Autoantibodies to vWF form immune complexes and increase clearance by Fc-bearing cells. This may reduce the concentration of vWF overall, giving rise to subtype 1 or selectively deplete HMW multimers, giving rise to subtype 2A. Binding to functional epitopes reducing von Willebrand activity has also been described.[85,109–112,139] This mechanism is associated with lymphoproliferative disorders, autoimmune disorders such as SLE and some patients with myeloproliferative disorders.[85,109–112,139] This mechanism sometimes causes severe depletion of vW factor (type 3).

Direct Adsorption of HMW Multimers

Adsorption of vWF protein, particularly the HMW multimeric forms, onto surfaces of tumor cells, platelets, or endothelial cells of abnormal blood vessels is a common mechanism giving rise to acquired type 2 VWD. This is the predominant mechanism in myeloproliferative disorders and solid tumors but has also been described in cardiovascular disease with angiodysplasia and lymphoproliferative disorders. This mechanism gives rise to type 2A AvWS. It has been thought that there may be adsorption of vWF to platelets when the platelet count is particularly high in myeloproliferative disorders, improving when the platelet count falls below 1,000.[107,108]

Increased Viscosity of Blood, Proteolytic Degradation of HMW Multimers

This mechanism, associated with circulating proteases, is also found in patients with cardiovascular disease, myeloproliferative and lymphoproliferative disorders, and solid tumors. It gives rise to type 2A AvWS.[85,86]

Sheer Stress-Induced Proteolytic Digestion

This results in selective depletion of HMW multimers, giving rise to 2A vWD in cardiovascular disorders.[86,109–112] Specific proteases such as the neuramidase produced by Wilms tumors may also result in type 2A AvWD[128–130] resolving when the tumor is successfully treated.

Decreased Synthesis/Secretion

This is the cause of AvWS in hypothyroidism, giving rise to type 1 AvWS[109,110] which resolves when the condition is treated with thyroxin.[116]

Treatment of Acquired von Willebrand Syndrome

There are two strands to the treatment of AvWS, identification and treatment of the underlying condition and management of bleeding. Management of bleeding depends to some extent on the subtype of AvWS and on the mechanism(s) causing the AvWS. Treatment of the underlying condition will usually lead to resolution of the AvWS. Unfortunately, an underlying diagnosis is not always identified and when it is it may sometimes be untreatable or, in the case of MGUS, for example, may not normally be treated. In such cases, bleeding must be managed according to one of the strategies described below.

Bleeding has been managed using a variety of strategies alone or in combination including Desmopressin (DDAVP), vWF/FVIII concentrate, high-dose IVIG, steroids, rituximab, and other immunosuppressive agents and Novoseven.[141]

Desmopressin (DDAVP) and vWF/FVIII Concentrates

Consistent with the mechanisms responsible for the decreased vWF activities in type II AvWS, treatment with Desmopressin (DDAVP), cryoprecipitate, or vWF/FVIII:C concentrates may yield poor and unsustained vWF incremental increases and relatively poor clinical responses. Success rates for DDAVP varied according to the nature of the underlying disorder. Federici et al.[86] reported 10% response in cardiovascular disorders, 21% in myeloproliferative disorders, 33% in autoimmune disorders, 44% in lymphoproliferative disorders, and 75% in patients with solid tumors. In 10 patients with MGUS, vWF activity improved 30 minutes after DDAVP administration in all patients, returning to baseline at 4 hours postinfusion.[142] In contrast, type 1 AvWS in untreated hypothyroidism, in which the synthesis of vWF is decreased but in which FVIII:C and vWF has a normal circulating half-life responds well to administration of Desmopressin (DDAVP)[113] and their vWF activities can be normalized by treatment with thyroxin.[113–117]

High doses of vWF concentrate and/or continuous infusion may be required to compensate for increased clearance of HMW vW multimers. The half-life may be very short, particularly in patients with MGUS or inhibitor antibodies.[141–143] Very close monitoring of the response is required for the dose-rate to be optimized.

Novoseven (recombinant factor VIIa, rVIIa, Novo Nordisk, Denmark)

Novoseven has been used successfully in standard dosage (90 μg/kg) in patients with AvWS, with a reported response rate of 96%.[141,144] Few adverse events have been reported though some caution should be exercised since elderly patients may be at greater risk of thrombosis. One case of myocardial infarction has been reported in a patient with type 2A vWD following treatment with Novoseven.[145]

Antifibrinolytic Drugs

The antifibrinolytic agents, ε-aminocaproic acid and tranexamic acid may be useful, particularly in combination with either DDAVP or Novoseven, for mucous membrane, gastrointestinal, and urinogenital bleeding. For minor bleeding, antifibrinolytic

tahir99-VRG & vip.persianss.ir

agents may be tried on their own. The use of antifibrinolytic agents may also reverse vWF proteolysis associated with activation of fibrinolysis induced by mechanical or damaged heart valves.

High-Dose Immunoglobulin

Standard doses of IVIG (1 g/kg/d for 2 days or 0.4 g/kg/d for 5 days) can be more effective than either DDAVP or concentrate in producing a sustained increase in vWF activity, normalization of the multimeric structure, and shortening of the bleeding time in patients with IgG MGUS.[141,143,146] This effect usually becomes apparent within 12 to 24 hours and so is not immediate.[141,143,146] Other hemostatic strategies may have to be used in the actively bleeding patient while waiting to see if immunoglobulin is going to be effective. This effect, though transient, reaches a maximum after 4 days, returning to baseline over 2 to 3 weeks.[143] It is unclear whether this improvement is related to binding of the offending IgG by anti-idiotype antibodies in the intravenous gammaglobulin, or whether improvement is due to blockade of the Fc receptors in the reticuloendothelial system with decelerated clearance of the vWF from the circulation. Low-dosage IVIG regimens have also proven to be effective for planned surgery.[98,147] As would be anticipated, high-dose intravenous gammaglobulin has been shown to be effective in other lymphoproliferative and autoimmune disorders but is ineffective in patients with IgM-MGUS states.[98,141]

Steroids and Other Immunosuppressive Strategies

Although immunosuppressive strategies might be expected to be effective in AvWS of autoimmune etiology, the response to steroids alone and in combination and also to rituximab have all been somewhat disappointing and do not have a big role to play.[141]

Plasmapheresis

Plasmapheresis has been reported to be useful in patients with IgM-MGUS.[141] Plasmapheresis should be conducted with fresh frozen plasma (FFP) as replacement material to prevent depletion of fibrinogen. Plasmapheresis may also be usefully combined with other treatment modalities such as DDAVP or vWF/FVIII replacement therapy.

ACQUIRED FACTOR X DEFICIENCY

Acquired factor X deficiency is a rare condition associated usually with significant bleeding. Almost all cases are caused by rapid clearance of factor X by adsorption onto amyloid fibrils in the vasculature and organs of the reticuloendothelial system in amyloid light-chain (AL) amyloidosis.[147–152] Only a few, isolated, cases of true, circulating, autoantibodies to factor X have been reported.

Factor X deficiency is the most common coagulopathy acquired in association with systemic light chain (AL) amyloidosis.[147–152,154] The factor X level in these cases is usually between 0.02 and 0.5 IU/L and bleeding and bruising tend not to occur until the factor X level falls to below 0.25 IU/L.[213] The factor X deficiency is typically an isolated abnormality, but occasional patients have combined deficiencies with other vitamin K-dependent clotting factors, including factor IX[153,155,157] or factor VII.[156]

It is thought that the bleeding tendency in patients with systemic amyloidosis cannot be attributed solely to acquired factor X deficiency or to combined clotting factor deficiencies but also to a synergistic contribution to impaired hemostasis by the physical changes in the integrity of the microvasculature caused by the amyloid deposition.[158,159]

There are approximately 10 published reports of transient factor X deficiency unassociated with amyloid and probably caused by a circulating inhibitor antibody.[160–162] Evidence of specific factor X inhibition was demonstrated in the plasma of only one of these transient cases, a woman with pneumonia following the use of erythromycin.[162] Otherwise, specific autoimmune antifactor X inhibitory antibodies are extremely rare[160–163] and have been detected in three elderly, previously healthy individuals who experienced sudden onset of bleeding[163,164,166] without any obvious underlying disease; three cases of inflammatory bowel disease or gastrointestinal malignancy; a child with extensive burns;[165] and a woman whose pneumonia was being treated with erythromycin.[162] In three cases, the antifactor X inhibitor was characterized as an IgG antibody.[163,164,166] The best characterized IgG autoimmune factor X inhibitor antibody inhibited activation of factor X by VIIa/TF, by IXa/VIIIa/phospholipid complex, and by Russell viper venom.[164] The antibody failed to inhibit the proteolytic activity of factor Xa toward a chromogenic substrate. However, under reaction conditions of limited factor Xa availability, the IgG could be shown to impair hemostatic functions of factor Xa that require the participation of its light chain: activation of prothrombin by prothrombinase; activation of factor VII bound to TF; and inhibition of VIIa/TF activity by factor Xa/TF pathway inhibitor complexes.[164]

Nonspecific nonneutralizing inhibitors of factor X activity, which were associated with transient factor X deficiency and major hemorrhagic complications, have been detected in two individuals in conjunction with a lupus-like anticoagulant.[224] Because no specific neutralizing antibodies were isolated from their plasmas, it was surmised that the nonspecific, nonneutralizing antibodies formed factor X–IgG immune complexes and mediated the accelerated clearance of factor X from the circulation.[167]

Diagnosis

The diagnosis rests on the emergence of abnormal bleeding in an individual with no previous personal or family history of bleeding. Screening tests reveal a prolonged PT and aPTT that corrects with normal plasma and is associated with a reduced factor X level.[168] The thrombin time (TT) may also be prolonged as may the reptilase.[168,169] Where present, prolongation of the TT and reptilase usually reflect hepatic amyloid infiltration and/or the nephrotic syndrome.[168,169] The prolonged PT is most predictive of clinical bleeding but was independent of whole body amyloid load. The prolonged PT and aPTT are explained by reduced factor X activity without evidence of an inhibitor; however, the corresponding factor X antigen levels are discordantly and consistently higher than the corresponding decreased factor X activity levels (median FX:Ag/FX:C = 2.5). The etiology of this phenomenon has not been explained.[168] Because multiple clotting factor deficiencies may occur in conjunction with decreased factor X activity in the context of systemic amyloidosis, for example, factors VII, IX, and V,[225] other specific clotting factor assays may be called for. In those whose decreased factor X levels do not correct with mixing studies, serial dilutions for specific clotting factor assays will indicate if a specific

tahir99-VRG & vip.persianss.ir

neutralizing autoimmune antifactor X antibody inhibitor or a nonspecific lupus-like antibody exists.

Treatment of Acquired Factor X Deficiency

Treatment strategies for patients with acquired factor X deficiency must be individualized and depends on the etiology of the coagulopathy. Treatment of bleeding due to acquired factor X deficiency secondary to systemic amyloidosis is often challenging because infused factor X is extremely rapid cleared. The administration of prothrombin complex concentrates (PCCs) (inactivated or activated) may be useful even though they may only be transiently effective. Splenectomy has been reported to result in a significant rise in the plasma factor X level; but surgery may be hazardous since adequate hemostasis cannot be guaranteed. There are anecdotal reports of the successful use of Novoseven to prevent bleeding and to facilitate splenectomy.[170,171] FFP may be utilized in plasmapheresis and exchange protocols intended to expedite factor X replacement, or when the physical removal of autoimmune antifactor X antibody inhibitors is deemed necessary to control bleeding[172] but should not be used as a replacement therapy for acquired factor X deficiency since they will be ineffective. Thompson et al.[173] reported 60 patients with acquired factor X deficiency of all severities who underwent 112 surgical procedures using a variety of hemostatic strategies. Only six of these individuals were severely affected (X < 0.1 IU/L). This report is remarkable for not using PCC in any of the 13 major invasive procedures reported, though only 4 of those individuals had a factor X level of <0.1 IU/L. Two patients bleed excessively following splenectomy, one with a baseline X of 0.03 IU/L and the other with a baseline of 0.06 IU/L, both despite the use of Novoseven. Milder cases (X > 0.1 IU/L) were generally given no hemostatic replacement therapy and did not bleed abnormally.[173]

The usual course of the coagulopathy is linked to the ability to eradicate the underlying plasma cell dyscrasia in systemic amyloidosis, although spontaneous resolution of amyloid-associated factor X deficiency does, very rarely, occur.[174] Therefore, aggressive treatment with high-dose melphalan chemotherapy, with or without corticosteroids and stem cell rescue, has emerged as the treatment of choice for systemic amyloidosis. This approach usually reverses or at least ameliorates the factor X deficiency.[158,175,176]

Acquired circulating autoantibody inhibitors of factor X are usually transient and so long-term eradication strategies are not usually necessary in those cases.[163,164] Active bleeding is treated optimally with PCCs or rVIIa,[162] and/or daily plasmapheresis combined with IVIG and steroids.[166] Intravenous γ globulin may sometimes facilitate the disappearance of factor X antibody inhibitors when used alone.[165]

ACQUIRED AUTOIMMUNE INHIBITORS TO FIBRIN FORMATION AND POLYMERIZATION AND TO FACTOR XIII

The final stages of blood coagulation consist of fibrin formation, mediated by thrombin cleavage of fibrinopeptides A and B from fibrinogen, followed by polymerization of fibrin monomers, concluding with the covalent cross-linking of the α and γ chains of adjacent fibrin molecules by factor XIIIa, which stabilizes the fibrin clot.[177] Spontaneously acquired, neutralizing inhibitory antibodies have been identified that specifically target each of these reactions associated with the development of severe clinical bleeding.

Although alloantibody inhibitors that target fibrinogen have, rarely, been observed following replacement therapy with FFP or cryoprecipitate for hereditary afibrinogenemia,[178] acquired autoimmune antibodies are considerably commoner. These may complex with fibrinogen and fibrin monomers inhibiting fibrin polymerization and thrombus stabilization. Acquired polyclonal IgG autoantibodies have also been shown to inhibit both thrombin-mediated release of fibrinopeptide A from fibrinogen[179] and fibrin monomer formation[180] without interfering with fibrin polymerization or cross-linking. The affected individuals presented with a severe hemorrhagic syndrome reminiscent of congenital afibrinogenemia. Antibodies targeting fibrinogen should be suspected when the aPTT, PT, TT, and reptilase time are all prolonged and chronometric assays for fibrinogen are reduced. Mixing studies with the TT show significant prolongation.

Impaired fibrin polymerization has also been reported in patients with monoclonal and polyclonal IgG autoantibody inhibitors. These antibodies specifically targeted fibrinopeptide epitopes on fibrinogen[181–184] and/or fibrin monomers.[182–184] Clinical bleeding was consistent with dysfibrinogenemia, but their purified fibrinogens were functionally and structurally normal and, when isolated, their inhibitors did not interfere with fibrinopeptide cleavage or fibrin cross-linking.[182,183] These acquired autoimmune neutralizing autoantibody inhibitors were detected in individuals with *de novo* coagulation defects arising in association with chronic aggressive hepatitis, postnecrotic cirrhosis, and ulcerative colitis,[182] SLE,[183] and benign and malignant monoclonal gammopathies.[184–186] In one study, autoantibodies directed specifically against fibrinogen and fibrinogen fragments X, Y, and D were detected in pregnant and postpartum women, particularly in those who are Rh immunized, and their newborns.[187] Laboratory abnormalities were observed in these cases, but the significance of these "physiologic" antibodies remains unclear because no hemorrhagic diathesis was apparent.

Acquired antibodies that inhibit cross-linking of fibrin polymers might be expected to target epitopes on the factor XIII molecule or the cross-linking sites on fibrin. Only isolated case-reports of alloantibody inhibitors complicating replacement therapy of congenital factor XIII deficiency have appeared in the literature. Acquired factor XIII deficiency, caused by autoantibody inhibitors has been described complicating a wide variety of mainly autoimmune conditions[188–193] and drug therapies.[194–197] These have included SLE, Henoch-Schonlein purpura, inflammatory bowel diseases, psoriatic arthritis, IgG monoclonal gammopathies, and acute leukemias (promyelocytic, lymphoblastic, and myeloid).[198,199] Long-term isoniazid treatment for TB and the use of procainamide, penicillins, diphenylhydantoin, and practolol have also been implicated in the development of clinically relevant autoimmune antifactor XIII antibody inhibitors.

