. Scopolamine is one option and can be administered 40–120 mg/day via continuous IV/SC infusion or more conveniently as a 1.5 mg TD patch, with the latter being a practical option in the home setting. Scopolamine is a tertiary amine and, as such, crosses the blood–brain barrier and places patients at a higher risk of delirium. Glycopyrrolate is another anticholinergic drug less studied in the palliative population,[63] but one still often used empirically due to lower risk of potentiating delirium, as it is a quaternary amine and crosses the blood–brain barrier less. Initial dosing is 0.1–0.2 mg IV/SC every 6 hours, up to a maximum of 0.8 mg/day.
- *PPIs and H_2 blockers*: Both were shown in a meta-analysis by Clark et al. to reduce gastric secretions and bile reflux in patients with inoperable MBO, with the H_2 blocker ranitidine acting to a greater degree than PPIs.[44] Options include omeprazole 20 mg SC twice a day, pantoprazole continuously or via 40–80 mg IV bolus daily, and ranitidine 50–150 mg IV twice a day.
- *Somatostatin analogues*: Somatostatin is a peptide hormone secreted by the hypothalamus and the gut, and it inhibits peripheral secretion of vasoactive intestinal peptide. This in turn decreases splanchnic and portal blood flow, reduces gastric secretions and GI motility, and increases GI water reabsorption and production of intestinal mucous, ultimately resulting in improvement of nausea and vomiting.[59,64] Octreotide is an analogue of somatostatin used for a variety of reasons in the palliative population. A 2012 review of 15 randomized controlled trials and observational studies involving 281 patients with inoperable MBO treated with octreotide showed a 60–90% therapeutic success rate.[65] A more recent 2016 review of seven randomized controlled trials was somewhat less conclusive but did suggest mild benefit compared to placebo.[66] Octreotide is typically not used first-line, at least in part due to cost, but it can be considered as first-line therapy in early recurrence of bowel obstruction for patients who have previously responded well to octreotide. Suggested initial dosing is 100–200 mcg IV/SC every 8 hours. Up-titration should be considered if gastric output is greater than 1 L/day, with maximum dose of 900 mcg/day. A depot version is available and can be given 30 mg IM every 28 days. Because the depot takes a week to reach steady state, it is recommended to continue giving the immediate-release form for 6 days after the depot was initiated.

Analgesics

Many clinicians may be wary of providing opioids to patients with MBO given the common side effect of decreased GI motility. However, obstruction often results in significant discomfort, and opioids are still the mainstay of treatment for the cancer patient with moderate to severe pain. There are no controlled trials comparing different opioids for the indication of MBO. Hydromorphone and morphine are often used due to wide availability, and patient controlled analgesia (PCA) is one route of administration that can allow patient control and easy titration. The oral route is not preferred for opioid administration as the patient is often unable to tolerate oral medications due to nausea and vomiting; additionally, if the patient has decompressive NGT or gastrostomy, it is unclear how much drug will actually be absorbed. Other routes to consider are IV and SC, though these may be challenging in the home setting, or PR, though this option may be less desirable to the patient and caregiver. TD fentanyl or buprenorphine can be convenient means of providing long-acting analgesia. TD fentanyl is sometimes preferred to other opioids due to less influence on GI motility and less constipation,[26] as well as better tolerance in patients who are dehydrated or have acute renal failure. Fast-acting fentanyl is also available as a nasal spray, sublingual spray, lozenge, and buccal tablets, but require Risk Evaluation and Mitigation Strategy (REMS) certification to prescribe. Both TD and fast-acting fentanyl are not appropriate in an opioid-naïve patient. Another option to consider for patients at home without IV access and with lower opioid requirements is morphine or hydromorphone oral concentrates. When given sublingually, each has a bioavailability of approximately 20%, which is often sufficient to provide pain relief in select patients with low opioid requirements.[67]

Case Study 2 (continued)

Ms. S is started on IV hydration and placed NPO. CT scan shows carcinomatosis and obstruction of the small bowel. Due to multiple sites of involvement, she is deemed not a surgical candidate and is instead started on dexamethasone 8 mg IV daily, scopolamine TD patch, and haloperidol as needed for nausea. She declines a nasogastric tube. Her abdominal pain is able to be controlled with a fentanyl patch and concentrated sublingual liquid morphine. Her goals of care are discussed, and, given her desire to focus on QOL, she is transitioned home with hospice care.

Diarrhea

Case Study 3: A Patient with Metastatic Colon Cancer

Ms. P is a 54-year-old woman with metastatic colon cancer on 5-fluorouracil and oxaliplatin chemotherapy who was recently hospitalized for pneumonia. She now presents with 8–10 loose, nonbloody bowel movements per day, accompanied by mild abdominal cramping.

Definition

Diarrhea is defined as stool that is abnormally loose, with decreased consistency and/or increased frequency or volume.[69] It is defined more specifically by the World Health Organization as more than three watery bowel movements per day.[70] Diarrhea is considered acute when present for less than 14 days, subacute or persistent between 14 and 30 days, and chronic when present for greater than 30 days.

Prevalence and Impact

Although not as common as constipation, affecting less than 10% of patients admitted to the hospital or palliative units,[71] diarrhea still has a significant effect on many patients receiving palliative care, as well as an impact on utilization of healthcare resources.[72]

Physical Impact

In terms of physical impact, a patient may suffer from dehydration, electrolyte disturbances, malabsorption, and weight loss. Perianal skin breakdown, ulcers, and hemorrhoids often occur concomitantly and increase discomfort, especially in the bedbound patient. The need to frequently evacuate often leads to poor sleep, with subsequent fatigue and drowsiness.

Diarrhea is also associated with increased morbidity and mortality and can even be fatal when untreated in patients on chemotherapy.[69,70]

Medication Adherence

From a treatment standpoint, iatrogenic diarrhea may lead to poor adherence to treatment regimens. For patients with diarrhea related to chemotherapy, the dose may be reduced, delayed, or even discontinued altogether, which can affect prognosis. HIV patients with diarrhea related to antiretroviral therapy (ART) may take their medications inconsistently, leading to increased viral resistance and putting them at risk for opportunistic infections.

Psychological Impact

Perhaps less well appreciated is the psychological impact that diarrhea can have. Patients may have anxiety about frequent restroom visits or soiling themselves, which can discourage them from social interaction, leaving the home, or participating in sexual activity. Persistent diarrhea has been associated with decreased QOL in the palliative population.[72] Recognizing how diarrhea can affect a patient's QOL can help care providers offer empathy and support to their patients.

Pathophysiology and Risk Factors

Diarrhea can be broken down into various categories, including osmotic, secretory, exudative, motility-associated, and functional. However, because most diarrhea is related to a combination of these classifications,[70,71] it may be easier to group by associated causes and conditions.

Infection-Related Diarrhea

Bacterial and Viral Enterocolitis

Most acute cases of diarrhea in both the general and palliative populations are related to viral enterocolitis and are self-limited.[69] Bacterial enterocolitis from *Salmonella, Shigella, Campylobacter*, and *Escherichia coli* can similarly occur in both the immunocompetent and immunocompromised host via spread by contaminated food or water.

Opportunistic Infection-Related Diarrhea

Many patients in the palliative population are immunocompromised, including patients with AIDS, malignancy, or patients on immunosuppressive treatments or chemotherapy, placing them at risk for diarrhea from opportunistic infections. Viral causes include herpes simplex virus, as well as the most common viral cause of diarrhea in patients with AIDS, cytomegalovirus. Cytomegalovirus infection often results in colitis with symptoms of rectal bleeding, abdominal pain, fever, and weight loss.[73] Parasitic opportunists may also cause diarrhea, including *Cryptosporidia, Microsporidia, Giardia lamblia*, and *Entamoeba histolytica*. In the severely immunocompromised, *Mycobacterium avium* complex is another cause of diarrhea.

AIDS-Related Diarrhea

In patients with AIDS, the prevalence of diarrhea at end of life is 6–54%.[70,73] Historically, this has been related to opportunistic infections such as those mentioned previously, especially in patients with $CD4^+$ T-cell counts under 200 cells per mm^3. In recent years, however, as use of ART has improved, the proportion of noninfectious-related diarrhea has increased. Diarrhea related to side effects of ART itself may represent up to 19% of diarrhea complaints and is thought to result in part from protease inhibitor-induced apoptosis of the GI epithelium.[73] Another noninfectious cause is HIV enteropathy, which is a distortion of the GI architecture caused by the HIV virus itself that results in malabsorption and weight loss.[73] HIV enteropathy may occur in both acute HIV and in advanced AIDS.

Cancer-Associated Diarrhea

In patients with advanced cancer, the prevalence of diarrhea is approximately 7–10%.[70] For some, diarrhea may be related to effects of the cancer, such as secretory diarrhea in carcinoid syndrome, diarrhea from malabsorption in patients with pancreatic insufficiency from pancreatic cancer, or in cases of rectal cancer. For other patients, diarrhea is related to cancer treatment, including secretory diarrhea in patients with GI graft versus host disease following stem cell transplant. Radiation-induced secretory and/or exudative diarrhea is also common and can occur either acutely or as a late effect of treatment. This is most common in patients receiving radiation to the pelvis and is dose-dependent.

Chemotherapy-induced diarrhea is worth discussing in more detail, as some randomized controlled trials have shown a frequency of severe diarrhea of up to 47%.[74] Many chemotherapies work by targeting rapidly dividing cancer cells but unfortunately also affect the rapidly dividing cells of the GI epithelium. This leads to mucositis with resultant secretory and hypermotile diarrhea.[74] Chemotherapy can also alter the normal intestinal microbiota, making a patient prone to infectious diarrhea.[75]

The severity of chemotherapy-related diarrhea is directly correlated to dose, with 22% of patients requiring dose reduction, 28% requiring dose delay, and 15% requiring discontinuation of treatment.[75] 5-fluorouracil represents a common cause of diarrhea, with grade 3–4 symptoms in 32% of patients on bolus therapy and 6–13% of those on infusion therapy.[74,76] In clinical trials, 1–5% of these patients even die from complications of 5-fluorouracil–induced diarrhea.[74,76] Irinotecan is another common culprit, with total incidence of 60–90%,[77] including 16–22% with grade 3–4 symptoms.[76] Up to 50% of patients on tyrosine kinase inhibitors develop diarrhea.[74] Some additional examples are provided in Box 14.5.[74–77]

Box 14.5 Examples of Cancer Medications Associated with Diarrhea

- 5-fluorouracil
- Cisplatin
- Cytosine arabinoside
- Hydroxyurea
- Interferon
- Irinotecan
- Monoclonal antibodies
- N-phosphonoacetyl-L-aspartate
- Nitrosourea
- Oxaliplatin
- Topoisomerase inhibitors
- Tyrosine kinase inhibitors

Iatrogenic Causes of Diarrhea

Just as with chemotherapy, sometimes clinical treatments provided to patients in palliative care can result in diarrhea as a side effect. The most common cause of diarrhea in patients with advanced illness is erratic laxative use.[71] A patient with constipation may use high doses of laxatives, with resultant rebound diarrhea. Antibiotics are another frequent cause of diarrhea, both as a direct side effect as well as by affecting the intestinal microbiome and placing patients at risk for secondary infection. *Clostridium difficile* (*C. diff*) is a bacterial infection that commonly occurs in patients taking antibiotics or spending time in healthcare facilities. *C. diff* results in pseudomembranous colitis and, in severe cases, can even lead to toxic megacolon.[73] Antacid use is also associated with diarrhea. Finally, surgery can be an iatrogenic cause of diarrhea, such as secretory diarrhea in a patient with short gut syndrome following bowel resection or hypermotile diarrhea in a patient with ileal resection or colectomy.

Additional Causes of Diarrhea

- *Malabsorption*: Lactase insufficiency (including temporary deficiency following acute viral enterocolitis) can result in osmotic diarrhea, and biliary or pancreatic problems can lead to fat malabsorption with resultant hypermotile diarrhea.
- *Fecal impaction with overflow*: More than half of elderly patients without cancer in the hospital have diarrhea due to fecal impaction with overflow diarrhea.[71]
- *Partial bowel obstruction*: Patients with partial bowel obstruction may additionally have overflow diarrhea.
- *Ingestion of hyperosmolar products* (e.g., sugary fruit drinks) may result in osmotic diarrhea.
- *Enterocolic fistula* may result in osmotic diarrhea.
- *GI hemorrhage* may result in osmotic diarrhea.
- *Inflammatory bowel disease*.
- *Functional diarrhea and irritable bowel syndrome*.

Assessment

History

Given a wide variation in normal bowel habits, it is first important to elucidate the patient's "usual" bowel routine. Details to assess include the quantity, frequency, color, and consistency of stools, as well as the timing of episodes in relation to oral intake or medication use.[69] It is useful to determine if the patient has high intake of fiber, lactose, or alcohol because all of these can contribute to diarrhea. The presence of anorexia can help determine the severity of the situation. Symptoms of fatigue, tenesmus, and nocturnal episodes should also be assessed. Concerning symptoms include the presence of blood or mucous in the stool and associated fever, weight loss, and severe abdominal pain or cramping. As with all patient histories, past medical history and medication use should also be discussed, with careful attention to prior GI surgeries, recent antibiotic use or hospitalization, and sick contacts.

The National Cancer Institute has developed a Common Toxicity Criteria to better define the severity of diarrhea by grades 1 through 5, with 1 being most mild (Box 14.6).[74]

Box 14.6 National Cancer Institute Common Toxicity Criteria[74]

- Grade 1: 2–3 more bowel movements (BMs) per day over baseline, or mild increase in stoma output.
- Grade 2: 4–6 more BMs per day over baseline, or moderate increase in stoma output, in addition to moderate cramping or nocturnal stools.
- Grade 3: 7–9 more BMs per day over baseline, incontinence, or severe increase in stoma output, in addition to severe cramping or nocturnal stools; symptoms interfere with activities of daily living.
- Grade 4: More than 10 BMs per day over baseline, grossly bloody diarrhea, need for intravenous hydration.
- Grade 5: Death.

Physical Examination

Vital signs should be assessed, including orthostatic measurements of heart rate and blood pressure, to help determine if hypovolemia is present.[78] Other signs of dehydration to notice are decreased skin turgor, pallor, and delayed capillary refill. If the patient is found to have an abnormal temperature, this may be more indicative of infectious causes.

Abdominal examination should include visual inspection for surgical scars and distension. Presence of tenderness, rebound tenderness, and guarding should be determined. The examiner should also palpate for masses, hepatosplenomegaly, and ascites, which may provide information about risk factors or possible etiologies.[78] Patients with ostomies should have these examined for functionality and leakage.

Assuming the patient does not have neutropenia or thrombocytopenia, a rectal exam should be performed to rule out fecal impaction as this is a common cause of overflow diarrhea. Assessing for competence of the external sphincter is also useful as lack of competency may explain incontinence. Presence of bloody stool is a more concerning sign. The perineal skin should be examined for presence of skin breakdown, hemorrhoids, and fissures as these contribute to patient discomfort.

Diagnostic Studies

Most cases of acute diarrhea do not warrant laboratory testing. In some situations, however, blood tests may provide helpful information. A complete blood count will determine if anemia or thrombocytopenia are present, indicating possible bleeding risk, and leukocytosis may suggest an infectious or inflammatory condition. Blood cultures should be considered for patients with fever or who appear clinically ill. Assessing electrolytes and renal function can help determine degree of dehydration and prerenal dysfunction. In select situations, elevated C-reactive protein suggests an inflammatory state, and liver function, glucose level, and thyroid-stimulating hormone may provide useful information on risk factors and etiologies of diarrhea. For a patient with HIV, the viral load and the $CD4^+$ T-cell count help determine risk for opportunistic infectious causes of diarrhea, especially when the $CD4^+$ T-cell count is less than 200 cells per mm^3.

Treatment of diarrhea is often performed empirically, and stool studies are reserved for more complicated situations, including persistent symptoms, severe illness, or high-risk patients. Enzyme immunoassays or polymerase chain reaction tests for toxigenic *C. diff* are perhaps some of the most useful stool studies as treatment is quite specific if the result is positive.[78] Checking for fecal occult blood and fecal leukocytes may help diagnose inflammatory causes of diarrhea. Stool bacterial cultures are rarely helpful in the setting of acute diarrhea and are typically reserved for situations where a positive test will change the patient's management.

Imaging studies are often not necessary in the evaluation of diarrhea. However, a CT of the abdomen is indicated when there is presence of guarding or rebound tenderness on exam and may help detect evidence of enterocolitis, bowel perforation, diverticulitis, pancreatitis, or abscess. Abdominal x-rays are usually low yield.

In severe, persistent cases of diarrhea, further investigation can be performed via sigmoidoscopy, colonoscopy, or endoscopy. These studies allow a visual assessment of the intestinal walls, as well as the opportunity to biopsy for signs of inflammation or infectious causes like cytomegalovirus or *C. diff*. However, these procedures should be avoided in patients with neutropenic enterocolitis, those with high risk of bowel perforation, or those in whom goals of care preclude invasive procedures.[78]

Management

Prevention

Certainly prevention is always superior to treatment. Unfortunately, while multiple studies have evaluated options to prevent diarrhea related to chemotherapy or radiation (e.g., probiotics, celecoxib, absorbents, and activated charcoal), supporting evidence is lacking.[74,76] The best prevention for infection-related diarrhea is good hand hygiene to avoid spread.

Nursing Interventions and Supportive Care

Patients and families should be educated about the causes and treatments for diarrhea. When a patient will receive chemotherapy with high risk for diarrhea, they should be aware of this side effect ahead of time and know when to contact their healthcare providers. It is important to consider that patients may be wary of notifying their healthcare team about diarrhea as they may fear it will exclude them from continuing chemotherapy. However, it should be stressed that providers be informed of symptoms early on in order to help treat them. Serious symptoms indicating a need for hospitalization include severe diarrhea (grade 3–4), significant nausea and vomiting, fever, sepsis, neutropenia, bleeding, inability to eat, and severe cramping. In some cases, a dose reduction or break in therapy may help with chemotherapy-related diarrhea,[47] but "drug holidays" are not recommended for HIV patients with ART-related diarrhea.

Beyond education, other supportive interventions include access to equipment (e.g., bedside commode or bedpan) to improve convenience when frequent diarrhea would otherwise cause several trips to the bathroom. Teaching and assisting in good skin care is key, with appropriate cleaning and drying to limit skin irritation related to moisture, as well as use of barrier creams to reduce skin breakdown.

Dietary recommendations are also helpful. Food triggers should be avoided, including those that are gas-forming.[69] Common foods to avoid include dairy products, caffeine and alcohol, foods with high sugar or sorbitol, high-fiber legumes (raw vegetables), high-fat foods, spicy meals, and high-risk foods (e.g., raw foods, food left out, food from street vendors). Instead, patients should increase bulk in their food by including psyllium, bran, or pectin. Eating frequent, small meals is preferred to a few large meals.

It is important for the patient with diarrhea to stay well hydrated. They should attempt frequent sips of clear liquids as tolerated and can consider oral rehydration solutions with sodium chloride and sugars, like sports drinks or soups. A good goal is 8–10 large glasses of clear liquids per day,[76] though this may be challenging in the palliative population. For patients with severe diarrhea and dehydration, parenteral hydration or subcutaneous hypodermoclysis may be helpful. In that situation, electrolyte repletion (e.g., magnesium, calcium, and phosphate) can also be considered.

Pharmacologic Management

Opioid Agonists

For patients who fail conservative management of diarrhea, opioid agonists represent the first-line pharmacologic option for symptomatic relief. These function by binding and agonizing peripheral opioid receptors in the gut, resulting in decreased peristalsis, increased water reabsorption, and promotion of fecal continence, all of which improve diarrhea.[69–71] Side effects include ileus, constipation, abdominal cramping, irritability, drowsiness, and dizziness.[75] Some common examples are discussed here.

- *Loperamide*: 4 mg by mouth initially, followed by 2 mg after each loose stool, up to 16 mg per day; titrate until diarrhea-free for 12 hours. Loperamide is generally used as the first medication in symptomatic treatment and is available without a prescription. It should be tried prior to diphenoxylate due to less crossing of the blood–brain barrier, with a subsequent lower risk of delirium. It is additionally less sedating than codeine. Its use should be avoided if there is blood in the stool or suspected *C. diff* infection.
- *Diphenoxylate/atropine*: 2.5 mg/0.025 mg, 1–2 tabs by mouth every 6 hours as needed, up to 20 mg/0.2 mg per 24 hours. This is a combination medication, with diphenoxylate working as a peripheral opioid agonist and atropine functioning as an anticholinergic, which together help to diminish GI secretions and decrease peristalsis.[69] Onset of action is 45–60 minutes.
- *Tincture of opium*: 0.7 mL by mouth every 4 hours, titrate to effect.
- *Codeine*: 10–60 mg by mouth every 4 hours as needed. As previously mentioned, sedation is a common side effect.

Adsorbent Agents

Adsorbent agents function by adding bulk to stool, binding bacterial toxins, and binding fluid, all which improve stool consistency.[73] Bismuth subsalicylate is a common example, and it additionally possesses an anti-inflammatory and mild antimicrobial effect. This is often utilized in acute diarrhea and can be administered as 30 mL liquid or two tablets by mouth every 30 minutes as needed, up to 8 doses per day.[69] Methylcellulose and pectin are other examples of adsorbent agents, the latter of which may take up to 48 hours to have effect.

Anticholinergics

As with atropine previously discussed in combination with the opioid agonist diphenoxylate, anticholinergics improve diarrhea by reducing GI secretions and decreasing peristalsis. Atropine is also used in combination with phenobarbital/hyoscyamine/scopolamine, 1–2 tablets every 6–8 hours as needed; this option may additionally improve abdominal cramping. Scopolamine alone administered via transdermal patch might also be considered in refractory cases, especially if nausea is concomitant.

Anti-inflammatories

The corticosteroid budesonide is occasionally used in chemotherapy-induced diarrhea refractory to loperamide. It can be given as 9 mg/day for 3–5 days.[74] Aspirin and indomethacin have been used to treat radiation-induced enteritis, although supporting evidence of efficacy is minimal. For patients with chronic diarrhea related to inflammatory bowel disease, mesalamine may provide relief.

Antisecretory Agents

Somatostatin is a peptide hormone secreted by the hypothalamus and the gut, and it inhibits peripheral secretion of vasoactive intestinal peptide. This is turn decreases splanchnic and portal blood flow, reduces gastric secretions and GI motility, and increases GI water reabsorption and production of intestinal mucous.[59,64] Octreotide is an analogue of somatostatin and is used for a variety of reasons in the palliative population. It can be used as first-line treatment in grade 3–4 chemotherapy-induced diarrhea or as a second-line treatment for grade 1–2 symptoms. Other indications include profuse secretory HIV-related diarrhea, high stoma output, or intractable diarrhea. Typical initial dosing is 50 mcg IV/SC every 8–12 hours, with titration of 100 mcg per dose every 48 hours up to 500 mcg every 8 hours. It can also be administered via continuous infusion at 10–80 mcg/hr, or as a depot injection of 20 mg IM once a month.[69] Some studies have examined whether octreotide can play a role in prophylaxis of diarrhea related to chemotherapy or radiation, and, while the evidence at this time is limited,[79] the depot may play a better role in prophylaxis than the immediate-release preparation.[80]

Ranitidine is a histamine-2 antagonist that reduces GI secretions and may help in cases of diarrhea related to fat malabsorption from pancreatitis or in patients with Zollinger-Ellison syndrome.[71]

Crofelemer is an antisecretory agent that represents the only FDA-approved therapy for symptomatic relief of noninfectious diarrhea in patients with HIV on ART.[73]

Microbial Agents

Antibiotics occasionally play a role in the treatment of diarrhea in palliative medicine. Just as in the general population, a patient with severe acute bacterial diarrhea, or "traveler's diarrhea," may benefit from azithromycin or a fluoroquinolone. Metronidazole or oral vancomycin are indicated for patients with diarrhea related to *C. diff* infection.

Probiotics are live microorganisms that are administered in hopes of reestablishing a healthy gut microbiome by competing with pathogenic microorganisms that cause infection. There is some evidence of probiotic efficacy in preventing antibiotic-induced diarrhea (e.g., *C. diff*), though the optimal strain and dosing are unclear.[77,81] There have additionally been efforts made to determine whether probiotics can prevent diarrhea associated with chemotherapy or radiation, but unfortunately their use for this reason is controversial due to lack of convincing evidence.[77,81] However, probiotics are generally well tolerated and so might be considered in a select population.

Other Antidiarrheal Options

Additional medications can be considered for specific causes of diarrhea. For instance, patients with diarrhea related to pancreatic insufficiency may benefit from 30,000 international units of pancreatic lipase with each meal, in combination with a low-fat diet. Lactase supplements will assist with diarrhea related to lactase deficiency. Bile acid sequestrants (e.g., cholestyramine) can sometimes reduce output in radiation-induced colitis or in steatorrhea from bile acid malabsorption. Alpha-2 adrenergic agonists (e.g., clonidine) are occasionally used for diarrhea related to opioid withdrawal. One case report showed resolution of octreotide-resistant diarrhea following the anticholinergic glycopyrrolate in a patient with neuroendocrine tumor.[82] Finally, the antihistamine cyproheptadine can assist in diarrhea related to carcinoid syndrome.[71]

Case Study 3 (continued)

Given Ms. P's recent hospitalization, her stool is checked for *C. diff* infection and returns negative. Her 5-fluorouracil, which commonly causes diarrhea, is switched from bolus to continuous dosing, and she is recommended to start loperamide 4 mg initially, followed by 2 mg every 4 hours as needed for loose stool. Her vital signs remain stable, she is able to maintain hydration through frequent sips of oral rehydration solution, and her stools decrease to twice per day.

Ascites

Case Study 4: A Patient with Alcoholic Cirrhosis

Mr. N is a 65-year-old man with alcoholic cirrhosis who develops weight gain, increasing abdominal girth, and yellowing of the skin. He now reports early satiety and has discomfort breathing when lying flat.

Definition

Ascites is an abnormal collection of fluid within the intraperitoneal cavity. There are multiple etiologies of ascites, but, regardless of the cause, it often results in significant discomfort and diminished QOL.

Prevalence and Pathophysiology

The etiology of ascites can be broken down into conditions associated with portal hypertension, peritoneal disease, and hypoalbuminemia.

Portal Hypertension

Portal hypertension is a condition of resistance to portal blood flow due to either structural changes in organs involved or due to dynamic changes affecting the velocity of blood flow. In either case, the end result is buildup of pressure with increased vascular permeability and resultant accumulation of fluid in the intraperitoneal space. Liver cirrhosis is the most common cause of ascites related to portal hypertension and represents 81% of all patients with ascites.[83] Nearly half of patients with cirrhosis develop ascites.[84] Of those with cirrhosis who develop ascites, 2-year mortality decreases to 50%.[85] When ascites becomes refractory to medical therapy, mortality is 50% within only 6–12 months.[85]

Other common causes of portal hypertension that can lead to ascites are:

- *Heart failure*: Represents 3% of patients with ascites [83]
- *Hemodialysis-associated (nephrogenic)*: Represents 1% of patients with ascites [83]
- *Liver metastases*
- *Portal vein thrombosis* (prehepatic resistance to portal blood flow)
- *Budd-Chiari syndrome* (posthepatic resistance to portal blood flow)

Peritoneal Disease

When the peritoneum is damaged, lymphatic drainage is impaired and vascular permeability increases. This results in accumulation of fluid within the peritoneal cavity.[86] Malignancy with peritoneal carcinomatosis is a common cause of this and represents roughly 10% of all patients with ascites.[83] When ascites is present in a patient with malignancy, it often signifies a poor prognosis in the range of 1–4 months, with the exception of ovarian and breast cancer, which have better prognoses.[86] For this reason, the development of ascites in a patient with cancer is often an appropriate time to readdress a patient's goals of care. Tuberculosis can also damage the peritoneum and represents about 2% of patients with ascites.[83]

Hypoalbuminemia

Conditions resulting in hypoalbuminemia also place a patient at risk for development of ascites primarily due to loss of oncotic pressure within the cardiovascular system, which leads to increased vascular permeability and again results in increased fluid in the peritoneal cavity. Therefore, nephrotic syndrome, severe malnutrition, and protein-losing enteropathies can all increase a patient's risk of developing ascites.[83]

Assessment

History

A patient presenting with ascites should be questioned about medication use and past medical history, including presence of any of the conditions discussed in the pathophysiology section. Additionally, risk factors for liver or infectious disease should be assessed, including a history of heavy alcohol use, hepatitis, hepatocellular carcinoma, or travel to tuberculosis-endemic regions.[87]

The hallmark symptom of ascites is abdominal distension, which patients might describe as their pants "fitting tighter." Patients may report weight gain and edema. Pain is often present, not only in the abdomen, but also in the pelvis or back due to carrying unaccustomed additional weight. Anorexia and early satiety may develop, as well as nausea and vomiting. Additional symptoms to review are presence of fatigue, dyspnea and orthopnea, urinary frequency, and constipation.[88] A patient may describe reduced mobility and poor body image concerns as a result of their distended abdomen and associated weight gain.[89] In patients with liver disease, concomitant pruritus may be present due to hyperbilirubinemia or confusion related to hepatic encephalopathy.

Physical Examination

It is challenging to diagnose ascites by physical examination alone, especially in a patient with obesity.[87,88] However, a thorough abdominal exam is still warranted, including assessment for distension and hepatosplenomegaly. The abdomen should be percussed and may result in a dull tone over the flanks in comparison to the tympanic sound more often present in bowel obstruction. Of note, at least 1.5 L of fluid must be present to appreciate dullness to percussion, and this in combination with bulging flanks yields a 75% sensitivity and 57% specificity in the diagnosis of ascites.[87] Dullness to percussion may also shift as the patient changes from the supine position to lateral decubitus, and this sign is more predictive of ascites than presence of a fluid wave.[87]

A cardiac exam should be performed, including observation for signs associated with heart failure, such as jugular venous distension, a third heart sound, pulmonary rales, and peripheral edema of the lower extremities or scrotum.

Presence of lymphadenopathy may be concerning for malignancy, and presence of inguinal or umbilical hernias may suggest increased intraabdominal pressure.

Examination should also include evaluation for the stigmata of liver disease, including visible changes (e.g., palmar erythema, spider telangiectasias, jaundice, scleral icterus, caput medusa, and gynecomastia), as well as neurologic changes (e.g., asterixis, encephalopathy).

Diagnostic Studies

The primary value of obtaining blood tests is to look for conditions that predispose to ascites. Presence of thrombocytopenia, elevated coagulation studies, elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST), alkaline phosphatase, and bilirubin all suggest liver dysfunction. Elevated creatinine and urea are suggestive of renal dysfunction,[87] and high brain natriuretic peptide (BNP) levels suggests heart failure. Electrolyte abnormalities such as hyponatremia can indicate volume overload. In severe malnutrition or nephrotic syndrome, albumin level is decreased.

Imaging Studies

Abdominal ultrasound is the first-line study in evaluation for ascites and can detect as little as 100 mL of ascitic fluid.[88] Not only will ultrasound help confirm the presence of ascites, but it will also determine the amount, and this can offer guidance during paracentesis.

On ultrasound as well as on CT, there may be evidence of a small, nodular liver if cirrhosis is present or evidence of liver metastases in the setting of malignancy. CT is often more helpful than ultrasound in determining overall disease burden in a patient with ascites related to cancer.[88]

Diagnostic Paracentesis and Laparoscopy

Any patient who presents with new-onset ascites warrants a diagnostic paracentesis to determine the cause.[83] The color of the ascitic fluid should be observed, with straw color common in liver cirrhosis, while bloody ascites may be more consistent with a traumatic tap or malignancy. In the past, testing whether the fluid was exudative versus transudative was often performed, with total protein concentrations of less than 1.5 g/L associated with a higher risk of spontaneous bacterial peritonitis.[87] However, this concept is now generally considered less helpful in diagnosis as compared to determination of the serum-ascites albumin gradient (SAAG). SAAG is obtained by subtracting the albumin level in the ascitic fluid from the serum albumin level. If the gradient is greater than or equal to 1.1 g/dL, there is a 97% chance of portal hypertension being present.[83] Lower gradients are more suggestive of malignancy, pancreatitis, or infection.

For a patient with suspected cancer, a positive cytology evaluation of the ascitic fluid is 100% specific for the diagnosis of malignancy. However, cytology is only 60% sensitive as not all tumors shed cells into the peritoneal space.[83] At times, checking for serum tumor markers such as alpha-fetoprotein levels for hepatocellular carcinoma or CA 19-9 for pancreatic cancer may be enlightening.

Infectious workup of ascites includes a microscopic analysis to rule out spontaneous bacterial peritonitis. Presence of more than 250 neutrophils per mm^3 is suggestive of infection.[90] Gram stain may quickly reveal information about the type of bacteria present, with a culture providing even more conclusive data. Leukocyte esterase strips are commonly used for analysis of urine but have also been found to have a sensitivity of 80–93% and specificity of 93–98% for diagnosing spontaneous bacterial peritonitis in the ascitic fluid.[87] If tuberculosis is suspected, checking adenosine deaminase activity or polymerase chain reaction for mycobacterium tuberculosis DNA are useful tests to consider.

Many additional studies exist, with common examples including amylase level for pancreatitis and triglyceride level for chylous ascites.

In some situations, diagnostic laparoscopy may allow for detailed visual examination of the intraperitoneal space to look for a cause of ascites, as well as the option to take tissue biopsies.[90] In the case of malignancy, this additionally allows the opportunity to perform surgical debulking.

Management

There are few randomized controlled trials that evaluate and compare various treatments for ascites. Most of the data available come from studies on cirrhotic ascites and, to a much lesser extent, from other causes, including malignancy.[89]

Nursing Interventions and Supportive Care

Because the presence of ascites in most situations indicates terminal illness, the goal of treatment is palliation of symptoms.[90] Nursing and clinical staff can provide education on dietary changes to minimize buildup of intraperitoneal fluid, including fluid restriction and sodium restriction (less than 2 g/day).[84] Good skin care remains important to prevent skin breakdown. Assisting with proper positioning additionally improves discomfort and dyspnea, and physical therapy can be considered to assist with mobility concerns.

Pharmacologic Management

Diuretics are commonly used in management of cirrhotic ascites. The use of diuretics in malignant ascites is more controversial, with studies showing a response rate of approximately 44%.[88] There are no well-studied dosing guidelines for diuretics for this indication, and typical dosing guidelines are followed.[89] Common examples of diuretics include potassium-sparing diuretics like spironolactone, which is an aldosterone receptor antagonist. Spironolactone is often considered a first-line treatment in cirrhotic patients, and it is sometimes considered for patients with malignancy who have a low chance of successful treatment with chemotherapy.[90] Doses used are 150–450 mg/day.[89] Loop diuretics like furosemide are also sometimes tried, though evidence of its utility for this indication is limited. Unfortunately, there is not a reliable way to predict which patients will benefit from diuretics,[91] and ascites is often refractory to pharmacologic management. Caution should be taken to ensure that the use of diuretics does not induce renal failure.

Other pharmacologic treatments to consider include chemotherapy for patients with chemosensitive malignancies, especially in ovarian and some GI cancers. Another possible option is octreotide, which in a single case series showed a reduction in ascites.[88]

Procedural and Surgical Management

Therapeutic Paracentesis

Therapeutic paracentesis is the first-line treatment for ascites refractory to supportive and pharmacologic interventions. This provides definite, albeit usually temporary, relief of symptoms and can be performed on an outpatient basis up to every 2 weeks.[85] In cases of cirrhosis, large-volume paracentesis can place a patient at risk for hypotension and renal dysfunction,[90] although patients with ascites from malignancy tend to have lower complication rates.[88] In fact, some studies have shown that removal of up to 5 L of fluid in patients with malignant ascites can be performed safely without resultant hypotension or need for IV fluids.[89] The patients with malignant ascites who benefit most from paracentesis are those who suffer from abdominal distention, dyspnea, anorexia, fatigue, insomnia, and decreased mobility; patients with severe pain at baseline tend to show less of a benefit.[92] Paracentesis includes rare but life-threatening side effects, including a 1% chance of significant bleeding and a 0.4% chance of small bowel perforation.[85]

Catheters

Patients requiring frequent paracentesis for symptomatic relief may benefit from an indwelling catheter for ease of fluid removal. Pigtail catheters are currently used only rarely due to 35% infection rate, 30% rate of blockage, and 20% rate of leakage.[86] A single-cuffed indwelling peritoneal catheter (e.g., PleurX or Rocket) is much more common and is indicated for patients with symptoms in spite of large-volume bimonthly paracentesis who are otherwise not candidates for transjugular intrahepatic portosystemic shunt (TIPSS) or peritoneovenous shunt (discussed in more detail later).[85,86] Patients with single-cuffed indwelling peritoneal catheters are typically drained 2–3 times per week in the home setting by a nurse or trained caregiver.[93] These catheters have a high rate of technical success, though with an increasing risk of infection the longer they are present, especially after 3 months. This option may preserve renal function better than large-volume paracentesis and possibly improve dyspnea and QOL. Some studies have shown improvement in abdominal distension, anorexia, and constipation.[94] A final catheter option is a double-cuffed pigtail peritoneal dialysis catheter (e.g., Tenckhoff), which allows for drainage of malignant ascites and the option to infuse cytotoxic medications, with an overall low complication rate.[95]

Shunts

TIPSS is typically reserved as a second-line option for patients with refractory ascites. This angiographic procedure involves creation of a low-resistance pathway from the hepatic vein to an intrahepatic branch of the portal vein, allowing for more balanced distribution of fluid volume. For cirrhotic patients, TIPSS offers better control of ascites than large-volume paracentesis and can improve QOL but unfortunately yields a higher risk of severe hepatic encephalopathy and so is best for those with lower risk of encephalopathy.[84] Many contraindications to this procedure exist, including significant heart failure, pulmonary hypertension, systemic infection, and biliary obstruction.

Another type of shunt is the peritoneovenous (e.g., Denver or Le Veen) shunt. In this situation, ascitic fluid is shunted from the intraperitoneal space into the superior vena cava via a pressure gradient.[90] This is sometimes utilized in patients unable to benefit from TIPSS or large-volume paracentesis and has 70% rate of symptom palliation.[90] There is also evidence of utility in symptomatic patients with refractory chylous ascites.[96] However, there is a lack of survival advantage and a high 25–40% complication rate, including pulmonary edema, shunt occlusion, pulmonary embolism, infection, and disseminated intravascular coagulation.[85,86,90] It is typically not performed in patients with a prognosis of less than 1 month. Bilirubin levels of more than 6 mg/dL are a contraindication to this procedure as this is associated with a higher risk of intravascular coagulation.[90]

Liver Transplant

For patients with cirrhosis or low-volume hepatocellular carcinoma in otherwise good health, liver transplantation may be an option to improve both symptoms and prognosis. However, fewer than 10% of patients with end-stage liver disease are eligible for transplant, and even fewer will have the opportunity to receive transplant.[93] This is unfortunately only very rarely an option in the palliative population.

HIPEC

“Closed abdomen” hyperthermic intraperitoneal chemotherapy (HIPEC) is a newer procedure indicated for malignancy with ascites and peritoneal carcinomatosis.[97] It involves the removal of ascites through drainage tubes and washout of the peritoneal cavity with isothermic saline, followed by intraperitoneal infusion of chemotherapy (often carboplatin or paclitaxel for ovarian and cervical cancer, or cisplatin or mitomycin for GI cancers), instilled at approximately 41°C. Ovarian cancer tends to be more susceptible to this approach than GI cancers.[97] HIPEC is generally well tolerated with less toxicity than systemic chemotherapy, but it does require hospitalization. Small studies have shown that it results in longer intervals between required paracenteses, decreased abdominal circumference, and improved QOL.[97] HIPEC is typically most successful when performed after surgical removal of all visible tumor (“optimal debulking”). Limitations of HIPEC include high expense, requirement of technical expertise not present at many institutions, and limited penetration of chemotherapy into the tumor.[90]

CART

Concentrated ascites reinfusion therapy (CART) is another newer treatment for ascites. The process involves paracentesis, followed by filtration of ascitic fluid to remove any malignant cells, bacteria, and excess fluid or electrolytes, after which the filtered, concentrated ascites is reinfused.[98] CART is indicated for patients with resistance to or who have adverse effects from diuretics. In patients with ascites from multiple causes, it has resulted in significant improvement in performance status, dietary intake, urine volume, body weight, and abdominal circumference.[98] Fever is a common adverse effect, and additional prospective studies utilizing this technique are warranted.

Case Study 4 (continued)

Mr. N undergoes ultrasound, which confirms ascites. He receives diagnostic paracentesis, which is not suggestive of infection, and workup is consistent with portal hypertension. He is started on spironolactone without significant improvement, but later receives therapeutic paracentesis with 5 L of straw-colored fluid removed, which greatly improves his discomfort for about 2 weeks. He is scheduled in clinic for recurrent paracentesis every 2 weeks and is taught positioning techniques, which aid in maintaining his QOL.

Bowel Management Summary

- Constipation is a common symptom in the palliative population and requires a proactive approach involving patient education, lifestyle changes, and, at times, pharmacologic intervention, often with stimulant or osmotic laxatives.
- Malignant bowel obstruction is associated with poor prognosis, and should prompt discussion about goals of care, as well as aggressive symptom management through procedural or pharmacologic approaches.
- Diarrhea negatively impacts QOL in the palliative population, and patients should be educated to involve their medical team in treating symptoms.
- The presence of ascites frequently portends a poor prognosis, and patients often benefit from drainage of the fluid and discussion about goals and values.

CHAPTER 15

Medically Administered Nutrition and Hydration

Katy M. Lanz, Michelle S. Gabriel,
and Jennifer A. Tschanz

Key Points

- For many people, food and drink are synonymous with care, but medically assisted nutrition and hydration should be considered a medical intervention rather than a basic form of comfort.
- Decreased appetite or inability to tolerate or enjoy food and fluids is a natural sign of advanced disease and can be a source of distress for patients, family, and caregivers.
- Discussions and decisions regarding initiating or withholding medically administered nutrition and hydration at the end of life are guided by goals of care, evaluation of benefits and burden, ethical and cultural considerations, and the beliefs and wishes of the patient and family. These wishes should be documented in an advance directive.
- It is medically and legally acceptable for patients or families to choose to voluntarily refuse any form of nutrition or hydration.
- Nurses caring for patients and families faced with the decision to start or withhold or withdraw medically administered nutrition and hydration (MAHN) are responsible for promoting patient autonomy, providing education regarding benefits and burdens of interventions, promoting informed decision-making based on values, and delivering quality care with the rest of the care team.
- It is not recommended to provide MAHN at the end of life, particularly for those with end-stage cancer.

Case Study: A Patient with Chronic Obstructive Pulmonary Disease

Mrs. M is a 68-year-old woman with end-stage chronic obstructive pulmonary disease (COPD) and progressive functional decline who lives at home with her husband of 50 years. In the past 3 months, she was admitted to the hospital twice for pneumonia, with one admission requiring mechanical ventilation. Her primary care physician has been worried about her continued weight loss, and, despite his efforts with steroids and appetite stimulants, she has continued to lose weight and no longer has the energy to eat. She weighs 80 pounds and has lost 45 pounds in the past 6 months. A home-based palliative nurse visited her in her home, and, during the visit, Mrs. M's husband brings up the fact she only drinks her protein shake twice a day and is no longer eating anything else. He was worried about her "starving" and asked that she consider a feeding tube to "help her get her strength back." Mrs. M had the capacity to make her own decisions. The nurse proceeded with a conversation about goals of care regarding medically administered hydration and nutrition.

Introduction

In the context of providing palliative care, decisions to initiate or withhold and withdraw the interventions of medically administered nutrition and hydration (MAHN) can be challenging for the patient, the family, and members of the healthcare team. For patients in palliative care who are in the last days to weeks of life there is little evidence that nutrition or hydration offers any benefit at this stage of illness. In many cultures, providing food and fluids is synonymous with caring, hope, and comfort.[1] Decreased appetite or inability to tolerate or enjoy food and fluids is often a hallmark of the terminal phase of an illness. Individuals and their families may ask for MAHN to address a variety of situations (e.g., fears of starvation, weight loss, and dehydration). Clinicians may recommend medically administered nutrition (MAN) or hydration in specific circumstances (e.g., malnutrition, dehydration, new onset of delirium). As with any palliative care intervention, the nurse needs to understand the patient's illness trajectory and patient and family goals of care, which can be influenced by a person's culture or religion. The nurse also needs to be familiar with the current evidence for MAHN for patients with advanced illness as nurses often participate in conversations regarding treatment options and have a critical role in supporting the patient in identifying interventions that best meet his or her goals.

Natural Fluid Deficits in Advanced Disease

Homeostasis of fluids is achieved in normal individuals by matching daily water intake and fluid loss. This match ultimately provides maintenance and balance for stable composition of body fluids. About 2,500 mL is the average amount of water consumed and lost per day. Fluid can be lost through kidneys, the gastrointestinal (GI) tract, lungs, and skin. Fluid deficits in terminal patients can have varying etiologies and be multifactorial. Regardless of the cause, the result is a naturally occurring fluid deficit disorder with both hypovolemia and dehydration.

As patients enter the dying process, it is most often characterized by diminished oral intake, progressive fluid deficits, and progressive accumulation of drugs, which can cause new symptoms or exacerbate existing ones (e.g., fatigue, dizziness, myoclonus, sedation, and hallucinations).[2,3] This phenomenon results in a further decline in the ability to drink fluids. During this phase, the evidence suggests diminished awareness, which may decrease the patient's perception of thirst and hunger.[4–6]

Medically Administered Nutrition

MAN is the provision of nutrition that involves non-oral enteral or parenteral delivery of nutrients. Enteral approaches include nasogastric (NG), percutaneous endoscopic gastrostomy (PEG), percutaneous endoscopic gastrostomy jejunostomy (PEG-J), or gastrojejunostomy (G-J) tubes.[2] Parenteral approaches include central or peripheral venous access.

MAHN is a medical intervention to address malnutrition, which has been linked to poorer outcomes such as increased mortality, infections, and pressure ulcers.[3] Malnutrition occurs when the body does not get the nutrients it needs.[7] Causes of malnutrition include an inadequate diet, mechanical issues with digestion or absorption of nutrients, and specific medical conditions.[8] In patients with advanced chronic disease or terminal illness, specific causes for malnutrition may result from anorexia, cachexia, and physiological issues. When caring for multimorbid patients with advanced disease there are often a myriad of etiologies for malnutrition and fluid electrolyte imbalances. The hospice and palliative nurse plays an integral role around assessment, treatment, support, and ongoing evaluation for patients contemplating MAHN. Anorexia manifests with a decrease in appetite, which can lead to a loss of fat tissue. The weight loss that results can be reversible depending on the underlying causes. Many patients with advanced illness experience anorexia.[4] Cancer cachexia is a multifactorial syndrome in which there is loss of skeletal muscle that cannot be completely reversed by nutritional support, resulting in a negative impact on functional status.[8] Mechanical issues include malignant bowel obstruction and dysphagia.

Benefits and Burdens

While the benefits of MAN are clearer in patients who are expected to recover, they are not as clear in patients who have advanced chronic illness or who are terminally ill.[9] The expected benefits include improving a patient's nutritional status to alleviate distressing symptoms resulting from malnutrition; however, MAN in the palliative care setting does not always have a positive impact. In amyotrophic lateral sclerosis (ALS), there are guidelines recommending the use and timing of MAN since malnutrition and weight loss are prognosticators for survival.[10–12] In patients with cancers of the oropharynx or esophagus, MAN may be appropriate earlier in the disease trajectory, especially when the cause of malnutrition is directly related to the inability to maintain intake due to mechanical blockages and acute treatment effects (e.g., mucositis secondary to chemoradiation).[13] For patients in a permanent vegetative state (PVS), life expectancy can be extended by months to years.[14] Outside of these clinical diagnosis and settings, studies indicated that MAN has no effect on prolonging life or improving functional status in advanced illness.[15]

Table 15.1 Potential complications of enteral support

Complication	Symptom	Cause
Aspiration	Coughing	Excess residual
	Fever	Large-bore tube
Diarrhea	Watery stool	Hyperosmotic solution
		Rapid infusion
		Lactose intolerance
Constipation	Hard, infrequent stools	Inadequate fluid
		Inadequate fiber
Dumping syndrome	Dizziness	High volume
		Hyperosmotic fluids

A study looking at whether clinical, functional, or nutritional indices could determine if patients would benefit from MAN found that comorbidity, cognitive function, and social function could predict a patient's success with MAN.[16] This same study found that predictors of the ineffectiveness of MAN on clinical outcomes included severe cognitive impairment and frailty.

While there may be some benefit in certain populations with end-stage diseases, enteral and parenteral feedings are interventions with the potential for associated morbidity and increased suffering. Patients and families worry about anorexia and believe MAN to be beneficial to address both physical and psychosocial symptoms.[17,18] Therefore it is critical for the nurse caring for these patients and families to not only review the benefits and burdens medically, but also to explain the long-term caregiving, financial, social, and emotional impact of long-term MAN.

Potential complications from the administration of MAN are listed in Table 15.1. Potential additional burdens include complications from tube placement, increased risk of infection or skin excoriation around the tube, and use of mechanical or pharmacologic restraints to preserve access.[19]

Malnutrition, Anorexia, and Cachexia

In many end-stage diseases, weight loss due to malnutrition, anorexia, or cachexia is a common occurrence. In cancer patients with persistent anorexia and cachexia, MAN has not been shown to reverse the weight loss.[20] It is commonly thought that weight loss may be secondary to the release of cytokines that increase protein degradation.[21] In one study looking at body mass index (BMI) as a specific marker of nutritional status, the provision of MAN helped to stabilize decreases in BMI for patients who were alive at the 3-month follow-up (10 out of 17 patients); however, the study did not measure quality of life (QOL) for the same population. [22] In the terminal phase of diseases such as cancer, MAN may not be metabolized in a way that would reverse the effects, and the intervention for palliative purposes is rarely recommended.[23,24]

Dysphagia

When a patient has difficulty swallowing, MAN may be considered to ensure that the patient receives adequate nutrition or to reduce the risk for aspiration pneumonia. In certain disease states, such as ALS and dementia, it is a matter of when, not if, dysphagia will occur. For ALS patients, the goal for enteral feeding is to improve the QOL and the preferred mechanism to deliver MAN, if indicated, is via a PEG tube.[25] The onset of dysphagia and the resulting weight loss are indications of when to start MAN in the ALS patient population.[12] Providers may consider initiating enteral feeds to reduce the risk for aspiration pneumonia due to "food going down the wrong way"; however, recent studies have shown that enteral nutrition does not reduce, and may increase, the risk for aspiration pneumonia.[20,26,27]

Hunger

Families often express concern about their loved one experiencing hunger or have fears about their loved one starving at end of life, yet patients will often deny sensations of hunger in the terminal phase. A study looking at the incidence of hunger in a terminally ill population found that most patients (63%) denied hunger on admission and did not report any hunger during the admission. Of the remaining patients, only 3% (one patient) reported hunger throughout the admission; the others complained initially, but the hunger disappeared over time. These patients were offered food by mouth as requested, and the small amounts they tolerated satisfied their hunger; none was given MAN.[4] In advanced cancer and dementia, hunger is not a symptom often experienced due to the natural disease process.

Pressure Ulcers

Patients who are malnourished are at increased risk for pressure ulcers, yet, at the end of life, there is no evidence to support the use of MAN to treat or prevent pressure ulcers.[20,26] One study showed that in patients with dementia, the use of a PEG tube to administer MAN was associated with an increased risk of developing new stage 2 pressure ulcers and a decreased likelihood of the healing of existing pressure ulcers.[29] Potential reasons for this association include risk factors such as increased likelihood of immobility due to the use of restraints that may be used to ensure that feeding tubes are maintained and potential for diarrhea due to the composition of the enteral feeds.[29]

Survival Time

There is no compelling evidence that MAN increases the survival of patients with end-stage diseases.[20,26] For patients with advanced dementia, studies do not indicate that MAN prolongs life.[27] The literature suggests that there is also no indication of improved overall function, prevention of aspiration, or reduced pressure sores.[30,31] One study found a median survival post–feeding tube insertion of 165 days and a 64% mortality rate, with half of those who died doing so within the first 2 months following insertion.[32] Another study compared the impact on survival time of PEG tube insertion or the timing of the insertion and found no impact.[33] Other studies have shown an increase in survival in specific populations. One study compared survival time in dementia patients in Japan who used self-feeding oral intake versus home parenteral nutrition or PEG feeding and found that the groups who used either home parenteral nutrition or PEG feeding survived almost twice as long.[33] In this study, patients were not in the end-stage of dementia, which may explain the longer survival time. Another study looked at whether dementia was a risk factor for survival after PEG and found no difference in survival between patients with dementia and patients without who received a PEG tube.[34] The authors did not include the stage of dementia in their analysis.

Quality of Life

There have not been many studies that specifically measure QOL for patients with end-stage illness receiving MAN. In a Cochrane review of enteral tube feeding in an older population with advanced dementia, there were no studies reviewed that measured QOL. Another Cochrane review found two studies that did not demonstrate improved QOL in both a population with motor neuron disease or with advanced cancer.[35] Patients and their families determine the impact of interventions such as MAN on QOL. Some studies have shown that patients and families perceive MAN to have a positive impact on reducing burden from physical and psychosocial symptoms, such as maintaining the fight against the disease, reducing anxiety due to anorexia, and alleviating symptoms. Other studies have looked at the use of MAN and the prevalence of interventions that may be thought to negatively impact QOL, such as the use of restraints. In studies looking at patients with dementia receiving tube feeds, MAN has been correlated with an increased use of restraints, either physical or pharmacological.[28,36] In a study assessing family members' perceptions of the impact of a feeding tube, only 32.9% of the people who responded stated that the intervention improved the patient's QOL.[37]

Summary

MAN has been shown to have a positive impact on survival and nutritional parameters in certain populations, such as earlier in the disease trajectories for ALS or some cancers. However, there is not enough evidence to support a specific recommendation on when or if, in a palliative care population, it is best to use MAN.[28] The individual patient's condition, along with the goals of care, needs to be considered to best determine the benefit of employing MAN compared to the burdens of the intervention.

Hydration

Medically administered hydration is the provision of water or electrolyte solutions by any route other than the mouth. This can be achieved by intravenous, subcutaneous (hypodermoclysis), and rectal (proctoclysis) administration.[37]

Hydration is an intervention used to address situations such as fluid deficits and altered mental status secondary to medication toxicities in advanced disease. Fluid deficit disorders include dehydration and volume depletion. *Dehydration* is intracellular water depletion with hypernatremia (hyperosmolality) and usually presents with symptoms of thirst, anorexia, nausea/vomiting, fatigue, and irritability. Physical findings may include lethargy, confusion, muscle twitching, and hyperreflexia. *Volume depletion* is the loss of intravascular water (with varying sodium levels) and presents with diminished skin turgor/capillary refill and orthostatic hypotension and dizziness.[29] Patients with advanced illness experiencing anorexia may also experience a loss of interest in drinking.[38] During the terminal phase, fluid deficits, similar to malnutrition, may result from anorexia/early satiety, nausea/vomiting, bowel obstruction, dysphagia, and cognitive impairment.[29,39,40]

Some patients and families believe that decreased oral intake and the ensuing dehydration causes suffering. Patients and families are concerned that dehydration may precipitate symptoms of delirium, confusion, myoclonus, somnolence, fatigue, neuromuscular irritability, restlessness, thirst, hunger, and constipation, especially in the presence of opioids, benzodiazepines, and neuroleptics.[41] There is limited information regarding the effects of hydration in addressing these symptoms. Many patients with advanced cancer and their caregivers perceive that hydration provides hope and comfort, improves symptoms and QOL, and fulfills a basic human need for water. Emphasis on the importance of taking the patient's specific diagnosis, wishes, and hopes into consideration when discussions about medically administered hydration arise is imperative.[42]

When considering hydration, it is important to consider where the patient is on the disease trajectory (e.g., acutely ill or in the dying phase) to help establish goals of care. Hydration can be used for the temporary relief of symptoms of fluid loss such as nausea, vomiting, diarrhea, and fevers; to decrease fatigue; to improve mental cognition status associated with medication toxicities; and as a respect to cultural and familial beliefs.

Methods of Administration

There are various alternative routes to oral administration to meet the goals of care and wishes of the patient and family. Standard methods for replacement of fluids, similar to nutrition, can be achieved by the use of enteral feeding tubes and parenteral methods, such as subcutaneous or intravenous infusion.

Intravenous access requires a competent vein. Clinicians may use permanent access devices if they have previously been placed or if ongoing hydration is anticipated. *Hypodermoclysis* is the subcutaneous infusion of isotonic solution. It does not require special access devices and can be used for patients who have poor venous access for intravenous placement. The absorption of the subcutaneous fluids has been found to be comparable with absorption of intravenous fluids when administered appropriately.[37,39] *Proctoclysis* is used to administer water or saline into the GI tract via the rectum using a nasogastric tube. Researchers have found proctoclysis to be safe and economical, but there has been cultural and social reluctance to accept this mode of administration.[41]

There is no consensus regarding the volume or type of fluid replacement. Clinicians make choices based on previous experiences and knowledge of the patient's condition and wishes. Some providers allow the individual to have 1 L/day even though it may be inadequate replacement. Risks and burdens must be considered (Table 15.2).

Table 15.2 Potential complications of routes for medically administered hydration

IV Peripheral	IV Central	SC Hypodermoclysis
Pain	Sepsis	Pain
Short duration of access	Hemothorax	Infection
Infection	Pneumothorax	Third-spacing
Phlebitis	Central vein thrombosis	Tissue sloughing
	Catheter fragment thrombosis	Local bleeding
	Air embolus	
	Brachial plexus injury	
	Arterial laceration	

IV, intravenous; SC, subcutaneous.

Benefits and Burdens

The decision for hydration needs to include an evaluation of goals of care, discussion of the risks and benefits, and timely reevaluation to determine if goals or symptoms are improving or worsening. Insurance coverage, impact on healthcare benefits, social impact, and maintenance of administration should be carefully evaluated and requires input from the other healthcare team members. Risks for overhydration, as evidenced by worsening fluid retention, signs of increased shortness of breath, increased emotional distress, or change in mental status, must be monitored. Advantages of not providing medically administered hydration can include reduced urine output, leading to reduced incontinence and need for catheterization; reduction of GI secretions, leading to decreased incidence of vomiting; and decreased respiratory tract secretions, leading to decreased cough and need for suction.[41]

Factors arguing against initiating hydration include increasing the incidence of pulmonary and peripheral edema and increased respiratory tract secretions, cough, and ascites.[41–43] Starting intravenous hydration can cause pain, be distressing, restrict mobility, hinder family contact, and increase the use of restraints.[44]

Review of the Literature

Dehydration and Fluid Retention

Dehydration can cause unpleasant symptoms such as confusion and restlessness in non–terminally ill patients.[45] These problems are common in the dying. There is limited research regarding the effect of hydration on alleviating dehydration at the end of life. Results can be challenging to interpret due to the ways various studies define and measure dehydration. Findings suggest that providing medically administered hydration may or may not affect physical signs and symptoms of dehydration at the end of life. One study demonstrated no difference in hydration status after 7 days between advanced cancer patients who were given 1,000 mL/day versus 100 mL/day. The same study also scored four dehydration symptoms (fatigue, myoclonus, sedation, and hallucinations) and noted no difference in the sum of the scores after the 7-day hydration trial.[46] A retrospective chart review study showed that medically administered hydration in the last 48 hours of life had no significant impact on symptoms related to hydration status (e.g., agitation, myoclonus, urinary retention, confusion, congestive cardiac failure, respiratory tract secretions, nausea and vomiting, and ascites).[41] These findings suggest that there is no benefit of hydration during the terminal phase.

Depending on the volume of hydration administered, hydration may increase the risk of developing fluid retention symptoms. In a study that measured the effect of hydration volume on terminally ill cancer patients with abdominal malignancies, dehydration was evaluated based on physical findings that included moisture on the mucous membranes of the mouth, axillary moisture, and sunken eyes within 72 hours of death. Patients in the hydration group who received 1,000 mL or more of medically administered hydration per day 1 and 3 weeks before death were found to have less deterioration in dehydration symptoms than the nonhydration group who received on average less than 1,000 mL of medically administered hydration over the 3 weeks prior to death. However, the patients who were in the hydration group were noted to have increased symptoms of overhydration such as edema, ascites, and bronchial secretions. No difference was noted between the groups regarding pleural effusion.[46] These findings are similar to a study that showed increased dehydration status in the nonhydration group who did not receive hydration and increased fluid retention symptoms of peripheral edema and ascites in the hydration group.[44] A prevalence of bronchial secretions in the last 48 hours of life was noted more in the large-volume group that received more than 1,000 mL hydration per day compared to those in the small-volume group that received less than 1,000 mL/day.[47]

A national guideline for parenteral hydration therapy was established in Japan in 2007 that encouraged respecting patient and family wishes, conducting a comprehensive assessment of patient's QOL, allowing for total parenteral nutrition to be administered if bowel obstruction was present, and recommending that hydration be decreased to less than 1,000 mL/day if fluid retention signs were present.[48] A study to measure the efficacy of this guideline demonstrated that providing hydration to patients with advanced cancer according to the guidelines led to stable measurements in global QOL, discomfort, most physical symptoms, and fluid retention signs.[49]

Thirst and Dry Mouth

Thirst is thought to be a nonspecific symptom of dehydration. One study looked at interventions for thirst and dry mouth as an alternative to hydration. Researchers found that routine care, defined as offering food and fluids, administering ice chips, and providing mouth care, helped to alleviate these symptoms.[4,47] Dry mouth is treated with an intensive, every 2-hour schedule of mouth care, including hygiene, lip lubrication, and ice chips or popsicles. Elimination of medications that cause dry mouth, such as tricyclic antidepressants and antihistamines, should be considered. Sometimes, drugs that contribute to these symptoms are being administered to palliate other symptoms, such as the opioids for pain and anticholinergics to minimize oral secretions. Mouth breathing can also contribute to dry mouth. *Candida* infection, a frequent cause of dry mouth, can be treated. Agents such as pilocarpine can be used to increase salivation.

In one study, hydration was shown to alleviate symptoms of dry mouth in patients with advanced cancer who have a relatively longer prognosis. It was noted that dry mouth intensity decreased significantly in the group receiving a large volume of hydration (1,000 mL/day or more) than those in the small-volume group (less than 1,000 mL/day). This same group also experienced a higher incidence of bronchial secretions.[49]

Delirium, Confusion, Agitation

Delirium can be caused by multiple factors including end-organ failure, dehydration, and medications. Symptoms of delirium can be distressing for patients and families. In advanced cancer patients, no significant difference in delirium and agitation was noted between patients receiving more hydration than less hydration.[46,48]

Medications such as opioids, anticholinergics, antihistamines, and corticosteroids have been known to impact delirium. If delirium is related to the accumulation of opioids, interventions to decrease or rotate opioids and to increase hydration are believed to control the symptoms of hyperactive delirium, such as agitation and hallucinations of opioid-induced neurotoxicity, by assisting with the clearance of toxic opioid metabolites.[49]

Myoclonus

Myoclonus, or involuntary contractions of muscles, is commonly associated with chronic opioid use at the end of life. It has also been reported in cancer patients without opioid use who are experiencing decreased oral intake.[39] There is limited and mixed information regarding the effects of hydration on myoclonus depending on patient setting. Myoclonus was shown to improve in the intervention group who received 1,000 mL normal saline over 4 hours for 2 days versus 100 mL.[51] However, no difference in myoclonus symptoms was noted between patients with advanced abdominal malignancies in the hydration group who were given on average 838 to 1,405 mL/day during the last 3 weeks of life and in the nonhydration group who received an average of 200 mL/day.

Survival Benefit

There is limited research regarding the survival benefit of hydration. Two studies noted that hydration provided no survival benefit for terminally ill cancer patients with short prognosis.[46,48]

Quality of Life

There is limited research regarding the impact of hydration on QOL in the terminally ill. Research on patients with advanced cancer shows that parenteral hydration of 1,000 mL/day did not improve symptoms associated with QOL over placebo of 100 mL/day.[50] Another study showed that QOL measurements remained stable when hydration was administered according to Japanese guidelines that took into account QOL and symptoms of fluid retention whether patients received small (<1,000 mL/day) or large (>1,000 mL/day) volumes of hydration.[49] In a study that interviewed patients with advanced cancer and their caregivers, both patients and their caregivers perceived hydration as fulfilling the basic human need for water, promoting hope and dignity, and enhancing QOL. Caregivers in the same study reported that hydration improved pain management and that the patient had more energy, better sleeping habits, an improved appetite, and a healthier physical experience. The study did not include information on volumes or duration of hydration.

Summary

Parenteral hydration has been found to be effective in temporary, short-term situations to alleviate symptoms related to dehydration and improve mental cognition. In the palliative care setting, research does not support that parenteral hydration improves signs of dehydration, survival, or QOL. In the setting of delirium related to opioid toxicity, there is mixed evidence supporting hydration and possible opioid rotation to improve delirium symptoms. When deciding to initiate or stop hydration, it is important to assess goals of care, risks and benefits, and the patient's preferences related to his or her values and needs.

Case Study: A Patient on Dialysis

Mr. D is a 54-year-old man with dialysis-dependent renal disease. He was sent to the emergency room from his dialysis center secondary to lethargy and confusion. He lives independently at home and has no advance directives. After an evaluation, he was found to be dehydrated and was given a slow infusion under observation at the hospital. Once he returned to baseline, he was sent home. One month later, Mr. D had decompensated with functional and nutritional decline. His primary care provider referred him to the community-based palliative team. He was visited by his palliative nurse practitioner at home, and Mr. D explained that he no longer wanted to go back to the hospital for any form of treatment. His daughter was worried that, if he became dehydrated again, she would be unable to get him fluids and insisted that he go if he needed them.

Review of Position Statements and Guidelines

Many professional organizations have published position statements or guidelines on the use of MAHN. Common themes across these documents include:

- MAHN is an intervention that should be evaluated by the patient, family, and care team with careful consideration of its benefits and burdens.[52,53]
- MAHN is considered a medical intervention that can be refused, withheld, or withdrawn based on the patient's clinical condition and goals of care.[28,54]
- Decisions about MAHN need to reflect the patient's and family's values, beliefs, and culture.[54]

In addition to general position statements regarding MAHN, disease-specific recommendations are summarized in Table 15.3.

Decision-Making and MAHN

Decisions about the initiation or withholding and withdrawing of MAHN are complex.[54] In addition to the review of the clinical evidence regarding the efficacy of MAHN to improve symptoms and QOL, it is important to consider ethical principles and legal precedents that highlight the role nurses have in advocating for the patient as well as their responsibilities in respecting patient and family wishes. While the withdrawing of medically administered nutrition and/or hydration may cause more emotional distress for clinicians as well as for patients and their families than withholding such treatment, there is no ethical or legal distinction between them.[2] When decision-making is difficult or complicated by a particular goal or value, a short goal-based trial can be offered with the intention of temporary support being emphasized. In this circumstance, the patient should be routinely assessed for adverse effects of the MAHN intervention (Table 15.4).

Ethical Issues

Initiating or withholding or withdrawing MAHN, like other medical interventions, needs to be done utilizing ethical principles. The three ethical principles that are most relevant in decision-making for MAHN are autonomy, beneficence, and nonmaleficence.[55] Autonomy refers to the patient's or surrogate's right to self-determination. Respecting autonomy in decisions about MAHN means that a patient or family has the choice to accept or refuse the intervention based on their personal values and beliefs.[55] Beneficence means "to do good" and implies that nurses must act in the interest of the patient.[55] The nurse has a responsibility to engage the patient and family in a conversation about what "good" looks like, respecting the individual's values and goals for care. For example, a patient with end-stage cancer may be experiencing dysphagia yet still finds enjoyment in small sips of liquid. While the risk for aspiration exists in this situation, the nurse would exhibit beneficence by supporting the intake of fluids. Nonmaleficence means "to do no harm" and can be exemplified by not administering treatments that increase the risk of suffering and have no benefit or whose benefit is less than their burden (Table 15.5).[55]

Table 15.3 Disease specific guidelines for medically administered nutrition and hydration (MAHN)

Advanced Dementia[21]	◆ Feeding tubes are not recommended. ◆ Enhance oral feedings by improving the environment and supporting patient-centered approaches.
End-stage Cancer[18,19]	◆ Use of nutritional support for terminally ill cancer patients is not usually indicated.
ALS[20]	◆ Early insertion of a feeding tube is recommended if enteral feeding is determined to be an appropriate intervention.

Legal Precedent

Landmark cases such as the Quinlan case, Cruzan case, Barber case, and *Vacco v. Quill* have set the foundation for current decision-making regarding MAHN within the healthcare system. Karen Ann Quinlan was 21 years old when she was deemed to be in a persistent vegetative state due to anoxic brain injury. Her father sought guardianship to cease "extraordinary" measures keeping her alive.[56] In this case, the court supported the standard of substituted judgment, enabling her father to speak for her as if she could speak for herself.[57] Nancy Cruzan was thrown from her vehicle in a car accident. Although found by the paramedics with no pulse, they were able to resuscitate her. She was in a coma for several weeks before being determined by her physicians to be in a persistent vegetative state.[58] In her case, the court supported the right to refuse treatment for competent individuals. The court also supported the need for "clear and convincing evidence" since she was incompetent and had not previously recorded her wishes. This case helped to support the federal Patient Self-Determination Act passed in 1991 in an effort to help patients document their wishes.[59] The *Vacco v. Quill* case also supported the right to refuse treatment, distinguishing respecting patient wishes from intentionally hastening death.[59] In the Barber case, the court found two physicians who had discontinued MAHN to be innocent from charges of murder and conspiracy to commit murder, reinforcing the precept that MAHN is considered a medical intervention and not basic care.[59]

Religious and Cultural Issues

To deliver patient-centered care, nurses must recognize the role that religious or spiritual beliefs and culture, including race and ethnicity, play on patient and family values surrounding food and fluids. Understanding these factors and encouraging a dialog about patient values will enable nurses to respect patient autonomy and engage in a dialog of how to meet patient needs regarding nutrition and hydration to maximize beneficence ("to do good") and minimize nonmaleficence ("to do no harm"). Integrating other care team members with experience in this area can be extremely helpful to all stakeholders. In particular, social work and chaplain support will assure that patient and family psychosocial and spiritual needs are met.