Autoimmune factor XIII deficiency can be produced by predominantly IgG autoantibody inhibitors directed against factor XIII. These neutralize factor XIII clotting activity by: inhibition of factor XIII activation by thrombin (type I inhibitor)[190,200]; or interference of factor XIIIa-mediated transamidase activity and fibrin polymer cross-linking (type II); or blockade of factor XIIIa binding sites on fibrin (type III).[201–204]

Acquired factor XIII deficiency can also develop by non-immunologic mechanisms. The venom of caterpillars in the *Lonomia* species produces a severe hemorrhagic syndrome due

tahir99-VRG & vip.persianss.ir

to direct proteolysis of the factor XIII molecule.[205,206] The crude salivary gland extract of the giant Amazon leech, *Haementeria ghilianii*, contains a unique peptide, named tridegin, which specifically inhibits the transglutaminase function of plasma factor XIIIa.[207] This is the most potent, naturally occurring inhibitor of factor XIIIa yet described. Synthetic, low molecular weight inhibitors (nonspecific thiol reagents and specific azol derivatives and azolium salts) exert their factor XIII inhibitory effects at nanomolar concentrations.[189]

The presence of inhibitor antibodies and nonimmunologic inhibitors of factor XIIIa can usually be detected *in vitro* with mixing experiments, using patient plasma or purified IgG fraction to inhibit the cross-linking of α chains of fibrin in normal plasma.[190,208] There is also reduced fibrin clot stability in dissociating agents, such as 5 M urea (urea clot solubility test).[190,208] Global coagulation assays, such as aPTT, PT, TT, and fibrinogen levels, are usually normal although the thromboelastogram may show a pattern consistent with factor XIII deficiency. Decreased factor XIII activity can be quantitated specifically by the dansylcadaverine incorporation assay.

Clinical Presentation and Management

The severe, recurrent, and spontaneous hemorrhagic complications[191–202,209] caused by acquired inhibitors to factor XIII or fibrin stabilization are associated with a high mortality rate. Gastrointestinal, genitourinary, pulmonary, and intraperitoneal bleeding often occurs in combination with dramatic soft tissue hematomas and ecchymoses; intracranial hemorrhage has also has been described[194] and emphasizes the need for prompt diagnosis and treatment. The day to day bleeding pattern of acquired factor XIII deficiency is considerably more severe than congenital factor XIII deficiency and includes hemarthroses, poor wound healing, recurrent miscarriage, though fatal intracranial bleeds may occur in both.

When treating acute hemorrhage, one must attempt to overcome the inhibitor and replace factor XIII activity or fibrinogen substrate in plasma. Cryoprecipitate or fibrinogen concentrate or factor XIII concentrate is likely to be much more effective than FFP but neither may be adequate to overcome the inhibitor. Administration of large doses of plasma-derived, viral-attenuated factor XIII concentrate (Fibrogammin P, factor XIII concentrate, ZLB Behring,) appears to be the safest and most effective and efficient alternative method of controlling or preventing acute episodes of bleeding in patients with acquired FXIII deficiency.[210,211] Plasmapheresis or protein A column immunoadsorption, to physically remove the inhibitor, followed by exchange transfusion with factor XIII concentrate, cryoprecipitate, or FFP, are sometimes necessary to reverse refractory bleeding. Longer-term care is directed at eradication of antibody production, which can be approached with immunosuppressive drug regimens employing corticosteroids and alkylating agents.[193,203] Spontaneous remission may be observed, particularly if the problem is drug-induced and the offending drug is discontinued.

Inhibitors of Prothrombin and Thrombin

Acquired inhibitors of thrombin or prothrombin may cause bleeding diathesis but more rarely, thrombosis, whereas antibodies to prothrombin are frequently associated with thrombosis. Nonneutralizing, antiprothrombin antibodies lead to a prothrombotic state associated with the LAC.[212] Antiphospholipid antibodies are a heterogeneous group of antibodies that can be detected as anti–β_2-glycoprotein I antibodies, antiprothrombin antibodies, and the LAC.[213] These antibodies are relatively common; Nojima et al.[214] reported such antibodies in 51% of 96 patients with SLE. These authors showed that the coexistence of IgG antiprothrombin antibodies and LAC activity is the most significant risk factor for VTE in patients with SLE.[214] Rarely, however, severe bleeding may occur in patients with SLE because of antibodies causing acquired hypoprothrombinemia-lupus anticoagulant syndrome.[215] Immunosuppressive therapy may be helpful in such cases.

Generally, inhibitor antibodies to coagulation factors specifically bind to coagulation factors and either neutralize their procoagulant activity,[216] accelerate their clearance,[217] or proteolytically degrade them.[218] A novel mechanism has been described of an autoantibody directed toward prothrombin and induced protease-like activity to facilitate a stable stoichometric complex formation with its physiologic inhibitor antithrombin without thrombin conversion.[219] This resulted in potent inhibition of coagulation associated with recurrent bleeding, retroperitoneal, and pulmonary hematoma, in the absence of an underlying disease.

In contrast to antiprothrombin antibodies, neutralizing autoantibodies against thrombin are very rare. Most appear in patients exposed to topical preparations of bovine thrombin or fibrin "glue" during major surgery and these antibodies consequently react mainly with bovine coagulation proteins.[220–223] Acquired inhibitors directed primarily against human thrombin are usually associated with predisposing, usually autoimmune, conditions such as rheumatoid arthritis or SLE[222,224–227] and are extremely rare in patients without an underlying disease. Some patients with either monoclonal or polyclonal gammopathies occasionally have inhibitors of thrombin.[228–231] Isolated cases of antithrombin autoantibodies have been reported in patients with liver cirrhosis, or even without any apparent disease.[227,232] Sometimes these inhibitors cause a serious bleeding disorder[217,233–235] but in cases where the antibody binds to a site involved in the molecule's anticoagulant function, thrombotic disease results.[236]

Apart from these sporadic cases, most examples of acquired thrombin inhibitors occur in patients exposed to bovine topical thrombin or fibrin-glue preparations during major surgery.[222] Prospective studies found evidence of immunization to bovine thrombin and/or factor V in a 3rd to one-half of such patients.[223,237] Most of these patients are asymptomatic, but some bovine thrombin inhibitors cross-react strongly with human thrombin causing severe and even life-threatening bleeding.[237]

Antithrombin antibodies should be suspected if coagulation tests show a prolonged PT, a prolonged aPTT, and a markedly prolongedTT. Antithrombin inhibitors more typically cause bleeding than antiprothrombin antibodies and the TT is also more prolonged than the PT. Factor-activity levels are markedly decreased, and mixing studies show a poor correction with normal plasma, suggesting the presence of an inhibitor of thrombin. Given the possibility of an unfavorable outcome, in the presence of prolonged PT, aPTT, and TT, with normal platelet count and fibrinogen, a search for an inhibitor of thrombin should be pursued in patients with either bleeding or thrombosis. Timely diagnosis and the initiation of prompt aggressive treatment may reduce morbidity and mortality.

tahir99-VRG & vip.persianss.ir

Acute bleeding episodes associated with autoantibodies to prothrombin or thrombin may be difficult to reverse and there is no consensus on the best approach to replacement therapy. The administration of "bypassing" agents, such as aPCC and rFVIIa concentrate, used alone or in combination with each other or with plasmapheresis and exchange transfusions with FFP, probably constitutes the best strategy.[238,239] The concurrent use of antifibrinolytic agents, such as ε aminocaproic acid or tranexamic acid and human-derived fibrin glues may increase efficacy. Corticosteroid use has also been reported to be helpful for the long-term attempt to reverse the coagulopathy and to suppress autoantibody formation.[238]

ACQUIRED INHIBITORS TO FACTOR V

Etiology and Natural History

Alloantibody inhibitors of factor V are rare, even after repeated replacement therapy in individuals with congenital factor V deficiency.[240] Neutralizing autoantibodies targeted specifically at factor V are extremely rare. Acquired factor V inhibitors occur primarily in elderly individuals[241] who have received treatment with β lactam or aminoglycoside antibiotics (streptomycin and Gentamicin) or who have malignant diseases.[242,243,244] More recently, approximately two-thirds of factor V inhibitors were reported to have developed following the application of topical bovine thrombin alone or fibrin glue prepared with bovine thrombin for surgery.[242,243] Both of these bovine products are contaminated with small amounts of bovine factor V, stimulating the production of antibovine thrombin or factor V antibodies, which cross-react with human thrombin and factor V.[245] Hemorrhagic complications, due to acquired neutralizing factor V antibodies, usually occur after repeated exposures to bovine thrombin products but have also been reported after single exposure.[246] The prognosis for factor V inhibitors is generally good. Patients exposed to bovine thrombin have the best prognosis and "idiopathic" inhibitors the worst prognosis.

Most factor V inhibitors are polyclonal IgG, although mixed IgG associated with IgM[247] or IgA inhibitors[248] have also been reported. Autoimmune factor V antibody inhibitors usually disappear spontaneously within 8 to 10 weeks after their 1st appearance. Their mechanism(s) of inhibition are variable and resemble antibodies to FVIII:C. This is not surprising given the considerable base-sequence homology between the two molecules. The inhibitor may be directed to epitopes on the C2 domain of factor V, thereby interfering with the interaction of factor Va with phospholipids and disrupting formation of the prothrombinase complex.[249] Alternatively, antifactor V IgG autoantibodies have been detected in both patient plasma and platelets and in neutralized factor V procoagulant activity by reacting with an epitope contained on the factor V light chain.[250]

Curiously, acquired antifactor V autoantibodies may rarely cause a paradoxical hypercoagulable state. Thrombotic rather than hemorrhagic manifestations were described in a woman in whom severe activated protein C resistance arose because of the blockade of the factor Va proteolytic cleavage sites by an acquired antifactor V antibody. The patient's factor V coagulation protein activity was unaffected; however, her purified antifactor V antibody produced a "factor V_{Leiden}-like" defect when incubated *in vitro* with normal plasma.[251]

Acquired factor V deficiency, unassociated with the presence of an autoantibody inhibitor, has been described as a complication of primary systemic amyloidosis.[252]

Clinical Presentation

In general, the bleeding manifestations of autoantibody inhibitors to factor V are similar to those observed in congenital factor V deficiency. The clinical presentation of factor V deficiency due to autoantibody inhibitors ranges from mild epistaxis, or gingival bleeding, to life-threatening retroperitoneal hemorrhage.[253] Other reported presentations include hematospermia, hematuria, and severe gastrointestinal bleeding.[250] The severity of clinical bleeding varies considerably and typically correlates with the inhibitor titer and degree of factor V deficiency. Some patients have little if any bleeding even with surgery, despite overtly abnormal laboratory findings.[253] The propensity to clinical hemorrhage induced by antifactor V antibodies may be related to the content of factor V in the α-granule of the platelet and the susceptibility of that factor V to neutralization by the circulating antibody.[254,255] Platelet factor V may be relatively protected from neutralizing antifactor V antibodies even though plasma factor V is completely neutralized.[254] Platelet transfusion may be particularly useful in treating bleeding in acquired factor V deficiency for this reason.[255] In contrast, severe bleeding complications have been observed when antifactor V IgG was present in both the patient's plasma and platelets.[250]

Diagnosis

An inhibitor to factor V should be suspected when mixing studies with patient and pooled normal plasma do not correct the abnormally prolonged aPTT and PT in patient plasma. Factor V activity should be absent in the patient plasma and the mixture with normal plasma but progressive dilutions of patient plasma with factor V-deficient plasma will eventually allow for the expression of factor V activity as the inhibitor is sufficiently diluted out. A further confirmatory laboratory assay for autoimmune factor V antibody inhibitors includes a prolonged dilute Russell viper venom time, which does not shorten after incubation with an excess of phospholipid, in contrast to LACs.

Treatment of Factor V Inhibitors

Patients with acquired factor V inhibitors can usually be managed adequately with transfusions of FFP or platelets.[255,256] Platelet transfusions appear to be an especially effective means of "bypassing" the inhibitor because platelet factor V does not become accessible to the inhibitor until platelets are activated.[255] Salvage therapy for unresponsive patients includes the administration of FEIBA or rFVIIa to bypass the inhibitor to factor V. Alternatively, both high-dose IVIG[257] and plasmapheresis with extracorporeal immunoadsorption methods have been used.[258]

Because most autoimmune factor V antibody inhibitors are transient, disappearing spontaneously over weeks to months, it is uncertain whether immunosuppressive regimens actually hasten the disappearance of the inhibitor. Combination treatment with plasmapheresis and corticosteroids;[238] corticosteroids, Azathioprine, and plasmapheresis;[251] or prednisone and cyclophosphamide have all been reported to reverse the coagulation

tahir99-VRG & vip.persianss.ir

defect over time, but the effect of these agents on the natural history of this disorder is not yet known.

AUTOIMMUNE ANTIBODY INHIBITORS TO FACTOR XII

Most cases of autoantibodies directed against factor XII have been described in the context of primary or secondary antiphospholipid syndrome (APS) with a LAC.[259,260,261] Twenty-one of forty-two patients with APS in one study were reported to have either IgG or IgM autoantibodies targeting factor XII and four of these had decreased factor XII levels.[261]

The clinical significance, if any, of these autoantibodies is obscure, since factor XII deficiency does not cause bleeding and probably does not cause thrombosis.[262–265] Unsurprisingly, autoantibody inhibitors to factor XII do not cause bleeding but may be either a marker or epiphenomenon of hypercoagulability and fetal loss in patients with APS,[266,267] independent of a concurrent LAC or β_2-glycoprotein antibodies. Acquired inhibitors directed against factor XII have also been described in association with various liver diseases: metastatic liver disease from gastric carcinoma, autoimmune hepatitis, and severe chronic hepatitis B.[184] The coagulation abnormalities corrected after partial hepatectomy, corticosteroid treatment, and hydroxychloroquine therapy, respectively.[268] Replacement therapy is therefore not indicated, but heparin and aspirin may improve the outcome of pregnancy if the patient gives a history of recurrent fetal loss.

ACQUIRED AUTOIMMUNE ANTIBODY INHIBITORS OF FACTOR XI

Autoimmune antibody inhibitors typically arise in association with an underlying collagen vascular disease, such as SLE [274,275,269–273] and less frequently in association with hematologic malignancy,[276,277] autoimmune gastrointestinal diseases[278], or treatment with phenothiazines.[272,279]

The autoimmune antibody inhibitor against factor XI usually results in apparent reductions in all intrinsic coagulation factors, though excessive bleeding is not usually observed. Factor XI inhibitors are typically detected only when coagulation is tested for some other reason and shows a prolonged aPTT. Autoantibody-induced factor XI deficiency has been shown to improve following corticosteroid therapy in patients with SLE[273] and chemotherapy of CLL.[276] A patient with chronic myelomonocytic leukemia and a factor XI inhibitor has also been reported to respond to Novoseven (rVIIa) given for an invasive procedure.[277]

ACQUIRED DEFICIENCIES AND INHIBITORS OF FACTOR IX

Autoimmune Acquired Factor IX Inhibitors

Spontaneously acquired factor IX autoantibody inhibitors are extremely rare. [274,275,280–285] The associated disease states are quite similar to those underlying acquired factor VIII inhibitors. Most autoimmune factor IX inhibitors resolve spontaneously within 1 to 7 months, but it is not clear whether the natural history is altered by immunosuppressive therapy. Corticosteroids with or without high-dose IVIG (400 mg/kg/d for 5 consecutive days by intravenous infusion), has been reported anecdotally to be successful.[265] Furthermore, removal of an associated malignant tumor may allow for spontaneous resolution of factor IX antibodies.[286] Recurrence of the autoantibody is unusual following successful treatment. As a general rule the strategies for treatment of acquired autoimmune hemophilia A can be applied for acquired autoimmune factor IX antibody inhibitors.

Acquired Nonimmune Factor IX Deficiency

Acquired isolated factor IX deficiency due to nonimmune mechanisms leading to loss or increased clearance of factor IX are more common than autoantibody inhibitors causing factor IX deficiency. This coagulopathy has been associated with heavy proteinuria in nephrotic syndrome,[287,288] primary amyloidosis,[289] Gaucher disease,[290] and pituitary insufficiency.[291] Laboratory assessment confirms the absence of an inhibitor and bleeding manifestations are treated with factor IX replacement in the form of PCCs (activated or unactivated), ultra-high purity plasma-derived or recombinant factor IX concentrates, or rFVIIa for salvage therapy. The replaced factor IX protein usually has accelerated plasma clearance in these situations, except for pituitary insufficiency, which may be treated successfully with administration of thyroxin.