In reviewing the common beliefs of various religious traditions and cultures, it is important to remember that not everyone of a particular faith or a particular culture will have the same beliefs,

Table 15.4 Hydration and/or nutrition in advanced illness or end of life: Key studies

Author, Year, Design	Sample Size and Characteristics	Variables Evaluated	Results	Overall Impact of Hydration
Nakajima, Hata, Kusumuto, 2013 Observational Study	75 terminally ill patients with GI malignancy	Hydration score	Dehydration score was higher in nonhydration group (35% vs. 13%, p. 03); edema/ascites/bronchial secretions higher in hydration group (57% vs. 33%, p. 04)	No benefit secondary to adverse effects
Bruera, Hui, Dalal, et. al, 2013 Randomized Controlled Trial	129 patients in hospice care	Symptoms for dehydration, delirium, myoclonus, and survival	No difference between treatment and control groups in delirium, dehydration	Negative
Morita, Hyodo, Yoshimi, et al, 2005 Prospective Controlled Trial	226 advanced cancer patients (59 hydrated and 167 non-hydrated)	Dehydration and fluid retention symptoms	No significant difference in dehydration or retention symptoms	Negative
Bruera, Sala, Rico, et al, 2005 Randomized Controlled Trial	60 dehydrated patients with advanced cancer	Symptoms of dehydration	Mixed for sedation and myoclonus improvement, composite score for fatigue, hallucinations	Mixed
Morita, Tei, Tusnoda, et al, 2001 Observational Study	88 terminally ill cancer patients in hospice	Assessment using visual analogue scale (VAS) on symptoms of thirst	No correlation of thirst scores	Negative
Cerchietti, Navigante, Sauri, Palazzo, 2000 Randomized Controlled Trial	42 advanced cancer patients who were dehydrated	Thirst, nausea, delirium and mini-mental status exam (MMSE), anguish, mood	No significant differences in groups	Negative
Ellershaw, Sutcliffe, Saunders, 1995 Observational Study	82 cancer patients two days before death	Thirst, respiratory secretions, dry mouth	No correlation between hydration status and thirst	Negative
Musgrave, Bartal, Opstad, 1995 Uncontrolled Trial	30 cancer patients in the last day of life	Thirst level	All patients who were alert experienced some level of thirst.	Negative
McCann, Hall, Groth-Juncker, 1994 Uncontrolled Trial	32 terminally ill patients who were mentally aware	Thirst, hunger, and dry mouth	63% no hunger, 34% initial hunger only, 62% no thirst or initial thirst	Negative
Waller, Hershkowitz, Adunsky, 1994 Observational Study	68 cancer patients within 48 hours of death, 13 received fluids	Consciousness	No correlation in improvement of consciousness and administration of fluids	Negative

and nurses should inquire as to how much influence a patient's faith or culture has on his or her beliefs regarding MAHN. Clinicians should be aware that some religions may view voluntary cessation of hydration and nutrition as an intentional and forbidden shortening of life. Even within religions, there can be varying opinions or interpretations of religious law to guide decisions on whether to initiate or withdraw MAHN. Table 15.6 summarizes beliefs by selected religious traditions specific to MAHN.

In addition to religious influences, culture also affects patient and family perspectives on MAHN. Studies have shown variance associated with race in the use of tube feedings, with Caucasians having lower rates than people of other cultural backgrounds.[60] In studies

Table 15.5 Medically administered nutrition and hydration (MAHN): Examples of nursing interventions that reflect ethical principles

Ethical Principle	Nursing Actions
Autonomy: Respecting an individual's right to make choices regarding care	Encourage a conversation that provides information on the benefits and burdens of MAHN to empower the patient to make an informed decision. Focus on patient's preferences, especially when working with family and caregivers. Ask, "Did we do everything to meet the patient's goals?" not "Did we do everything possible?"
Beneficence: "To do good"	Seek to understand the patient's goals and values to understand what "good" means for them. Provide interventions that match with patient goals.
Nonmaleficence: "To do no harm"	Evaluate the potential risks or burdens of MAHN to minimize harm, taking into account the patient's values.

Table 15.6 Various religious beliefs about medically administered nutrition and hydration (MAHN)

Religious Faith	Beliefs
Buddhism[1]	◆ Belief that all beings suffer. ◆ Main focus at end of life is on spiritual comfort. ◆ Less focus on extending life through MAHN and other interventions.
Catholicism[2,3]	◆ Current position (as of 2011) focuses on "life prolongation based on fundamental human dignity." ◆ Some within the church assert that MAHN is not considered a medical technology, but an ordinary measure to preserve life. ◆ Others feel that MAHN should be evaluated using the proportionate/disproportionate framework (ordinary vs. extraordinary) on an individual basis. ◆ Catholic healthcare facilities are obligated to offer food and fluids regardless of disease state. ◆ MAHN can be considered extraordinary in conditions where the underlying disease would be the cause of death, not the withholding of MAHN.
Hinduism[1]	◆ Withholding or withdrawal of MAHN at the very end of life is acceptable. ◆ Some Hindus fast to prepare for death.
Islam[4]	◆ "Guiding purpose of Islamic law is to protect and preserve religion, life, progeny, intellect, and wealth." ◆ Islamic rules regarding care for terminally ill are based on the principle that one should prevent or avoid injury or harm. ◆ Islamic law permits withdrawal of MAHN and allowing the disease to take its natural course. ◆ There can be various beliefs among Muslims, so it is necessary to ascertain the patient's values. ◆ "Islamic law states that palliative care should not shorten a patient's life, but futile treatment is not justified." ◆ "Islamic law forbids passively or actively causing death." ◆ Nutritional support is considered basic care and not medical treatment, leading to a duty to feed patients who are no longer able to feed themselves. ◆ Varied opinion among different Islamic communities regarding withdrawing and withholding MAHN.
Judaism	◆ Provision of food and fluids are considered ordinary measures, not extraordinary. ◆ Withholding food and fluids is not consistent with Jewish law. ◆ Administration of food and fluids, even via IV or feeding tube, is not considered to be artificially administered. ◆ "The religious authorities hold that [MAHN is] ordinary supportive measures rather than heroic."[5] ◆ Terminal dehydration, hospice without provision of MAHN, and withdrawing or withholding MAHN is not considered aligned with Jewish teaching unless there is proof of *goses* (less than 72 hours until death) and futility of intervention under any denomination of Judaism. ◆ "While the [Israeli] law respects the right of a competent dying patient to refuse nutrition and hydration, it introduces a legal requirement to persuade 'the use of oxygen, nutrition and hydration,' even by artificial means."[6]
Protestantism	◆ There is diversity in positions regarding MAHN across denominations. ◆ Common belief that interventions such as MAHN that allow time for repentance may outweigh other burdens of treatment.

looking at the use of feeding tubes between white subjects compared to African American subjects, use was consistently higher in the latter group.[61] Studies have also shown that African Americans have a stronger preference for more intensive care.[62] One study looked at preferences between African American and Caucasian participants using focus groups, assessing for factors that might affect decisions about care at end of life, including MAN. From the qualitative data gathered in the focus groups, the researchers found more similarities than differences in how the two groups thought about food, AN, and decision-making at end of life.[62] The differences were not by category, but more on focus within common themes.[62]

In a study looking at what meaning Singaporean Chinese caregivers attributed to feeding, the researchers found three major themes emerge. One theme was a sense of filial piety, where duty to one's family may motivate a push for more aggressive interventions even if the patient is at the end of life. Another theme was the link between providing nutrition and hope. A third theme was that providing food showed caring for their loved one, a theme common across many cultures.[63]

While there is not a large body of research on how differing religious and cultural backgrounds influence individual preferences for MAHN, there are resources that nurses can access to learn the information needed to initiate a conversation with a patient on this issue. Whether it is through position statements from religious organizations or talking to leaders within a religious, tradition, or ethnic community, nurses can seek to understand how these factors play a role in each specific situation with the patient for whom they are caring.

Engaging in Conversations and Goals of Care about MAHN

In working with palliative care and terminally ill patients, nurses play a pivotal role in exploring a patient's values and hopes to ensure that care related to the provision of food and fluids is person-centered. Because decisions about MAHN are complex, nurses have multiple responsibilities. Nurses need to self-reflect, understand the literature, understand the position statements, understand the prognosis, and thoroughly assess the patient and family unit as a whole prior to making a nursing plan or recommendations.

One of the primary tasks of the nurse is to ensure that a patient's autonomy and dignity is respected in a way that is culturally acceptable to the patient by understanding the patient's values regarding MAHN and the broader goals that the individual is hoping to achieve. This task can be accomplished by promoting early conversations regarding patient and family preferences. The focus should be on the patient as the decision-maker, even if the patient is not participating in the conversation. While open-ended questions may encourage exploration of knowledge and understanding of patient and family hopes, focused and directed questions regarding preferences may guide patients and families to more concrete goals and decisions. Two important questions to consider in the decision-making process regarding MAHN are (1) What are the views and preferences of the patient? and (2) What are the individualized goals of care? Having an evidence-based goals of care framework that addresses both short- and long-term goals and the feasibility of those goals can be helpful. A challenge in performing this task arises when patient and family preferences conflict with a nurse's or health care team's preferences for treatment. The focus of discussions should be "Did we do everything to meet the patient's goals?" not "Did we do everything possible?"

Additionally, nurses can empower patients and families by educating them about the normal symptoms of the dying process and the known benefits and burdens of MAHN as an intervention to effectively treat symptoms associated with dying. To facilitate informed decision-making, education can focus on symptoms and progression of the normal dying process, available options for MAHN, and known benefits and burdens of MAHN interventions, as well as the limitations of evidence supporting MAHN in managing some symptoms and alternative options to treat distressing symptoms. Patients and families should also be informed that MAHN can be withheld and withdrawn. If a nurse is unable to provide appropriate information, the nurse should feel comfortable with saying "I do not know" over providing false reassurances.[62] It is recommended that the nurse seek counsel from available resources such as the primary team, the interdisciplinary team, or the palliative care team and then return to the patient and family with information. By providing this care coordination, the channels of communication are opened between individuals caring for the patient and will allow for improved alignment as a team in supporting complex care decisions.

Initiating and Withdrawing or Withholding MAHN

If the decision is made to initiate MAHN in a patient to meet the goals of care, the nurse has a responsibility to continually assess the patient's condition, evaluating the impact of the intervention on symptoms and the patient's responses to treatment. MAHN can be offered as a time-limited trial to determine whether the patient experiences any benefits from the intervention compared to burdens. As MAHN is often instituted during an acute event while in the hospital, nurses can inquire about previous medical history or expressed wishes and promote conversations that look at the bigger picture beyond the acute admission.[64] Nurses in any setting can inform patients and families early in the disease continuum of the progression of the illness and ensure that wishes are elicited and documented by the healthcare team regarding MAHN. The nurse needs to facilitate ongoing conversations about MAHN to ensure that the role of this therapy continues to meet patient and family goals without excessive burden.

If the decision is made to either withdraw or withhold MAHN, the nurse can provide emotional support and assurances that the patient's dignity will be respected with comfort care. If the patient is able, it is OK to gently encourage oral intake if it is compatible with the patient's overall goals. If eating and drinking becomes too difficult or requires too much effort, the patient should not be pressured. Alleviation of symptoms of dry mouth and thirst should be a focus and can include gentle oral cleaning, ice chips or popsicles, moistened sponges, lip moisturizer, and artificial saliva.[50,65] If unable to support a patient or family's decision regarding MAHN for religious or personal reasons, it is the responsibility of the nurse to request a change in assignment and for the healthcare system to ensure that a nurse who is comfortable in these situations can provide patient-centered care when MAHN is being withheld or withdrawn.

Conclusion

Food and fluid requirement changes in the terminally ill are frequently multifactorial in etiology and a naturally occurring, expected phenomenon. MAHN should be considered an intervention, rather than a basic provision of comfort. When a patient experiences a decreased desire to eat or drink as part of the end stage of illness, the patient along with the family may struggle to seek interventions to extend life, reduce the impact of possible symptoms such as hunger or dehydration, or fulfill a religious or cultural need at the end of life. Decisions about MAHN are complex and must be guided by the ethical principles of autonomy, beneficence, and nonmaleficence. Nurses need to understand the factors, such as religion and culture, which influence a patient's preferences. Nurses need to provide accurate and complete information about the benefits and burdens of MAHN to both the patient and other care team members. In doing so, nurses will ensure that decisions to initiate, withhold, or withdraw MAHN will be patient-centered. When the patient is no longer taking in hydration or nutrition in any form, nurses must be attentive to comfort and support for both the patient and family.

CHAPTER 16

Dyspnea, Cough, and Terminal Secretions

DorAnne Donesky

Key Points

- Dyspnea management incorporates both attention to correction of the physiological defect causing dyspnea and interventions aimed at the common neurological pathway for dyspnea.
- People living with chronic dyspnea or cough should be encouraged to notice what works well for them in managing those symptoms using "*N* of 1" trials and then implement those strategies whenever the symptom recurs.
- Terminal secretions do not seem to bother the patient but can be distressing for family, friends, and caregivers. Education that normalizes the condition and reassures observers that the terminal secretions do not cause discomfort for the patient is important for minimizing distress of those who observe the condition.

Introduction

Breathing is the one vital body function that can be controlled consciously or can continue without any awareness or thought, completely subconsciously, when conscious attention is placed elsewhere. The breath is the focus of many spiritual traditions and serves as a bridge between the conscious and subconscious mind.[1] Attention to the breath as a method to optimize well-being has been documented since ancient times.[2,3] Conscious breathing is used to release stress and tension, build energy, support emotions, manage symptoms, improve physical and mental performance, and facilitate spiritual transformation.[4] Breathing is an important component of many mind–body therapies including yoga, guided imagery, and somatic grounding.[5] The respiratory system is a topic of interest for both popular self-help authors and basic, translational, and clinical researchers who are searching for ways to optimize the health and minimize the symptoms of patients living with serious illness.

We take breath for granted, we rarely think about it, but when something goes awry, it is the cause of serious panic and fear. Difficulty breathing feels dangerous and like a sign of impending suffocation in the setting of chronic lung disease.[6] Patients tend to stop their activity if they perceive danger, which leads to deconditioning and increased dyspnea over time in the vicious cycle of inactivity.[7] Patients with chronic dyspnea related to severe cardiopulmonary disease may live with dyspnea for many years and experience the stigma of a debilitating invisible disability.[8] Dyspnea correlates with mortality more than other measures such as pulmonary function.[9] Given its impact on depression, mortality, and quality of life (QOL), the importance of dyspnea has been recognized with the description of dyspnea as "the first vital symptom."[10]

The metaphorical significance of dyspnea has been recognized by the Life of Breath project (https://lifeofbreath.org/), which explores breath at the intersection of medicine, art, and the humanities—a medical humanities approach. The disciplines of anesthesia and engineering may also supplement the traditional work of pulmonology and palliative care in offering a new perspective on dyspnea management.[11] The purpose of this chapter is to review the current understanding of the pathophysiology, assessment, and management options for people living with serious illness who experience dyspnea, cough, or terminal secretions.

Dyspnea

Terminology of Breathing

Breathlessness, shortness of breath, and dyspnea are often used interchangeably when talking about the difficulty of breathing experienced by patients living with serious illness. Other terms include labored breathing or breathing discomfort. Dyspnea can be categorized into three primary groups. "Work" or "effort" is often used to describe the sensation of patients with impaired or fatigued respiratory muscles.[2] "Chest tightness" is used to describe the dyspnea experienced in asthma.[12] "Unsatisfied inspiration" or "air hunger" describes the sensation at the end of exercise or when breathing high levels of carbon dioxide.[13] In addition, breathless patients report anxiety, distress, discomfort, fear, and other negative terms when describing their breathing experience.[14]

The nomenclature for dyspnea continues to develop. Dyspnea can be acute or chronic, continuous or episodic, with variation in the timing and coping response.[15] Evidence is beginning to accumulate that chronic breathlessness, previously called *refractory breathlessness*,[16] is a distinct syndrome with unique neural activity in the brain which persists after treatment of underlying disease.[17] *Dyspnea crisis* is a term used for patients whose dyspnea overwhelms their ability to cope, but who do not want to return to the emergency department and undergo intubation and mechanical ventilation.[18] These crises often happen in the context of a patient who is living with chronic breathlessness.[15] The pattern of dyspnea is unique with each individual and includes both continuous and breakthrough dyspnea.[14]

Patient Experience

Dyspnea is one of the most distressing symptoms at the end of life[19] and occurs in the majority of patients diagnosed with chronic obstructive pulmonary disease (COPD), lung cancer, or heart failure.[14] Dyspnea is frequently also present in community-dwelling older adults who do not have any of the diagnoses traditionally associated with dyspnea.[20] The trajectory of dyspnea is distinct according to diagnosis; patients with COPD often experience moderate to severe fluctuating dyspnea for months with little change as death approaches, while many patients with cancer experience increasing dyspnea as they approach death, even if the cancer is not in the lungs.[21]

When people are living with chronic lung disease, their life can begin to revolve around their breathing needs. The case study details the personal experience of a woman living with idiopathic pulmonary fibrosis (IPF). Along with the dyspnea, there are many logistical challenges to living with chronic lung disease and dyspnea—the need for oxygen and coordination with the medical equipment company, learning to use an oximeter, potential weight gain or loss. Self-care activities focus on managing the physical manifestations of the illness, coping with the psychological effects, minimizing the social burden of the illness, and developing the knowledge and skills necessary to interact wisely with the health-care team.[22] Patients often feel stigmatized and blamed for their disease because of the association between smoking and lung disease, and the insidious onset of the disease often interferes with early initial treatment.[8] The uncertainty of the symptom contributes to fear and difficulties with coping.[14] Chronic breathlessness is frightening and distressing for both patient and family,[14] but evidence-based multidimensional interventions can provide relief.[23,24]

Case Study: A Patient Living with Idiopathic Pulmonary Fibrosis

Robin was 54 years old when she first noticed that it was difficult to take a deep breath. She was on a ski vacation and attributed it to the elevation. She developed a dry cough that was not responsive to treatment, and 5 years later, some abnormalities ("honeycombing") showed up on her chest x-ray. After several false diagnoses, she was told that she had idiopathic pulmonary fibrosis and enrolled in a clinical trial of an antifibrotic medication.

At first, the persistent cough didn't change much. She felt more fatigue and decreased stamina rather than shortness of breath, but 5 years after diagnosis, she first noticed shortness of breath while showering. For the next 7 years, she experienced progressively increasing bouts of dry cough and shortness of breath triggered by less and less activity. The dry cough got longer, more frequent, and intense. She began to use supplemental oxygen, cut down on her volunteer activities, and carried an oximeter with her.

Robin contracted influenza in January 2017, and she was left with a constant cough and sensation of sputum in her lower lobes. Her oxygen requirements increased considerably, she began to cough uncontrollably while walking, and she began to breathe through her mouth as she didn't feel like she could get enough air when breathing through her nose. She developed atrial tachycardia, which caused wide fluctuations in heart rate. During these episodes, she found that forcing herself to cough and laying on her bed with her head hanging over the side, below the level of the heart, would help her regain her equilibrium. She used large quantities of guaifenesin, nose blowing, water, and rest.

In the month before she died in November 2017, at the age of 68, she was very short of breath with minimal activities, and she required 10–15 L/min of oxygen to maintain an oxygen saturation of 90%. She was coughing at least hourly, and the coughing episodes lasted 2–5 minutes. She tried low-dose opioids for dyspnea management, but was concerned that her respiratory secretions became more difficult to expectorate. Up until the last week of her life, she was pleased with her QOL. She appreciated her scooter that gave her mobility (with her oxygen tanks) to attend her grandchildren's soccer games and dance recitals. She enjoyed the opportunity to move nearer her son for the last few years of her life, and she was satisfied with the "lasting good" she had done in this world.

Pathophysiology of Dyspnea

Dyspnea is a complex phenomenon that includes the sensation of respiratory discomfort, an affective response to the sensation, and the impact on physical functioning and daily activities.[13] A beneficial model of breathlessness includes perception of both intensity and unpleasantness, emotional response, and functional consequences.[25] Many factors contribute to the sensation of dyspnea.[26] At its most basic level, the respiratory system is a pump that brings fresh oxygen to the tissues and removes carbon dioxide waste. The pump is activated by a neurological feedback system in communication with the musculature. The prevailing theory is that dyspnea results from a mismatch between respiratory demand and ventilatory mechanics,[27] an imbalance between the demand to breathe and the ability to breathe.[2] The automatic drive to breathe originates in the brainstem and communicates through a feedback system with the lungs and chest wall. When a mismatch occurs between the urge to breathe and actual ventilation, the brainstem communicates through a corollary discharge with the cortex and limbic regions of the brain, which triggers emotions, memories, abstract thoughts, and the evaluation and affective response to the dyspnea sensation.[9] A "final common pathway" of dyspnea, which is not linked to any specific etiology, may be explained by a central perception of breathlessness[27] triggered by the corollary discharge. The insular cortex, anterior cingulate cortex, and amygdala are areas in the brain that are active during breathlessness, as recognized by functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scanning. These areas are also active in the fear response and influence the emotional reaction to dyspnea.[28]

Any factors that increase the demand to breathe or reduce the body's ventilatory capacity may trigger a sensation of dyspnea (see Figure 16.1). Physical deconditioning may do both and is therefore a primary reason for dyspnea, regardless of whether other causes of dyspnea are present.[29] Physical deconditioning contributes to dyspnea, even in otherwise healthy adults.[20] People with dyspnea learn to limit their activities to minimize their dyspnea, leading to reduced muscle bulk and increased deconditioning and thus contributing to a vicious cycle of inactivity.[7]

Increased Respiratory Demand

Increased respiratory demand can be triggered by multiple factors. Metabolism naturally increases in the setting of exercise or fever, and the built-in reserves of the ventilatory mechanics can easily accommodate those usual demands. Systemic illness such as

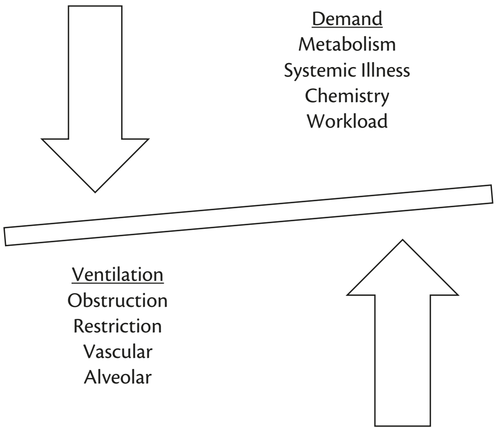

Figure 16.1 Imbalance between demand and ventilation.

hyperthyroid, sepsis, or cachexia also stimulate an increased demand on the respiratory system.[9] The muscle wasting of cachexia seen in COPD, heart failure, and cancer is linked to increased sympathetic drive, neurohumoral changes, and inflammation. The resulting skeletal muscle loss is independently associated with dyspnea, and exercise training possibly combined with nutritional supplementation may reverse breathlessness with the associated myopathy, exercise intolerance, and fatigue.[27]

A chemical imbalance between oxygen and carbon dioxide in the blood will also increase the respiratory demand. In anemia, the decreased hemoglobin available to carry oxygen prevents the cardiovascular system from supplying adequate oxygen to the tissues.[9] The healthy body can accommodate when traveling to altitude, but the lower oxygen concentration increases the respiratory demands on the body. In hypercapnic respiratory failure, the body's respiratory demand to expire carbon dioxide overwhelms its ventilatory capabilities and carbon dioxide builds up in the blood, leading to life-threatening respiratory acidosis.

Anything that increases the external workload on the respiratory system will increase respiratory demand and may fatigue the muscles beyond their ability to function. Obesity increases the body's requirements for respiration. Carrying heavy equipment or using the accessory respiratory muscles when they are needed for respiration may also overwhelm respiratory demand beyond its reserve capacity. Neuromuscular disorders increase the workload relative to the body's ability to move the respiratory pump, given reduced muscular strength and/or neurological input. Multiple sensory receptors throughout the respiratory system monitor lung mechanics, chemistry, and respiratory muscle function[2] and provide feedback to the brainstem respiratory centers when breathing adjustments are necessary to correct or maintain optimal respiratory function.

Reduced Ventilatory Capacity

Problems with airway obstruction, a restrictive defect, vascular problems, or fluid build-up in the air sacs can interfere with ventilation or gas exchange. In these situations, the body is not able to supply enough ventilation to meet the demand.[26] Obstruction occurs when something is preventing the movement of air, usually on exhalation. The obstruction can be caused by mucus build-up or constriction of smooth muscle surrounding the airways, which is often the case with asthma or chronic bronchitis. Obstruction also occurs when the air sacs/alveoli responsible for gas exchange are damaged and no longer able to function, such as what occurs with emphysema, or filled with fluid due to pneumonia or pulmonary edema. A mechanical obstruction can occur when a tumor or scar tissue blocks either the upper or lower airways. When obstruction continues over time, the lungs may become hyperinflated when exhalation does not match the volume of inhalation, thus reducing the space available in the lung for movement of air.

A restrictive pulmonary defect either prevents the lungs from expanding completely or requires additional effort to expand the lungs. The restriction can occur because of decreased compliance of the lung tissue where the lungs become stiff from a condition such as fibrosis or scarring. The pleural space and lining of the lung may be restricted due to plaque, or the restriction may be external due to obesity, kyphoscoliosis, or neuromuscular disease.

Common pulmonary vascular disorders include pulmonary emboli and pulmonary hypertension. Pulmonary emboli interrupt blood flow in a pulmonary artery. Small emboli may interrupt perfusion of blood into the capillaries surrounding the alveoli, causing a mismatch between ventilation and perfusion.[30] Large catastrophic pulmonary emboli may interrupt blood flow to an entire region of the lung and cause immediate death. Pulmonary hypertension may be idiopathic, genetic, drug-induced, or secondary to connective tissue or other cardiopulmonary diseases that increase blood flow to the lungs. Lymphadenopathy, superior vena cava obstruction, and ascites are complications of other serious illnesses that can also contribute to dyspnea.[9]

Pneumonia or pulmonary edema may interrupt ventilation when the alveoli fill with fluid or exudate, preventing the oxygen from entering the alveoli and reaching the capillaries. Pneumonia may be caused by bacteria, viruses, toxins, or aspiration. Pulmonary edema occurs when hydrostatic pressure from fluid overload moves fluid from the vascular space into the interstitial space and alveoli.

Final Common Pathway of Dyspnea

Breathlessness related to the physiology of the lungs, chest, airways, and blood vessels can be addressed by correcting the mismatch between respiratory demand and ventilatory mechanics. When breathlessness remains after the mismatch has been addressed, the breathlessness may be related to central neurological processing and perception, the "final common pathway," as confirmed by fMRI and PET imaging studies focused on the emotion-related areas of the insula, anterior cingulate cortex, and amygdala in the brain.[28]

The final common pathway of dyspnea may contribute to *symptom clusters*, the coexistence of two or more concurrent symptoms that may have a common cause.[31] Symptoms can occur because of the disease itself, treatment side effects, or comorbidities.[31] As serious illnesses progress, interventions may benefit the multiple symptoms in a symptom cluster simultaneously due to a shared common symptom pathway. Pain and dyspnea often coexist, frequently in the context of depression and functional impairments, and symptom-specific interventions may also relieve the other symptoms in the cluster.[20] A symptom cluster of cough, breathlessness, and fatigue has been identified in lung cancer.[32] Dyspnea has been correlated with anxiety, depression, fatigue, and cough.[33] Distress related to dyspnea is associated with symptom clusters that include fatigue and nausea.[34] Attention to both the mismatch between respiratory demand and ventilatory mechanics and the final common pathway of dyspnea provides keys to both measurement and interventions for dyspnea.

Measurement of Dyspnea

Patient-reported outcomes are the foundation of dyspnea measurement as no physiological correlate has been identified that accurately predicts dyspnea.[26] Dyspnea scales measure one or more of the sensation of respiratory discomfort, an affective response to the sensation, and the impact on physical functioning and daily activities (see Table 16.1).[13] When only one aspect of dyspnea is measured, unidimensional scales typically measure the intensity of the sensation. Scales such as the visual analogue scale (VAS), Borg scale, and numeric rating scale (NRS) can be used to measure intensity or distress related to the symptom. These scales are easy to implement in a clinical setting and familiar to patients who have often used similar scales for other purposes. Given the importance of the three domains of dyspnea, the Multidimensional Dyspnea Profile (MDP) was developed to measure sensory and affective dimensions of dyspnea.[35,36] It is easy to administer, acceptable to nurses for administration in the clinical setting,[37] and responsive to change over time. Identification of patients with a strong affective dimension to their dyspnea through the use of the MDP may provide a new target for interventions or optimize selection of interventions that are likely to benefit the affective component.[38]

With the modern development of psychometric theory, several short scales have been developed that provide additional information with minimal patient burden. The Dyspnea-12 (D-12) rates dyspnea using commonly used descriptive terms.[39] Both the MDP and D-12 provide a multidimensional assessment of dyspnea; the D-12 provides one single breathlessness severity score within the context of daily life while the MDP separates sensation and emotion.[40] The Shortness of Breath with Daily Activities Questionnaire (SOBDA) assesses dyspnea in COPD with 13 common activities.[41,42] The Dyspnea Management Questionnaire has a computer-adaptive test capability to measure intensity, anxiety, activity avoidance, and self-efficacy.[43] The Functional Assessment of Chronic Illness Therapy-Dyspnea (FACIT-Dyspnea) scale is a 10-item scale using interactive response technology methods to rate dyspnea with a variety of activities. The FACIT questionnaires are available free of charge on the FACIT website (www.facit.org).[44,45]

Early dyspnea research typically used psychometrically sound instruments that were not easily translated into the clinical setting because of their length and subject or provider burden. The Baseline/Transitional Dyspnea Index (BDI/TDI) assesses severity of dyspnea and change over time, taking functional impairment into account.[46] The UCSD Shortness of Breath Questionnaire rates dyspnea during a variety of common activities.[47,48] The dyspnea domain of the Chronic Respiratory Questionnaire quantifies dyspnea as a component of QOL.[49,50]

Because patients often experience dyspnea only with activities, tools have been designed that quantify the impact of activity on dyspnea. The modified Medical Research Council Dyspnea Scale is a simple, classic, four-level tool that categorizes dyspnea according to activity level. This tool is not very sensitive to change over time so it is used to categorize patients according to symptom severity but not to document dyspnea improvement in intervention research.[51,52] The American Association of Cardiovascular and Pulmonary Rehabilitation has developed an outcomes toolkit to guide clinicians and researchers in selecting the best instruments for their projects. The AACVPR toolkit includes measures of functional status, exercise capacity, dyspnea, health-related QOL, and psychosocial tools with information about psychometric properties, clinically important differences, and brief description of each tool.[53] For patients who are not able to provide self-report, the validated Respiratory Distress Observation Scale provides an objective measure using respiratory and behavioral signs that have been correlated with dyspnea.[54,55]

When a brief overview of a variety of symptoms is needed for clinical practice or for the assessment of symptom clusters, dyspnea can be assessed as part of a symptom assessment survey. The Edmonton Symptom Assessment Survey (ESAS) is commonly used in palliative care and includes a 10-point NRS for nine symptoms including dyspnea.[56] ESAS has been validated in many languages other than English.[57–60] The Memorial Symptom Assessment Scale (MSAS) evaluates the intensity, frequency, and distress of 32 symptoms including dyspnea,[61,62] and validated translations of MSAS are also available in multiple languages.[63–66]

When measuring dyspnea, response shift,[67] the variety of available tools, and the effect of attention to the symptom are important factors to consider. Many patients subconsciously decrease their activity levels to cope with dyspnea, termed "response shift,"[67] so their actual dyspnea scores may not change but further inquiry into their current activity levels in comparison to several years prior may reveal dyspnea as the reason for reduced activity levels. The variety of available dyspnea tools provides the clinician or researcher with choices that can meet the needs of their individual project, but the variety also interferes with the ability to do meta-analyses or systematic reviews. There is a question on whether it is good to measure dyspnea or whether attention to a symptom causes increased distress from that symptom.[68] Increased suffering from the additional awareness of dyspnea may be an unintended consequence of measuring dyspnea.[27]

Interventions for Dyspnea

When considering management options for patients with dyspnea, the first consideration is to target specific mechanisms of dyspnea as correcting the physiological defect will often improve dyspnea.[27] After optimizing the pathophysiology of the symptom, dyspnea management strategies ultimately may provide relief through their effects on the central common pathway of dyspnea. With a focus on evaluating interventions where dyspnea was specified as an outcome, a task force of the Hospice and Palliative Nurses Association (HPNA) presented a review of the evidence available through December 2016 at the 2017 HPNA/American Academy of Hospice and Palliative Medicine Annual Assembly.[69] The strongest evidence supported long-acting beta agonist (LABA) combined with long-acting muscarinic antagonist (LAMA) inhaler therapy, immediate-release oral morphine, oxygen for patients with COPD or hypoxemia, pulmonary rehabilitation (PR), and specialist dyspnea service. Although the evidence is not as strong, short-acting beta agonist (SABA) and short-acting muscarinic antagonist (SAMA) inhalers, other forms of opioids, acupressure, fans, dyspnea self-management programs, and transcutaneous electrical nerve stimulation (TENS) of acupressure points are likely to be effective. Interventions that may be considered on an individual basis, balancing benefit with harm, include noninvasive ventilation, high-flow nasal oxygen, acupuncture, and co-enzyme Q10. The effectiveness of benzodiazepines, Heliox (a mix of helium and oxygen), and mindfulness for dyspnea management has not been established. Nebulized furosemide or morphine are unlikely to be effective for dyspnea relief. Many gaps in the literature exist, including populations beyond COPD and cancer, routes of delivery, alternate formulations, timing and dosage, safety profiles,

Table 16.1 Dyspnea measurement instruments

Name	Description	Considerations
Unidimensional Scales		
Borg-CR scale	Category ratio (CR) scale measures intensity of experience, using verbal anchors related to numbers	Requires permission from author for use (www.borgperception.se)
Numeric rating scale (NRS)	Eleven point scale from 0 to 10 for self-report of symptom experience	Commonly used for pain so many patients are familiar with NRS Can be used with any symptom or term
Visual analogue scale (VAS)	100 mm horizontal line with "none" on the left end of the line and "very severe" on the right end. Subjects select a place on the line to represent their subjective experience of the symptom.	Numbers are not placed along the line. VAS score is 0 to 100 but the subject is not aware of the numbers. Can be used with any symptom or term (distress, discomfort)
New Generation Dyspnea Measurement (since 2010)		
Dyspnea-12	Rating of breathlessness with 12 items	Extensive validity testing has been done
Dyspnea Management Questionnaire	Computer adaptive test with test bank of 71 items for multidimensional measurement; maximum of 20 items required to obtain subscale scores.	Questions are selected based on respondent's answers to previous questions Four subscales: dyspnea intensity, anxiety, activity avoidance, and activity self-efficacy.
Functional Assessment of Chronic Illness Therapy (FACIT)-Dyspnea	Seven-day recall developed using item response theory	Dyspnea is one scale in the FACIT measurement system. More information available at www.facit.org A 10- or 33-item version is available English version is free; multiple other languages available
Multidimensional Dyspnea Profile (MDP)	Measurement of the sensory and affective dimensions of dyspnea during a specific event or time.	Designed for both clinical and laboratory research Not disease specific Administration takes 1–3 minutes
Shortness of breath with daily activities questionnaire (SOBDA)	Evaluates dyspnea in patients with COPD in relation to 13 common physical activities, using e-diary	Developed as a patient-reported outcomes instrument for use in clinical research Development funded by GlaxoSmithKline
Classic Dyspnea Measurement (prior to 2000)		
Baseline/Transitional Dyspnea Index (BDI/TDI)	Interviewer-administered dyspnea rating according to functional impairment and magnitude of both task and effort. TDI assesses change from baseline. BDI range from 0 (severe) to 4 (unimpaired) and TDI ranges from −9 (deterioration) to +9 (improvement)	Request permission for use from donald.a.mahler@hitchcock.org Available in 73 languages More information available at http://mapi-trust.org/questionnaires/bdi-tdi/
Chronic Respiratory Disease Questionnaire (CRQ) –Dyspnea subscale	One of four subscales in a self-report or interviewer-led quality of life instrument.	Sensitive to change with interventions
Modified Medical Research Council (mMRC) dyspnea scale	Quantifies disability related to dyspnea on a 5-point scale with lower number indicating less dyspnea	Public domain May have low sensitivity to change In use for more than 50 years
UCSD Shortness of Breath Questionnaire	Rating of breathlessness on 6 point scale for 24 activities of daily living. Range from 0 to 12 with lower scores indicating greater breathlessness	Copyright by University of California Free to use with permission and acknowledgment for education and research
Dyspnea Proxy Measurement for Nonverbal Patients		
Respiratory Distress Observation Scale (RDOS)	Behavioral evaluation of 8 physical signs associated with respiratory distress when a patient is not paralyzed but unable to self report.	A 2-point change (out of 17 total points) indicates meaningful change in the patient's condition
Symptom Surveys		
Edmonton Symptom Assessment System (ESAS)	Quantitative assessment of 10 symptoms that allows for simple and rapid documentation of multiple patient-reported symptoms at the same time	Commonly used for screening and monitoring in palliative care Multiple permutations exist
Memorial Symptom Assessment Scale (MSAS)	Assessment of severity, frequency, and distress for 26 symptoms, and severity and distress for 6 symptoms when frequency is not important	Subscales include physical distress, psychological distress, and The Global Distress Index Short form includes 32 symptoms and one dimension Condensed version has 14 symptoms and one dimension

and variations across the disease trajectory. The search strategy did not yield literature related to nonpharmacologic therapies such as breathing strategies,[70] energy conservation,[71] cognitive behavioral therapy,[72] or yoga.[73]

The concept of "total dyspnea,"[74] which acknowledges the multiple components of distress related to dyspnea and incorporates the meaning of the symptom within a context of whole-person care, provides a rationale for the value of pharmacological, mechanical, and behavioral dyspnea management strategies that address patient suffering in the psychological, social, and existential as well as physical realms. Quality of care for patients with dyspnea includes attention to dyspnea intensity, distress, functional impact, and qualitative descriptors that may distinguish causes of dyspnea.[75]

Pharmacological Strategies

Beta agonist and muscarinic antagonist inhaler therapies are the mainstay of treatment for many patients with chronic lung disease, especially COPD. Inhaled medications can be administered by nebulizer, metered-dose inhalers, dry powder inhalers, or soft mist inhalers. Characteristics of the device, patient capabilities, and optimal technique are all important considerations when selecting inhaled medications.[76] Although oral steroids may be beneficial for dyspnea relief near end of life,[77] the systemic side effects may not be worth it for people who are not imminently dying. Opioids are a mainstay of pain management in palliative care, and low doses of oral or parenteral opioids are also beneficial for dyspnea management.[54] The beneficial effects on dyspnea of opioids and oral steroids may be synergistic when used in combination.[78]

Oxygen therapy may be beneficial for dyspnea and even prolong life in patients with hypoxemia,[79] but the mortality benefit is not present in patients with mild hypoxemia at rest (SpO_2 89–93%) or during exercise (SpO_2 80–89% for no more than 5 minutes during a 6-minute walk).[80] Nasal high-flow oxygen therapy may be useful for improving lung mechanics and for short-term emergency treatment of dyspnea.[81,82] As end of life approaches and comfort becomes the primary focus, maintaining oxygen saturation is no longer the goal, and a fan or pursed lip breathing may be more advantageous.[83]

Opioids have become an important foundation for treatment of chronic dyspnea after medical therapy focused on the underlying pathophysiology has been optimized. Concerns arising from the opioid epidemic have encouraged the search for other medications that can be used for dyspnea management.[84] The increasing focus on the central neural pathway of dyspnea has renewed interest in alternative and repurposed medications that can reduce chronic dyspnea through effects on the dyspnea pathway. Several classifications of medications including anxiolytics, antidepressants, antihistamines, cannabinoids, and herbal-based treatments have been studied but evidence is insufficient to recommend them for dyspnea treatment.[84] The question has been raised whether opioids might improve exertional dyspnea if taken prior to exercise,[7] and further research is required to answer that question. Recent evaluation of patient-controlled therapy for breathlessness resulted in less administration of total opioid dose over time and better control of breathlessness.[85] Another innovative possibility that might prove beneficial for the palliative relief of dyspnea may be very-low-dose ketamine, which has been shown to decrease the body's response to hypercapnia.[86]

Mechanical

Patients with serious life-threatening illness increasingly seek palliative care concurrently with pursuing surgical interventions for their lung disease. In addition to mechanical ventilation that is used to relieve respiratory distress,[87] surgical and bronchoscopic procedures may be appropriate for some patients with dyspnea. Lung volume reduction surgery has been shown to improve dyspnea, exercise tolerance, and survival in patients with predominantly upper lobe emphysema and low exercise capacity.[88] A variety of noninvasive endoscopic options for lung volume reduction are now available, including the use of bronchial valves, coil implants, and thermal vapor ablation.[89] These therapies may be appropriate considerations for patients with dyspnea primarily related to lung hyperinflation.[90] Patients with emphysema, pulmonary fibrosis, cystic fibrosis, pulmonary hypertension, bronchiectasis, and other diagnoses[91] experience improvement in dyspnea after lung transplantation.[92]

When the lung is not able to expand because of a malignant pleural effusion or a trapped lung due to pleural fibrosis or inflammation, relief from dyspnea may occur with the placement of a tunneled pleural catheter to drain excess fluid into the abdominal cavity, pleurodesis to adhere the lung to the chest wall and prevent future build-up of fluid, or decortication (removal of restricting tissue) by video-assisted thoracoscopy.[93,94] Patients may experience obstruction of the central airways due to tumors or stenosis. Airway stents, balloon dilatation, laser ablation, cryotherapy, or radioactive brachytherapy may provide symptomatic relief in those situations.[95]

The ideal role for noninvasive ventilation for the palliation of dyspnea is still being explored.[96,97] High-intensity positive pressures, using the highest inspiratory pressures that the patient can tolerate, may provide more dyspnea relief, improvement in hypercapnia, and improved mortality above that experienced with the usual low-intensity noninvasive ventilation.[98] Other noninvasive mechanical interventions to consider for airway clearance and optimal breathing are oscillatory positive pressure devices such as the Acapella, Flutter, or Aerobika[99]; autogenic drainage[100]; active cycle of breathing[101]; and high-frequency chest wall oscillation.[102] Although the evidence is not strong for any of these noninvasive options, an "*N* of 1" trial with careful consideration of the risk–benefit analysis may be beneficial for people living with breathlessness.[103]

Behavioral

Dyspnea is a complex multifactorial symptom, and therefore complex interventions are often necessary to adequately address the multiple causes of the symptom. Pulmonary rehabilitation (PR) is an interdisciplinary program that combines exercise training, patient education, and psychosocial support in a comprehensive evidence-based intervention for patients with lung disease.[104] PR classes typically meet 2–3 times per week for several hours per session over a 6- to 12-week interval. Some PR programs also provide maintenance exercise indefinitely after the completion of the initial program. PR shares many similarities with palliative care in its focus on symptom management and QOL. The foundation of PR is exercise training, whereas palliative care integrates more of a focus on advance care planning and the spiritual dimension of health.[105] Now that palliative care is recognized as a valuable treatment for patients across the spectrum of serious illness, it makes sense to get palliative care involved earlier, soon after PR and as soon as

Table 16.2 Nonpharmacological interventions for dyspnea

Professional	Self-management	Complementary
Pulmonary rehabilitation	Posture: braced forward lean	Relaxation/Mindfulness-based Stress Reduction (MBSR)
Breathlessness intervention	Pursed lip breathing	Biofeedback
Pacing/Energy conservation	Abdominal breathing	Spinal movement
Cognitive Behavior Therapy (CBT)	Fan/Air movement	Acupuncture/acupressure
Music/Distractive auditory stimuli	Exercise	Yoga/Tai Chi/Qigong
Chest wall vibration	Acceptance	Branch-chain amino acids
Noninvasive ventilation	Socialize	
Education		
Walking aid: rollator/cane		
Dyspnea plan		
Neuromuscular electrical stimulation		

patients are symptomatic. The beneficial outcomes following PR decline over time, and perhaps palliative care follow-up after PR would support maintenance of PR outcomes over time.

Despite the attention that dyspnea management has received in the literature, patients and their families spend many hours on their own between medical appointments coping with dyspnea to the best of their abilities. Self-management is still the primary mainstay of dyspnea treatment.[22] Activated patients who embrace their own personal initiative and engagement can increase their independence and QOL in the presence of their dyspnea.[6] Patients report many strategies for managing their symptoms, and very few of those strategies include evidence-based or medically prescribed interventions. Patients find themselves strategically planning their daily activities, using creative thinking and assistive devices to accomplish their daily tasks.[22] Integrating exacerbation action plans in self-management interventions improves health-related QOL and decreases the probability of hospitalization.[106]

Several excellent models and treatment algorithms for dyspnea management have been published.[6,9,103] Principles of high-quality dyspnea management can be applied in all settings, and the treatment algorithms are similar even in the emergency department.[107] Many interventions have minimal effect on their own but contribute to a cumulative benefit when used in combination.[26] Nonpharmacological and complementary therapies are recommended if they have research evidence to support them[108] or if the safety profile merits an "*N* of 1" trial with minimal concern.[103] (See Table 16.2 for a list of nonpharmacological professional, self-management, and complementary therapies to consider.) Most of the nonpharmacological and complementary therapies that patients use or providers recommend for dyspnea management are focused on the central pathway of dyspnea. Interventions focused on anxiety, depression, and other symptoms commonly found with dyspnea in symptom clusters can be beneficial for improving dyspnea as well.[30]

When patients living with chronic dyspnea experience a dyspnea crisis, the sense of helplessness experienced by family caregivers contributes to the distress caused by dyspnea.[14] Patients at risk for dyspnea crisis can plan in advance with their families so that when a dyspnea crisis occurs, each family member will have a practiced response that will normalize the experience, decrease the panic, and quickly institute predetermined strategies that will mitigate the breathing crisis.[18] A "dyspnea plan" can include both pharmacological and nonpharmacological measures and rituals to enact when dyspnea crisis occurs.[6]

Several outpatient dyspnea clinic models have been tested with promising results.[23,24] Complex interventions for breathlessness assess both the sensory and affective components and focus on modulating the central perception of breathlessness regardless of the original pathophysiology of the symptom. The interprofessional team assists patients to manage their affective response to the symptom while still addressing the original pathophysiology of the illness that caused the symptom. The "softer skills" such as empathic listening in the context of new service models may provide relief for dyspnea.[11]

The interprofessional team offers unique perspectives related to dyspnea management interventions. From a physical therapy perspective, physical conditioning, reassurance, positioning, and explanations of the anatomy and physiology related to breathing strategies are effective means to support patients in managing their dyspnea.[109] Occupational therapists use energy conservation and supervised practice to support patients in maintaining their everyday activities.[110–112] Although respiratory therapists have traditionally practiced in hospital settings, their experience in leading PR programs demonstrates their expertise in supporting dyspnea management within a whole-person context.[113–115] Given the ubiquity of dyspnea within the healthcare system, it makes sense to educate allied health providers and health coaches on strategies specific to dyspnea management.[116,117] Successful interventions for dyspnea benefit from multiple perspectives.

Cough Physiology, Measurement, and Interventions

Despite cough being a very distressing symptom that interrupts social situations and is physically exhausting,[118] no interventions are consistently effective in treating cough. Over time, cough can affect physical, mental, and social health. It interferes with sleep, fatigues the muscles, interferes with vocal quality, and contributes to urinary incontinence.[119] Cough is one of the most common symptoms that spur medical visits.

Pathophysiology of Cough

The cough reflex in the brainstem protects the airways from mechanical or chemical irritants mediated by sensory nerves in the large and peripheral airways. Voluntary cough and the urge to cough are centered in the cerebral cortex.[119] Early brain imaging evidence suggests that the conscious regulation of cough occurs in brain regions and neural pathways that are separate from the urge to cough. Both the voluntary and the reflex pathways are involved in cough control.[120] Overlap with the descending inhibitory pathways related to other stimuli may explain why cough is suppressed in the presence of other stimuli.[121] Cough is stimulated by mechanical (airway size), biochemical (capsaicin), and neurosensory changes.[119] Irritation can be caused by the presence of pathology in the airways, parenchymal inflammation from treatment, heightened cough reflex sensitivity, or comorbidities such as gastroesophageal reflux disease (GERD) or sinusitis.[121] With hypersensitivity, even minimal irritation such as laughing, talking, or temperature changes can lead to cough.[121] Other irritants include smoking and perfume. Central processing may occur in several brain regions.[119]

The most common causes of cough are smoking, lung pathology such as asthma, postnasal drainage (PND), GERD, and medications.[120] New pathologies have been identified for cough. Obstructive sleep apnea can manifest with cough, possibly because of pressure buildup in the upper airway which may increase diaphragmatic pressure and contribute to GERD; treatment with continuous positive airway pressure (CPAP) can alleviate the cough. Cough from enlarged tonsils can be treated with tonsillectomy. Other unusual sources of cough might be protracted bacterial bronchitis; basidiomycetes fungus, treated with antifungal medications; cervical spondylosis; and abnormal salivary glands at the base of the tongue.[122] *Cough hypersensitivity syndrome* (CHS) signifies neuronal activation, sensitization, and/or dysfunction which leads to excessive coughing.[123] Chronic dry cough is very common in IPF, possibly due to traction of the parenchyma related to fibrosis.[119] GERD may cause microaspiration of acid and reflux of gastric contents into the airways. Medications such as angiotensin converting enzyme (ACE) inhibitors and beta blockers have been associated with cough.[119] Chronic lung disease such as COPD/emphysema or infection can also contribute to chronic cough. Chronic sinusitis and postnasal drip (PND) syndrome may be asymptomatic, or patients may not notice PND which can contribute to chronic cough.[119] Cough can also be the first sign of lung cancer. The recognition of laryngeal irritability and chronic hypersensitivity has led to the idea that cough is a sensory neuropathy.[120] Other triggers include foods, smells, laughing, and laryngeal dysesthesia or "tickle" in the throat.[120] Sensory neuropathic cough may present with chronic cough, laryngospasm, or paradoxical vocal cord dysfunction.[120]

Cough can be completely voluntary and under conscious control, completely reflexive in response to a stimulus, or a combination of reflexive and voluntary. Reflexive coughing can become more pronounced as a person becomes sensitized to a given stimulus. Sensitization is triggered by inflammatory mediators that may be released after exposure to viruses, antigens, or inhaled toxins like cigarette smoke.[123]

Measurement of Cough

Intensity, frequency, and disruptiveness are components of cough that should be measured.[124] VAS subjective scales are easy to use for each component. Several instruments including the Leicester Cough Questionnaire[125] and the Cough Specific Quality of Life Questionnaire[126] measure the global impact of cough. A seven-item Cough Severity Diary has been tested in patients with chronic and subacute cough.[127] Objective measurement of cough has been attempted with ambulatory cough monitoring (ACM) such as the Leicester Cough Monitor and the VitaloJAK (Vitalograph, Inc., Lenexa, KS).[128] Although objective measurement is intuitively attractive, many threats to validity exist including the difficulty in distinguishing cough from other sounds, determining the marker of severity, and objective quantification. Perhaps both subjective and objective measures need to be assessed together.[121]

Cough can be divided into acute, subacute, and chronic cough.[122] Cough hypersensitivity syndrome encompasses chronic idiopathic cough, chronic refractory cough, and sensory neuropathic cough.[120] Recent guidelines for the evaluation and treatment of unexplained chronic cough provide an assessment algorithm.[129] Sputum eosinophils or exhaled nitric oxide should be evaluated to identify patients with bronchial hyperresponsiveness who might respond to inhaled corticosteroids.[129]

Interventions for Cough

The goal for cough treatment is to allow normal cough while blocking pathological cough.[123] Many therapies have been suggested for cough, seemingly because none of them work very well. It may be that cough appears to be one entity but actually has multiple causes that have not yet been identified or linked to an effective intervention. Behavioral cough control techniques and vocal hygiene strategies taught by a speech therapist may reduce cough symptoms.[130,131] Additional strategies may include pursed lip breathing, swallowing to diminish the urge to cough, avoiding smoking and mouth breathing, minimizing alcohol and caffeine, increasing water intake, or using steam inhalation.[130]

The CHEST Expert Cough Panel is developing clinical practice guidelines as living documents that are continually updated as new evidence, technologies, and recommendations become available.[132] For cough in adult patients with lung cancer, they recommend a stepped approach starting with the identification and treatment of coexisting causes of cough, nonpharmacological cough suppression exercises, endobronchial brachytherapy, and graduated trials of various cough suppressants.[133] Although many substances including glaucine, Chinese herbs, Duopect, moguisteine, pipazethate, guaifenesin, N-acetylcysteine, diphenhydramine, loratadine, erythromycin, ipratropium, and inhaled corticosteroids have been tested as antitussives, codeine and dextromethorphan are the only two agents that have been shown to reduce frequency and severity of chronic cough.[134] Slow-release morphine and dextromethorphan, which is a codeine analog, both act centrally to inhibit the cough reflex. Thalidomide has been tested for cough because of its anti-inflammatory properties, but the side effects are severe, including birth defects and sensorimotor peripheral neuropathy. With the recognition that cough may be triggered by sensory neuropathic cough or laryngeal irritability, neuromodulators used to treat neuropathic pain, such as gabapentin, pregabalin or amitriptyline, may be helpful.[120]

Disease-directed treatment for cancer-related cough may include drainage of pleural effusions, brachytherapy (radiation in direct contact with tissue), or photodynamic therapy.[130] A Cochrane review of randomized controlled trials (RCTs) for cancer-related cough treatment found minimal evidence but suggested that pharmacologic treatments like butamirate linctus, codeine 60 mg, morphine, dihydrocodeine, cromoglycate, and hydropropizine or levodropropizine may be beneficial for cough.[130] Given the low level of evidence and the age of the research, proposed recommendations for palliative cough management balance risk with benefit. The first step is to consider disease-directed treatment and review medications to see if any might be exacerbating the cough. Evaluate and treat any comorbidities that may be contributing to cough. Then consider sodium cromoglycate, which is relatively safe but supported only by minimal evidence. If still not responsive, consider opioid derivatives such as morphine, codeine, or dextromethorphan.[118]

In patients with unexplained cough that has not responded to a trial of inhaled corticosteroids, speech therapy and gabapentin trials are recommended.[129] A recent systematic review of treatments for cough related to the common cold found many treatment options available, but the evidence was not compelling for any of the options. The evidence was not strong enough to support recommendations for decongestants, antihistamines, acetylcysteine, nonsteroidal anti-inflammatory drugs (NSAIDs), honey, zinc lozenges, over-the-counter (OTC) antitussives, expectorants, mucolytics, or combination products.[135] The evidence base has not changed since previous guidelines were published in 2006, and the majority of the research on cough interventions was published before 2000.[134]

Terminal Secretions: Physiology, Measurement, and Interventions

Many terms are used to describe terminal secretions, usually including phrases such as "movement of bronchial secretions," "noisy breathing," or "sound in relation to respiration."[136] These secretions occur in the terminal phase of illness and are distressing for professional and family caregivers. The study of terminal secretions is inhibited by ethical concerns about randomizing dying patients who may not be able to give consent or share their perspective.[137] Does anyone know what it feels like to have terminal secretions? We have strong opinions on how to manage it, but we don't really know for sure because no one can tell us that the interventions were helpful or not.

Pathophysiology of Terminal Secretions

Terminal secretions, also called "death rattle," are caused by breathing through secretions in the upper airways as a patient approaches death and is no longer able to clear the secretions through swallowing or coughing.[137] The tongue may also cause obstruction and contribute to noisy breathing in patients who are nearing end of life.[137] Most patients die within 48 hours after developing terminal secretions.[138]

Hipp and Letizia propose that brain hypoxia causes ongoing release of acetylcholine from the parasympathetic nervous system, which activates the salivary and bronchial glands, leading to excessive secretions. Inability to swallow, weakened gag and cough reflexes, and decreased level of consciousness all contribute to the development of noisy breathing.[139] Dehydration may make secretions more tenacious and difficult to clear, especially in the setting of dysphagia and decreased mental status.[140] Noise during respirations occurs when the movement of air disturbs the oropharyngeal secretions, and the sound is amplified through the mouth and nasal passages.

Measurement of Terminal Secretions

Terminal secretions can be caused by excessive oral and salivary secretions, also termed type 1 or "real" death rattle. It occurs when the patient's level of consciousness has decreased and seems to be amenable to anticholinergic treatment. Type 2 or "pseudo" death rattle is caused by bronchial secretions that are formed due to pulmonary pathology such as infection, aspiration, or edema. Type 2 secretions are not as amenable to anticholinergic treatment and can be very distressing as the patient may be conscious when experiencing these secretions.[141] A combination of both types of terminal secretions may occur. The Victoria Respiratory Congestion Scale (VRCS) has been developed to quantify terminal secretions and noisy breathing using a 0–3 scale depending on the distance at which noisy congestion is audible.[141]

Interventions for Terminal Secretions

Antimuscarinic (most anticholinergic agents act on muscarinic acetylcholine receptors) medications are typically used to decrease secretions, but their efficacy is questionable. Perhaps they would be better used as preventive measures and started early, prior to the development of terminal secretions, since anticholinergic drugs do not remove existing secretions but prevent the formation and accumulation of secretions after the medication has been initiated.[142] Another option to maximize treatment might be to gently suction the secretions prior to beginning anticholinergic treatment.[143] Side effects such as urinary retention and dry mouth are problematic for patients near the end of life.[137] Withholding hydration is another management technique that was the focus of an observational study. No difference in terminal secretions was found after withholding hydration, although those in the nonhydration group experienced less frequent peripheral edema, pleural effusion, and ascites.[144] Guideline-based hydration improved family satisfaction and may decrease terminal secretions at end of life.[145]

Although the evidence in favor of anticholinergic therapy is weak,[136,146] such therapies are regularly used in clinical practice so Bennett and colleagues developed an evidence-based guideline that outlines the characteristics and considerations of each of the available anticholinergic options.[140] Specific information regarding dosage and cost were published by Brock and colleagues.[147] Nonpharmacological interventions to reduce terminal secretions and noisy breathing include repositioning, suctioning, and restricting medically administered hydration, although these interventions have not been scientifically studied. Educating the family about behavioral indicators that affirm the absence of distress can be very helpful. The phrase "death rattle" can be distressing, and other terms are preferable in discussions with families.[148] Although nurses often worry about the meaning of terminal secretions for family members, many families actually express relief that the terminal secretions indicate that the patient will soon be done with suffering.[149] Staff education can lead to higher quality care of patients with terminal secretions and also preserve scarce resources with lower cost options.[147] Both families and staff can find terminal secretions to be distressing, although the distress can be relieved with careful education that the patient is not uncomfortable, it is a normal part of the dying process for many people, and it won't last long. Many times, families get their cues from the staff on whether or not to be distressed by situations such as terminal secretions.[147]

Conclusion

When faced with patients experiencing dyspnea, cough, terminal secretions, and associated distress caused by cardiopulmonary, neuromuscular, or metastatic disease, the goal often becomes eradicating or managing the symptom. In the context of the bothersome respiratory conditions that are often present in patients receiving palliative care, it is possible to achieve a positive sensation of breathing, relief from cough, and an absence of excessive secretions at the end of life. Nurses must use all available resources to provide relief and optimize breathing status for patients with serious illness.

CHAPTER 17

Bladder Management in Palliative Care

Naomi Farrington and Catherine Murphy

Key Points

- Urinary dysfunction in palliative care can cause great distress and discomfort for both patients and their caregivers. Nursing management of these issues is a priority for care and should be matched with the patient's own clinical situation and preferences.
- The causes of urinary dysfunction in the patient receiving palliative care are myriad, including the presence of a malignant tumor, iatrogenic factors, infection, neurological factors, or other comorbidities. Treatment or management strategies that reflect the etiology of the patient's condition should be considered, and this may include the selection of products or devices as well as pharmacological solutions or behavioral interventions.
- There is little robust evidence to support many aspects of nursing management of urinary issues in palliative care, including the insertion of indwelling urethral urinary catheters. As such, nurses are required to work in partnership with patients, families, and other members of the patient's healthcare team, bringing to bear their clinical and interpersonal skills in order to deliver high-quality care.

Introduction

Our overall goal as nurses caring for patients approaching the end of life must be to intervene to reduce distress and discomfort without causing further distress and discomfort. Management of urinary difficulties in palliative care should be as much a priority for nursing care as symptoms such as pain and nausea, as these, too, can cause great distress and discomfort.[1] The challenge is to manage the patient's bladder symptoms in a manner that pays attention to their medical situation (including proximity to death), emotional state, and personal preferences. As such, goals of care are likely to be different in each individual case, and management strategies must reflect this.

This chapter discusses the urinary and bladder difficulties that may occur in a patient approaching the end of life and the options for nursing care that can be considered, with personalized, holistic care in mind.

The urinary system can be divided into the upper urinary tract and the lower urinary tract (see Figures 17.1 and 17.2). The upper urinary tract comprises the kidneys and the ureters. The lower urinary tract comprises the bladder and the urethra. The kidneys are essential for maintaining water and electrolyte homeostasis within the body. They filter nearly 200 L of fluid from the body's bloodstream every day, which allows toxins, metabolic wastes, and excess ions to leave the body in the form of urine, while returning vital substances to the blood.[2] The two ureters transport the urine produced in the kidneys to the bladder, where it is stored temporarily before being carried through the urethra to the exterior of the body in the process of micturition or urination.

Factors affecting urination in a patient receiving palliative care include:

- *Pharmacological or treatment factors*: Medications such as sedatives or opioid analgesics may affect a patient's ability to recognize the need to void, or to access toileting facilities or products effectively. Diuretics may increase urine production, leading to urinary frequency. Oncological treatments including chemotherapy and radiotherapy can cause bladder irritation, bladder spasm, or hemorrhagic cystitis.
- *Urinary tract infection (UTI)*: UTI may cause urinary incontinence[3] (or exacerbate existing urinary incontinence), bladder irritation, and bladder spasm.
- *Restricted mobility*: Severe pain or dyspnea can impair a patient's ability to access toileting facilities or products in a timely fashion. In addition, the disease process itself can lead to weakness or exhaustion.
- *Cognitive impairment*: Chronic cognitive impairment such as dementia, or acute cognitive impairment such as delirium or confusion may mean that a patient is unable to recognize or respond to cues to urinate. Delirium is common in the last weeks or days of life and can be caused by metabolic disturbance, organ failure, certain drugs (including benzodiazepines and opioids), sepsis, hypoxia, and primary or secondary cerebral tumors.[4]
- *Constipation or stool impaction*: Constipation is common in the palliative patient due to factors including immobility, dehydration, metabolic factors, intestinal dysmotility, and opioid use.[5] Constipation can have a negative impact on urinary function as bladder and bowel function are intimately connected.[6]
- *Surgery*: Urethral surgery such as prostatectomy, or surgery which indirectly affects the urethra such as hysterectomy,[7,8] can lead to intrinsic sphincter deficiency and therefore urinary incontinence.
- *Neurological factors*: Whether associated with terminal disease itself or arising from existing long-term comorbid conditions,

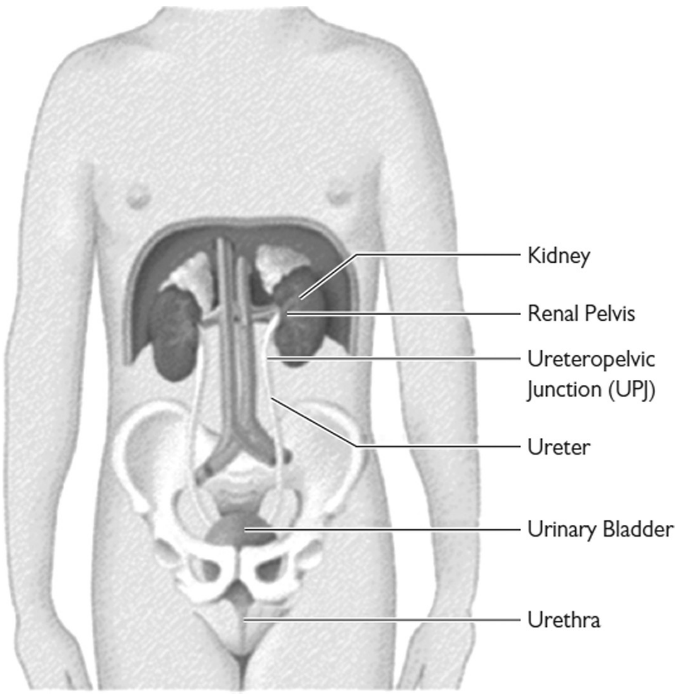

Figure 17.1 The female urinary tract.
Source: Ferrell BR. *Oxford Textbook of Palliative Nursing*. 4th ed. New York: Oxford University Press; 2015. Reprinted with permission.

neurological factors can significantly contribute to bladder dysfunction in the palliative patient, causing urinary incontinence, voiding difficulties, or urinary retention. In order for the bladder to enact its dual functions of storage and voiding effectively, the connections between the micturition center in the brain, the spinal cord, and peripheral nerves which enervate the bladder and sphincter must be intact. Disruption to these pathways leads to urological dysfunction. *Neurogenic bladder or neurogenic lower urinary tract dysfunction* (NLUTD) is the term often given to bladder dysfunction caused by neurological damage.[9]

- *Presence of tumor*: In addition to neurological effects that can be caused by primary or secondary tumors in the brain or spinal column, bladder outlet obstruction can result when there is a carcinoma of the prostate or urethra or a pelvic tumor which causes urethral compression. Primary bladder tumors can cause inflammation of the bladder.

Many of the issues discussed in this chapter are not specific to palliative care, but the management strategies are specific in that they take into account goals of care and proximity to death.

Voiding Dysfunction

In the terminal phase of life, production of urine sometimes slows or ceases altogether.[10,11] This is an expected part of the dying process and is not usually cause for alarm. However, a reduction or cessation in urinary output prior to this phase can signal an underlying problem which merits attention and can potentially be reversed. Distinction must be made between lack of urine output caused by failure of the kidneys to filter blood and make urine (*anuria/oliguria*), blockage preventing flow of urine between the upper and lower urinary tracts (*urinary stasis*), and failure of the bladder to empty (*urinary retention*).[12]

Urinary retention is the inability to empty the bladder completely. It can be categorized by several factors: complete or partial emptying, acute or chronic duration, painful or not, by underlying cause (obstructive or nonobstructive), and as high- or low-pressure.[13] However, retention lacks a clear, widely accepted clinical definition, thus having the potential to lead to both under- and overtreatment. It is caused by one of two disorders: bladder outlet obstruction (in which flow from the urethra is obstructed) or deficient detrusor contraction strength (in which bladder muscle strength is insufficient to effectively empty the bladder),[12] detailed in Table 17.1.

Management will depend on the root cause; therefore, it is important that an accurate history is taken and examination (including using an ultrasound bladder scanner if available) is thorough. It is

Table 17.1 Causes of bladder outlet obstruction and deficient detrusor contraction strength in the patient receiving palliative care

Causes of bladder outlet obstruction	Malignant tumors of the prostate, urethra, or bladder (anatomic obstruction); Detrusor-sphincter dyssynergia (functional obstruction); Inflammation of the prostate, for example due to radiotherapy; Urethral stricture; Bladder calculi; Fecal impaction.
Causes of deficient detrusor contraction strength	Denervation caused by a neurological lesion; Radiation damage to the detrusor muscle itself; Decompensation of the detrusor muscle after a period of prolonged obstruction; Medication including opioids or antimuscarinics.[60]

important to distinguish between urinary retention and oliguria. If more than 400 mL is present in the bladder, retention is probable. In a dying patient who may be unable to communicate verbally, restlessness could signal urinary retention. Initially, conservative measures should be employed in an attempt to rectify urinary retention in the palliative patient, such as rectal emptying (most commonly by way of aperients rather than by more invasive methods like manual evacuation), or, for male patients, assistance to stand to void. In addition, pharmacological review to assess the need for drugs which have the potential to cause constipation or reduced detrusor activity should be conducted. If these measures are ineffective, an indwelling or intermittent urinary catheter may be employed if retention is confirmed by use of ultrasound bladder scanning. The choice between an intermittent and an indwelling urinary catheter will depend on the context of care, including the availability of a caregiver who can catheterize and the preferences of the patient.

Neurological lesions are caused by damage to nervous tissue as a result of injury or disease and can lead to voiding difficulties. The type of urological dysfunction that occurs depends on the location of the damage; for example, neurological lesions above the pontine micturition center in the brainstem (caused by presence of a posterior fossa tumor) can lead to voiding dysfunction, commonly urinary retention,[14] while a lesion that occurs below the pons in the spinal cord often leads to detrusor-sphincter dyssynergia (lack of coordination between bladder and sphincter) and therefore retention.[15]

Neurological lesions leading to bladder dysfunction can be caused by multiple factors including but not limited to:

- *Brain and brainstem*: Brain tumors, dementia, Parkinson's disease, cerebrovascular accident (CVA), or traumatic brain injury
- *Spinal cord*: Multiple sclerosis (MS), spina bifida, traumatic spinal cord injury, spinal surgery
- *Peripheral nervous system*: Diabetes, chronic alcohol abuse, chemotherapy-induced peripheral neuropathy, Guillain-Barré syndrome
- *Other*: HIV, systemic lupus erythematosus (SLE)[16]

In a patient undergoing palliation, it is unlikely that many of the usual investigations (such as urodynamic testing) or treatments (such as injection of botulism toxin, electrical nerve stimulation, or surgery) designed primarily for a nonpalliative population would be recommended. Conservative management is likely to be more appropriate. Depending upon the primary urological issue, this may include:

- Indwelling urethral or suprapubic catheter/intermittent catheterization[9]
- Continence products such as urinary sheaths[17]
- Anti-muscarinic therapy[18]
- Behavioral treatment
- Toileting assistance.

The benefits of these methods will need to be balanced with potential risks to the patient (e.g., urinary tract infection introduced by catheterization). Other options may be considered in discussions with the patient and his or her clinical team if survival for some months is expected or if the symptoms are severe and uncontrolled by conservative management.