Laboratory Evaluation of Factor IX Inhibitors

Allo- and auto-antibodies to factor IX present with prolongation of the aPTT and a low factor IX activity assay, which does not correct in mixing studies with normal plasma. Both allo- and auto-antibodies to factor IX are immediate-acting with no progressive loss of activity following prolonged incubation at 37°C.[282,292,293] Antifactor IX alloantibodies may also form circulating immune complexes capable of precipitating anaphylactic reactions when the patient is reexposed to factor IX containing replacement products. This has not been described with autoantibodies. Specificity of the factor IX alloantibody or autoantibody inhibitor can be confirmed in factor IX coagulation assays, and the degree of inhibition can be quantified using a modified Bethesda assay.[294,295]

Patients with factor IX alloantibodies present most commonly with hemarthroses. In contrast, hemorrhagic complications with autoimmune antifactor IX inhibitors are similar to those reported for acquired hemophilia A, with few hemarthrosis, severe and extensive ecchymoses, and intramuscular bleeds, as well as gastrointestinal and genitourinary bleeding.[296]

The mainstay of therapy for patients with hemophilia B and with high-titer factor IX inhibitory alloantibodies, is the administration of recombinant or plasma-derived factor IX for low-level inhibitors and activated PCCs (FEIBA) or rVIIa for higher level inhibitors[297–301] Novoseven (rFVIIa) is the treatment of choice in patients who have had anaphylaxis since these patients cannot be given factor IX concentrate. These treatment products are used in regimens similar to those for FVIII:C alloantibody inhibitors and are equally effective[296–301] with an 80% complete and partial response rate.[302] Treatment failures require alternative strategies, such as combining the PCCs with rFVIIa.[303] Patients who are high responders with low-titer alloantibodies may experience an anamnestic response to any source of infused factor IX protein within 2 to 5 days. Occasionally, in high-titer inhibitor situations, plasmapheresis or extracorporeal

immunoadsorption is necessary to transiently decrease inhibitor titers and facilitate control of acute bleeding.[296]

ACQUIRED FACTOR VII DEFICIENCY

Acquired factor VII deficiency is common, though seldom arising in isolation, associated with Coumadin therapy, broad-spectrum antibiotic therapy, liver disease, and vitamin K deficiency caused by diet or malabsorption. In contrast, isolated, acquired factor VII deficiency caused by specific autoantibodies to factor VII is exceedingly rare, an anecdotal phenomenon and clinical curiosity.

The pattern of bleeding in individuals with acquired autoimmune factor VII deficiency tends to be more severe and is more likely to be life-threatening than in congenital factor VII deficiency.[303–307] This may reflect publishing bias. Hemarthroses are uncommon in both congenital and autoimmune factor VII deficiencies. Acquired autoimmune factor VII deficiency has developed in association with various clinical situations, including aplastic anemia with the use of antithymocyte globulin [308]; administration of drugs such as penicillins, cephalosporin's, and interleukin 2 (IL-2) therapy[307,309]; septicemia[310]; pancreatitis[311]; and malignancy, such as multiple myeloma.[312] A specific factor VII autoimmune antibody has also been isolated from the plasma of an AIDS patient with a concurrent lupus-like anticoagulant.[313]

These acquired factor VII autoantibody inhibitors are predominantly neutralizing IgG antibodies.[306,314] Rarely, factor VII deficiency has occurred because of IgG–factor-VII complex formation with accelerated clearance of the immune complex.[308] Alloantibody formation has also been reported in individuals with severe congenital factor VII deficiency after treatment with rFVIIa concentrate.[315]

Acquired deficiency of factor VII, unrelated to autoimmune antibody inhibitor formation, is most commonly due to vitamin K deficiency states associated with hepatic diseases (severe cirrhosis, ethanol or acetaminophen toxicity, Dubin-Johnson syndrome, Rotor syndrome, Gilbert disease, etc.)[316,317] or with medications classified as vitamin K antagonists (Warfarin and Coumadin derivatives). Factor VII deficiency has also accompanied amyloidosis,[318,319] presumably caused by adsorption of the clotting factor to amyloid fibrils.

Laboratory analysis of plasma samples from individuals with specific autoimmune factor VII antibody inhibitors usually reveals isolated prolongations of the PT assays and factor VII activity assays, which do not correct with mixing studies performed with normal plasma. The aPTTs are typically normal. In contrast, for factor VII deficiency due to hepatic disease or Warfarin effects, mixing studies with patient and normal plasmas should show immediate normalization of prolonged PTs and aPTTs (reflecting deficiencies in all vitamin K-dependent clotting factor proteins) and depressed factor VII activity assays.

Because of the rarity of autoimmune acquired factor VII deficiency due to circulating inhibitors, there is no consensus on the best treatment strategy for significant bleeding complications. Anecdotal reports indicate that eradication of the associated underlying disease state is clearly crucial over the long term, for example, normalization of autoimmune factor VII deficiency that occurred after an allogenic bone marrow transplant-cured aplastic anemia[308] and after tumor regression by chemotherapy. Factor VII activities decreased again when the tumor relapsed.[312]

For significant active bleeding, administration of plasma-derived or genetically engineered factor VII concentrates is probably the most efficient and consistently effective first-line treatment strategy to overcome the inhibitor. FFP has limited usefulness because of the large volumes required, the prolonged administration time, the possible transmission of blood-borne pathogens, and the low likelihood that the factor VII inhibitor can be overwhelmed. PCCs may be of value but also may induce hypercoagulability with repeated doses. When these strategies are unsuccessful in reversing bleeding or if achieved factor VII increments after replacement therapy are short lived because of the inhibitory antibody, extracorporeal plasmapheresis with or without concomitant intravenous gammaglobulin may be lifesaving.[316,320] Antifibrinolytic agents and fibrin glues may be useful adjunctive therapies.

CHAPTER

58

Laboratory Markers of Activated Coagulation and Its Regulation

KENNETH A. BAUER AND HELEN A. IRELAND

The development of blood tests to predict thrombotic events, or to confirm or exclude the presence of thrombosis, has been a goal of scientists working in the field for many years. The hemostatic mechanism comprises platelets, vessel wall components, and procoagulant, inhibitory, and fibrinolytic proteins. Advances in our knowledge of the biochemistry of these processes have facilitated the development of sensitive and specific assays that are able to detect platelet activation, generation of coagulation enzymes, products of intravascular fibrin formation or dissolution, and activated inhibitory proteins in addition to the inactive coagulation factors (zymogens) and their inhibitors. This chapter focuses on measures of activated markers of hemostasis and their relationship to thrombotic disease. While many of these assays have not found a place in clinical practice, their use as research tools has furthered our understanding of the hemostatic mechanism and its perturbation in many disease states.

Due to the short half-life of most of the hemostatic enzymes, it has not been possible to measure directly the levels of most of the active forms *in vivo*. Many of the enzymes are neutralized rapidly by naturally occurring protease inhibitors or bound to cellular receptors in the locale in which they are generated. Faced with these obstacles, immunochemical assays have been developed for peptides that are liberated with the activation of coagulation zymogens or for enzyme–inhibitor complexes. The assays that have been developed, along with the reported *in vivo* half-lives for some of the species, are listed in Table 58.1 and described in detail in a later section of this chapter. Most of these assays were initially developed in research laboratories, but some are now available commercially in kit form using either polyclonal or monoclonal antibodies.

The assay formats for these markers are generally of two types. The first approach that has been used is a competitive radioimmunoassay procedure. This requires an antibody population that recognizes antigenic determinants on the activation fragment or enzyme–inhibitor complex that are hidden in the parent zymogen or inhibitor. The need for highly specific antibodies to the marker of interest could sometimes be obviated by devising sample processing procedures that efficiently remove the cross-reacting species in plasma before assay. The use of the radioimmunoassay has, however, waned due to the requirement of radioactive tracers. The second approach, used more commonly today, is the enzyme-linked immunosorbent assay. In most instances, immunoglobulin G (IgG) or F(ab′) two fragments directed toward epitopes on one region of the marker are bound to wells of plastic microtiter plates to "capture" the antigen from the plasma specimen. After washing away unbound species, a second IgG or F(ab′) two population recognizing epitopes in a different domain of the marker molecule is added to the wells. These antibodies are coupled to an enzyme capable of cleaving a suitable colorimetric substrate, allowing the development of a titration curve.

Successful execution of clinical investigations seeking to establish a relation between markers of coagulation, fibrinolysis, and thromboembolic disease requires, first, that the selected assays are specific for the products of interest and possess sufficient sensitivity. Second, the tests must be standardized so that the assays perform in a reproducible manner. Third, care must be taken to ensure that technical factors do not introduce *in vitro* artifacts that can significantly alter the immunoassay results (e.g., drawing of blood samples through indwelling intravenous catheters). These include venipuncture quality, choice of anticoagulant, sample processing procedures (if required), and plasma storage conditions.

ASSAYS FOR COAGULATION ACTIVATION

Many of the protein components of the hemostatic mechanism are inactive zymogens that are converted to their active forms, serine proteases. For coagulation system enzymes to be generated at any significant rate, a zymogen, a cofactor, and a converting enzyme must form a multimolecular complex on a natural surface. These transformations are suppressed if the converting enzyme is inhibited, the protein cofactor is destroyed, or the surface receptors that are essential for the assembly of the macromolecular complex are sequestered. For an overview of the blood coagulation mechanism, see Chapter 8.

Assays for Contact System Activation

Contact system activation can be monitored by immunoassays for factor XIIa, factor XIIa–C1 inhibitor complex, kallikrein–C1 inhibitor, and kallikrein–α_2-macroglobulin. Factor XI activation can be measured as factor XIa and factor XIa–factor XIa inhibitor (α_1-antitrypsin, antithrombin, C1 inhibitor, and α_2-antiplasmin) complexes.[1–3,6,7]

Assays for Intrinsic and Extrinsic Pathway Activation

The activation of factor IX can be monitored by measuring the levels of the factor IX activation peptide[10,47] or factor IXa–antithrombin complexes.[11] These assays reflect the action of factor XIa, the factor VII–tissue factor complex, or both, on factor IX (FIGURE 58.1). Factor X activation mediated by the extrinsic or intrinsic pathways can be monitored by measuring the factor X activation peptide.[12]

Table 58.1

Immunochemical and enzymatic markers of coagulation and fibrinolytic system activation

Biochemical Step	Marker (Reference)	T1/2 (Reference)
Coagulation		
Factor XII–factor XIIa	Factor XIIa[1]	
	Factor XIIa–C1 inhibitor complex[2,3]	
Prekallikrein–kallikrein	Kallikrein–C1 inhibitor complex[3,4]	
	Kallikrein–α_2-macroglobulin complex[5]	
Factor XI–factor XIa	Factor XIa–XIa inhibitor complexes[6,7]	
Factor VII–factor VIIa	Activated factor VII[8,9]	
Factor IX–factor IXa	Factor IX activation peptide[10]	15 min
	Factor IX–antithrombin complex[11]	30 min
Factor X–factor Xa	Factor X activation peptide[12]	30 min
	Factor X–antithrombin complex[13]	
Prothrombin–thrombin	Prothrombin activation fragment F1+2[15–18]	90 min[14]
	TAT complex[19,21,22]	15 min[20,23]
Protein C–activated protein C	Protein C activation peptide[24]	5 min
	Activated protein C–protein C inhibitor complex[26,27]	40 min[25]
	Activated protein C–α_1-proteinase inhibitor (antitrypsin)[27]	140 min[25]
Fibrinogen–fibrin	Fibrinopeptide A[28–30]	3–5 min[29]
	Fibrinopeptide B[31,32]	
Fibrinolysis		
Plasminogen–plasmin	Plasmin–α_2-antiplasmin complex[22,33–38]	
	Plasmin–α_2-macroglobulin complexes[34]	
Plasmin action on fibrin I	Bβ1–42 fragment[39,40]	
Plasmin action on fibrin II	Bβ15–42 fragment[41]	
Plasmin action on fibrinogen/fibrin	Fibrinogen (fibrin) degradation products[42,43]	
Plasmin action on cross-linked fibrin	D-dimer[44,45]	8 h[46]

An assay for factor VIIa uses a clotting assay utilizing recombinant tissue factor that has undergone a *C*-terminal truncation.[8,9] This tissue factor mutant maintains cofactor activity toward factor VIIa but does not support factor VII activation.

Assays for Measuring *In Vivo* Thrombin Generation

Prothrombin activation fragment F1+2 (F1+2): Thrombin generation takes place at an appreciable rate under physiologic conditions only in the presence of factor Xa, factor Va, calcium ions, and activated platelets. During this process, the amino-terminus of the prothrombin molecule is released as F1+2 (see FIGURES 58.1 and 58.2).

Thrombin–antithrombin complex measurement: Thrombin and other serine proteases within the coagulation pathway can be rapidly inhibited by circulating antithrombin, in a mechanism potentiated by endogenous heparan sulfate. Thrombin–antithrombin (TAT) complex can be measured in plasma and used as a marker of thrombin generation[19,21,48] (FIGURE 58.2).

Assays for Thrombin Activity

Once evolved, the serine protease, thrombin, converts fibrinogen into fibrin, releasing fibrinopeptides A and B from the amino-terminal regions of the Aα and Bβ chains of fibrinogen, respectively[49] (see FIGURE 58.3A). The rate of fibrinopeptide A release from fibrinogen is considerably faster than that of fibrinopeptide B.[31,49,50] Cleavage of fibrinopeptide A from fibrinogen generates an intermediate known as *fibrin I* that can polymerize but cross-links poorly.[51,52] Further proteolysis of fibrin I can occur through the action of either thrombin or plasmin. If thrombin action predominates, fibrinopeptide B is released, and fibrin II is formed. Immunoassays for fibrinopeptide A [28,30,53,54,55] and fibrinopeptide B[31,32] provide an index of thrombin action on fibrinogen.

ASSAYS FOR INHIBITOR COMPLEXES AND ACTIVATED INHIBITORS OF COAGULATION

Protein C Pathway

Thrombin activity and generation can also be inhibited rapidly by activation of the protein C pathway. Thrombin binds to

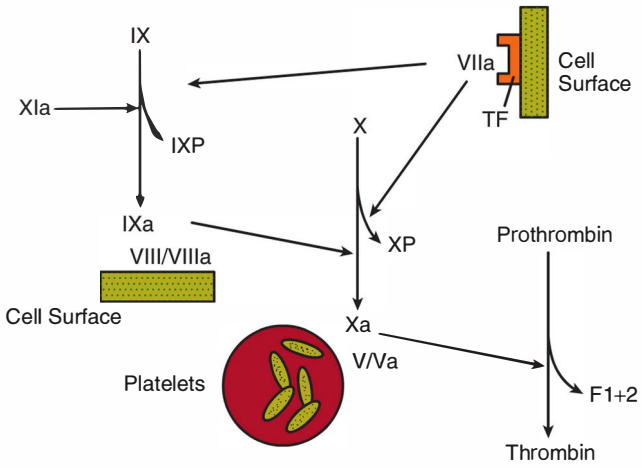

FIGURE 58.1 Pathways of coagulation activation. The activation of factor IX by factor XIa or the factor VII–tissue factor (TF) mechanism liberates the factor IX activation peptide (IXP). The conversion of factor X to factor Xa by the factor IXa–factor VIII/VIIIa–cell surface complex releases the factor X activation peptide (XP). The generation of thrombin from prothrombin is mediated by factor Xa in the presence of factor Va and activated platelets. During this process, the F1+2 fragment is released.

thrombomodulin on vascular endothelial cells and once bound can no longer participate in procoagulant mechanisms, either to activate platelets or to cleave fibrinogen. Endothelial protein C receptor, which lies adjacent to thrombomodulin within the caveolae region of the endothelial membrane, augments this mechanism by capture of protein C from the circulation, particularly in large vessels, and presents protein C to the thrombin–thrombomodulin complex. Thrombin–thrombomodulin activates protein C, which then inactivates factor Va and factor VIIIa by cleavage, thereby also regulating thrombin generation. Assays have been developed to monitor this pathway (FIGURE 58.2). Immunoassays to measure protein C activation include measurements of the protein C activation peptide,[24] an immunoactivity assay for activated protein C,[56,57,58] and activated protein C–inhibitor complexes.[26,27,59]

ASSAYS FOR ACTIVATED FIBRINOLYSIS AND ITS INHIBITION

Tissue plasminogen activator (tPA), produced by endothelial cells, converts circulating plasminogen to plasmin, the enzyme responsible for degradation of the fibrin clot. This process can be suppressed by complex formation between tPA and circulating plasminogen activator inhibitor 1 (PAI-1).