Metastatic spinal cord compression (MSCC) is developed by about 5% of patients with cancer.[19] It is a medical emergency and often presents in the acute setting; however, by its very nature (metastatic cancer) it is a concern for palliative care nurses. It occurs when the spinal cord or cauda equina is compressed (e.g., by direct pressure of a tumor) in such a way that could cause neurological disability.[20] If diagnosis and treatment is delayed, the consequences can be serious, with irreversible loss of motor and bladder function.[21] Urinary incontinence is a late feature of spinal cord compression, but with cauda equina syndrome, bladder dysfunction in the form of retention or overflow incontinence may present at an earlier stage.[22] The following patient case study illustrates the potential management for a patient presenting with MSCC.

Case Study: A Patient with Advanced Prostate Cancer

Mr. Taylor is a 67-year-old man with advanced hormone-resistant prostate cancer. He has recently discontinued chemotherapy due to disease progression. He is admitted to the hospital from primary care with symptoms including bilateral sciatic pain and urinary retention. Due to the presence of known metastases, spinal cord compression is suspected. The following management strategies are employed following an urgent magnetic resonance imaging (MRI) scan confirming cauda equina syndrome:

- Administration of analgesia for comfort
- Flat bed rest with neutral spine alignment (venous thromboembolism prophylaxis and pressure area care is necessary)
- Bladder scan and indwelling urinary catheterization for relief of retention
- Administration of high-dose dexamethasone to relieve peri-tumoral edema
- Plan for surgical decompression of the spine followed by radiotherapy

This management plan is discussed with Mr. Taylor, his wife, and his two adult sons. Mr. Taylor understands the potential risks, but is reluctant to undergo surgery, and therefore radiotherapy with further high-dose steroids to combat radiation-induced edema is initiated. Following successful treatment, Mr. Taylor undergoes a trial removal of his indwelling urinary catheter. He successfully manages to pass urine and is discharged home with his wife and the support of the community palliative care nursing team.

Many patients like Mr. Taylor are catheterized due to urinary dysfunction. However, there is little research-based evidence to guide urinary catheter use at the end of life.[1] Despite this, a significant proportion of patients in receipt of palliative care in an acute or hospice setting are catheterized.[23,24] Insertion of a urinary catheter in the patient receiving palliative care must be carefully considered. Although insertion of the catheter may provide comfort from retention and keep an incontinent patient dry, the act of insertion itself may cause distress, and an indwelling catheter may be uncomfortable.[25] In addition, urinary catheters may present problems of their own, including leakage due to bypassing, blockage, and infection.[26–28] There are a number of reasons it is generally deemed appropriate to insert a urinary catheter at the end of life.

- Urinary retention/distended bladder
- Immobility due to severe pain (meaning that using a bedside commode is impossible and that frequent changes of bed linen caused by episodes of incontinence is distressing)
- Management or prevention of wound damage such as sacral pressure ulcers[29]

Urinary incontinence alone is not an indication for urinary catheterization. If an indwelling urethral catheter is inserted, daily assessment should be made as to whether the catheter is still required. Intermittent catheterization may be considered as an alternative to indwelling catheterization, depending on each patient's health condition, preferences, and life expectancy.

Incontinence and Toileting

Almost everyone will need help to manage toileting (intentional opening of bladder or bowels) or urinary incontinence (involuntary loss of urine) at the end of life. High rates of toileting problems and incontinence at the end of life are associated with functional and cognitive decline, often with additional impact from curative and palliative treatments. Prevalence varies by diagnosis and proximity to death, with sudden death associated with lowest rate (range 28.6–37.0%) and frailty or dementia the highest (65.3–72%) in the last year of life.[30–32] By the last month of life 67–89% of people in nursing homes were found to experience incontinence,[31] and in acute palliative care environments, incontinence increases in last 7 days of life (30% to 65%).[10] However, decreased urine output is associated with high likelihood of death within 3 days.[10]

As cognitive and functional abilities decline, the ability to self-manage toileting reduces and people become more reliant on caregivers to access toileting facilities (e.g., commodes or urinals) or voiding becomes involuntary and containment products are required. Generic assessment tools assessing a broad range of symptoms at the end of life do not include the detail required to fully assess incontinence, but currently no specific tool is available to guide end-of-life continence assessment.[33] However, everyone approaching the end of life should be assessed for current or potential incontinence or toileting problems, including:

- Identifying any potentially modifiable causes and precipitating or relieving factors
- Determining the frequency and severity of urinary leakage or toileting difficulties
- Establishing current containment methods used and their usefulness and exploring alternatives
- Evaluating the impact on the patient's quality of life, including a holistic assessment of the individual's experience of his or her symptoms
- Identifying changing needs and planning ahead[34]

Appropriateness of interventions to reduce either the frequency or severity of urinary leakage or the impact of the leakage needs to be judged in the context of proximity to death, as well as cognitive and physical limitations. In the terminal phase of life, there are two main bladder management goals: symptom management including avoidance of pain or discomfort and achieving social continence to protect personhood and dignity. There is no evidence to support or refute any of the commonly used pharmacological, lifestyle, or behavioral interventions aimed at the wider population or the frail elderly to achieve these goals in the last days and weeks of life.[34] Most commonly used interventions, such as dietary modifications or bladder training, are unlikely to be appropriate in the last weeks of life. For some people, behavioral interventions such as prompted voiding could support the maintenance of continence while physical and cognitive functionality allows.[34]

Where the trajectory of decline is clear, increasing reliance on caregivers and toileting or incontinence aids should be anticipated. As functional ability declines, patients will require increased support to reach and use toilets or toileting aids (such as commodes or urinals) or assistance with containment products such as absorbent pads or urinary sheaths. Indwelling urinary catheters are commonly used, and although guidelines widely accept symptom management at the end of life as a valid reason for using a catheter, uncertainty about best practice at the end of life remains.[1,34]

Choosing the right toileting aid or containment product can be complex. The individual's physical needs and personal preferences, daily activities, the context of care (e.g., who will be providing day-to-day care—family caregiver or healthcare professional) and the availability of devices will impact on decision-making. It can be necessary to trial several products to find the one that best meets an individual's needs, as illustrated by the following patient case study.

Case Study: A Patient with Incontinence

Mrs. Patel was 84 and lived in a nursing home. She recently fractured a hip, was very frail, and was believed to be in the last weeks of life. She had been unable to get out of bed to use a toilet or commode, she found bed pans painful to use due to the need to move her hips, and found absorbent insert pads often leaked, leading to uncomfortable changes of bed linen. After discussions on the risks and benefits of catheter use with her nurse, Mrs. Patel requested to try an indwelling device. Her catheter continuously drained into a urine collection bag which was emptied by her caregivers. However, after a few days, Mrs. Patel became agitated because the catheter was uncomfortable and she developed a urinary tract infection, requiring antibiotics. After further discussions with her nurse, Mrs. Patel asked for the catheter to be removed and to try absorbent pads again, but this time with a wrap-around diaper design. This design better contained her urine and allowed for less frequent and less complex changes.

As seen in Mrs. Patel's case, a choice of products can be helpful. Table 17.2 details some commonly used products.

All products can be potentially hazardous, and those at the end of life are vulnerable to adverse effects; for example, infection from catheters or urinary sheaths, leakage leading to uncomfortable changes of bed linen, or trauma to skin or tissue from body-worn devices. With all of these products, regular careful attention to hygiene and washing should be maintained to minimize harm to skin from the urine,[35] to help maintain comfort, and to avoid unpleasant smells.

Common Bladder Disorders and Emergencies

If the nursing goal of palliative care is to lessen the patient's distress without causing further distress, a key issue for discussion must be bladder discomfort. Bladder discomfort in patients approaching the end of life can arise from a number of sources.

Table 17.2 Toileting aids and containment products suitable for patients receiving palliative care

Toileting aids provide an alternative to the toilet for when a patient can voluntarily void urine	**Bedside commodes** can be used by patients who can safely transfer (with or without support) from bed to commode and back and maintain a seated position, but are unable to reach a conventional toilet. Different size designs, from paediatric to bariatric are available to accommodate different body frames. The commode should be emptied and cleaned after every use to avoid smell. As condition can change rapidly at the end of life, care should be taken to assess the patient's ability to transfer before each use. **Handheld urinals** are available in designs (reusable or disposable) suitable for either men or women and can be useful when mobility is limited. Products for women tend to have a flat end which can be put into position underneath the patient, whereas products for men ("bottles") generally have an aperture to accommodate the penis. Urinals can often be used in a supine or seated position and might help to maintain independence by reducing the need for a caregiver to help with mobility. Different designs are available to help with different limitations, for example poor grip. **Bedpans** are more commonly used when people wish to move their bowels but are unable to safely or comfortably transfer to a commode or conventional toilet. Bedpans can be uncomfortable and difficult to clean outside hospital environments, and, generally, handheld urinals are preferred for micturition, particularly for men. Some women might prefer a bedpan if handheld urinals do not work well for them.
Containment products are used when the patient cannot comfortably or reliably control voiding. Many people benefit from using a combination of products (e.g., different products for day and night).	**Absorbent products** are the most commonly used containment products to manage urinary incontinence and are available in a wide range of designs and styles, including disposable and washable. Pads should contain leakage and smell, be comfortable, discreet, and easily changed. To get the right pad, assessment must consider level (light, moderate, or heavy) and type of leakage (e.g., urinary only or urinary and fecal), whether the person can stand for product changes (e.g., avoid pull-ups if the person cannot stand), convenience (e.g., washables can work well for heavy leakage, but require washing and drying facilities), and individual preferences. Product design requirements are likely to change as functional abilities decline. **Male devices** include urinary sheaths (condom catheters) and body-worn urinals that are attached via tubing to urinary collection bags. Sheaths come in different sizes, styles, and materials (latex or silicone), and men should be carefully measured to ensure a good fit. A new sheath should be fitted at least daily after washing. For men with a retracted penis, an external device that fits to the glans is available. Body-worn urinals can offer an alternative if a sheath is not successful, but might not be suitable for men nursed in bed. The use of **indwelling catheters** is described elsewhere, and indications for use in the terminal phase include urine retention, skin protection, or patient preference for comfort (e.g., frequent product changes cause pain). However, it is important to remember that catheterization is an invasive procedure and alternatives should be fully explored.

Bladder spasm (sometimes discussed as *overactive bladder*) occurs when the detrusor muscle contracts suddenly. This can cause intense suprapubic and urethral pain. Spasms can also cause an urge to urinate and can force urine out of the bladder, leading to leakage. These spasms can therefore be very distressing for the patient. Common causes of bladder spasm include:

- *Disease-related*: Tumor infiltration, blood clots, spinal cord injury or other neurological conditions
- *Treatment-related*: Radiation fibrosis, chemotherapy- or radiation-induced cystitis, bladder or other lower abdominal surgery, medications such as intravesical bacillus Calmette-Guerin (BCG) or mitomycin (MM)
- *Mechanical causes*: Presence of indwelling catheter or ureteral stent
- *Infective causes*: Urinary-tract infection

Treatment for bladder spasm will depend on the cause and also the situation and preferences of the patient. If the cause is an indwelling catheter, the catheter could be changed, the volume of the balloon could be reduced, or a bladder washout could be performed to reverse catheter sludging, although there is not enough evidence of the efficacy of this technique to recommend a particular protocol.[36] If these are not sufficient, consideration should be made as to whether the catheter could be removed altogether or whether intermittent catheterization could be employed as an alternative. Pharmacological treatments can be employed to reduce bladder spasm or relieve the resulting pain. Antimuscarinic drugs such as oxybutynin or tolterodine reduce the sensitivity of the bladder muscle, decreasing bladder contractions.[37] Tricyclic antidepressants such as imipramine and amitriptyline may also help to reduce spasms.[38] Analgesics such as morphine can be used to reduce pain if it is severe. Antibiotics can be administered for urinary tract infection if it is believed that the patient's quality of life will be improved.[39] Overactive bladder in the absence of spasm or pain can be managed with the use of a condom catheter, adaptation of the home environment, and effective nursing support where pharmacological treatments cause significant side effects or are of no therapeutic benefit.[40]

Hemorrhagic cystitis occurs when the epithelium of the bladder is damaged, leading to lower urinary tract symptoms including bladder irritation, painful and/or frequent voiding, and hematuria. Oncology patients are at risk as the causes include chemotherapy (particularly cyclophosphamide and ifosfamide, which are excreted through the bladder) and pelvic radiation. Bone marrow transplant patients are at particular risk due to the high levels of chemotherapy drugs they receive as part of their treatment[41] and their consequent susceptibility to BK virus–associated hemorrhagic cystitis. Hemorrhagic cystitis may also be caused by infection. This is an important condition for both nurses and patients to recognize as consequences can be severe, including urinary outlet obstruction, anemia due to bleeding, or even urosepsis (a severe systemic infection). Management strategies involve removing the cause of the problem, for example cessation of chemotherapy (if chemotherapy is the cause), or administration of antibiotics (if infection is the cause). Comfort measures such as administration of analgesics may also be appropriate.

Treatment interventions for hemorrhagic cystitis can include:

- Administration of intravesical medications such as hyaluronic acid
- Administration of hyperbaric oxygen
- Surgical options, including cutaneous ureterostomy, cystoscopy and diathermy, vesical artery embolization, and supravesical urinary diversion[42]

With all of these treatments, their appropriateness for palliative patients must be assessed.

As always, prevention is better than cure. Aggressive intravenous hydration, the administration of mesna (2-mercaptoethane sodium sulphonate), and continuous bladder irrigation alongside cyclophosphamide or ifosfamide can reduce the risk of the patient developing hemorrhagic cystitis, although these are not universally effective.

Hematuria is the presence of blood in the urine. It can be caused by invasive tumors, clotting defects, urinary tract infection, urinary tract stones, or chemotherapy- or radiation-induced cystitis. Bleeding can be microscopic or gross. In palliative care, intervention is not necessarily required if there is microscopic hematuria or if gross hematuria does not lead to urinary outlet obstruction or a clinically significant reduction in hematocrit or hemoglobin. For gross hematuria requiring treatment, required nursing actions are as follows:

- Review medication to check whether the patient is taking anticoagulants or NSAIDS (these may need to be suspended)
- Urinalysis (dipstick and microscopy) to determine infection status and location of bleeding

If bleeding persists, cystoscopy may be considered, but this must be carefully balanced with the goals of care for patients with advanced illness. The same may be said for intravenous fluid infusion and transfusion of red blood cells. Catheterization with a large-gauge catheter (22–24 French) and irrigation may be necessary if gross bleeding results in clots and obstruction, and if the patient can tolerate the catheter in situ.[43]

UTIs are common at the end of life, with an increased prevalence associated with having an indwelling urinary catheter.[44] However, diagnosing a UTI is not always straightforward and distinguishing between UTI and an asymptomatic bacteriuria that does not require treatment can be problematic, particularly in older adults or those unable to report symptoms.[45] Consensus guidelines have developed UTI definitions that generally include a urine culture with 10^5 CFU/mL or higher combined with the presence of genitourinary symptoms (i.e., dysuria, suprapubic pain or tenderness, frequency or urgency of urination).[45] UTIs can cause significant discomfort and delirium for patients at the end of life and can lead to sepsis and unwanted admission into acute care,[46] so it is important that symptom burden is minimized. Treatment guidance recommends considering narrow-spectrum antibiotics such as trimethoprim or nitrofurantoin as first-line treatments. Broad-spectrum antibiotics (e.g., amoxicillin/clavulanate, quinolones, and cephalosporins) should be avoided as they increase the risk of *Clostridium difficile* infection, methicillin-resistant *Staphylococcus aureus* (MRSA), and resistant UTIs that are becoming increasingly problematic.[47] However, UTIs are also one of the most common reasons for using antimicrobials at the end of life,[45] and unnecessary use should be avoided due to the potential for unwanted side effects (e.g., nausea or allergic reaction) and the burden of antimicrobial resistance. Asymptomatic bacteriuria should not be treated with antibiotics.

Psychosocial Factors and Care Environment

As the end of life nears, the focus of care shifts from treatment to maintaining dignity and comfort. Taboos around both death and bladder care, particularly incontinence, continue and patients, caregivers, and many healthcare professionals can find the topic difficult to discuss. However, patients have identified loss of dignity as a major concern as they approach death,[48] and, to help protect dignity, nurses must not shy away from conversations on bladder management and the dying process. This is particularly important if people wish to die at home and informal caregivers will be involved in day-to-day care.

Little is known about patients' preferences for bladder management at the end of life. However, we do know that maintaining privacy during intimate care such as washing, toileting, catheterization, and bowel interventions is viewed as important to patients and their informal caregivers.[49] Additionally, many people wish to die at home,[50] but this can be prevented due to the lack of support available for activities such as bladder care in community settings, and, even in countries where palliative care provision is advanced, the lack of "dying out of hours" services leads to the burden of care falling to informal caregivers,[49,51] which can be problematic for both the patient and the caregiver. Some patients might worry about having intimate care provided by family members,[52] and needing help with managing bladder emptying can add to patients' fears at the end of life. Furthermore, coping with incontinence problems has been demonstrated to greatly add to distress and workload for caregivers[53,54] who report feeling unprepared and unsupported in their role[55] and have requested more practically focused help to avoid crises, including information and guidance.[56]

Particularly when informal caregivers are involved in day-to-day bladder care at the end of life, they should be provided with the information, support, and equipment to successfully undertake the role, including preparation for sudden deterioration to avoid crisis situations. However, caregivers are often reluctant to seek help for incontinence-related problems.[57] To help individuals and their caregivers to protect dignity, avoid chaos or exhaustion, and maintain social continence, healthcare professionals should be proactive in openly discussing bladder problems and management strategies.[58]

Proactive discussions with patients (where possible) and informal caregivers should include explaining the need for regular assessment to take into account changing circumstances, listening to patient preferences, establishing the context of care (e.g., who will be caring for the patient), and the likely trajectory of incontinence needs and potential interventions (e.g., provision of bedside commode or absorbent products) that might be beneficial. Different palliative trajectories, such as short illness with rapid decline or long illness with intermittent acute episodes have been identified[59] and might impact on the nature of incontinence symptoms encountered and the speed of adaptation required. It is likely that, particularly when the person declines quickly, the need for rapid adaptation will increase the level of support and information required.

Conclusion

Bladder management in a patient receiving palliative care, whether in a hospital, hospice, or home environment, is a complex issue. It is, however, one which nurses and other healthcare professionals must be prepared to address, especially as doing so and finding a solution to a problem that has been perceived as intractable can make a tangible difference to the daily lives of both patients and caregivers. Nurses involved with looking after patients with bladder difficulties nearing the end of life may face barriers including lack of resources or knowledge about products available to assist these patients as well as the psychological and clinical considerations described in this chapter. Knowledge of local policies, procedures, and guidelines is therefore essential, in addition to the general overview provided by this chapter.

CHAPTER 18

Lymphedema Management

Mei R. Fu, Bonnie B. Lasinski,
Janet H. Van Cleave, and Charles P. Tilley

Key Points

- Lymphedema is a syndrome of abnormal accumulation of lymph fluid and multiple symptoms that is caused by irreversible damage to and congenital malformation of the lymphatic system.
- There is no cure for lymphedema, and management of lymphedema requires daily self-care and changes in lifestyle.
- Promotion of lymph fluid flow and prevention of infection is fundamental to achieve long-term effective lymphedema management.

Definitions

Lymphedema is the pathological accumulation of protein-rich lymph fluid in the interstitial tissue spaces due to an imbalance between lymph fluid production and transport, manifested clinically by tissue swelling and other physical symptoms (e.g., pain, heaviness, tightness, tingling).[1–3] *Edema*, a symptom, refers to excessive accumulation of fluid within interstitial tissues and is one of the manifestations of lymphedema. Long-term, neglected edema, such as lower extremity venous insufficiency, can develop into chronic lymphedema. Discerning the difference between edema and lymphedema ensures appropriate treatment.

One or several factors can precipitate an imbalance in extracellular fluid volume. Excess fluids, proteins, immunological cells, and debris in affected tissues can produce chronic inflammation and connective tissue proliferation, including hypertrophy of adipose tissue.[1,3,4] Some degree of progression usually occurs and can produce subcutaneous and dermal thickening and fibrosis.[2] Lymphedema and edema are contrasted in Table 18.1, which provides definitions, signs and symptoms, and basic pathophysiology.[3,4]

Prevalence and Risk Factors

The world prevalence of edema is unknown and that of lymphedema is poorly documented. Primary lymphedema, a genetic disorder, is attributed to embryonic developmental abnormalities, which may be sporadic or part of a syndrome caused by either chromosomal abnormalities (e.g., Turner's syndrome) or inherited single-gene defects.[5,6] Primary lymphedema occurs in about 1 in 6,000 individuals and is more common in women than men, with a 3:1 ratio.[7]

Secondary (acquired) lymphedema results from obstruction or obliteration of lymph nodes or lymphatic vessels.[1,8–10] Cancer, trauma, surgery, severe infections, cardiac disease, poor venous function, immobility, or paralyzing diseases are major causes of secondary lymphedema.[1,8–10] In developing countries, lymphatic filariasis, a parasitic infection transmitted by mosquitoes, is the predominant cause of secondary lymphedema. Mosquitoes transmit filariasis nematodes, which embed in human lymphatics and release inflammatory substances that cause progressive lymphatic damage. It is estimated that the worldwide incidence of filariasis is 856 million.[11] In developed countries, the most common causes of lymphedema are cancer and/or its treatment (e.g., surgery and radiation therapy) that damages the lymphatic system and surrounding soft tissues, resulting in the inability of the lymphatic system to transport lymph fluid from the tissues to the blood vascular system.[8–10] As a chronic and progressive disease, lymphedema is a significant health issue for many cancer survivors, including people with breast cancer (20–40%), gynecologic cancer (20%), melanoma (16%), genitourinary cancer (10%), head and neck cancer, and sarcoma (4%)[12,13] Risk factors related to cancer treatment include extent of surgery, extent of lymph node resection, and radiation therapy.[14–17]

Other major factors of lymphedema risk include inflammation, infection, and higher body mass index (BMI).[2,10,14] Breast cancer survivors who undergo surgery and dissection of lymph nodes and vessels are known to have a compromised lymphatic system, which makes them more vulnerable to infection and impaired lymphatic drainage.[2,10,15] Women who had previous infections were more likely to develop lymphedema; weight gain and obesity (BMI >30 kg/m^2) increase lymphedema risk.[10,14–16] Nevertheless, these risk factors only partially explain who develops lymphedema. Lymphedema can and does occur in women lacking these risk factors. Research on the effect of genetics or genetic variations on secondary lymphedema related to cancer treatment is very limited. However, mutations and genetic variations in lymphatic-specific growth factors are associated with hereditary lymphedema and secondary lymphedema related to breast cancer, such as vascular endothelial growth factor (VEGF-C, VEGF-D, VEGFR2, VEGFR3) and inflammatory cytokines (interleukin [IL]-4 and IL-13).[15,17,18] Understanding the biological mechanism of lymphedema through the exploration of inherited genetic susceptibility is essential for finding a cure.

Table 18.1 Comparison of edema and lymphedema

	Edema	**Lymphedema**
Disorder	A symptom of various disorders	A chronic, currently incurable edema
Definition	Swelling caused by the excessive fluid in interstitial tissues—due to imbalance between capillary filtration and lymph drainage over time	Swelling (edema) caused by accumulation of lymph fluid within interstitial tissues as a result of lymphatic drainage failure, increased production of lymph fluid over time, or both
Signs and symptoms	Swelling, decreased skin mobility	Swelling, decreased skin mobility
	Tightness, tingling, or bursting	Tightness, heaviness, firmness, tingling, feeling of fullness, or bursting sensations
	Decreased strength and mobility	Decreased strength and mobility
	Discomfort (aching to severe pain)	Discomfort (aching, soreness to severe pain)
	Possible skin color change	Progressive skin changes (color, texture, tone, temperature), impairment in integrity such as blisters, weeping (lymphorrhea), hyperkeratosis, warts, papillomatosis, and elephantiasis
	Pitting scale is often used:	*Pitting scale is NOT used.*
	1+ Edema barely detectable	
	2+ Slight indentation with depression	
	3+ Deep indentation for 5–30 s with pressure	
	4+ Area 1.5–2 times greater than normal	
Pathophysiology	Capillary filtration rate exceeds fluid transport capacity	Inadequate lymph transport capacity
		Primary—Inadequately developed lymphatic pathways
	Example: Heart failure, fluid overload, and/or venous thrombosis are common causes of increased capillary pressure, leading to an increased capillary filtration rate that causes edema	*Secondary*—Damage outside lymphatic pathways (obstruction/obliteration)
		Initial sequelae of transport failure:
		Lymphatic stasis → Increased tissue fluid → Accumulated protein and cellular metabolites →lymphedema
	Note: Timely treatment of the underlying cause or causes usually reduces edema	Further increased tissue water and pressure
		Potential long-term sequelae:
	Prolonged, untreated edema can transition to lymphedema	Macrophages seek to decrease inflammation
		Increased fibroblasts and keratinocytes cause chronic inflammation
		Gradual increase in adipose tissue
		Lymphorrhea (leakage of lymph through skin)
		Gradual skin and tissue thickening and hardening progressing to hyperkeratosis, papillomatosis, and other problems
		Ever-increasing risk of infection and other complications

Impact

Lymphedema impacts an individual's quality of life (QOL), causing physical discomfort, functional disabilities, impaired occupational roles, poor self-image, decreased self-esteem, interrupted interpersonal relationships, financial burden, and lifestyle changes.[19,20] Physically, lymphedema leads to distressing symptoms such as swelling, firmness, tightness, heaviness, pain, fatigue, numbness, and impaired limb mobility.[8,9,16] In addition, lymphedema predisposes individuals to skin and tissue fibrosis, cellulitis, infections, lymphadenitis, and septicemia.[10,16,20] Prolonged fluid stasis can lead to severe skin and tissue symptoms, sometimes referred to as *elephantiasis*. Symptoms include hyperkeratosis (hard, reptile-like skin), warts, and papillomas (engorged and raised lymph vessels on the skin surface).[10,16] Chronic lymphedema, over a number of years, has also been associated with the development of the rare, usually fatal cancer, lymphangiosarcoma.[2] Functionally, lymphedema makes it difficult for individuals to accomplish tasks and impairs their abilities to fulfill work that involves heavy lifting, gripping, holding, fine motor dexterity, and repetitive movement of the affected limb.[20,21] Psychologically, individuals feel stigmatized and some experience loss of sexual attractiveness because of obvious disfigurement, which often elicits emotional distress, social anxiety, depression, and disruption of interpersonal relationships.[19,21] Routine check-ups for lymphedema management, long-term physical therapy, management equipment (compression garments, bandages, special lotions), and repeated cellulitis, infections, and lymphangitis create financial and economic burdens not only for survivors but also for the healthcare system.[22]

Anatomy, Physiology, and Pathophysiology

Edema

Edema is a symptom that results from an imbalance between capillary filtration and lymph drainage. Edema requires treatment of the underlying disorder that is precipitating tissue fluid excess. Precipitators can include cardiac, hepatic, renal, allergic, or hypoproteinemic disease; venous obstruction; and medication complications[23] (see Table 18.1). Chronic edema can develop into secondary lymphedema with sufficient lymphatic damage, such as in chronic venous insufficiency, posttraumatic swelling from significant soft tissue injury, or fractures of the lower extremities.[24]

Lymphedema

A healthy lymphatic system helps regulate the tissue cellular environment, including collecting and returning plasma and proteins.[25,26] Daily, 20–50% of the total accumulating plasma proteins travel through 2–4 L of lymph fluid in a healthy lymphatic system.[25,26] Lymphatics also remove cellular waste products, mutants, and debris; eliminate non–self-antigens; and regulate local immune defense in the process of maintaining homeostasis.[25,26] Unidirectional vessels traverse from superficial to deep lymphatics through 600–700 lymph nodes, carrying lymph fluid to the venous system at the right or left venous angle of the anterior chest on either side of the neck. Lymph nodes filter, concentrate, and purify lymph fluid, eliminating defective cells, toxins, and bacteria, explaining the increased risk of infection for patients with compromised lymphatics.[25,26] Lymphedema pathology signifies malfunction in any part of the process of collecting, transporting, filtering, and depositing lymph into the venous system. Lymphedema pathophysiology suggests disruption of these processes and is described in Table 18.1.

In brief, lymph fluid is transported initially from the interstitium by the initial lymphatic vessels, moving proximally through progressively larger collecting lymph vessels, filtered through lymph nodes, then drained into the two large lymph-collecting ducts, and finally returned to the venous bloodstreams via the left and right subclavian veins. Damage to any structures of the lymphatic system can lead to accumulation of lymph fluid in the affected area. Furthermore, physiological variations in each individual's lymphatic system, such as numbers or sizes of lymph nodes, make it difficult to quantify each individual's risk for lymphedema.

Secondary lymphedema from cancer treatment is caused by trauma to the lymphatic system mainly from surgery and radiotherapy.[8,11] Surgery creates disruption to the lymphatic system by directly dissecting lymph vessels and removing lymph nodes.[9] Unfortunately, lymph nodes do not regenerate once dissected.[25,26] Formation of scar tissue and tissue fibrosis from surgery create further impairment to lymph flow. The disruption or blockage of the lymphatic system reduces its ability to transport and filter the lymph, resulting in a functional overload and insufficient capability of the lymphatic system to transport the normal volume of lymph.[27] As a result, an abnormal accumulation of lymph fluid occurs, which leads to the swelling of the affected area.

Radiation exposure during radiotherapy is also traumatic to the lymphatic system. Radiation impairs the lymphatic system by causing tissue fibrosis surrounding the lymphatic vessels,[9] and it reduces lymphatic transport reserve by increasing long-term changes in basal lymph circulation and lymph flow in the affected area.[9,26] While lymphatic vessels are relatively insensitive to radiotherapy, lymph nodes are radiosensitive to conventional doses of radiotherapy.[26,27] The radiated lymph nodes respond first with lymphocyte depletion, followed by fatty replacement, then by fibrosis.[26,27] As a result, radiation hinders lymph nodes from properly filtering and transporting lymph and alters immune function. Research has not clarified the specific roles of chemotherapy in contributing to lymphedema. In addition to the definite risk from cancer treatment, certain personal risk factors such as weight gain or obesity (BMI >30), infection, and immobility increase an individual's risk for lymphedema.[8,9,14] Please check the mHealth System: http://optimallymph.org/ for the Lymphatic System video.

Precision Assessment and Diagnosis

Assessing and diagnosing lymphedema remains a challenge for research and clinical practice. Several factors contribute to the challenge: lack of universally recognized diagnostic criteria, failure to precisely evaluate symptoms, coexisting conditions, and lack of awareness of lymphedema among healthcare professionals.[15,27,28] Inconsistency in the criteria defining lymphedema and the use of different measures in research have presented tremendous challenges in the assessment and diagnosing of lymphedema.[3,9,15,28] Often, lymphedema is diagnosed via provider observation of swelling in clinical practice. Lymphedema can occur in the head, neck, shoulder, breast and thoracic regions, abdomen, lower extremities, foot, or ankle. No epidemiological studies have explored the incidence of lymphedema in these difficult-to-measure body areas, mainly due to lack of instruments to quantify swelling. As a result, precision assessment of lymphedema phenotype remains an ongoing challenge in research and clinical practice.[3,9,15,28] A critical need exists to understand heterogeneity (i.e., different types) of lymphedema phenotype to advance precision phenotype assessment of lymphedema and provide insights to biological mechanisms.

To optimize the precision assessment of heterogeneity of lymphedema phenotypes and ensure accurate diagnosis, it is important to conduct a careful review of the patient's health history to rule out other medical conditions that may cause similar symptoms, such as recurrent cancer, deep vein thrombosis, chronic venous insufficiency, diabetes, hypertension, and cardiac, hepatic, thyroid, and renal diseases. These alternative diagnoses should be ruled out before establishing a diagnosis of lymphedema and referring the patient for lymphedema therapy. "Best practice"[9–28] components of lymphedema nursing

Box 18.1 Sequential Components of Lymphedema Assessment

- *Rule out or address immediate complications* (i.e., infection, thrombosis, severe pain, new or recurrent cancer, significant nonrelated disorders)
- *History and physical examination*
  - Routine physical assessments: Vital signs, blood pressure, height and weight, body mass index
  - Past and current health status, including medications and allergies (especially antibiotic allergies and history of infection, trauma, or surgery in affected area)
  - Current activities of daily living (job, home responsibilities, leisure activities, sleep position, activities that aggravate lymphedema)
  - Current psychological health, support people, view of lymphedema and health
  - History of lymphedema etiology, presentation, duration, and progression
- *Patient knowledge of and response to lymphedema, interest in assistance and goals*
- *Third-party payer status*
- *Quantification of lymphedema status* (lymphedema signs and symptoms, volume, pain and other neurological symptoms, tissue status, range of motion of nearby joints, site-specific and overall patient function)

assessment are displayed in Box 18.1. The first assessment priority is proper diagnosis. For example, the assessment of a frail elderly woman with suspected lymphedema reveals that early symptoms of congestive heart failure are responsible for a suspected lymphedema. When the results of the physical assessment and patient history are combined with dialogue, the patient reports that she has replaced her cardiac medication with several natural supplements in order to save money and avoid "toxic drugs." Her edema resolves within several days after she resumes her cardiac medications. Some patients, especially those who are elderly, chronically ill, or significantly distressed, are not able to provide an accurate medical history. Reviewing the medical record can provide excellent assessment information. However, even the best medical record isn't always complete.

Supportive communication with the patient can encourage them to be open and not afraid to "admit" to deviations from their recommended treatment/medication regimens, which helps the clinician to accurately assess the patient's condition and response to treatment. Supportive communication helps to understand patient's perspectives and gain essential information, including the patient's (1) view of lymphedema, (2) readiness for instruction and treatment, (3) pertinent work and lifestyle, (4) spiritual concerns, (5) illness and adjustment issues, and (6) desired goals. Often the patient's initial goal is cure, which is unattainable. In this situation, the patient needs time to understand the chronicity of lymphedema and to formulate new goals. Nurses' awareness of patient quality-of-life goals fosters collaboration and management success. Instruction, support, multidisciplinary referrals, goal setting, assistance with self-care, complication avoidance, and long-term management are improved by nurses' and healthcare providers' understanding of patients' perspectives and knowledge.[29]

An early lymphedema diagnosis is often determined solely from a history and physical examination,[28] especially if conservative management is planned and symptoms are not severe. Questionable clinical symptoms or etiology may require further evaluation. Lymphoscintigraphy (isotope lymphography) can ensure definite lymphedema diagnosis.[9] Lymphography (direct) is now rarely used in lymphedema patients because of its potential to cause lymphatic injury and its inability to clarify function.[9]

Assessment for infection, thrombosis, or cancer metastasis is required at every patient contact.[9,16] Although later signs of infection or thrombosis are well known, awareness and careful assessment allow early diagnosis and treatment. Lymphedema progression or treatment resistance may be the earliest sign of complication or may represent a lack of response to current treatment. Changes in pain or comfort, skin (color, temperature, condition), or mobility and range of motion are other possible early signs of major complications.[3] Most infections develop subcutaneously, beneath intact skin. Cultures are not recommended because they rarely document a bacterial source and can further increase the risk of infection.[9] Suspected thrombosis or new or recurring cancer requires appropriate diagnostic evaluation (e.g., Doppler ultrasonography, magnetic resonance imaging, positron emission tomography, computed tomographic scanning). Venous ultrasonography is reported to be safer than venography for evaluation of suspected thrombosis in a limb with or at high risk for lymphedema.[9,26]

Basic treatment of complications are also included. Signs and symptoms of metastasis can include pain, neuropathies, new masses or lesions, skin/tissue color and texture changes, and treatment-resistant rashes. For thrombosis, signs can include distended veins, venous telangiectasia, and rapid edema progression beyond the affected limb into adjacent areas of the torso. Thrombosis requires anticoagulation, pain control, rest, and avoidance of use of external compression. Currently, no research clarifies the appropriate timing for use of compression after thrombosis, and the traditional 6-month delay until use of compression should be assumed. Discussion of this issue with the physician is appropriate. In contrast, some physicians recommend the use of limb support for several days or longer after painful thrombosis-related swelling, especially in the presence of metastatic cancer. Some clinicians suggest that compression can be safely applied post acute central venous thrombosis (CVT) and can ameliorate the exacerbation of swelling and other symptoms that occur in postthrombotic syndrome. Until research enables a practice standard, the timing of support and compression is based on clinician preference.

Case Study: A Patient with Thrombosis and Lymphedema

A diagnosis of early thrombosis was made for a 67-year-old patient with advanced metastatic lymphoma and leukemia when left leg thrombosis developed rapidly while the patient was hospitalized for a cancer complication. Thrombosis encompassed the entire leg. During anticoagulation, leg edema, pain, and signs of venous insufficiency continued to progress. Several weeks later, the patient was referred to the clinical nurse specialist for assistance. Excess edema volume in the affected leg (compared with the unaffected leg) was 94% (4,816 mL). A compression garment (similar to those elastic garments used after cosmetic surgery) was provided (with physician approval) for 1 week, and 9% limb reduction was achieved. Good product tolerance was reported. A demonstration of compression legging (lower extremity, full-leg product that uses high-low foam and a Spandex compression sleeve) was then provided with instructions to use it as tolerated, reverting to the compression garment whenever the compression legging was removed. One week later, follow-up assessment revealed edema reduction of 43%, compared with the initial volume. Excess volume had decreased from 94% to 54% (2,730 mL). The patient also agreed to referral to a lymphedema therapist to obtain daytime compression stockings and to undergo several sessions of lymphatic drainage massage. Five weeks after the initial assessment, the patient returned for follow-up wearing her new stockings, her "tight-legged" slacks, her wig, and a large smile. Pain level, skin color and condition, gait, and range of motion of the ankle, knee, and hip were significantly improved. Edema reduction in the lymphedema limb was 81%; excess volume was 18% (926 mL). By 4.5 months following the initial assessment, edema reduction had continued. Treatment included daytime stockings and compression legging usage several nights a week. Edema reduction at this time was 87%. Excess limb volume, compared to the contralateral leg, was 12% (634 mL).

Assessment of Symptoms

Lymphedema is a sign of an impaired lymphatic system.[1,2,9,26] Impairment in the lymphatic system leads to a chronic disease state with multiple associated symptoms, such as heaviness, tightness, firmness, pain, numbness, or impaired mobility.[3,10,15,16] The experience of lymphedema symptoms is an ongoing debilitating complication that impacts QOL.[20–22] Symptom assessment is essential since very often observable swelling and measurable volume changes are absent during the initial development of lymphedema.[3,10,15] Table 18.2 presents an example of a symptom checklist for breast cancer–related lymphedema.[4] Assessing lymphedema symptoms plays an important role in diagnosis until objective measurements capable of detecting latent stage of lymphedema are established in at-risk individuals.[26] Recent research shows that limb volume change (LVC) has significantly increased as breast cancer survivors' reports of swelling, heaviness, tenderness, firmness, tightness, and aching have increased.[3,30] In addition, a diagnostic cutoff of three symptoms was able to detect breast cancer survivors with lymphedema from healthy women with 94% of accuracy, while a diagnostic cutoff of nine symptoms identified survivors with lymphedema with 64% of accuracy. As early intervention leads to better clinical outcomes, patients with nine or more symptoms should be evaluated immediately and treated in a timely manner.[3] Recent research also examined if symptom clusters, denoted as groups of more than two symptoms, indicate different biological mechanism.[15] Three major symptom cluster phenotypes were identified: fluid accumulation, impaired limb mobility, and discomfort. The identification of different symptom cluster phenotypes provides a foundation for future research to explore the biological mechanism, so that targeted precision intervention for each symptom cluster phenotype can be developed to achieve optimal symptom management.

Table 18.2 Example of symptom checklist: breast cancer and lymphedema symptom experience index

The following questions are about symptoms in your affected arm, hand, breast, axilla (under arm), or chest today or in the past month.
Have you had ____? No Yes
1. Limited shoulder movement
2. Limited elbow movement
3. Limited wrist movement
4. Limited fingers movement
5. Limited arm movement
6. Hand or arm swelling
7. Breast swelling
8. Chest wall swelling
9. Firmness
10. Tightness
11. Heaviness
12. Toughness or thickness of skin
13. Stiffness
14. Tenderness
15. Hotness/increased temperature
16. Redness
17. Blistering
18. Pain/aching/soreness
19. Numbness
20. Burning
21. Stabbing
22. Tingling (pins and needles)
23. Arm or hand fatigue
24. Arm or hand weakness

Quantification of Lymphedema

A variety of measurement approaches make quantification of lymphedema a problem.[15,28,31] Methods of measuring limb volume or circumference include sequential circumference limb measurement, water displacement, and infrared perometry.[31] Bioelectrical impedance is emerging as a possible alternative.[28] Unfortunately, lymphedema can also occur in the face, neck, shoulder, breast, abdomen, thoracic regions, and genital areas, which presents a challenge for quantification.[3,15,32]

Sequential Circumferential Arm Measurements

Measuring limb volume and circumference are the most widely used diagnostic methods. A flexible nonstretch tape measure for circumferences is usually used to assure consistent tension over soft tissue, muscle, and bony prominences.[28,31] Measurements are done on both affected and nonaffected limbs at the hand proximal to the metacarpals, wrist, and then every 4 cm from the wrist to axilla. Limb size and limb volume are calculated based on sequential circumferential arm measurements. The formula often used for calculating limb volume with a presurgery baseline limb volume is: Limb Volume Increase = (Affected Frustum Limb Volume$_{\text{Follow-up}}$ /Affected Frustum Limb Volume$_{\text{baseline}}$)/ (Contralateral Frustum Limb Volume$_{\text{Follow-up}}$ /Contralateral Frustum Limb Volume$_{\text{baseline}}$).[28,31] If presurgical baseline limb volume is not available, the following formula can be used: Limb Volume Ratio = Affected Frustum Limb Volume/Contralateral Frustum Limb Volume; Limb Volume–Difference = Affected Frustum Limb Volume–Contralateral Frustum Limb Volume.[28,31] Arm lymphedema is often arbitrarily defined as 2 cm or more in limb girth or 200 mL or greater difference in limb volume as compared to the unaffected limb or 10% volume increase in the affected limb from presurgery baseline limb volume.[28,31] Recent research has shown that among breast cancer survivors, a 5% or greater limb volume increase from presurgical baseline enables detectable differences in QOL and better clinical outcomes with interventions to promote lymph flow[30] (Figure 18.1).

Water Displacement

Although water displacement has been considered the "gold standard" for limb volume measurement and is identified as a sensitive and accurate measure in the laboratory setting, water displacement is seldom used in clinical settings because of spillover and hygienic concerns.[28] Patients submerge the affected arm in a container filled with water and the overflow of water is caught in another container and weighed. This method does not provide data about localization of the edema or shape of the extremity.[28] The method is contraindicated in patients with open skin lesions. Patients may find it difficult to hold the position for the time needed for the tank overflow to drain.

Infrared Perometry

The infrared perometer, an optoelectronic device developed to meet the need for a quick, hygienic, and accurate method for volume calculation, works similarly to computer-assisted tomography, but makes use of light instead of x-rays (Figure 18.2).[31,33] The perometer maps a three-dimensional graph of the affected and unaffected extremities using numerous rectilinear light beams and interfaces with a computer for data analysis and storage. A three-dimensional limb image is generated, and limb volume is calculated automatically. This optoelectronic method has a standard deviation of 8.9 mL (arm), less than 0.5% of limb volume with repeated measuring.[30,31] Perometer can be operated by nurses or lymphedema therapists after training.

Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) measures impedance or resistance of the extracellular fluid using low frequency electrical current.[34] BIA provides an impedance ratio to calculate a Lymphedema Index (L-Dex ratio). With the development of lymphedema, the limb impedance decreases and the L-Dex ratio therefore increases. The L-Dex ratio ranges from −10 to +10. Since approximately 20% of true arm lymphedema cases are still missed by BIA with a cutoff point of greater than +7.1, it is critical for healthcare professionals to incorporate other assessment methods, including self-report, clinical observation, or perometry to ensure precision assessment of arm lymphedema[34] (Figure 18.3).

Lymphedema Risk Reduction

Patient education focusing on risk-reduction strategies holds great promise for reducing the risk of lymphedema. A recent systematic review based on findings from several randomized clinical trials (RCTs) from 2009 to 2014 have suggested that prevention and early intervention protocols focusing on the implementation of prophylactic patient assessment/monitoring and relevant interventions are effective to reduce risk of arm volume increase and to identify early stages of lymphedema development.[8] A recent one-group trial (N = 140) was completed with 4% attrition rate.[30] All the participants received face-to-face, nurse delivered *The-Optimal-Lymph-Flow* intervention to promote lymph flow and healthy weight. During the study period, two patients with sentinel lymph node biopsy and two patients with the axillary lymph node dissection had measurable lymphedema (>5% limb volume). At 12-month follow-up, among the four patients with measurable lymphedema, two patients' limb volume returned to preoperative levels without compression therapy but by maintaining *daily lymphatic* exercise. At 4–8 weeks after breast cancer surgery, 100% of participants reported at least one symptom (average seven symptoms); at 12 months after surgery, 65% participants were symptom free and the other 35% participants had an average of two symptoms. Furthermore, *The-Optimal-Lymph-Flow* has been developed as a digital therapy that uses behavioral and lifestyle changes to treat or manage health conditions, such as treating chronic pain or symptoms or optimizing management of

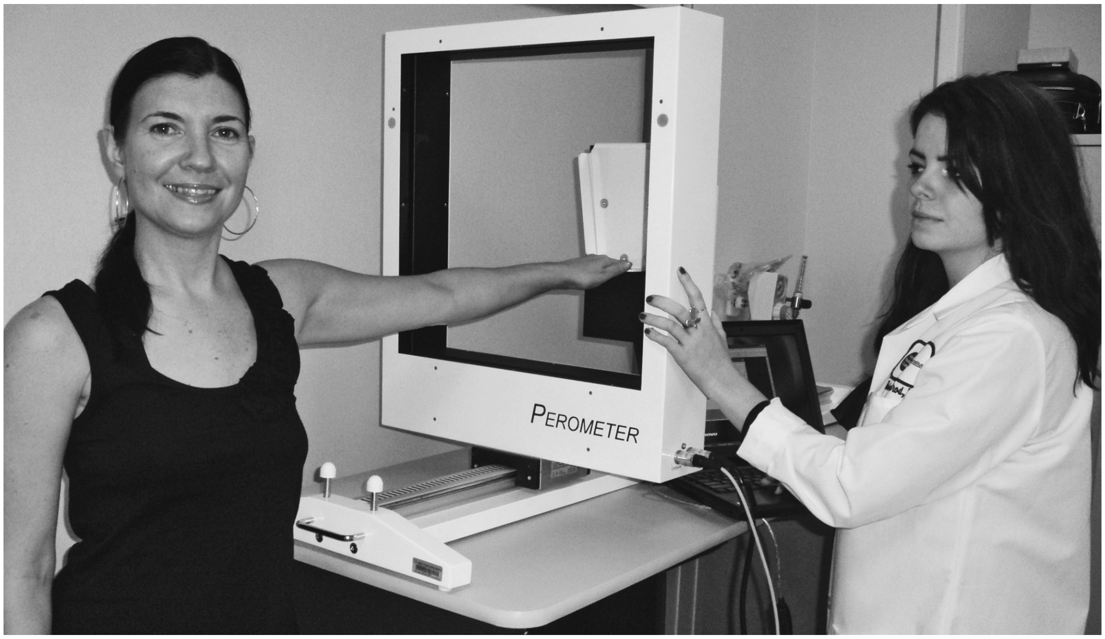

Figure 18.2 Infrared perometer measurement.

chronic illness or reducing the risk of lymphedema by utilizing web- and mobile-based digital technology to deliver treatment and monitor progress.[35,36] *The-Optimal-Lymph-Flow* mHealth system is a patient-centered, web- and mobile-based digital therapy focusing on safe, innovative, and pragmatic electronic assessment and behavioral strategies for lymphedema symptom management. Preliminary findings from the pilot research is promising.

Infection prevention is vital for lymphedema risk reduction.[30,35,36] Infection is a significant risk factor and is the most frequent lymphedema complication.[10,16,37] Risk increases with breaches in skin integrity. Occasional drawing of blood from the limb at risk is necessary for some patients when no other reasonable option exists.[8] Patients can request an experienced phlebotomist and emphasize their increased infection risk. Subcutaneous, intramuscular, or intravenous injections in the limb at risk can cause an allergic or inflammatory response and/or infection that may compromise a weakened lymphatic system. These risks must be compared with the benefit and risk of use of a central venous catheter or suboptimal venipuncture site such as the lower extremity.[8] Diabetes potentially increases breast cancer patients' lymphedema risk when the affected limb is used for continual blood sticks or insulin injections. Patients with bilateral limb risk, especially of the upper extremities, face lifelong decisions regarding adherence to precautions.

Breast cancer disease and treatment factors are associated with increased lymphedema risk, including advanced cancer stage at diagnosis and radiation therapy to the axilla or supraclavicular area after a mastectomy. The benefits of early nursing intervention in decreasing lymphedema occurrence, severity of secondary lymphedema, and lymphedema symptoms in breast cancer survivors have been well documented.[30,35,36] Nurses can assist high-risk patients by presenting or reinforcing prevention information and encouraging use of a well-fitted compression sleeve and gauntlet or glove at the earliest sign of edema. Emphasis on self-protection rather than rigid rules fosters patient empowerment.[30,35,36] For example, an empowered patient assumes responsibility for reminding staff to avoid use of the affected arm rather than expecting medical personnel to remember to do so.

In the past, breast cancer survivors were cautioned to restrict exercise as a way to reduce their risk for lymphedema. However, a growing body of evidence suggests that exercise does not necessarily increase lymphedema risk.[8] Research suggests that breast cancer survivors should be encouraged to carry out all postoperative exercises, resume normal precancer activities as tolerated, and be as fit as possible while regularly monitoring their high-risk or affected limb.[8] In addition to the importance of physical exercise in general health, weight control, and QOL, physical exercise can promote lymph fluid drainage through large muscle movement. Individuals should be instructed to perform physical exercise according to the general exercise guidelines[8]: (1) initiate exercise at lower intensity gradually increasing intensity as tolerated, monitoring the at-risk limb/s for signs and symptoms of swelling; (2) exercise to the extent that the affected body part is not fatigued; (3) modify physical exercise to reduce the risk of trauma and injury; and (4) use a compression garment during exercise if recommended by healthcare professionals with lymphedema training.

Case Study: A Patient with Ovarian Cancer

Ms. S is a 51-year-old woman who underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy in April 2008 (TAH BSO 4-08) for ovarian cancer. She received postop external beam radiation treatment to her abdomen and pelvis. Postoperatively, she developed a pelvic abscess, sigmoid perforation, and an ileovaginal fistula. The fistula and perforation were repaired, and an ileostomy was done. Ms. S stated that the swelling in her right lower extremity began after the fistula repair and ileostomy surgery 12/12. She presented for evaluation in February 2013 with genital swelling and fluid leakage from vagina as well

as moderate pitting edema of her right lower extremity, toes to groin, with complaint of ache and heaviness 4 out of 10 (4/10). She denied swelling in her left lower extremity, which was at risk because of lymph node dissection (LND) and radiation treatment (XRT). The skin of both lower extremities was intact but taut with a slight violaceous discoloration suggestive of some venous impairment. She had chemotherapy-induced peripheral neuropathy in both feet (CIPN both feet), chronic low back pain (chronic LBP) related to herniated disc L5–S1, hypertension, adult onset diabetes mellitus, hypothyroidism, and asthma. Patient scored herself 52% impairment on the Lower Limb Functional Index tool. She reported that her right lower extremity and pelvic area become more swollen and painful as the day progresses, limiting her ability to walk or drive any distance. Ms. S was taking ibuprofen and oxycodone/acetaminophen to control her pain and duloxetine for depression. Pretreatment volume difference between legs was 49.7% (5,288 mL). Complete decongestive therapy (CDT) 5 days per week for 4 weeks was recommended to address Ms. S's goals to decrease her pain, tightness, and edema in her right lower extremity and genital area as feasible, improve collateral lymph drainage from her lower extremities and trunk to the axillae, and increase her endurance for functional activities as tolerated. Ms. S needed to be able to walk long distances and wanted to drive with her eldest son, a high school senior, to visit colleges. At the completion of treatment, she did achieve an 81% (4,270 mL) reduction in volume in her right lower extremity and a reduction in the genital swelling. She was fitted with custom flat-knit chap and thigh-style compression stockings Class 3 (36.1–44.5 mm Hg compression) for the right lower extremity. Pantyhose, while theoretically optimal to apply pelvic and abdominal compression, were not feasible because of abdominal discomfort, and her ileostomy appliance often leaked, causing her great distress. She was fitted with a custom thigh-length inelastic foam and fabric compression legging for night compression on her right lower extremity. She did obtain an inexpensive, ready-to-wear, lightweight microfiber panty shaper (we cut out a window for the ileostomy appliance) to provide some genital compression when she could tolerate it. Initially, post CDT treatment, she was able to walk longer distances with more comfort; she made several college visits with her eldest son and was able to take a family vacation with her husband and two sons. However, her back and abdominal pain increased and she was later admitted to the hospital with a bowel obstruction from progression of the cancer. She was able to control her swelling in the hospital with her inelastic compression legging, which she donned with nursing assistance. Although her disease progressed, she was able to obtain some relief of the pain and heaviness as well as reduce her risk for cellulitis infection in her right leg. She was happy that by treating her lymphedema, she was able to travel with her son to help him choose the college he wanted to attend the next year.

Case Study: A Patient with Lymphedema

Mrs. M is an 84-year-old woman with a history of swelling in right upper extremity (RUE). Mrs. M was diagnosed with right breast cancer after sudden onset of swelling in right arm. Mrs. M had a right mastectomy with axillary dissection and hormone therapy followed by four cycles of chemotherapy. Mrs. M self-scored the heaviness and discomfort in her RUE as 5/10. She denied pain and scored 8% impairment on the Quick Dash Upper Extremity Functional Tool.

Mrs. M was left-hand dominant, but was able to perform multiple activities with both arms. There was severe mixed pitting and fibrotic, nonpitting edema of the RUE from the fingers to axilla, extending into right posterior axilla and right lateral trunk. Skin of the right chest wall was adherent and puckered. The skin of the RUE had a pinkish, violaceous discoloration typical of malignant lymphedema. Multiple small varices were visible on the right shoulder that extended to the anterior axillary line, suggestive of malignant lymphedema. Circumferential measurements taken of both upper extremities revealed differences as follows: mid hand 1.7 cm, wrist 3.8 cm, forearm 8.8 cm, elbow 8.5 cm, upper arm 14.7 cm, and axilla 9.8 cm. Mrs. M had impaired range of motion (ROM) in the RUE as follows: shoulder flexion was 0–120 degrees, shoulder abduction was 0–90 degrees, internal and external rotation were 0–60 degrees, elbow flexion was 0–110 degrees, wrist flexion was 0–10 degrees, and wrist extension was 0–45 degrees.

Mrs. M started a 4-week course of lymphedema treatment after she completed external beam radiation treatment to the right chest and axilla. She stated that she did not have any significant burns during the radiation treatment. Lymph drainage followed the right axillo-inguinal collateral lymph pathway, and multilayer, short-stretch compression bandages were applied to the RUE from the fingers to the axilla. Foam chip pads were placed under the compression bandages and they greatly reduced the fibrotic tissue in the RUE. The wound in the right axilla healed slowly. A custom elastic compression arm-sleeve and glove (Compression Class 1–20 mm Hg) were ordered for daytime compression, and a ready-to-wear foam and fabric alternative compression sleeve and gauntlet were provided for night compression. Mrs. M was instructed in a modified exercise program emphasizing abdominal breathing exercises. At the end of her 4-week course of treatment Mrs. M's RUE exhibited a reduction of 34.7 cm or 47%, comparing it with her uninvolved LUE. She self-scored the heaviness and discomfort in her RUE as 3/10, an improvement from 5/10 prior to treatment.

At Mrs. M's 1-month follow-up, her RUE was stable, so she was scheduled for a 3-month follow-up. Her RUE began to show increase in edema causing her difficulty in wearing her compression garments and compression bandaging. Mrs. M was placed on oxygen due to shortness of breath. Pulmonary lesions were suspected and test results were pending. Mrs. M lost some of her initial edema reduction, which now measured 28.9 cm/37% at this 3-month follow-up. At her 8-month follow-up Mrs. M's RUE exhibited a significant increase in swelling: 55 cm from initial baseline measurements. An unusual rash was noted on Mrs. M's chest and back at this time. Her daughter was encouraged to have Mrs. M seen by her oncologist. The diagnosis of recurrent cancer was made. Mrs. M started a course of palliative lymphedema treatment. Multiple open, draining skin lesions were present on the right chest wall, in the right axilla, and on the proximal portion of the right upper arm. Mrs. M was in severe pain but refused to take pain meds. She had a difficult time lying on the treatment table due to pain. Modified positioning with Mrs. M sitting facing the treatment table with her arms supported on a pillow was used. We encouraged Mrs. M to take her pain meds at home prior to coming to treatment. Mrs. M experienced severe itching during treatment. She was resistant to taking her opioid pain medications. She began to develop swelling in her lower extremities. Upon questioning, Mrs. M's daughter revealed that her mom was not taking her prescribed diuretic (diuretics are not a treatment for lymphedema itself, but are helpful in cases of malignant lymphedema or when there are medical comorbidities that require diuretic treatment). We encouraged her to take her medication as prescribed and contacted her oncologist to advise them of this. The custom elastic arm-sleeve and glove she had from her initial course of treatment in October 2013 would no longer fit because of the marked increase in her edema. She was measured for a custom inelastic Velcro adjustable arm-sleeve and gauntlet.

Mrs. M's chest lesions began to drain profusely, and her pain worsened significantly as her malignant disease progressed. Her family members were instructed in donning the Velcro compression garments and compression bandaging for home use as tolerated. She was discharged from palliative treatment. Mrs. M was admitted to hospice care and expired. Her family was grateful that they were able to assist in Mrs. M's care in those last months and felt that having some tools to help control the swelling gave both Mrs. M and the family some measure of comfort during a difficult time.

Edema Treatment

Edema treatment focuses on detection and intervention related to the causative factor or factors. Effective treatment stabilizes the interstitial fluid volume.[23] Tissue support and/or gentle compression can be useful in relieving edema that might progress to lymphedema.

Lymphedema Treatment

Lymphedema treatment refers to therapies to help reduce swelling and associated symptoms as well as maintain reductions achieved through treatment while minimizing exacerbations of swelling. Treatments include surgery, pharmacological therapy, and CDT.[8,9] Pharmacological therapy and surgery have limited proven effectiveness. Although diuretics are not recommended for the treatment of lymphedema and are proved to be ineffective,[8] there are cases where lymphedema is combined with edema from other comorbid conditions such as heart or renal failure in which diuretics are part of the medical management of these combined edemas. Patients may have heard that "diuretics are not a treatment for lymphedema," and they need to be cautioned to continue their diuretics if they have been prescribed to treat hypertension, heart or renal failure, or other comorbid conditions.

Surgical Approach

A recent systematic review for research from 2009 to 2014 concludes that the effectiveness of surgical treatment for lymphedema has not been established.[8] The various surgical treatment options for lymphedema can be broadly categorized as excisional procedures, liposuction, lymphatic reconstruction, and tissue transfer procedures. In the past decade, significant progress has been made in contemporary surgical treatment for lymphedema, particularly microsurgical procedures (e.g., lymphaticovenous anastomosis, vascularized lymph node transfer, and lymphaticolymphatic bypass). With proper diagnosis and the careful selection of the appropriate procedure, surgical techniques can be used to treat lymphedema in patients when combined with integrated lymphedema therapy.[8,31] However, the efficacy and long-term outcomes of the surgical approaches in this population have yet to be reported. At this point, surgical treatment of lymphedema is reserved primarily for patients who have lymphedema that is refractory to standard treatment modalities.[8,31]

Complete Decongestive Therapy

CDT or decongestive lymphatic therapy (DLT) evolved in Europe when Michael Foldi[8,9,26,31] combined Vodder's manual lymph drainage (MLD) technique with bandaging, exercises, and specialized skin care. Dr. Foldi described his four-modality lymphedema treatment as "complete decongestive therapy." CDT is the current standard of care for treatment of lymphedema. It consists of an intensive lymphedema therapy (phase I of CDT) followed by an ongoing, individualized maintenance and self-management phase (phase II of CDT).[8,9,26,31] In the intensive therapy phase, therapists use MLD, compression garments, multilayer short-stretch compression bandaging, remedial exercise, and skin care to reduce visible or palpable swelling.[8,9,26,31] The duration of the intensive lymphedema therapy phase, averaging about two to three treatments per week for up to 8 weeks, varies with the severity of lymphedema and patient response. Clinically, phase I of CDT ends when swelling has been reduced and symptoms have been controlled. Following the completion of intensive lymphedema therapy, the patient is taught to initiate self-management (phase II of CDT) for control of chronic soft tissue changes and to conduct the individual components of CDT, including self-MLD, skin care, exercises, and application of prescribed compression garments and/or bandages to prevent exacerbation of swelling and symptoms. The self-management phase is a lifelong process; regular check-ups with the primary care provider and the lymphedema therapist are necessary.[8,9,26,31]

Adherence to the prescribed treatment can be difficult because even the most customized garments or sleeves sometimes are uncomfortable, unsightly, and laborious to put on.[16,21] A constellation of complex factors (e.g., physical, financial, aesthetic, time) can influence survivors' adherence with treatment. Lymphedema is a complex condition that needs to be treated by therapists with special training and experience in this field, as outlined by the National Lymphedema Network position paper on educational training for lymphedema therapists (http://www.lymphnet.org/pdfDocs/nlntraining.pdf) and the Lymphology Association of North America (LANA) (http://www.clt-lana.org/). These multidisciplinary organizations have outlined training requirements for clinicians to gain certification in this field.

Bandages and Garments

Both compression garments and bandages are effective in treating lymphedema by providing proper compression to improve muscle and joint pumps during activity, to aid in moving lymph fluid from the affected area, to prevent the reaccumulation of evacuated lymph fluid, and to maintain the results achieved during MLD.[8,9,26,31]

Compression bandages or multilayer lymphedema bandaging (MLLB) are an effective and flexible form of compression, particularly in the early stages of lymphedema therapy. MLLB provides external compression. For some patients, MLLB may be used as part of long-term or palliative management. MLLB uses inelastic or low-stretch bandages to produce a massaging effect and stimulate lymph flow and is especially important for patients with severe lymphedema, such as lymphedema complicated by morbid obesity or neglected primary lymphedema. It is also important for patients who choose self- or caregiver-bandaging to enhance comfort or for nighttime compression when they wear a compression garment during the day.[8,9,26,31] Foam or other padding is often used under bandages to improve edema reduction, soften fibrosis, and restore normal limb contours. The time, effort, and dexterity required for bandaging can become burdensome and is not practical or possible for some patients, necessitating the use of an alternative compression method.[27] MLLB should be avoided for the following conditions: (1) severe arterial insufficiency with an ankle/brachial index (ABI) of less than 0.6, although modified MLLB with reduced pressures can be used under close supervision; (2) uncontrolled heart failure; and (3) severe peripheral neuropathy.[37] Some components of the MLLB system can be washed and dried according to the manufacturer's instructions and reused. Over time, inelastic bandages will progressively lose their extensibility, which will increase their stiffness. Heavily soiled, cohesive, and adhesive bandages should be discarded after use.[8,9,26] Patients with lymphedema graduate from bandages to elastic compression garments. Compression garments generally need to be worn throughout the patient's life.

Compression garments are recommended for patients with lymphedema of the extremities.[8] Compression garments may be used in the initial management of patients who have mild upper or lower limb lymphedema with minor pitting, no significant tissue changes, no or minimal shape distortion, or palliative needs.[8,9,26,31] Proper fit of the compression garment is imperative. An ill-fitting garment can cause swelling to develop in an area proximal or distal to the end of the garment (i.e., in the hand or in the anterior or posterior axillary/shoulder areas or in the toes or genital/pubic/buttock/abdominal areas). Patients must be instructed to remove their garment if this type of swelling, pain, numbness, or muscle cramps occur and consult with their lymphedema specialist regarding revision of the garment to ensure proper fit and function. Gradient compression provides the greatest pressure distally and less pressure proximally; this is optimal for improved lymphatic transport.[38,39] Skin care, exercise or body movement, elevation, and self-lymph drainage should be taught, along with self-monitoring to help to relieve lymphedema symptoms in individuals receiving palliative care. Patients should be reassessed 4–6 weeks after initial fitting and then approximately every 3–6 months.[38,39]

Compression garments should be laundered every time they are worn and replaced every 3–6 months. Patients need to moisturize and check their skin daily for signs of irritation/infection. A variety of helpful products exist to assist patients in applying garments, which may be an especially challenging task for elderly and disabled patients. Usually, ridged rubber gloves (dishwashing gloves) facilitate application of garments and extend their longevity. Timely garment replacement (usually every 6 months) is essential for good edema control.[38,39] If a compression garment causes pain, neurological symptoms, or color or temperature changes, it should be removed and the patient instructed to consult with his or her lymphedema specialist to resolve the problem.

Pneumatic (Mechanical) Pumps: Intermittent Pneumatic Compression Devices

Mechanical pneumatic pumps use electricity to inflate a single-chamber or multichamber sleeve that produces external limb compression. A decreased tissue capillary filtration rate facilitates tissue fluid reduction and, consequently, limb volume decrease.[8,40] A recent systematic review on research from 2009 to 2014 concluded that the effectiveness of pneumatic compression devices (PCDs) on limb volume reduction has not been established; furthermore, adverse events related to PCD use are reported, such as increased swelling of hand and torso, forearm pain, finger numbness, and pain in the axilla and back.[8] After more than 50 years of pump use in lymphedema care and long-established Medicare reimbursement, no guidelines exist, significant complications are reported, and research has not clarified benefit. Clearly, more studies with rigorous design and adequate sample sizes are needed.[8]

Infection Prevention and Treatment

Infection is the most common lymphedema complication.[10] Lymph stasis, decreased local immune response, tissue congestion, and accumulated proteins and other debris foster infection.[2] Traditional signs and symptoms (fever, malaise, lethargy, and nausea) are often present. Decades of literature support prompt oral or intravenous antibiotic therapy.[31] Because streptococci and staphylococci are frequent precipitators, antibiotics must have good skin penetration and cover normal skin flora, as well as gram-positive cocci.[9,31] Early detection and treatment of infections can help prevent the need for intravenous therapy and hospitalization.[9,31] Intravenous antibiotic therapy is recommended for systemic signs of infection or insufficient response to oral antibiotics. Nursing activities include assisting patients in obtaining prompt antibiotic therapy, monitoring and reporting signs and symptoms, and providing instruction regarding high fluid intake, rest, elevation of the infected limb, and avoidance of strenuous activity. Garment-type compression is encouraged as soon as tolerable during infection. Wound care or infectious disease specialists can be helpful in complicated cases. Infection prophylaxis has been highly effective for patients who experience repeated serious infections or inflammatory episodes.[31] Effective edema reduction and control may also help reduce the incidence of lymphedema infection.[31,41]

The feet, which are especially susceptible to fungal infections in lower extremity lymphedema, can exhibit peeling, scaly skin, and toenail changes. Antifungal powders are recommended prophylactically. Antifungal creams should be used at the first sign of fungus. Diabetic-like skin care and use of cotton socks and well-fitted, breathable (leather or canvas), sturdy shoes are beneficial.[31,41]

Lymphedema Management

Edema usually subsides with proper treatment, whereas lymphedema is a lifelong and chronic condition requiring long-term management.[8,9,16,31] Lymphedema management focuses on daily activities and strategies undertaken to decrease the swelling, relieve symptom distress, and prevent acute exacerbations and infections.[8,9,16,31] Components of long-term lymphedema management are listed in Box 18.2 and described throughout the chapter. Long-term management is a process of fostering optimal physical, functional, psychosocial, and spiritual wellness. Spiritual care guidelines have been gradually evolving in nursing for several decades. Spiritual care supports patients' efforts to make meaning out of illness and to redefine themselves in their new state of being. Specific spiritual interventions can include (1) support during the struggle with and exploration of life's ambiguities, (2) acknowledgment of patients' real and potential losses and victories, and (3) guidance in patients' exploration of end-of-life issues and decisions.[8,9,16,31]

Lymphedema management necessitates a multidisciplinary approach.[9,31,42] Nurses should assess for signs of infection, changes in limb volume or limb size, as well as limb or torso contour, pain, and degree of swelling at each patient visit. Additional inquiries need to be made as to any other symptoms patients may be experiencing because of the lymphedema. Nurses should assess self-care behaviors and encourage patients with lymphedema to wear their compression garment as prescribed. Patients with new-onset or worsening lymphedema should be referred to certified lymphedema therapists for volume reduction treatment. Antibiotics may be prescribed for infections. Certified lymphedema therapists provide assessment and treatment for the swollen limb or area as well as any musculoskeletal impairment that may develop as a consequence of surgery, radiation, and or chemotherapy to treat cancer. In addition, certified lymphedema therapists also design individualized patient education about self-care practices, skin care, wear and care of compression garments, exercise and exercise progression based on individual lymphedema risk factors, and level of fitness. Certified lymphedema therapists have the expertise to recommend home and workplace modifications if needed to reduce risk for injury or overuse of the at-risk or affected limbs. Collecting and reviewing outcomes with patients over time fosters ongoing instruction, complication prevention, sustained lymphedema improvement, and patient empowerment.[9,31,42]

Box 18.2 Components of Long-Term Lymphedema Management

- History, physical examination, and ongoing assessment and support
- Individualized and holistic care coordination
- Multidisciplinary referrals
- Comprehensive initial and ongoing patient instruction
- Ongoing psychosocial support
- Promotion of ongoing optimal self-care management
- Facilitation of appropriate evidence-based, individualized treatment
- Patient and practice outcome measurement
- Access and long-term follow-up and management
- Communication and collaboration with related healthcare providers

Pain and Lymphedema Symptom Management

Approximately 30–60% of patients with lymphedema post breast cancer treatment reported pain.[3,10,15,20, 37] Causes of pain included infection, postoperative changes in the axilla, postmastectomy pain syndrome, brachial plexopathy, various arthritic conditions, peripheral entrapment neuropathies, vascular compromise, and cancer recurrence. Sudden onset of pain requires careful assessment for complications. Use of the 0–10 pain scale is recommended for cancer pain assessment.[3,10,15,20, 37] Standard pain management principles are applicable for lymphedema-related pain.