Fibrinopeptides Released by Plasmin

Plasmin action on fibrin I releases Bβ1–42 from the amino-terminus of the Bβ chain and cleaves the carboxyl terminus of the Aα chains, thereby generating fragment X[60] (FIGURE 58.3B). In contrast, plasmin proteolysis of fibrin II results in the release of Bβ15–42 rather than Bβ1–42 because fibrinopeptide B has already been removed by the action of thrombin. Plasma levels of Bβ1–42[39,40] and Bβ15–42,[41] peptides released by the proteolytic action of plasmin on fibrinogen and fibrin, respectively, have been used as indices of *in vivo* plasmin activity. The antisera used in these assays show significant, but not absolute, specificity for the various fibrinopeptides relative to fibrinogen. Consequently, cross-reacting fibrinogen must be removed from plasma samples before analysis, using techniques that do not alter the levels of the peptides.[29,61]

The initial assay for Bβ1–42 was indirect and involved measurement of fibrinopeptide B immunoreactivity before and after thrombin addition to fibrinogen-depleted plasma. The resultant increase in immunoreactivity, termed thrombin-increasable fibrinopeptide B, reflects the presence of Bβ1–42, a fibrinopeptide B-containing fragment.[62] Assays were subsequently developed that directly measured the levels of Bβ1–42 with either a polyclonal[40] or a monoclonal antibody.[39] These antisera are specific for Bβ1–42 and do not cross-react with fibrinopeptide B or Bβ15–42. An alternative approach is to use an antiserum raised against Bβ15–42 that cross-reacts completely with Bβ1–42 because it recognizes the carboxyl-terminal region of these peptides.[63] However, the Bβ1–42/Bβ15–42 assay may underestimate the circulating levels of Bβ1–42 because release of the carboxyl-terminal arginine residue by circulating carboxypeptidases decreases the immunoreactivity of the peptide when measured with a carboxyl-terminal–directed antisera.[40]

Using a monoclonal antibody, a specific assay for Bβ15–42 has been developed[41] that provides a marker of plasmin action on fibrin II. However, two factors limit the utility of this test. First, because the antibody exhibits some cross-reactivity with Bβ1–42, the assay may not be a specific marker of fibrin proteolysis in patients with marked fibrinogenolysis.[64] Second, only low levels of Bβ15–42 are generated during thrombolysis,[65,66] probably because the Bβ42–43 bond of fibrin II is not cleaved as readily by plasmin as is the same bond of fibrinogen or fibrin I. Exploiting this phenomenon, the fibrin specificity of thrombolytic agents has been increased by linking them to monoclonal antibodies against the Bβ15–42 domain of fibrin, thereby targeting them to fibrin.[67,68]

Assays for Large Fragments of Fibrinogen and Fibrin

The levels of fibrinogen or fibrin degradation products (FDPs) can be measured using a variety of immunologic techniques[42,43] or by use of the staphylococcal clumping reaction.[69] Most of the antisera used in these assays cross-react with fibrinogen, and the tests therefore must be performed on serum samples. These assays, like those for fragment E,[70,71] a degradation product found in most high molecular weight derivatives produced by plasmin proteolysis of fibrinogen or fibrin, do not differentiate between fibrin and fibrinogen degradation products. Furthermore, serum FDP measurements can be problematic[72] because incomplete removal of fibrinogen in the formation of serum falsely elevates FDP levels, whereas adsorption of degradation products to the clot results in a spurious reduction in FDP values.[73] These limitations have prompted the development of antibodies against neoantigenic determinants on plasmin-derived fibrinogen or fibrin fragments that do not cross-react with fibrinogen. Both polyclonal and monoclonal antibodies against neoantigens on fragments D and E[74–77] have been developed for this purpose. Although some clinical testing has been done with these assays,[78,79] they have largely been replaced by assays for D-dimer.

Plasmin-induced lysis of cross-linked fibrin results in the formation of a variety of degradation products, D-dimer being

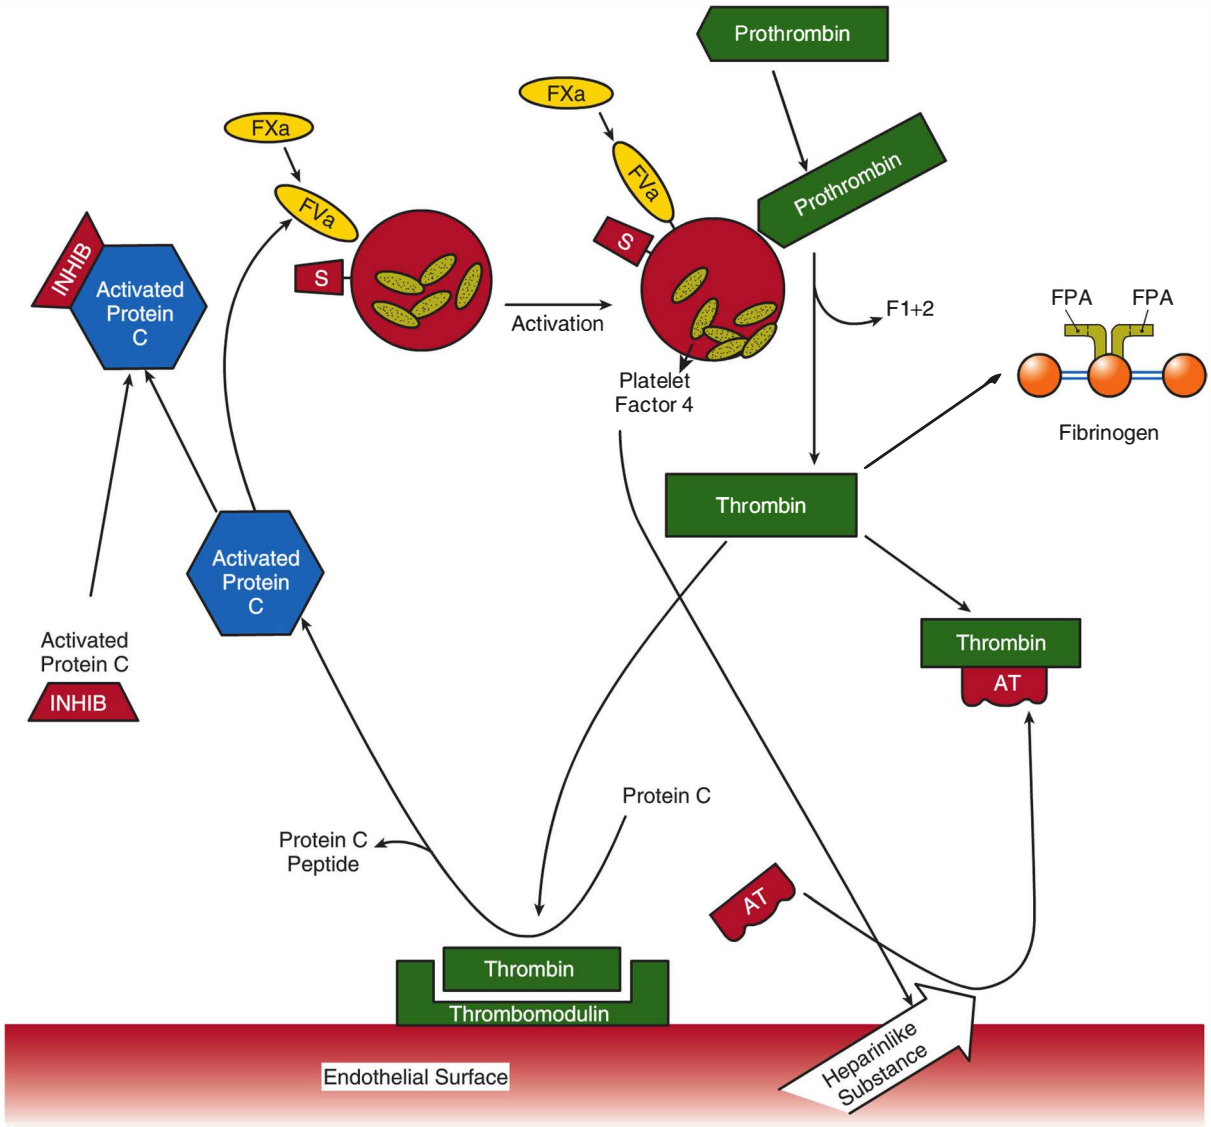

FIGURE 58.2 Regulation of thrombin generation by the natural anticoagulant mechanisms of the endothelium. Factor Xa, factor Va, protein S, prothrombin activation fragment F1+2, fibrinopeptide A, antithrombin, and activated protein C inhibitor(s) are designated as FXa, FVa, S, F1+2, FPA, AT, and activated protein C inhibitor, respectively. Thrombin may be inactivated by forming 1:1 stoichiometric complexes with its major physiologic inhibitor, antithrombin, thereby resulting in the formation of TAT complexes. Activated protein C can be neutralized by inhibitors of activated protein C (e.g., protein C inhibitor, α_1-proteinase inhibitor, and α_2-macroglobulin), which results in the generation of activated protein C inhibitor complexes.

the smallest. This fibrin derivative is comprised of two fragment D moieties covalently linked by their γ chains.[80,81] D-dimer levels in whole blood can be measured by red cell agglutination, whereas levels in plasma can be quantified using an enzyme immunoassay (EIA) or latex bead agglutination. All assays use monoclonal antibodies that recognize neoepitopes on D-dimer that are not expressed on the D-domains of non–cross-linked fibrinogen or fibrin.[44,45] Although agglutination assays can be done more rapidly than the EIA, latex agglutination assays are less sensitive and provide only semiquantitative results.

The performance of each D-dimer assay differs, depending on the specificity of the monoclonal antibodies used in the test, variability in the cutoff value selected to identify positive results, and characteristics of the patient populations in which the test was evaluated.[82–84] Most commercial D-dimer assays use authentic D-dimer as the reference standard, others use fibrinogen. When a fibrinogen standard is used, results are reported as fibrinogen equivalent units, with two of these units approximately equivalent to a single D-dimer. The use of different standards makes it difficult to compare study results because the units for D-dimer measurement are rarely specified.

The concept that D-dimer is derived only from the breakdown of cross-linked fibrin in thrombi has been challenged, because it was observed that the levels of D-dimer in patients undergoing coronary thrombolysis are higher than those that would be predicted given the volume of the coronary

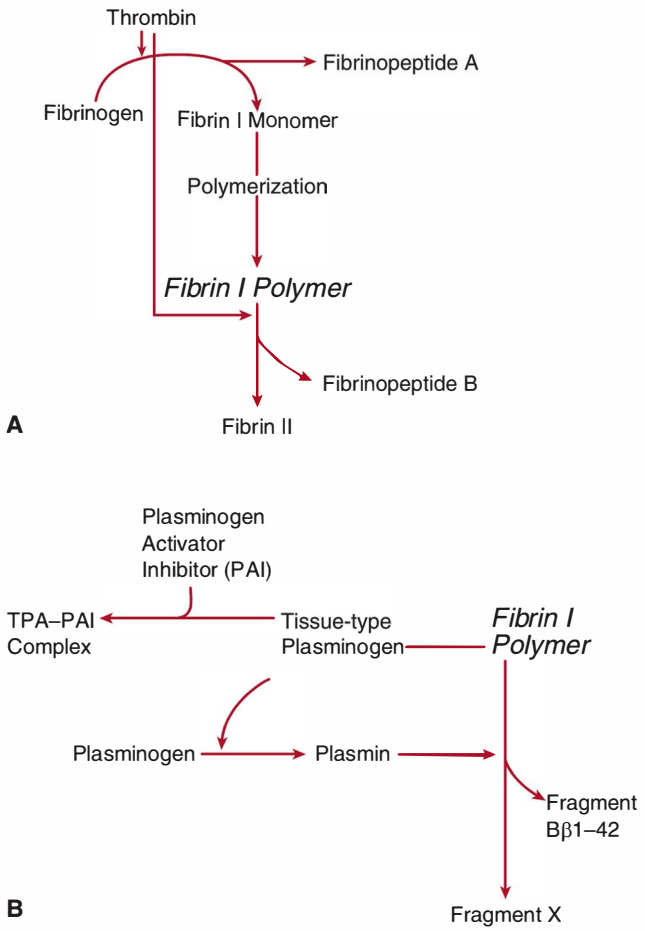

FIGURE 58.3 The actions of thrombin **(A)** and plasmin **(B)** on fibrin I polymer. **A:** The conversion of fibrinogen to fibrin II polymer by thrombin. **B:** The action of plasmin on fibrin I polymer. The fibrinolytic capacity of human plasma is determined primarily by the activity of tissue-type plasminogen activator (tPA) and its inhibitor (plasminogen activator inhibitor 1 [PAI-1]), which are released from vascular endothelial cells. tPA is able to bind to fibrin I polymer, which allows plasminogen to be activated to plasmin at an increased rate.

thrombus.[85] In addition, D-dimer levels can be elevated in the absence of concomitant evidence of angiographic reperfusion after thrombolysis.[85] There are two potential explanations for these findings. The first is that a flaw in the design of D-dimer assays can limit its specificity and lead to higher than expected plasma levels.[64,86] Although a monoclonal antibody is used to "capture" the D-dimer in plasma, a panspecific antibody is sometimes used to identify the bound antigen. Cross-reactivity of this "tag" antibody with FDPs would lead to an overestimate of D-dimer levels in the setting of thrombolytic therapy. Rather than reflecting clot lysis, a second possibility is that the elevated D-dimer levels after thrombolytic therapy may reflect large amounts of circulating soluble cross-linked fibrin,[64] thereby explaining the increased D-dimer levels that occur in the absence of angiographic evidence of reperfusion.[64]

As an alternative to D-dimer, plasma levels of soluble fibrin monomer, a complex of fibrin monomer with fibrinogen, can be measured as an index of thrombin action on fibrinogen. Early assays used protamine sulfate to precipitate soluble fibrin monomers,[87] but newer tests use monoclonal antibodies against fibrin-specific epitopes on the α or γ chains, or examine the cofactor activity of fibrin monomer in a tPA-induced plasminogen activation assay.[88] The two types of assays yield different results, highlighting the need for standardization. Theoretically, assays for soluble fibrin monomer may be superior to D-dimer assays if patients with thrombosis have reduced fibrinolytic activity, as has been suggested by some investigators.[89]

Assays for Plasmin–α_2-Antiplasmin

α_2-antiplasmin, the major plasma inhibitor of plasmin, forms a 1:1 stoichiometric complex with the enzyme.[90–94] The reaction between plasmin and α_2-antiplasmin is extremely rapid and the enzyme–inhibitor complex is stable and devoid of enzyme activity.[33,95,96] Assays that measure the plasma levels of plasmin–α_2-antiplasmin complexes have been developed and can be used as an index of *in vivo* plasmin generation.[22,33,34,35–38] Increased levels of complex have been detected in patients with intravascular coagulation,[97] consistent with the activation of fibrinolysis that occurs in this disorder.

APPLICATIONS OF ASSAYS

Influence of Physiologic Factors and Organ Dysfunction

A number of variables can result in overlap of assay results between individuals with a pathologic condition or altered physiologic status and health. Although values further from the mean of the normal distribution are more likely to be abnormal, appropriate interpretation requires an appreciation of the factors that can influence measurements.

The normal aging process alters coagulation activation in a predictable fashion.[18,98,99] With advancing age from 45 to 70 years, an increasing number of patients who are otherwise healthy exhibit elevated levels of F1+2. This reflects increased thrombin generation because clearance of radiolabeled F1+2 is unchanged.[98] The levels of the factor IX and X activation peptides also increase with advancing age.[10] Significant, but somewhat less striking, positive correlations have been observed between increasing age and the levels of fibrinopeptide A and protein C activation peptide.[98] In a study of 25 healthy Italian centenarians, coagulation and fibrinolysis measurements were compared with two control groups of healthy adults ranging from 18 to 50 years and 51 to 69 years.[99] Older controls generally had slightly higher values of several measurements than younger controls. Centenarians had striking signs of heightened coagulation enzyme activity as assessed by plasma measurements of factor VIIa ($P < 0.01$ compared with either control group) or the activation peptides of factor IX, factor X, and prothrombin and TAT complexes ($P < 0.001$ for all). Heightened coagulation enzyme activity was accompanied by enhanced formation of fibrin (high fibrinopeptide A and D-dimer, $P < 0.001$) and secondary fibrinolysis (plasmin–antiplasmin complex, $P < 0.001$).

It has been reported that strenuous exercise in the form of long-distance running leads to increased TAT complex levels without elevations in the levels of fibrinopeptide A.[100] Cigarette smoking has been associated with elevations in activation markers of blood coagulation.[101]

Certain medications that are not known to have a direct effect on blood coagulation can alter the activity of the coagulation mechanism. Caine et al.[102] showed that administration of conjugated equine estrogen daily to menopausal women for 3 months increased the levels of F1+2 in a dose-dependent manner. The activity of fibrinopeptide A also increased, and levels of protein S and antithrombin were decreased as compared to placebo treatment. In women who had undergone oophorectomy, Kroon et al.[103] confirmed that 0.625 mg of conjugated equine estrogen, as well as 0.05 transdermal 17β-estradiol daily for 6 weeks increased levels of F1+2. Scarabin et al.[104] found that 2 mg of estrogen valerate daily with cyclic progesterone increased F1+2 levels and decreased antithrombin activity, whereas transdermal estrogen (2.5 mg 17β-estradiol daily with cyclic progesterone) did not. The treatment of patients with coronary heart disease with gemfibrozil, a drug used to lower serum cholesterol and triglyceride concentrations, reduces F1+2 levels by approximately 25%.[105]

In healthy volunteers, postprandial elevations in the levels of factors VIIa and IX activation peptide have been demonstrated, but no changes were observed in the levels of factor XIIa or indices of thrombin generation.[106–108] The roles of factors XII, XI, and IX in factor VII activation were evaluated by investigating patients with isolated deficiencies of these factors after a fatty meal.[106,108] Factor VIIa levels increased postprandially in patients with factor XII deficiency but did not change in those with factor IX deficiency. In patients with factor XI deficiency, Miller et al.[106] found that factor VIIa levels rose postprandially, whereas Silveira et al.[108] did not observe significant alterations. From these studies, it can be concluded that factor IX plays a critical role in the events linking postprandial lipemia to factor VII activation, but factor XII does not. This implies that factor XII is not involved in the activation of factor VII by lipolysis of triglyceride-rich lipoproteins.

Dysfunction in normal physiologic clearance mechanisms can also result in substantial elevations in the levels of activation peptides. For F1+2, this has been demonstrated in patients with chronic renal failure on dialysis.[109,110] Caution is required, therefore, in interpreting an elevated level of a marker as evidence of heightened coagulation or fibrinolytic activity in disorders associated with renal (e.g., thrombotic thrombocytopenic purpura, systemic lupus erythematosus, nephrotic syndrome, renal transplant rejection) or hepatic dysfunction. In a prospective epidemiologic study of healthy middle-aged males, the Second Northwick Park Heart Study (NPHSII) measured the levels of F1+2, fibrinopeptide A, factor IX activation peptide, factor X activation peptide, factor VIIa, and factor XIIa. The factor IX activation peptide was the only coagulation activation marker found to correlate with creatinine.[111]

To determine the influence of inflammation on levels of activated markers of coagulation, correlation analysis was done between C-reactive protein (CRP) and factor XIIa, factor VIIa, factor IX activation peptide, factor X activation peptide, F1+2, and FPA in healthy individuals within NPHSII.[111] Only weak significant correlations (Pearson correlation 0.15, $n >$ 1,135) were observed for each analyte with CRP, suggesting that inflammation does not contribute a great deal to levels of coagulation activation markers. The Pearson correlation between CRP and fibrinogen in the same individuals was 0.45, suggesting a large influence of inflammation upon fibrinogen. Stronger correlations were, however, observed between the coagulation activation markers downstream from FVIIa-tissue factor. Factor IX activation peptide and factor X activation peptide were highly correlated (0.47, n = 1,335), while the correlation coefficients between factor X activation peptide and prothrombin F1+2 or factor VIIa were 0.23 and 0.21, respectively.

Disseminated Intravascular Coagulation

A number of factors can trigger disseminated intravascular coagulation (DIC), and increased coagulation system activation and secondary fibrinolysis are cardinal features of the disorder. The aforementioned assays should therefore be sensitive markers of acute or chronic DIC syndromes, and elevations in levels of factor X activation peptide,[12] protein C activation markers,[27,59,112] F1+2,[16,24] TAT complex,[16,113–115] fibrinopeptide A,[24,29,30,53,55,116] fibrinopeptide B,[31,32,62] and Bβ1–42[62] have been observed in such patients. However, the sensitivity and specificity of these assays for the diagnosis of DIC have yet to be determined, and the diagnosis of DIC can usually be made with simpler laboratory tests.

Nossel et al.[62] used radioimmunoassays for fibrinopeptide A, B, and Bβ1–42 (measured as thrombin-increasable fibrinopeptide B) to investigate the pathophysiology of DIC in patients receiving hypertonic saline to terminate pregnancy. Immediately after intrauterine infusion, there was a marked increase in fibrinopeptide A levels, an index of thrombin action on fibrinogen. This was followed by a rise in the concentration of Bβ1–42, a measure of plasmin action on non–cross-linked fibrin I polymer. On the basis of these observations, it was hypothesized that the relative rates of proteolysis of the Bβ chain of fibrinogen by thrombin and plasmin were determinants for venous thrombosis.[60] Supporting this concept, a study of patients undergoing neurosurgery and craniotomy found that individuals who developed venous thrombosis exhibited fibrinopeptide A levels that were considerably greater than those of Bβ1–42 during the 4 days preceding the onset of this disorder. These observations suggest that thrombosis occurs at a time when thrombin action predominates over that of plasmin. Studies have also been carried out to determine whether elevated levels of plasmin–α_2-antiplasmin complexes before surgery are predictive of postoperative venous thrombosis.[117,118] These data suggest that patients subjected to major abdominal surgery, who have enhanced fibrinolytic activity preoperatively, have a lesser tendency to develop postoperative deep venous thrombosis.

Venous Thromboembolism

Levels of F1+2,[14,119,120] TAT complex,[113,115,119,120] fibrinopeptide A[29,53,121,122] and B,[31,32] and protein C activation peptide[24] are frequently elevated in symptomatic patients with venous thrombosis, pulmonary embolism, or both. Although these parameters are sensitive indices of hemostatic enzyme generation, the tests are not specific for intravascular thrombosis. Elevated values have been reported in nonpathologic, as well as in pathologic conditions, including localized and generalized infections, cancer, and connective tissue disease (Table 58.2).

D-dimer testing has emerged as a cost-effective strategy to help exclude the diagnosis of acute venous thromboembolism, thereby obviating the need for serial imaging studies (see Chapter 83). The D-dimer tests with the highest sensitivity are those that use the EIA format. Although initial EIA technology

Table 58.2

Conditions associated with elevated levels of markers of coagulation activation (excluding thrombosis or DIC)

Condition	Marker (Reference)
Physiologic	
Normal aging	F1+2,[18,98,99] FPA,[98] PCP,[98] factor IX activation peptide,[10] D-dimer[99]
Strenuous exercise	TAT[100]
Alimentary lipemia	Factor VIIa,[106–108] factor IX activation peptide[108]
Normal pregnancy	F1+2,[123] D-dimer[124]
Pathologic	
Cigarette smoking	Activation peptides of factor IX and X, F1+2[101]
Postmenopausal estrogen use	F1+2, FPA[102]
Systemic lupus erythematosus	FPA[30,124]
Malignancy	F1+2, FPA[12,125,126]
Acute myelogenous leukemia	F1+2, FPA[24,127,128]
Sickle cell disease	F1+2, FPA, D-dimer[129–132]
Prothrombin complex concentrate administration in hemophilia B	Factor X activation peptide, F1+2, TAT, FPA[133,134,135]
Hemolytic uremic syndrome in children	F1+2, TAT[136]

FPA, fibrinopeptide A; PCP, protein C activation peptide; TAT, thrombin–antithrombin complex.

was cumbersome, time-consuming, and only amenable for batch assays, current assays can be done rapidly and samples can be assayed individually.[137–139] The accuracy of rapid EIA methods is similar to that of the original, more cumbersome assays, and these tests are considered to be the gold standard for measuring D-dimer levels.

The results of quantitative D-dimer assays, measured at the end of warfarin therapy and then 1 month after its discontinuation may also help stratify patients with an initial unprovoked episode of venous thromboembolism with respect to recurrence risk.[140–146] A meta-analysis of seven studies including a total of 1,888 patients who completed at least 3 months of anticoagulation found that a D-dimer level of less than approximately 500 ng/mL ("a negative test") was associated with a 3.5% (95% CI 2.7 to 4.3) annual risk of recurrence, while a D-dimer over this level ("a positive test") was associated with an 8.9% (95% CI 5.8 to 11.9) risk in each of the first 2 years.[147] Potential difficulties in applying this approach in the clinic, however, are lack of agreement and different cutpoints for different commercially available D-dimer assays (there is no D-dimer "standard"). Clinicians must therefore rely on an assay manufacturer's cutpoint for a positive or negative D-dimer test based upon published studies assessing recurrence risk.[148]

Although assays for fibrin monomer have accuracies similar to those for D-dimer,[149–151] they have yet to be rigorously tested in clinical management studies. It is important to point out that each assay is different, and results obtained with one assay cannot be extrapolated to another.[82,152] Consequently, each individual assay must be evaluated in prospective management studies before it can be adopted into clinical practice.

Sepsis

Septicemia frequently results in disturbances of the hemostatic mechanism. In septic shock, DIC can lead to the deposition of fibrin in the microvasculature and the failure of multiple organs. Endotoxin, a lipopolysaccharide present in the outer membrane of gram-negative bacteria, plays an important role in the development of the clinical and laboratory manifestations of septicemia. The intravenous administration of *Escherichia coli* endotoxin to healthy volunteers under controlled conditions increases thrombin generation, as monitored by F1+2 and TAT complex assays, that is maximal 3 to 4 hours after infusion without evidence of contact system activation.[153] Evidence exists that this activation is driven by the tissue factor pathway (see subsequent text). Factor XI, interposed between the contact system and factor IX, is activated after endotoxin infusion.[6] The fibrinolytic system also is triggered by endotoxin, as evidenced by increased levels of tPA and plasmin–α_2-antiplasmin complex at 2 to 3 hours.[153,154] This rise in fibrinolytic activity subsequently is offset by the release of PAI-1.

Many of endotoxin's biologic effects appear to be mediated by cytokines synthesized and released by macrophages and monocytes. High levels of cytokines, tumor necrosis factor (TNF), and interleukin-6 (IL-6) have been observed within the first 2 hours of administering endotoxin to healthy subjects.[153–156] Bauer et al.[157] showed that TNF has a potent procoagulant effect *in vivo* by studying the changes in the levels of F1+2, protein C activation peptide, and fibrinopeptide A after the administration of the recombinant cytokine to patients with cancer. In healthy volunteer studies, the early dynamics and route of

coagulation activation in response to TNF administration were investigated.[158] This resulted in the early activation of factor X, probably by the factor VII–tissue factor pathway. Infusion of recombinant IL-6 into patients with renal cell carcinoma results in elevated plasma concentrations of F1+2 and TAT complexes; fibrinolysis is not affected.[156]

Because the immunoreactivities of coagulation system zymogens and their respective activation peptides are virtually identical in humans and chimpanzees, it has been possible to reproduce a coagulopathic response to intravenous endotoxin in this animal that is similar to that in humans.[159] To investigate the molecular pathways elicited by endotoxin, pentoxifylline, a xanthine oxidase inhibitor that interrupts "immediate early" gene activation by monocytes, or a potent monoclonal antibody that rapidly neutralizes tissue factor–mediated initiation of coagulation, was administered to chimpanzees just before infusing endotoxin. Pentoxifylline markedly inhibited the endotoxin-elicited increases in serum levels of TNF and IL-6, as well as the effects on coagulation (as measured by assays for F1+2, TAT complex, and fibrinopeptide A) and fibrinolysis (as monitored by assays for plasminogen activator activity and plasmin–α_2-antiplasmin complexes). In contrast, the monoclonal antibody to tissue factor completely abrogated the augmentation in thrombin generation, but had no effect on cytokine levels or the fibrinolytic response. These data indicate that the fibrinolytic response triggered by endotoxin is not dependent on the generation of thrombin and that cytokines may be important in mediating the activation of both the coagulation and the fibrinolytic mechanisms *in vivo*. In addition, treatment with an antibody to IL-6 prevents coagulation activation after administration of a low dose of endotoxin to chimpanzees and does not affect activation of the fibrinolytic system.[156] IL-6 probably augments coagulation by an indirect mechanism, because this cytokine has not been reported to influence the hemostatic properties of vascular endothelium or monocytes *in vitro*. Studies of administration of live *E. coli* to primates (baboons) indicate that, although an antibody to factor XII can inhibit activation of the contact system, it has no effect on the manifestations of DIC (see Chapter 15B).

Hereditary Deficiencies of Coagulation Factors

The investigation of patients with hereditary coagulation factor deficiencies using the activation peptide assays has generated information about the pathways responsible for coagulation activation *in vivo* under basal conditions (i.e., the absence of thrombosis or provocative stimuli). Patients with factor VII deficiency, but not factor XI deficiency, have reduced levels of factor IX activation,[10,11] whereas patients with deficiencies of factor VIII or factor IX have normal levels of factor X and prothrombin activation.[12] The administration of relatively small doses of recombinant factor VIIa (10 to 20 μg/kg of body weight) to patients with factor VII deficiency results in substantial elevations in the plasma concentrations of the factor IX activation peptide, factor X activation peptide, and F1+2.[160] Therefore, these data demonstrate that the factor VII–tissue factor pathway is largely responsible for the activation of factor IX, as well as factor X in the basal state.[10,12,160] Using a clotting assay for factor VIIa, patients with severe factor IX deficiency were found to have circulating levels of factor VIIa <10% of those in healthy individuals.[8,161] This suggests that factor IXa is the principal activator of factor VII *in vivo* under basal conditions. These observations were corroborated in NPHSII, in which a haplotype in the F7 gene was associated with particularly reduced factor VII coagulant activity levels, and significantly reduced factor VIIa and factor IX activation peptide levels; this suggests that under basal conditions factor VIIa is also a principal activator of factor IX.[162]

To provide direct proof that basal level activation of the hemostatic mechanism occurs via factor VIIa–dependent activation of factor X, a monoclonal antibody directed against human tissue factor was administered to normal chimpanzees before infusing relatively high concentrations of recombinant factor VIIa (~50 μg/kg body weight).[163] The monoclonal antibody used in this study is a potent inhibitor of factor VIIa–tissue factor complex function *in vitro*.[164] The administration of antibody before factor VIIa abolished the significant increases in the plasma levels of factor IX activation peptide, factor X activation peptide, and F1+2 mediated by the infused recombinant protein alone.

Infusions of highly purified factor IX concentrate to individuals with hemophilia B increase plasma factor IX activation peptide levels that are initially greatly decreased, but do not change factor X activation peptide or F1+2 measurements.[160] Administration of highly purified factor VIII concentrates to patients with hemophilia A results in no significant change in concentrations of factor X activation peptide and F1+2.[160] These observations therefore indicate that the factor IXa–factor VIIIa–cell surface complex is unable to activate factor X under basal conditions. In response to vascular injury or thrombotic stimuli, it is surmised that increased formation of free thrombin or factor Xa via the action of the factor VII–tissue factor pathway generates factor VIIIa on a natural surface (e.g., activated platelets) on which assembly of the factor IXa–factor VIIIa complex takes place. This hypothesis is consistent with the severe bleeding tendency of most patients with factor VIII or factor IX deficiency and with the insensitivity of the factor X activation peptide and F1+2 assays to significant deficiencies of these two proteins.

The earlier mechanistic findings derived from studies of patients with coagulation factor deficiencies have significant potential implications regarding the utility of basal coagulation system markers in diagnosing patients with prethrombotic disorders.[160] It follows that the conversion of a prethrombotic state to a thrombotic event occurs due to small increases in the generation rates of hemostatic enzymes that exceed the inhibitory threshold of an individual's endogenous anticoagulant mechanisms. It remains to be determined whether persons with elevated basal levels of coagulation system markers are more likely to respond in a hypersensitive fashion to environmental stimuli. Because the activity of the blood coagulation mechanism in such individuals is closer to the threshold of normal inhibitory processes, they may generate slightly more thrombin by the extrinsic pathway. This thrombin could then be used to ignite the dormant intrinsic cascade, which could ultimately result in the generation of large amounts of free thrombin and the development of arterial or venous thrombosis.

Hereditary Thrombotic Disorders

Hereditary deficiencies of proteins C, S, and antithrombin, as well as activated protein C resistance caused by the factor V–Arg506Gln variant have all been associated with hypercoagulable states, and coagulation activation has been investigated in patients with each of these disorders. In asymptomatic individuals with heterozygous deficiencies of protein C or protein S, the mean F1+2 level is significantly increased as compared

to age-matched controls.[165,166,167] Approximately one third of patients have levels greater than the upper limit of normal controls (defined as the mean +2 standard deviations).[165,166] The elevated F1+2 concentrations are not caused by diminished clearance of the polypeptide.[165] Fibrinopepetide A levels are elevated in approximately 20% of subjects.[165,166]

Protein C activation as measured by its peptide or an immunoenzymatic assay for activated protein C is reduced to approximately 50% of normal in asymptomatic persons with heterozygous protein C deficiency.[24,56] In two adult patients with homozygous protein C deficiency, it was shown that the levels of protein C activation peptide as well as F1+2 can be normalized by administration of a monoclonal antibody–purified protein C concentrate.[168] Therefore, augmented activity of the protein C anticoagulant pathway can inhibit prothrombin activation *in vivo*, and protein C activation by the thrombin–thrombomodulin complex is a tonically active mechanism in the regulation of coagulation system activation.