Self-Care

Optimal patient self-care typically includes adherence to risk-reduction behaviors, use of compression, weight management, fitness and lymphedema exercises, optimal nutrition and hydration, healthy lifestyle practices, and seeking assistance for lymphedema-related problems.[8,30] Patient empowerment for optimal self-care is a great impetus to long-term management success.[8,9] Evidence from breast cancer patients indicates that weight management, including reduction of body mass index or weight, appears to be an effective means of assisting in the reduction of arm volume during lymphedema treatment.[8]

Exercise

Exercise or body movement is an integral part of lymphedema management and risk reduction. Exercise improves muscular strength, cardiovascular function, psychological well-being, and functional capacity.[8] Research evidence from patients with upper extremity lymphedema have clearly shown that exercise (e.g., progressive weight lifting and other resistance exercises) under close supervision is not associated with a worsening of lymphedema or related symptoms. Exercise may help stabilize limb volume and improve joint mobility in the affected area.[8]

Gentle resistance exercise stimulates muscle pumps and increases lymph flow; aerobic exercise facilitates changes in intraabdominal pressure, which facilitates pumping of the thoracic duct.[8] A tailored exercise or body movement program that combines flexibility, resistance, and aerobic exercise may be beneficial in reducing the risk of and controlling lymphedema. General exercise guidelines include the following[8]:

- Start with low to moderate intensity exercise.
- Walking, swimming, cycling, and low impact aerobics are recommended.
- Flexibility exercises should be performed to maintain range of movement.
- Appropriate warming up and cooling down phases should be implemented as part of exercise to avoid exacerbation of swelling.
- Compression garments should be worn by individuals with lymphedema during exercise.

Skin Care

Skin care is important for lymphedema risk reduction and management, which optimizes the condition of the skin and prevents infection.[8,9,31] Lymphedema can cause skin dryness and irritation, which is increased with long-term use of compression products. Bland, unscented products are recommended for daily cleansing and moisturizing.[8,9,31] Low pH moisturizers, which discourage infection, are recommended for lymphedema because skin and tissue changes increase infection risk. Water-based moisturizers, which are absorbed more readily, are less likely to damage compression products but are not suitable for all patients. Cotton clothing allows ventilation and is absorbent.

Advanced lymphedema can cause several skin complications, including lymphorrhea, lymphoceles, papillomas, and hyperkeratosis. *Lymphorrhea* is leakage of lymph fluid through the skin that occurs when skin cannot accommodate accumulated fluid. Nonadherent dressings, good skin care, and compression are used to alleviate leakage. Compression and good skin care also reduce the occurrence of lymphoceles, papillomas, and hyperkeratosis; these complications reflect skin adaptation to excess subcutaneous lymph.

Unusual Lymphedemas

Palliative care may require the management of unusual and challenging lymphedema sites, such as breast, head, neck, trunk, or genitals.[39,42] MLD, skin-softening techniques, foam chip pads, and external compression (if possible) are recommended.[42] External compression may be achieved with collars, vests, custom pants or tights, scrotal supports,[42] or spandex-type exercise apparel. The assistance of occupational or physical therapists and a seamstress may be helpful. Nationally, instructional courses are available to provide guidance for managing these difficult lymphedemas. Therapists can obtain professional certification for lymphedema treatment from the Lymphology Association of North America (LANA) (http://www.clt-lana.org/). Box 18.3 presents detailed information about neck lymphedema from head and neck cancer.

Box 18.3 Lymphedema Secondary to Cancer of the Head and Neck

Lymphedema secondary to head and neck cancer commonly presents following surgery and radiotherapy. Lymphedema is frequently found below the chin in the anterior neck. Difficulty in swallowing and breathing are the major symptoms causing distress from neck lymphedema. Mild swelling often progresses fairly rapidly to firm, nonpitting swelling and thus may often not be recognized or treated as lymphedema.

Quantification of neck edema can be achieved by measuring from the tip of one ear lobe to the tip of the contralateral ear lobe along the line of the chin, and then measuring this distance for every 2 cm (or 4 cm) interval down to the intersection of the neck and chest. Quantifiable outcome measurement over time fosters patient participation, improved long-term outcomes, and might be beneficial as substantiation for third-party payers.

Compression supports used after cosmetic facial surgery can be useful for neck lymphedema. These products provide gentle compression to the chin using two sets of long narrow Velcro straps that extend from the chin to the top of the head and to the back of the neck. This size-adjustable "chin strap" provides gentle, size-adjustable compression to the chin and neck. Patients are encouraged to use the product continually for at least several weeks or a month to achieve optimal edema reduction. Although lifelong product use is encouraged for optimal lymph function, some patients have been able to transition to mainly night-time product use and still maintain acceptable edema control.

Nursing interventions for head and neck lymphedema include:

- Help patients to make an informed decision in a supportive environment.
- Instruction and support in establishment of a lifelong daily self-care regimen including range-of-motion exercises, skin assessment, and application of moisturizers and early, skilled patient complication assistance and use of safe external compression. A written self-care program may foster patient self-care adherence.
- Monitor external neck compression. External neck compression must provide sufficient pressure to stimulate lymphatic function without causing skin irritation/injury or impairment of breathing, eating, or swallowing.
- Encourage the use of daily self-care using MLD and exercises for facial, neck, and postural muscles to further improve edema control and posture.
- Document patient outcomes, including interval neck circumferences, skin integrity, pain level, and neck range of motion.

Conclusion

Edema is a symptom usually relieved by addressing the causative factor. Lymphedema is a chronic disorder that requires lifelong management. Oncology nurses and other nurses have increasingly contributed to lymphedema management as they have improved cancer survivorship. Nursing's unique focus and scope of practice is ideally suited to chronic illness management, both at entry and advanced practice levels. To meet the physical and psychological needs of patients, nurses and other healthcare professionals must make an effort to understand the pathophysiology and chronic nature of lymphedema, as well as its physical, functional, and psychosocial impact. Armed with such information, nurses can then engage patients in supportive dialogue about risk reduction and lymphedema management.[8,9] With the advent of precision health that aims at discovering the right treatment, for the right patient, at the right time, as well as determination of factors contributing to or protecting from common and complex diseases, researchers started to explore the role of inherited genetic susceptibility and the pathogenesis of lymphedema.[43]

CHAPTER 19

Palliative Wound, Ostomy, and Continence Care

Charles P. Tilley, Mei R. Fu, and Jana M. Lipson

Key Points

- Palliative wound, ostomy, and continence (WOC) care emphasizes an interprofessional, patient-centered approach to alleviate suffering and promote well-being and quality of life (QOL) through the palliation of symptoms and the preservation or restoration of functional performance.
- Specialist-level WOC care guides advanced symptom and disease management with the goal of restoring normalcy and improving self-confidence, body image, socialization, and QOL.
- Palliative wound care is a dynamic, interprofessional, patient- and family-centered process that combines the principles of evidence-based wound care with the science of advanced symptom management to preserve or restore functional performance and psychological well-being, thereby promoting QOL.
- Palliative care of the patient with a urinary or fecal diversion or fistula centers on expert guidance to manage advanced symptoms and adapt product selection and utilization to the progressive cognitive, psychomotor, and physiologic decline experienced in advanced or terminal illness, with an eventual shift of responsibilities to the caregiver.
- Urinary and fecal incontinence management in palliative care balances advanced symptom control with minimally invasive, highly individualized interventions adapted to the terminally ill patient's progressive cognitive, psychomotor, and physiologic decline.

Introduction

The exact prevalence of wound, ostomy, and continence (WOC) issues in hospice and palliative care is unknown. An early study, the 1999 National Home and Hospice Survey (conducted in 1996), found that 60% of current and 80% of discharged hospice patients had incontinence, a urinary catheter, an ileostomy, or a colostomy.[1] In 2015, 1,007,753 Medicare beneficiaries died while enrolled in hospice, translating to potentially 800,000 patients with incontinence or stomas.[2] In a study of 593 patients with advanced illness, 53% of cancer patients and 67% of noncancer patients developed wounds.[3] Forty-three types of wounds were identified, with pressure injuries (PIs) accounting for 66% of all wounds.[3] PIs occurred predominately in noncancer patients, commonly on the sacrum/coccyx.[3] These numbers are staggering and certain to increase exponentially as the population aged 65 and over is projected to be 83.7 million in 2050, almost double the estimated population of 43.1 million in 2012.[4]

The rapidly escalating need for palliative WOC care in those with advanced or terminal illness is clear; however, this emerging area of palliative nursing remains poorly defined and underresearched. There is no globally accepted definition of palliative WOC nursing, but there is agreement in the literature concerning the goals of this approach, which may occur in a curative, care-a-tive, or end-of-life setting. "End of life" is defined as a terminal prognosis of 6 months or less by the Centers for Medicare and Medicaid (CMS) and National Quality Forum (NQF), who also provides a distinction between "curative" and "care-a-tive" palliative care.[5,6] Care-a-tive palliative care is provided to those with incurable conditions who are not terminally ill.[6] It is generally accepted that the overarching goals of palliative WOC nursing are to alleviate suffering and promote quality of life (QOL).[7–10]

There is consensus that palliative WOC care includes (1) expert guidance[7,10]; (2) an interprofessional team approach[7,10]; (3) a center of care that includes both the patient and their caregivers[7–10]; (4) a focus on the prevention of complications, advanced symptom management, and preservation of functional performance and well-being[10]; and (5) highly individualized care centered on respect for the patient's advance directives and preferences.[8–10]

This chapter will address palliative WOC-specific assessment, prevention, and management strategies as well as broader, general approaches to advanced symptom management, psychosocial support, maximization of functional performance, and product selection. The first part of the chapter concentrates on palliative wound care, including the concepts of skin changes at end of life (SCALE), skin failure, and avoidable versus unavoidable pressure injuries (PIs), Kennedy terminal ulcers (KTUs), and Trombley-Brennan terminal tissue injury (TB-TTI); strategies for the prevention, management, and symptom palliation of PIs; medical device–related pressure injuries, skin tears, and medical adhesive–related skin injuries (MARSIs); chronic critical limb ischemia with gangrene; malignant fungating wounds (MFWs); and less commonly encountered wounds (Marjolin's ulcers, calcinosis cutis, calciphylaxis, radiation dermatitis). The next part of the chapter will discuss the palliative management of continent and incontinent diversions and fistulas, and the last section will discuss the management of incontinence-associated dermatitis (IAD) in palliative settings.

Case Study: A Patient with Metastatic Cancer and a Colostomy

A single, 66-year-old woman with metastatic colorectal cancer, a colostomy, and multiple comorbidities presented to the inpatient hospice unit with her sister. Her sister flew in from out of state to care for the patient at end of life and found her colostomy nonfunctioning with a poorly fitting pouching system and her sister with painful, inflamed buttocks from lying in urine. The patient was now bedbound, requiring total care, with limited home health aide hours and financial resources. The patient's wish was to die at home, but her sister had no experience in caregiving and feared she didn't have the strength to perform skin care nor the knowledge to care for her colostomy. The Hospice Nurse Practitioner, also a WOC nurse, was consulted to devise a plan of care that would enable the pair to return to the patient's apartment with home hospice.

The Role of the Wound, Ostomy, and Continence Specialist

The WOC nurse plays an integral role in providing expert guidance related to WOC issues in hospice and palliative care.[11] The evolving role of the WOC specialist in these settings ideally incorporates the scope and standards of both WOC specialty practice nursing and palliative nursing.[12,13] Palliative and hospice WOC nurses are experts uniquely qualified to provide both basic and advanced care, at either the baccalaureate or advanced practice level.[11] Box 19.1 outlines the responsibilities of the WOC nurse on a hospice team or palliative care service.[10,11–13] Every hospice program should employ or consult with a WOC nurse ideally certified in hospice and palliative care (CHPN, ACHPN). Dual certification ensures a level of expertise in caring for those with advanced illness requiring palliative WOC services and allows nursing professionals to practice under the full scope of their licensure in the palliative care setting.

Case Study: Resolution

The Advanced Practice Hospice WOC nurse diagnosed acute opioid-induced constipation after a comprehensive history and a physical exam that included digitalizing the stoma. The impaction resolved after colostomy irrigation and titration of the patient's bowel regime. Upon further examination of the patient's abdomen and stoma, the APRN discovered uneven abdominal planes from new tumor burden, inhibiting adherence of the two-piece extended-wear appliance. The patient was placed in a flexible one-piece pouching system after filling in larger deficits with adhesive paste. Her sister was instructed in changing the appliance every 3 days and as needed. IAD was diagnosed after inspection of the patient's buttocks, and the patient agreed to a Foley catheter insertion. The catheter placement, in combination with a zinc-oxide barrier ointment, assisted in healing the IAD and facilitated her return home, as now her sister was able to manage her sister's urinary incontinence. The hospice home-care team seamlessly resumed care after consultation with the Advanced Practice WOC nurse.

Box 19.1 Role of the Hospice and Palliative Care Wound, Ostomy, and Continence Nurse

Educator

- Patient and caregiver education
- Staff education (orientation, staff development, faculty development)
- Profession education at the local, national, and international level

Clinician

- Specialist-level wound, ostomy, and continence intra-agency consultation
- Specialist-level consultation to outside or referring agencies
- Chair of the hospice and palliative care wound, ostomy, and continence nurse committee
- Supportive role: helping staff decision-making concerning palliative approaches to care

Researcher

- Conducts or participates in research based on the National Institute for Nursing Research: Palliative Care Research Foci:
  a. End-of-life and Palliative Care
  b. Advancing the Quality of Life: Symptom Management and Self-Management
- Promotes evidence-based nursing

Administrator

- Wound, ostomy, and continence supply management:
  a. Cost analysis and containment
  b. Formulary development
  c. Product evaluation
- Continuous quality improvement:
  a. Patient satisfaction
  b. Pressure injury prevalence and incidence
  c. Wound prevalence registry
- Policy, procedure, and protocol development

Palliative Wound Care

Case Study: Wound Care

A married, 45-year-old woman on home hospice was seen by the nurse case manager for the first time. As the nurse entered the front door, he was assaulted by a foul odor that permeated the house. Upon meeting his patient, he discovered she had terminal vulvar cancer and the odor was emanating from a malignant fungating vaginal wound. She was wearing underwear with obstetric pads secondary to exudate leakage. Her husband reported she had not left the house since returning from the hospital 4 weeks ago. He explained she was profoundly embarrassed by the odor and exudate and that she had to shower and change her clothes several times a day and was "very depressed."

Palliative wound care is a holistic, integrated approach that emphasizes symptom management, enhancement of psychosocial well-being, integration of patient and family goals, and an interprofessional approach[7]. The concept of palliative wound care is still evolving, with the term first appearing in the literature in the 1980s. Since then, the palliative care and hospice movement has gained international attention, and each subsequent decade has seen a steady increase in both palliative wound care research and evidence-based literature.[7,8] There is no consensus and few explicit definitions of palliative wound care.[7] Palliative wound care is a dynamic patient- and family-centered process that utilizes an interprofessional framework to combine the principles of evidence-based wound care with advanced symptom management to preserve or restore functional performance and ultimately improve psychological well-being and QOL. Symptoms are considered advanced when conventional therapies and symptom management no longer work, exerting a negative impact on physical and psychosocial functioning and QOL.[14] Although management of advanced symptoms is a priority, it is erroneous to make the assumption that the goals of palliative wound care can never include wound healing.[15] The PALCARE mnemonic (Prognosis, Advance care planning, Living situation, Comprehensive history, Assessment, evidence-based Recommendations, and Education of patient, family and staff) is a comprehensive framework for developing a holistic, interprofessional, patient-centered palliative plan of care for patients with advanced or terminal illness and complex, nonhealing wounds (see Box 19.2).[10]

Box 19.2 A Systematic Approach to Palliative Wound Care: PALCARE

Prognosis:

- Hospice diagnosis and Palliative Performance Score (PPS)
- Is the patient's life expectancy weeks or months?
- Is the patient in the last hours or days of life?

Advance care planning:

- Goals of care
  - Further hospitalizations (under what circumstances)
  - Resuscitation wishes: full code status versus natural death
  - Antibiotics: intravenous, oral, topical
  - Medically administered nutrition or hydration
  - Emergency management clarification (hemorrhage, sepsis)
- Advance directives
  - Complete MOLST, POLST, Health Care Proxy, Living Will

Living situation:

- Caregiver availability
- Caregiver participation (willingness)
- Caregiver ability (cognitive/physical)
- Caregiver reliability
- Environment/setting (domiciled vs undomiciled, running water, shower facilities)
- Fiduciary or food insecurity
- Consider appropriate hospice level of care
  - Inpatient hospice (IPU) for uncontrolled symptoms
  - Hospice home care (symptoms manageable in the community)
  - Respite care (caregiver is overwhelmed or unavailable)

Comprehensive history:

- Review of symptoms, activities of daily living, complementary alternative medicine
- Wound(s) and associated symptoms (pain, pruritus odor, exudate, bleeding, lymphedema, bulk effect of wound or dressing, number of dressing changes, current dressing plan)
- Psychiatric (Patient Health Questionnaire 2, Generalized Anxiety Disorder 7)[125]
- Social (legal status, insurance, employment, fiduciary/housing/food insecurity)
- Spiritual (FICA tool)[127]

Assessment:

- Comprehensive physical assessment
- Focused wound assessment
- Wound photographs (follow institution policy)
- Wound cultures, laboratory studies (as necessary)

Recommendations:

- Establish symptom management priorities (pain, pruritus, odor, exudate, bleeding, lymphedema, bulk effect of wound or dressings) and palliative wound care goals
- Topical and/or systemic interventions
- Referrals: wound, ostomy and continence nurse (if not already involved), psychiatry, spiritual care, social work, and so forth

Education:

- Patient, family, caregivers
- Staff education
- Hospice medical directors, administrators, wound care resource nurses

Skin Changes at Life's End and Skin Failure

The concepts of SCALE, skin failure, TB-TTI, KTUs, and unavoidable PIs have received growing attention over the past decade as practitioners struggle to define and classify these underresearched phenomena, relying primarily on expert opinion and consensus.[16] SCALE is defined as physiological changes occurring as a result of the dying process that may affect the skin and soft tissues and may manifest as objective changes in skin color, turgor, or integrity, or as subjective symptoms such as localized pain.[17] In 2009, an expert panel utilized a modified Delphi process to reach consensus on 10 statements describing the etiology, risk factors, signs and symptoms, and management of SCALE (see Table 19.1).[17]

The skin is the largest organ of the body and is vulnerable to organ dysfunction and failure.[17] Skin failure is a clinical syndrome, "the state in which tissue tolerance is so compromised that cells can no longer survive in zones of physiological impairment such as hypoxia, local mechanical stresses, impaired delivery of nutrients, and buildup of toxic metabolic byproducts."[16] Skin failure occurs across the illness continuum and may be classified as acute, chronic, or end-stage.[18] Acute skin failure is an event in which critically ill patients experiencing hemodynamic instability become hypoperfused, leading to skin and underlying tissue death.[18] A study of 549 ICU patients found five variables significantly and independently associated with skin failure: peripheral arterial disease, respiratory failure, mechanical ventilation, liver failure, and severe sepsis/septic shock.[19] Chronic skin failure results in skin and underlying tissue death due to hypoperfusion in patients with a chronic disease state such as peripheral arterial disease, nephropathy, diabetes, or neurodegenerative disorders.[18] Hypoperfusion concurrent with end of life that leads to skin and underlying tissue death is termed *end-stage skin failure*.[18]

Kennedy Terminal Ulcers, Trombley-Brennan Terminal Tissue Injuries, and Avoidable vs. Unavoidable Pressure Injuries

Rapidly developing sacral ulcers in actively dying patients were first described in 1877 by French physician Jean-Martin Charcot, who termed the wound *decubitus ominosus,* as most died shortly thereafter.[20] More recently, terminal wounds over bony prominences (KTUs) and in tissues not prone to pressure (TB-TTIs) have been described parallel to the evolving attributes that define avoidable versus unavoidable PIs.[21–23]

In 1989, the term "Kennedy terminal ulcer" was coined to describe wounds that commonly develop anywhere from 24 hours to 8 weeks prior to death, are ominous prognostic signs, often progress to full-thickness wounds, and are commonly attributed to the hypoperfusion seen in end-stage skin failure.[21,24,25] These ulcers have five essential characteristics: sacrococcygeal location; a butterfly or pear shape; purple, red, blue, or black color (often variegated); sudden onset; and irregular borders.[21,24,26]

TB-TTIs are spontaneously appearing skin alterations that rapidly evolve and enlarge over areas of little to no pressure, such as the thighs, and that may display mirror imaging in patients at the end of life.[22] A study of 80 adult patients in a palliative care unit found that the median time of identification of a TB-TTI to death was 36 hours.[22] The wounds presented over seven different locations on the trunk and upper and lower extremities, both anteriorly and posteriorly, were of varying morphology, and, strikingly, 79 out of 80 wounds remained intact to time of death.[22] Renal (19%) and neurological (19%) diseases were the main diagnosis of these patients, with primary cardiac comorbidities most prevalent (42%).[22] Both KTUs and TB-TTIs are considered unavoidable skin ulcers and do not imply poor quality of end-of-life care.[27]

In 2016, the Wound, Ostomy, Continence Nurses Society (WOCN Society) published an updated position paper on avoidable versus unavoidable PIs, affirming that not all PIs are preventable. The definitions were originally developed by the Centers for Medicare and Medicaid (CMS) for long-term care standards[28,29] but were broadened and applied to all clinical practice settings by the National Pressure Ulcer Advisory Panel (NPUAP).[30] The current definitions are:

Avoidable pressure injury: An avoidable pressure injury can develop when the provider did not do one or more of the following:

Table 19.1. SCALE consensus statements

Statement 1	Physiological changes that occur as a result of the dying process may affect the skin and soft tissues and may manifest as objective changes in skin color, turgor, or integrity, or as subjective symptoms such as localized pain.
Statement 2	The plan of care and patient response should be clearly documented and reflected in the entire medical record.
Statement 3	Patient-centered concerns should be addressed including pain and activities of daily living.
Statement 4	SCALE area reflection of compromised skin (reduced soft-tissue perfusion, decreased tolerance to external insults, and impaired removal of metabolic wastes).
Statement 5	Expectations around the patient's end of life goals and concerns should be communicated among members of the interprofessional team and the patient's circle of care (potential for SCALE, skin breakdown, pressure injuries).
Statement 6	Risk factors, symptoms, and signs associated with SCALE have not been fully elucidated, but may include weakness, progressive immobility, suboptimal nutrition, diminished tissue perfusion, impaired immune function, and loss of skin integrity.
Statement 7	A total skin assessment should be performed regularly and document all areas of concern consistent with the wishes and condition of the patient.
Statement 8	Consultation with a qualified healthcare professional is recommended for any skin changes associated with increased pain, signs of infection, skin breakdown, and whenever the patient's circle of care expresses a significant concern.
Statement 9	The probable skin change etiology and goals of care should be determined. The 5 P's is recommended for determining strategies: prevention, prescription, preservation, palliation, and preference.
Statement 10	Patients and concerned individuals should be educated regarding SCALE and the plan of care.

evaluate the individual's clinical condition and PI risk factors; define and implement interventions consistent with individual needs, individual goals, and recognized standards of practice; monitor and evaluate the impact of the interventions; or revise the interventions as appropriate.

Unavoidable pressure injury: An unavoidable PI can develop even though the provider evaluated the individual's clinical condition and PI risk factors; defined and implemented interventions consistent with individual needs, goals, and recognized standards of practice; monitored and evaluated the impact of the interventions; or revised the approaches as appropriate.

A retrospective study of 20 patients who developed hospital-acquired pressure ulcers (injuries) despite appropriate risk assessment and prevention identified 10 prevalent physiologic comorbidities: hypoalbuminemia, severe anemia, respiratory failure with intubation, hypoxia with sedation or chemical paralysis, hypotension, infection or sepsis, malignancy, diabetes, renal failure, and/or congestive heart failure.[31] These comorbid conditions mirror hospice eligibility criteria and are common comorbidities encountered in those with advanced or terminal illness. Experts have additionally identified malnourishment, advanced age, dehydration, and obesity as factors contributing to unavoidable pressure injuries[32] as well as hospitalization in a critical care unit,[31,33,34] corticosteroid use,[35] and treatment with vasopressors.[33]

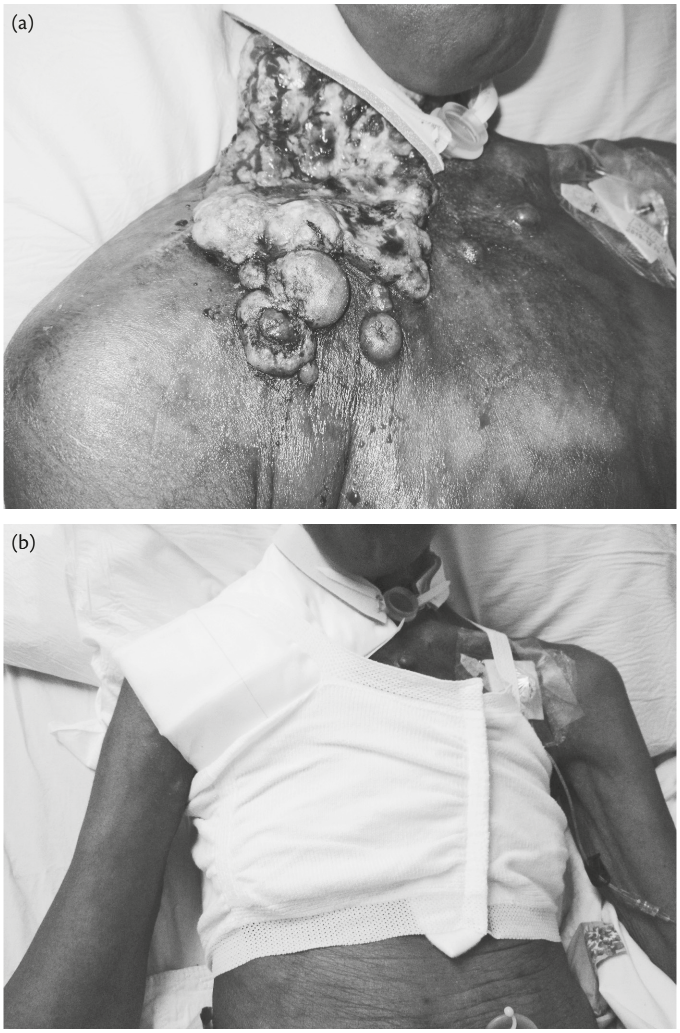

Figure 19.1 Fungating wound of head and neck extending to right chest wall before (A) and after (B) dressing change secured with surgical bra.

Advanced Symptoms in Complex and Nonhealing Wounds

A combination of traditional pharmacologic therapies, basic and advanced dressings, debridement, complimentary medicine, and cognitive behavioral therapy are used in palliative wound care to manage pain, pruritus, infection, odor, exudate, bleeding, lymphedema, and bulk effect of the wound or dressings (Figure 19.1).[10,36,37]

Pain: The skin has the most sensory nerve endings of any organ in the body and has special nociceptors that can perceive mechanical, thermal, or chemical injury, which may be somatic, neuropathic, or mixed in nature.[38] Pain occurs in up to 84% of patients with pressure ulcers, reported both at rest and with dressing changes.[39] The prevalence of MFW pain is 30.2–77.3%.[40,41] Pain descriptors in breast cancer wounds point to a mixed neuropathic and somatic etiology and an association with wound status (morphology, tissue type, size, symptoms).[40] Lower extremity wound pain has been identified in several qualitative and quantitative studies as the worst advanced symptom reported by patients with lower extremity ulcers.[42] Box 19.3 lists pathologic and iatrogenic causes of temporary (incident) and persistent wound pain (between dressing changes, at night, and at rest).[43]

Box 19.3 Etiology of Wound Pain

Pathologic

- Direct tumor compression of an organ
- Dermal erosion and exposure of nerve endings
- Damage of nerves related to direct tumor invasion or compression
- Edema secondary to impaired lymphatic or drainage, or wound infection
- Inflammation secondary to wound infection

Iatrogenic

- Manipulation of dressings
- Inappropriate dressing selection
- Adhesives
- Wound cleansing or irrigation
- Debridement

Evidence-based management of fungating wounds. *Wounds* (Palliative Wound Care Supplement), 2010; and Reference 46: Price P, Fogh K, Glynn C, et al. Managing painful chronic wounds: the wound pain management model. *Int Wound J*. 2007;4(Suppl 1):4–15.

Box 19.4 Total Pain Management

Total pain origin

- Physical factors
  - Malignancy or underlying disease-specific pain
    - Somatic, neuropathic, or mixed
  - Wound pain
    - Somatic, neuropathic, or mixed
  - Wound care
    - Vigorous irrigation or rubbing of fragile tissue with cleansing
    - Frequent dressing manipulation and changes
    - Adherence of dressings to the wound bed during dressing removal
    - Painful wound bed
    - Infection
    - Medical adhesive-related skin injury
- Psychological and social factors
  - Housing, food, fiduciary insecurities
  - Anxiety, depression, grief, and prebereavement issues
  - Body image disturbances
- Spiritual factors
  - Existential angst

Interventions and referrals

- Long-acting opioids, short-acting breakthrough opioids, adjuvant pharmacologic and nonpharmacological interventions per nurse practitioner or hospice medical director
- Gentle irrigation, patting or blotting of wound bed
- Decrease number of changes with moisture-retentive dressings
- Soaking dressing before removal with normal saline (NS) or tepid tap water
- Nonadherent dressings: foams, petrolatum-based, silicone
- Topical opioids (10 mg morphine in 8 g hydrogel)[48]
- Topical anesthetics (2% lidocaine jelly 3–5 minutes before wound care)[48]
- Antimicrobial dressings and/or systemic antibiotics
- Use of burn net or garments, such as postsurgical bras, Lycra, or Attends undergarments to secure dressings and normalize body image (see Figure 19.1)
- If adhesives are necessary use skin protectants and apply paper tape
- Referral to social work, grief counselor
- Referral to spiritual care

Source: Adapted from Reference 48: Walsh A, Bradley M, Cavallito K. Management of fungating tumors and pressure ulcers in a patient with stage IV cutaneous malignant melanoma. *J Hosp Palliat Nurs*. 2014;16(4):208–214.

Comprehensive pain assessment is guided by the *total pain* concept, which includes physical, psychological, spiritual, and social factors.[47] A valid and reliable pain assessment tool is recommended, as is inclusion of both wound- and non–wound-related pain or discomfort and exploration of temporary and persistent wound pain etiologies. The total pain approach (see Box 19.4) includes advanced symptom management for malignancy or underlying disease-related pain, interprofessional involvement to address psychosocial or spiritual factors, and specialist-level wound care for local discomfort.[48]

Pruritus: The etiology of wound-related pruritus may be either pruritoceptive (cutaneous) or neuropathic (afferent neuronal pathways).[49] Wound-related pruritus has been reported in venous ulcers, burns, MFWs, pressure ulcers, and postsurgical wounds.[49] Itching may be part of the normal healing process[50] or due to inflammation, dryness, nerve regeneration,[51] exudate,[52] compression garments,[53] or dressings. Periwound moisture-associated dermatitis may also contribute to both pruritus and pain.[54] Periwound moisture-associated dermatitis is defined as inflammation and erosion of skin caused by prolonged exposure to wound effluent.[54] The principles behind the treatment of wound-related pruritus are similar to that of pain. The practitioner must first identify the underlying cause of the pruritus, if possible. Once the etiology has been addressed, a multifaceted approach to symptom management is recommended, combining systemic pharmacologic agents with topical therapies. Table 19.2 demonstrates periwound skin management options.

Infection, odor, and exudate: Infection may retard wound healing and contribute to odor, exudate formation, and pain.[18] Devitalized tissue enhances bioburden proliferation, contributes to malodor and excessive exudate, and is an impediment to wound healing.[55] Whenever possible, infections should be eliminated and necrotic tissue should be removed, two of the four key components of wound bed preparation[56,57] (see Box 19.5).

The degree of aggressiveness in managing infection and the removal of devitalized tissue is guided by the patient's advance directives and preferences. Wound infections at end of life may be treated empirically, by either oral or parenteral route, with or without concurrent topical antimicrobials, and rarely require cultures. Clinical diagnosis of infection in chronic wounds is more important than qualitative cultures.[58] Surface cultures are controversial and deep tissue cultures are rarely appropriate in palliative wound care.[58] The choice of wound debridement method depends on many factors, as shown in Box 19.6.

Table 19.3 summarizes the common debridement methodologies used in palliative wound care, the advantages and disadvantages of each, and contraindications. Mechanical debridement (wet-to-dry) is nonselective, painful, and labor-intensive and is not recommended in palliative patients.

Odor has been described as one of the most distressing symptoms to people with chronic wounds.[59] The source of the malodor may be related to moist necrotic tissue, bioburden, infection, unchanged or saturated dressings, or old dressings that have not been properly disposed of. The prevalence of malodor in MFWs is reported as 10.4%.[41] "Garbage," "rotting flesh," "putrid," and "moldy" are descriptors elicited from patients, family members, and other caregivers, including nurses.[60–62] One subject likened the smell to a "cadaver."[60] Malodor is pervasive; caregivers recall altering their

Table 19.2. Periwound skin management options

Skin protectant	Description	Consideration	Examples
Liquid polymer acrylates	Liquid polymers that contain solvents that when they evaporate, form a protective film	Periwound maceration Protection Preparation of skin attachment sites for drainage tubes, external catheters, surrounding ostomy sites, and adhesive dressings	Cavilon (3M) No-sting Skin Prep (Smith & Nephew)
Dimethicone	Silicone-based oil	Modest maceration Protection Good skin hydration Variable periwound skin irritant protection	Remedy Olivamine Dimethicone Moisture Barrier (Medline)
Zinc oxide-based skin protectant	White powder mixed with a cream or ointment base	Periwound skin irritant Protection Incontinence barrier Calazime contains menthol, which cools irritated skin Zinc offers poor skin hydration and does not avoid maceration Messy, difficult to remove Interferes with dressing adhesion and absorption	Remedy Phytoplex Z-Guard Skin Protectant Paste (Medline) Remedy Olivamine Calazime Skin Protectant Paste (Medline) Critic-Aid thick Moisture Barrier Skin Paste (Coloplast)
Petrolatum-based skin protectant	Blend of castor seed oil and hydrogenated castor oil	Periwound skin irritant and maceration Modest skin hydration Incontinence barrier Messy, difficult to remove Interferes with dressing adhesion and absorption	ConvaTec Sensi-Care Protective Barrier (ConvaTec) Remedy Phytoplex Z-Guard Skin Protectant Paste (Medline)

breathing patterns to avoid the smell and having vivid memories decades later.[62]

Multiple studies have documented the detrimental role malodor has had on body image,[61,63,66,67] relationships,[61,62,67] and sexuality and femininity,[61,63,66] resulting in shame, embarrassment, anxiety, and lack of self-confidence,[61–67] leading to social isolation[61,63,64,66,67] and diminished QOL.[58,61]

Prevalence of exudate in MFWs was reported at 14.6%[60] and identified as one of the most challenging symptoms to manage, seriously impacting psychosocial function[60,61,63,64,66] and contributing to the development of periwound moisture-associated dermatitis.[66] Losing the physical boundaries of their skin, with wounds described as "festering like a running nose,"[60] participants described being humiliated and exhausted by the wounds, and the frequent dressing changes and cleaning of soiled clothing becoming all-consuming.[60,63] Public soiling of their clothing also forced the women into self-imposed isolation, "safe from scrutiny and negative comments that damaged their identity."[66] Management of odor and exudate may be difficult, requiring WOC nurse consultation. Table 19.4 displays the dressings and antibacterial agents to manage infection and control odor and drainage.

Bleeding: Bleeding may range from superficial, isolated rupture of microvasculature in the wound bed to erosion of large vessels and hemorrhage. Disruption of blood vessels, either by direct tumor invasion or friable wound beds with excessive bioburden, was described by patients as "unpredictable."[68] One woman recalled spontaneous bleeding during a work meeting, the blood camouflaged by her jacket, necessitating an impromptu clothing change.[66] Uncontrolled bleeding was so severe at times that it forced women, experiencing disbelief and shame, to seek the medical care they had been avoiding.[64] Table 19.5 outlines interventions for bleeding.

Goals of care discussions surrounding bleeding are an integral part of advance care planning for the hospice patient with a complex, nonhealing wound because interventions may range from the benign (i.e., direct pressure, vitamin K replacement,

Box 19.5 Key Components to Wound Bed Preparation: TIME

Tissue that is nonviable must be debrided.
Infection (or inflammation) must be reduced and managed.
Moisture imbalance or exudate control must be addressed to avoid desiccation or maceration.
Epidermal margins of the wound must be examined for nonadherence.

modification of topical antimicrobial therapy) to aggressive and/or invasive (i.e., vascular interventions for hemorrhage, blood products, radiation). The discontinuation of anticoagulation for patients with atrial fibrillation, deep vein thrombosis, pulmonary embolism, or embolic stroke requires a discussion of risks versus benefits (Figure 19.2).

Lymphedema: Lymphedema is known to have a negative psychological and social impact on patients.[70] Patients with lymphedema secondary to MFWs of the breast reported a sense of compromised normalcy. Restricted mobility limited wardrobe choices, as did the desire to "hide" the arm swelling due to embarrassment, ultimately restricting access to social support and contributing to isolation.[60] Chapter 18 provides in-depth information on lymphedema.

Box 19.6 Factors Influencing Choice of Wound Debridement Method

- Amount of debris
- Available time for debridement
- Cost of debridement process
- Nature of care setting
- Patient allergies
- Patient's pain level
- Patient's prognosis and treatment plan
- Patient's wishes and opinions
- Potential patient problems
- Maceration of wound
- Tissue trauma
- Bleeding (hemorrhage)
- Presence of infection
- Size of wound
- Skill of the clinician
- Type of debris
- Type of exudate
- Wound depth and undermining and tunneling

Source: Reprinted with permission Reference 55: from Beitz J. Wound debridement: Therapeutic options and care considerations. *Nurs Clin North Am*. 2005;40:233–246.

Bulk effect of wounds and dressings: Bulk effect of wounds and dressings refers to the profile of either the wound tissue itself or the contour of dressings and bandages against the normal planes of the body. This can impact clothing choices, restrict mobility, and result in additional symptoms such as discomfort or pruritus.[60] Conscious utilization of surgical bras (see Figure 19.1), burn net, and gender-specific absorptive undergarments to secure dressings may help reduce bulk effect.

Periwound Moisture-Associated Dermatitis

Periwound moisture-associated dermatitis is one of four subcategories included under the umbrella term moisture-associated skin damage (MASD) and is a key consideration in palliative wound care. Heavily exudating wounds may cause an overhydration of the skin and maceration, leading to further skin breakdown, infections, pain, or pruritus.[71] Maceration of the skin is described as irritation and damage of the skin adjacent (within a 4 cm periwound border) to a wound caused by supersaturation.[72] The bordering skin may present as maceration; pale, white, or gray wrinkled skin or inflammation; erythema; and swelling, usually associated with pain or pruritus.[71]

Composition of exudate, in addition to volume, has been shown to correlate with risk of developing MASD.[73,74] One study of women with fungating breast wounds found exudate with higher levels of putrescine and with the presence of cadaverine were associated with higher incidence of periwound moisture-associated dermatitis and pruritus.[75,76]

Treatment and prevention of pruritus caused by MASD starts with the selection of an appropriate absorbent dressing and cleansing of the wound bed. Periwound skin protection is the crucial next step in preventing MASD with several product options available (see Table 19.2).

No studies have specifically compared products used in periwound skin protection in patients with MFWs. A meta-analysis by Schuren and coworkers in nonmalignant wounds found film barrier to be superior to a placebo in four studies and no significant differences when compared with zinc oxide–based or petrolatum-based products.[77]

Hospice formularies may already include petrolatum, Calazime, and zinc oxide-based skin barriers as part of their incontinence protocols. A liquid-forming acrylate is also recommended because it does not interfere with adherence of dressings or pouching appliances and is used to protect the skin from MARSI[78] and to prevent or treat MASD.[54]

Multiple factors should be considered when selecting a skin barrier, including location, allergies, and caregiver support. A liquid polymer acrylate for upper body, head, and facial wounds is appropriate because there is less mess and no interference with adhesion of dressings.[10] Consider a zinc oxide–based or petrolatum-based skin barrier for genital or groin wounds, especially in the presence of fecal or urinary incontinence.[10]

Wound Assessment Principles

Wound assessment should be performed upon admission to a hospice or palliative care service, weekly thereafter, and with any change in condition. The use of a systematic approach with a comprehensive assessment tool is recommended (see Box 19.7). Monitoring of the wound by less-skilled caregivers with dressing changes is helpful, with the clinician reporting changes or

Table 19.3 Common debridement types and methodologies in palliative care

Method/Definition	Advantages	Disadvantages	Contraindications
Chemical (nonselective) Hypochlorites (e.g., Dakin's solution) Povidone iodine Cadexomer iodine (e.g., Iodosorb, Iodoflex)	Helps debride necrotic tissues slowly Lowers microbial count Cheap and readily available Broad-spectrum antimicrobial May help dry slough for easier debridement Slow release Safe for cellular viability Absorbs exudate Helps with autolytic debridement	Deleterious to healing tissue Possibly irritating to periwound skin Stains tissue Deleterious to fibroblasts Safe for fibroblasts Use with caution in patients with thyroid disease	Clean, noninfected wound Clean, noninfected wound Iodine allergy Clean, noninfected wound
Enzymatic (selective) Enzymes that work by degrading and debriding necrotic tissue by digesting and dissolving it	Good for patients who decline sharp debridement or surgery, or are on anticoagulants or home care Will not harm normal tissue Can be used in infected wounds, sometimes used with topical antibiotics Cost effective if used properly	Not effective for advanced cellulitic wounds Require prescriber's order Expensive Cannot be used with other common wound products such as metal ions (e.g., silver) or with topical antiseptics (e.g., Dakin's) Cross-hatching of eschar recommended	Clean, granulating wound Allergies
Autolytic (selective) Use of body's own wound fluid enzymes to liquefy necrotic tissue; fully or semi-occlusive moisture-retentive topical therapy. Hydrogels, alginates, foams, hydrofibers, films	Hydrogels, alginates, foams, and hydrofibers will absorb some wound fluid Maintain moist wound therapy Easy to perform in any care setting Comfortable and soothing Good choice if not a candidate for sharp debridement	Works slowly compared to other methods Requires constant monitoring for infection Hydrocolloid dressing fluid odor often mistaken for "infected" Absorptive dressings can dry out wound bed if not discontinued when appropriate	Dry wound beds are not appropriate for absorptive dressings
Conservative Sharp Debridement (selective) Use of instruments to remove necrotic tissue from wound bed	Fast and effective Can be performed at the bedside Preferred if debridement is urgent (sepsis) May be performed by specially educated nurses, therapists, and physicians	Analgesia required pre-procedure Require discernment of viable vs. nonviable tissue Potential for bacteremia Requires special training and/or licensure	Bleeding disorders Severe immune compromise Ischemic extremity

disconcerting findings to the registered nurse or advanced practice registered nurse.

Pressure Injuries and Medical Device Related Pressure Injuries

The NPUAP changed the term "pressure ulcer" to "pressure injury" (PI) in 2016 to lessen confusion over staging PIs with intact skin versus open ulcers.[26] A PI is localized damage to the skin and/or underlying soft tissue, usually over a bony prominence or related to a medical or other device.[26] PIs in palliative care settings are often not preventable, and interventions to eradicate them in the terminally ill are complicated by the population's frailty, extensive risk factors, and comorbid conditions.[18–21]

"Medical device–related pressure injury" describes an etiology of PI and should be staged using the same pressure injury staging system (see Table 19.6). These injuries are caused by prolonged pressure from diagnostic (temperature-sensing Foley catheters) or therapeutic (nasogastric tubes, rectal tubes) devices and usually result in an injury that conforms to the shape of the device.[26]

Risk Factors, Risk Assessment, and Risk Reduction

A variety of factors exist in those with advanced and terminal illness that put them at risk for PI development and nonhealing. Risk factors include advanced age, protein-calorie malnutrition, immobility and inactivity, shear, friction, moisture, incontinence, and altered sensory perception.[80,85] Screening tools ascertain patients at risk for PI development through identification of specific risk factors, which then allows for targeted risk-reduction interventions. The NPUAP has recommended assessing the risk for new PI development on admission, at regular intervals

Table 19.4 Dressings and antibacterial agents to control odor and drainage

Dressings and antibacterial agents examples	Examples of brands	Beneficial effects and considerations	Cost
Foams	Allevyn (Smith & Nephew) Aquacel Foam (Convatec) Tegaderm Foam (3M) Mepilex (Monlynlycke Health Care)	Promotes moist wound environment and does not adhere to tissue. Prevents strikethrough. Multiple shapes and sizes available to fit difficult dressing sites (i.e., heels) and conforms to the body.	5 × 5 box = $$ 5 × 5 box = $$ 6 × 6 box = $$ 6 × 6 box = $$
Calcium alginates	Algicell (Derma Sciences) Algisite M (Smith & Nephew) Tegaderm High Gelling (3M)	May be used to cover or fill wound bed. Dressing material becomes a gel and absorbs any drainage while promoting a moist wound bed. May act as a hemostatic agent.	4 × 4 box = $ 4 × 4 box = $ 4 × 4 box = $
Honey	Activon Tulle (Avancis) Medihoney (Medihoney)	Supersaturated sugar solution with high osmolarity, low water activity. Bactericidal, moistens wound and removes necrotic tissue. Lowers wound pH to promote healing.	4 × 4 box = $ 4 × 4 box = $
Silver	Aquacel Ag hydrofiber (Convatec) Acticoat 3 (Smith & Nephew) Optifoam Ag (Medline)	Gradual release of silver provides sustained broad-spectrum bactericidal effects.	12 box = $$$ 4 × 4 box = $$$ 4 × 4 box = $$
Charcoal	CarboFlex (Convatec)	Absorbs small gas molecules and bacterial spores. Used as either primary or secondary dressings	4 × 4 box = $$
Dakin Solution	0.25% Concentration	Broad-spectrum bactericidal effects, promotes dissolution of necrotic tissue. May require twice-daily dressing changes	1 16-oz bottle = $
Metronidazole	1% Flagyl spray 5% Flagyl powder Crushed tablets 0.71% Flagyl gel	Bactericidal, effective against anaerobes	100 mL = $ 57 g = $ 14 tablets = $ 71% gel (1 tube,45 g) = $$

Prices: $, <$100; $$, >$100; $$$, >$200.

thereafter, and with any change in condition using a validated risk assessment tool.[80,85] Multiple PI risk assessment tools have been developed. The Norton Scale[81] and the Braden Scale[82] are two of the most widely used tools, despite minimal data on their validation in hospice populations. The Hunters Hill Marie Curie Center Risk Assessment Tool[83] and the Hospice Pressure Ulcer Risk Assessment Scale[84] were specifically developed for and validated in hospice populations. A comparison of these 4 scales is shown in Table 19.7.

Risk reduction interventions include pressure redistribution, skin and incontinence care, and maximizing nutrition and hydration.[80,85] Avoid foam rings, foam cut-outs, or donut-type devices because they concentrate pressure on the surrounding tissue.[85] Table 19.8 summarizes select recommendations from the *WOCN 2016 Guideline for Prevention and Management of Pressure Injuries (Ulcers)* for preventing PIs[85] and palliative care-specific considerations or adaptions. The patient at end of life may not tolerate all recommendations due to symptoms of pain, dyspnea,

Table 19.5 Interventions for wound-related bleeding

Category of bleeding	Interventions	Considerations
Prevention	Dressing selection and wound cleansing	1. Nonadherent dressings are recommended as a contact layer (silicone, foam, or petrolatum-based gauze) 2. Gentle cleansing or irrigation 3. Wet dressings before removal to loosen and prevent adherence to the wound bed
Minor bleeding (controllable at the bedside)	Direct pressure Silver nitrate Epinephrine soaks Calcium alginate	1. Apply local pressure with clean gauze 2. See Figure 19.2 3. Soak gauze with 1mg of epinephrine and 1ml of NS (1:1 ratio) applied for 10 minutes of direct pressure to promote local vasoconstriction [10]
Major bleeding (requiring invasive or aggressive interventions)	Vascular intervention Radiation	1. If using as a hemostatic agent, may embed itself in the wound and be difficult to extract
Hemorrhage as a terminal event	Comfort measures	1. Dark towels should be readily available and used to contain and absorb blood loss 2. Sedate with a benzodiazepine and manage pain with an opioid 3. Cover with blankets because blood loss may lead to hypothermia and cause chills or rigors

Source: Reprinted with permission from Tilley, C, Lipson, J, Ramos, M. Palliative wound care for malignant fungating wounds: Holistic considerations at end of life. *Nurs Clin North Am.* 2016;48(3):479–501.

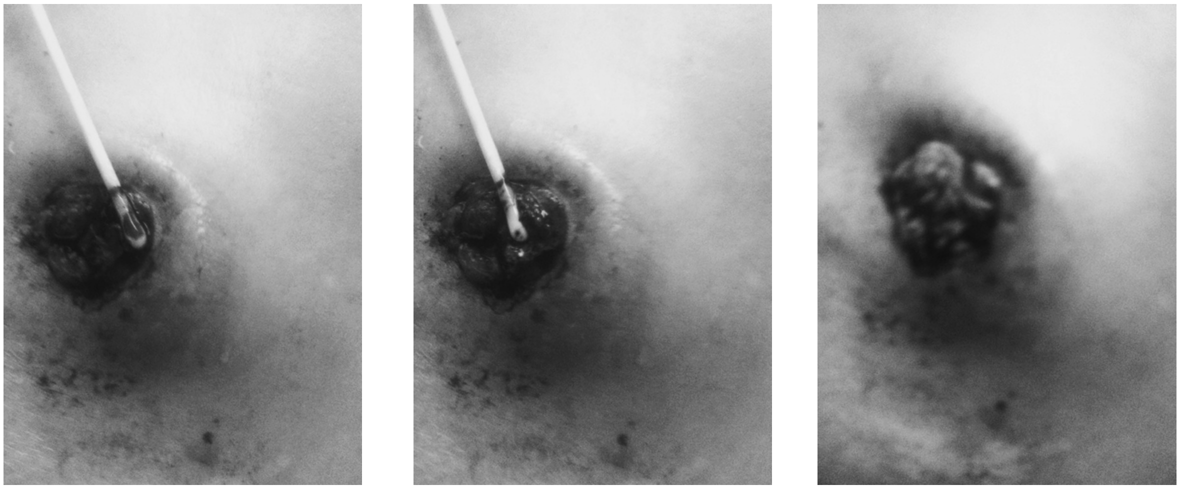

Figure 19.2 Cauterization of bleeding abdominal malignant lesion with silver nitrate sticks. Note the stick is rolled over the bleeder, causing a pearly gray appearance to the tissue. This may be repeated with each dressing change at bedside, is relatively inexpensive, and is easy to learn. Assess for stinging or burning, and, if uncomfortable, consider alternatives.

Box 19.7 Systematic Wound Assessment

1. Etiology/type of skin damage
2. Location
3. Stage (PIs only)
4. Dimensions: (length [head-to-toe], width [hip-to-hip], depth [use a q-tip], height)
5. Undermining/Tunneling (Stage III or IV pressure injuries [PIs] only)
   Measure undermining clockwise, then the deepest part of the undermining
   Measure depth of sinus tract/tunnel and give direction by the clock method
6. Wound Base Description
   Granulation: Pink or beefy red, shiny, moist, granular
   Necrotic Tissue: Gray to black and moist
   Eschar: Gray to black and dry/leathery
   Slough: Yellow to white and may be stringy (loose) or appear as a layer over the wound base (adherent)
   Epithelial: New or pink shiny tissue
   May be mixed so approximate in percentages
7. Drainage
   Amount: scant, moderate, or copious
   Color/Consistency: Serous, serosanguineous, purulent, or other
8. Odor: Present or not
9. Periwound skin
10. Pain
    Associated with the wound dressing removal, cleansing, debriding, or dressing application
11. Infection
    Yes or no. Describe signs or symptoms

delirium, or terminal secretions, or may make the conscious choice not to participate based on his or her goals of care and advance directives. The patient's and family's wishes and preferences at end of life must be respected and documented in the patient's medical record and plan of care.

Treatment

Palliative wound care is an emerging field of research. Currently, there are no evidence-based protocols for treating PIs in the terminally ill and dying.[86] Seven principles for the palliative management of wounds in the terminally ill have been proposed: preventing wound development and/or deterioration, correcting or treating the underlying cause of the wound, controlling wound-related symptoms, using patient self-assessment, providing psychosocial support, promoting independence, and improving QOL.[87]

Palliative wound care combines the advanced symptom management previously discussed in this chapter with evidence-based interventions. Again, the patient's and family's wishes and preferences drive the plan of care. Table 19.9 summarizes select evidence-based treatment recommendations from the *WOCN 2016 Guideline for Prevention and Management of Pressure Injuries (Ulcers)* for the treatment of PIs[85] and palliative care-specific considerations or adaptions. Comfort is of the utmost importance and may supersede wound care for those who are actively dying or have a condition causing them to have a single position of comfort.[59]

Skin Tears and Medical Adhesive-Related Skin Injury

Skin tears are wounds caused by shear, friction, and/or blunt force trauma resulting in separation of skin layers.[88,89] A skin tear can be partial thickness (separation of the epidermis from the dermis) or full-thickness (separation of both the epidermis and dermis from underlying structures).[88] Skin tears may increase patient morbidity and mortality[88,89] and are associated with increased pain and decreased QOL.[90] There are three classification systems for skin tears: the original 1993 Payne-Martin classification tool,[91] the 2007 Skin Tear Audit Research (STAR) classification system,[92] and, most recently, the 2013 International Skin Tear Advisory Panel (ISTAP) Skin Tear classification system displayed in Figure 19.3.[90] Skin tears are a subset of MARSI, but have varied etiologies.[78] Few studies have evaluated the prevalence of skin tears, and none have exclusively studied this phenomenon in hospice and palliative care populations. A 2017 systematic review reported prevalence of skin tears to be between 3.3% and 22% in the acute care setting and between 5.5% and 19.5% in the community setting.[93] Long-term care studies have reported skin tear prevalence to be between 2.23% and 92%.[96]

A MARSI is an occurrence in which erythema and/or other manifestation of cutaneous abnormality (including, but not limited to, vesicle, bulla, erosion, or tear) persists 30 minutes or more after removal of the adhesive.[94] Types of MARSI by etiology include (mechanical) epidermal stripping, tension injury or blister, skin tear (dermatitis), irritant contact dermatitis, allergic dermatitis, (moisture) maceration, and (inflammatory) folliculitis.[94] MARSI prevalence is largely unknown, with no studies reporting the prevalence in hospice and palliative care populations. Limited studies have found daily subject prevalence to be from 3.4% to 25% in acute care,[94] a cumulative incidence of 15.5% in long-term care,[95] and MARSI to be the primary cause of skin breakdown in 2,820 neonatal intensive care unit patients.[96]

Risk Factors and Prevention

Patients with advanced illness, including those at end of life, are most at risk for skin tears and MARSI. Factors that increase the risk for both types of injury are similar. Intrinsic factors include extremes of age, race/ethnicity, dermatologic conditions (eczema, dermatitis), underlying medical conditions (e.g., diabetes, infection, immunosuppression), malnutrition, and dehydration.[78,88] Extrinsic factors include repeated taping, tape/dressing/

Table 19.6 NPUAP pressure injury staging system

Stage	Definition and clinical description	Illustration
Stage 1 Pressure Injury: Non-blanchable erythema of intact skin	Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Changes in sensation, temperature, or firmness may precede the presence of blanchable erythema. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.	Stage 2 Pressure Injury: Partial-thickness skin loss with exposed dermis	Partial-thickness skin loss with exposed dermis. The wound bed is viable, pink or red, moist, and may also present as an intact or serum-filled blister. Adipose and deeper tissues are not visible and granulation tissue, eschar and slough are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture associated skin damage (MASD) including incontinence associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).	Stage 3 Pressure Injury: Full-thickness skin loss	Full-thickness loss of skin, in which adipose is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Slough and/or eschar may be visible, and undermining,[a] tunneling,[b] or sinus tracts[c] may occur. Fascia, muscle, tendon, ligament, cartilage and/or bone are not exposed.	Stage 4 Pressure Injury: Full-thickness skin and tissue loss	Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage or bone in the ulcer. The depth of tissue damage varies by anatomical location. Slough and/or eschar may be visible, and epibole, undermining,[a] tunneling,[b] or sinus tracts[c] may occur.	
(*continued*)

Table 19.6 Continued

Stage	Definition and clinical description	Illustration
Unstageable Pressure Injury: Obscured full-thickness skin and tissue loss	Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed.	Deep Tissue Pressure Injury: Persistent non-blanchable deep red, maroon or purple discoloration	Intact or non-intact skin with localized area of persistent non-blanchable deep red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood filled blister. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury, or may resolve without tissue loss.	
[a] Undermining: Deep tissue (subcutaneous fat and muscle) damage around the wound margin.

[b] Tunneling: Tunnel under the skin surface that doesn't involve deep tissue.

[c] Sinus tracts: A narrow tract that moves away from the wound margins and downward into the wound.

Table 19.7 Pressure injury risk assessment tools

Pressure injury risk assessment tool	Year developed	Subscales	Validation in hospice & palliative populations
Norton Scale	1958	Physical condition, mental state, activity, mobility, incontinence	Minimal information on the validation in hospice patients[81]
Braden Scale	1983	Sensory perception, moisture, activity, nutrition, friction/ shear, mobility	Minimal information on the validation in hospice patients[82] Braden scores are highly correlated with Karnofsky and Palliative Performance Scale scores
Hunters Hill Marie Curie Center Risk Assessment Tool	2000	Sensation, mobility, moisture, activity in bed, nutrition/weight change, skin condition, friction/shear	Developed specifically for palliative care and validated in hospice patients[83]
Hospice Pressure Ulcer Risk Assessment Scale	2003	Physical activity, mobility, age	Developed specifically for palliative care and validated in hospice patients[84]

Table 19.8 Risk factors for pressure injuries and risk reduction strategies in palliative care

Risk factor	Risk reduction intervention	Palliative considerations
Pressure & Immobility	1. Minimize/eliminate pressure from medical devices 2. Schedule regular repositioning and turning for bed-bound and chair bound patients 3. Use heel suspension devices and protective dressings in at-risk patients 4. Utilize support surfaces on beds and chairs to redistribute pressure. 5. Place patients at high risk on pressure redistribution surfaces. 6. Educate patients and caregivers about the causes and risk factors for developing PIs and ways to minimize the risks	1. Equipment such as Bi-PAP masks and oxygen tubing may need protective hydrocolloid over the bridge of the nose or padding over the ears 2. Assess and premedicate for pain 20–30 minutes prior to care, patients with uncontrolled symptoms may not tolerate repositioning 3. Introduce the possibility of unavoidable pressure ulcers due to skin failure, assure the family it is not from poor care
Friction/Shear	1. Maintain the HOB elevation at/or below 30 degrees 2. Use a 30-degree side-lying position	1. Patient with increased intracranial pressure, ascites, end-stage pulmonary or cardiac disease, or orthopnea may not tolerate 2. May facilitate drainage of secretions
Incontinence	Use incontinence skin barriers to protect and maintain intact skin	Consider Foley placement for those with dyspnea or pain who cannot tolerate frequent skin care
Nutrition	Offer individuals with nutritional and pressure ulcer risks a minimum of 30–35 kcal/kg body weight per day, 1.25–1.5g of protein/kg body weight per day, and 1mL of fluid intake per kilocalorie per day	The patient with advanced disease or who is at end of life may not realistically tolerate these nutritional recommendations. Dysphagia, odynophagia, anorexia-cachexia syndromes, advanced symptoms or voluntarily stopping eating and drinking will warrant an individualized plan of care

Source: Adapted from Reference 87: Wound, Ostomy and Continence Nurses Society-Wound Guidelines Task Force. WOCN 2016 guideline for prevention and management of pressure injuries (ulcers). *J Wound Ostomy Continence Nurs.* 2017;41(3):238–243.

Table 19.9 Palliative considerations in the treatment of pressure injuries

Treatment	Palliative considerations
1. Float the heels completely off the surface with a pillow for stage I or II PIs or a heel suspension device for Stage III or IV PIs.	1. Assess patients for uncontrolled symptoms, especially pain, prior to heel suspension and premedicate 20–30 minutes prior if needed. Patients at end of life may not tolerate heel suspension, follow individual preferences.
2. Turn and reposition the patient regularly and frequently.	2. Assess patients for uncontrolled symptoms, especially pain and dyspnea prior to turning and premedicate 20–30 minutes prior if needed. Patients at end of life may not tolerate frequent repositioning, so develop a flexible schedule and follow individual preferences, including their "position of comfort."
3. Utilize support surfaces for patients with pressure injuries that meet the individual's needs and are compatible with the care setting (both seating and lying redistribution).	3. Consider changing the support surface to improve pressure redistribution and comfort.
4. Utilize an individualized bowel/bladder management program for the patient with incontinence.	4. Foley catheters may be preferred to manage urinary incontinence in patients who cannot tolerate toileting due to advanced symptoms (pain, dyspnea).
5. Cleanse the wound and periwound at each dressing change with potable tap water, distilled water, wound cleanser or normal saline.	5. Use care to remove devitalized tissue to control wound odor.
6. Consider a 2-week course of topical antibiotics for nonhealing, clean PIs.	6. Review the patient's advance directives to discern their willingness to trial antibiotics.
7. Consider the use of topical antiseptics for "maintenance wounds," which are defined as wounds not expected to heal for wounds that are critically colonized.	7. Dakin solution may sting in the wound and can be irritating to the respiratory system.
8. Use systematic antibiotics in the presence of bacteremia, sepsis, advancing cellulitis, or osteomyelitis.	8. Review the patient's advance directives to discern their willingness to trial antibiotics.
9. Debride the PI of devitalized tissue.	9. Review the patient's advance directives and goals of care. Avoid sharp debridement with fragile tissue that bleeds easily.
10. Implement appropriate treatment of PIs to optimize healing, recognizing that complete healing may be unrealistic in some patients.	10. Use dressings that can remain in place for longer periods of time to promote comfort.
11. Offer individuals with nutritional and pressure ulcer risks a minimum of 30–35 kcal/kg body weight per day, 1.25–1.5 g of protein/kg body weight per day, and 1mL of fluid intake per kilocalorie per day	11. Allow the patient to ingest fluids and foods of choice. Offer several small meals per day. Adequate nutrition is often not attainable when the patient is unable or declines to eat.

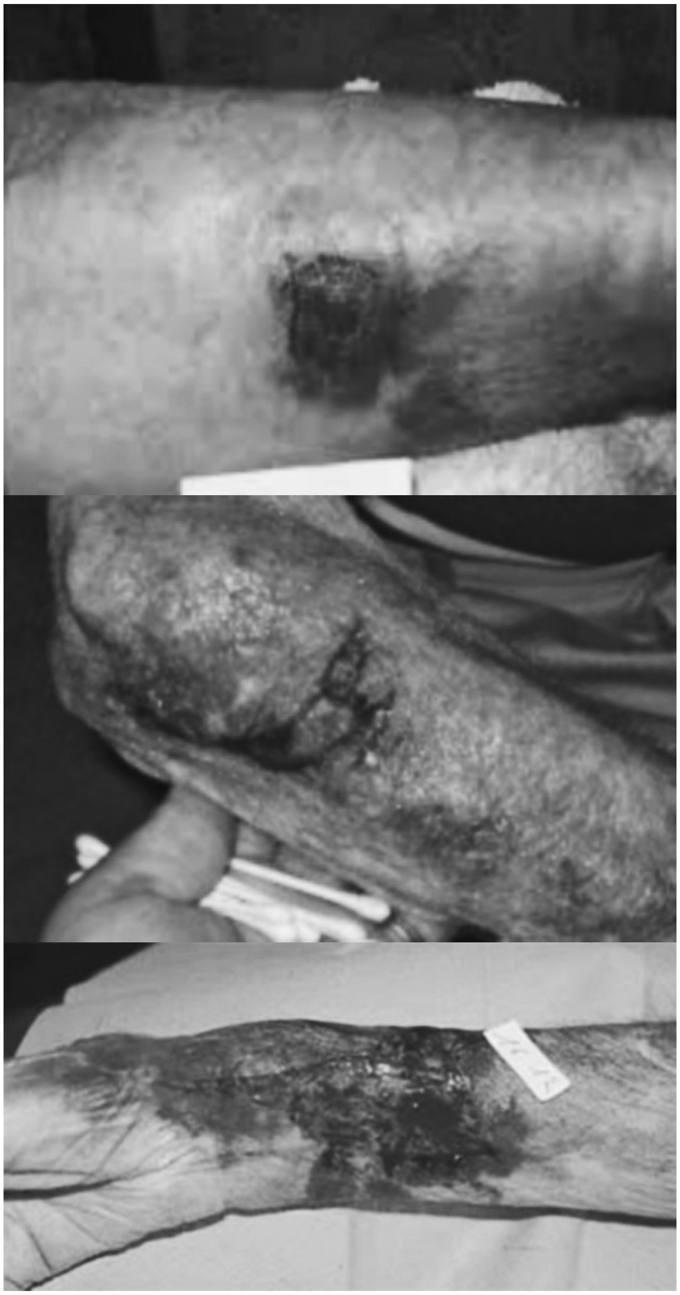

Figure 19.3 ISTAP Skin Tear Classification System:
Type I: No skin loss
Type II: Partial flap loss
Type III: Total flap loss

device removal, photodamage, radiation therapy, maceration, certain medications (long-term corticosteroids, anticoagulants), and drying of the skin due to harsh skin cleansers or excessive bathing.[88,93] Falls, previous skin tears, the presence of edema, and handling during care are additional risk factors that contribute to skin tears.[88,93] Not all skin tears are preventable in high-risk patients (multiple comorbidities, multiorgan failure, dementia with aggression), and incurring this type of wound does not necessarily imply poor quality of care.[78] Table 19.10 shows interventions to prevent skin tears and MARSI. In addition to the interventions listed in Table 19.10, the ISTAP maintains that it is essential to incorporate fall prevention as part of skin tear prevention programs.[90]

Treatment

The best management for both skin tears and MARSI is prevention. When these wounds do occur, it is generally recommended that the practitioner follow evidence-based wound care principles and consult a wound specialist if the wound doesn't heal within 7 days or deteriorates.[97,98] A dressing should be chosen that (1) maintains constant moisture, (2) suits the local wound environment, (3) protects the periwound skin, (4) controls or manages exudate, (5) controls or manages infection, and (6) optimizes caregiver time.[97,98] Adhesive strips, hydrocolloids, and traditional films are not recommended for either injury.[97,98] Best practices in skin tear management include (1) cleansing with a nontoxic solution, such as normal saline; (2) approximate the skin flap (if possible); (3) control bleeding and remove clots; (4) apply a skin protectant periwound; and (5) apply a hydrogel, alginate, foam, soft silicone, or nonadherent dressing.[97,98] These best practices may be considered in the care of MARSI as well. Never secure dressings covering either type of wound with adhesive products; instead utilize burn net, stocking-like products, or cotton gauze wraps.

Chronic Critical Limb Ischemia with Gangrene

Chronic critical limb ischemia (CCLI) is a condition related to arterial occlusive disease that manifests as rest pain, ulceration, or gangrene.[99] Wound healing is usually not a realistic goal when invasive vascular interventions are not feasible. Palliative wound care goals often include delaying an inevitable amputation.[100] Gangrene is the localized death and decomposition of body tissue, resulting from either obstructed circulation or bacterial infection and may be classified as either dry or wet.[100] Dry gangrene develops slowly, with a line of demarcation between viable and gangrenous tissue and ischemic pain during early development.[101] As the limb or digit mummifies, the gangrenous appendage becomes painless.[101] Dry gangrene is usually odorless and may be painted with povidone iodine every 48 hours and wrapped with a dry gauze dressing, with caution not to moisten the necrotic tissue to prevent conversion to wet gangrene. Cadexomer iodine was also shown to be an effective palliative dressing in a retrospective study of 11 patients on the antimicrobial effect of iodine preventing wet gangrene.[100]

Wet gangrene signals bacterial infection which can spread quickly to other tissues, causing pain and fevers.[101] The tissue becomes discolored, boggy, blistered, and malodorous with exudate. *Clostridium perfringens* is a gas-forming organism with an affinity for necrotic tissue that may cause crepitus in the affected limb.[101] Half- or quarter-strength Dakin solution once or twice daily has been used successfully to manage odor and exudate due to its broad-spectrum bactericidal properties. Dakin solution has been shown to be effective against *C. perfringens*, aerobes, anaerobes, biofilms, and multidrug-resistant organisms.[102] Anecdotally, Dakin solution also has desiccant properties, drying the wound bed and thereby decreasing exudate.

Malignant Fungating Wounds

In 2018, there will be an estimated 1,705,347 new cancer cases diagnosed and 575,610 cancer deaths in the United States.[103] MFWs are nonhealing wounds resulting from aggressive

Table 19.10 Preventing skin tears and medical adhesive–related skin injuries (MARSI)

Skin tears	MARSI
1. Assess for risk upon admission to healthcare service and whenever the individual's condition changes 2. Implement a systematic prevention protocol 3. Have individuals at risk wear long sleeves, long pants/trousers, or knee-high socks 4. Provide shin guards to those individuals who experience repeated skin tears to shins 5. Ensure safe patient handling techniques and equipment/environment 6. Involve individuals and families in preventive strategies 7. Educate registered and nonregistered staff and caregivers to ensure proper techniques for providing care without causing skin tears 8. Consult dietitian to ensure adequate nutrition and hydration 9. Keep skin well-lubricated by applying hypoallergenic moisturizer at least 2 times per day 10. Protect individuals at high risk from trauma during routine care and from self-injury	1. Application of adhesive-containing products ◆ Ensure the area is clean and dry ◆ Clip excessive hair ◆ Apply a skin barrier ◆ Allow skin prep to thoroughly dry ◆ Apply the adhesive product without tension, pulling, or stretching ◆ Smooth the adhesive product into place ◆ Use gentle, stretchable adhesive products if edema/movement anticipated ◆ If compression needed, stretch the adhesive over the dressing only and press remaining tape onto skin without tension 2. Removal of adhesive-containing products ◆ Loosen edges of the adhesive product ◆ With the fingers of the opposite hand, push the skin down and away from the adhesive ◆ Remove the adhesive product low and slow in the direction of hair growth ◆ Use the stretch and relax technique to remove transparent films ◆ Slowly remove tape strips by each side, towards the wound ◆ Use medical adhesive remover

proliferation of malignant cells and infiltration of the skin, blood, and lymph vessels by tumors in patients with advanced cancer.[104] Unchecked local tumor extension inflicts widespread tissue damage and causes disfigurement, loss of vascularity with subsequent tissue hypoxia and necrosis, polymicrobial proliferation and fungating ulceration of the wound bed (see Figure 19.4).[104] MFWs are visible markers of underlying neoplastic disease,[105] predominately developing during the last 6 months of life,[106,107] and indicate a grave prognosis.