Markers of thrombin generation have been measured in asymptomatic nonanticoagulated patients from thrombophilic families with the factor V–Arg506Gln variant. Martinelli et al.[169] reported that the median levels of F1+2 and TAT complex were significantly elevated in 69 heterozygotes from 23 families as compared to age- and sex-matched controls (for F1+2 and TAT complexes, 1.24 nM and 3.3 ng/L vs. 1.08 nM and 2.4 ng/mL, $P < 0.005$, respectively). Similar results were obtained by Zöller et al.[167] for F1+2 in 38 nonanticoagulated patients (1.7 vs. 1.3 nM, $P < 0.001$). In the NPHSII, a prospective cardiovascular survey of healthy men, aged 50 to 61, with no antecedent history of thrombosis, the mean levels of F1+2 were found to be significantly increased among heterozygous carriers of either the factor V–Arg506Gln variant or the prothrombin G20210A variant.[170]

In asymptomatic patients with hereditary antithrombin deficiency (levels ~50% of normal), it was initially reported that F1+2 levels are frequently increased as compared to age-matched unaffected siblings,[14] while fibrinopeptide A measurements were similar in both groups. Subsequently, it was shown that the high concentrations of the fragment resulted from an *in vitro* effect due to the presence of low amounts of heparin (final concentration of 4 U/mL) in the anticoagulant cocktail used for sample collection in the presence of reduced blood levels of antithrombin.[171] Other studies of antithrombin-deficient subjects did not demonstrate significant elevations in plasma F1+2 or fibrinopeptide A levels.[166,172] An investigation of a single large family with functional antithrombin deficiency (antithrombin Hamilton, a type II mutation having diminished serine protease reactivity) found significantly higher levels of F1+2 in affected family members than in those without the mutation.[173] However, the mean F1+2 level was within the normal range, and the majority had normal levels. The mean levels of TAT complex and fibrinopeptide A were not significantly different between the antithrombin-deficient individuals and their unaffected family members.[173] The reason for this apparent paradox in patients with heterozygous antithrombin deficiency, which is generally considered as the most prothrombotic disorder among the hereditary thrombophilias, is unknown.

Lupus Anticoagulants

Ginsberg et al.[174] found that the presence of anticardiolipin antibodies in patients with systemic lupus erythematosus is associated with a prothrombotic state as measured by the F1+2 and fibrinopeptide A assays. This relation was maintained even after excluding from analysis those individuals with prior thrombotic histories. Another study by Tripodi et al.[175] of patients with systemic lupus erythematosus and lupus anticoagulants found significant elevations in fibrinopeptide A, but not F1+2.

Acute Coronary Syndromes

This section reviews data about coagulation activation markers in patients with acute coronary syndromes (ACS) and describes how this information has helped to clarify the pathophysiology of coronary artery thrombosis. Most patients with acute myocardial infarction and unstable angina have high plasma levels of fibrinopeptide A.[176,177] The levels of fibrinopeptide A in spot urine samples and 24-hour urine collections from these patients also have been found to be elevated.[178,179] These findings are consistent with the results of angiographic, angioscopic, and pathologic studies that have clearly shown that intracoronary thrombosis plays a pivotal role in the pathogenesis of these coronary syndromes.[180]

Abnormally high plasma F1+2 or fibrinopeptide A levels are found in approximately 50% of patients during the acute phase of the disease.[181] No difference in the magnitude of the elevation in the levels of these peptides has been observed between patients with unstable angina than in those with acute myocardial infarction.[181] This may indicate that plasma F1+2 and fibrinopeptide A levels are not dependent on the characteristics of the thrombus (which is nonocclusive and platelet-rich in unstable angina, but occlusive and fibrin-rich in myocardial infarction),[182] but rather reflect a systemic condition of hypercoagulability.

The degree of coagulation activation seems to be related to prognosis. Ardissino et al.[183] measured both plasma and urinary fibrinopeptide A levels in patients with unstable angina on hospital admission and found that elevated plasma levels were associated with a higher risk of developing primary (death or myocardial infarction) or secondary (refractory angina requiring emergency coronary revascularization) clinical end points during hospitalization. Granger et al.[184] found that higher baseline levels of F1+2 were associated with an increased likelihood of death or myocardial reinfarction during a 30-day follow-up period in patients with myocardial infarction receiving thrombolytic therapy.

The serial measurement of coagulation activation peptides over time has provided interesting information concerning the pathophysiology of ACS. Merlini et al.[181] measured F1+2 and fibrinopeptide A plasma levels in patients with unstable angina or acute myocardial infarction during the acute phase and 6 months after their initial acute presentation. Both analytes were elevated during the acute ischemic episode, thereby reflecting the presence of an intracoronary thrombosis. However, in patients with an uneventful clinical course at 6 months, fibrinopeptide A levels had returned to the normal range, whereas F1+2 levels remained high. This observation indicates that increased thrombin generation persists after ACS episodes but is not sufficient to initiate fibrin formation and deposition. It is not known whether the presence of such biochemical hypercoagulability state is a risk factor for the occurrence (or recurrence) of coronary events, but studies to address this question in both healthy populations without prior cardiac events, as well as patients with recent prior coronary events are ongoing.

Coronary angioplasty mechanically causes plaque disruption that exposes the procoagulant matrix of the plaque itself to blood flow, giving rise to thrombosis. Abrupt coronary artery occlusion still represents one of the major complications of the procedure. Marmur et al.[185] measured arterial blood F1+2 and fibrinopeptide A during uncomplicated coronary angioplasty. Although no changes occurred in most patients, seven of 32 showed an increase in F1+2, which was associated with an increase in fibrinopeptide A in four. These data show that most patients do not experience heightened coagulation system activation during uncomplicated coronary angioplasty under antithrombotic treatment with heparin; however, a few do, and this could be due to the biochemical characteristics of the plaque itself[186] or to deeper trauma of the vessel wall induced by the angioplasty procedure. In another series of patients undergoing mechanical revascularization, Oltrona et al.[187] showed that a failure to normalize fibrinopeptide A levels during the procedure (heparin resistance) was associated with a higher risk of complications. In a study comparing fibrinopeptide A, F1+2 and TAT complex following plain old balloon angioplasty, coronary stenting, and cutting balloon angioplasty, coagulation was found to be less activated following cutting balloon angioplasty.[188]

Atrial Fibrillation

Chronic atrial fibrillation predisposes to thromboembolism, and cardioversion itself also is associated with cerebral, systemic, and pulmonary embolic events. The mechanism underlying the occurrence of embolic episodes after the restoration of sinus rhythm in these patients is poorly understood. The reduction in the incidence of cardioversion-related embolic events induced by the administration of warfarin has led to the widespread recommendation that anticoagulation should be prescribed for several weeks before and after cardioversion in patients with chronic atrial fibrillation.[189] The use of anticoagulants, however, is not recommended in patients with acute atrial fibrillation lasting <48 hours who undergo cardioversion, although definitive data about the risk of postcardioversion embolism in these patients are scanty. The finding of atrial thrombosis in 14% of patients with recent-onset atrial fibrillation suggests that these individuals also are at risk for developing embolic events.[190] Oltrona et al.[191] measured the plasma concentrations of TAT complex and fibrinopeptide A in a series of patients with acute nonvalvular atrial fibrillation and found a significant increase in the plasma concentrations of both markers early after pharmacologic cardioversion as compared to hospital admission; the levels decreased toward baseline values 1 month after restoration of sinus rhythm. This finding of a hypercoagulable state early after cardioversion in patients with recent-onset atrial fibrillation thereby raises the important question as to whether prophylactic antithrombotic treatment also should be adopted for these cases.

Predicting Risk of a Heart Disease Event in Health

Geometric mean levels for coagulation activation markers were assessed at baseline in the prospective study, NPHSII, and analyzed for those who went on to have a myocardial infarction (clinical and silent), and those who went on to have coronary intervention procedures. There was no indication that increased thrombin generation occurred in the baseline samples of those who developed a coronary ischemic event, neither was there any indication that increased factor XIIa contributed to future development of coronary ischemic events. However, geometric mean levels of FVIIa were significantly lower in each coronary heart disease (CHD) group compared with those who had no event, while factor IX activation peptide levels were significantly higher in those who had a future myocardial infarction (MI). Further analysis confirmed that low factor VIIa and high factor IX activation peptide levels were independently associated with future development of MI or total coronary ischemic events when included in the same model. While these results seem rather counterintuitive, further analysis of NPHSII using haplotype data for the factor VII gene has also revealed a haplotype associated with low levels of FVII (factor VII antigen and particularly low factor VIIc), but also resulting in low factor VIIa levels, and the haplotype was associated with increased risk of a future coronary ischemic event. However, this factor VII haplotype, as mentioned previously, was associated with reduced factor IX activation peptide levels.[156] One of the variants in this factor VII haplotype codes for the amino acid substitution R353Q. This variant has also been identified in patients with factor VII deficiency, particularly associated with a functional deficiency,[192] and interestingly, thrombotic events were also recorded in some of these patients.[193,194] Whether these findings suggest the possibility that a dampening of the tissue factor stimulated blood coagulation can lead to a coronary ischemic event, or whether these findings are specific to factor R353Q polymorphism, requires further study.

Antithrombotic Therapy

Intravenous heparin, a mainstay in the treatment of patients with ACS, acts by inhibiting thrombin and activated factors X and IX, and less potently activated factors XI and XII. The anticoagulant action of heparin is due primarily to its ability to bind antithrombin, thereby accelerating the rate of inhibition of the major coagulation enzymes, particularly thrombin. Biochemical studies of patients with ACS have demonstrated clearly that intravenous heparin rapidly inhibits the action of thrombin on fibrinogen and lowers plasma fibrinopeptide A levels to within the normal range.[195–197] Merlini et al.[198] showed that intravenous heparin at doses giving an activated partial thromboplastin time of more than double its baseline value reduced plasma fibrinopeptide A levels, but did not lower F1+2 levels in most patients. Studies have shown that hirudin, a high-affinity direct thrombin inhibitor, does not decrease thrombin generation in patients with stable angina or ACS.[199] Because thrombin plays a critical role in the amplification of the coagulation cascade by activating factor V and factor VIII, persistent thrombin generation may contribute partly to the persistent thrombotic risk that exists despite anticoagulation. Plasma levels of both fibrinopeptide A and F1+2 have been found to be higher in patients developing infarction, reinfarction, or refractory ischemia, suggesting that the presence of a persistent hypercoagulable state in patients with ACS, notwithstanding heparin therapy at the usual dose, still may be associated with an unfavorable outcome.[198,200]

The measurement of coagulation peptides after the discontinuation of heparin or hirudin has revealed the presence of a so-called rebound phenomenon. Gallino et al.[196] have shown that, although a decrease in plasma fibrinopeptide A levels occurs during heparin infusions, a sharp increase occurs once the infusion is over, which suggests a reactivation of coagulation

system activity. This finding has been confirmed by Granger et al.,[200] who found the same phenomenon for F1+2 and activated protein C levels (which also reflect, in part, increased thrombin generation). A similar effect has been observed after the discontinuation of argatroban, another direct thrombin inhibitor.[201] It is tempting to speculate that the increase in clinical events observed after the cessation of heparin or argatroban therapy is linked to this rebound in coagulation,[201,202] most likely due to the persistence of the original procoagulant activity that necessitated anticoagulation in the first place.

Therapy with oral anticoagulants such as warfarin suppresses prothrombin activation *in vivo* as measured by the F1+2.[203,204,205] In patients with prior thrombotic histories and high F1+2 levels, Conway et al.[203] demonstrated that stable anticoagulation at moderate intensity as reflected by international normalized ratios (INRs) of 2.5 to 3.5, produces 5- to 10-fold reductions in the extent of prothrombin activation. It also has been shown that the mean values of F1+2 decrease in parallel with the intensity of warfarin therapy. A study has demonstrated that a target INR range as low as 1.3 to 1.6 results, on average, in a 50% reduction in prothrombin activation from baseline levels.[205] It is important to note that the findings of these studies cannot be translated into clinical practice because the F1+2 level that confers antithrombotic protection has yet to be determined.

Although F1+2 levels often are suppressed below normal in stably anticoagulated patients on oral agents, this has not been observed for TAT complexes and fibrinopeptide A. However, it has been observed that plasma fibrinopeptide A concentrations increase above the normal range in patients with a history of myocardial infarction several weeks after the cessation of the drug.[206]

On the basis of these data, clinical studies have been carried out in situations in which the monitoring of coagulation system function by standard methods has been unsatisfactory (e.g., the prophylaxis of subacute thrombosis after stent implantation). The main problem of intracoronary stenting is subacute thrombosis, which often occurs unpredictably even in conditions of optimal anticoagulation according to classic standard coagulation tests. It has been shown that an increase in F1+2 levels, despite optimal anticoagulation, is a sensitive indicator of subacute thrombosis.[207] In a case–control study,[208] a study population on oral anticoagulants was investigated using F1+2 measurements, as well as classic coagulation tests and compared to a control population in which only the classical tests were used to monitor the level of anticoagulation. It was found that the incidence of subtotal occlusion was 3.5% in the study group, but 17% in the control group. For elective and nonelective stenting, the monitoring of F1+2 levels therefore may be associated with a reduced rate of subacute thrombosis.[208]

Extracorporeal Circulation

Using activation markers of coagulation, Boisclair et al.[52,109,172] have examined whether extracorporeal circulation in patients undergoing hemodialysis for chronic renal failure or cardiopulmonary bypass for coronary artery bypass grafting activates the contact system. They did not find that exposure of blood to foreign surfaces triggers contact activation and rather postulated it to be a consequence of defective neutralization of downstream coagulation proteases (e.g., factor Xa, thrombin) caused by the absence of normal vascular endothelium. In patients undergoing cardiopulmonary bypass, it was suggested that the surgery itself was primarily responsible for increased factor VII–tissue factor mechanism function and the subsequent generation of factor Xa and thrombin.[47] These findings, however, must be reconciled with the observations of increased kallikrein—and factor XIIa–C1 inhibitor complexes during bypass (see Chapter 15B). The fibrinopeptide assay was found to be a useful marker of thrombin activity in the extracorporeal circuit and has been used for objectively monitoring the required dose of heparin, low molecular weight heparins, and heparinoids,[209–215] and assessing activated coagulation over the longer term in hemodialysis.[216]

Thrombolytic Therapy

The availability of biochemical markers that reflect the activation of the coagulation and fibrinolytic systems has led to a number of important observations in patients receiving thrombolytic therapy. The measurement of coagulation activation markers during thrombolytic therapy in patients with acute myocardial infarction has demonstrated the prothrombotic effect of thrombolytic therapy. In patients receiving streptokinase or recombinant tPA, there is an increase in the plasma levels of fibrinopeptide A, TAT complex, and F1+2.[217–220] Although the concomitant administration of heparin prevents fibrinopeptide A levels from increasing,[221] F1+2 levels increase in most patients despite the associated anticoagulant therapy.[222] These findings raise the question of the role of hypercoagulability in the pathogenesis of the failure of reperfusion or postthrombolytic reocclusion. The possibility exists that the ability of plasmin to activate platelets contributes to this. In patients receiving thrombolytic therapy, the behavior of coagulation activation markers after treatment seems to be predictive of outcome. Gulba et al.[223] have shown that patients in whom TAT complex levels increase 90 minutes after the start of thrombolytic therapy are those with no reperfusion or in whom reocclusion occurs. Granger et al.[184] have assessed the relation of fibrinopeptide A and F1+2 levels with subsequent reinfarction and death in patients who received either recombinant tPA or streptokinase; lower levels of fibrinopeptide A or F1+2 after 12 hours were associated with a trend toward a lower likelihood of subsequent reinfarction.

Merlini et al.[224] found that there was an increase in F1+2 levels in patients with unstable angina who received thrombolytic therapy in addition to heparin. In the patients who developed refractory angina or infarction, higher fibrinopeptide A levels also were measured, thereby suggesting that the hypercoagulable state induced by thrombolytic therapy may be detrimental in the setting of the nonocclusive thrombosis typical of unstable angina. This perhaps explains the unfavorable results of this therapy in such patients.

The validity of using plasma fibrinopeptide A and B levels as specific markers of thrombin activity in the setting of thrombolytic therapy has been questioned on the basis of observations that tPA and urokinase have direct catalytic activity against fibrinogen. Under plasminogen-free conditions, tPA releases fibrinopeptides A and B from fibrinogen, but unlike thrombin action on fibrinogen, the rate of tPA-induced fibrinopeptide B release is faster than that of fibrinopeptide A, and release of both fibrinopeptides is unaffected by heparin.[225] Urokinase also has catalytic activity against fibrinogen but only releases fibrinopeptide B.[226] Although pharmacologic concentrations of tPA may directly cleave fibrinopeptide A from fibrinogen, the observation

that therapy with either streptokinase or tPA leads to increased levels of fibrinopeptide A[218–220] that are rapidly lowered with high doses of heparin[220] suggests that thrombin is the major mediator of the elevated fibrinopeptide A levels in this setting.