MFWs occur in patients with various types of cancer. Malignant wounds of the breast are most prevalent (63%), followed by head and neck (24%), then groin, genitals, and back (3%), with all other sites accounting for the remaining 8% (see Figures 19.5 and 19.6).[108]

MFWs afflict 5–14.5% of people with advanced cancer,[38,109,110] with more than half of those experiencing death within 24 weeks of discovery of the cutaneous lesion.[109] Average life expectancy ranges from 6 to 12 months.[110,111] Studies report grimmer survival rates for certain primaries from first appearance of cutaneous metastasis: 6 weeks for genitourinary cancers[112] and 3 months for lung, cervical, or esophageal cancers.[113] Additionally, one study reported a 30% reduction in average survival in patients

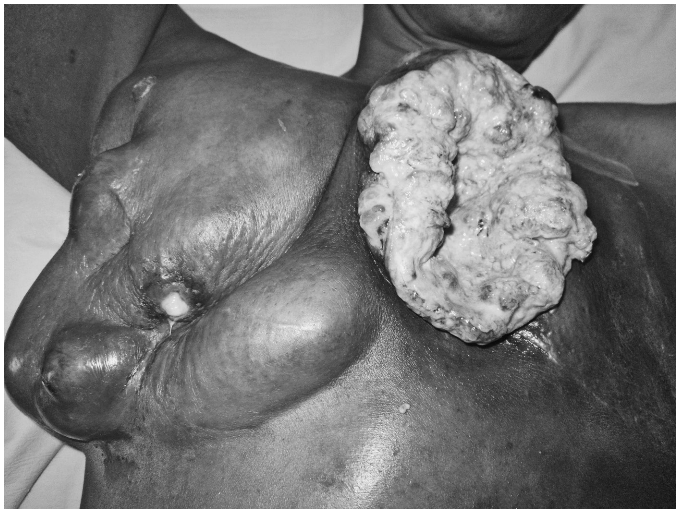

Figure 19.4 A 49-year-old African American woman with metastatic breast cancer and a malignant fungating wound of the breast.

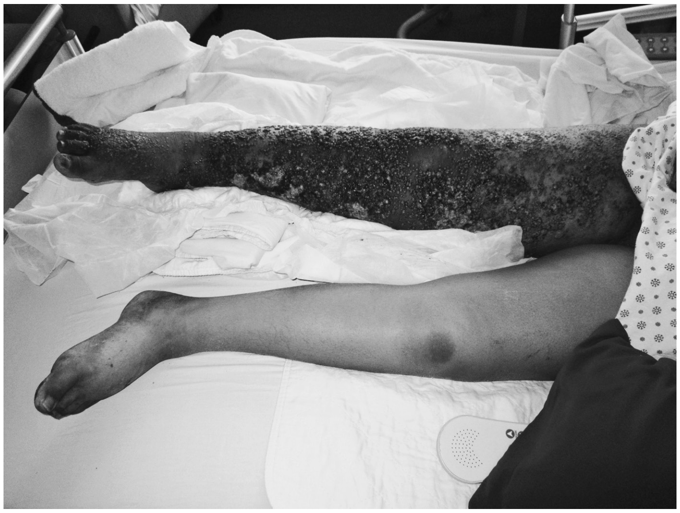

Figure 19.5 Malignant fungating wound of entire right leg with lymphedema from metastatic colon cancer.

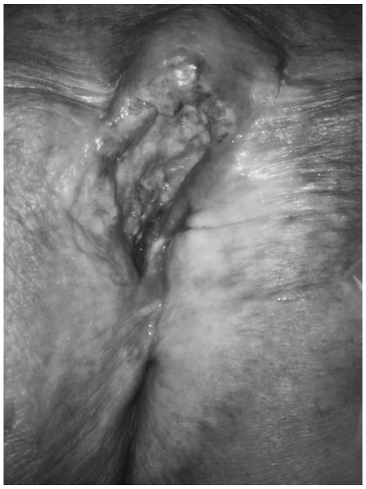

Figure 19.6 I. The first three steps to the PALCARE method: Prognosis, Advance care planning, and Living situation. P: 45-year-old Caucasian woman with metastatic vulvar cancer status post vulvectomy, radiation, and chemotherapy. She has a life expectancy of 2–3 weeks and a Palliative Performance Score of 30%. A: She has a do not resuscitate/do not intubate (DNR/DNI) order, declines hospitalization or heroic measures, and will accept oral and/or topical antibiotics. L: She is transferred to the hospice inpatient unit from home with uncontrolled pain, malodor, and excessive exudate from a vaginal malignant fungating wound. She was self-managing the wound with obstetric pads, showers, and frequent changes of underwear and pants when soiled. Her primary caregiver is overwhelmed and unable to care for her at home.
II. Course of hospice care. C: On admission to the inpatient unit (IPU), she screened positive for depression and anxiety, c/o painful moisture-associated skin damage (MASD) along the periwound/vaginal border, odor noted at the door of her room, and exudate that stained her underwear and pants two to three times per day. C/o intermittent abdominal pain, not controlled with four to five doses of short-acting opioid. A: Friable, yellow-pink tissue with moderate, yellow, foul exudate and circumferential periwound maceration and erythema. Odor noted at the door with dressing intact. R: Wound Care: Cleanse with warm soapy water via a peribottle, pat dry, 1% flagyl spray to wound bed, petrolatum-based barrier periwound and ABD pads held in place by Attends mesh undergarments. MASD resolved, odor and drainage were controlled within 3 days. Pain Management: Pain resolved with local care and a long-acting opioid and daily corticosteroids with a short-acting opioid for breakthrough pain. The short-acting opioid was administered a half hour before wound care and again after completion if needed. Psychosocial: Licensed clinical social worker and rabbi consulted for counseling; mirtazapine started for depression, insomnia and anorexia; and a short-acting benzodiazepine for anxiety as needed. E: IPU staff, patient, and her husband were educated in the wound care orders and protocol. The patient was able to participate in her own wound care but as her health and cognition failed, the staff assumed total responsibility until her death 2 weeks later.

with multiple sites of metastasis as compared to single-site cutaneous involvement.[114] Articles have also reported that malignant wounds disproportionately affect women and older adults.[108]As life-prolonging treatments continue to evolve and life-expectancy increases, it is reasonable to expect the percentage of people with MFWs to rise.

MFWs originate from one of three etiologies: primary skin neoplasms, local extension and integumentary erosion from primary tumors or malignancy recurrence, and from metastatic cutaneous lesions.[109,115,116] MFWs may arise from any type of underlying malignancy, but the most common involvement includes neoplasms of the breast, lungs, skin, and gastrointestinal tract.[111,114,116] Metastatic invasion of the basement membrane is essential for the development of an MFW. Characteristically, these wounds have a tendency to expand rapidly[111]; to occur along pathways of least resistance such as surgical incisions, tissue planes, and blood or lymph vessels[111]; and a tendency to cause lymphedema secondary to local lymphatic vessel invasion.[111]

Assessment

Initially, MFWs present as inflammation, peau d'orange appearance, smooth raised nodules varying in size and pigmentation, erythematous plaques or patches, areas of alopecia, or violaceous papules.[116] They rapidly progress to cauliflower-shaped lesions (proliferative) or an ulcerated area (erosive), sometimes forming fistulas or a sinus tract.[106,116–118] Carville differentiated fungating from ulcerating lesions by morphology, the former protruding and grotesque, the latter cavity-forming, with both prone to bleeding, infection, and malodorous exudate.[119] A survey of nurses reported a variety of MFW morphologies: ulcer (56%), fungating shape (31%), a crust (25%), nodular shape (24%), crater shape (23%), and other (6%).[38] Initial and periodic, detailed wound assessment is essential in monitoring the deterioration of MFWs for the development of new or worsening advanced symptoms.

MFWs have a negative impact on psychosocial, physical, and functional health[68,69,117,118] resulting in compromised QOL.[75] Given the high symptom burden experienced and the incurable nature of their wounds, this population will require aggressive palliative care until death. Developing a pragmatic, patient- and family-centered palliative wound care plan is essential to alleviate suffering. The case study of the 45-year-old woman with stage IV vulvar cancer and a vaginal MFW presented at the beginning of this section is used to demonstrate the use of the PALCARE mnemonic (see Box 19.2) as a framework for developing a holistic, systematic, patient-centered plan of care.

Psychosocial Aspects of Care

Individuals with MFWs may struggle with both advanced cancer-related and treatment-related symptoms and symptom clusters, as well as side effects from palliative therapies. Lawton, during her 10-month observational study of hospice patients enduring horrific physical and psychological suffering, introduced the concept of being "unbounded."[69] The state of becoming unbounded was caused by odors, exudate, pain, bleeding, and disfigurement as a result of "the disintegrating, decaying body," with the dying experiencing marginalization, isolation, and loss of self and social identity.[69] Her study notably included patients with fungating tumors of the head and neck, groin and genitalia, and breast. The presence of a malignant wound was found at times to cause more psychological suffering than the cancer diagnosis itself.[67]

Body image has a great impact on psychological well-being because it is associated with one's identity. Studies on femininity demonstrate a loss of confidence among women with MFWs. Because of the breast's connection with sexuality and being female, women report feeling less attractive and avoid intimacy with their partners.[120] Furthermore, women report feeling mutilated and disgusted by their wounds, as though they are witnessing their bodies decompose.[120] As a result, these individuals feel as though they have lost control over their lives and are marginalized, subsequently withdrawing from society.[60,120,121]

The hospice team uses timely screening, assessment, interventions, and referrals in addressing these psychosocial issues.

Box 19.8 Patient Health Questionnaire 2 (PHQ2)

1. Over the past 2 weeks, have you felt down, depressed, or hopeless?
2. Over the past 2 weeks, have you felt little interest or pleasure in doing things?

Source: Adapted from Reference 122: Pfizer. Patient Health Questionnaire screeners. http://www.phqscreeners.com (accessed October 23, 2017).

Depression and anxiety screening tools, such as the Patient Health Questionnaire 2[122] (see Box 19.8) and the Generalized Anxiety Disorder 7[122] (see Box 19.9), should be used to identify patients at risk for depression and anxiety and allow for timely interventions and referrals. The authors recommend screening on entry into the hospice program, at least every 2–4 weeks thereafter, and with each contact by the hospice nurse practitioner or hospice medical director. Decisions to refer to a licensed clinical social worker (LCSW) or psychologist for counseling or to a psychiatrist for evaluation and pharmacologic recommendations should be a shared decision with the patient and family.

Complementary Alternative Medicine

The role of complementary alternative medicine (CAM) in the holistic care of MFWs is promising, although research is limited. Massage and touch therapy, music therapy, aromatherapy, and occupational therapy have been shown to decrease suffering and improve overall well-being.[60] Research in the area of CAM ranges from expert opinion and case reports to small, nonrandomized qualitative studies. Guided imagery and meditation may also prove to be therapeutic, although no studies to date examine these techniques in patients with MFWs.

Spiritual Aspects of Care

Suffering and limited prognosis cause patients to consider their own mortality[62] and review their existential beliefs and connection to spirituality. Loss of hope may occur as the fungating wound grows in size, new lesions appear, or new symptoms emerge.[121,123] Additionally, five studies found MFWs were constant reminders of advanced and incurable disease, robbing patients of hope[60–62,65,67]: "this wound looks as if death is more and more near me. I can't escape."[61] Visibility of the tumor provoked fears that it mirrored what was occurring internally and conveyed a threat to their body and existence.

Box 19.9 Generalized Anxiety Disorder 7

Over the past 2 weeks, how often have you been bothered by the following problems?

1. Feeling nervous, anxious, or on edge
2. Not being able to stop or control worrying
3. Worrying too much about different things
4. Trouble relaxing
5. Being so restless that it's hard to sit still
6. Becoming easily annoyed or irritable
7. Feeling afraid as if something awful might happen

Source: Adapted from Reference 122: Pfizer. Patient Health Questionnaire screeners. http://www.phqscreeners.com (accessed October 23, 2017).

Additional Management Considerations in Malignant Fungating Wounds

Pain associated with MFWs has multiple etiologies, detrimental effects on QOL,[75] and is a common distressing complaint.[61,65,66,123–125] Pain in advanced cancer is one of the most common and distressing symptoms reported. Pain assessment must include wound- and non–wound-related pain or discomfort and exploration of temporary and persistent wound pain etiologies, and the use of a valid and reliable tool is recommended. The total pain approach (Box 19.4) includes symptom management for malignancy-related pain, interdisciplinary involvement to address psychosocial or spiritual factors, and specialist-level wound care for local discomfort.

Topical antimicrobial therapy and absorbent dressings, combined with cleansing and odor-eliminating interventions, have been the mainstay of MFW odor and exudate treatment. Despite multiple studies, a Cochrane Review[126] identified only one randomized control trial by Kalemikerakis[127] that provided weak evidence suggesting silver foam dressings may reduce malodor.[126] The effect of topical antimicrobial dressings on microbial resistance, biofilms, and the characterization of microbiomes in MFWs is also largely unknown. Table 19.5 lists select interventions that may be used to control odor and exudate.

Postsurgical bras (i.e., Dale bras), Lycra, and Attends undergarments to secure dressings, minimize bulk effect, normalize appearance, and reduce MARSIs are recommended. Carrying an extra set of clothing in the event of strike-through is also suggested.

Goals of care discussions surrounding bleeding are an integral part of advance care planning for the hospice patient with an MFW because interventions may range from the benign (i.e., direct pressure, vitamin K replacement, modification of topical antimicrobial therapy) to aggressive and/or invasive (i.e., vascular interventions for hemorrhage, blood products, radiation). The cause of bleeding in advanced cancer is usually multifactorial and may be thought of in terms of reversible and irreversible factors (see Box 19.10).

If MFWs are in close proximity to large vessels (i.e., femoral or carotid artery), the sensitive probing of patient wishes in the event of hemorrhage should be undertaken. This discussion should include comfort (sedation, pain management, temperature control, and family support) versus emergent transfer to a general inpatient level of care or acute care setting (i.e., emergency room).

Marjolin's Ulcers, Calcinosis Cutis, Calciphylaxis, and Radiation Dermatitis

Marjolin's ulcers, calcinosis cutis, calciphylaxis, and radiation dermatitis are wounds less commonly encountered in palliative settings. These wounds have the propensity to cause advanced symptoms and intense suffering, presenting unique challenges for the palliative care service or hospice team.

Marjolin's Ulcers

Like MFWs, Marjolin's ulcers have cancerous wound beds; however, their etiology is quite different. Marjolin's ulcers are rare, malignant degenerations that most commonly arise from areas

Box 19.10 Bleeding Etiologies in Advanced Cancer

Malignant fungating wounds

- Direct vessel invasion
- Microvascular bleeding
    - Dressing selection/removal
    - Friable tissue: bioburden

Thrombocytopenia

- Chemotherapy
- Paraneoplastic syndromes
- Idiopathic thrombocytopenia purpura
- Thrombotic thrombocytopenia

of chronic inflammation or injury, developing over years or even decades (see Box 19.11).[130,131] One recent review found that the average time for malignant transformation is 29 years.[132] The ulcers were first described by French surgeon Jean Nicholas Marjolin in 1784, after observing villous changes arising in a burn scar.[133] Classically, these ulcers transform from their original etiology to a squamous cell carcinoma (SCC), but basal cell carcinomas and malignant melanoma have also been reported.[131] Marjolin's ulcers may arise in nearly any location on the body, but they are most commonly found in the lower extremities.[132] They are associated with a poor prognosis.[133]

Marjolin's ulcers are diagnosed by attaining both a thorough history and physical (including a detailed wound assessment), and a tissue biopsy. The magnitude of the wound, clinical presentation, and the patient's goals of care will guide more extensive oncologic workups. These ulcers may not present as a classic SSC, but as a characteristic triad of nodule formation, induration, and ulceration suggestive of the diagnosis.[133] Other clinical signs may include chronic ulceration greater than 3 months, rolled wound margins, an irregular base or margins, excessive granulation tissue, crusting over, and an increase in size despite appropriate treatment.[132,133] Marjolin's ulcers may also be associated with advanced symptoms: bleeding on contact, foul odor, purulent exudate, pain, pruritus, and bulk effect.[131]

Treatment

Early detection with immediate referral to plastic surgery for biopsy and wide excision with grafting are the key to successful curative treatment.[131] Palliative care practitioners are likely to encounter Marjolin's ulcers that have either progressed beyond curative treatment or are considered secondary to a more dire diagnosis. Palliative treatment of Marjolin's ulcers follows the same guiding principles of palliative wound care previously discussed in this chapter.

Calcinosis Cutis and Calciphylaxis

The exact etiology behind calcinosis cutis and calciphylaxis is unknown, but abnormal fluctuation in calcium levels and tissue damage is common to both. Calcinosis cutis is characterized by abnormal deposition of insoluble calcium salts in the skin.[134] The cause may be idiopathic (with normal calcium levels) or due to an underlying disease process that causes hypercalcemia, such as metastatic cancer, chronic kidney disease, hyperparathyroidism, or sarcoidosis.[134] The wounds are commonly found on the lower extremities but can be located anywhere. Calciphylaxis is a closely related disorder characterized by calcification of small vessels of the skin and subcutaneous tissues resulting in localized ischemia and tissue damage.[135] Two clinical forms exist, differing in location of the lesions and prognosis. Proximal lesions on the trunk or thigh carry a worse prognosis than distal lesions.[135] Calciphylaxis may affect multiple body areas including the fingers and toes and occasionally even the peristomal skin.[136] Calciphylaxis is usually associated with end-stage renal disease, with or without hemodialysis.

There are no specific laboratory tests to diagnosis either skin pathology. However, serum calcium and phosphate levels, a comprehensive metabolic panel, and a serum parathyroid hormone level should be considered regardless of underlying etiology.[137] Additional laboratory studies, imaging, and tissue biopsy may be indicated.[137]

Treatment

Treatment is complex and should be based on goals of care. If possible, the underlying disease process should be managed, electrolyte abnormalities corrected, and a plan for local wound care developed. There are no standard wound care protocols. Bryant and Nix recommend six general principles: (1) remove impediments from the wound (loose, hard, calcium deposits and slough), (2) balance wound bed moisture, (3) reduce bioburden (prevent and treat infections), (4) reduce edema, (5) control venous insufficiency, and (6) protect periwound skin.[137] One case study of peristomal calciphylaxis reported successful use of a methylene blue + gentian violet foam ring in the peristomal area, a secondary hydrocellular adhesive foam dressing to provide a surface for the pouching system to adhere to, and barrier strips to enhance the pouching system seal.[136] A 24-hour wear time was eventually achieved.

Radiation Dermatitis

Ninety-five percent of cancer patients receiving radiation therapy will develop some form of radiation dermatitis which may result in treatment delay, disfigurement, pain, and/or diminished QOL.[138,139] Radiation dermatitis is also known as *radiodermatitis, radiation burn, radiation injury*, or *radiation-induced skin reaction*.[139] Radiation injures rapidly dividing cells of the epidermis (stratum germinativum, stratum spinosum) and epidermal appendages: hair follicles, sebaceous glands, and nails.[138,140] This results in impaired strength and elasticity of the integumentary, immune compromise, vulnerability to chemical and mechanical trauma, and delayed healing.[138,140]

Radiation dermatitis may be acute or delayed. Early or acute side effects of ionizing radiation delivered to the skin during cancer treatment may manifest as erythema, dry desquamation (see Figure 19.7), or moist desquamation (see Figure 19.8).[139] The acute reactions result from a combination of direct radiation injury and subsequent inflammation.[143] Concurrent chemotherapy or targeted therapy increases the risk of skin toxicity,[138] as do larger number of doses and higher total doses of radiation due to cumulative effects.[137] Delayed or chronic reactions may occur months or even years after the completion of radiation therapy and usually develop as chronic dermatitis and/or skin fibrosis.[139,140]

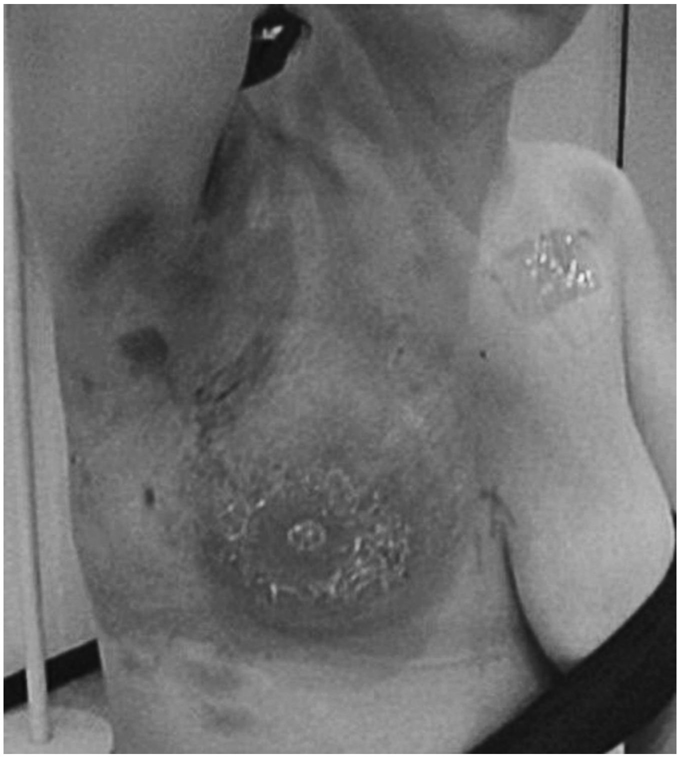

Figure 19.7 Dry desquamation and moderate erythema in a breast cancer patient undergoing radiation treatment.

Assessment and Grading

Skin assessment should be performed prior to the start of radiation and regularly thereafter. Universally, all patients should be assessed for erythema, edema, skin breakdown, pain, skin sensitivity, and tightness. Those with dry desquamation should additionally be assessed for xerosis, pruritus, and scaling.[138,139] The skin of patients with wet desquamation should be inspected for moistness, tenderness, crusting, and the presence of serous exudate and superimposed infections.[139] Several severity grading scales for radiation dermatitis exist, but the National Cancer Institute (NCI) Common Toxicity Criteria for Adverse Events (CTCAE) is the most commonly used in the United States.[138] The CTCAE defines acute reactions as those occurring within 86 days after therapy.[138] Table 19.11 displays the definition and prominent characteristics of each grade of the CTCAE scale.[141]

Treatment

Broadly, goals of treatment should include the promotion of healing, prevention of infection, and the management of advanced symptoms (pain, pruritus, exudate). There is a dearth of evidence supporting specific recommendations in the treatment of acute and chronic radiation dermatitis.[139] General skin care during radiation therapy includes the use of mild soaps and deodorants, loose-fitted clothing over the irradiated site, avoiding sun exposure and scratching, and adequate nutrition.[138,139] Prophylactic use of steroids and silver sulfadiazine (SSD) has shown promise in the reduction of acute radiation dermatitis.[139] Calendula and SSD have weak evidence supporting their effectiveness in acute reactions.[138] One case study of a 57-year-old man with neck radiation burns reported the effectiveness of slow-released, silver hydrofiber dressings in improved healing and decreased dressing

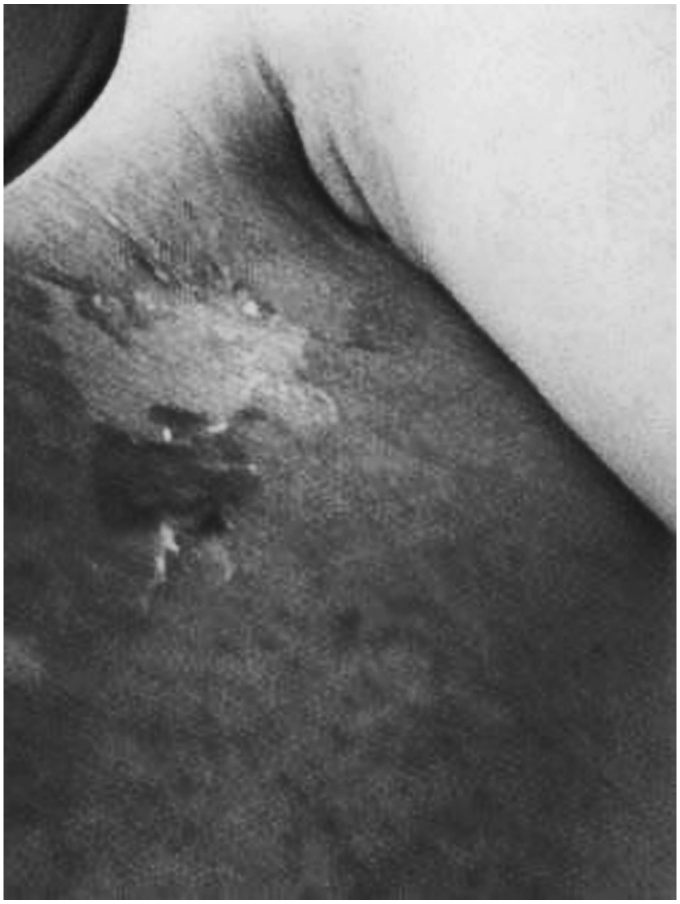

Figure 19.8 Moist desquamation and severe erythema in a breast cancer patient undergoing radiation treatment.

changes and pain.[142] Another case study described complete healing of wet desquamation in a 51-year-old woman with breast cancer after mastectomy, chemotherapy, and radiation using trypsin, Balsam Peru, and hydrogenated castor oil ointment.[143]

Table 19.11 Common toxicity criteria for adverse events scale: radiation dermatitis

Grade of reaction	Definition and characteristics
Grade 1	Faint erythema or dry desquamation. Arising within the first 2-4 weeks of treatment, these reactions cause skin redness and warmth and a rash-like appearance. The patient may complain the skin feels tight or sensitive.
Grade 2	Moderate to brisk erythema; patchy, moist desquamation usually confined to the skinfolds or creases. Moderate edema, dryness, pruritus, and flaking of skin layers (dry desquamation) also may occur.
Grade 3	Moist desquamation in areas other than creases and skinfolds. Bleeding may arise from minor trauma, such as abrasion.
Grade 4	Life-threatening consequences, such as full-thickness skin ulcers, necrosis, and spontaneous bleeding.
Grade 5	Death

Source: Adapted Reference 141: from Chen AP, Setser A, Anadkat MJ et al. Grading dermatologic adverse events of cancer treatments: the Common Toxicity Criteria for Adverse Events Version 4.0. *J Am Acad Dermatol*. 2012;64(5):1025–1039.

Pentoxifylline for the reduction of fibrosis has been used with success in patients with chronic radiation-induced telangiectasia and fibrosis.[144]

Palliative Care of Continent Diversions, Incontinent Diversions, and Fistulas

Palliative care of the patient with a urinary or fecal diversion or fistula centers on expert guidance to manage advanced symptoms and adapt product selection and utilization to the progressive cognitive, psychomotor, and physiologic decline experienced in advanced or terminal illness, with an eventual shift of responsibilities to the caregiver.

Case Study: A Patient with Metastatic Colon Cancer

A 55-year-old man with widely metastatic colon cancer and a malignant bowel obstruction and moderate-output abdominal fistula was admitted to an inpatient hospice unit for end-of-life care after his wife and daughter decided they were no longer able to care for him at home. Due to the change in his abdominal planes from abdominal distention and the large amount of effluent (467 mL per day), the fistula pouching system leaked, causing perifistula moisture-associated skin damage. The erosions and inflammation were very painful, and pouch changes distressed both the patient and family. They called the hospice team and the decision was made to transfer him to the inpatient unit (IPU).

Continent and Incontinent Fecal and Urinary Diversions

No published research specifically addresses the current prevalence, management, or quality-of-life aspects related to ostomy issues in men, women, and children facing life-limiting illness.[9] An ostomy is a surgically created stoma for the elimination of urine or stool that can be permanent or temporary.[145] Indications for stoma creation are listed in Box 19.12, and Table 19.12 describes the different continent and incontinent fecal and urinary diversions

Box 19.12 Indications for Stoma Creation

Malignancy

- Colon, rectal, or anal cancer
- Bladder cancer

Nonmaligancy

- Inflammatory bowel disease (IBS): Ulcerative colitis, Crohn's disease
- Trauma
- Congenital disorders: Hirschsprung's disease, imperforate anus
- Diverticular disease
- Severe neurogenic bladder not otherwise manageable

Source: Adapted from Wound Ostomy and Continence Nursing Society. WOCN Society clinical guideline: Management of the adult patient with a fecal or urinary ostomy—an executive summary. *J Wound Ostomy Continence Nurs*. 2018;45(1):47–55.

Table 19.12 Continent and incontinent fecal and urinary diversions

Type of diversion	Continent or incontinent	Description
Ileostomy	Incontinent (fecal)	A stoma (surgical opening) constructed by bringing the end or loop of ileum out onto the surface of the skin. A one or two-piece pouching system is then worn to collect the effluent.[146]
Colostomy	Incontinent (fecal)	A stoma (surgical opening) constructed by drawing the healthy end of the large intestine or colon through an incision in the anterior abdominal wall and suturing it into place. A one or two-piece pouching system is then worn to collect the effluent. Conversely, colostomy irrigation and a stoma cap may be chosen for patients with distal stomas.[146]
Continent ileostomy (Koch pouch)	Continent (fecal)	The small intestine is connected to an internal, S-shaped reservoir created from a section of ileum. A one-way valve is constructed through which a Medena catheter (30 Fr) is inserted 4–8 times a day to drain the fecal effluent.[146]
Urostomy (ileal conduit)	Incontinent (urinary)	The ureters are surgically resected from the bladder and drain the urine into a detached section of ileum. The end of the ileum is brought out through a stoma in the abdominal wall. The residual small bowel is reanastomosed with the residual terminal ileum. A collection pouch fitted with a belt is then worn snugly against the abdomen and over the stoma to collect the urine.[147]
Ureterostomy	Incontinent (urinary)	One or both ureters are detached from the bladder and brought through the abdominal wall to form a stoma. A collection pouch fitted with a belt is then worn snugly against the abdomen and over the "ureteral buds" or stomas to collect the urine as it passes through the ureters.[147]
Heterotopic continent bladder replacement (Indiana pouch)	Continent (urinary)	Following cystectomy, an ileal or ilio-cecal segment is used to form a reservoir. The ureters are connected to the reservoir. A one-way valve is constructed through which a catheter is inserted 4–6 times a day and at bedtime to drain the urine.[147]
Orthotopic bladder substitution (neobladder)	Continent (urinary)	Treatment of choice when the intent is curative. This is closest to the natural bladder's urine storage and voiding function. Following cystectomy, a reservoir is created from a section of ileum and situated in the pelvis minor and connected to the patient's urethra. Continence is achieved through the patient's own sphincter.[147]

the palliative care nurse may encounter. Most stomas require a pouching system which maintains peristomal skin health, provides a secure seal, and allows the patient with an ostomy to maintain their functional performance status. Pouching change procedures for either one- or two-piece pouching systems can be complex and challenging and include essential tasks such as emptying and removing the pouching system, washing and drying the skin, measuring the stoma, putting on a new pouching system, and disposing of the used pouching system.[9] As taxing as this process can be for an otherwise "well" person with a stoma, basic ostomy care, supply ordering, pouch disposal, and trouble-shooting leakage may present an insurmountable challenge for persons with a life-limiting illness. Specifically, palliative care ostomy challenges may include the presence of motor, sensory, vision, and cognitive deficits as the illness progresses, as well as peristomal complications and pharmacological considerations.[9]

Motor and Sensory Deficits

An overview of the chronic and often lethal diseases the nurse will commonly encounter in palliative care and hospice, as well as their potential effect on the person with a stoma, must begin by reiterating the importance of obtaining a complete patient history and performing a physical assessment. It is essential to obtain a meticulous individualized evaluation of the patient's history of the present illness, past or current medical or surgical treatments, allergies (including to latex or adhesives), medications (including herbal, over-the-counter, and homeopathic remedies), and functional performance level.[9] A psychosocial evaluation and an ostomy and/or continence assessment also must be performed.

For many persons living with chronic, debilitating illness or life-limiting disease, alterations in their physiological functioning and the often devastating sequelae of their treatment regimens may lead to motor and sensory deficits. Neuromuscular illness can affect people with stomas in numerous debilitating and often painful ways (see Table 19.13).[148–153]

Progressive neurodegeneration, peripheral neuropathies (from either disease process or treatment modality), and autoimmune diseases may interfere with a person's ability to care for his or her stoma, requiring the expertise of the WOC nurse to help modify the pouching system or care routine or teach the caregiver how to care for the stoma, if accommodation is not possible. Key to ensuring adherence to the treatment plan and stoma health, as well as to maintaining the patient's autonomy and self-esteem, is the development of a realistic plan of care for the palliative care or hospice patient.[9]

For patients with impaired motor skills secondary to disease or treatments (see Table 19.13), it is important to realistically assess patient functional status, enlist the help of a caregiver or staff members if the patient is institutionalized, and recommend options that simplify ostomy care. Velcro pouches that eliminate the need to use clips, one-piece appliances, and two-piece pouches that can be attached to a skin barrier with one hand for easy applications may be suggested. Convatec's (Skillman, NJ) moldable technology also may be an option for persons with minimal manual dexterity, vision impairment, chronic metacarpal joint pain, or polyneuropathies of the hands. These skin barrier products do not need to be cut (eliminating the need to manage scissors or visualize patterns), and they are molded to fit snugly against the stoma, facilitating adaptation to changing stoma size and shape.[9] Colostomy patients may consider using a disposable, closed-end pouch, thus eliminating the need for a clip, while urostomy patients may need to try various spouts and tabs to find the product easiest for them to use.[154] The WOC nurse may need to refer a patient to occupational therapy to assist in teaching manual skills and to recommend needed adaptive

Table 19.13 Advanced neuromuscular disease and stoma care considerations

Illness/treatment modality	Pathophysiology	Sequelae	General and stoma-specific considerations
Advanced Parkinson's disease	Loss of dopaminergic neurons and the appearance of Lewey bodies[166]	Freezing, hypokinesis, akinesis, dyskinesias, and dystonia[148]	Careful assessment to ensure maximization of dopaminergic agents. May necessitate collaboration with the prescribing neurologist.
Multiple sclerosis (MS)	Multifocal plaques of demyelination within the central nervous system.[148] If diagnosed under the age of 40 years, recurring episodes of neurologic impairment followed by periods of spontaneous remission are common.	Spasticity[148] Pain syndromes have been reported in up to 76% of patients.[148]Along with pain syndromes, dysesthesias are extremely common.	Spasticity is usually treated with baclofen or tizanidine. May respond to both pharmacologic and nonpharmacologic interventions. Consider caregiver training early in the disease process because recurring episodes may be sporadic and debilitating or increase in frequency with increasing age
Amyotrophic lateral sclerosis (ALS)	Loss of both upper motor neurons (UMN) in the motor cortex and lower motor neurons (LMN) in the brainstem and spinal cord[148]	Spasticity, slow movements, hyperreflexia, and poor dexterity are sequelae of UMN disease. Weakness, atrophy, reduced tone, and hyporeflexia are due to LMN involvement[148]	5,000 new cases of this irreversible disease diagnosed each year, with an average lifespan post diagnosis of 3–5 years.[148] Persons with ALS and a stoma will need caregiver assistance, whether at home or in a long-term care setting, at some point in their life spans.
Stroke	May affect sensory or motor function and often both depending on location and extent of injury. May be ischemic (thrombotic, embolic), hemorrhagic (intracerebral, subarachnoid), or lacunar.	Hemiparesis Ataxia Paresthesia Adhesive Capsulitis (Frozen shoulder)	Presents the challenge of caring for a stoma with one, possibly the nondominant, hand. Challenges utilizing or accessing toilet facilities. Inability to feel a clip or flange, or to recognize it as such (stereognosis).
Quadriplegia or paraplegia	Spinal cord trauma, spinal stenosis, or cord compression due to primary tumor or metastasis	Injuries from C4 through C7 may effect shoulder and arm musculature; C6 through C8 (forearm extensors and flexors); and C8 through T1 (hand musculature).[149] Total cord transection syndrome results in the loss of all types of sensation and motor function below the level of the lesion.[149]	May lack the physical coordination to perform majority of gross and/or fine motor skills needed to perform daily care, depending on level of injury. Focus on modifying a plan to accommodate abilities or teach caregiver ostomy care.
Peripheral neuropathy	Common diseases causing polyneuropathies include diabetes, alcoholism, shingles, HIV/AIDS, hepatitis C, rheumatoid arthritis (RA), end-stage kidney or liver disease, and tumor invasion, as in brachial plexopathy commonly seen in metastatic lung cancer.[150] Chemotherapy-induced peripheral neuropathy (CIPN) is a well-known side effect of cancer treatment.[151]	Symptoms may range in severity from minimal, transient numbness and tingling in the extremities to burning pain and lack of coordination.[149]	Most notorious classes of chemotherapeutic agents responsible for CIPN are the taxanes (paclitaxel, docetaxel, Abraxane), vinca alkaloids (vincristine, vinblastine, vinorelbine), and platinum compounds (cisplatin, carboplatin, oxaliplatin).[151] Oxaliplatin, in combination with 5-FU and leucovorin, is considered first-, second- or third-line therapy for metastatic colon and rectal cancer; the recipient commonly has either a temporary or permanent ostomy.[151]
Rheumatoid arthritis (RA)	Acute and chronic inflammation in the synovium associated with joint tissue destruction.[153] Joint damage that results in disability often occurs early in disease (<2 years). Although the course of RA varies and patients may have long clinical remissions or intermittent disease, the majority of patients have progressive disease that can lead to joint destruction and instability.[153]	Loss of joint mobility and dexterity, as well as crippling pain, accompany RA.[153]	Must be diligent about pain control during acute flares or with end-stage disease. The loss of hand dexterity could impair the patient's ability to apply and remove a clip, cut a pattern, or empty a pouch.

devices. A thorough assessment also may show that self-care is not possible. In this instance, caregiver possibilities must be explored for providing daily stoma care or, in the case of a continent diversion or neobladder, regularly scheduled intubation. If this resource does not exist or is not available, home care agencies or long-term care placement may be necessary.[9]

Vision Deficits

Vision deficits are common among palliative patients and are an often-overlooked complication of chronic illnesses. In ostomy care, compromised eyesight can greatly hinder the ability of the patient with a stoma to measure for an appliance, note peristomal complications, or empty the pouch. Ultimately, the potential inability to perform self-care may encroach on the patient's independence, which can negatively influence body image.[145] Diabetic retinopathy,[159] conjunctival erythema (the "red eyes of uremia")[156] in patients with chronic kidney disease (CKD),[156] primary brain tumors,[157,158] and MFWs of the head and neck can be devastating to physical structures of the eye and vison.[10] The palliative care nurse may also encounter secondary ocular manifestations of rheumatoid arthritis[163] and visual dysfunction secondary to multiple sclerosis (MS). Surgery, such as enucleation or local resection and brachytherapy or external beam radiation, are also possible causes of blindness.[157,158] Although relatively uncommon, certain chemotherapy agents acting as either single agents or in combination therapies are known to induce ocular toxicities (see Table 19.14).[160]

There are multiple strategies that may be used to address visual deficits in patients with stomas. Educational materials with large font on blue- or cream-colored paper that reduces glare is suggested.[161] Bright lights, readers, and magnifying glasses also may be needed. Audiotapes with step-by-step instructions that can be conveniently played as frequently as the patient with a stoma or caregiver require may be employed.[162] In the absence of peripheral neuropathy, focus on the patient's strength and keen sense of touch.[163] Changing the ostomy appliance when the stoma is not functioning (i.e., when there is no output) and utilizing a two-piece pouching system are recommended, because it is easier to center the skin barrier by feeling the stoma by touch.[163] If the patient has an ileal conduit, he or she may be taught to wick the urine with a tampon or dental wick, both to keep the peristomal skin dry and to help center the skin barrier.[9] Tactile aides also have been developed by Coloplast Corporation (Marietta, GA).

Table 19.14 Chemotherapy and resultant ocular toxicities

Ocular toxicity	Chemotherapeutic agent
Epiphora	Cyclophosphamide, methotrexate, and 5-fluorouracil
Retinopathy	Cisplatin, etoposide, tamoxifen, interferon
Corneal or conjunctival damage	Carmustine, mitomycin
Glaucoma	Interferon
Cataracts	Tamoxifen, busulphan, methotrexate
Optic nerve or oculomotor nerve damage	Carmustine, vinblastine, vincristine
Optic neuritis	Cisplatin, tamoxifen

Cognitive Deficits

The successive stages of the cognitive learning process include the acquisition of knowledge, comprehension, application (the patient can apply the knowledge to ostomy care), synthesis, and evaluation (the patient performs ostomy care independently and recognizes when to ask for help).[154] The adult learner must be evaluated for the ability to achieve each component of the learning process with the goal of developing a realistic plan of care.

Many disease processes may cause cognitive deficits in the palliative care population.[148,164,165] The ostomy patient diagnosed with one of these diseases will eventually experience loss of memory and cognitive skills, as well as functional impairment. The WOC and palliative care nurse will need to be vigilant about decline in any of these areas because of their impact on daily ostomy care and the eventual added caregiver burden in the later stages of the disease.[9] Ongoing assessment of cognitive function is critical; interventions by the WOC nurse must be directed at the patient's level of functioning. Early in the cognitive disease trajectory, it is prudent for the palliative care nurse to identify one or more caregivers willing to learn about and assist with the patient's ostomy care. At early stages of memory loss, the patient may need visual reminders to prompt him or her to empty the pouch, intubate a continent diversion, or order equipment.[9] As memory and cognition diminish, step-by-step instructions, coaching/prompting, or visual aids may be considered.[9] Simpler pouches, such as pre-cut, one-piece appliances with Velcro closures, may be suggested. Eventually, the caregiver(s) will need to assume total daily care. This will necessitate the development of a teaching plan for either family or staff depending on home care or facility placement. The additional caregiver burden of providing stoma care or diversion intubation should be considered, and the need for respite care, support groups, or counseling routinely assessed.

Peristomal Complications

No statistical data or research directly describe peristomal complication prevalence and incidence in hospice and palliative care settings. Tilley has observed that these issues may be more pronounced or prevalent in the hospice population due to an increase in the frequency and duration of risk factors.[9] The Peristomal Skin Assessment Guide is a tool developed by the WOCN Society that provides basic guidance to clinicians on identifying and treating peristomal skin complications, including instructions for patient care and conditions that warrant referral to a WOC nurse.[166] Changes in abdominal planes, mucocutaneous separation, peristomal varices (caput medusa), and peristomal moisture-associated skin damage are among the most commonly encountered complications and will be discussed next.

Changes in Abdominal Planes

The peristomal plane is the surface area under the solid skin barrier and adhesive of the pouching system, extending out approximately 4 inches by 4 inches from the base of the stoma.[167] Assessing the plane with the patient lying down, sitting, and standing helps the practitioner decide on the type of skin barrier needed.[168] The following factors should be considered when selecting a pouching system: type of ostomy, stoma type and location, abdominal contours, lifestyle, personal preferences, visual acuity, and manual dexterity.[145,167,168] The skin surrounding the stoma should be assessed for firmness, excessive softness, unevenness caused by subcutaneous tumors, the presence of fungating wounds, and rounded protrusion caused by ascites, scars from prior surgeries, or areas of breakdown or trauma.[9] The type of pouching system included in the plan of care may need to be changed multiple times during the palliative to hospice continuum as the disease process progresses and abdominal tumor burden or ascites increase, weight loss occurs, or malignant bowel obstruction develops.[9]

The skin barrier should mirror the topography of the peristomal plane. In the case of a protruding abdomen or a peristomal plane with creases, wrinkles (as seen with excessive weight loss common to palliative care patients), or scars, a convex pouching system may be considered.[166] This system also may be used in patients with uneven planes due to tumors; barrier paste can be used to fill in uneven areas.[9] An extended-wear barrier, left in place for up to 7 days, may be chosen for a patient with a large abdominal tumor burden who is experiencing pain to decrease frequent changes and discomfort.[9] Premedicating with a short-acting opioid before the wafer change should be included in the plan of care, if indicated.[9] In all cases, the back of the skin barrier should be examined during each pouch change to ascertain undermining by effluent, and the skin should be assessed for irritant dermatitis.[145]

Mucocutaneous Separation

Mucocutaneous separation is the complete or partial detachment of the stoma from the surrounding skin (see Figure 19.9).[167] Risk factors include smoking, administration of corticosteroids, chemotherapy, abdominal radiation, diabetes, IBD, infection, malnutrition, or stoma necrosis,[167] and recurrence of malignancy or any of the chronic, debilitating diseases mentioned throughout this chapter.[9]

Corticosteroids, a mainstay in the treatment of pain, dyspnea, and cerebral edema, are used routinely in palliative care settings. The sequelae of diabetes and smoking, coronary artery disease, stroke, and end-stage renal disease are all common comorbidities seen in persons with chronic disease. Malnutrition and anorexia cachexia syndromes may be seen in several chronic, debilitating illnesses such as acquired immune deficiency syndrome (AIDS), chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), dementia, tuberculosis, malaria, CKD, liver disease, and rheumatoid arthritis.[169] Cachexia occurs in up to 70% of patients with advanced cancer.[169] Infection and recurrence of disease due to the debilitating nature of chronic illness may be anticipated.

Conservative management is key because, at end of life, the etiology of the complication most likely will not be correctable.[9] The wound left by the skin separation should be flushed with normal saline or tap water and filled with an absorbent material such as skin barrier powder, skin barrier paste, hydrofiber, or calcium alginates to absorb drainage as well as to prevent excessive soiling from urine or feces.[167] The pouching system is then placed over the area to protect from effluent. Consider using a two-piece system with a floating flange to facilitate comfort during pouch removal and reapplication.[167] A convex pouching system should be avoided because it may cause deeper tissue destruction and impaired healing at the stoma–skin junction.[167]

Peristomal Varices (Caput Medusa)

Peristomal varices occurring at the site of the stoma may be seen in patients with portal hypertension and end-stage liver disease (ESLD) either from malignancy or cirrhosis. This condition, often referred to as *caput medusae*, accounts for between 1% and 5% of all variceal bleeding.[170] A purple hue caused by dilation of mucocutaneous vessels and profuse bleeding may surround the stoma if it is eroded or traumatized (see Figure 19.10). In the case of acute bleeding, apply direct pressure, and if needed, cauterize with silver nitrate, use epi-soaked gauze or gel foam, or suture ligation.[9,167] Educate the caregiver about the need to (1) use skin barriers that are easily removable, (2) use adhesive removers when possible, (3) use flexible pouching devices, and (4) avoid rigid ostomy products and covexity.[167] If unable to stop the bleeding, instruct the caregiver to seek emergency care (if consistent with the patient's advance directives).

Peristomal Moisture-Associated Dermatitis

Peristomal moisture-associated dermatitis is defined as inflammation and erosion of skin related to moisture that begins at the

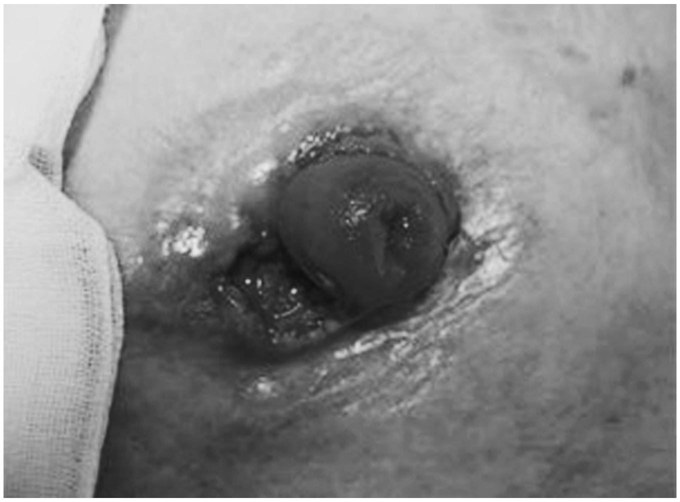

Figure 19.9 Partial mucocutaneous separation.

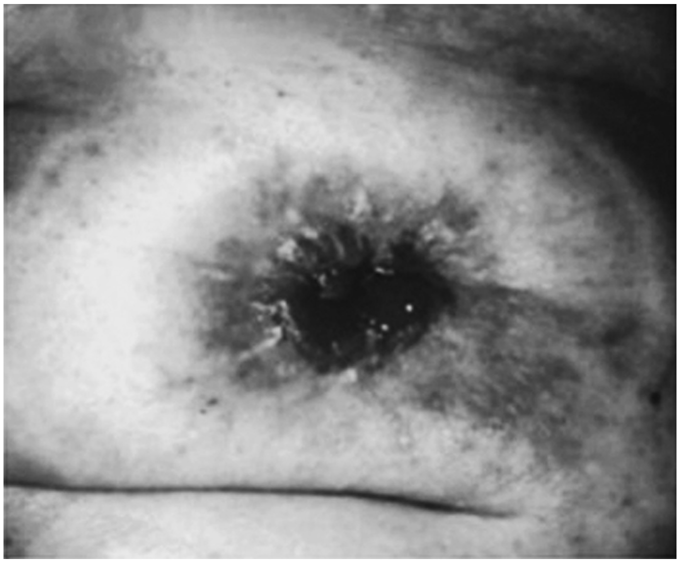

Figure 19.10 Peristomal varices.

stoma–skin junction and extends outward.[54] The etiology of peristomal moisture-associated dermatitis is prolonged exposure of the peristomal skin to urine or stool, perspiration, an external water source (swimming or bathing), or wound or fistula drainage.[54] The etiology of the skin damage drives the treatment plan and pouching system selection. The ultimate goal is to choose a pouching system that fits closely around the stoma and prevents leakage under the barrier.[167] Damaged skin can exude serous fluid and contribute to pouch adherence failure. "Crusting" is a technique that layers no-sting barrier film and stoma powder, forming a dry, protective barrier over denuded skin. The patient with a urostomy should connect the pouch to a bedside drainage bag at night to prevent urine from undermining the skin barrier.[167]

Fistulas

Fistulas negatively impact patients' QOL and present a unique challenge to the palliative care practitioner. A fistula is an abnormal passage or opening between two or more body organs or spaces. Fistulas are named either for the two communicating biological structures or spaces involved or the originating organ (see Table 19.15).[174] The majority of fistulas arise mainly from the gastrointestinal and genitourinary systems. The etiology of fistula development may be related to postoperative complications or spontaneous events. Surgical adhesions, a foreign body next to the suture line, tension on a suture line, breakdown of intestinal anastomosis, and compromised vascular supply can lead to fistula formation in the surgical patient.[175] Spontaneous occurrences may be seen in malignancy (malignant bowel obstruction, tumor invasion), small bowel obstruction, and Crohn's disease, while factors such as infection, poor nutritional status, steroid therapy, and endocrine and metabolic disorders can predispose patients with advanced and terminal illness to fistula development.[175] Fistulas occur in 1% of patients with advanced cancer.[176,177] Patients with gastrointestinal malignancies and those who have received pelvic irradiation are at highest risk.[175,176]

Table 19.15 Fistula terminology

Name	From	To
Enteroatmospheric	Intestine	Open wound base
Enterocolonic	Intestine	Colon
Enterocutaneous	Intestine	Skin
Enterovesical	Intestine	Bladder
Enterovaginal	Intestine	Vagina
Colocutaneous	Colon	Skin
Colovesical	Colon	Bladder
Pancreatic	Pancreas	Skin
Rectovaginal	Rectum	Vagina
Spit fistula (esophagostomy)	Esophagus	Skin
Vesicocutaneous	Bladder	Skin
Vesicovaginal	Bladder	Vagina

Fistulas can be classified in different ways, but the most useful for the palliative care practitioner is by output. Low-output fistulas produce less than 200 cc/day of effluent (most will close spontaneously if they can epithelialize), moderate-output fistulas produce 200-467 cc/day (variable spontaneous closure rates), and high-output fistula produce greater than 467 cc/day (requires surgical therapy to close).[178] The goals of care may be palliative if spontaneous closure of the fistula, which usually occurs within 4–7 weeks, cannot be achieved. Factors that inhibit fistula closure include complete disruption of bowel continuity, distal obstruction, foreign body in the fistula tract, epithelialization of the tract, presence of cancer, previous radiation, and Crohn's disease (see Box 19.13).[175,176,178]

Mortality in patients with fistulas is related to fluid and electrolyte imbalances, malnutrition, failed operative closure, cholestatic liver failure, and sepsis.[182] Mortality may be as high as 10–30% in patients with enterocutaneous fistulas.[178,179] Box 19.14 lists frequent complications, some of them life-threatening, associated with fistulas.[178,179]

Diagnosis and Assessment

Fistulogram, a radiographic imaging technique where water soluble contrast is injected directly into the fistula tract to determine the involved structures, is usually the initial imaging of choice.[175] This may be followed by upper gastrointestinal series, a barium enema, a computerized tomography scan, cystoscopy, or an intravenous pyelogram depending on the presenting symptoms. Once

Box 19.14 Commonly Occurring Complications Associated with Fistulas

Table 19.16 Characteristics of fistula effluent

Fistula type	Effluent color	Daily output	pH	Components
Colocutaneous	Brown, tan	1–1.5 L/day	6.8–7.8	Water, mucous, sodium, potassium, and bicarbonate
Enterocutaneous	Bilious, tan, beige	7–8 L/day	6.5–7.5	Water, mucous, potassium, and bicarbonate
Pancreatic	Colorless	670–1000 ml/day	8.3	Water, bicarbonate, sodium, and potassium
Spit fistula (Esophagostomy)	Clear or color of fluids ingested	1–1.5 L/day	7.1–7.5	Water, mucous, amylase

Source: Adapted from Reference 174: Bryant RA. Anatomy and physiology of the gastrointestinal tract. In: Colwell JC, Goldberg MT, Carmel JE, eds. *Fecal and Urinary Diversions: Management Principles*. St. Louis: Mosby, 2004:33–59.

diagnosed, meticulous assessment is required to correct potentially distressing or even lethal complications. Comprehensive assessment includes nutrition and hydration status, vital signs, mental/cognitive status, pain assessment, inspection of the surrounding skin or wound bed, the quality and amount of fistula effluent, and electrolyte and acid–base evaluation. The effluent should be assessed for odor, color, consistency, amount, and pH.[175] Characteristics of the most common types of fistula effluent are displayed in Table 19.16.[174,180]

Palliative Fistula Management

Ostomy pouching techniques are the mainstay of palliative fistula management. Skin cleansing, skin protection, uneven skin surface management, dressing or pouch selection, containment of output, and odor control are essential components to fistula management in those with terminal illness.[175,178] Table 19.17 offers management considerations based on fistula output, number of fistula tracts, and location. In addition to these considerations, the type of pouching system should be chosen based on effluent consistency

Table 19.17 Palliative fistula management

Fistula classification	WOCN consult recommended	Pouching/Containment system	Odor control
Low-output	No, unless odor is uncontrollable	Skin barrier/Skin deficit management Gauze dressings Foam dressings Pediatric pouches Colostomy caps (small closed-end pouches)	Gauze dressing with charcoal Silver foams Pouching Pouch change in a well-ventilated room
Moderate-output	Yes	Skin barrier/Skin deficit management Pouches that allow direct visualization and/or access through a valve or door Spit fistulas may benefit from pediatric pouching due to difficult-to-pouch locations Multiple fistulas may be amenable to saddlebagging[a] Enteroatmospheric fistulas may be amenable to troughing[b] or bridging[c]	Pouching Pouch change in a well-ventilated room Internal body deodorants: bismuth, charcoal, peppermint oil
High-output	Yes	Pouches that allow direct visualization and/or access through a valve or door High output pouching system Spit fistulas may benefit from pediatric pouching due to difficult-to-pouch locations Multiple fistulas may be amenable to saddlebagging[a] Enteroatmospheric fistulas may be amenable to troughing[b] or bridging[c] Negative Pressure Wound Therapy (NPWT) may be considered	Pouching Pouch change in a well-ventilated room Internal body deodorants: bismuth, charcoal, peppermint oil

[a] *Saddlebagging*: Cut fistula openings on the back of two or more cut-to-fit ostomy pouches, off-center. Cleanse skin with warm water, apply skin protectant and fill deficits with stoma paste. Apply ostomy pouches, adhered to each other in an overlapping "saddlebag" fashion.[181]

[b] *Troughing*: Line the skin surrounding the wound and fistula with a skin barrier wafer and seal the edge nearest the wound with stoma paste. Place thin film dressings over the anterior aspect of the wound, continuing down to the fistula orifice and posterior aspect of the wound. Then place a cut-to-fit pouch over the opening in the film dressing that exposes the fistula orifice.[181]

[c] *Bridging*: (Prevents fistula output from contaminating the wound site.) Build a "bridge" by consecutively layering small pieces of skin barrier wafers together until it is the same height as the depth of the wound. Using barrier past, adhere the skin barrier "wedge" to the wound bed near the fistula opening. Cut to fit an ostomy pouch around the fistula using the bridge to adhere the pouch. Dress the anterior aspect of the wound.[181]

Source: Adapted from Hollister Education. Ostomy care tips: Fistula management. 2016: http://www.hollister.com/~/media/files/pdfs–for–download/ostomy–care/hol_os_fistula–management–care–tips_na_883064-1016.pdf (accessed December 26, 2017); and Reference 181: Seaman S, Bates-Jensen BM. and location.[175,181] Thick pasty output is better managed with a pouch that has an open end and clamp, thin watery effluent with a narrow spigot or tube.[181] Spit fistulas may be better managed with neonatal or pediatric pouches, as anatomical structures of the head and neck region present unique challenges. All pouches must be emptied frequently, when one-third to one-half full. WOC consultation for moderate- to high-output fistulas is important to select the appropriate containment system, train staff and caregivers, and contain cost in terms of supplies and human resources. WOC consultation is also necessary if negative pressure wound therapy (NPWT) is chosen for both fistula and wound closure in enteroatmospheric fistulas.

Pharmacologic Management

Management of fistula effluent may require pharmacologic interventions aimed at reducing gastric secretions, gut-slowing, and/or minimizing output.[177] Gut-slowing and decreasing the amount of effluent help maintain intact pouching systems and the integrity of perifistula skin and maximize the ability to use the gut for nutrition.[175,177]

Reduction of fistula effluent includes the use of histamine-2 receptor antagonists or proton pump inhibitors to decrease gastric acidity and the volume of secretions.[182] Gradual titration and stepwise addition of medications such as loperamide, diphenoxylate hydrochloride and atropine sulfate, codeine, tincture of opium, and octreotide may reduce fistula output and slow gastrointestinal motility.[177]

Somatostatin is a hormone produced in the hypothalamus and other regions of the brain[182] that inhibits the secretion of nearly all alimentary hormones, thereby enhancing absorption of fluids and electrolytes and inhibiting secretion of gastric acid, pepsin, and bile.[182] In some studies, somatostatin analogues, such as octreotide, have been shown to decrease overall fistula output.[182] The efficacy of the role of somatostatin analogues in enterocutaneous and pancreatic fistula closure is, however, inconclusive.[182] Sufficient evidence does exist to use octreotide on a case-by-case basis for patients with moderate- and high-output fistulas.[182] WOC nurse consultation is recommended when considering the use of octreotide, typically given subcutaneously as 100 mcg every 8 hours over at least 7 days.[182,183] The WOC nurse will monitor for both efficacious and adverse effects, such as abdominal discomfort, nausea, flatulence, diarrhea, and steatorrhea.[183]

Nutrition Management

Nutritional support and fluid and electrolyte balance are essential components of fistula management. Malnutrition, dehydration, and electrolyte imbalances should be addressed based on the patient's preferences and goals of care. The gastrointestinal system should be used whenever possible for nutritional support, but intravenous fluid, parenteral electrolyte replacement, and total parenteral nutrition (TPN) may be necessary. If nutrition can bypass the fistula site, absorption and tolerance are better with use of the intestinal tract, but this isn't always possible.[181] Feeding via the fistula itself, termed *fistuloclysis*, has been documented using a 14-French tube and semielemental (partially digested) tube feeding formula.[177] WOC nurse and registered dietician consultation is recommended for all patients who warrant fistuloclysis or parenteral nutrition therapy.

Comprehensive management of fistulas in the patient with advanced or terminal disease requires an interprofessional team approach guided by a specialist-level WOC practitioner. Odor and effluent containment, perifistula skin protection, and maintenance of adequate nutrition and hydration combined with the prevention of sepsis, anemia, acid–base and electrolyte imbalances, pain, and delirium are essential in maintaining QOL.

Case Study: Resolution

The WOC nurse was consulted by the hospice team. She used a "crusting" technique (layering no-sting skin protectant with stoma powder) to cover the denuded skin and create a dry surface for the skin barrier to adhere to. She then chose a flexible one-piece pouching system that would fit the newly rounded contours of the patient's abdomen. She instructed the nursing staff on the pouch changing regimen (wear-time goal is 24–45 hours) and the importance of emptying the pouch when it was one-third full to avoid tension on the skin barrier. She recommended premedication with a short-acting opioid 20–30 minutes prior to the pouch change as part of pain management. The WOC nurse also suggested octreotide 100 mcg subcutaneously (through a subcutaneous line) every 8 hours over 7 days to slow and decrease the amount effluent. She educated the nurses on proper administration of octreotide and to monitor for side effects.

Urinary and Fecal Incontinence in Palliative Settings

Urinary and fecal incontinence management in palliative care balances advanced symptom control with minimally invasive, highly individualized interventions adapted to the terminally ill patient's progressive cognitive, psychomotor, and physiologic decline.

Incontinence and Quality of Life

Incontinence remains taboo in modern society and has a devastating effect on psychosocial well-being and QOL.[69,184] Incontinence in hospice and palliative care has many etiologies and can lead to shame, embarrassment, anxiety, depression, and social isolation.[71] Incontinence is a common impetus for institutionalization in the elderly and terminally ill.[69,185] Urinary incontinence also creates an extraordinary financial burden on patient and caregivers.[190] Caregiver strain associated with frequent incontinence care of a loved one is significant and can lead to multiple respite admissions and possibly long-term care placement. This may undermine the patient's goals of care if his or her wish is to die at home.

There is little published research about incontinence in palliative care and hospice settings. The focus of this section is the prevention and management of IAD. The most common types of incontinence or dysfunction encountered in hospice and palliative care, functional and transient urinary and fecal incontinence and urinary retention, and their management are discussed in Chapters 14 "Bowel Management" and 17 "Bladder Management in Palliative Care."

Incontinence-Associated Dermatitis

IAD is a form of irritant dermatitis that develops from chronic exposure to urine or liquid stool.[187] Repeated exposure to urine in the presence of occlusion or fecal material puts the skin at higher risk.[191] The skin has an "acid mantle," part of its protective barrier. The ammonia in urine is converted to ammonium by fecal bacteria which raises the skin's pH to alkaline.[188]

Prevention and Management

Prevention starts with the least invasive containment products (absorptive products, fecal pouches, condom catheters, female urinals), although more invasive strategies (indwelling Foley catheters, fecal management systems) may be considered on a case-by-case basis.

Perform incontinence care after each episode and daily with a pH-balanced, no-rinse cleanser.[187] Care should be taken to check closely in skin folds and not to scrub the skin vigorously. A skin moisturizer with humectants and emollients should be applied after cleansing and a skin barrier applied to protect the skin.[87] See Table19.2 for skin protectant options. For denuded or inflamed skin, implement the preventive steps, add a skin protectant, eliminate cutaneous candidiasis, and consider diversion of urine and/or stool using one of the aforementioned strategies.[188]

Conclusion

WOC maladies contribute to suffering and diminished QOL. Lawton observed that certain nursing interventions and adequate symptom management could once again "bind" the body, alleviating suffering and palliating the dying patient and his or her family's psychological distress.[69] In addition to a methodical, evidence-based approach to nursing care, this chapter highlights the dearth of research in palliative WOC care and the need for rigorous studies. Evidence-based palliative interventions combined with expert WOC nurse consultation is the key to providing high-quality palliative care and alleviating the multidimensional suffering experienced by patients and families at end of life.

CHAPTER 20

Pruritus, Fever, and Sweats

Angel Smothers

Key Points

- Pruritus, fever, and sweats can decrease the quality of life for a patient living with a serious chronic illness.
- Both nonpharmacological and pharmacological interventions could improve these symptoms for patients.
- The underlying pathophysiology for all three symptoms is multifaceted and complicated.

Introduction

Palliative care is at the root of good nursing care. The Hospice and Palliative Nurses Association (HPNA) endorses the definition of palliative care originating from the National Consensus Project for Quality Palliative Care (NCP), which states: "Palliative Care means patient and family centered care that optimizes quality of life (QOL) by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness involves addressing the physical, intellectual, emotional, social, and spiritual needs and [facilitating] patient autonomy, access to information, and choice."[1] Care of the patient with a serious chronic illness is multifaceted and includes both pharmacological and nonpharmacological interventions. The symptoms that are experienced by patients who are living with serious chronic illness can vary depending on the diagnosis as well as treatment plan for their diagnosis.[2] There are times when symptoms result from a disease, but there are also times when they occur as a side effect of a medication or other treatment modality. Because each patient's response to a serious chronic illness is unique, it is important to have a broad understanding of what the research shows as being effective in the management of symptoms.

In this chapter, emphasis will be placed on three of the symptoms that are commonly seen in patients who are living with serious chronic illness. Symptom presentation is unique in each patient and can occur individually but also can occur simultaneously. There is evidence to support the occurrence of a new symptom in response to the treatment of another symptom.[2] This vicious cycle often results in the discontinuing of a treatment modality or adding another treatment that results in other symptoms. By having a strong knowledge base of the underlying reasons for a symptom, the nurse can help select the best treatment option that will also result in the least number of negative sequelae. Each common symptom—pruritus, fever, and sweats—will be examined individually and then collectively at the end of the chapter. For each of the symptoms, a case study will be included to assist in identifying the potential of treatment options.

Pruritus

Pruritus is defined as an unpleasant sensation that triggers the need for a mechanical response such as scratching, rubbing, or pressure.[3] This sensation can negatively impact QOL and impair sleep.[4] However, pruritus is itself not a disease but instead a symptom of a disease or of an alteration of physiological functioning of one or more of the body's regulatory systems. There are common underlying triggers for pruritus: alteration of liver or biliary duct function, alteration in urinary secretory function, malignancy, or human immune deficiency virus (HIV) or the pruritus could be medication-induced.[3] Pruritus can further be defined as peripheral (prurioreceptive) or central (neuropathic). When considering a peripheral cause, the nurse might identify sources such as dermatitis, insect bites, or other skin reactions that would result in itch. On the other hand, with neuropathic causes, identifying the source of the pruritus in nursing assessment is often more difficult. With a neuropathic cause, the underlying source is often renal, biliary, hepatic, or malignancy related.[5,6] There are additional sources of pruritus, with none of the sources being fully understood. Each of the potential sources will be reviewed in the following sections.

Nursing Assessment with Pruritus

Nursing assessment of a patient with the complaint of "itching" will focus on different aspects using the assessment process. The nurse would start with an assessment of the patient's subjective complaint. Then, he or she should ask probing questions, such as: "How long has this been happening? When did this start? Is there anything that makes it worse or better? Has this happened before? If so, what helped relieve it?"

Next, the nurse would do a visual assessment of the areas where the patient is complaining of an itch. Often the sensation is generalized, and the patient is not able to pinpoint a location.[4] The nurse would assess for peripheral or dermatological sources of the itch, including rash. Afterward, the nurse would discuss with the patient his or her past medical history to include medications, recent changes in the treatment plan, past medical diagnoses, and any changes in cosmetics, lotions, laundry detergent, or soap. Collecting as much information as possible on the patient's complaint will allow for a thorough report to the practitioner who will be potentially prescribing medication or other treatments for the patient.[5]

Case Study: A Hemodialysis Patient with Pruritus

Sarah was a 76-year-old patient who was admitted to the hospital post hemodialysis after a significant drop in her blood pressure and heart rate. Sarah had a long-term history of the following medical diagnoses: diabetes, hypertension (HTN), congestive heart failure (CHF), hyperlipidemia, and anxiety disorder. Sarah had been receiving hemodialysis 3 days a week for the past 4 years, after she developed end-stage renal disease (ESRD) related to her long-term uncontrolled diabetes. Sarah had a family history of type II diabetes and had struggled since the age of 38 with managing her glucose level. During her hospital stay, Sarah developed severe pruritus and multiple skin abrasions had resulted due to her constant scratching. Sarah stated the symptoms were causing her great distress and were altering her QOL due to lack of sleep.

The nurse consulted the palliative care team at the hospital where the patient was staying, and the following treatment plan was developed.

1. The underlying source of pruritus was most likely uremic in nature. Patient and family were provided education on this as the potential source of the itching.
2. Nonpharmacological interventions that are supported in the literature were implemented and included: Cool baths, aloe vera gel, and phototherapy. Medications that are supported in the literature as being helpful in the management of pruritus were reviewed. See Table 20.1.
3. After review of patient's current medication list, which already included gabapentin, it was determined the next medication to try would be cromolyn sodium.

Sarah was started on the nonpharmacological interventions as well as on cromolyn sodium and reported improvement in symptoms within 24 hours.

Nonpharmacological Treatment for Pruritus of Varying Origin

Research supports the use of nonpharmacological treatments as a part of a treatment plan for pruritus of any origin. Nonpharmacological treatments shown to be effective in the management of pruritus utilizing skin application include baby oil, aqueous gel with aloe vera, lotion with mud from the Dead Sea, and cream containing sericin.[7] There is some evidence to support the effectiveness of phototherapy, which involves an ultra-violet (UV) lamp; acupuncture by a trained acupuncturist; and thermal therapy using far-infrared radiation as nonpharmacological treatments for pruritus.[7] An additional study examined the effectiveness of aromatherapy and found it to be a viable management option.[8] Transcutaneous electronic nerve stimulation (TENS) units have some research support as an effective option for nonpharmacological management of pruritus of varying origins.[6]

Pharmacological Management of Pruritus of Varying Origins

Pruritus management in palliative care patients can be difficult due to the multiple underlying mechanisms that could be linked to the symptoms. The treatment plan is individualized since there could be overlapping reasons for the symptoms. Therefore, understanding medications that could help manage pruritus in the palliative care population is important. Table 20.2 shows classes of medications that have some research to support them as potential treatment options for patients with varying underlying reasons for pruritus.[9–16]

Table 20.1 Medications indicated in the treatment of uremic pruritus

Name of medication	Class of medication
Gabapentin (Neurontin)	Antiepileptic
Pregabalin (Lyrica)	GABA analogue
Nalfurafine (Winfuran): In clinical trials in US	Kappa-opioid receptor agonist
Cromolyn sodium	Mast cell stabilizer
Hydroxyzine (Vistaril)	Antihistamine
Sertraline (Zoloft)	Selective serotonin reuptake inhibitor(SSRI)

Pruritus of Uremic Origin

Uremic pruritus (UP) is a common symptom that has been reported in as many as 42–75% of ESRD patients.[16] For patients who have been adequately dialyzed, the report is the same. Pruritus of uremic origin can be acute, short, or chronic in duration.[13] The exact cause of pruritus of uremic origin is not well understood, but evidence supports the relationship between this symptom in ESRD patients and a chronic inflammatory response involving sensory neurons, specifically unmyelinated C fibers.[16] Some of these sensory nerves respond only to itch, while others respond to both pain and itch; thus, these systems are closely linked. Mediators that have been linked to this response include histamine, endogenous opioids, and serotonin.[13]

Pharmacological Treatments for Uremic Pruritus

Research has supported the effectiveness of pharmacological treatments in the management of pruritus. Because the underlying origins of pruritus are not well understood, the medications to treat it are based on potential underlying causes for the itching sensation in patients. Additional research is needed to assess effectiveness. Inui (2015) found that nalfurafine hydrochloride was an effective treatment for UP.[12] There is evidence that the upper motor neuron system plays a role in the development of pruritus in renal failure. While this medication has been approved for use in Japan, it is currently in clinical trials to be evaluated for use in the United States. Therefore, nalfurafine as a k-opioid receptor agonist may improve pruritus in these patients through binding the k-opioid receptors.

Gabapentin has been studied and identified as an effective treatment option for UP. Gabapentin is classified as an antiepileptic drug and has been successfully used for many years in the management of nerve-related symptoms including neuropathy, pain, and itch. Because there is a neuronal mechanism that has been identified as a potential source of pruritus, gabapentin has been studied and determined to be effective in managing pruritus of uremic origin.[6]

There is some evidence that mediators released from mast cells play a role in UP. Therefore, cromolyn sodium has been studied as a potential treatment for UP. This medication blocks mast cell degranulation and therefore leads to decreased release of histamine.[9] A study identified a potential role for the medication sertraline in the management of UP.[16] Other selective serotonin reuptake inhibitors (SSRIs) have been researched and shown to be effective

Table 20.2 Medications indicated in the management of pruritus

Class of medication	Name of medication	Indication
Histaminergic (antihistamines)[9–11]	Hydroxyzine (Vistaril)	Has shown effectiveness in management of pruritus in HIV patients. Prevents fixation on the surface of the histamine receptors.
	Ketotifen (Zaditor)	Prevents fixation on the surface of the histamine receptors.
Opioid antagonist[9,10]	Naltrexone (Revia, Vivitrol)	Found effective in managing pruritus of cholestatic origin. Prevents the activation of spinal neurons that can lead to pruritus.
K-opioid receptor agonist[9,12]	Nalfurafine hydrochloride (remitch): currently in clinical trials in the US. Approved for use in Japan.	Found effective in managing pruritus of uremic origin. Prevents the activation of spinal neurons that can lead to pruritus.
Serotonergic medications[9,12,14,15]	Ondansetron (5-HT3 antagonist) (Zofran)	Blocks the pathway that could lead to itch by inhibiting the neurotransmitter 5-hydroxytryptamine.
SSRI (selective serotonin reuptake inhibitor)[9,16]	Sertraline (Zoloft) Paroxetine (Paxil)	Has been shown to be effective in pruritus of any known cause. Increases the amounts of serotonin available extracellularly which can then bind to the postsynaptic cleft preventing the transmission of the itch sensation.
Antiepileptic[6,9]	Gabapentin (Neurontin) Pregabalin (Lyrica)	Has been found effective in managing pruritus of uremic origin. May inhibit the transmission of nociceptive sensations to the brain thereby suppressing pruritus.
Antibiotics[9]	Rifampicin (Rifadin)	Has an indication in the management of pruritus of cholestatic origin. May change the GI bacterial growth which may influence the absorption of pruritogens.
Immunomodulator[9]	Thalidomide (Thalomid)	May act as a peripheral and central nerve depressant.
Benzhydryl derivative[9]	Flumecinol (Zixoryn)	Has been shown to lower serum bilirubin so could be effective in the management of pruritus of cholestatic origin.
Anion exchange resin[9]	Cholestyramine (Questran)	Interrupts the enterohepatic circulation of bile acids and has therefore been considered a treatment for pruritus of cholestatic origin.
Mast cell stabilizer[9]	Cromolyn sodium	Works by preventing the release of substances in the body that cause inflammation. Has also been shown to reduce serum tryptase levels.
Leukotriene modifier[9]	Montelukast (Singulare)	Prevents the inflammatory response produced by leukotrienes.
Hormone/glycoprotein[9]	Erythropoietin	May work to lower the effect of the hormone on plasma histamine concentrations.
Binding agent[9]	Activated charcoal	May work to bind the agents that lead to uremic pruritus.
Topical antipruritic/alkaloid[9]	Capsaicin (activate component of chili peppers)	Targets the transient receptor potential vanilloid receptor and counteracts itch by activating pain neurons.
Immunosuppressant/ calcineurin inhibitor[9]	Tacrolimus (Prograf)	Works by suppressing the differentiation of Th1 lymphocytes and ensuing interleukin (IL)-2 production.
Local anesthetic[9]	Pramoxine hydrochloride (Caladryl)	May work by blocking sodium channels within the neuronal membrane, decreasing conduction.
Vitamins/herbal[9]	Ergocalciferol (Vitamin D_2, calciferol)	May have antipyretic effect in uremic causes of pruritus due to impaired vitamin D metabolism that can occur in dialysis patients.
	Nicotinamide (niacinamide)	May have antipyretic effect through its anti-inflammatory and histamine-release blocking action.
	Omega-3 fatty acids	Has been shown to reduce inflammation, free radicals, and leukotriene B-4 so could work in uremic pruritus.
	Turmeric (powder of *Curcuma longa L.*)	Curcumin, a substance in turmeric, has an anti-inflammatory effect.
	Zinc sulfate	May act as an antagonist of calcium and prevents degranulation of mast cells.

in UP but do require dose adjustment in ESRD. Sertraline appears to be a better option due to the limited need for dose adjustment with ESRD.[16]

Pruritus of Cholestatic Origin

There is evidence available supporting the use of medications to mitigate pruritus in patients with cholestatic pruritus (CP) (Table 20.3). Evidence supports the use of rifampin, which is a class of antibiotic, as a pharmacological treatment of pruritus. Because rifampin has been shown to induce detoxicating hepatic enzymes and, therefore, competitively inhibit the reuptake of bile acids, there is evidence to support that it would lead to a decreased rate of pruritus in patients with pruritus of cholestatic origin.[17] In addition, flumecinol, which is a benzhydryl derivative, has been shown to lower serum bilirubin levels and would limit the amount of pruritus in cholestatic cases.

Table 20.3 Medications indicated in the treatment of cholestatic pruritus

Name of medication	Class of medication
Rifampin (Rifadin)	Antibiotic
Flumecinol	Benzhydryl derivative
Naltrexone (Revia)	Opioid antagonist
Ondansetron (Zofran)	Selective 5-HT3 receptor antagonist

Naltrexone, an opioid antagonist, has indications based on evidence for the management of CP. A higher than usual dose may be indicated for better management; however, higher doses in a palliative care patient could bring about worsening pain so its use would need to be individualized for each patient.[9] There is limited support suggesting that the use of corticosteroids may have a potential benefit for CP.[18] Research supports the use of ondansetron as a potentially effective management strategy for CP, but additional studies are needed to support this as a viable option.[13]

Pruritus of HIV Origin

Pruritus in HIV patients can have varying and complicated underlying mechanisms. The prevalence of pruritus in this population can be as high as 45%.[19] A significant percentage of pruritus in this population is cutaneous in nature.[20] Limited research, including studies that consist of small numbers of subjects, provides some support for medications in the pharmacological management of HIV-related pruritus (HIVP). Hydroxyzine HCL, an antihistamine, has demonstrated some effectiveness in the management of HIVP. The anti-inflammatory effect of pentoxifylline, indomethacin, and triamcinolone may have some impact on HIVP as well (Table 20.4).[9]

Opioid-Induced Pruritus

For patients who require pain or dyspnea management with opioids, the risk of pruritus related to this treatment can be high. Although pruritus is common with opioid use, the intensity can range from mild to severe.[21] In mild cases, patients may get relief with nonpharmacological treatment but with more severe cases, pharmacological treatment may be indicated. Pharmacologic treatments that have evidence to support them include naloxone and nalbuphine. The primary mediator of opioid-induced pruritus appears to be the central mu-opioid receptors. Therefore, these medications could decrease the rate and severity of pruritus from opioid treatment. Naloxone is an opioid antagonist and could therefore improve pruritus from opioid use but could also lead to worsening pain. The route of administration could also be a potential barrier for the use of naloxone; therefore, more evidence is needed regarding the benefits of naloxone. However, nalbuphine is a partial opioid antagonist and has been shown to treat opioid-induced pruritus more effectively than naloxone (Table 20.5).[22]

Table 20.4 Medications indicated in the management of pruritus of HIV origin

Name of medication	Class of medication
Hydroxyzine hydrochloride (Vistaril)	Antihistamine
Pentoxifylline (Trental)	Vasodilator/anti-inflammatory; phosphodiesterase inhibitor
Triamcinolone (Kenalog)	Corticosteroid
Indomethacin (Tivorbex)	NSAID

Table 20.5 Medications indicated in the management of opioid-induced pruritus

Name of medication	Class of medication
Naloxone (Narcan)	Opioid antagonist
Nalbuphine (Nubain)	Opioid agonist-antagonist

Fever

Fever has been defined as an elevation of body temperature that is mediated by the hypothalamus in response to exogenous pyrogens and pyrogenic cytokines.[23] The underlying mechanism of fever can vary in individual patients, particularly in the palliative care population. Fever can result in emergency department (ED) visits and hospitalization in palliative care patients.[24] Patients who exhibit an elevated temperature must be evaluated for the underlying source for the fever.[25] A fever of unknown origin (FUO) is generally defined as an immunologically normal host with oral or rectal temperatures of 38°C or higher at least twice a week for more than 3 weeks with no identified cause.[26] A FUO can be broken down into four potential causative categories: infection, malignancies, noninfectious inflammatory disease, and other miscellaneous causes.[27] The category of noninfectious inflammatory disease has been linked to potential causes such as vasculitis and autoimmune, rheumatic, and granulomatous disorders.

A complete history and physical exam is needed to identify the source of the fever. A FUO in a patient with a malignant disease might be related to the malignancy or from an underlying infection. Fever is a common occurrence during malignancy, especially during chemotherapy.[28] There are times when the use of antibiotics would be of potential benefit for the palliative care patient by reducing painful urination and related symptoms. When this is the case, antibiotics could be offered to the patient as an option for palliation. In situations where the patient is actively dying, antibiotics would have no benefit and could potentially make things worse. The use of an antipyretic medication such as acetaminophen, ibuprofen, or aspirin could be of benefit for the patient with a fever even if the patient has entered the actively dying phase by reducing pain, diaphoresis, and discomfort.[29]

Nursing Assessment and Diagnostic Evaluation with Fever

The nursing assessment in a patient with fever starts with the history of the fever. Collecting information such as when the fever first started, how long it has been present, other related symptoms, and whether this has happened in the past could help with current and future management of the fever.[28] A general nursing assessment that include auscultations of the lungs and heart, skin assessment including any wounds, and assessment of edema and capillary refill could help to identify signs of infection or a source for the fever. Potential diagnostic tests that might aid in identifying the source of the infection include complete blood count (CBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), tuberculin test, blood culture, antinuclear antibody (ANA), stools cultures, and spinal tap. Some of the diagnostic tests could be considered minimally invasive, but a spinal tap could be considered a very invasive procedure.[29] The patient's overall status and goals of care should be considered before the more aggressive tests are planned. The question should be asked "Will the test change our plan for therapy?"

Case Study: Management of Fever in Relation to a Patient's Goals of Care

Mr. Markman was a 67-year-old man with a diagnosis of stage IV non–small cell lung cancer (NSCLC); because of the advanced stage, he was not a candidate for surgery. He had received chemo therapy for the past 6 months, with his last treatment a few days ago, yet recent scans revealed wide spread metastases to bone, liver, and brain, and he had been told by his oncologist that the treatment plan no longer includes chemotherapy. The patient was referred to hospice for home palliative care. Upon arrival at the home, the nurse found Mr. Marksman's temperature to be 40°C. He was not experiencing chills and had no other complaints. His pain was managed by oral oxycodone/acetaminophen (Percocet) 3 or 4 tablets per day. The nurse reviewed his past medical history and found diabetes, hypertension, and a smoking history of two packs per day for 50 years. Lab work demonstrated a normal CBC, ANA, ESR, CRP, and blood cultures.

The nurse provided assessment data including updated lab work to the hospice medical director who was overseeing Mr. Marksman's admission to hospice, noting that he had a chemo treatment a few days before. The patient confirmed that he sometimes had an elevated temperature after getting chemo. The patient was prescribed acetaminophen 500 mg every 6 hours for elevated temperature as needed. The nurse also asked the medical director to change the oxycodone/acetaminophen to oxycodone alone so as not to deliver doses of acetaminophen exceeding 2,000–3,000 mg/day.

Mr. Markman took the acetaminophen for 24 hours and his fever subsided.

Nonpharmacological Treatment Options for Fever

Evidence for nonpharmacological management of fever goes back many years. Some of the evidence-based nonpharmacological treatments for fever include fans, cool cloths to head and axilla, ice packs, drinking cool liquids, tepid water bath, and other treatments including a cooling blanket.[30]

Pharmacological Treatments for Fever

Pharmacological treatment for fever focuses on the use of antipyretic medications including acetaminophen, ibuprofen, and aspirin. In the palliative care patient, it is important to consider the potential methods for administration. For patients who have a fever and are not able to take medication by mouth, these medications can be administered by suppository.[31]

Sweats

The human body contains more than 4 million sweat glands that help to thermally regulate it. These glands are subdivided into three different types: apocrine, eccrine, and apo-eccrine.[32] There are two underlying types of sweating: emotional and thermoregulatory.[33] Thermoregulatory sweating is controlled primarily through the hypothalamus, and emotional sweating is controlled through the limbic system. Excessive sweating, referred to as *hyperhidrosis*, can be generalized or focal. When generalized, hyperhidrosis occurs in more than one location and can occur in any location where sweat glands are located. Focal hyperhidrosis is primarily seen in the axillae, hands, feet, and face. In the palliative care population, sweating could be related to either an emotional cause or be related to thermoregulation. Some of the common causes of sweating in palliative care patients include opioids, hormonal changes, and tumors. And since sweating often accompanies fever, many of the treatments for fever will, in turn, improve outcomes for a patient who is experiencing sweating.[33]

Nursing Assessment of Sweats

The nursing assessment of a patient who is experiencing sweating should focus on identifying the underlying cause. Some assessment data that should be collected during this nursing assessment include timing of the symptoms, temporal pattern, medication history, and changes in severity of symptoms.[33] Understanding that there are both emotional and thermoregulatory factors involved can help the nurse to ask probing questions during the assessment. Because both the limbic system and the hypothalamus can be involved with sweating, there may be an underlying neurological issue that is leading to the sweating, which could mean the sweating is unrelated to any fever that the person may have. Some common neurological issues might include stroke, seizure disorder, multiple sclerosis, and paralysis. However, sweating could be linked to fever; so therefore, when they are occurring together, the assessment of them should be made at the same time.[33] Nursing assessment should also focus on ways to improve the patient's comfort related to the sweating. Protecting the integrity of the skin is important and assessment for this would be a nursing priority.[34]

Case Study: Sweats that Can Alter the Course of a Chronic Illness Due to Decreased Sleep and Quality of Life

Rebecca was a 16-year-old patient who had a diagnosis of a malignant spinal cord lesion. The primary site of the malignancy had not been determined. The patient was being evaluated for symptom management by the acute care palliative care team. Rebecca complained of excess sweating of palms and back of the neck for the past week. She stated it kept her from sleeping, and she was reluctant to leave the house because of the sweating. On assessment, the patient had no fever, was alert, oriented, and ambulatory. The only other complaint she had was back pain around the lesion, pain controlled with oxycodone/acetaminophen.

The nurse's assessment findings were discussed with the palliative care team nurse practitioner to develop a treatment plan. Because of the lack of other related symptoms including fever, chills, signs of infection, or change in level of consciousness, the nurse practitioner felt the symptoms were neurologically linked. Since the sweating was focal in nature, the nurse practitioner prescribed a cream that included aluminum chloride 15%.

The patient's sweating lessened, and she returned to her regular routine including playing in her church band on Sundays.

Nonpharmacological Treatment Options for Sweating

For patients who are suffering with sweating, management should start with a conservative approach. The use of a technique called *tap* *water iontophoresis* has patients immerse their hands in cool tap water where electrodes are applied.[31] The goal of this nonpharmacological treatment for sweating is to disrupt the ion transport in the secretory tangle of the sweat glands and is primarily effective for excessive sweating in the palms or feet. More aggressive surgical options are available with the use of an endoscopic thoracic sympathectomy if the symptoms are progressive, debilitating, and altering the patient's QOL. Surgical removal of the sweat glands in a focal region of excessive sweating is another aggressive treatment option, one not likely to be used in the palliative care setting.[31]

Pharmacological Treatment Options for Sweating

For patients who do not respond to nonpharmacological options, the use of medications may be of benefit. These medications vary in response rate and underlying reason for effectiveness. Topical creams containing aluminum chloride 15–25% have been shown to be effective in focal areas of sweating.[32] The injection of botulinum toxin has evidence to support its effectiveness for focal sweating. This will inhibit the release of acetylcholine from the sudomotor synapses, which will limit the glands ability to secrete.[32] Anticholinergic medications, including glycopyrrolate and oxybutynin, are used for sweating due to their drying effect.[32] There is research that supports the use of antidepressants such as amitriptyline for decreasing sweating in the palliative care patient.[33] Finally, there is research to support the use of antihypertensive medications, such as beta blockers, calcium channel blockers (diltiazem), alpha blockers (phentolamine), and alpha 2 blockers (clonidine).[32,33]

Conclusion

Patients who experience pruritus, fever, or sweating often report impaired QOL. For the palliative care patient who may be approaching or currently is in the terminal phase of chronic illness, symptom management in a timely manner can be enhanced using evidence to guide practice.[34] More research is needed to better understand the mechanisms of pruritus, fever, and sweating along with appropriate and effective interventions.[35,36] This includes the need for improved research on the nonpharmacological interventions to treat these symptoms.[37] The significance of these symptoms must not be underestimated in the patients who experience them.

CHAPTER 21

Neurological Disorders

Margaret A. Schwartz

Key Points

- All patients are at risk of developing neurologic complications of their diseases.
- Many neurologic diseases are incurable and will result in a high symptom burden.
- Palliative care nurses must be alert to these possibilities and knowledgeable about management.

Introduction

The palliative care nurse is likely to encounter a patient with advanced neurological disorder or with a medical condition with neurological complications. It behooves the palliative care nurse to prepare for the variety of symptoms and diagnoses that he or she will clinically encounter. This chapter aims to lead the palliative care nurse to the appropriate, evidence-based interventions for the patient with neurological disturbances. We will address broad symptom categories as well as common neurological diseases with heavy symptom burden deserving of special attention.

Abnormal Movements

The human body is capable of a broad variety of involuntary and abnormal movements—shivering, tremor, seizures, fasciculations, myoclonus, and chorea to name a few. See Table 21.1 for definitions of the abnormal movements most frequently encountered. Although it is beyond the scope of this chapter to delve into all of the possibilities, we will review those most relevant to the practice of the palliative care nurse.

Seizures

> "I woke up to Frank saying 'ah, ah, ah' in his sleep. Then his breathing changed and his arms went up to his chest. After a minute or two he started shaking all over. I called 911. By the time they got here it was all over. He was confused for an hour in the ER."
>
> —A wife describing her husband's first seizure

Seizures are defined as electrical discharges of the cerebral cortex with resulting changes in the functions of the central nervous system (CNS). For an aberrant electrical phenomenon to propagate and result in a seizure, three physiologic conditions must exist: neurons capable of undergoing excitation, capacity for spread of the electrical phenomenon to surrounding neurons, and diminished ability of gamma-aminobutyric acid (GABA)-nergic neurons to suppress excitatory events. Any condition that disturbs the normal environment of the CNS can result in a seizure. Thus, any given patient has the capacity to experience a seizure. There are a number of conditions that increase the risk of an epileptic event. Most common are acute metabolic derangements, medications and substances, space-occupying lesions of the brain, ischemic events, and infection (see Tables 21.2 and 21.3). It is important to note that a single seizure does not constitute epilepsy.

Witnessing a seizure can be a traumatic event for caregivers and providers. Additionally, the emotional burden for patients with seizures is great. The impact of seizures on health is enormous—an estimated 50 million people worldwide have epilepsy. The incidence of a single unprovoked seizure event is estimated to be between 23 and 61 per 100,000 person-years.[1] Research on patients with epilepsy and their caregivers reveals persistent societal and individual stigma associated with this disorder and the resulting seizures.[2] Patients with epilepsy are at higher risk of impaired sleep, mood disorder, pain, social withdrawal, and psychological distress.[3,4] Unchecked, seizures can result in significant morbidity—delirium, physical injury, aspiration, rhabdomyolysis and renal injury, pain, temporary paralysis, and loss of function. Among oncology patients there are a number of factors increasing the risk for seizures. Brain metastases, chemotherapy, and radiation, as well as metabolic and endocrine changes in the patient with cancer increase the risk for seizures. In patients with primary brain tumors, the burden of seizures is staggering. Estimates of the prevalence of seizures in this group vary across specific tumor histology. The financial, emotional, and social burden of seizures is also an important consideration. There are many interventions available to the palliative care nurse to reduce the impact of seizures.

The palliative care nurse begins with a careful history and physical exam. Any new physical findings may suggest an underlying physiologic change that has lowered the seizure threshold. Recent medication changes require careful review as these changes are frequently implicated in new-onset seizures. In patients with primary brain tumors or intracranial metastatic disease, seizures are generally a result of edema and blood–brain barrier disturbance, mass effect, and cortical involvement. Additionally, the patient entering inpatient or hospice care with a history of substance abuse is at elevated risk for seizures if the patient is newly abstinent from alcohol, benzodiazepines, opioids, or illicit substances. If no source is immediately identified, radiographic or metabolic evaluation may be indicated if it is within the goals of care.

Family and patient teaching are important to dispel fear and to maximize patient comfort. Education goals focus on safety during seizures, postictal care, medications, eliminating the cause of the

Table 21.1 Commonly encountered neurologic definitions

Agraphia	Inability to write. Of note, agraphia rarely occurs in isolation.
Akathisia	A sensation of restlessness, often accompanied by a compulsion to move the effected limbs. Most commonly found in patients with Parkinson's disease, dementia, and those receiving neuroleptics.
Alexia	Inability to read.
Aphasia	Impaired verbal or written communication because of an acquired insult to the brain. Expressive aphasia is an impairment in the ability to generate spoken language (also known as anterior/nonfluent/Broca's/motor aphasia). Receptive aphasia is difficulty or inability to understand spoken word (also known as posterior/fluent/Wernicke's/sensory aphasia). Global aphasia is the inability to utilize language. Patients with global aphasia can neither read nor write.
Asterixis	Also known as "flapping tremor," asterixis is commonly encountered in patients with metabolic and toxic encephalopathy (most notably in ammonia-retention). It is characterized by irregular lapses of a sustained posture, often followed by an overcorrection. It is also observed in neck and arms of the drowsy person.
Ataxia	Lack of coordination of voluntary movements.
Athetosis	Involuntary and abnormal slow, complex writhing movements. Most commonly involves fingers, hands, toes, and feet. Encountered in various forms with encephalitis, hepatic encephalopathy, Parkinson's disease, Huntington's disease, and cerebral palsy.
Chorea	Arrhythmic movements characterized by a writhing, rapid, and jerky quality. The movements are purposeless and involuntary. Often accompanied by a general state of hypotonia—the limbs hang slack. The major distinguishing feature of Huntington's disease.
Clonus	Rhythmic contraction and relaxation of antagonistic muscle groups.
Corticospinal tracts	The neurons connecting the cortex of the brain (gray matter) with the lower motor neurons in the ventral horn of the spinal cord.
Dysarthria	Impaired speech output due to oral, lingual, or pharyngeal motor impairment.
Dyskinesia	A wide-encompassing term meaning abnormal movement. Movements can be intermittent or persistent. In tardive dyskinesia, the movements are slow, rhythmic, and automatic.
Dysmetria	Ataxia with overshoot or undershoot of movement, dysmetria results from difficulty processing or perceiving the position of the body in relation to its surroundings.
Dysphagia	Impaired ability to swallow in a coordinated and timely fashion.
Dystonia	A unilateral movement defined by involuntary muscle contraction of both the agonist and antagonist muscles. The result is the limb held in a twisted, distorted posture. Can affect a limb, the head and neck, the face, or the spinal muscles.
Fasciculation	A small, localized pattern of muscle contraction and relaxation, often observable through the skin. Commonly noted in the eyelid of healthy individuals, it can also be seen in ALS, progressive spinal muscle atrophy, or in states causing nerve fiber irritability (dehydration, muscular exhaustion, and metabolic imbalance).
Lower motor neuron	The neurons that connect the upper motor neurons to the muscle fibers. Lower motor neurons originate in the ventral horn of the spinal cord or in the brainstem motor nerve nuclei and terminate on the neuromuscular plate of effector muscles.
Myoclonus	Rapid and irregular shocklike contractions of a group of muscles. The most commonly experienced myoclonic events are hiccups and "sleep starts." Palliative care nurses are likely to encounter opioid-induced myoclonus.
Myokymia	The irregular firing of several motor units, seen as a rippling of the skin.
Nystagmus	Involuntary jerking movement of the eyes in either a lateral or vertical direction.
Opsoclonus	Involuntary and irregular multidirectional movement of the eyes.
Seizures	Aberrant electrical activity of a part or the entire cortex of the brain, resulting in altered neurological functions.
Tardive dyskinesia	A specific dyskinesia characterized by repetitive and stereotyped movements often of the face, mouth, and tongue. It is most commonly an effect of antipsychotic medications.
Tremor	Rhythmic contraction of a muscle or group of muscles in opposing directions.
Upper motor neuron	The motor neurons originating in the motor cortex of the brain or brainstem and carrying synapses down to the lower motor neurons. Upper motor neurons do not directly contact the target muscle.

seizure when feasible, and determining when to contact the provider. Safety during a seizure focuses on minimizing injury—falls and physical trauma during clonic movements as well as minimizing the length of the seizure if possible. Padding the patient's surroundings (bed rails) is traditionally done in patients with refractory seizures. Although a prudent intervention, no data exist to support this long-standing nursing intervention. See Box 21.1 for seizure first-aid and safety suggestions. Placing objects in the mouth and restraining the patient are absolutely contraindicated. Patients should not be given food or liquid until they have fully recovered consciousness. Should the patient fail to regain full consciousness between seizures or continue to seize after several minutes—a

Table 21.2 Common conditions resulting in seizures

Metabolic changes	Electrolyte imbalances Thyrotoxic storm Uremia Hypertensive encephalopathy Hypertension of pregnancy (eclampsia and preeclampsia) Fever Dehydration and overhydration Hyperventilation
Medication-related, illicit substance-related	Missed doses/withdrawal New medications Metabolite accumulation
Intracranial tumors	Metastatic tumors Primary central nervous system tumors
Ischemia	Stroke Diffuse cerebral hypoxia
Infections	Encephalitis Meningitis Intracranial abscess Parasitic lesions
Paraneoplastic syndromes	NMDA-receptor encephalitis
Trauma-related	Subdural hematoma Subarachnoid hemorrhage Intraventricular hemorrhage Trauma-induced gliosis Post-traumatic epilepsy
Vascular lesions	Atriovenous malformation Intracranial aneurysm Subdural hemorrhage or fluid collection Epidural hemorrhage Subarachnoid hemorrhage
Idiopathic or congenital disorders	Birth injury Congenital malformation Enzyme deficiencies Lysosomal storage disorders Channelopathies

condition known as *status epilepticus*—urgent action is required. Status epilepticus is treated as a serious and life-threatening situation requiring immediate administration of medication to break the seizures. If the seizure occurs in the home, emergency medical services may be appropriate if consistent with the goals of care. Of note, there remain several states in the United States that require providers to report seizure events to the Department of Motor Vehicles. Certainly, patients with seizures should abstain from driving until cleared by a neurologist.

Of utmost importance for patient comfort and safety is to stop the seizure as it happens. Seizure-ablative medications may be limited by the specific patient situation. The patient receiving hospice at home will likely be best served by administration of rapid-acting benzodiazepines. Orally administered concentrated lorazepam drops are readily available from the hospice pharmacy. Other choices include rectal diazepam gel, nasal lorazepam gel, or clonazepam wafers applied to the buccal surface. In the patient with intravenous access, slow intravenous push administration is generally the preferred choice. The patient with significant risk of seizures, a history of status epilepticus, or currently on antiepileptic seizure medications is well-served by an at-home seizure management plan. Particularly for patients with complex seizure management, a seizure management plan is developed in concert with the neurologist. This intervention offers the patient, family, and caregivers peace of mind and a sense of agency in the face of a potentially terrifying event. The National Health System in the United Kingdom is trialing a protocol to provide patient, family, and caregiver training for seizures in an effort to improve home management and family/caregiver confidence in managing seizure and to reduce emergency room visits and medical costs.[5]

Several issues require specific attention in the palliative care setting. In a patient with a reversible condition, antiepileptic drugs (AEDs) may not be required. Patients with epilepsy or significant risk for ongoing seizures will require careful consideration for AED choice. If the patient with metastatic or primary brain tumors has never experienced a seizure, the current recommendation is not to prophylactically administer anticonvulsants.[6] For a brief overview of factors to be considered when introducing AEDs, see Box 21.2. Notably, several choices have arisen in recent years for the patient with medically refractory seizures. A restrictive diet inducing a ketogenic state has been studied for decades for medically refractory childhood epilepsy with some success.[7–9] Surgical options include resection of the seizure focus or lesion as well as vagal nerve stimulator placement.[10–13] Careful consideration must be given to the life expectancy and appropriateness of the patient for such procedures and interventions.

Seizures at the end of life are a concern for all terminally ill patients. When patients have lost the ability to swallow, seizure management of multi-drug AED regimens may require careful tailoring to the situation. Several interventions have been tried and small case series have been published. However, there is no universally accepted management protocol, and the hospice team may need to be creative. Subcutaneous levetiracetam administration in end-of-life (EOL) care has been reported in a United Kingdom trial.[14,15] However, randomized controlled trials do not yet support the integration of this route into standard of care.

Myoclonus

Case Study: A Pediatric Patient with Opsoclonus-Myoclonus Syndrome

Franklin was just a few years old when his mother noticed his balance was off. Then she noticed his "fits"—he was unable to walk, his trunk and limbs would jerk randomly, and his eyes seemed to dance around. Ultimately, Franklin was found to have opsoclonus-myoclonus syndrome from an autoimmune response to a neuroblastoma tumor in his abdomen. With treatment, the fits stopped.

Myoclonus is a series of brief muscular contractions. The contractions are irregular in both the amplitude of contraction and rhythm, and it denotes a disturbance of the CNS. There are a wide variety of myoclonic syndromes. In the palliative care setting, the nurse is

Table 21.3 Seizure definitions

Simple focal (partial) seizure	The uncontrolled electrical activity in a simple partial seizure is limited to a small area of the cortex. The resulting seizure is not accompanied by loss of consciousness. Symptoms include shaking of a single area of the body. Less commonly, simple partial seizures can result in abnormal sensations of the affected limb or in abnormal sensations such as auditory, visual, or gustatory changes. Rarely, simple partial seizures can result in behavior and emotional changes.
Complex focal (partial) seizure	Affecting a larger area of the brain, complex partial seizures result in impairments in the ability of the person to interact with his surroundings. Often starting with a blank look or staring spell and progressing to stereotyped, repetitive movements. Also termed "psychomotor seizures."
Generalized seizure	The most common and obvious of the seizures. Generalized seizures involve the entire cortex of the brain. The typical generalized seizure begins with limb stiffening (tonic posturing) and a period of apnea or hypoventilation. This gives way to clonic movements (jerking of the limbs and/or head as muscles contract and relax together). During the clonic phase, breathing returns although it is often irregular.
Absence seizure	A generalized seizure in which the patient abruptly ceases activity and stares blankly. The patient is unable to interact with his environment during the seizure. As soon as the seizure is finished, the patient returns to the activity preceding the ictal event.
Atonic seizure	Atonic (drop-attack/astatic/akinetic) are generalized seizures resulting in an abrupt loss of postural tone. Loss of tone can vary from head drooping to full collapse.
Aura	In epilepsy, an aura is the initial phase of a focal seizure. It is generally experienced as a motor, sensory, autonomic, or psychic event. For some patients, the aura alone constitutes the seizure.
Epilepsy	A syndrome of repeated seizures.
Febrile seizure	A seizure occurring in infants and children (ages 6 months to 5 years) in the setting of a temperature usually above 38°C. Febrile seizures are usually a single generalized motor seizure as the patient's temperature peaks. Be certain to distinguish between febrile seizures and complicated febrile seizures, the latter occurring repeatedly during a febrile illness.
Ictal	Latin for "stroke," ictal has come to mean the height of a seizure or migraine.
Psychogenic nonepileptic seizures	Also called "pseudoseizures," these are events characterized by changes in neurological function in the absence of electroencephalographic changes indicating abnormal electrical activity of the cortex.
Status epilepticus	A cluster of seizures without return to full neurological baseline between events or a single, ongoing seizure lasting more than a few minutes. Considered a medical emergency, status epilepticus carries an elevated risk of brain damage, hypoxia, and death.

Box 21.1 Seizure Safety

Seizure First Aid

Prevent injury by moving furniture or hard objects out of the way

Refrain from putting anything in the mouth of the patient

Place a pillow or soft item under the patient's head

Loosen tight clothing around the neck

After-Seizure Care

Avoid situations dangerous to the epileptic (open flame, unaccompanied boating/swimming/tub-bathing)

Avoid seizure triggers (sleep deprivation, blood sugar lows, alcohol consumption, and excess caffeine intake)

most likely to encounter diffuse myoclonus rather than myoclonus simplex or segmental myoclonus. See Table 21.4 for other causes of myoclonus. Diffuse myoclonus is characterized by random jerks, widespread throughout the body. It can be either a passing or persistent phenomenon. Myoclonus has gained increasing awareness in the palliative care setting as it can lead to increased pain, fatigue, and other distressing symptoms. Intervention begins with recognizing the causative factors. The palliative care nurse is most likely to encounter diffuse myoclonus from acquired neurologic disease or metabolite accumulation. Several other causes of myoclonus are known: epileptic, hereditary (sometimes called essential or familial), immune, and toxic disorders. Myoclonus also occurs in some forms of degenerative neurological disorders.

The palliative care nurse begins with careful examination and review of medications. An interview of the patient and family may elicit a recent change. Renal impairment is associated with opioid-induced myoclonus (OIM). The patient or family will describe nonrhythmic jerking movements. Stimulation of the patient or tapping on the muscles may bring on or worsen myoclonus. Hyperalgesia and hallucinations in the setting of myoclonus raise the suspicion of OIM and should trigger an evaluation of pain medications. In the patient with opsoclonus-myoclonus syndrome, the myoclonus is typically diffuse or focal with titubation (rhythmic tremor of the head or trunk). Ataxia and other cerebellar symptoms may also be apparent. The diagnosis of opsoclonus-myoclonus is based on clinical, serological, and radiographic testing. In the palliative care setting, the goals of care are always considered when deciding whether to conduct this testing.

Elimination of the causative factor, if possible, is most likely to induce remission of the myoclonus. In the patient on opioid medications, opioid rotation is indicated. The precise mechanisms behind OIM are unknown. The leading theorized mechanism points to accumulation of neuroexcitatory metabolites, particularly hydromorphone-3-glucuronide and morphine-3-glucuronide in the setting of impaired kidney function.[16] Although higher doses of opioids are more commonly implicated in OIM, it can occur in patients with relatively low doses and preserved renal function. Opioids implicated in OIM in the literature include morphine, hydromorphone, fentanyl, methadone, and meperidine. If OIM is

Box 21.2 Special Considerations when Introducing an Antiepileptic Drug (AED)

Drug interactions are common with AEDs, especially older generation medications that induce the cytochrome P450 hepatic enzymes

Many AEDs can alter mood and are used as psychotropic medications

Carefully review comorbidities; for example, phenytoin can cause osteoporosis, topiramate can induce weight loss

In the patient with limited life-expectancy, impaired level of consciousness or diminished ability to swallow make most oral AEDs poor choices—consider scheduled benzodiazepines

Most AEDs do not require drug level monitoring

Dexamethasone is neither an antiepileptic medication nor a seizure-ablating drug

Phenytoin increases metabolism of corticosteroids, and corticosteroids can alter the metabolism of phenytoin—consider a different AED

Consultation with a neurologist may be warranted

Table 21.4 Etiologies of myoclonus

Drug-related	Opioid-induced myoclonus (OIM) Lithium toxicity Haloperidol Phenothiazines Cyclosporine Beta-lactam antibiotics Antidepressants
Metabolic disorders	Hepatic encephalopathy Nicotinic acid deficiency Uremia Storage diseases
Inflammatory disorders	Thyroiditis
Infectious diseases	Whipple disease of the central nervous system Tetanus Herpes zoster myelitis
Central nervous system disorders	Hypoxic brain injury Multiple sclerosis Paraneoplastic syndromes AIDS dementia complex Viral encephalitis Advanced dementias Cerebellar degenerative conditions Basal ganglia degenerative conditions Creutzfeldt-Jakob disease Parkinson's disease Subacute sclerosis panencephalitis Myoclonic epilepsy syndromes

suspected, opioid rotation, addition of a benzodiazepine such as clonazepam or midazolam, and a trial of adjuvant medications are indicated.[17]

Treatment of non-OIM myoclonus includes eliminating causative conditions. Few medications have been found to ease myoclonus. Anticonvulsants can be helpful in chronic myoclonus, although typically multidrug therapy is needed. Clonazepam is the most frequently used and most effective agent. Other drugs have been tried, including valproic acid, levetiracetam, zonisamide, acetazolamide, and sodium oxybate, although strong data for each of these medications are lacking.[18] Several non-AEDs have been tried for myoclonus, including baclofen and dantrolene, also with varying success.

Nursing-specific care for myoclonus is multifaceted. Safety takes priority. Padded side rails and helmets may be necessary. For patients with severe myoclonus, ambulation may not be possible. Physical or occupational therapy assessment will determine whether durable medical equipment, assistive devices, or a gait belt are needed. Offer strategies for safe patient transfers to families and caregivers. As with all palliative care measures, assessment for pain is necessary. During opioid rotation, the risk for discomfort is high because of variability in cross-tolerance. Myoclonus is fatiguing. Teaching patients and family members energy conservation is important. Myoclonus increases caloric expenditure, and, in the medically frail patient, nutritional supplementation or counseling may prevent weight loss. Provide a low level of stimulation (low light, minimizing noise).

Spasticity

Case Study: A Patient with Spasticity

Keira was in a car accident as a young woman. She suffered head trauma with a hemorrhage in the deep white matter of the right hemisphere of her brain. Keira was unable to move the left side of her body. With therapy, she regained some movement on the left but was left with increased muscle tone and spasms. Her physiatrist assesses her yearly—the spasms and hypertonicity make fine motor tasks more difficult but allow her to walk without any assistive devices.

Spasticity is increased muscle tone to the extreme. It results from denervation of muscles or from demyelination of neurons in the CNS—typically because of a lesion of the upper motor neuron (UMN). Spasticity occurs in many neurologic conditions. It is commonly encountered with spinal cord injury, multiple sclerosis (MS), cerebral palsy, stroke, brain or head trauma, amyotrophic lateral sclerosis (ALS), hereditary spastic paraplegias, and metabolic diseases.

The most sensitive indicator of an UMN lesion is a positive Babinski sign. It is elicited by firmly stroking the lateral plantar surface of the foot. A positive Babinski sign is extension of the large toe accompanied by fanning and extension of the other toes during and immediately after the stimulus. The Babinski sign mimics the physiologic reflex observed in infancy. Spasticity shows a predilection for antigravity muscles: brachialis, brachioradialis, biceps, pectoralis, anterior deltoid, and the flexor carpi muscles of the arms as well as the hip flexors, gastrocnemius, hamstrings, and popliteus muscles of the legs. Other physical exam signs include hyperreflexia of the deep tendon reflexes, clonus, muscle spasms, and scissoring of extremities. Spasticity can occur in any muscle or muscle group. One notable example is the spasticity and dystonia of cranial nerves in bulbar or pseudobulbar palsy.

Spasticity can be uncomfortable and painful. It can also severely limit functional abilities and thus requires considered treatment. The palliative care nurse will consider whether the condition is established spasticity with worsening, as with our case study. In this situation, the nurse will seek secondary causes—infection, constipation, pain, or autonomic dysreflexia. If the spasticity is new, further investigation is required. In a patient with MS, the primary concern is for disease progression. It is imperative to balance spasticity with the functional abilities of the patient. For example, the patient with spastic cerebral palsy must preserve some muscle tone in order to ambulate.

Many treatments are available for spasticity. Research into the neurochemical changes of spasticity has demonstrated that glutamic acid is the primary neurotransmitter of the corticospinal tracts. Baclofen, a GABA derivative, is the mainstay treatment. Other commonly used oral antispasmodics include dantrolene, diazepam, and tizanidine for the desired effect of diminished force of contraction. Spasticity is one of the few generally agreed on medical uses for marijuana.[19–21] See Table 21.5 for a summary of oral antispasmodic medications. Phenol and botulinum toxin are injected for patients with persistent spasticity and torticollis. Surgical interventions are also available for the patient with medically intractable spasticity. Intrathecal administration of baclofen has become a mainstay of treatment for patients with persistent spasticity with significant side effects from oral baclofen.[22] These

Table 21.5 Medications used to treat spasticity

Drug name	Mechanism of action	Most common use	Common side effects
Baclofen	Inhibition of synaptic reflexes at the spinal cord level	Spasticity Hiccups	Central nervous system (CNS) depression, weakness, hypotension, gastrointestinal (GI) disturbance, polyuria
Carisoprodol	Unknown	Spasticity Muscle pain due to injury Adjunctive to opioids—use carefully in combination with any CNS depressant, especially synthetic opioids	CNS depression, idiosyncratic reactions of weakness and euphoria, seizures
Chlorzoxazone	Reduces polysynaptic reflexes	Muscle spasm and pain	Withdrawal if abruptly discontinued, CNS depression, paradoxical stimulation, GI disturbance, rash, hepatotoxicity, hypersensitivity reaction
Cyclobenzaprine	Unknown	Spasticity	CNS depression, dry mouth, dizziness, agitation
Dantrolene	Local action on the excitation-contraction units of the muscle	Spasticity Malignant hyperthermia Serotonin syndrome "Ecstasy" intoxication	CNS depression, hallucinations, hepatotoxic effects, GI disturbance
Diazepam	Reduced neuronal excitability via enhanced GABA-ergic inhibition	Agitation Alcohol detoxification Anticonvulsant Anxiolysis Spasticity Sedation	CNS depression Anterograde amnesia Psychiatric disturbance Seizures if acutely withdrawn Abuse
Gabapentin	Reduced neuronal excitability via enhanced GABA-ergic inhibition	Anticonvulsant Neuropathic pain Spasticity	CNS depression, dizziness, weight gain, fatigue, peripheral edema, risk of suicidality
Orphenadrine	Anticholinergic	Low back pain, sciatica Adjuvant treatment of neuropathic pain and spasticity	CNS depression, dry mouth, dizziness, restlessness, insomnia, constipation, urine retention, orthostasis, euphoria
Metaxalone	Unknown	Muscle pain due to spasticity	CNS depression, rash, GI disturbance, leukopenia, hemolytic anemia, hepatotoxicity
Methocarbamol	Unknown	Spasticity Tetanus	CNS depression, seizures, bradycardia, syncope, hypotension, rash, GI disturbance, leukopenia, vision changes, hypersensitivity reactions
Tizanidine	Reduced neuronal excitability via alpha-2 adrenergic agonist	Spasticity Chronic headache Migraine	CNS depression, hepatotoxicity, sweating, GI disturbance, dry mouth, constipation, urine retention

interventions must be carefully weighed, particularly for the palliative care patient who may have limited life expectancy.

Nursing care for spasticity focuses on comfort and maximizing function. Physical and occupational therapy consultation are invaluable for prescribed stretching regimens and to determine appropriate durable medical equipment. Patient and family education are important to set realistic goals. Education also focuses on factors that worsen spasticity, prevention of pressure ulcers and contractures, fatigue, and psychosocial concerns. Early education is crucial to prevent complications. Appropriate medication use and indications for their use are also taught. Repositioning, application of heat, and strategies to improve functional abilities are helpful.

Headaches

Case Study: A Patient with Migraine

Juana was 14 when she had her first migraine. Her migraine frequency gradually increased during her teen years. As a young woman, she missed 2–3 days of work per month as a result of her pain. After losing her job as a result, Juana went to see a neurologist. She had gained 80 pounds from a combination of inactivity and medication effects. With adjustments in her sleep, exercise routine, and medications Juana was able to return to full-time work.

Headaches are a common ailment—an estimated 78% of Americans will experience a tension-type headache in their lifetime and 16% will suffer a migraine.[23] Quality-of-life studies demonstrated that the impact of migraines on an individual is striking—in one study, 59% of migraine sufferers reported missing a family or social activity as a result of a migrainous event.[24]

A wide variety of conditions can trigger headaches and migraines. Common conditions encountered in the palliative setting include intracranial tumors, vascular disorders, infection, and head trauma. A selection of etiologies is found in Table 21.6. Of certain importance to the palliative care nurse is the medication overuse headache (MOH, also known as rebound headache), in which attempt at withdrawal from certain substances leads to onset of headache. The typical scenario encountered in MOH is a patient using acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or combination migraine preparation. Other identified substances include caffeine, triptans, antidepressants, cocaine, estrogen, marijuana, and opioids.[25] The headache typically resolves in the absence of the offending substance after a period of days to weeks. In some cases, gradual reduction of dose may be a safer option, particularly if the substance has the potential for an acute withdrawal syndrome, as with opioids.

Migraines are not managed by pharmaceuticals alone. Lifestyle changes can change the frequency and intensity of migraine headaches. Nurses play a key role in patient education with many chronic and disabling conditions. Palliative care nurses are ideally situated to provide interventions aimed at improving patient self-management. Reducing or eliminating caffeine and tobacco use, adequate nutrition and hydration, weight reduction and exercise, appropriate sleep hygiene, and stress management are important. Education also focuses on appropriate medication use and avoidance of medication overuse.[26–28] A program in the United Kingdom documented the impact of a nurse-led intervention program focusing on these topics. At the completion of the study period, patients reported feelings of self-efficacy at headache management.[29]

Table 21.6 Causes of head pain

Headache syndromes	Cluster headache Tension-type headache Withdrawal/medication overuse headache
Migraine syndromes	Migraine with or without aura
Cranial and intracranial lesions	Metastatic brain tumors Primary brain tumors Skull base tumors Leptomeningeal metastases
General medical diseases and conditions	Fasting state/hunger Eyestrain Stress Muscle strain/tension, prolonged sitting, poor posture Sleep deprivation Stroke Vascular disorders Multiple sclerosis Increased intracranial pressure Sinus infection Temporal arteritis Varied infections, both systemic and CNS
Head trauma	
Atypical pain syndromes	Trigeminal neuralgia Postherpetic neuralgia

As with all neurologic changes in the palliative setting, the nurse begins with an assessment. The pain and its accompanying characteristics (intensity, location, quality, exacerbating/alleviating factors, response to previous therapies, related symptoms) can guide care. The typical tension-type headache is bilateral and characterized by a sensation of constant pressure. Episodic-type headache is thought to transform into tension-type headache with constant pericranial muscle tension. The pain can range from mild to moderate and, in extreme cases, can be severe. Conversely, migrainous events are commonly unilateral. The pain can be pulsatile in nature and is often associated with phonophobia, photophobia, and nausea/vomiting. Sleep alleviates the migraine and physical activity aggravates it. A significant number of migraineurs will experience an aura of transient sensory (usually visual), language, or motor disturbance. Focal deficits indicate either a complex migraine or, more seriously, a new intracranial lesion. The "thunderclap" headache of subarachnoid hemorrhage is a sudden-onset and very severe headache often accompanied by profuse vomiting and mental status changes. A headache accompanied by nuchal rigidity, vomiting, and photophobia suggests irritation of the meninges and warrants emergent evaluation. The typical headache of a patient with intracranial metastasis is dull, poorly localized, and of moderate intensity. Some patients will have ipsilateral pain to the metastatic lesion. Signs of increased intracranial pressure include an increase in pain intensity when lying down, coughing, or sneezing as well as nausea, vomiting, mental status changes, and pupillary changes. In some situations of headache, radiographic evaluation will be appropriate. Cerebrospinal fluid sampling via lumbar puncture may also be warranted.

Physical assessment includes palpation over the area of pain. Careful neurological examination may elicit deficits—skull base metastases will commonly compress an isolated cranial nerve. Leptomeningeal metastases will commonly result in multiple cranial or spinal neuropathies as well as headache.

Treatment is dictated by the classification of headache or migraine as well as by the etiology. The patient with an isolated skull base metastasis may find symptom stabilization and pain relief with palliative radiation or chemotherapy. Dexamethasone is commonly used in the palliative care setting because of its oral and parenteral formulations, lower mineralocorticoid effects, and ease of dosing.

Nursing interventions also include patient and family education. It is distressing to care for a loved one with severe, persistent headaches. Caregivers may express feelings of impotence to change the symptoms as well as loss and sadness in the setting of progressive neurologic deficits. Patients and family members benefit from education regarding pain management measures and medications. In the event of neurologic deficits, education about safety measures is important. Other nonpharmacologic interventions can be useful—ice and heat, reduced light/sound exposure, meditation and distraction, physical activity or rest, and positioning. Commonly, head-of-bed elevation is useful in the setting of increased intracranial pressure.

Impaired Communication

Case Study: A Patient with Speech Arrest Seizure

PJ was at his father's house when he had his first speech arrest seizure. He was found to have a brain tumor. Treatment stabilized the tumor, but PJ's speech was never the same—it was halting and difficult to understand. PJ's speech therapist made him a book for the bad days—he could flip through the laminated pages and find the picture for what he needed to communicate.

Communication is arguably at the heart of the human existence. Impaired communication is distressing to both the patient and his or her caregivers. Impairments in communication from neurological disorders can take the form of aphasia, mutism, deafness, agraphia, alexia, or dysarthria. Additionally, several conditions can impede the patient's ability to express wishes—the ventilator-dependent patient is one such example. The patient with a massive brainstem injury from a basilar artery occlusion is "locked-in" and has retained cognitive abilities but lost all control of his body save for voluntary eye movement.

Any number of disorders can result in impaired communication. Aphasia is caused by any disease disturbing the cortex of the brain responsible for language production or reception. Traditional neurologic teaching identifies the key cortical areas as Broca's area, Wernicke's area, and the supplemental motor area. Functional hemisphere dominance determines the localization of language in the right or left cerebral hemisphere. For most people, language production and comprehension occur in the left hemisphere.

Nursing care for the patient with disorders of speech or language focuses on strategizing alternative means of communication and maximizing functional ability for speech. As the case study illustrates, impaired communication is highly distressing and frustrating for patients and caregivers alike. If the patient is capable of cognition, the nurse identifies alternative communication strategies regardless of the patient's prognosis and the setting of care. Intensive care nurses and home hospice nurses alike can use communication boards, yes/no questions, and written instructions. Several key points are important for the patient with aphasia (Box 21.3).

Box 21.3 Key Points for Optimizing Communication

- Provide the optimal setting for communication: Ensure the patient has glasses on and hearing aids in if appropriate, adequate lighting.
- Avoid correcting grammatical mistakes or speaking for the patient.
- Do not raise the volume of your voice unless the patient is hearing impaired.
- Use facial expression to emphasize spoken communication.
- Face the patient directly while communicating.
- If the patient has other neurologic impairment such as a visual field cut, compensate by standing on the patient's best side.
- Simplify the message.
- Allow adequate time for cognitive processing and response.

Speech-language pathology consultation can be immensely helpful to clarify the specific communication deficiencies. Speech pathologists are a wonderful resource to the palliative care nurse for strategizing alternative communication methods. One particularly fascinating communication strategy for the patient with expressive aphasia is to use song rather than spoken word to communicate. Patients with nonfluent aphasia may be able to put words to a familiar melody in order to communicate. A technique known as *melodic intonation therapy* has been developed for patient with left-hemisphere lesions to increase length of spoken phrases. Music therapy has a potential role as well for the patient with communication difficulty.

Neurologic Diseases

A number of neurologic diseases result in devastating symptom clusters and require increasingly complex nursing care. Many of these diseases are progressive neurologic degenerative disorders such as ALS, MS, and Parkinson's disease (PD). This section will address the palliative care needs of these patients.

Amyotrophic Lateral Sclerosis

ALS, also known as Lou Gehrig's disease, is a devastating progressive neurologic condition characterized by progressive muscle wasting from denervation (amyotrophy) with hyperreflexia. ALS is the most common of all motor neuron diseases. It results from the destruction of both upper and lower motor neurons. There are both familial and sporadic cases of ALS, with familial cases accounting for approximately 10–20% of total cases.[30] The mechanism of neuron destruction is a defect in the degradation of misfolded proteins. The resulting accumulation and clumping of nonfunctional proteins results in neuronal death. The end result of the disease process is paralysis and respiratory failure.

Case Study: A Patient with Amyotrophic Lateral Sclerosis

Fred enlisted in the Marines as a young man. During training exercises he noticed his feet would cramp up. Within a few weeks, he noticed that he couldn't grip his flip-flop shoes in the shower and would walk out of the shoes without meaning to. The physician on base sent Fred for a magnetic resonance imaging (MRI) study of his back, but the scan was normal. An electromyogram revealed a pattern of fibrillations and positive waves—Fred had ALS at the age of 19. "I joined the military—I'm not afraid of dying. I'm afraid of being disabled and not having control of my body."

Fred's story highlights the fears and psychological distress that underlies a diagnosis with a progressive and devastating neurologic disorder. Table 21.7 highlights the typical symptom clusters of ALS.

The treatment team is prepared to address a number of symptoms as well as the emotional impact of the disease. Goals-of-care discussions are important early in the disease trajectory. Median life expectancy is less than 5 years, although life expectancy is considerably shorter if the patient declines medically administered nutritional or respiratory support. Riluzole is the only therapy demonstrated to extend survival and time to tracheostomy.[31] Gastrointestinal distress and liver enzyme elevation can occur with riluzole treatment. Nursing interventions for the patient with ALS focus on the impact on quality of life (QOL), symptom palliation, and functional ability as well as EOL planning and support. Family and caregiver support is key as data strongly suggest a heavy caregiver burden with this disease.

The ALS patient requires an extensive team. Neurologists, pulmonologists, speech pathologists, physical and occupational therapists, nurses (see Table 21.8), and social workers will all play a role. Functional assessment and physical/occupational therapy needs are immediate; patients may require assistive devices at diagnosis. Therapy services have been shown to maintain endurance and strength, promote functional independence, and limit complications and pain.[32–34] Formal speech-language pathology and nutrition assessment is needed for swallowing evaluation and feeding strategies. The patient with ALS is at high risk for malnutrition from dysphagia,[35] depression, cognitive impairment, difficulty with self-feeding and meal preparation, hypermetabolism, anxiety, respiratory insufficiency, and fatigue with meals—some of these problems can be managed with speech pathology and dietary intervention. Early intervention to maximize nutrition and feeding is shown to extend survival and improve QOL.

Augmentative communication strategies will become key as paralysis progresses. Both low-tech strategies such as alphabet boards and high-tech solutions like speech-generating devices can be helpful. Sialorrhea is a common and uncomfortable symptom of ALS. Unilateral radiotherapy to the salivary or parotid gland and botulinum toxin injection are effective interventions.

Table 21.7 Symptoms common to the patient with amyotrophic lateral sclerosis

Bulbar-onset	Limb-onset
Dysphagia	Muscle weakness
Dysarthria	Hyperreflexia
Sialorrhea	Fasciculations

The terminal phase of ALS is characterized by significant challenges, and symptoms are best managed by a hospice team.[36–38] The dying phase of ALS is often marked by pain, psychological distress, episodes of choking and loss of respiratory capacity, diminishing communicative ability, and increasing physical dependency. Sadly, symptoms from disease progression are commonly inadequately controlled. A remarkable responsibility thus falls to the family and caregivers. Should the patient opt for long-term ventilatory support (LTVS) or noninvasive ventilation (NIV), the family and caregivers will require considerable teaching—from managing the tracheostomy wound to airway suctioning and maintaining equipment. Aggressive symptom control is clearly indicated. Palliative sedation may be useful in select patients with ALS choosing to avoid or discontinue invasive ventilation.[39,40] Palliative sedation and physician-assisted suicide remain a topic of exploration and debate.[41]

The wish to hasten death is expressed not uncommonly in patients with terminal illness. The palliative care nurse must be prepared for assessment, intervention, and thoughtful discussion of these issues. Suicidality and depression are associated with poorer QOL in patients with ALS.[42,43] Depression and hopelessness require urgent attention. Pseudobulbar affect (PBA, also been called emotional incontinence) is common in patients with ALS. It is characterized by uncontrolled expression of emotion that does not correlate to the underlying mood. Frequently, the emotion expressed is inappropriate to the situation. Importantly, PBA is not isolated to ALS. It has been described in other neurologic disorders—MS, traumatic brain injury, Alzheimer's disease, and PD. Coadministration of dextromethorphan 20 mg with quinidine 10 mg (the latter to slow the metabolism of the first) has been found effective at treating PBA. A combination pill was approved by the US Food and Drug Administration (FDA) in 2010 under the trade name Nuedexta.

Parkinson's Disease

Case Study: A Patient with Parkinson's Disease

Angie's mother and grandmother died of Parkinson's disease. Angie knew she had a risk of developing it, and, when she was 52, she saw a neurologist for hand tremors. Within a few months, she had lost 10 pounds from the constant muscle tremors. By 57, Angie walked slowly with a stooped posture. She fell on her way to the bus stop and fractured her hip. While in rehab after her hip surgery, Angie's physical therapist encouraged her to take up a dance class for people with movement disorders. "That class has given me back a little piece of my life. I am more confident when I walk now. Who knew that it would take falling to make me not so afraid of falling."

Parkinson's disease is the second most common neurological degenerative disorder. Related conditions include multiple system atrophy and progressive supranuclear palsy. The defining characteristics of PD are tremor, postural instability, bradykinesia, and rigidity of the extremities or trunk. It is important to distinguish PD from *parkinsonism*. Parkinsonism is an umbrella term indicating that the patient has symptoms of PD that may not originate from loss of dopaminergic neurons in the substantia nigra.

As with ALS, care for the patient with PD requires a team of healthcare providers. The palliative care nurse will be initially focused on maximizing functional ability and diminishing falls.

Table 21.8 Nursing management of amyotrophic lateral sclerosis

Airway and secretions	Interventions
Sialorrhea	◆ Excessive saliva in the oral cavity: ◆ Anticholinergics, use with care due to risk of mucous plugging, orthostasis, confusion, sedation ◆ Glycopyrrolate, amitriptyline, atropine, benztropine mesylate, trihexyphenidyl, hyoscyamine, transdermal scopolamine[35] ◆ Radiation to salivary gland[58] ◆ Botulinum toxin to parotid gland (Scott et al.)
Mucous pooling	◆ Suction ◆ Cough-assist device ◆ Guaifenesin ◆ Beta blockers
Airway	◆ Early discussion of goals of care and patient preferences: ◆ Noninvasive ventilation (NIV) such as positive-pressure ventilation with CPAP, BiPAP ◆ Tracheostomy with or without long-term mechanical ventilation (LTMV) ◆ Oxygen support ◆ Positioning
Communication impairment	◆ Speech-language pathologist evaluation ◆ Alphabet boards, picture board, yes/no board ◆ Electronic equipment if appropriate
Pseudobulbar affect (PBA)	◆ Not a mood disorder but a separate mood disorder may underlie the PBA: ◆ SSRIs ◆ TCAs ◆ Dextromethorphan/quinidine[49]
Falls, loss of mobility	◆ Early physical and occupational therapy referral ◆ Home nursing referral ◆ Durable medical equipment ◆ Assistive devices ◆ Stretching, range of motion ◆ Positioning, exercises ◆ Anticipating toileting needs ◆ Energy-sparing strategies
Spasticity, cramps, ALS-specific pain	◆ Pain is common in ALS: ◆ Opioids ◆ Nonopioids ◆ Balancing opioids with concerns for tenuous respiratory status and patient preferences
Mood disorder, anxiety	◆ Strategies for managing requests for euthanasia/assisted suicide ◆ Increased risk for suicide, suicidal ideation ◆ Treat underlying depression, anxiety
Nutrition	◆ Changes in food and liquid consistency ◆ Smaller, more frequent meals ◆ Ensuring solid foods are soft and moist ◆ Using straws, chin-tuck maneuver if appropriate ◆ Gastrostomy tube if consistent with patient's preferences
Cognitive changes	◆ Frontotemporal dementia, although an unusual presentation, can occur in ALS patients ◆ Managing dementia behaviors
Terminal phase of ALS	◆ Early discussion with patients and caregivers about when to refer to hospice ◆ Highly aggressive symptom management ◆ Palliative sedation has been explored for patients with ALS[46]

Medication education, home safety, physical and occupational therapy, and establishing a routine of exercise and rest are important goals of nursing care. Interestingly, dance therapy and Tai-Chi have been found to improve objective measures of gait and balance for PD.[44–47] As PD and the dopaminomimetic therapies can result in a degree of autonomic instability, the nurse will evaluate for hypotensive episodes and gastrointestinal dysmotility. The speech therapist also has a role in the evaluation of the patient with PD—dysphagia, impaired communication, drooling, and aspiration are common. Fluctuating energy expenditure, medication–food interactions, impaired gastrointestinal motility, and impaired fluid balance leaves patients with PD at risk of nutritional deficiencies.[48,49] The nutritionist has a role across the disease trajectory for the patient with PD. One key point for the nurse is the potential for diminished drug absorption when PD medications are taken with protein-rich meals.

Box 21.4 Medications Commonly Used for Movement Disorders in Parkinson's Disease

Levodopa and Levodopa-Modifying Drugs

- Levodopa (l-dopa), levodopa/carbidopa (LC), and levodopa/benserazide (LB)
- Mechanism of action: Levodopa is the metabolic precursor to dopamine, carbidopa and benserazide increase the availability of levodopa in the central nervous system
- Dosing schedule: to prevent the "on/off" effects of levodopa treatment in some patients, tightly follow the prescribed schedule
- Rationale: Increases survival and quality of life
- Adverse effects: Nausea and vomiting, psychosis, compulsive behaviors
- Bioavailability of LC and LB when taken with protein-rich meals is reduced

Catechol-O-Methyl Transferase Inhibitors (COMT Inhibitors)

- Mechanism of action: Decreases metabolism of l-dopa
- Increases the half-life of l-dopa, LC, and LB, simultaneously increasing efficacy of doses
- Available as entacapone and tolcapone
- Leads to longer "on" periods and shorter "off" periods
- Notably, does not decrease the dyskinesia effects of l-dopa

Monoamine Oxidase Inhibitors

- Dopamine metabolizer
- Can reduce the needed dose of l-dopa by 30–40%

Dopamine Agonists

- Often used for initial treatment
- Lower risk of causing dyskinesia
- Available in extended-release formulations
- Shortened "off" time compared with l-dopa
- Risk of compulsive behaviors such as gambling, hypersexual behavior, and eating disorders
- Available in oral formulations, continuous subcutaneous infusion or as a continuous duodenal infusion via portable minipump
- Apomorphine injection for sudden "off" periods

The psychosocial needs of the patient with PD and the family must be addressed. The nurse assesses for depression, anxiety, and caregiver distress. Grief, feelings of loss, and uncertainty of the future are common. Financial concerns and social isolation should also be addressed. A summary of available medical treatments can be found in Box 21.4. The medication regimens for PD can be complex, and doses are terrifically time-sensitive due to the rapid onset/offset of activity of most levodopa-containing medications. For a select group of patients, surgical intervention has a role. Currently available surgical interventions include deep brain stimulator placement and ablative surgical techniques such as thalamotomy and pallidotomy.

The terminal phase of PD is typically heralded by progressive loss of mobility, worsening dysphagia, and aspiration. Parkinson's-associated dementia can occur as well. The palliative care nurse will expand the goals of nursing intervention to include continence care, preserving patient preferences, managing medication effects, and patient/family education about symptoms at the end of life (Table 21.9).

Huntington's Disease

Case Study: A Patient with Huntington's Disease

No one spoke of Theresa's grandfather. He had died after years in a state-run facility as a middle-aged man. Theresa was in journalism school when she decided to write a project on his life and death. Theresa uncovered records indicating the hospital was a psychiatric facility. She was able to interview a retired nurse who had worked there over the years when her grandfather was hospitalized. Theresa discovered the uncomfortable truth that her grandfather died of Huntington's disease (HD). In her research on HD, Theresa discovered that it is an incurable and hereditable condition. Theresa documented her reaction to this news, her subsequent interview with a geneticist, and her diagnosis months later as a carrier of the mutation.

Table 21.9 Nursing care in Parkinson's disease

Fatigue, falls, loss of independence	◆ Referral for physical, occupational therapy ◆ Dance therapy ◆ Tai-Chi to improve balance ◆ Home modifications ◆ Home nursing evaluation ◆ Durable medical equipment ◆ Evaluate for hypotensive episodes
Communication and swallowing disorders	◆ Impaired facial expression ("masked face") further impairs functioning ◆ Assess for pseudobulbar affect (PBA) if expressed mood and affect are discongruent

HD is characterized by a classical triad—dementia, choreoathetosis, and autosomal dominant inheritance. It is a devastating disease with all-encompassing effects on the patient and family. Indeed, the family is often familiar with the disease—typically a family will have affected members across several generations. HD is caused by the accumulation of the huntingtin protein and the resulting destruction of many brain structures, particularly the cerebral cortex and basal ganglia. Repetition of the trinucleic acid CAG encodes for huntingtin on the short arm of chromosome 4. The disease is diagnosed when the number of repeats exceeds 35. Patients are typically diagnosed in the third through the fifth decades of life, although juvenile-onset HD is well established. In the case of Theresa, she was found to have 52 repeats of CAG. As her case illustrates, identification of the causative gene has allowed recent generations to make informed life decisions. There is also a psychological burden of knowing that one will die of a devastating neurological disease. The ideal setting for the HD patient is in a multidisciplinary clinic that includes nurses with palliative care training. Affected patients ultimately require care with all personal needs.

Palliative care nursing for the patient with HD ideally begins with early identification. There is currently no cure for HD. There are little data to guide specific interventions but multidisciplinary palliative care teams will likely augment the care provided by the neurologist team.[50] The most outwardly obvious symptom is the movement disorder. Notably, the chorea may not be bothersome to the patient and should be treated only if it is functionally impairing to the patient. Treating the chorea must be done carefully and ideally with the assistance of a skilled neurologist. Dopamine-blocking agents and dopamine-depleting agents are both used.

Psychiatric disorders in HD are common and highly disabling. The cognitive dysfunction is progressive, but the psychiatric symptoms are typically static. Cognitive dysfunction typically precedes the onset of motor symptoms and evolves into full dementia. In the case of Theresa, she opted for semiannual neurocognitive evaluation: “I don’t want to be surprised by my disease. I want to be proactive and move into a living situation that fits my needs.” The neurocognitive effects of HD are characterized by bradyphrenia, poor spatial memory, diminished working memory, impaired capacity for planning, poor judgment, and decreased mental flexibility. No agent has been found to be effective at delaying the cognitive decline of HD—ACH-ase inhibitors such as donepezil are ineffective. Rivastigmine was studied in a small open-label study with modest improvements in motor function and cognitive impairment but has yet to be replicated in a large phase III trial. Psychiatric disturbances range from emotional lability and behavior disorder to major mood disorder, suicidality, or homicidality. Psychiatric hospitalization may be necessary for careful titration of medications.