Using concomitant measurements of Bβ1–42 and Bβ15–42 in patients receiving tPA therapy, Eisenberg et al.[65] demonstrated that the fibrinolytic effect of tPA therapy persists for some time after fibrinogenolysis ceases. This finding is consistent with the results of studies in experimental animals showing that tPA-induced clot lysis continues after the drug is cleared from the circulation,[227] likely reflecting enzymatically active tPA bound to the thrombus. In accord with these findings, it is of interest to note that the rapid administration of tPA in an animal model produces an enhanced thrombolytic effect with reduced bleeding, as compared to more prolonged infusions.[227] Despite the affinity of tPA for fibrin, its administration to patients with acute myocardial infarction or venous thromboembolic disease causes significant fibrinogenolysis. Using plasma levels of Bβ1–42 as an index of fibrinogenolysis, Owen et al.[228] demonstrated that streptokinase, a plasminogen activator without fibrin specificity, as well as tPA produced significant fibrinogen proteolysis. Although it was predicted that high doses of tPA would produce systemic fibrinogen breakdown, studies have provided a mechanism by which even physiologic concentrations of tPA can induce fibrinogenolysis. It has been shown that soluble FDPs, particularly (DD)E, potentiate tPA-induced plasminogen activation by binding both plasminogen and tPA.[229,230] These findings are not surprising given the potentiating activity of cyanogen bromide fragments of fibrin or fibrinogen[231–235] that are frequently used as stimulators in commercial tPA activity assays. Studies indicate that tPA binds to (DD)E with an affinity similar to fibrin. Likewise, plasminogen also binds to (DD)E with high affinity, suggesting that, like fibrin, (DD)E serves as a template to which both tPA and plasminogen bind.[236]

The interaction of tPA with (DD)E is mediated by its second kringle domain.[240] In contrast, tPA binds to fibrin mainly by its finger domain.[236,237] These findings rationalize the greater fibrin selectivity of vampire bat plasminogen activator (b-PA) relative to tPA. Although structurally similar to tPA, b-PA lacks a second kringle domain.[238] Consequently, unlike tPA, b-PA does not bind to (DD)E.[236]

Other Conditions Associated with Elevated Levels of Markers of Coagulation Activation

Elevated levels of markers of coagulation activation have been reported in settings in which thrombosis or DIC is not evident clinically. A list of some of these disorders is shown in Table 58.2.

CONCLUSION

This chapter has summarized the results of clinical studies that indicate that a biochemical imbalance between procoagulant and anticoagulant mechanisms can be detected in the blood of humans before the appearance of thrombotic phenomena. The continuing application of biochemical and clinical approaches to investigations of the hemostatic system should generate a greater appreciation of the mechanisms that lead to venous and arterial thrombotic disorders in humans.

CHAPTER 59

Overview of Acquired and Inherited Clinical Platelet Disorders

JOEL S. BENNETT

An insufficient number of platelets (thrombocytopenia) or impaired platelet function (thrombocytopathia) can produce bleeding. Both situations are encountered frequently in clinical practice, engendering substantial and appropriate concern about the risk and prevention of bleeding. A summary of key points to be taken from this overview are listed in Table 59.1.

QUANTITATIVE PLATELET DISORDERS

Definition of Thrombocytopenia and Risk of Bleeding

The normal range for platelet counts in healthy individuals is 150,000 to 350,000/μL. However, as discussed in Chapter 60, mean platelet counts are higher in women than men, independent of the presence of iron deficiency, and decline with age, especially after age 60.[1] Although the significance of severe thrombocytopenia is usually readily apparent, the significance of borderline thrombocytopenia, defined as a platelet count between 100,000 to 150,000/μL, is often unclear. Some platelet counts in this range are outliers of the normal platelet count distribution, but they can also represent an early manifestation of an unrecognized disease. Many patients with borderline thrombocytopenia carry a diagnosis of autoimmune thrombocytopenia (ATP), but in a prospective study of 217 healthy individuals with incidental borderline thrombocytopenia, 88% still had a platelet count of >100,000/μL after 5 years without a specific diagnosis being established.[2] Based primarily on this study, the International Working Group of the Vicenza Consensus Conference has set the threshold for the diagnosis of idiopathic thrombocytopenia (ITP) as a platelet count of <100,000/μL.[3]

The number of circulating platelets is the composite of the rate of platelet production, the rate of platelet destruction, and platelet sequestration in the spleen. In humans, the platelet lifespan is 7 to 10 days and reflects both nonrandom platelet senescence and random platelet consumption.[4] Platelet senescence is likely explained by an intrinsic apoptotic pathway that acts as an "internal timer," determining when an aged platelet should be removed from the circulation.[5,6] Based on measurements of platelet kinetics in patients with marrow hypoplasia, it has been predicted that there is a fixed platelet requirement of approximately 7,100 platelets/μL/d and that these platelets are used to support the integrity of the vasculature.[7] There is also a pool of platelets in the spleen that accounts for approximately 30% of the platelet volume in normal individuals and that is in dynamic equilibrium with platelets in the circulation.[8,9] However, >30% of the platelet volume may be sequestered in an enlarged spleen due to conditions such as portal hypertension or infiltrative diseases such as in myeloproliferative neoplasms.[10]

The normal platelet count is far in excess of the number of platelets required for hemostasis. Although the cutaneous bleeding time, a measure of platelet function *in vivo*, can be increased at platelet counts <100,000/μL,[11] significant spontaneous bleeding does not usually occur in an otherwise hemostatically normal individual until the platelet count declines to <5,000/μL.[12] Clinical trials of patients receiving chemotherapy or being treated for aplastic anemia indicate that a threshold of 10,000 platelets/μL is sufficient to minimize the risk of spontaneous bleeding,[13] and hemorrhage following trauma or surgery usually does not occur if the platelet count is >50,000/μL.[14,15] Nonetheless, there is no absolute threshold for spontaneous bleeding due to thrombocytopenia, and it can occur at higher platelet counts when fever, sepsis, severe anemia, or other hemostatic defects are present or when platelet function is impaired, for example, by medications.

Differential Diagnosis of Thrombocytopenia

From a practical clinical standpoint, thrombocytopenic disorders can be divided into those having an immunologic basis and those that do not.

Antibody-Mediated Thrombocytopenia

Immune Thrombocytopenia

Immune thrombocytopenia, also known as ITP or ATP, is an acquired disorder caused by antiplatelet antibodies.[16,17,18] As discussed in Chapter 61, ITP is characterized by the presence of an isolated platelet count of <100,000 in the context of normal red and white cell counts, a peripheral blood smear only remarkable for a decreased number of platelets, and the absence of splenomegaly.[17] In addition, a diagnosis of ITP requires that there be no family history of thrombocytopenia and no use of medications that can cause thrombocytopenia.[17,19] Because there is no standard diagnostic laboratory test for ITP, it is a diagnosis of exclusion.[20] Thus, when a patient's clinical presentation deviates from the paradigm given above, the diagnosis of

Table 59.1

Key points regarding thrombocytopenia and thrombocytopathia

- The platelet count of most asymptomatic patients with borderline thrombocytopenia (platelet counts of 100,000–150,000/μL) remains stable without a specific diagnosis.
- Significant spontaneous bleeding usually does not occur in an otherwise hemostatically normal individual until the platelet count declines to <5,000/μL.
- ATP is characterized by an isolated platelet count <100,000 in the context of normal red and white cell counts, a peripheral blood smear only remarkable for a decreased number of platelets, and the absence of splenomegaly. When a patient's clinical presentation deviates from this paradigm, the diagnosis of ATP must be reconsidered.
- The differential diagnosis of ATP includes pseudothrombocytopenia, drug-induced thrombocytopenia, underlying autoimmune disease, lymphoproliferative disorders, immunodeficiency, myelodysplasia, and infections with hepatitis C virus, human immunodeficiency virus, or *H. pylori*.
- Although many medications impair platelet function *in vitro*, only a few, including aspirin, the thienopyridines and the $\alpha_{IIb}\beta_3$ antagonists, regularly cause clinically significant bleeding.
- Nonimmune mechanisms can cause thrombocytopenia by decreasing platelet production by the bone marrow, platelet sequestration in an enlarged spleen, or by decreasing the lifespan of circulating platelets.
- Inherited thrombocytopenia is rare but must be considered in the differential diagnosis of a thrombocytopenic patient.
- Hereditary disorders of platelet adhesion, aggregation, and platelet secretion must be considered in the evaluation of easy bruising, menorrhagia, and excessive postoperative and postpartum blood loss.
- Abnormal hemostasis specifically due to perturbed platelet function is a feature of the chronic myeloproliferative disorders (PV, ET) and of dysproteinemias (multiple myeloma).

ITP must be reconsidered. ITP can occur at any age, in either sex, and can present with either spontaneous mucocutaneous bleeding or unexplained asymptomatic thrombocytopenia. Characteristically, the bone marrow of patients with ITP is normal, except for a compensatory increase in megakaryocytes, so that bone marrow examination is rarely necessary or helpful. Although assays are available to detect antiplatelet antibodies, they lack sensitivity and specificity and are rarely useful diagnostically.

In approximately half of the patients who are considered to have ITP, platelet antibodies are secondary to another disorder, for example, autoimmune diseases (systemic lupus erythematosus), lymphoproliferative disorders (chronic lymphocytic leukemia), immunodeficiency disorders (common variable immunodeficiency), myelodysplasia, and infections with hepatitis C virus, human immunodeficiency virus, or *Helicobacter pylori*.[20]

In adults, ITP is generally a chronic disease; only 15% of patients remit within a year of onset. By contrast, childhood ITP is often preceded by a febrile illness and more than 70% remit within 6 months, regardless of treatment; only 5% to 10% of children go on to develop chronic disease.[20] The goal of treatment of ITP is to maintain a safe, but not necessarily normal, platelet count with minimal toxicity from therapy.[17] As bleeding is usually minimal or absent until the platelet count is <30,000/μL, asymptomatic patients with a platelet count >30,000/μL can be followed with no treatment. Nonetheless, maintenance of a hemostatically effective platelet count may require the chronic administration of a low dose of corticosteroids (i.e., 10 mg of prednisone daily), splenectomy, or immunosuppression with drugs such rituximab, azathioprine, or cyclophosphamide. For patients refractory to therapy, treatment with the thrombopoietin receptor agonists romiplostim or eltrombopag can be considered.[21] When patients with ITP present emergently with severe thrombocytopenia (<5,000/μL) and/or major or life-threatening hemorrhage, treatment usually includes high-dose corticosteroids and/or intravenous immunoglobulin (IVIgG).[22] Anti-D immune globulin may be substituted for IVIgG in Rh-positive patients who have not undergone splenectomy. Platelet transfusions are generally unable to increase platelet counts in patients with severe ITP because of the rapid clearance of antibody-coated transfused platelets, but the concurrent transfusion of IVIgG and platelets has been reported to increase platelet counts in most patients.[23,24]

Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia results from sensitization to platelet alloantigens such as PI^{A1} following platelet or red cell transfusion to a patient lacking this antigen (post-transfusion purpura, PTP) or maternal sensitization to a foreign platelet antigen during pregnancy, similar to Rh incompatibility (neonatal alloimmune thrombocytopenia, NATP).[25,26] PTP causes profound thrombocytopenia 7 to 10 days after transfusion and can be treated with IVIgG or plasma exchange. NATP causes severe thrombocytopenia and bleeding in neonates and is treated with platelet transfusion, corticosteroids, and IVIgG.

Drug-Induced Thrombocytopenia

Antiplatelet antibodies induced by sensitization to drugs can cause acute platelet destruction and must be considered in the differential diagnosis of thrombocytopenia[27] (see Chapter 62). Although there is a long list of drugs reported to cause antibody-mediated platelet destruction, the evidence for the 24 drugs listed in Table 59.2 is particularly strong.[19] In general, drug-dependent antibody binding to platelets requires initial reversible binding

Table 59.2

Drugs associated with antibody-mediated thrombocytopenia

Abciximab
Acetaminophen
Amiodarone
Ampicillin
Carbamazepine
Eptifibatide
Haloperidol
Ibuprofen
Irinotecan
Naproxen
Oxaliplatin
Phenytoin
Piperacillin
Quinidine
Quinine
Ranitidine
Rifampin
Simvastatin
Sulfisoxazole
Tirofiban
Trimethoprim/Sulfamethoxazole
Valproic acid
Vancomycin

of a drug to platelet membrane glycoproteins.[28,29] Uncommonly, drugs such as penicillin act as haptens by covalently binding to platelet membrane glycoproteins or drugs such as gold salts, levodopa, and procaine amide induce platelet-specific neoantigens and a clinical scenario mimicking ITP.[30] In another variation of drug-induced thrombocytopenia, platelet counts may decrease immediately after administration of the chimeric human/murine anti-$\alpha_{IIb}\beta_3$ monoclonal antibody fragment abciximab due to preexisting antibodies against the murine portion of the drug, or thrombocytopenia can be delayed for 5 to 10 days during which time new antibodies are generated.[31] Similarly, acute thrombocytopenia can follow the administration of the small molecule $\alpha_{IIb}\beta_3$-antagonists eptifibatide and tirofiban.[31] Here, the thrombocytopenia is thought to be due to naturally occurring antibodies recognizing platelet neoepitopes induced by antagonist binding. Emergent treatment for severe drug-induced thrombocytopenia with bleeding includes stopping the likely offending medication, platelet transfusion, corticosteroids, and IVIgG, similar to the emergent treatment for severe ITP.

Heparin-induced thrombocytopenia (HIT) is a special case of drug-induced thrombocytopenia since it is associated with arterial and venous thrombosis rather than bleeding (see Chapter 108). Depending on the clinical population at risk, HIT occurs in approximately 1% to 5% of patients given unfractionated heparin for 5 to 10 days and is due to the formation of antibodies against a complex of heparin and the platelet α granule protein platelet factor 4.[32] HIT is a clinical diagnosis with criteria that include an acute decrease in platelet count of 50% or to >150,00/μL; the diagnosis is confirmed by appropriate testing for heparin-related antibodies.[32,33] If HIT is a possibility, all heparin administration should be stopped and alternative anticoagulation instituted with a direct thrombin inhibitor such as argatroban, at least until the platelet count returns to normal.[33] Warfarin should not be used for acute HIT because it can be associated with venous limb gangrene, a syndrome similar to warfarin-induced skin necrosis that may lead to amputation.[34]

Nonimmune Thrombocytopenia

Nonimmune mechanisms can cause thrombocytopenia by decreasing platelet production by the bone marrow, by decreasing the lifespan of circulating platelets, or by increasing platelet sequestration in an enlarged spleen.

Inherited Thrombocytopenia

Inherited thrombocytopenia can present in childhood in association with developmental disorders (Chapter 63). However, the diagnosis is easily overlooked in adults when thrombocytopenia is the major finding. Inherited thrombocytopenia often presents as macrothrombocytopenia, as in the Bernard-Soulier syndrome (BSS)[35] and MYH9-related disorders[36] (Chapters 63 and 65). Exceptions are the Wiskott-Aldrich syndrome and its variant X-linked thrombocytopenia that are characterized by small platelets[37] and rare reports of isolated familial thrombocytopenia with normal-sized platelets linked to mutations on chromosome 10.[38]

Nonimmune Causes of a Shortened Platelet Lifespan

These disorders include sepsis, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS), preeclampsia/eclampsia, cardiopulmonary bypass, and giant cavernous hemangiomas (Kasabach-Merritt syndrome) (see Chapter 64). The thrombocytopenia in these disorders resolves following treatment of the underlying disorder and platelet transfusion is rarely necessary. As noted for HIT, TTP/HUS is primarily a thrombotic, not a bleeding, disorder. DIC evolves first as a thrombotic disorder, with bleeding manifestations following consumption of platelets and coagulation factors.

Thrombocytopenia Due to Decreased Platelet Production

Thrombocytopenia due to decreased platelet production is caused by bone marrow disorders such as acute leukemia, aplastic anemia, myelodysplastic syndromes, and myelophthisic processes that results from bone marrow replacement by tumor (carcinoma, lymphoma, myeloma) or fibrous tissue, as well as by bone marrow suppression by chemotherapy, radiation, ethanol toxicity, and infection (HIV, measles, CMV, varicella). These disorders should be readily apparent by history and by careful examination of a peripheral blood smear. When the cause of decreased platelet production cannot be readily reversed,

long-term prophylactic platelet transfusion is frequently considered, but such treatment may lead to alloantibody development and refractoriness to platelet transfusion. To minimize the risk for refractoriness to transfusion, a threshold of 10,000 platelets/μL has been found to be sufficient for prophylactic transfusion to prevent spontaneous hemorrhage in patients being treated with cytotoxic chemotherapy, undergoing bone marrow transplantation or being followed for aplastic anemia.[13]

Thrombocytopenia Due to Platelet Sequestration in an Enlarged Spleen

Approximately 30% of the circulating platelet mass is normally present in the spleen,[8,9] but a greater percentage can be sequestered when the spleen is enlarged.[10] Platelet counts in this situation are generally in the range of 40,000 to 50,000/μL, but bleeding due to thrombocytopenia alone is unusual.