As HD progresses, end-stage symptoms emerge (Table 21.10). Chorea progresses until the patient is unable to be still for more than a few moments at a time. Eventually, chorea gives way to a hypokinetic, abulic state and then to a vegetative state. Muscles become rigid. Patients may experience tremor, bradykinesia, and dysphagia. Many patients will be placed in residential facilities by this stage. Nursing care involves safety assessment, positioning, and feeding assistance. Patients commonly suffer pain from falls,

Table 21.10 Symptomatic treatment of Huntington’s disease

Chorea	◆ Treat carefully and only if distressing to the patient/functionally impairing ◆ Haloperidol 2–10 mg/day ◆ Olanzapine has been found to reduce chorea, stabilize mood, and augment antidepressants; may also improve ambulation ◆ Tetrabenazine improves motor function/suppresses chorea; monitor closely for Parkinsonism, mood disorder, suicidality, sedation, akathisia
Parkinsonism of HD	◆ Treated with standard PD therapy ◆ Poor candidates for neurosurgical interventions ◆ Often characterized by rigidity in the terminal stages of disease
Bruxism	◆ Separate from the effects of neuroleptics ◆ Well-managed with botulinum toxin
Dystonia	◆ May be painful ◆ Functionally impairing ◆ No specific treatment has been evaluated in trials
Aggressive behavior, mood disorder	◆ Antidepressants ◆ Antipsychotics ◆ Propranolol ◆ Mood stabilizers ◆ Buspirone ◆ Suicidal and homicidal assessment
Sleep-wake cycle disruption	◆ Sleep-wake disturbance may exacerbate HD symptoms in cognitive and emotional domains of functioning. ◆ Although efficacy is not established, scheduled hypnotics are reported in the literature ◆ See recommendations for practical management of disordered sleep in HD[59] ◆ Interventions for sleep-wake cycle disturbances

injuries, and hyperkinetic movements. The palliative care nurse facilitates occupational and physical therapy referrals when necessary. Speech therapy and dietetic assistance are also commonly required. Food and drink consistency may be modified, and dietary modifications can slow the weight loss. One fascinating feature of HD is weight loss in the setting of preserved appetite.

Certainly the most difficult task is supporting the patient and family through the inevitable decline. Emotional support and evaluation for mood disorder will be ongoing tasks for the nurse. Family and caregiver education will focus on the disease process and the risk for potentially affected family members. Early discussions about EOL preferences are also important. Because of the financial burden of care, the nurse will also facilitate conversation about financial planning.

Multiple Sclerosis

Case Study: A Patient with Multiple Sclerosis

Jon was a respiratory therapist. He noticed his left hand was numb when he was tightening the connections on a ventilator. The numbness slowly improved over a few months. When his left foot went numb, Jon talked with his doctor. An MRI scan demonstrated multiple lesions of various ages in the periventricular white matter of Jon's brain, consistent with MS.

MS is a neuroimmunologic disease with widely varying clinical courses. MS is typically diagnosed in young to middle adulthood. It is more commonly found in people of northern European decent and those living farther from the Equator. Prevalence is estimated at 5 to 200 per 100,000 persons.

MS symptom clusters have been well described in the literature. Although no cure exists for MS at present, much can be done to alleviate the symptom burden. Cognitive dysfunction is seen in severe disease. Patients describe disabling fatigue, functional impairments, bowel and bladder dysfunction, and sexual dysfunction among others (Table 21.11).

Managing disability is at the heart of nursing interventions for the patient with MS. Mobility and activities of daily living typically decline as the disease progresses. Early and scheduled physical and occupational therapy assessments are wise. Home and workplace modifications can preserve the patient's functional independence. As with most incurable diseases, emotional support is frequently necessary. MS is traditionally a disease of young adults—it strikes at a time when the patient may be contemplating marriage and pregnancy. The risk for depression is high. Referral to the MS Society can be helpful for patients—both peer support and case management services are available.

Myasthenia Gravis

Myasthenia gravis (MG) is a life-threatening neuroimmunologic disease. The disease stems from the destruction of acetylcholine receptors at the neuromuscular junction. The common presentation is a patient with fluctuating weakness of the muscles, especially the muscles innervated by brainstem motor neurons. Weakness can be induced with repetitive movement and strength is restored

Table 21.11 Managing symptoms of multiple sclerosis

Fatigue	Neurostimulants Amantadine Regular exercise Planned rest breaks, energy-sparing techniques
Cognitive dysfunction	Neuropsychological assessment
Neurogenic bladder: urinary frequency, urgency, bladder spasticity, incomplete emptying	Urinary retention: ◆ Bethanechol ◆ Intermittent catheterization ◆ Monitor and treat high postvoid residual volumes to reduce risk of urinary tract infection Frequency and urgency: ◆ Propantheline, oxybutynin
Sexual dysfunction	Men: PDE-5 inhibitors
Pain	Pain assessment Traditional methods of pain control can be effective, especially neuroleptics, gabapentin, tricyclic antidepressants
Tremor	Severe postural tremor can respond to isoniazid with pyridoxine Carbamazepine, Clonazepam Limb weights of small poundage applied to the wrists
Neurogenic bowel	Prescribed bowel program of: ◆ Scheduled toileting (especially after eating or exercising) ◆ Stool softeners, laxatives, suppositories, enemas if needed ◆ Digital rectal stimulation if needed
Mood disorder	Aggressive management of depression Referral for neuropsychological testing

with rest. Strength is characteristically restored dramatically with anticholinesterase drugs.

Case Study: A Patient with Myasthenia Gravis

Maggie was a college freshman. One afternoon after coming home from class, she noticed her face felt funny and it was hard to smile. Her roommate thought she was just anxious because midterms were coming up. While standing at the sink to brush her teeth that night Maggie noticed her eyes "were at half-mast like someone who's drunk and can't stay awake." She sought care in the emergency room. By the time she was admitted to the ER 8 hours later, Maggie's speech was slurred and she was having difficulty keeping her head up. She was admitted to the intensive care unit for respiratory insufficiency. The respiratory therapist assisting with the set-up for intubation checked Maggie's forced vital capacity (FVC) and found it to be dramatically low. Before the night was over, Madeline was intubated and on mechanical ventilation for respiratory failure.

MG was once a fatal disease shortly after diagnosis. Discovery of anticholinesterase-inhibiting medications has allowed many patients with MG to pursue full lives. Although there is no cure for MG, many with MG enjoy a full life. Treatment is initiated with thymectomy—hyperplastic thymus tissue is found in 70% of newly diagnosed patients with MG.[51] Anticholinesterase medications and immunomodulation are the backbone of therapy. Symptom control focuses on managing and preventing acute MG crisis. During crisis, palliative management focuses on symptoms of dyspnea and anxiety. In the long-term care of patients with MG, careful discussions about intubation and the possibility of prolonged mechanical ventilation are warranted. Some patients will ultimately require tracheostomy.

Intracranial Lesions

Intracranial tumors encompass both primary and metastatic tumors and may involve cerebrospinal fluid, bony structures of the skull and skull base, dura, and cranial nerves. Cancers that commonly metastasize to the CNS are lung, melanoma, renal cell carcinoma, breast, and colorectal. The most common primary CNS tumors include meningioma, the gliomas, embryonal tumors such as medulloblastoma, and primary CNS lymphoma.[52] The palliative care goals will be different for the patient with widely metastatic cancer, newly diagnosed intracranial metastases but stable system disease, and the patient with primary CNS tumors. A thoughtful discussion with the oncologist can be immensely helpful for the nurse in any of these settings. Symptoms of intracranial lesions vary widely by location of tumor (Table 21.12). Notably, patients with intracranial lesions can be asymptomatic.

Symptoms from CNS tumors result from edema, infiltration of normal brain by tumors, and mass effect—displacement of normal brain structures. The concern in cases of large lesions or significant edema is for brain herniation. Herniation involves displacement of a piece of brain tissue under a rigid structure such as the foramen magnum, tentorium, or falx cerebri. There are six distinct herniation syndromes: uncal (transtentorial), central, cingulate (subfalcine), transcalvarial, upward cerebellar, and tonsillar (downward cerebellar). In the uncal herniation, the most common herniation syndrome, the medial temporal gyrus compresses the brainstem and nearby cranial nerves. This scenario is typically heralded by an ipsilateral third cranial nerve palsy (the pupil fails to constrict when stimulated with light and the eye deviates inferiorly and laterally). Treatment for the palliative care patient typically incorporates high-potency corticosteroids. Corticosteroids restore the blood–brain barrier by reducing the permeability of vascular endothelial cells and thus reducing intracranial pressure. Steroids can alleviate headache and pain from metastases. The nurse will also avoid hypotonic intravenous solutions (this includes all dextrose-containing IV solutions except D5 0.9% NS). In emergency and intensive care situations, hypertonic intravenous solutions such as mannitol and 3% saline are used. This intervention is for short-term situations only as the brain gradually increases osmolality. Controlled hyperventilation is also used in these scenarios, although it is typically reserved for aggressive last-ditch efforts. In scenarios where it is consistent with goals of care, neurosurgical intervention may be appropriate. For the patient with impending herniation, removal of a portion of the skull (craniectomy) and lobectomy may be performed. Some patients may benefit from removal of the lesion—this applies to patients with most primary CNS tumors and to some patients with metastatic disease.

Seizures are not uncommon with intracranial tumors. Typically, seizures from primary brain tumors are focal in onset and can have localizing significance. Seizures from all intracranial tumors are usually well-managed with AEDs. Seizures also tend to respond well to lesionectomy. Patients with seizures from primary CNS tumors will usually experience improved seizure control with tumor treatment. Patients with known intracranial tumors who have not experienced a seizure do not require prophylactic treatment with AEDs.[6]

Muscular Dystrophy

The muscular dystrophies (MDs) are a heterogeneous group of inherited progressive degenerative diseases of the muscles. The pattern of muscle involvement, presence or absence of mild mental retardation, age at symptom onset, degree of creatinine kinase (CK) elevation, rate of symptom progression, and presence or absence of cardiomyopathy can suggest the specific class of MD. There are many types of MDs, with Duchenne and Becker MDs being the most common.

Advances in molecular and genetic science and the discovery of the dystrophin protein in 1986 by Kunkel heralded a phenomenal scientific leap. Diagnostic techniques have rapidly evolved in recent decades to allow relatively inexpensive and rapid diagnosis. For potential family carriers of dystrophies, the ability to detect genetic carriers is not insignificant. The palliative care nurse will appreciate the gravity of such information for affected families.

MDs generally affect skeletal muscles. The most common variety is Duchenne MD (DMD). This disease follows an X-linked pattern of inheritance and thus affects primarily boys. These children will commonly present before the age of 3 years with a rapid and progressing course of muscle weakness. Typically, the child will develop difficulty walking, standing, and stair-climbing first. This represents the initial involvement of the gluteal, quadriceps, and iliopsoas muscles. The walking difficulties will advance with the involvement of the pretibial muscles (as evidenced by foot drops and toe-walking). Eventually, shoulder girdle muscles weaken and the scapulae become winged. Eventually, the individual can be expected to develop spinal deformity such as kyphoscoliosis. Most

Table 21.12 Symptoms of intracranial lesion by location

Structure	Normal function	Altered function in the presence of tumor
Frontal lobe	Personality Voluntary skeletal movements Fine repetitive motor movements Eye movements	Personality change or disinhibition Altered responses to stimuli, emotional lability Difficulty with speaking, chewing, or facial expressions Uncoordinated swallowing, or movement of hands, arms, torso, pelvis, legs, and feet
Parietal lobe	Sensory processing: tactile, visual, gustatory, olfactory, auditory, body position	Trouble integrating language, vision and tactile stimuli Loss of sense of body positioning or vibratory sense Difficulty with verbal and nonverbal memory Paresthesias Loss of tactile discrimination Inability to write or do math calculations
Occipital lobe	Interpretation of visual input	Difficulty naming visual images and words Difficulty reading and writing, identifying colors Inability to identify if an object is moving
Temporal lobe	Auditory perception and interpretation	Right lobe: Difficulty hearing, understanding, organizing, and concentrating on what is seen or heard Inability to recognize musical tones and nonspeech information like illustrations Olfactory or gustatory hallucinations Vertigo, unsteadiness, or tinnitus Left lobe: Difficulty hearing, understanding, organizing, and concentrating on what is seen or heard Inability to recognize spoken words Vertigo, unsteadiness, or tinnitus
Cerebellum	Processing of sensory information from eyes, ears, and tactile and musculoskeletal receptors Refining motor activity into coordinated movement	Frequent loss of balance, unstable posture or gait Uncoordinated movement of extremities Alterations of some reflexive movements Nystagmus, muscle tremors, or ataxia
Brainstem and cranial nerves (CN)	*Brainstem:* gateway from cerebrum and cerebellum to spinal cord. Maintains consciousness, cardiovascular and respiratory functioning Relays motor and sensory information *Cranial nerves:* Nuclei of cranial nerves III-XII arise within the brainstem structures	CN I: loss of smell (anosmia) CN II: vision compromise, visual field defect CN III: loss of pupillary constriction and ability to raise eyelid, extraocular movements, diplopia CN IV: loss of inferior/medial eye movement CN V: inability to clench jaw and chew, numbness of mouth and nose, numbness of face, loss of corneal reflex CN VI: inability to abduct the eye CN VII: facial paralysis, taste disturbance, salivary and lacrimal dysfunction CN VIII: loss of hearing, disequilibrium CN IX: swallowing difficulty, taste disturbance CN X: loss of ear sensation, GI disturbance, voice hoarseness CN XI: difficulty turning head and shrugging shoulders CN XII: difficulty swallowing and articulating lingual sounds

boys with DMD are wheelchair bound by their second decade of life. These patients will most commonly develop respiratory insufficiency, pulmonary infections, and heart failure. Survival into the 20s and 30s was historically unheard-of.

In DMD, the normal dystrophin protein is not found in muscle cells. This leads to a loss of dystrophin-associated proteins and dystrophin-associated glycoproteins. These molecules are necessary for maintenance and function of the sarcolemma (the cell membrane of striated muscle cells). Without these proteins and glycoproteins, extracellular calcium and fluid flood the cell, leading to cell dysfunction and death. As muscle damage progresses, respiratory failure becomes evident. The initial clinical evidence of respiratory failure may be sleep apnea and/or weight loss as work of breathing increases. Ongoing discussions with the patient and family are clearly important with regard to patient wishes for assistive ventilation, electrophysiologic intervention, and resuscitation. Early screening (starting at age 10) and intervention at the first sign of an arrhythmia both in patients with DMD and carriers of DMD is considered the standard of care.

Treatment for DMD is limited and was historically aimed at slowing the disease. The management was limited to corticosteroids in an attempt to mitigate the inflammatory responses to intracellular myocyte damage. With advances in cardiac and respiratory care, some individuals are now living into their fourth and fifth decades. In recent years, pharmacotherapy advancements have led to FDA approval of a novel corticosteroid compound with indication of use in DMD.[53] Recent drug development targeting specific exons of the dystrophin gene have resulted in the first therapy (eteplirsen, marketed as Exondys 51) aimed at increasing skeletal muscle dystrophin levels.[54]

The role of the palliative care nurse for patients with DMD will evolve in coming years as treatments advance. Several disease-specific difficulties are currently common.[55] Patients with MD may struggle with constipation from immobility and poor abdominal muscle tone. Weight gain and osteoporosis can also be problematic as a result of chronic steroid therapy. Dietary education and interventions may alleviate these to some degree. The palliative care nurse will continue to advocate for independence, access to rehabilitation and respiratory therapy services, appropriate exercise goals, periodic cardiac evaluation, safety in the patient's environment, and educational achievement (including special education services). As the patient grows, seating, wheelchair, bracing, and equipment needs will evolve and require reevaluation with appropriate physical and occupational therapists. The palliative care nurse will remain attuned to the life-limiting nature of MD as well as to the potential impact on childbearing choices as patients reach adulthood. There is limited research available to the palliative care nurse on specific psychosocial needs of patients with MD. However, social integration and family caregiving needs are clear areas of needed support.[56,57]

Conclusion

Arguably, the role of the palliative care nurse is first to alleviate suffering and second to advocate for the patient's choices. The task of assisting the patient to identify his or her healthcare choices in the face of a devastating and often terminal neurological illness is no easy one. Box 21.5 lists additional resources to assist the nurse, patient, and caregivers. Several other themes emerge—advocating for early therapy referral, pain control, bowel and bladder care, preserving functional abilities, maintaining patients' independence, and providing education about medications and disease processes.

CHAPTER 22

Anxiety and Depression

Jaroslava Salman, Emma Wolfe,
and Sunita K. Patel

Key Points

- Emotional distress in the context of palliative care is ubiquitous and multifactorial.
- Palliative care clinicians need to be attuned to patients' distress and the possibility of clinically significant depression or anxiety.
- Anxiety and depression are common but often underrecognized and untreated.
- Accurate screening and differential diagnosis are prerequisite for appropriate intervention, which may include various treatment modalities.
- Up-to-date education of patients and their families enhances their ability to successfully participate in their care.

Introduction

Anxiety and depression are terms that have penetrated our daily life vocabulary and have been used in clinical settings for identifying both symptoms and specific disorders marked by clinically significant anxiety and/or depressive symptoms. Depression has been shown to have negative consequences on both the patient and family, with data indicating a role of this clinical condition in reducing adherence to treatments, in increasing subjective perception of physical symptoms, and, possibly, in worsening prognosis.[1] Depression is also a major risk factor for suicide and desire for hastened death.[2] Palliative care nurses are uniquely positioned to confront the complex range of medical and psychosocial challenges faced by their patients. Psychological distress can affect patients' abilities to experience joy during their final days. It can amplify physical pain and impair their ability to do the emotional work of advance care planning or saying good-bye to family and friends.[3]

Prevalence

The National Consensus Project for Quality Palliative Care identifies psychological and psychiatric aspects of care as one of its domains and provides guidelines to the interdisciplinary team to assess and address psychological and psychiatric components of care based on the best available evidence to maximize patient and family coping and quality of life (QOL).[4] Table 22.1 introduces data on the prevalence of depression and anxiety in palliative care patients in various settings of care.

Patients with advanced disease often experience psychological problems as their physical symptoms worsen and previously mentally healthy individuals can become psychologically vulnerable as their disease progresses. In a study by Austin, 20% of palliative care patients showed clinically meaningful anxiety and depression as measured by the Hospital Anxiety Depression Scale (HADS). Younger age and lower Karnofsky Performance Status Scale scores were associated with higher HADS total scores.[5] In a study of patients with terminal cancer, mixed anxiety and depressive symptoms were the most prevalent subtype (16%), whereas 14.9% reported only elevated anxiety symptoms and 13.4% reported only elevated depressive symptoms on a HADS screening instrument. Anxiety was significantly positively correlated with other measures of psychological distress including depression, hopelessness, and desire for hastened death, and negatively correlated with social support. Women reported significantly higher levels of anxiety than men.[6]

A meta-analysis of mood disorders in long-term cancer survivors by Mitchell revealed a pooled prevalence of syndromal (clinical) depression to be 16.5%, prevalence of adjustment disorder 15.4%, and anxiety disorders 9.8%. They noted no association between mean age or sex and prevalence of depression or anxiety. Individual studies in this meta-analysis noted that predictors of depression or adjustment disorder included low performance status, high burden of symptoms such as pain and fatigue, previous depression, and low levels of support.[7]

Interestingly, a study by Hayes found the prevalence of depression to be higher in men compared to women (25.7% vs. 12.8%, respectively) and the odds ratio (2.3) was not reduced after controlling for stage of illness, time until death, delay in diagnosis, level of social support, diagnosis, age, and ethnicity. Among those who did need help with basic tasks, there was a strong association between gender and depression, with 37.8% of men who were dependent on others being depressed compared to only 2.4% of similarly affected women.[8]

Considerations in Non-Cancer Patients

Symptom burden in end-stage chronic obstructive pulmonary disease (COPD) is often equivalent to or worse than in cancers, as well as the end stages of other chronic diseases such as dementia, congestive heart failure, renal failure, and liver failure.[9] Although dyspnea is often the most prominent and debilitating symptom, patients with COPD also experience depression and anxiety. These are sometimes related to the functional and social consequences of dyspnea and may decrease QOL independent of disease severity.[10] In addition, depression is an independent risk factor for mortality, hospital readmission, and longer hospital stay.[11]

Table 22.1 Prevalence of depression and anxiety in palliative care patients

Study (Reference number)	Population	N	Interview	Prevalence
6	Stage IV cancer patients	193	HADS (cutoff 8)	13.4% only depression 14.9% only anxiety 16% mixed anxiety and depression
5	Mixed cancer, HIV/AIDS, and chronic pulmonary disease. Comparison between home-based and inpatients	92 (46 home-based and 46 inpatients)	HADS (cutoff 8) HADS H ≥19	Anxiety: 35% home-based 50% inpatients Depression: 37% home-based 53% inpatients 22% home-based 35% inpatients
7	Meta-analysis of 24 studies of mood disorders in palliative care settings	4007	Psychiatric interviews (e.g., structured, semi-structured or clinical interview)	16.5% syndromal (clinical) depression 15.4% adjustment disorder 9.8% anxiety disorders
8	Mixed home care and inpatient palliative service.	300	PRIME-MD	Depression: 25.7% men 12.8% women
23	Community palliative care patients with advanced progressive disease.	50	MINI	Major depressive disorder: 20%

HADS, Hospital Anxiety Depression Scale; PRIME-MD, Primary Care Evaluation for Mental Disorders; MINI, Mini International Neuropsychiatric Interview.

In a study of outpatients with symptomatic heart failure, the most commonly endorsed symptoms on the Edmonton Symptom Assessment Scale (ESAS) were anxiety (45%) and depression (43%).[12] Depression is one of the most common psychological symptoms seen in heart failure. Patients with heart failure and depression are at greater risk for multiple all-cause admissions and rehospitalizations and overall morbidity and mortality. When depression is comorbid with anxiety, the risk of mortality is even higher. Depressive symptoms are also associated with worse health-related QOL (HRQOL) in patients with heart failure, especially when depression is persistent.[13]

In a study of patients hospitalized with heart failure who were administered the HADS questionnaire, 41% of patients were identified with anxiety, 59% with depression, and 33% with both anxiety and depression. Female gender and poor social support were found to be associated with higher rates of depression and anxiety.[14] A meta-analysis of 23 studies including more than 10,000 participants with heart failure demonstrated that the prevalence of major depressive disorder was 20% in outpatients and inpatients. The prevalence of depressive symptoms rose to 30% when self-reported questionnaires were used.[15]

A systematic review of 60 studies in end-stage renal disease (ESRD) dialysis patients showed mean prevalence of anxiety to be 38% and depression 27%.[16]

While it is useful to acknowledge the similarities between the palliative care needs of patients with cancer and chronic illnesses, particular differences are also evident.[17] Individuals with chronic illness often have a more prolonged illness trajectory than cancer patients and, for that reason, may have different palliative care needs. Chronic illness typically robs individuals of physical and psychological well-being, employment, hobbies, friends, and self-esteem from an earlier age than those with cancer. Thus, after decades of progressive deterioration in their health and functional ability, individuals with chronic illness often reach the terminal phase of their life without many of the physical and social resources available to other dying patients.[18]

Screening

A number of instruments have been studied regarding how to screen for depression and anxiety, with the Depression Cancer Consensus Group reporting validity studies involving at least 19 tools designed to help clinicians identify depression in the cancer setting.[19] The American Society of Clinical Oncology's guidelines recommend that all patients with cancer and cancer survivors be evaluated for symptoms of depression and anxiety at periodic times across the trajectory of care. Assessment should be performed using validated measures, such as the Patient Health Questionnaire (PHQ-9) and the Generalized Anxiety Disorder (GAD-7) for screening of depression and anxiety, respectively.[20] If moderate or severe symptomatology is detected through screening, individuals should have further diagnostic assessment to identify the nature and extent of the symptoms and the presence or absence of a mood or an anxiety disorder.[20]

There is no consensus on how to best screen for depression in patients receiving palliative care. Low completion rate due to patient frailty, refusal, or cognitive impairment is not uncommon. Shorter screening tools may be easier to use for both patients and providers. The sensitivity and specificity of different screening tools for depression in palliative care range from 0.72 to 1.0 and 0.50 to 1.0, respectively.[21]

In a study by Chochinov involving palliative care inpatients, sensitivity and specificity of a single question, "Have you felt depressed most of the day, nearly every day for two or more weeks?" was 1.0 and therefore diagnostic of depression.[22] In a small study within community palliative care patients, the same single question had a high specificity of 0.85 and low false-negative value of 0.94.[23] Thus, this single question seemed most helpful at screening out those patients who are not depressed and therefore do not need more in-depth assessment of their mood. Due to low positive predictive value (0.57) in this study, it was determined that patients identified as possibly depressed by the single question need further assessment of their mood before they are started on treatment.

As far as screening for anxiety, the State-Trait Anxiety Inventory (STAI), the GAD-7, and the Fear of Disease Progression Scale have been reported as tools to be applied in cancer settings, although their acceptability is reported to be modest. The HADS is a suitable tool for initial screening for both anxiety and depression but it cannot be proposed as a diagnostic instrument. [24]

Diagnosis

Despite the fact that depressive and anxiety symptoms are common in patients receiving palliative care, these disorders are often misunderstood, underdiagnosed, and, hence, untreated. Studies indicate that up to 50–60% of depression in cancer patients is not properly recognized.[1]

There can be many barriers interfering with the recognition of clinically significant depression or anxiety. These may include:

- The clinician's own lack of knowledge or skill to diagnose and treat depression or anxiety
- Reluctance to bring up potentially upsetting topics (a very low proportion of patients discuss their low mood with their doctors or oncologists and choose to address somatic rather than affective and emotional symptoms)[25]
- Belief that depression is "normal" at the end of life
- Concerns about possible drug–drug interactions with antidepressants

Table 22.2 Psychiatric disorders with depression as a predominant symptom

Adjustment disorder with depressed mood	Significant depressive symptoms in response to a life stressor causing undue distress and interference with daily functioning.
Major depressive disorder	Depression or anhedonia lasting for 2 weeks or more and present for most of the time. Associated symptoms include: weight loss, insomnia vs. hypersomnia, psychomotor agitation or retardation, fatigue, feelings of worthlessness or inappropriate guilt, difficulty concentrating and suicidal ideation.
Dysthymia	Depressed mood is present for most of the time for at least 2 years. Additional symptoms include changes in appetite and weight, fatigue, poor concentration, feelings of low self-esteem and hopelessness.

Table 22.3 Psychiatric disorders with anxiety as a predominant symptom

Generalized anxiety disorder (GAD)	Pervasive and excessive anxiety about a number of events/activities, occurring more days than not for at least 6 months. Additional symptoms include restlessness, easy fatigue, difficulty concentrating, irritability, muscle tension, and sleep disturbance.
Panic disorder	Recurrent unexpected panic attacks
Adjustment disorder with anxiety	Occurs within 3 months of a major stressor and causes significant distress and functional impairments.
Phobias	Significant fear brought about by specific situations or objects (e.g., closed spaces, blood draws, needles). Often accompanied by avoidance of a feared stimulus.
Posttraumatic stress disorder (PTSD)	Follows a traumatic event. Presents with intrusion symptoms (e.g., memories), avoidance of stimuli associated with trauma and negative alterations in cognition and mood. Increased arousal and reactivity are also present.

The most widely used criteria to diagnose depression are those outlined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5, 2013). If patients don't meet the full criteria for major depression or primary anxiety disorder, they can be classified as "adjustment disorder" with depressive and/or anxiety features. A proposal to adopt a "substitutive" approach to diagnosis of depression has been debated for years. It suggests replacing somatic criteria (e.g., poor appetite, fatigue, impaired sleep) thought attributable to medical illness or its treatment with other substitutes, such as depressed appearance, social withdrawal, brooding/self-pity/pessimism, and lack of reactivity in situations that would normally be pleasurable.[26]

However, most experts agree that, for clinical purposes, the use of an inclusive set of diagnostic criteria that incorporates both neuro-vegetative (somatic) and psychological symptoms of depression and emphasizes the presence of hopelessness, worthlessness, guilt, and suicidal ideation is most appropriate for the palliative care population.[27]

For the purpose of this chapter, we will focus on major diagnostic categories for both depressive and anxiety disorders that are most likely to be encountered in a palliative care patient population (see Tables 22.2. and 22.3). A reader interested in more detailed diagnostic criteria is recommended to turn to two commonly used systems in nosology, the DSM-5 (2013) and the International Classification of Diseases (ICD-10) for further information.

Depressive Disorders

Depressive syndromes are a common mental health problem in the palliative setting but they are often unrecognized and undertreated. Clinicians often fail to appreciate the extent of a patient's depression until too late in the course of the disease.[28] Depressed mood, sadness, grief, and anticipatory feelings of loss are all appropriate responses to advanced disease and dying. However, feelings of hopelessness, helplessness, worthlessness, excessive guilt, lack of pleasure, and suicidal ideation (even passive) are among the best indicators of depressive syndromes in these patients.[29,30]

On the other hand, feelings of hopelessness, helplessness, and guilt must be considered in the context of the patient's illness. Hopelessness may be difficult to interpret in the setting of a disease where there is no hope for cure or recovery.[31] Almost all patients with advanced illness experience a certain degree of disengagement from areas of interest. However, a pervasive anhedonia that extends to loss of interest and pleasure in almost all activities warrants attention as an important indicator of clinically significant depression. Symptoms that seem out of proportion to the patient's actual situation should prompt concern for major depressive disorder. Major depression affects approximately 7% of the general population (8–9% of female and 3–4% of men), with data in oncology indicating a prevalence between 15–40%, depending on several factors (e.g., type, stage of cancer, in/outpatient, on/off treatment, type of diagnostic tool used).[32]

Differential Diagnosis

Depressive symptoms caused by medications or underlying medical conditions need to be taken into consideration. The following list is certainly not exhaustive and outlines only a few common examples:

- Medications: corticosteroids, benzodiazepines, hormonal agents, amphotericin B, opioids
- Chemotherapeutic agents: vincristine, vinblastine, procarbazine, asparaginase, tamoxifen, interferon, interleukin-2
- Medical disorders: electrolyte abnormalities, folate and/or vitamin B_{12} deficiencies, hypothyroidism, adrenal insufficiency[33]

Many of these medications or medical conditions can also cause delirium, which often presents in a hypoactive form.[34] Patients may look depressed, withdrawn, or apathetic, and one has to have a high level of suspicion to make this important distinction between clinical depression and hypoactive delirium.

Symptoms of depression should also be differentiated from normal grief reactions. During their end-of-life stage patients often go through a period of sadness or mourning while adjusting to loss and working through the existential issues that may arise. This "preparatory grief" process is considered to be adaptive and appropriate. However, when a patient's grief becomes severe and lasting and includes pathological signs or symptoms such as persistent social withdrawal, pervasive hopelessness, or thoughts of suicide, they may be clinically depressed.[35] This distinction has clinical relevance for treatment as support for grieving patients may be different from support needed by those who are clinically depressed.[36]

Another important concept to consider as separate from major depression is demoralization. Loss of meaning and hope can determine a sense of worthlessness of one's own life which is the hallmark of demoralization. A number of studies have shown that demoralization in cancer patients is related to confrontation with existential stressors that, throughout the illness, can impair their sense of mastery and competence.[24] While patients with major depression perceive the source of distress within themselves, have feelings of guilt and anhedonia, and feel lack of motivation, those with demoralization perceive the source of distress outside the self, do not feel guilty (but feel subjectively incompetent to cope), do not present with anhedonia, and their sense of motivation is generally intact.[37,38]

Anxiety Disorders

Anxiety can be a natural response to suffering, uncertainty, disability, disfigurement, and impending death. Although exact figures are not available, anxiety that rises to the level of a psychiatric disorder likely impacts less than 10% of patients in palliative care.

For example, in the Coping with Cancer study, 635 patients underwent a prospective evaluation to determine the presence of anxiety disorders using DSM-IV criteria.[39] The main results were that:

- An anxiety disorder was present in less than 8% of patients.
- Anxiety disorders were more common among certain subgroups, including women, physically impaired patients, and in younger patients.

Patients themselves may not identify as "anxious" and may prefer to use different terms, such as "concerned," "scared," or "worried."[40] Although it does not always reach a clinically significant level, it is important to recognize the presence of anxiety and its potential sources[41]:

- Anxiety as part of one of psychiatric disorders
- Component of pain, dyspnea, nausea, or cardiac arrhythmias
- Metabolic causes: Hyperthyroidism, hypoxia, hyperthermia, hypoglycemia, hypocalcemia
- Adverse drug effects: Psychostimulants, corticosteroids, some antidepressants
- Drug withdrawal: Alcohol, opiates, benzodiazepines, nicotine, cannabis
- Psychosocial and spiritual concerns: Family, finances, dying, spirituality

Treatment

Anxiety or depressive symptoms warrant treatment if they are causing significant distress or impacting the patient's QOL or functioning. Treatment should be individually tailored and take into consideration the patient's overall medical condition, prognosis, frailty, and ability to actively participate in treatment (e.g., psychotherapy).

One should always take care to relieve any uncontrolled symptoms, especially pain. All patients should have an appropriate medical evaluation to assess for possible medical contributors to the patient's mood.

Different modalities can be employed separately or in combination to treat anxiety or depressive symptoms. Although there is a lack of controlled trials to support the efficacy of combined therapy, most experts recommend an approach that combines supportive psychotherapy with patient and family education along with judicious use of antidepressant medication[2]:

- Pharmacotherapy
- Psychotherapy (see the psychotherapy section of this chapter)
- Integrative therapies (e.g., hypnotherapy, art therapy, aromatherapy, meditation, massage, relaxation, music therapy)
- Patient and family education

Pharmacotherapy

Newer antidepressants (e.g., selective serotonin reuptake inhibitors [SSRIs]and serotonin-norepinephrine reuptake inhibitors [SNRIs]) have a favorable side effect profile and are generally safe to use in older adults and the medically ill population. All antidepressants are started at low doses and require at least 4–6 weeks at a particular dose to show efficacy. Patients who are not told this when beginning treatment may stop the medication prematurely. The dose may need to be increased after this initial period.[33] Tables 22.4 and 22.5 provide a list of commonly used antidepressants and psychostimulants, respectively.

Psychostimulants have a faster onset of effect and are the preferred initial option for patients whose life expectancy is less than 2–4 months or for those who need more urgent treatment. They can be administered along with an antidepressant, benefiting from the activating effect of the stimulant within days

Table 22.4 Medications frequently used to treat depression in palliative care patients

Medication	Side effects to consider	Comments
Serotonin reuptake inhibitors (SSRIs)		
	GI disturbances (nausea, diarrhea) Sexual side effects (decreased libido, delayed orgasm) Increased anxiety or restlessness, especially early in treatment. Headache Insomnia/somnolence	Full benefit in 4–8 weeks
Fluoxetine		Usually administered in A.M. The longest acting SSRI agent, does not require gradual discontinuation.
Sertraline		Usually administered in A.M.
Citalopram/escitalopram		May be either activating or sedating. A.M. or P.M. administration is reasonable. QTc monitoring warranted for at risk patients.
Paroxetine		Shortest acting SSRI agent: gradual discontinuation is recommended, otherwise unpleasant discontinuations syndrome (flu-like symptoms occurring within 2–7 days of stopping an SSRI) symptoms may occur. Tends to be sedating and administered in the evening.
Serotonin-norepinephrine reuptake inhibitors (SNRIs)		
	Similar to side-effects of SSRI: GI disturbances Sexual side effects Dry-mouth, constipation, urinary retention Treatment-emergent hypertension	Often first-line agents for patients who have comorbidities such as pain, neuropathy, or stress incontinence.
Venlafaxine		Can be beneficial for treatment of vasomotor symptoms of menopause. Discontinuation syndrome common when stopped abruptly.
Duloxetine	Hepatotoxicity in patients with pre-existing liver disease	Approved for treatment of fibromyalgia as well. Discontinuation syndrome common when stopped abruptly.
Other antidepressants:		
Mirtazapine	Dry mouth, sedation, weight gain Limited sexual side effects	Sedating, appetite-stimulating, administered at night. Anti-nausea treatment in chemotherapy. Solu-tab formulation available. May be used to augment other antidepressants (e.g., add sedating or appetite-stimulating effect).
Bupropion	Insomnia, dry mouth, tremor	Indicated for treatment of depression but not effective for anxiety disorders. May be useful in fatigued or lethargic patients. Also indicated for smoking cessation. Safe in depressed cardiac patients.

* Adapted from Mehta R., Roth A.: Psychiatric Considerations in the Oncology Setting[33]

Table 22.5 Psychostimulants used to treat depression or augment antidepressant treatment

Medications	Side effects	Comments
Methylphenidate Dextroamphetamine	Anxiety, insomnia, tachycardia, mood instability. At higher doses: nightmares, insomnia, tics, paranoia.	Useful in depressed patients at the end of life to help improve their mood, wakefulness and energy more immediately. May potentiate the analgesic effect of opioid analgesics and counteract opioid-induced sedation.
Modafinil	Headache, anxiety, insomnia, hypertension, palpitations, dry mouth, diarrhea, nausea, anorexia.	Possibly safer for patients with a history of seizures or cardiac arrhythmia.

Source: Adapted from Reference 33.

and from the longer acting benefits of the antidepressant effects in 4–6 weeks.[33]

For patients with chronic anxiety or mixed anxiety and depressive symptoms, an antidepressant is often the treatment of choice (e.g., an SSRI). However, as mentioned earlier, antidepressants usually do not provide immediate relief and may take a few weeks to reach a full effect.

Adding a benzodiazepine agent may help "bridge" the patient until that time. Benzodiazepines are also helpful in the management of acute anxiety reactions. One of the most commonly prescribed benzodiazepines is alprazolam. However, it is also one of the shortest acting agents in this group of medications (along with oxazepam and triazolam), which makes them less suitable for treatment of anxiety as they remain effective for limited periods of time and are associated with a higher risk of rebound anxiety and withdrawal syndromes.

Lorazepam can be dosed more frequently and is useful not only for anxiety, but also to alleviate nausea and panic attacks. Patients with compromised hepatic functions may do better with lorazepam, oxazepam, or clonazepam given that these drugs are metabolized by conjugation (no oxidation) and have no active metabolites.

Regardless of the agent chosen, the lowest dose should be used with careful titration to the desired effect. Benzodiazepines should be tapered off if they are causing adverse effects, such as oversedation, delirium, falls, or cognitive impairment. As disease states progress, especially during the last 6 months of an illness, these adverse events are more likely and benzodiazepines may need to be avoided, cross-titrated to longer acting agents, or discontinued.[42,43] They should preferably be tapered off gradually, when practically and medically possible.

At a low dose, sedating antipsychotic medications, such as olanzapine and quetiapine, are effective in patients with severe anxiety that is not controlled with benzodiazepines or who cannot take benzodiazepines. They can also be useful for patients with respiratory complications as they do not cause the respiratory depression that benzodiazepines can. Patients who have difficulty falling asleep may also benefit from sedating medications in the antidepressant family, such as mirtazapine, amitriptyline, trazodone, or doxepin.[33]

Psychotherapy

Every patient must find ways to cope with the life-threatening illness, its treatment, and its impact on QOL and family functioning. From the initial diagnosis of the disease to the challenges of survivorship and uncertainty of a disease condition that might change for the worse, some degree of distress is inevitable. Often the disease and illness are not the only major stressors patients experience in palliative care. Patients may experience concurrent stressors such as serious illness in their partner or in another family member; economic problems including work, insurance, and housing; and low levels of social support. Symptoms of anxiety and depression in the context of a high-level threat such as disease progression or imminent death represent an appropriate response and can be distinguished from reactions indicative of poor coping and unstable emotional status.[44]

Psychotherapeutic interventions to reduce anxiety and depression symptoms are effective irrespective of whether the patient's responses are a normal reaction to his or her illness experiences versus a pathological reaction. The typical modalities for psychotherapeutic interventions are individual- and/or family-based depending on the patient's needs, functional status, and capacity. Psychotherapy for outpatients is sometimes augmented with referral to supportive group therapies where patients benefit from peer support and psychoeducation.[45]

Psychotherapeutic interventions for anxiety and depression in inpatient palliative care settings are typically highly focused and often undertaken to assist the interdisciplinary team with behavioral management and reducing psychosocial complications that could prolong hospitalization. The initial goal is to reduce symptoms to a manageable level rather than to "cure" the underlying causes or to address the full scope of the patient's psychological concerns. Instead, the patient and therapist work together to identify one or two priorities that can benefit from immediate attention.[27,46,47]

Particularly for frail patients, engaging in "talk therapy" may not be necessary as environmental modifications or other logistical interventions can be highly effective in reducing distress. These adjustments may involve providing the patient with more autonomy and control over decisions such as daily activities, timing of medication administration and nursing assessments, as well as food delivery schedules. Other examples of brief interventions that can substantially support the patient's coping include helping the patient communicate with the medical team to clarify understanding for informed decision-making or with family members to broach highly charged issues that require timely attention. All efforts undertaken to support the patient's coping and reduce distress should align and synergize with the overall goals of the interdisciplinary palliative care team.[47-49]

Regardless of whether the patient is referred for anxiety and depression management during the course of hospitalization or as an outpatient, some degree of assessment is necessary to clarify the presenting symptoms and their context. The initial assessment focuses on identifying the patient's primary biological, psychological, and social concerns and detailing the associated symptoms, duration, and situational factors that contribute to the difficulties that have been identified by the palliative care team.

Such descriptive information leads to diagnostic clarifications, including differentiation between normal responses to stressors that may improve with limited intervention versus meeting criteria for psychiatric conditions that warrant more intense treatment approaches.[50]

Patients with complex presenting problems require the clinical assessment to be comprehensive enough to pinpoint the underlying beliefs, conflicts, and dynamics driving the anxiety and depression symptoms that the patient outwardly expresses to the world. The assessment must also remain sufficiently focused on specific problems in order to formulate interventions that are targeted and relevant to the patient's current health status.[50]

Key considerations in individual psychotherapy in the palliative care setting are the development of a strong therapeutic alliance with the patient and the establishment of trust to normalize the symptoms, fears, and concerns that characterize the illness experience and to provide coping strategies for dealing with negative emotions and the crisis at hand. Techniques to facilitate adaptation help patients use more effective coping strategies and are typically embedded in one of several theoretical frameworks of psychotherapeutic interventions. These frameworks provide a roadmap to guide assessment and interventions, and most therapists blend elements from different approaches and tailor their treatment according to each client's needs.

Psychotherapeutic treatment in palliative care is typically short-term with a duration ranging from a single session to multiple visits across several weeks focused toward goals that are relevant and feasible to achieve. A common approach in brief psychotherapy is to help the patient identify what is out of their control and what can be changed. For the latter, an active, problem-focused coping approach can be most helpful. In cases where the stressor cannot be changed, such as the need to cease employment due to illness, the therapist may guide the patient toward emotion-focused coping strategies such as cognitive reappraisal or acceptance.

Many of the interventions used in short-term psychotherapy in palliative care originate from the cognitive-behavioral therapy (CBT) framework. The fundamental premise in the cognitive behavioral framework is that psychological distress is connected to cognitive factors, including cognitive schemas, belief systems, cognitive distortions, and dysfunctional or maladaptive beliefs. Interventions are designed to target and alter these maladaptive cognitions or beliefs.

Patients are helped to understand and restructure their maladaptive cognitions and beliefs surrounding anxiety-provoking situations and to learn to develop a coping plan for distressing situations. Techniques used toward these goals include self-talk, relaxation training, worksheets for behavioral activation and cognitive restructuring, daily logs of thoughts, feelings and behaviors, and more.[51]

Other evidence-based interventions that are increasingly incorporated in palliative care are rooted in emerging psychotherapeutic frameworks such as acceptance and commitment therapy (ACT), and mindfulness. The main focus of ACT is to increase psychological flexibility by engaging in acceptance, cognitive diffusion, practicing being in the present moment, and identifying and working toward the individual's values and committing to actions.[52]

Mindfulness is the awareness that emerges through paying attention, purposefully and nonjudgmentally, to the unfolding of experience from moment to moment, including one's thoughts, feelings, and bodily sensations.

Therapists and patients work together to address problems with adjustment to illness. Challenges with adjustment are often characterized by anxiety about treatment or existential concerns and depressive symptoms, including decreased motivation and sadness. Some patients also exhibit beliefs and behaviors that interfere with adherence to their medical treatment, and these may need to be addressed collaboratively with the palliative treatment team.

Treatment may include providing resources and assessing the specific needs of the patient, such as the need for a new or updated assessment for psychotropic medication and referrals for pain management or assistance with lifestyle management to reduce disease-related risks (e.g., nutritional and physical activity counseling) and to other members of the palliative care team (spiritual care, etc.).[50]

Key considerations in family therapy for the palliative care patient are to help the family manage communication about the illness, particularly as it concerns balancing the amount of information given to the frail or disabled patient about his or her illness and ensuring that secrets about the disease are not kept. Therapists may work to help activate social support and assistance from family members to the patient, if not already provided, and to actively collaborate with the multidisciplinary team. Communication technology such as texting, sharing photos over the Internet, emailing, and using social media may reduce the sense of isolation experienced by both the hospitalized patient and the family remaining at home.

For some patients, therapists may encourage the primary caregiver to avoid isolation and find sources of support for themselves. Caregivers may also be encouraged to set new routines while continuing to meet the needs of others in the family. In this manner, the therapist attempts to encourage the family to not let the illness dominate their lives. For patients in a partnered/marital relationship, the stress of a chronic illness has the potential to take a toll, particularly if a marriage was fragile prior to the diagnosis. Financial pressures, time spent apart due to the hospitalizations, changing roles in the relationship, and disrupted family routines can result in a loss of closeness and intimacy as well as direct conflict. Referral to a marriage and family therapist in the community may be helpful.

Therapists can partner with caregivers to look for opportunities for patients to exert control and gain a sense of mastery in their environment. Opportunities for making decisions, voicing wishes, and exercising appropriate control can reduce feelings of hopelessness, bolster a sense of self-efficacy, and improve mood and adjustment. Helping family members learn how to support patients as they work to maintain a level of independence can also be extremely important for the patient and the caregivers.[53]

Integrative Therapies

Evidence-based interventions that have shown promise with patients with depression include integrative therapies such as a acupressure, breathing exercises, guided imagery, relaxation, and emotive imagery in management of symptoms of depression and anxiety in patients with cancer.[54] Massage therapy has also been shown to reduce patient–reported experience of pain, anxiety, and depression symptoms. A systematic review of the effects of massage therapy on the alleviation of pain, anxiety, and depression yielded some promising results. Patients with limited social support and limited experience with physical contact and affection benefited most from the massage experience.[55]

Patient and Family Education

Educated and empowered patients and families are better equipped and motivated to understand and manage their chronic illness. Effective patient education has been shown to improve adherence with patient instruction and reduce pain and anxiety.[56] Effective patient education is evidence-based and includes materials that reinforce understanding. In most facilities, nurses can partner with health educators who are skilled at developing patient-friendly, culturally sensitive, and health literacy–appropriate patient education. The goal of patient education is to increase patient/caregiver knowledge of health information and to assist patients who struggle to understand instructions. It seeks to engage, motivate, and empower patients with skills to self-manage their illness.[57]

Nursing's Role in Patient Education

Team-based care is becoming the paradigm in delivering complex care for patients with chronic disease.[58] Nurses are ideal for delivering psychoeducation to reduce symptoms of anxiety and depression in palliative care.[54] Educating patients and their caregivers is an integral part of nursing practice,[59] with nurses having the established rapport and inherent trust with patients to facilitate the transfer of crucial knowledge. The education should be systematic, sequential, and take into account the patient's/family's specific wishes and cultural, linguistic, and socioeconomic background.[59]

In palliative care, patient education should focus on empowering patients to self-manage anxiety and depression.[60] Nurse-delivered, evidence-based, psychoeducational interventions focusing on problem-solving, coping techniques, and management of depression symptoms improve outcomes among depressed palliative care patients.[61,62] In a 2017 study, patients who received palliative care with education and coping skill-building at the time of hematopoietic stem-cell transplant experienced "remarkable and sustained improvement" in depression and posttraumatic stress disorder (PTSD) symptoms 6 months posttransplant.[63]

Health Literacy

Patients face myriad challenges in understanding health messaging, including language and reading problems and a complex healthcare system. Nearly 9 out of 10 American adults have difficulty using everyday health information.[64] Margolis (2014) found that patients retained 50% of the health information they received, with half of it being recalled incorrectly.[65] Pain, illness, worry, medication, and lack of sleep can make it hard to process and remember health information.[66]

The impact of health literacy and patient empowerment on physical and mental health is significant. Lower health literacy is associated with worse physical health and depression and anxiety.[70]

The ability to understand and retain medical information depends on the clinician's communication style as well as the patient's education, language skills, motivation, cultural beliefs, and anxiety about the clinical encounter. The nurse must take precautions to assess the patient's readiness to receive information; to communicate that information in a calm, nonthreatening, and supportive manner; and to use plain language and limit medical jargon.[66]

Teach-Back

"Teach-back" is a simple intervention that improves provider communication and patient health outcomes.[56,68] It requires the patient who receives education to explain, in his or her own words, what he or she understands and needs to do. Research shows teach-back improves outcomes in cancer screening rates through provider communication training[68] and increases in glycemic control in diabetic patients.[69]

During patient education, the nurse should use teach-back frequently to ensure patient understanding. Listed here are some suggested techniques for utilizing this simple but powerful tool[67]:

- Use a caring tone of voice/attitude.
- Make eye contact and show relaxed body language.
- Use plain language.
- Ask the patient to explain back, using her own words.
- Ask nonshaming, open-ended questions.
- Avoid asking "yes" or "no" questions.
- Emphasize that the responsibility to explain clearly is on you.
- If the patient is not able to teach-back correctly, explain again and repeat teach-back.
- Use reader-/patient-friendly materials (print/images/video) to enhance learning.
- Document use of and patient response to teach-back.

Patient Empowerment and Self-Management

The Institute of Medicine defines self-management as "the systematic provision of education and supportive interventions to increase patient's skills/confidence in managing their health problems, including goal-setting and problem-solving support."[60] The Chronic Care Model posits that patients with chronic illness need education and support to become effective managers of their own health condition.[71]

Developing Self-Management Goals

To increase patient's self-management and self-efficacy skills, the nurse must provide:

- Easy-to-digest information
- Tools for building self-management and problem-solving skills
- Ongoing support from care team, friends, and family

The nurse and patient/caregiver should set achievable, patient-centered goals and create a follow-up plan:

- Nurse assesses patient's skill, understanding, and confidence in managing symptoms.
- Patient identifies an action plan with specific goals/behaviors.[60]
- Nurse creates structured follow-up to review goals/progress via clinic visit, phone, or email.

Follow-Up for Patients with Chronic Conditions

Structured follow-up is an essential part of chronic care and self-management development and reinforcement.[73] The following are helpful tips in planning follow-up calls with patients and families:

- Schedule follow-up based on mutual goals developed with patients and families. Be flexible in allowing patients to determine the follow-up method.
- Include problem-solving techniques to help patients identify problems and create solutions in follow-up.
- Don't skip follow-up.

- Follow-up can be by phone, email, fax, home visit, clinic visit, or other. If possible, use trained, culturally competent lay people for follow-up.

Web and Technology Solutions

Creative use of technology can help nurses connect with patients and provide effective, efficient patient education, self-management, and follow-up via web-based modalities/resources.[73] Telephone follow-ups and Internet-based interactive counseling/support have been shown effective in reducing depressive symptoms in cancer patients.[54] A recent systematic review of web-based CBT interventions found them to be effective for improving distress in physical illness, although evidence in cancer is still limited.[74]

Conclusion

Depression and anxiety are common in palliative care patients, but clinically significant symptoms are often unrecognized and untreated, which can add to patients' suffering and undermine their QOL. Active screening for depression and anxiety is recommended, and it should be combined with a systematic plan for appropriate intervention in order to be effective. Optimal treatment may involve the use of psychotropic medications, psychotherapy, and, in some cases, complementary treatment modalities. Patient and family education is indispensable in helping patients and their families to feel empowered by contributing to their care.

CHAPTER 23

Delirium, Confusion, and Agitation

Wendy Goldberg, Greg Mahr,
Amy M. Williams, and Michael Ryan

Key Points

- This chapter examines the symptoms, causes, and management of delirium, with a special emphasis on nursing management and family interventions.
- Delirium can be difficult to recognize.
- Delirium is preventable in some circumstances and, when present, can be treated to relieve symptom burden.
- Delirium is a critical issue in palliative care and requires thoughtful diagnosis and skilled management.

Introduction

Delirium is an increasingly common complication of modern medical care. As we succeed in keeping sicker patients alive longer, they are more likely to develop the signs of global brain dysfunction called *delirium*. Delirium is characterized by disturbances in awareness, cognition, and attention. Attention is the ability to focus, shift, or sustain concentration. An electroencephalogram (EEG), though not usually clinically necessary, will confirm the global nature of the brain deficits in delirium and show generalized diffuse slowing. Onset is acute or subacute, and patients are confused and disoriented. Typically, the symptoms of delirium are most severe at night, when patients are more likely to be alone and when the orienting stimuli of the home or hospital routine are reduced. This pattern of diurnal variation is known as *sundowning*. Sundowning occurs because of this global brain impairment. It describes a symptom pattern, not a cause of delirium.

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) defines five criteria for delirium: (1) deficits in attention and awareness, (2) symptom onset over a brief time period, change from baseline, and symptom fluctuation, (3) additional deficits in cognition (e.g., orientation, memory, perception), (4) not better explained by another neurocognitive disorder (e.g., dementia) or occurring in the context of severely decreased arousal (e.g., coma), and (5) the medical history, physical examination, or laboratory results indicate the delirium is a direct result of another medical condition(s) (e.g., disease, intoxication, or multiple etiologies).[1] The DSM also specifies subtypes based on duration and behavior.[1] Acute delirium lasts a few hours or days, while persistent delirium can last for weeks or months. Behavioral subtypes are hyperactive, hypoactive, and mixed delirium.[2,3] Patients with hyperactive delirium are more likely to become agitated. On the other hand, patients with hypoactive delirium are more likely to go undiagnosed and not receive treatment.[4] Delirious patients may become psychotic and develop hallucinations or delusional beliefs. Hallucinations in delirium are more commonly visual. Unlike the complex delusions sometimes seen in schizophrenia, delusions in delirious patients are usually vague and simple, like the belief that hospital staff are trying to kill the patient.

Epidemiology and Prognosis

The incidence of delirium varies from 40% to 80%.[5] In settings where more complex care is provided, such as the intensive care unit (ICU) and hospice settings, delirium is more common, affecting up to 80% of patients.[6] The mortality rate associated with delirium is 20%.[5] Dharmarajan et al.[7] hypothesized that the relationship between delirium and a series of hospital-acquired conditions such as falls, pressure ulcers, sleep deprivation, and aspiration likely explains the high mortality rate in this population. Persistent delirium is an ominous symptom associated with a very poor prognosis.[8,9] Terminal delirium is a label used to describe the persistent delirium which often occurs during the dying process.

Morbidity related to delirium includes cognitive decline,[10] extended hospital stay,[11–13] readmissions,[14] placement in long-term care facilities,[15,16] decreased quality of life,[3–4,17] caregiver burden,[4,17,18] and increased healthcare costs.[11] Management and treatment of delirium costs an estimated $164 billion per year.[15]

Medical noncompliance and other behavioral disturbances related to delirium can cause complications of their own.[3,19] A particularly troubling manifestation of severe delirium is agitation. When confused, agitated, or fearful, patients may remove catheters, physically hurt others, miss scheduled medications and procedures, wander, fall, and generally require intensive supervision.[3] Delirium contributes to cognitive decline, loss of independence, and mortality.[15] Yet delirium is not recognized about 60% of the time,[20] especially in its milder forms or when delirium is of the hypoactive type.[3,4,19] Oosterhouse et al. found ICU nurses frequently missed diagnosing delirium, especially in older patients or those experiencing hypoactive delirium.[3] Nurses did identify pertinent risk factors for delirium (sepsis, hypoxia, dehydration, sleep deprivation), but did not recognize the implications of these findings for altered mental status. Despite the existence of Clinical Practice Guidelines,[12] nurses demonstrated gaps in knowledge and problematic attitudes and beliefs about delirium. The study identified examples of coaching, team-based rounding, and utilization of care pathways with potential to improve nursing diagnosis of delirium.[3] Most delirium research has focused on acute care settings. Early interventions, both psychosocial and medical, have been shown to be effective in the management of this neurobehavioral syndrome, improving outcomes for patients and reducing stress for caregivers.[3,21]

Pathophysiology and Etiology

Delirium has been described as a combination of pathophysiology resulting from direct brain insults (e.g., hypoxia, infarcts, drugs) and/or abnormal stress responses (e.g., infection, postoperative metabolic dysregulation).[22] Although the precise mechanism of delirium remains unclear, there is general agreement that this syndrome involves aberrations in cholinergic, gamma-aminobutyric acid (GABA), and glutamate transmission; cerebral metabolism; the reticular activating system; and the inflammatory response.[22–25] Research to identify biomarkers for delirium is in an early stage.[20,26]

Hypoxia, infection, metabolic abnormalities, sleep deprivation, trauma, medications, drugs, and other derangements can cause or contribute to delirium. To help identify the multiple causes of delirium, the authors have found it helpful to use mnemonics. Two common mnemonics for the causes of delirium are "I WATCH DEATH"[27] and "DELIRIUMS"[28,29] (see Table 23.1).

Infection, a common cause of delirium, does not have to be severe to affect vulnerable brains. For example, in patients with dementia, even a mild urinary tract infection can cause delirium. Frequent pharmacological causes for delirium include anticholinergic medications (e.g., amitriptyline or cyclobenzaprine) and the over-the-counter antihistamine diphenhydramine. However, many other classes of medications like steroids, opioids, and sedatives can contribute to delirium. Metabolic and physiological factors such as dehydration, hyponatremia, and alcohol withdrawal can also produce delirium. Alcohol withdrawal can easily be missed when patients are not forthcoming about their alcohol history and families are unaware of the extent of alcohol use. When thinking about delirium, it is important to remember that delirium is usually multifactorial,[20] with between two and six possible causal factors.[30] A single causal factor can be identified in fewer than 50% of cases.[31]

Differential Diagnosis

Delirium can be distinguished from dementia on the basis of several factors. Delirium tends to be associated with acute onset rather than chronic progression and can sometimes be temporally associated with a disease process or a medication change. Although delirium and dementia are distinct disorders, they share the common substrate of a damaged brain. A brain damaged by dementia is much more likely to develop delirium.[10,15] A common clinical scenario is that of a patient with dementia who is pleasant and cooperative, but develops hypoxia. Here, delirium is superimposed on a preexisting dementia. Repeated

Table 23.1 Common mnemonics for the causes of delirium

***I WATCH DEATH* mnemonic**[27]		
I	Infection	Urinary tract infection, encephalitis, meningitis, pus, skin/soft tissue, pneumonia, Human Immunodeficiency Virus
W	Withdrawal	Alcohol, barbiturates, benzodiazepines, sedatives, illicit drugs
A	Acute metabolic disorder	Electrolyte imbalance, hepatic or renal failure, altered pH, hyper/hyponatremia, hyper/hypocalcemia
T	Trauma	Head injury, subdural hematoma
C	CNS pathology	Stroke, hemorrhage, tumor, ictal/postictal states
H	Hypoxia	Anemia, cardiac failure, pulmonary embolus
D	Deficiencies	Vitamin B_{12}, folic acid, thiamine, niacin
E	Endocrinopathies	Hypo/hyper thyroid, hypo/hyper glycemia, hypo/hyper cortisol
A	Acute vascular	Shock, septic hypotension, vasculitis, hypertensive encephalopathy
T	Toxins, substance use, medication	Alcohol, anesthetics, benzodiazepines, anticholinergics, narcotics, corticosteroids
H	Heavy metals	Arsenic, lead, mercury
***DELIRIUMS* mnemonic**[28,29]		
D	Drugs, dehydration, detoxification, deficiencies, discomfort (pain)	
E	Electrolytes, elimination of abnormalities, environment	
L	Lungs (hypoxia), liver (hepatic failure), lack of sleep, long emergency department stay	
I	Infection, iatrogenic events, infarction (cardiac, cerebral)	
R	Restraints, restricted movement/mobility, renal failure	
I	Injury, impaired sensory input (doesn't have glasses, hearing aids, dentures), intoxication	
U	Urinary tract infection, unfamiliar environment/people	
M	Metabolic abnormalities (glucose, thyroid, cortisol, poor nutritional status), metastasis (brain), medications (anesthetics, benzodiazepines, anticholinergics, narcotics, corticosteroids)	
S	Subdural hematoma	

episodes of delirium may worsen preexisting chronic brain disease like dementia, even after the delirium resolves.[15,16]

Delirium can also superficially resemble depression, particularly with hypoactive delirium. Delirious patients, in their confusion, can be quiet and withdrawn. They may also sleep poorly because of the sleep–wake cycle disturbances associated with delirium. A key feature distinguishing delirium from depression is disorientation.[32,33] Although depressed patients can perform poorly on cognitive tasks because of a lack of motivation and concentration, they are not disoriented and confused.

Sometimes delirium can be misdiagnosed as a primary psychotic disorder. Epidemiology is crucial here. For example, an 80-year-old person with no prior psychiatric illness does not suddenly develop schizophrenia. Also, patients with schizophrenia or bipolar disorder are not usually disoriented unless they are also delirious.

The term *catatonia*, which historically had been used to describe a subtype of schizophrenia, has now been defined more broadly. Features of catatonia can be seen in delirious patients. Catatonia is a psychomotor syndrome characterized by stupor, mutism, negativism, posturing, and stereotypical movements.[34] Catatonia can be associated with psychiatric disorders like schizophrenia or depression, but it can also occur in the kinds of metabolic derangements that cause delirium. Indeed, the two disorders can overlap. Because catatonia is relatively responsive to treatments like lorazepam, it is important to look for catatonic features in delirious patients. The Bush-Francis Catatonia Rating Scale, based on the DSM-5 diagnostic criteria, is a useful clinical screening tool for catatonia.[35]

Assessment

Delirium is usually first noticed when a patient acts confused, becomes agitated, or exhibits other worrisome behaviors. As symptoms of delirium may wax and wane, recognizing delirium sometimes requires ongoing assessment. The patient may appear vacant, abstracted, or emotionally labile. The regular use of delirium screening tools has been shown to improve early identification of this syndrome in complex care settings like ICU, geriatrics, oncology, and hospice.[12] Some instruments like the Confusion Assessment Method (CAM) screen for the diagnostic criteria of delirium,[36] while others, like the Memorial Delirium Assessment Scale, assess severity of symptoms.[37] Table 23.2 provides a limited

Table 23.2 Common screening or assessment measures for delirium and cognition

Test	Information	Time to admin
Presence of delirium		
Confusion Assessment Method[36] (various types)	Multiple versions ranging from 2–9 items Recommended in Clinical Practice Guidelines for Pain, Agitation, and Delirium (2013 – CAM–ICU) Recommended in the Geriatric Emergency Medicine Guidelines (2013 – Brief CAM) Requires training via manual Rater: clinicians	2–5 mins
Intensive Care Delirium Screening Checklist (ICDSC)[70]	Recommended in Clinical Practice Guidelines for Pain, Agitation, and Delirium Rater: clinicians	10 mins
NEECHAM Confusion Scale[71]	Rate a patient's behavior while providing routine care to elderly patients Assesses cognitive processing, behavior, and physiologic functions Rater: nurses	10 mins
Nursing Delirium Screening Scale[72]	Five-item tool designed to screen for delirium during routine clinical care Rater: nurses	1 min
Delirium severity		
Memorial Delirium Assessment Scale (MDAS)[37]	Ten-item tool that measures delirium severity Rater: physicians	10–15 mins
Delirium Symptom Severity Scale[73]	Measures delirium severity Rater: clinicians	10 mins
Delirium Rating Scale[74]	Ten-item tool which evaluates symptoms over a period of 24 hours Requires training Rater: clinicians	5 mins
Tests of cognitive functioning		
Montreal Cognitive Assessment (MoCA)[39]	Assesses different cognitive domains for rapid screening of mild cognitive dysfunction 30 points with cut score of 26 Rater: clinicians	10–15 mins
Mini-Mental State Exam (MMSE)[38]	Measure of cognitive impairment that examines multiple cognitive domains Rater: clinicians	10–15 mins
Mini-Cog[40]	Brief screening measure of cognitive impairment in older adults to be used in primary care setting Rater: clinicians	3 mins

sampling of standardized screening tools suitable for administration in multiple settings.

When delirium is suspected, the clinician should perform a full clinical assessment. Without a formal approach to assessment, clinicians risk misattribution (i.e., wrongly assuming the patient is tired, unmotivated, or unsociable) or misdiagnosis (i.e., concluding the patient is depressed or has a personality disorder). A clinical assessment should incorporate a mental status exam, review of the medical record, and clinical history. A comprehensive mental status assessment would include the use of cognitive screening tools such as the Mini-Mental State Examination (MMSE),[38] Montreal Cognitive Assessment (MoCA),[39] or Mini-Cog.[40] Table 23.2 also lists common screening tools and their features. Online training is available for many of these tools. Cognitive screening tools adequately assess cognitive function but do not adequately distinguish between delirium and dementia.[41] Questions required for a delirium workup can seem intrusive or bothersome to patients and families, but they are necessary to establish an accurate diagnosis. Once the diagnosis is established, questions should be limited to those necessary for periodic monitoring.

Examination of the medical record should include a review of vital signs, laboratory values (see Table 23.3), imaging results, and medications to identify possible causes of delirium and the need for additional testing, if appropriate. Collateral history should be obtained to clarify the patient's cognitive baseline and substance use. The time course of the recent mental status change should be considered as well. Since the onset of delirium is usually acute or subacute, understanding the time course aids in identifying possible etiologies and helps distinguish delirium from dementia.[42]

Assessing delirious patients may be challenging when patients are unwilling or unable to cooperate with the interview and workup. Even though delirious patients present as sad, withdrawn, or uncooperative, these presentations can mask the underlying confusion. Patients may present plausible-sounding rationalizations for their behavior and inability to grasp information. Statements such as "No one told me to stay in bed," "I was saving the pill for later," "I never know the date," "I don't answer silly questions," or "The nurse didn't explain things right" should not be accepted at face value. These defensive responses may represent unconscious attempts to appear rational when confused. Delirious patients may retain social skills despite deficits in cognitive function. Such patients may respond appropriately to casual questions, such as, "How are you feeling?" however, on specific questioning they may demonstrate difficulties with insight and problem-solving. In summary, delirium is more likely to be missed when depression, social withdrawal, or lack of cooperation are predominant presenting symptoms. Delirium may also be missed when the patient's social skills are preserved. In each of these scenarios, a comprehensive clinical assessment will reveal the underlying delirium. Figure 23.1 provides a decision tree to help guide the medical workup of delirium.

Table 23.3 Laboratory values when assessing for delirium

Lab	Why it matters
Complete blood count (CBC)	Rule out infection and anemia
Metabolic profile	Rule out dehydration, hypo/hypernatremia, hypo/hypercalcemia, other metabolic derangements
Liver function	Liver failure, hepatic encephalopathy
Blood/urine toxicity	Illicit or prescription drug toxicity
Urinalysis	Urinary tract infection
Thyroid function study	Hyper-/hypothyroidism
VDRL/RPR	Tertiary syphilis
B_{12}, folate, thiamine	Vitamin deficiency
Blood gases, pulse oximetry	Hypoxia, hypercapnia, acid–base abnormalities in blood

Management

An important aspect of palliative nursing care is preventing, treating, and managing delirium. As always in palliative care, the potential efficacy of any intervention must be weighed against the burden of treatment. According to Alici, Bates, and Breitbart, an ideal treatment goal in the palliative care setting is a patient who is awake, alert, calm, comfortable, without pain, cognitively intact, not psychotic, and communicating coherently with family and staff.[33] These benchmarks are good guidelines for judging how aggressively to intervene in cases of delirium. For example, a young person with excellent baseline function who becomes delirious during chemotherapy for a poor prognosis lymphoma might be expected to recover fully from a single episode of delirium. In contrast, a delirious geriatric patient with the same poor-prognosis lymphoma and multiple comorbidities might not recover from an episode of delirium.

Rather than hard and fast rules, clinical teams are urged to evaluate the impact of medical interventions after assessment of the patient's overall circumstances and the patient's previously expressed goals of care. Healthcare professionals should help the patient and family synthesize data to achieve a clear understanding of the "big picture." A single symptom or laboratory value might distract from an accurate understanding of the overall clinical scenario. For example, it might be possible to replace hemoglobin in a transfusion-dependent patient but not prevent multiorgan failure, so, in this case, hemoglobin replacement wouldn't impact the "big picture." A clear understanding of the patient's health status is a required component of goals of care discussions, but healthcare professionals should not wait for such discussions to clearly communicate the patient's complex health issues in relationship to treatment benefits and prognosis. For interventions to be considered beneficial, they must be achievable without undue patient burden and be sustainable for a meaningful period of time. Correcting primary causes of delirium may completely or partially resolve many instances of delirium and remains the preferred strategy when clinically and ethically feasible.

Healthcare professionals should enlist the family's assistance in caring for the delirious patient. Recognizing the complex nature of the modern family and the multitude of caregiving arrangements, the authors will use the terms "family" and "caregivers" interchangeably. Family members may understand the patient in ways healthcare professionals cannot. Seek input about the patient from family members; consider family to be experts on the patient's premorbid functioning. Caregivers may hesitate when they feel unsure about what to do. Involving the family fosters continuity in patient–caregiver relationships, reduces feelings of helplessness, and relieves some of the staff's burden. Caregivers will be

more willing to assist if they understand the rationale for their caregiving role, which may be emotionally uncomfortable and require new learning. Of note, caregiving may exacerbate preexisting tensions within the family unit. For instance, an adult child may be placed in the role of providing care for a parent she dislikes or with whom she has had a traumatic history. Sometimes out-of-town relatives continue to demand burdensome interventions long after local caregivers have shifted preferences to palliative measures. Healthcare professionals should anticipate family tension, attempt to identify the nature of the strain, and coach family members as part of routine comprehensive care.

The following case study highlights the multiple considerations in the care of the delirious patient. Some of these considerations have been previously described in the assessment section of the chapter. Other aspects of delirium, such as pharmacological and nonpharmacological treatments and family issues, will be discussed in subsequent sections of this chapter.

Case Study: A Patient with Delirium

CM was an 86-year-old woman with moderate dementia, anxiety, and a prior history of depression. She developed chest pain and confusion, was hospitalized and found to have suffered a myocardial infarction, her second. She remained confused. Further neurological workup revealed embolic strokes, but not of a sufficient size to adequately explain her delirium. Lab values were within normal limits. Because of her confusion, the patient's diazepam had been held, but now diazepam was resumed at her outpatient dose of 5 mg twice daily orally because of concerns about possible benzodiazepine withdrawal. Her confusion did not improve.

Code status was discussed with the patient's elderly spouse at the time of admission, late at night. He requested she be a full code. After subsequent discussions with nursing staff, it was clear the spouse, though highly educated, did not grasp the concept of code status. He said, "I don't want her to linger and suffer; if her heart stops, I want the code to be 'full' so they don't bring her back just 'part way.'" Clarification of the meaning of full code resulted in code status being changed to Do Not Resuscitate (DNR). Though she was DNR, the husband did not want her to "starve to death," so a feeding tube was placed.

Initially CM had lucid intervals when she spoke coherently to family members. CM had always had a difficult personality. One of her children commented that during her lucid intervals she was "nicer than she had ever been." Her delirium became persistent however, as she continued to deteriorate. She became agitated and aggressive, scratching and kicking at staff, and required restraints. Her spouse was concerned that she was aggressive because she was angry with her husband for bringing her to the hospital. After meeting with CM's nurse, the spouse seemed to benefit from an explanation of delirium and its symptoms, and understood his wife's aggressive behavior was probably not a meaningful attempt to communicate. The husband accepted a plan of care for comfort only and stopped insisting on tube feedings.

CM was started on quetiapine, and, at a dosage of 25 mg orally, at bedtime she became calm and only mildly sedated. She was then stable enough for discharge to home hospice care. She died peacefully there, with her husband at the bedside. He regretted there had been no deathbed resolution of their lifelong issues, blaming himself for CM's chronic unhappiness. He was reassured by staff and realized now that making peace with her would have to come from within himself.

Pharmacological Management

There is no pharmacological treatment for delirium itself,[15] but medications can be useful for managing symptoms that are distressing or interfere with care (see Table 23.4). Medications that can cause delirium, like anticholinergic drugs, steroids, and cannabinoids, should be avoided or used with special care in delirious patients.

When agitation, aggression, and paranoia occur in delirium, they can be effectively treated with antipsychotic medications.[33] Commonly used agents include quetiapine, risperidone, and haloperidol. The antipsychotics are equally effective for treating agitation, aggression, and paranoia.[43] For many clinicians, quetiapine is a first choice because it is least likely to cause extrapyramidal symptoms, such as muscle rigidity and tremor. The extrapyramidal symptom of akathisia can cause motoric overactivity, an urge to move that can resemble agitation. Quetiapine also has the potential advantage of being sedating. Risperidone, a more potent dopamine blocker than quetiapine, has greater risk of extrapyramidal side effects. Haloperidol, an older, high-potency antipsychotic, can be readily administered orally or intramuscularly and, in some settings, intravenously. Haloperidol is the standard treatment for acute agitation.

Benzodiazepines like lorazepam can reduce agitation but must be used with caution because they can cause delirium.[17,44] Benzodiazepines act on the GABA neurotransmitter system, which is widely distributed in the frontal lobes. Thus, benzodiazepines can cause behavioral disinhibition in much the same way alcohol does and must be used with care in delirious patients. The high-potency, short-acting benzodiazepine midazolam is sometimes used to produce complete sedation in agitated ICU patients. Benzodiazepines can also aid in reducing anxiety, regulating the sleep–wake cycle, and managing symptoms related to alcohol and central nervous

Table 23.4 Common medications used in the pharmacological management of delirium

Medication role	Medication type	Generic/brand name	Dose range/route
Agitation/psychosis	antipsychotic	Haloperidol/Haldol	0.5–5mg 2–3 times daily, PO/IM/IV
		Quetiapine/Seroquel	25–150mg daily PO
	benzodiazepine	Risperidone/Risperdal	0.25–2mg daily PO
		Lorazepam/Ativan	1–2 mg 3–4 times daily PO/IV
Alcohol/sedative withdrawal	benzodiazepine	Lorazepam/Ativan	1–2 mg 3–4 times daily PO/IV
Sleep–wake disruption	hypnotic	Zolpidem/Ambien	5–10 mg at bedtime PO
	hormone	Melatonin	3–6 mg at bedtime PO
Mood regulation	antipsychotic/mood stabilizer	Quetiapine/Seroquel	25–150 mg daily PO
	antidepressant	Escitalopram/Lexapro	5–10mg daily PO

system depressant withdrawal. Benzodiazepines, specifically lorazepam, are also very effective in treating catatonia. Benzodiazepines used in conjunction with haloperidol can be more effective for treating agitation than haloperidol alone.[45,46]

Delirious patients in whom affective symptoms, like tearfulness and weepiness, are prominent can be treated effectively with antidepressants, especially selective serotonin reuptake inhibitors (SSRI). End-of-life care sometimes requires high doses of pain medications, which can cause excessive sedation. Stimulants like methylphenidate can have a role in managing excessive sedation, although there is not enough evidence to recommend psychostimulants as standard treatment for hypoactive delirium.[33]

Some researchers have explored whether prophylactic use of antipsychotics, alpha-2 agonists, or melatonin might prevent delirium. Results in ICU and acute care studies have been mixed, with data suggesting need for further study.[12,23,33,47] Early research suggests that the alpha-2 agonist dexmedetomidine can be effective in both the treatment and prevention of delirium.[48] The use of dexmedetomidine may reduce postoperative delirium by as much as 50%.[48–51] However, the cost of dexmedetomidine has limited its widespread use.

Nonpharmacological Management

A wide array of nonpharmacological interventions may prevent delirium or limit its severity and duration.[5,15,47,52–54] Interventions which optimize overall functioning and thus prevent or mitigate delirium severity include preventing dehydration, optimizing nutrition and elimination, preserving sleep–wake cycles, maximizing mobility, and preventing or treating pain.[17,20,55] Limiting delirium-promoting medications and preventing or aggressively treating infection, electrolyte abnormalities, and hypoxia can reduce the incidence and severity of delirium.[20,56–58] Minimizing time on ventilatory support through frequent weaning challenges has been found to decrease the incidence and duration of delirium.[58,59] Finally, environmental interventions which facilitate sensory perception and communication have proved helpful.[6,15] Using environmental cues to maintain orientation, employing aids to overcome sensory impairment (e.g., glasses, hearing aids), and involving family in the patient's care are examples of environmental interventions. Evidence regarding the efficacy of nonpharmacological treatment has been mixed. However, many studies in ICUs, medical/surgical acute care, palliative, and hospice settings have shown a decrease in the frequency and duration of delirium in response to these interventions.[5,20,47,52–54,56] Interventions to prevent delirium have also resulted in other benefits including limiting decline in cognitive function among patients with preexisting cognitive impairment, fewer falls, and decreased use of hypnotics.[13,15,60]

Management

Since delirium is a global and fluctuating disorder, nursing care involves anticipating problems, not just responding to the patient's momentary performance status. Central to all interventions is establishing and maintaining a therapeutic alliance with the patient. Clinicians who cultivate a therapeutic relationship with patients (and their caregivers) will ease distress more successfully than those who focus on correcting the patient or enforcing rigid approaches to care.

Delirious patients may become difficult or socially inappropriate, causing caregivers to feel angry or embarrassed. Caregivers should understand that helping their delirious relative does not represent approval of present or past behaviors. Although a patient's behavior evokes unpleasant feelings in caregivers, a delirious patient can rarely control his or her behavior. Additionally, caregivers should be encouraged to care for themselves by realistically appraising their own needs and accepting help from others, rather than feeling guilty about their own limitations.

Safety

The healthcare team or family must assume ultimate responsibility for the patient's safety. With impaired cognition, patients often act impulsively or make ill-advised decisions. Patients may not understand, believe, or remember explanations about their own care, especially limitations on their autonomy. One should expect difficulties with eating and personal hygiene, attempts to dislodge tubes, neglect of ambulation restrictions, and wandering or efforts to leave against medical advice. Ensure tubes are in place, cover tubing so patients aren't distracted by it, reposition dislodged oxygen cannulas as needed, track and ensure adequate nutritional intake, encourage periodic toileting, track urine output, help the patient change positions, and maintain optimal mobility.

Physical restraints should be avoided, as recommended in the "Choosing Wisely" guidelines published by the American Geriatrics Society in April 2015.[61] Restraints can increase agitation, cause physical injury, and worsen psychological distress.[62] However, there may be rare instances when restraints are necessary. Each healthcare system should develop and adhere to guidelines for the safe and appropriate use of restraints, understanding that there are usually preferred alternatives including one-on-one monitoring and care provided by family or trained personnel. Ensuring safety absolutely includes preventing access to weapons, particularly firearms. Firearm access can be uncomfortable for healthcare professionals and caregivers to address.

Delirious patients aren't always agitated, but their unpredictable behavior mandates preparation for extreme scenarios. For example, delirious patients have been known to try escaping from moving cars while on the way to medical appointments. Providing simple explanations to the patient just prior to travel and asking a family member or friend to accompany the caregiver can help assure safety and limit caregiver burden. Consider enlisting the guidance of home care professionals if they are already working with the patient.

Communication

With difficulty attending to and processing information, even simple directions and explanations may puzzle, frustrate, or overwhelm the patient. Delirious patients may behave as if in their traditional roles (e.g., parent, executive) despite cognitive impairments. Patients may insist on illogical or unrealistic requests. Families who understand the nature of delirium will appreciate why they must act in the patient's best interest, even if this upsets the patient. Rather than feeling guilty for refusing their loved one, families can feel good about doing the right thing for their loved one in their time of need.

It is important to understand the purpose of your communication with the patient. For assessment purposes, some challenging questions may be necessary. Otherwise, therapeutic interventions should be calming and reassuring. Keep interactions pleasant and supportive; don't force conversations. Caregivers and healthcare professionals should avoid arguing with patients, whether about facts or opinions. State facts once in a noncritical, gentle manner.

If the patient tolerates inquiries, then simple concrete questions can be asked. It is reasonable to ask, "Are you in pain?" "May I give you a bath?" It is likely not helpful to ask, "What did the doctors say during yesterday's family meeting?" or explain, "Your sodium is low, and we're wondering whether to discontinue one of your medications or limit your fluids." Rely on the established therapeutic relationship and a kind, nonthreatening demeanor when seeking the patient's cooperation. "It's time for your MRI now," is more likely to result in a positive response than offering a complex explanation for the test. Some patients are more cooperative when family members are present. If so, work with family to coordinate visits with essential nursing and medical care.

Teaching caregivers how to interact with the patient by observing the caregiver's actual communication style can aid in management of the patient. Reinforce caregiver behaviors which facilitate successful delirium management. Healthcare professionals should convey instructions in as positive a manner as possible by limiting corrections. The goal is to have the family remain engaged with the patient. Provide support for attempts to be helpful whether or not the patient responds as one would have hoped.

Orientation

Patients may fluctuate in their level of orientation. They may be confused about the time of day (e.g., thinking it's daytime when it's the middle of the night), date (e.g., thinking it is April when it is actually October), or year (e.g., claiming it is 1918 rather than 2018). They may be disoriented to place (e.g., thinking they're home rather than in the hospital or that they've been taken to a jail rather than a healthcare facility). Usually patients know who they are, but may deny some aspect of their situation (e.g., "I'm not sick"). Disorientation sometimes includes not recognizing people they are familiar with. Gentle reorientation (e.g., "What a beautiful Fall day. I can see the leaves changing from your hospital window") is preferred to any attempts at orientation that upset the patient. Make use of clear environmental cues: light (natural, when possible) during the day, darkened room at night, visible clock and calendar, date and name of nurse on message board in the room. Avoid pressuring patients by repeatedly correcting them or excessively inquiring into orientation. Explain to caregivers how orientation counters feelings of disorganization and helps anchor patients so they can make sense of the world and feel less overwhelmed.

Sleep–Wake Disturbances

Sleep–wake disturbances in delirium can be difficult to correct. The delirium itself, lack of daytime stimulation, noisy nighttime environment, and bedrest may disrupt the ability to fall asleep, remain asleep, return to sleep after waking during the night, or awaken rested. Patients may get up in the middle of the night and begin unsafe, unsupervised tasks (e.g., cooking, house cleaning, hobbies), wander outside, or get in a car as if going to work. Sleep-deprived patients may be difficult to arouse during the day, resulting in missed opportunities for social interaction, nutritional intake, physical therapy, and more. The healthcare team and caregivers should facilitate clear day–night demarcation through environmental cues such as light–dark, noise–quiet, and activity–bed rest. Ensuring the patient has some activity during the day (e.g., a brief walk if health permits, moving from bed to chair, engaging in conversation with others) and a gentle transition to sleep at night (e.g., warm beverage if taking oral fluids, massage, dim lighting if a darkened room is upsetting, quiet surroundings, grouping of necessary medical care to decrease nighttime interruptions) can help normalize the sleep–wake cycle.

Ensuring adequate pain management is essential for decreasing agitation during the day and promoting sleep at night. When sleep disruption is severe, hypnotic medications may be necessary (see the section "Pharmacologic Management") even though hypnotics themselves may exacerbate delirium. Family members can help with time-consuming interventions such as keeping the patient awake and engaged during the day. Explain to families why awakening the patient is usually a better option than letting the ill person rest all day. Families can help prepare the patient for sleep by tidying the environment, playing quiet music, and offering gentle massage. When a full-body massage is impractical or unwanted, simply massaging hands or feet can be enough to soothe the patient. Normalizing sleep–wake cycles is an important goal except during a terminal delirium when death is imminent.

Environment

Calm, soothing environments can be beneficial in managing delirium. Delirious patients may perseverate on some aspects of their environment while ignoring other cues. Distorted perception is common. Patients may attribute meaning to innocuous background noise, misinterpret the identity of persons or items within their visual field, or experience frightening hallucinations. Placing familiar photos within view, encouraging the presence of family and friends, limiting the number of visitors at one time, providing consistent staff, and encouraging quiet conversation may be helpful. Ensuring the patient has access to assistive devices such as eye glasses, hearing aids, and dentures can help patients interact with the environment, feel safe, and decrease agitation. Familiar music can also soothe patients struggling to make sense of their environment. Take cues from the patient. That which is disturbing to one may be comforting to another. Sometimes variety helps relieve feelings of being closed in or trapped. A family member may be able to take the patient for a short walk or ride to enjoy a different view if the patient is calm enough to cooperate. Unfortunately, changing locations may also be disorienting for delirious patients who frequently misinterpret unfamiliar stimuli. Hospitalized patients may protest being taken from their rooms for procedures or tests. It helps if family or staff accompany patients to offer reorientation and reassurance.

Behavioral Interventions

Knowledgeable caregivers must adapt the environment to meet the patient's needs and adjust communication to match the patient's cognitive capacity. Covering tubing so the patient doesn't try to dislodge it or simplifying conversation so the patient remains calm are two examples of caregiver behaviors that can help delirious patients. While shared decision-making is a laudable goal, behavior modification techniques requiring patient insight and executive function have little role in the setting of delirium. For example, contingency limit-setting (e.g., "If you do x, I will do y") will only frustrate the delirious patient incapable of understanding complex instructions. Likewise, punishment, sometimes rationalized as a "consequence" for undesirable behavior, rarely improves the situation.

Goal-Setting

With impaired memory and executive function, delirious patients become easily overwhelmed. In delirium, it can be helpful to prioritize the multiple nursing and other medical care tasks. Some clinical tasks are more important than others. For example, if patients refuse a full bath, limit care to essentials to prevent infection and skin breakdown. Use enticements that appeal to the patient, rather than scientific logic. For example, "Let's get you dressed up for your wife's visit," might be more appealing than, "You haven't bathed in two days. That's not going to help you recover." If feeding is difficult, make sure foods are high value (i.e., high calorie, high protein, etc.) for maximal dietary efficiency. If the patient tends to refuse procedures, it may be helpful to schedule procedures in order of priority.

Collaborative Care and Clinical Pathways

Causes of delirium are usually multifactorial. Therefore, management interventions should target the multiple risk factors for the syndrome[33] as described throughout the "Management" section of this chapter. When these interventions are combined into single protocols or care pathways, they are referred to as *multicomponent* or *bundled interventions*. Sometimes known by their acronyms (e.g., HELP for Hospital Elder Life Program[60] and ABCDE + F for Awaken, Breathing, Choice of Sedative, Delirium Detection, Exercise, and Further Care[55,58]), multicomponent interventions usually share key characteristics, even though specific components vary. Bundled interventions stress (a) integration of delirium protocols into routine care; (b) adherence to all aspects of the protocol; (c) multidisciplinary participation from nurses, physicians, pharmacists, rehabilitation therapists, and relevant specialists for assessment and treatment; d) collaboration and coordination via team rounding, consultation, and documentation; and (e) sometimes inclusion of family or volunteers to implement parts of the intervention. In addition to assisting with direct patient care, family members may help track the patient's progress and communicate aspects of the treatment plan to other family, friends, and even healthcare professionals who interact with the patient. Benefits of implementing multicomponent interventions varied from decreasing the incidence of delirium to mitigating the severity and negative sequelae of the syndrome, to decreasing healthcare costs.[15,20,47,53–58,60,63,64]

Despite the prevalence of delirium, many healthcare professionals lack sufficient knowledge to understand, assess, diagnose, prevent, and manage delirium.[3,4,21,63,65–68] Since education alone is rarely sufficient to change practice, the use of protocols or clinical care pathways is recommended for the prevention, diagnosis, and management of delirium.[59]

Legal and Ethical Considerations

In those nations where adults are treated as autonomous individuals, patients have the right of self-determination, including control over their own bodies. When a patient's ability to exercise informed judgment is in doubt, certain healthcare professionals may be granted the legal authority to evaluate the patient's decision-making capacity. These healthcare professionals determine capacity by evaluating whether a patient is capable of understanding (1) the nature of a problem, (2) that a decision has to be made about the problem, (3) the consequences of the various clinical decisions, and then (4) whether the patient can integrate the necessary information to arrive at a decision consistent with the patient's values.[69] For example, to demonstrate capacity, a patient might need to recognize his diagnosis of kidney failure, understand why dialysis is being offered, consider the sequelae of accepting or declining dialysis, and then consider which decision fits more closely with his values or goals of care.

Delirious patients, by definition, have difficulty performing the four cognitive tasks required to maintain capacity. Of note, capacity is always narrowly defined. "Capacity for what?" is the operative question. Some patients lack capacity in a global way. Others may retain capacity in certain limited circumstances. Failure to recognize lack of capacity leaves delirious patients vulnerable to making uninformed and potentially harmful decisions which the patient would not have made if able to think clearly. If a patient appears confused or makes decisions a reasonable person would not have made, it is the healthcare team's responsibility to initiate a capacity evaluation as part of the care of the delirious patient.

That said, patients *with* capacity have the right to make ill-advised decisions, although caring professionals should attempt to inform, caution, and even persuade competent persons to make choices consistent with the patient's values. When a person lacks capacity, protection must replace persuasion. It isn't ethical or safe to rely on persuasion when a patient's cognitive capacity is too compromised to understand or cooperate. Protection takes the form of surrogate decision-making through identification of durable power of medical attorney, an identified medical patient advocate, or a court-appointed guardian ad litem. Most states have established hierarchies by statute for designating which relative becomes the official surrogate if the patient has not previously identified an advocate. Challenges arise when designated decision-makers disagree with other involved caregivers or when decision-makers lack some of the attributes of ideal surrogates (i.e., interested, involved, knowledgeable, caring, without personal agendas, and devoted to exercising decisions consistent with the patient's values and wishes).

Capacity, a clinical status determined through assessment by a healthcare professional, is distinguished from *competency*, a legal status which can only be determined by a court. In the United States, laws vary by state. Typically, Probate Courts process applications to declare a person incompetent and in need of a guardian. The procedure involves providing a court-appointed advocate for the patient to ensure patients do not lose their rights because of the whims of others or simply because the patient disagrees with medical advice.

In addition to questions of capacity and competency, a common ethical challenge in the setting of delirium is the question of whether certain medical interventions are appropriate, even when the healthcare team, patients, or families request these interventions. This issue is addressed in the "Nonpharmacological Management" section of this chapter. When questions about goals of care, beneficial/nonbeneficial treatment, capacity, and competency arise, consult with experts in palliative medicine, behavioral health, bioethics, or similarly prepared individuals who can provide guidance to the primary team.

Conclusion

Delirium is a common and important problem in the palliative care setting. Though delirium is sometimes an unavoidable consequence of severe illness and complex care, it may be possible to prevent delirium or mitigate its consequences. The use of systematic screening and clinical care pathways are highly recommended. Early recognition and appropriate treatment can avoid some of the severe burden this disorder imposes on patients, caregivers, and healthcare systems.

CHAPTER 24

Insomnia

Karla Schroeder

Key Points

- Insomnia is a symptom of impaired sleep that is characterized by inconsistent or ineffective sleep patterns.
- Assessment is a key component in the identification of insomnia.
- It is important to control insomnia symptoms for persons with serious illness.
- The plan of care should directly address the cause of insomnia.
- Cognitive-behavior therapy (CBT) is the first-line treatment for insomnia, with pharmacological interventions used as appropriate.

Introduction

Suffering from insomnia is an everyday problem for those with serious illnesses.[1–7] Comorbid conditions as well as symptomatology often contribute to insomnia. For the palliative care population, poorly managed insomnia is reported as a widespread symptom.[1–3]

Management of insomnia requires understanding and assessment of the multidimensional elements of the condition. These include the physical, emotional, psychosocial, and spiritual aspects affecting quality of life (QOL) and care.[1,2,5–7] Although insomnia is a common symptom of persons with serious illness, it remains undermanaged, and research is limited. This chapter provides a model for assessment and intervention, using a holistic approach to care for those who suffer from insomnia due to a serious illness.

Definition of Insomnia

The American Academy of Sleep Medicine defines insomnia as a subjective, self-reported experience.[3] Insomnia is characterized by chronic dissatisfaction with sleep quantity or quality, typically associated with difficulty falling asleep, frequent nighttime awakenings with difficulty returning to sleep, and/or awakening earlier in the morning than desired.[1,3–11] Insomnia is further characterized by its symptoms: functional daytime impairment such as fatigue, sleepiness, cognitive impairment, and disturbances in mood.[1,3–5,7,9–11] Insomnia is considered chronic if sleep disturbances occur more than three times per week, for a period longer than 3 months. These adverse effects can lead to a significant impairment to QOL.[1,7,12,13]

Diagnosis

Criteria for diagnosing insomnia based on the International Classification of Sleep Disorders include difficulty initiating and/or maintaining sleep and/or early waking/awakening.[1,3,5,6] This equates to 20–30 minutes or more of sleep latency.[1,3,5,6] Difficulty with sleep occurs despite adequate opportunity and circumstances to sleep which are not explained by another disorder.[1,3,5,6] Additional criteria include some type of daytime impairment due to difficulty with sleep. Daytime impairment related to difficulties in sleep may include fatigue, malaise, difficulty concentrating, memory impairment, or alteration in mood.[1,3,5,6]

Prevalence and Impact

Insomnia is among the most prevalent, distressing, and undermanaged symptoms experienced by persons with serious illness.[1–7] The prevalence of insomnia and associated symptoms in seriously ill persons is estimated at 70%.[6,12] However, prevalence of sleep disturbances for patients with serious illness varies by diagnosis. This equates to 24–95% of persons with cancer, 50% of persons with pulmonary disease, 35% of persons with heart disease, and 75–95% of persons with Parkinson's disease.[1,4,6,12,14] The wide error in margin may exist due to underreporting. Insomnia is associated with increased rates of depression, decreased QOL, and increased fatigue in persons with serious illness.[1,10] Further effects of poor sleep patterns include increased risk for anxiety, depression, cardiac disease, and increased mortality.[1,4,9,10] Without intervention, insomnia remains consistent from time of diagnosis throughout the trajectory of the illness.[1]

Case Study: A Patient with Insomnia

A 50-year-old woman was seen by her home health nurse. She had complaints of sleepiness during the day and the inability to sleep at night. Through further assessment and information gathering, the home health nurse noted a diagnosis of congestive heart failure and chronic obstructive pulmonary disease (COPD), along with use of an angiotensin-converting enzyme (ACE) inhibitor, diuretics, and bronchodilators. The woman told the nurse she felt "jittery," got up at night to urinate, and that "taking all that medication before bed makes my stomach hurt." The nurse asked her to expand further on her bedtime routine. She discovered that the patient often watched TV, then changed into her bed clothing and took her medications, including diuretics and bronchodilators at around 9:00 P.M., prior to going to bed. She also noted that she did not fall asleep until after midnight, awakened around 10:00 A.M., then was napping from 2:00 P.M. to 5:00 P.M. to make up for lost sleep. She also reported that her inability to sleep worsened after her husband passed away 6 months ago. She told the nurse that she had been with her husband for 25 years and had not slept alone since they were married. She expressed fear related to his end-of-life journey and concern as to how her life journey would end.

This case presents many potential causes of insomnia, including physical, emotional, spiritual, social, and treatment-related issues which could contribute to the woman's inability to sleep.

Pathophysiology

The pathophysiology of insomnia consists of multiple factors which include complex biological coordination and genetics.[1,5,11] Understanding the pathophysiology of insomnia for the individual may guide potential treatment options.[1,5,9,11,15]

Insomnia is multifocal and may coexist with physical, social, spiritual, and emotional components. Insomnia may be associated with stress, medications, substance use, poor sleep habits, or the environment.[1,3,5–9,11,15] Risk factors for insomnia include being female, older, or possessing certain comorbid conditions, personality traits, menopausal symptoms, or hyperarousal.[1,9,15]

The sleep cycle is a highly structured and well-organized activity following a circadian period.[1,5,9,11] The circadian rhythm directs the sleep–wake cycle and is regulated by a combination of biological processes and environmental factors.[1,5,9,11] Interruption of circadian rhythms may be a factor in insomnia.

Research also shows that patients with insomnia have higher day and night body temperatures, urinary cortisol, adrenaline secretion, and adrenocorticotropic hormone (ACTH) than patients with normal sleep patterns.[9] Insomnia is most likely to develop in those who have increased genetic risk and who experience abnormalities in neurobiological processes.[9]

Contributing Factors for Insomnia

Physical Factors

The preceding case study provides an example of insomnia as it correlates to comorbid conditions and treatments. Comorbid medical conditions which may increase the prevalence of insomnia include stress, asthma, COPD, gastroesophageal reflux disease (GERD), chronic pain syndromes, obesity, congestive heart failure (CHF), angina, hyperthyroidism, restless leg syndrome, or diabetic neuropathy.[3,4,9,10,15,16] Persons with serious illness may have shortness of breath, pain, fear, anxiety, and/or urinary frequency associated with these illnesses.[1,10] Lack of symptom control has been reported to be one of the most prevalent reasons for insomnia in the palliative care population.[1] Additionally, the treatments used during care for persons with serious illnesses may cause insomnia. Medications such as corticosteroids, bronchodilators, caffeine, chemotherapeutic agents, amphetamines, anticonvulsants (phenytoin), or diuretics may negatively impact the ability to rest without disturbance.[1,2,10,16,17]

Assessment for Physical Factors Contributing to Insomnia

When performing a thorough insomnia assessment, a holistic approach should be used to detect causes of impaired sleep patterns (Table 24.1). The physical and medical assessment includes a general medical, psychiatric, and determination of comorbid conditions.[2,5,16,17] The initial clinical assessment should focus on reversible factors which may be contributing to a sleep disturbance.[2,3,5,16,17] Box 24.1 outlines the essential

Table 24.1 Selected tools to assess sleep

Tool name	Description
Insomnia Symptom Questionnaire	Assesses and characterizes symptom burden
Insomnia Severity Index	Assesses and characterizes symptom burden
Athens Insomnia Scale	Assesses and characterizes symptom burden
Iowa Sleep Disturbances Inventory	General screening tool. Identifies underlying factors which contribute to the symptoms of insomnia to direct initial treatment recommendations
Auckland Sleep Questionnaire	General screening tool for contributing insomnia factors Identifies underlying factors which contribute to the symptoms of insomnia to direct initial treatment recommendations
Pittsburgh Sleep Quality Index	Useful screening tool Limited accuracy for specific sleep disorders
Global Sleep Assessment Questionnaire	Useful screening tool. Evaluates for seven different types of sleep disorders: insomnia, insomnia with mental disorders, shift work sleep disorder, sleep apnea, restless leg syndromes, periodic limb movement disorder, and parasomnias. Low specificity Limited usefulness as a diagnostic tool.

Box 24.1 Assessment of Insomnia

1. Assessment of sleep
    a. Subjective perception of reduced sleep time
    b. Description of sleep–wake patterns and variability
    c. Timing sleep pattern disturbances
    d. Daytime sleepiness or other daytime alterations
        i. Symptoms of daytime tiredness: fatigue, napping
2. Physical assessment
    a. Neurologic exam to include symptoms of restless leg syndrome
    b. Obesity
    c. Examine head and neck: neck circumference
    d. Crowded oropharynx
    e. Lab values
        i. Ferritin, magnesium, renal function, and vitamin B_{12}
3. Symptom assessment
    a. Pain
    b. Cough
    c. Shortness of breath
    d. Urinary frequency
    e. Anxiety

(*continued*)

Box 24.1 Continued

4. Medication and substance assessment
    a. Evaluate medications which may contribute to insomnia (beta or calcium channel blockers, antidepressants, steroids, stimulants, cold preparations, herbal or over the counter medication)
    b. Use of tobacco, caffeine, alcohol, or illicit drugs·

Source: References 12, 13, 20–24

components of the physical assessment.[3,5,15–18] The individual should be consulted in determining the most appropriate treatment modality.

Nursing Intervention for Physical Factors Contributing to Insomnia

In the case study presented earlier, the nurse first inquires about the physical aspects of insomnia: the sleep–wake cycle, sleep hygiene, and treatment-related issues. The nurse should counsel the patient about taking medications that may inhibit sleep earlier in the day, as opposed to directly before lying down. The nurse could instruct the woman to use the twice-daily bronchodilators when she awakens in the morning and at supper time and to take her once-daily diuretic in the morning. This will reduce the number of times the patient is awakened to use the bathroom and decreases bedtime "jitters" due to medications. Other instructions could include decreasing the amount of fluids in the hours prior to bedtime, avoiding caffeine after noon, or placing pillows in pain points. Taking a shower or bath before bedtime can assist with creating a bedtime routine as well as improving relaxation and decreasing pain. The nurse may suggest a referral to a licensed mental health professional for cognitive-behavioral therapy (CBT).[4,5,7,13,18,20,21] If such changes along with CBT do not work, a pharmacological intervention may be necessary.[1,3,5–7,9,11,13,17,18,20,21]

Environmental Factors Contributing to Insomnia

People with serious illness may also experience sleep pattern disturbances that are related to treatment locations, diversion from normal sleep routines, and light, as well as unfamiliar or noisy environments.[5,15,17,18] For example, the person may experience frequent hospitalizations which can exacerbate insomnia and/or other symptoms.

Assessment for Environmental Causes of Insomnia

The person's sleep environment should also be assessed to remove obvious stimuli and create an atmosphere conducive to sleep.[5,6,7,11,16–18,20] Environmental assessment should include:

- Light
- Noise
- Phone, computers, tablets, and other electronic devices
- Hospitalization
- Moving to an unfamiliar environment
- Television

Nursing Intervention for Environmental Factors Contributing to Insomnia

The nurse should inquire about the patient's bedtime, waking time, and napping time. She could instruct the person to decrease daytime napping and/or to nap earlier in the day. This would promote improved sleep–wake patterns. The nurse should instruct the patient to remove extraneous environmental stimuli and reduce noise stimuli by turning off the television; decreasing the number of visitors during the time of sleep; reserving the bedroom for sleep and sexual activities as opposed to reading, television, crossword puzzles, video games, or other mentally stimulating activities; and reducing the amount of light by using blackout curtains or removing unnecessary lighting. A night light in the bathroom instead of a bright overhead light will decrease stimuli at night. For the hospitalized patient or a person receiving around the clock care, nurses should group care tasks together to provide less environmental interruption of sleep.

Cognitive, Emotional, Existential Factors Contributing to Insomnia

Insomnia may also be caused by cognitive, emotional, and existential factors. Persons with chronic insomnia appear to have hyperarousal or increased somatic cognitive and cortical activation within the brain.[9] This also has been described as cognitive and emotional hyperarousal at night.[9] Hyperarousal in the physiologic, emotional, or cognitive networks is believed to prevent sleep regulatory processes from naturally occurring in patients with insomnia.[1,9] Persons with serious illness may also experience sleep pattern disturbances that are related to diagnosis, family, fear, anxiety, anticipatory grief, or stress.[1,2,5] Cognitive and behavioral mechanisms affect insomnia regardless of how insomnia is caused.[1,9,10,14,21,22] Persons may have misconceptions about normal sleep requirements and changes in needed amount of sleep.[1,4,6,11] This can lead to excessive worry about not having adequate sleep and create a cyclical pattern.[1,4,6,11] For example, the more a person worries about the inability to sleep, the more disrupted the sleep becomes.

Assessment for Cognitive, Emotional, Existential Factors Contributing to Insomnia

A proper assessment for insomnia should also include focus on cognitive, emotional, and existential issues which may be the cause.[5–7,10,11,16,19,20] For example, taking daytime naps, sleeping in late, or prolonged time in bed reduces the natural homeostatic drive to sleep within a person's natural circadian rhythm.[1,6,7,9,11] Patients develop a conditional arousal to stimuli that would normally be associated with sleep (i.e., heightened anxiety about going to sleep once they are in the bedroom).[1,4–7,9,11] Patients then develop a cycle in which the more they strive to sleep, the more agitated they become.[1,6,9] The patient may have ruminative thoughts or clock-watching behavior as he or she tries to fall asleep.[1] Assessment should include:

- Current or past stressors
- Sleep patterns prior to illness
- Sleep hygiene
- Fears, concerns
- Sleep–wake patterns

Nursing Intervention for Cognitive, Emotional, Existential Factors Contributing to Insomnia

In the case study, the nurse can intervene by providing instruction and supportive communication skills. The nurse would explain the importance of creating a pre-sleep routine such as going to bed at the same time every night and awakening at the same time every morning.[5–7,10,11,16,19,20]

Other ways to create improved sleep hygiene patterns include setting alarms or limiting daytime napping to 30 minutes.[5–7,10,11,16,19,20] Once a person encounters an inability to sleep, the person should rise from bed, remain in a dark room, sit up in a chair, and avoid stimuli such as the television or electronic devices.[5–7,10,11,16,19,20] This will help disconnect the bed from the inability to sleep.[5–7,10,11,16,19,20]

It is important to consider where the person is within their disease trajectory and their individual needs. Do they need to rest whenever possible based on clinical presentation? When end of life is near, provide instructions to both the patient and family regarding the likelihood of increased sleep.

When addressing emotional, social, or existential issues surrounding insomnia, consider fears of being alone, life changes, and grief, which may increase nighttime sleep difficulties. The nurse in the case study should provide supportive communication concerning the husband's death, taking the time to listen to the patient's concerns and provide social work, chaplaincy, and mental health referrals for further support and possibly CBT.

Management

Care of insomnia initially includes treatment of comorbid medical and psychiatric conditions, modifying sleep-hindering medications and substances, and optimizing environmental factors. Thus, the initial strategies for treating insomnia are to assess for underlying reasons that may be contributing to the sleep disturbance.[5–7,10,11,16,19,20]

Once the insomnia factors have been identified and addressed, treatment for insomnia may then proceed to other interventions. The treatment for insomnia for persons with serious illness should include both pharmacological and nonpharmacological interventions. The American College of Physicians recommends CBT as the initial treatment intervention for persons with chronic insomnia based on the clinical need.[1,4,5,10,11,13,21–23] Prognosis should be considered in therapeutic recommendations, as CBT takes time. If the person has a prognosis of several months, both CBT and pharmacological interventions should be incorporated into the plan of care.[1,4,5,13,21–23] Incorporating shared decision-making between patient and provider is key for successful treatment.[1,4,13,23]

Nonpharmacological Interventions

Several nonpharmacological interventions have been used for the treatment of insomnia within the general patient population. Evidence exists supporting the use of sleep hygiene, behavior therapies, and relaxation techniques. However, for persons with serious illness, limited studies are available to determine the efficacy of nonpharmacological interventions for insomnia. It is important to understand that CBT requires effort, participation, and time, which may make it inappropriate for persons who are at end of life.[4,10,13,14,21,22]

Cognitive-Behavioral Therapies

The American Academy of Sleep notes that CBT has been identified as the first-line treatment for insomnia.[4,10,13,14,21,22] For some patients, CBT therapies have produced significant improvement in the quality and duration of sleep. CBT used as part of the treatment for insomnia addresses the maladaptive processes and limits behaviors which cause insomnia.[1,3–5,10,13,14,21,22] In CBT, mental health clinicians address the relationship between thoughts, behavior, and meaning around difficulty with sleeping.[4,10,13,14,21,22] CBT works to help change unhelpful thought patterns and one's relationship to the thoughts.[4,10,13,14,21,22] Not all persons with insomnia will benefit from CBT alone. Many contributing factors such as inability or unwillingness to participate affect the successfulness of CBT.[4,10,13,14,21,22] Pharmacotherapy, in combination with CBT, should be considered for persons who are unsuccessful with CBT alone or for whom CBT is inappropriate.[4,7,10,13,16,19,21–23]

CBT to address insomnia usually consists of education on sleep hygiene, relaxation training, stimulus control, sleep restriction, and cognitive therapy.[1,4,10,11,13,14,21,22] The nurse can provide sleep hygiene education and assist with multidisciplinary team referrals.

Complementary Therapies

Complementary therapies are interventions generally not considered to be part of conventional medicine. For persons with serious illness, several complimentary therapies are available when appropriate, including massage, aromatherapy, Reiki, reflexology, mindfulness-based stress reduction, guided imagery, and/or acupuncture.[1] For some people, these therapies have improved sleep quality, duration, and efficiency; allowed use of fewer medications; and provided less daytime dysfunction.[1] Complementary therapies are based on the person's individual causes for sleep pattern disturbance and should be incorporated based on individual preference. For example, for persons whose insomnia is caused by elevated stress, some of the complementary therapies may be helpful.

Exercise Interventions

Exercise interventions involve any planned, structured, and repetitive bodily movement that are performed to condition any part of the body, improve health, or maintain fitness.[1] Exercise interventions assist with the regulation of activity and may improve the sleep–wake cycle.[1] Exercises should be completed in morning or early afternoon hours.[1] Exercise is based on the individual person's capabilities as well as clinical status. For example, passive range of motion, walking, stretching, or yoga may be appropriate.[1] Care should be taken to ensure safety during exercise. Studies have shown that exercise interventions improve mood, decrease depression, and improve the sleep wake–cycle for patients with serious illness and cancer.[1]

Several studies have noted that the use of nonpharmacologic therapies is first-line treatment for insomnia and may improve chronic insomnia, mood, long-term sleep quality, and/or depression (see Table 24.2). Nonpharmacological interventions are also recommended for older persons and those who use sedating medications.

Pharmacological Interventions

Pharmacological interventions should not be first-line treatment for insomnia.[3,5,6,7,11,16,19,23,24] Recommendations regarding pharmacotherapy must be considered within the context of specific treatment goals, comorbidities, prior treatment responses,

Table 24.2 Nonpharmacologic therapies for insomnia

Drug class	Common medication	Common doses	Recommended use	Research efficacy for the improvement of sleep	FDA-approved for insomnia
Orexin receptor antagonist	Suvorexant	10 mg, 15 mg, 20 mg	Sleep onset and/or maintenance	Moderate	Yes
Nonbenzodiazepines	Eszopiclone	≥2 mg	Sleep onset and sleep maintenance	Moderate to large	Yes
	Zaleplon	≥5 mg	Sleep onset	None	Yes
	Zolpidem	≥5 mg	Sleep onset and sleep maintenance	Moderate	Yes
	Zolpidem extended-release	≥6.25 mg	Sleep onset and sleep maintenance	Moderate	Yes
Benzodiazepines	Triazolam	≥0.125 mg	Sleep onset	Moderate	Yes
	Temazepam	≥7.5 mg	Sleep onset and maintenance	Small	Yes
Melatonin agonists	Ramelteon	≥8 mg	Sleep onset	None	Yes
	Melatonin	1 mg, 2 mg, 3 mg, 5 mg, 10 mg	Not recommended	Small	No
Antidepressants	Doxepin	>6 mg	Sleep maintenance	Small to moderate	Yes
	Trazodone	50 mg	Not recommended	None	No
Anticonvulsants	Tiagabine	4 mg	Not recommended	None	No
Over-the-counter preparations	Diphenhydramine	25 mg, 50 mg	Not recommended	None	No
	L-tryptophan	250 mg	Not recommended	Small	No
	Valerian		Not recommended	Unreported	No

availability, safety, patient preferences, and cost.[3,5–7,11,16,19,23,24] Pharmacologic management of unrelieved symptoms should be maximized if these are the underlying cause of insomnia. Medication can be used for insomnia which persists despite maximal symptom management and/or alternate treatments such as CBT.[3,5–7,11,16,19,23,24] Medications should not be used alone, but rather in conjunction with other methods of treatment such as CBT. [3,5–7,11,16,19,23,24] Medication considerations should include safety, pharmacokinetic profile, past treatments, and benefit versus harm.[4,6] Pharmacological intervention for insomnia should be used as a temporary adjunct or for persons who cannot participate in CBT.[3,5–7,11,16,19,23,24]

Caution should be taken when using pharmacological agents. For example, medication interactions, risk for falls, cognitive impairments, dependence, and adverse reactions should be thoroughly reviewed. Pharmacological agents currently approved by the US Food and Drug Administration (FDA) for the treatment of insomnia include benzodiazepines, nonbenzodiazepines, melatonin-receptor agonists, and histamine-receptor antagonists and are listed in Table 24.3.[1,3,5–7,11,16,19,23,24] Other medications which have been used to treat insomnia include tricyclic antidepressants, antihistamines, or antipsychotics because of their sedating effects.[1,3,5–7,11,16,19,23,24] Sedating medications should be carefully considered for each person based on indication for use, plan of care, and safety.

Over the past 20 years, pharmacological treatment of insomnia has declined. This may be linked to the potential for tolerance and

Table 24.3 Pharmacological interventions for insomnia

Therapy	Techniques
Sleep hygiene	Activity as tolerated with elimination of exercises 4 hours prior to bedtime. Avoid large meals Limit fluid intake in the evenings Limit caffeine, tobacco, alcohol Bedroom for sleep and sex only Maintain routine sleep–wake cycle Decrease daytime napping Decrease distracting stimuli close to time of sleep, such as noise, lights, computers, phone, television, extreme temperatures
Stimulus control	Lie down in bed for sleep only when sleepy Bedroom for sleep and sex only Avoid wakeful activities at bedtime, television, phone, eating Leave the bed if unable to fall asleep within 20 minutes, do not engage in stimulating activity, return to bed when sleepy Maintain sleep–wake cycles, set alarm, go to bed at the same time
Sleep restriction	Limit napping during the day Arise from the bed when awake

(*continued*)

Table 24.3 Continued

Therapy	Techniques
Relaxation	Imagery Mindfulness Meditation Hypnosis Yoga Abdominal breathing Progressive muscle relaxation
Cognitive therapy	Counseling Identify and replace dysfunctional beliefs regarding sleep Address overestimation and apprehension about sleep Journaling
CBT	Combination of cognitive therapies, stimulus control, sleep restriction therapy, relaxation

dependence and increased efficacy of CBT.[3] Despite the number of medications that can be used to treat insomnia, there is little high-quality evidence to support their use.[3]

Orexin Receptor Agonists

A new class of medication with moderate supporting evidence for the treatment of insomnia are the orexin receptor agonists. The orexin receptor is a G-protein-coupled receptor that binds the neuropeptide orexin. Suvorexant is the first-in-class dual orexin receptor antagonist for the treatment of insomnia; it was approved by the FDA in 2014.[24]

Benzodiazepine Receptor Agonists

There is moderate evidence to support the use of benzodiazepines for short-term relief of insomnia in the general population.[1,3,5–7,11,16,19,23,24] However, benzodiazepines are not recommended for the treatment of insomnia for persons with serious illness as they may cause symptom rebound.[5–7,11,16,19,23] Symptoms that may increase or rebound in persons with serious illness include anxiety or agitation.[5–7,11,16,19,23] Short-acting benzodiazepine receptor agents, newer benzodiazepines, or ramelteon are recommended as a treatment of insomnia.[1,3,5–7,11,16,19,23,24] Although benzodiazepines can be effective medications, they have several unwanted side effects, such as daytime drowsiness, dizziness, or light-headedness; cognitive impairments; motor coordination; tolerance; dependence; rebound insomnia; and daytime anxiety.[1,3,5–7,11,16,19,23,24] Benzodiazepines should be used with caution and are not recommended for older persons.

Nonbenzodiazepine Receptor Agonists

Nonbenzodiazepines are the most widely used medications in the treatment of insomnia. Examples of nonbenzodiazepines include zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta).[1,2,4–6,10,12,18,19] Nonbenzodiazepines are not recommended for long-term use or older persons.[25] Nonbenzodiazepines may worsen delirium.[25]

Sedating Antidepressants

Antidepressants have been increasingly used for the management of insomnia. Tricyclic antidepressants such as amitriptyline, doxepin, trazodone, and mirtazapine may provide a sedating effect.[1,3,5–7,11,16,19,23] Caution should be exercised in using sedating antidepressants such as trazodone and mirtazapine in the older population, with a black box warning for suicidality.[1,3, 5–7,11,16,19,23,24] Other risks include falls and increase in QT intervals.

Melatonin-Receptor Agonists

Melatonin-receptor agonists appear to have minimal side effects and a decreased potential for abuse or dependence. The only melatonin-receptor agonist approved by the FDA for the treatment of insomnia at this time is ramelteon.[1,3,5–7,11,16,19,23]

Others

Other classes of medications have been used "off label" to treat insomnia, including antidepressants, antihistamines, atypical antipsychotic agents, and neuroleptics. Antihistamines such as diphenhydramine and hydroxyzine are used for their sedative properties as well as for their anticholinergic properties.[1,3,5–7,11,16,19,23] Older persons tend to have negative cognitive effects when taking anticholinergic medications and thus these are not recommended. Neuroleptics, such as thioridazine, may promote sleep in persons with insomnia associated with organic mental syndrome and delirium.[1,3,5–7,11,16,19,23,24]

Ingestible Herbal Therapies

Several ingested herbal supplements are currently being used for managing insomnia, especially chamomile, hops, lavender, passionflower, California poppy, kava kava, St. John's Wort, lemon balm, valerian, and melatonin.[1,25] Although widely used, herbal supplements do not undergo rigorous regulation or clinical trials to determine efficacy and side effects and thus are not recommended by the FDA.[1,25] The studies evaluating the benefits of herbal therapies for managing insomnia have produced inconclusive or contradictory results.[1,25] Many people use herbal over-the-counter remedies, thus it is important to have a working knowledge of them.

Conclusion

Insomnia remains a common and distressing complaint for persons living with serious illness and contributes to a decreased QOL. Physical, medical, social, emotional, and spiritual factors have been linked to insomnia. Effective management of insomnia begins with a thorough assessment that includes the exploration of predisposing factors such as unmanaged symptoms, change in usual sleep patterns, emotional stressors, comorbid conditions, and medication.

Nurses in palliative care are key investigators in helping analyze the causes of insomnia and providing interventions to assist in improving sleep. The interventions suggested after the case study may allow the individual to create improved sleep–wake patterns and sleep hygiene practices. In the case presented here, the person's social and spiritual needs were related to her husband's death, fears, and possible anticipatory grief. The suggested interventions might allow the person to have restful nightly sleep, in addition to suggesting a shorter napping period during the day.

Nurses are challenged to integrate education within the plan of care to promote healthy sleep patterns as well as advocate for appropriate multidisciplinary referrals. Unfortunately, there is little research on insomnia in patients living with serious illness. More research is needed to fully understand the etiology and treatment modalities for patients with serious illness.

CHAPTER 25

Sexuality and Intimacy in Serious Illness and at the End of Life

Heather Shaw and Joshua Fronk

Key Points

- Sexuality and intimacy are different.
- Sexuality and intimacy are key human experiences that are impacted by serious illness and end of life.
- Palliation of sexual and intimate issues in advanced illness needs a multidisciplinary approach with attention to the physical, emotional, social, and spiritual aspects of care and quality of life.
- People with serious illness want to talk about their sexual functioning and intimate relationships.

Sexuality and Intimacy: Why They Are Different and Why It Matters

Case Study: A Patient with Congestive Heart Failure

Leo is a 75-year-old man with congestive heart failure who loves to salsa dance, work in his vegetable garden, and spend time with his wife, Rosa. Prior to and following his diagnosis, Leo experienced steady functional decline and weight loss. His symptoms, including dyspnea, required diuretics and long-acting opioids for management. Following repeated hospitalizations, conversations about hospice were initiated. Durable medical equipment (DME) was recommended to specifically improve safety in the home and help conserve energy overall. Following the recommendation for a hospital bed, Leo quietly inquired, "Would Rosa be able to lay in the bed with me?" Clarifying this response, Rosa was able to share that they had been sleeping together in the same bed for more than 50 years. Neither of them could contemplate such a big change and expressed a lot of concern about being able to sleep without lying next to one another.

The emotional and physical ties between people are a cornerstone of the human experience. Humans use their bodies to communicate emotions such as desire, affection, fear, and loss—the use of the physical person is just as powerful as the use of language. Kind words from a friend or the touch of a beloved person can turn one's day and mood for the better. Conversely, a lack of eye contact or a harsh tone of voice connotes more negative emotions and responses. The human need to communicate, to connect, and to make meaning out of life experiences holds true across the life span. In healthcare, there is an obvious focus on physical health and much time is dedicated to optimization of physical functioning. However, humans are very sociable creatures and interactions play a significant role in both physical and emotional well-being as well as in overall quality of life (QOL).[1]

The World Health Organization (WHO) currently defines *sexuality* as, "A state of physical, emotional, mental and social well-being in relation to sexuality . . . a central aspect of being human throughout life encompasses sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction. Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviors, practices, roles and relationships."[2] While healthcare providers often see or view sexuality as the actual involvement in physical sexual activity, the definition of healthy sexual behavior varies from person to person. The perception of a healthy sexual adult varies greatly depending on one's culture. A person's preparedness for engaging in sexual activity variably starts after the onset of puberty, and the extent of one's sexual health continues to evolve and grow over time. Sexual expression is one way in which humans can express love and affection as well as feel desire and pleasure. Both sexuality and intimacy are key components of QOL, and patients value the opportunity to express these aspects up through end of life.[3]

Intimacy is a positive physical and cognitive relationship with another committed person or group.[4] This can be shared between all people regardless of age or gender. Within an intimate relationship there exists a sharing of knowledge, familiarity, affection, or bonds that continues to develop and evolve. Examples would be the simple yet powerful act of a parent lovingly putting a child to bed or a friend showing up unexpectedly to provide companionship and support. As humans get closer to the end of life, intimate moments such as these can become more powerful and cherished, proof of connection and meaning. As in the case example with Rosa and Leo, sleeping in the same bed is an expression of intimacy as well as an avenue for sexual expression. Assessment, treatment, normalization, and support for patients with serious illness who are undergoing changes in both their sexual and intimate lives are all part of the scope of a palliative care provider.

The WHO defines palliative care as "an approach that improves the QOL of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."[5] Using this definition and framework, this chapter explores how serious illness impacts sexuality and intimacy in the physical, psychosocial, and spiritual domains of health.

Impact of Physical Changes on Sexuality and Intimacy

Case Study: A Patient Struggling with Body Image Issues

Jessa is a 46-year-old woman with history of acute myeloid leukemia (AML) status post allogeneic stem cell transplantation. Eight years from her transplant, she continues to be disease-free; however, her medical course post-transplant has been complicated by chronic skin and soft tissue graft versus host disease (GVHD) which requires multiple immunosuppressive agents including chronic steroid administration. Jessa always expresses gratitude for her successful transplant; however, she also reports a significant change in her QOL. She acknowledges having depression and long-standing anxiety. She openly grieves the loss of her previous self and often states, "If my doctors had told me about the true effects of GVHD and warned me that this would be as good as my life gets, I really don't think I would have gone through with it." When asked to speak more about this, she identifies a significant change in her physical appearance and body athleticism due to chronic steroid dependence. With loss of joint mobility and strength, she is no longer able to run marathons or participate in the other athletic activities which she previously enjoyed with her spouse. During counseling sessions in clinic, Jessa discusses feeling inferior to and isolated from her partner who is still able to work out and enjoy an active lifestyle. She no longer identifies with the new person she has become.

Serious illness, regardless of disease type, can directly impact or alter sexual function. These changes are often the result of underlying disease or its associated treatment and can impact physical anatomy, sexual functioning, and identity. Alterations to sexual or reproductive anatomy can have consequences other than more obvious biologic or physical symptoms. In cancer, there may be long-term effects on sexual function and relationships solely due to effects of surgery, chemotherapy, and other cancer-related treatments. For example, women with breast cancer who undergo unilateral or bilateral mastectomy may struggle with long-term impacts on body perception and identity.[6] Similarly, young men who undergo orchiectomy to treat testicular cancer can experience incongruent body image and psychological distress.[7] Any alteration to the physical body, whether directly associated with a disease or one that is secondary to a medical intervention such as surgery, can impact the wellness of one's sexuality and intimacy. These changes can and will directly change how one is willing to share one's body. Emotional and psychiatric factors can directly result in sexual dysfunction and disturbances.[8] As in Jessa's case, the physical changes she has experienced are only one part of her overall picture. Consequences of her transplant negatively affect her self-identity as well as her ability to achieve intimacy with her partner.

Female patients who have undergone or are receiving treatment for breast cancer with surgery, chemotherapy, or hormone-blocking agents may develop low libido, dyspareunia, vaginal dryness, and loss of sensation, as well as emotional distress related to postsurgical body changes.[9] Other potential impacts include decreased or altered nipple sensation and arousal following breast reconstruction for breast cancer.[10] Treatments for pelvic and abdominal cancers often include radiation, surgery, and chemotherapy, all of which can result in chronic pain, vaginismus, and vaginal stenosis.[11] Male patients may experience low libido and erectile dysfunction as a result of prostate cancer treatment.[12] Any person, regardless of their sex or gender identity, who has undergone any combination of chemotherapy, surgery, and radiation may find permanent physical and functional changes that require adjustment in one's sexual life.

Acute or chronic illnesses that involve one or more major organ system such as cardiac, renal, pulmonary, or neurodegenerative disease can alter sexual function and expression.[13,14] Medications as outlined in Table 25.1 may decrease libido, impair orgasmic function, or have other effects on sexual health.[15–19] Patients of childbearing age may also experience a decline or loss in fertility due to surgical interventions or treatments such as chemotherapy. Many of the physical changes associated with serious illness (e.g., fatigue, pain, dyspnea, sequelae of surgery, medication side effects) can not only impact the sexual function of the body but also a person's ability to feel confident and desirable and to find pleasure and connection.

Awareness of these changes can help patients and providers speak frankly about intimacy challenges and how best to navigate them. Given the many ways in which people can express their sexuality and identity, there is no "normal" when it comes to consensual sexual expression in adulthood. The degree to which a person's sexual expression and identity is altered by serious illness will

Table 25.1 Common medication classes associated with sexual dysfunction

Medication class	Subclass	Type of dysfunction
Antidepressants	Selective serotonin reuptake inhibitors (SSRIs)	Reduced libido, orgasmic dysfunction[15]
Hormone-blocking agents	Aromatase inhibitors	Reduced desire and arousal, vulvovaginal atrophy, dyspareunia[16,17]
	Estrogen receptor modulators (e.g., tamoxifen)	Vaginal dryness, vaginal discharge, hot flashes[16,17]
	Anti-androgen medications	Loss of desire, erectile dysfunction[12,17,18]
Opioid analgesics	Chronic opioids	Reduced libido[19]

depend on the individual. Healthcare providers should not assume that, just because someone is aging or near end of life, the desire for connection or pleasure has been lost.[20,21] Healthcare providers can offer help to patients and families by reframing what sexual activity and pleasure can look like and supporting exploration of the new or changing normal.

Concrete palliative treatments do exist for physical changes that come with serious illness and at the end of life. These include medications for erectile dysfunction, vaginal lubricants, or psychostimulant medications to combat disease-related fatigue. However, there may not be specific pharmacologic treatment options available for a given symptom. Similarly, some medications may be deemed too risky or ineffective given the current state of health. In these cases, medical providers can recommend adjustments to patient-disclosed sexual behaviors or intimate patterns. Patients may need to explore other ways of experiencing pleasure that may be different from usual habits or routine.

Control of core symptoms that impact QOL such as pain, dyspnea, constipation, anxiety, and depression are important regardless of the underlying disease process. Despite scrupulous symptom management, there may be sexual side effects and changes that create issues that do not respond to traditional palliative medications and techniques. Palliative care providers should recognize the importance of developing skill sets beyond traditional physical symptom management tools. Regardless of the complexity of each case, healthcare providers can use the same communication skill techniques used to discuss end-of-life issues when assessing and exploring the health of patients' sexual and intimate health. All members of the palliative care multidisciplinary team should feel comfortable asking open-ended questions, responding to emotion, and supporting patient desire to explore difficult subjects. Counseling and normalizing the physical changes that come with dying, such as fatigue, weight loss, and physical dependence on others, as well as being present for expressions of grief and loss, should be included in the symptom management skill set. Walking with patients as they experience permanent changes in their sexual functioning and intimate relationships, assisting with adaptation, and finding ways to encourage the expression of love are all part of the role of a palliative care provider and require a multidisciplinary approach.

Serious Illness Impact on the Social, Emotional, and Spiritual Aspects of Sexuality and Intimacy

---

Case Study: A Patient with a Colostomy

Maya is a 27-year-old woman with metastatic colon cancer who underwent a surgical resection of her colon as part of routine treatment, resulting in permanent placement of a colostomy. While this procedure allowed Maya to live a longer life, it came at the expense of her self-worth and identity. While many may find the tradeoff of having a colostomy for further extension of life reasonable, the adoption of a colostomy has become a permanent barrier and roadblock for Maya to live a normal, young adult life. Maya is always cognizant of the ostomy bag and its accompanying lack of control in stool passage and bowel sounds. She lives in a constant state of anxiety when around friends and family for fear of her ostomy being discovered. Maya purposely decided to stop hanging out with friends and playing volleyball, previously a huge part of her social life and identity. Body disfigurement and its associated effects on self-worth are more debilitating than the disease process itself. Maya stopped dating or pursuing relationships and often poses the question in clinic, "Why would anyone love me like this?"

The ability to connect and express affection, closeness, and affirmation in intimate relationships is just as important as physical sexual functioning. When a person is dying, intimate relationships are also changing and advancing toward the same end.[22] Coming to terms with grief and the loss of one's perceived role in life, the prior healthy functioning of the body, the old structure of family and friends, and future hopes is part of the emotional work at the end of life in intimate relationships.[23]

Part of the dying process is life review and making meaning out of one's life experience. Imbalanced or unfulfilled needs or an inability to cope with the changing nature of physical sexual functioning and the change in intimacy and closeness in relationships can all be a source of suffering as people living with serious illness approach the end of life. As seen in Maya's case, the changes wrought by her surgical interventions were in many ways worse than the fact that she was facing the end of her life at such a young age. Maya's grief for the loss of her previous body and, more importantly, her inability to make meaning out of her new life in the face of change, created a sense of existential isolation and suffering. Patients may further isolate themselves, disrupting any previously formed intimate relationships or creating insurmountable obstacles that prohibit new relationships from being formed. This type of distress is very different from traditional anxiety and depression.

The giving and receiving of closeness, intimacy, pleasure, and touch are fundamental ways in which humans find spiritual meaning and purpose as well as a sense of connectedness to one another. As people approach the end of life, it is normal to see changes such as fatigue, loss of desire, and other physical symptoms that can dampen traditional sexual expression. However, people often still desire physical closeness and intimacy, taking advantage of the opportunity to make meaning out of close relationships and find compassion for one another.[24,25] Table 25.2 summarizes how common diseases can impact both the physical as well as the psychosocial well-being of patients.[9,13,22,26,28–32]

Effects of Serious Illness on Sexuality and Intimacy through Adulthood

---

Case Study: A Patient with Erectile Dysfunction

David is a 58-year-old man with advanced pulmonary hypertension. He has been living with changes to his QOL from this disease for many years. Fortunately for David, he has the added support of his partner, Glenn, in the management of his day-to-day care. Despite maximal therapy, he eventually has become dependent on continuous supplemental oxygen. His energy level remains low, and he struggles with fatigue in performing his activities of daily living. During one clinic visit, David checks off "Relationship Difficulties" and "Intimacy Issues" as concerns during a self-assessment tool. Upon encouraging David to elaborate more on why he has checked these items, he shares that he has suffered from erectile dysfunction for many years. David becomes very emotional while sharing, "I just don't feel like I am a man anymore."

Table 25.2 Common diseases and the potential effects on sexuality and intimacy

Disease group	Physiologic	Psychologic	Social	Spiritual
Cancer	*Common Symptoms*: Somatic pain, neuropathic pain, fatigue, dyspnea, nausea, and vomiting *Other Considerations*: Alterations in anatomy, body modification (e.g., ostomy, tracheostomy, feeding tube) Facial appearance changes with head and neck cancers Erectile dysfunction with prostate and urogenital cancers Sexual organ modifications with breast and GYN cancers Radiation and medication side effects such as decreased vaginal lubrication or atrophy, vasomotor symptoms, dyspareunia[12]	Mood disturbances such as anger, anxiety, depression, grief Body image disruption[9, 12]	Modification or change in relationship Disconnection from relationship[22]	Loss of self-identity Family role changes (e.g., who is primary provider for family) Decrease in self-worth Decreased sense of connectedness[26]
Heart disease, congestive heart failure	*Common Symptoms*: Dyspnea, fatigue, edema, decreased mobility, erectile dysfunction Difficulty reaching orgasm, decreased desire, decreased arousal *Other Considerations*: Connected dependence to artificial technology (e.g. IV infusions, LVADs) Scrotal and penile edema in men [27]	Depression Anxiety Self-awareness or acknowledgment of change Decreased desire secondary to treatments Low body image[13,28]	Changes in relationship Fear of rejection from partner[13]	Loss of self-identity Role changes in family (e.g., who is primary provider for family) Decreases in self-worth Loss of control Loss of meaning-making[29]
Chronic respiratory disease, COPD, pulmonary hypertension	*Common Symptoms*: Dyspnea, cough, fatigue, decreased mobility, sleep disturbances *Other Considerations*: Use of supplemental oxygen	Feelings of isolation Changes in self-esteem/body image [30]	Change in sleeping position may result in difficulty or inability to sleep adjacent to partner	Role changes (e.g., who is primary provider for family) Decrease in sense of self-worth[30]
Dementia	*Common Symptoms*: Loss of relationship memory, debility, and frailty	Loss of self-awareness Apathy and indifference to sex Can develop inappropriate and/or disinhibited sexual behavior or desires Issues of consent[31]	Loss of previously held relationship Lack of fulfillment in partner needs and desires Caregivers may ignore or pathologize sexual desire[31]	Disruption in equality of relationships Loss of sense of identity
Chronic kidney disease	*Common Symptoms*: Fatigue, debility, erectile dysfunction, impaired orgasm[32]	Depressive symptoms[32]	Demands of dialysis Concerns over fertility[53]	Role changes Meaning-making

Sexual health and intimacy change and evolve over time as one ages. People experience the creation of new intimate relationships as a normal part of aging. Some important relationships adapt to be sustained over time. For example, the relationship between a child and parent expands as the child grows into an adult. When the parent ages, there can be a reversal of roles, where the child becomes more of the supervising figure to the parent. The onset of a new disease or serious illness can and will stress intimate relationships, causing areas of distress for the patient, family, and friends. Depending on the phase of adulthood, the impacts of grief and loss on one's identity, intimacy, and other aspects of health vary. People in partnerships may experience shifts in their roles within the relationship. Other relationships may dissolve completely to give way to the formation of new ones.

Young Adulthood

Living with a serious illness like cancer, cystic fibrosis, or other genetic diseases will have effects far beyond physical health in the QOL for young adults. While identity is traditionally well established, this age group experiences a high degree of loss and regret both from reviewing past events and from looking ahead and identifying events in which one might not be able to participate.[33] For example, the young adult will experience a life review of events not yet realized, such as not being able to experience a long-term relationship, marriage, achievement of one's desired career, or having children. Young adults also may not yet be at a place in which they have been able to experience traditional one-to-one intimate relationships, and such intimacy issues can center on that loss or revolve around intimacy with friends and other family members. Young adults can feel loss and regret during life review, as well as feel remorse about not being able to experience fulfilling relationships like their peers.[34]

During this phase of adulthood, people may contemplate their own posterity and identify that they may not be able to experience parenthood. The anticipatory grief of not being able to have biological children or experience life as a parent through adoption or other means can cause considerable emotional distress. Partners of people with serious illness are also affected with the realization of this loss, which can cause a considerable amount of strain. For young adults who are newly diagnosed with cancer and are facing radiation and/or chemotherapy regimens with the very high likelihood of diminishing fertility, it is important that conversations regarding offspring be had prior to starting any therapy. Patients should be given the opportunity to meet with and obtain egg harvesting or sperm collection, thus providing future options for a biological child should this be possible or desired.[35] In addition to cancer, fertility issues can also play a role in other disease groups and genetic disorders. For example, men with cystic fibrosis are at higher risk of being infertile compared to their age-congruent counterparts.[36] Young people with renal failure report barriers to sexual partnerships and forming partnered relationships.[53]

Middle Adulthood

Similar to the young adult age group, middle-aged adults will be faced with loss from both spectrums of life. Relationships are often well established, whether they are with partners, spouses, friends, family members, or children. Relationships can be quite complex as all parties are experiencing change, which can contribute to additional distress. Partners of patients with serious illness can also experience loss in sexuality and intimacy. For example, mood disturbances, lack of fulfillment, and loss of identity have been described by partners of those with cancer.[37]

Patients and families can and will experience times of emotional distress as they cope with difficult news, physical and emotional changes, and the challenges of saying goodbye. It can be normal for patients and families to experience changes in emotional well-being at different times during an advanced disease. At the time of initial diagnosis, for example, a person can experience a wave of emotions, from surprise to anger. As one is getting closer to the end of life, there may be a sense of guilt or loss in regard to goals not yet achieved or the realization that certain goals may no longer be possible. Facing death and separation from children is a source of considerable emotional distress. Professional counseling and spiritual support can be helpful for patients and families as part of a patient-centered treatment plan.[12,38]

Older Adulthood

As people reach older adulthood, there are natural changes in body function and resilience. Regardless of disease, people will experience a slowing of one's body over time and natural changes to sexual desire and sexual response. However, sexual expression and intimate connection are part of normal aging.[20] Expressions of closeness and intimacy inform QOL and should be expected and encouraged by healthcare providers. People with cognitive impairments may still desire physical closeness and touch.[39] However, it is important to be mindful of consent issues, especially if capacity concerns become apparent. Most people will find themselves in need of physical care and support at the end of life. For some, the physical and emotional experience of caregiving can alter intimate and sexual relationships because caring for the body of a loved one is a highly intimate act. While caregivers need breaks and support, caring for a loved one can also be an immense source of closeness and intimacy. As stated by Ira Byock in his book *The Four Things That Matter Most*, "Caregiving is a burden and can exact a costly toll, but it also fills an intrinsic need that people feel to love and care for one another."[40]

In addition to physical changes, as people age, all will be faced with the inevitable death of loved ones. The longer a person lives, the more exposure to death he or she will experience: parents, siblings, partners/spouses, or friends. The loss of these different intimate relationships can be very trying for people to endure. Loss of those loved is perhaps the most universal impact of aging that all will experience.

Meeting People Where They Are, or What to Do Next

There are multiple impacts of culture on intimacy and sexuality at end of life. While it is clear that people with serious illness want to talk about their sexual and intimate lives, the current culture of healthcare, one of provider discomfort with and lack of education and experience in assessing the sexual and intimate needs of people, is a barrier.[41,42] Similar to end-of-life discussions, engaging in and talking about these topics can be difficult because they elicit insecurities and discomfort in the healthcare provider who may even omit sexual health from the assessment.[43,44]

Healthcare providers may feel unsure or unclear about what to ask and when, as well as anxiety about what to do with the answers that may be provided. They may also feel unsure about what to say to patients who are experiencing normal grief and loss reactions to changes in their bodies and relationships. They may also fear not having the solutions to questions about the impact of disease and aging on sexuality and intimacy.[45] Although many assessment tools exist for taking a sexual history, there is nothing that is validated and used generally in the palliative care population. Likewise, the traditional heteronormative social constructs of the healthcare system can be alienating and viewed as unsafe by many people, such as those in the lesbian, gay, transgender and questioning (LGTBQ) community.[46,47] Creation of a safe, nonjudgmental space where patients can express themselves is a priority.[47] Establishing a trusting relationship and a nuanced and humanistic understanding of the breadth and depth of human sexuality and connection help to break down the barriers between providers and patients with serious illness.

Both communication between healthcare providers and their patients, as well as facilitating communication between the patient and loved ones are tools that can help bridge cultural barriers, though there are few prospective studies to guide providers in determining what kind of questions to ask. Kelemen et al. asked two simple questions of hospitalized palliative care patients, "How much has your illness affected intimacy?" and "How has your illness affected your relationships?"[41,42] Checklists for physical symptoms can be implemented in practice as can using standardized sexual history tools and making questions about sexuality part of standard clinical assessment.[9,48] It is reasonable for practice settings to look at their standard assessment tools and determine what kinds of standard questions can and should be asked based on the population they serve.

The multidisciplinary team can be a way of assessing the full spectrum of a patient's physical and emotional function through the use of chaplaincy and social work, in addition to medicine and nursing. An awareness of and a movement away from a traditional conception of sexuality as only encompassing the act of heterosexual intercourse is crucial to being able to create a welcoming and tolerant environment for patients, as well as the ability to assess and support patients where they are. Instead of assuming a person has a husband or wife, instead ask if he or she has a support person, or, as suggested by Kimberly Aquaviva in her book *LGTBQ Inclusive Hospice and Palliative Care*, "Who do you consider to be your family?" or "Who are the people who are sources of emotional support for you?"[49]

A self-reflective practice that encourages a provider's self-knowledge and understanding will assist with awareness of one's own response to emotions in general and may assist with the acknowledgment of comfort and discomfort when asking and talking about sexuality and intimacy.[49] Activities such as mindfulness meditation or any practice that encourages reflection, empathy, boundary setting, and meaning in work can be helpful to palliative care clinicians who are looking to be present with their patients.[50–52] Sexuality and intimacy are key components of QOL which are impacted by serious illness and the dying process. As healthcare providers become more comfortable in addressing these important issues, patients and families will experience an improved QOL.