Pseudothrombocytopenia

Platelet clumping in a blood sample anticoagulated with ethylenediaminetetraacetic acid (EDTA) can cause spurious thrombocytopenia when platelet counts are measured in automated counters.[39,40] This *in vitro* artifact is caused by platelet-agglutinating antibodies that recognize epitopes predominantly on $\alpha_{IIb}\beta_3$ that are exposed at low calcium concentrations.[41] It can be distinguished from true thrombocytopenia by examining a blood film prepared from a finger stick or by performing a platelet count in blood anticoagulated with citrate or oxalate (FIGURE 59.1). The prevalence of pseudothrombocytopenia is 0.11% to12.5% of patients with a platelet count of <100,000/μL.[42]

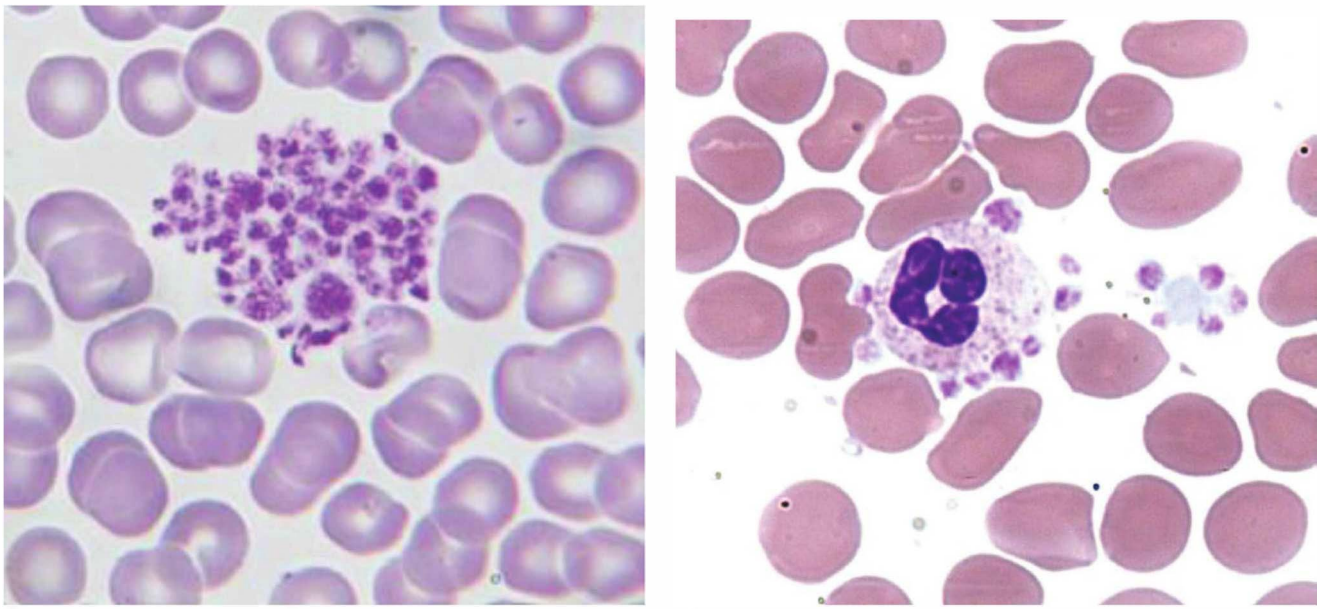
QUALITATIVE PLATELET DISORDERS

A prolonged bleeding time in a patient with a normal platelet count suggests a diagnosis of von Willebrand disease (Chapter 52) or an inherited or acquired qualitative platelet disorder (Chapters 65 and 66, respectively).

Inherited Qualitative Platelet Disorders

Inherited Disorders of Platelet Membrane Glycoproteins

Inherited abnormalities in the amount or function of the platelet membrane glycoprotein receptors for collagen (GPVI and the integrin $\alpha_2\beta_1$)[43–48] and for von Willebrand factor (vWF) (GPIb-IX-V)[35] impair platelet adhesion to the subendothelial connective tissue matrix under low shear and high shear conditions, respectively. The most common and best studied of these adhesion abnormalities is the autosomal recessive BSS caused by mutations in genes for GPIbα, GPIbβ, or GPIX.[35] The resulting deficiency or perturbed function of GPIb-IX-V produces macrothrombocytopenia, a markedly prolonged cutaneous bleeding time, absent ristocetin- and botrocetin-induced vWF binding to platelets, and mucocutaneous bleeding of variable severity that begins in infancy or childhood.[49] Glanzmann thrombasthenia (GT) is a rare autosomal recessive bleeding disorder in which platelets do not aggregate because of deficiency or abnormal function of the platelet fibrinogen receptor $\alpha_{IIb}\beta_3$ (also known as GPIIb/IIIa).[50] As with BSS, GT presents with mucocutaneous bleeding in infancy, but unlike BSS, the platelet count and



A B

FIGURE 59.1 Pseudothrombocytopenia. **A**: Peripheral blood smear from a patient with no history of bleeding, a normal hemoglobin, and a normal white cell count but a platelet count of 10,000/μL measured using an automated counter and blood anticoagulated with EDTA. The blood smear shows extensive platelet clumping. When the platelet count was repeated using blood anticoagulated with sodium citrate, it was normal. (Adapted from Chia J, Hsia CC. Pseudothrombocytopenia. *Blood* 2011;117:4168, with permission, Ref. [90]). **B**: An example of platelet satellitism in which platelets rosette around neutrophils due to antibody binding to EDTA-exposed epitopes on both platelet $\alpha_{IIb}\beta_3$ and neutrophil FcγIII receptors.

platelet morphology are normal and platelets in plasma agglutinate in the presence of ristocetin and botrocetin, but do not aggregate in response to ADP, collagen, or thrombin.[51]

Platelet Granule Disorders

Platelets contain three types of granules that are extruded from activated platelets in the platelet release reaction.[52] The granules include dense or δ granules containing ADP, ATP, calcium, serotonin, and pyrophosphate; α granules containing proteins either obtained from the plasma or synthesized and packaged by megakaryocytes; and lysosomes containing acid hydrolases and microperoxisomes. In these disorders, mucocutaneous bleeding can result from a decrease in the number of granules, a decrease in granular contents, or perturbations of granule secretion.

α granule deficiency is a rare cause of mild to moderate mucocutaneous bleeding and bone marrow fibrosis in which platelets have a gray appearance on peripheral blood smears due to the absence of α granules (gray platelet syndrome, GPS).[53] GPS is associated with mutations in the gene *NBEAL2* that encodes a protein involved in vesicular trafficking.[54–56] Dense granule deficiency (δ storage pool disease, δSPD) is the most common platelet secretion disorder and can be subclassified into δSPD associated with albinism (the Hermansky-Pudlack and Chediak-Higashi syndromes) and δSPD in otherwise normal individuals.[57] Patients with δSPD have a normal platelet count, a prolonged bleeding time, and abnormal platelet aggregation studies.[58] An increased ratio of platelet ATP to ADP because of absence of the dense granule pool of ADP is diagnostic.[58] Although bleeding in patients with secretion disorders can be controlled by platelet transfusion, this is seldom necessary because DDAVP can shorten the bleeding times and improve hemostasis.[59]

Disorders of Platelet Secretion

These are a heterogeneous collection of disorders of stimulus-response coupling in which the platelet function of affected individuals resembles that of individuals who have been given platelet inhibitory drugs such as aspirin. Thus, there may be marked impairment of aggregation and secretion in response to weak platelet agonists (ADP, epinephrine, low concentration of collagen), while responses to stronger agonists may be normal; the bleeding time is usually prolonged. Although inherited abnormalities in platelet signal transduction are rare, they have been particularly informative in understanding normal platelet physiology.

Disorders of Platelet Coagulant Activity

The plasma membrane of activated platelets provides a procoagulant surface for the assembly of the "tenase" and "prothrombinase" complexes that activate coagulation factor X and prothrombin, respectively (see Chapter 35). At a minimum, this activity results from the calcium-induced exposure of acidic phospholipids on the platelet surface, thought to be brought about by a membrane-associated scramblase.[60–62] Isolated deficiency of platelet procoagulant activity, designated Scott syndrome, is exceedingly rare[63] and results from the inability of platelets to translocate acidic phospholipids from the inner to the outer leaflet of the platelet plasma membrane. Mutations in the protein TMEM16F linked to scramblase activity may be causative of Scott syndrome.[62,64]

Acquired Disorders of Platelet Function

Acquired platelet function disorders are relatively common, but are usually asymptomatic or mild. Nonetheless, they can be of clinical importance when they occur concurrently with another hemostatic abnormality.

Drugs

Although a wide variety of drugs can impair platelet function *in vitro*, only a small number regularly produce clinically significant bleeding (see Chapter 66). These include aspirin,[65] other NSAIDs,[66–68] the thienopyridines and other $P2Y_{12}$ inhibitors,[69] and the $\alpha_{IIb}\beta_3$ antagonists abciximab, tirofiban, and eptifibatide.[70] Aspirin prevents platelet synthesis of thromboxane A2.[71] This has a minimal effect on hemostasis in normal individuals[72] but prolongs the bleeding time and can precipitate hemorrhage in individuals with other hemostatic defects such as von Willebrand disease.

Nonhematologic Disorders

Platelet dysfunction can be a prominent feature of liver disease, uremia, and cardiopulmonary bypass (Chapters 126, 127, and 129). Uremia regularly causes platelet dysfunction, but this has been mitigated to a great extent by effective dialysis. However, when uremia-induced thrombocytopathia does occur, it is treated with the vasopressin analog desmopressin (DDAVP)[73]; conjugated estrogens[74] and cryoprecipitate[75] have been used as well. Correction of anemia with transfusion or erythropoietin can also improve hemostasis in patients with renal failure.[76,77] Hemostatic abnormalities in liver disease are complex, and the contribution of platelet function abnormalities is uncertain.[78] Platelet dysfunction following cardiopulmonary bypass results from the interaction of platelets with the bypass circuit and from hypothermia induced during bypass[79] and generally resolves spontaneously in 2 to 24 hours.

Abnormal hemostasis related to abnormal platelet function occurs in patients with chronic myeloproliferative disorders such as polycythemia vera (PV) and essential thrombocythemia (ET), with dysproteinemias such as multiple myeloma and macroglobulinema, with myelodysplasia and leukemia, with acquired forms of von Willebrand disease, and in the presence of antiplatelet antibodies. Both thrombosis and hemorrhage are complications of the myeloproliferative disorders and are associated with increases in whole blood viscosity in PV, elevated platelet counts, intrinsic platelet function abnormalities, and leukocyte and/or endothelial cell dysfunction.[80,81] Some studies indicate that gain-of-function JAK2 mutations in ET confer an increased risk of thrombosis[81] (see Chapter 102). Marked increases in platelet count increase the risk for bleeding, likely due to the acquired von Willebrand disease that results from adsorption of vWF to the platelet surface.[82] Reducing the elevated red cell mass in PV into the normal range significantly reduces the hemostatic complications of this disorder.[83] Features predicting high-risk disease in patients with ET include age >60, a history of thrombosis, and platelet counts $>1.5 \times 10^6/\mu L$.[84] Although both hydroxyurea and anagrelide can reduce the platelet count in patients with myeloproliferative disorders, a randomized trial of patients with ET indicated that treatment with hydroxyurea was superior to anagrelide with a decreased rate of arterial thrombosis, major bleeding, and transformation to myelofibrosis.[85] Aspirin has been found to be beneficial in patients with PV, but it can also exacerbate a bleeding tendency in myeloproliferative patients with acquired von Willebrand disease.[86]

The platelet dysfunction associated with dysproteinemias improves when the concentration of paraprotein is decreased by plasmapheresis or chemotherapy. Although thrombocytopenia is the major cause of bleeding in acute leukemias and myelodysplastic syndromes, bleeding may occur even in patients with normal platelet counts because of platelet dysfunction. Causes of acquired von Willebrand disease include the depletion of hemostatically effective high molecular weight vWF multimers,[87–89] antibodies directed against functional domains in vWF, antibody-accelerated vWF clearance, shear stress–induced vWF proteolysis, cellular adsorption and removal of vWF by malignant or other cells, and decreased vWF synthesis. Administration of DDAVP, the transfusion of vWF concentrates, and IVIgG can improve hemostasis in these patients.[89]

CHAPTER

60 Differential Diagnosis of Thrombocytopenia

JOEL S. BENNETT AND CHARLES S. ABRAMS

Thrombocytopenia is encountered frequently in clinical practice, engendering substantial and appropriate concern about its etiology and the consequent risk and prevention of bleeding. For example, in patients admitted to intensive care units (ICUs), approximately 30% to 50% manifest thrombocytopenia at some point during their ICU stay.[1,2,3] In turn, the thrombocytopenia has been associated with increased bleeding, increased transfusion of blood products, more prolonged ICU stays, increased ICU and hospital mortality, and often extensive, usually fruitless, efforts to identify its etiology. In this chapter, we discuss the definition of thrombocytopenia, the lifespan of circulating platelets and mechanisms of platelet senescence, the risk of bleeding in thrombocytopenic patients, and mechanisms for the development of thrombocytopenia in clinical disorders. The salient points of this discussion are provided in Table 60.1.

DISTRIBUTION OF PLATELET COUNTS IN NORMAL INDIVIDUALS

The normal range for platelet counts in healthy individuals has been reported as 150,000 to 350,000/μL[4] and is essentially the same regardless of the type of automated hematology analyzer used to measure the platelet count.[5] As determined from an analysis of the cross-sectional Third National Health and Nutrition Examination Survey of the United States population from 1988 to 1994 (NHANES III), mean platelet counts of 26,327 individuals were higher in women than men, independent of the presence of iron deficiency, declined with age, especially after age 60, and were greater in non-Hispanic blacks as compared to non-Hispanic whites and Mexican Americans.[6] Similar differences had been identified in a large cohort of men and women in Israel,[7] in a population study of whites, Africans, and Afro-Caribbeans in London,[8] and in 3,311 HIV-negative Ugandans.[9] In a study of platelet counts in 12,517 individuals in 10 relatively isolated villages in the Ogliastra area of Sardinia, the prevalence of thrombocytopenia (defined as a platelet count <150,000/μL) in different villages ranged from 1.5% to 6.8%, and there was a progressive decrease in platelet number with aging.[10] It is noteworthy that the prevalence of thrombocytosis also differed between villages and was inversely related to the prevalence of thrombocytopenia. Thus, the normal range for platelet counts varied from village to village, implying that the normal range for platelet counts can be influenced by genetic factors and is consistent with the finding of significant heterogeneity in the distribution of single-nucleotide polymorphisms among the villages. Genetic polymorphisms that affect the platelet count in a negative and positive fashion have been identified in the genes for interleukin-6 and the thrombopoietin receptor c-mpl.[11–13] Although these differences in mean platelet count affect populations rather than individuals, and are relatively mild so that they are unrelated to the efficiency of hemostasis, it is important to be cognizant of the fact that there are differences in the normal range of platelet counts when analyzing the effect of medications, therapy, and devices that can affect the platelet count such as immunization.[14]

Although the clinical significance of severe thrombocytopenia is usually readily apparent, the nature and significance of borderline thrombocytopenia, that is, platelet counts between 100,000 and 150,000/μL, can be a vexing problem. With the advent of automated cell counting, asymptomatic individuals with incidentally discovered borderline thrombocytopenia are being identified with reasonable frequency. While some of these individual, by necessity, represent outliers of the normal distribution of platelet counts, the thrombocytopenia of others could represent an early manifestation of an unrecognized disease. In the absence of positive findings, many of these individuals are given a diagnosis of idiopathic autoimmune thrombocytopenia (ITP). To address the paucity of information about the fate of individuals with borderline thrombocytopenia, Stasi et al.[15] prospectively studied 217 apparently healthy individuals incidentally discovered to have borderline thrombocytopenia as defined above. When followed for 6 months, two of the subjects were found to have myelodysplasia and a third systemic lupus erythematosus (SLE). The platelet counts of 23 others increased into the normal range for at least 3 months, whereas the platelet counts of 11 declined to <100,000/μL, and they were classified as having ITP. One hundred ninety-one subjects who continued to manifest borderline thrombocytopenia at 6 months were then followed for a median duration of 64 months. Thirteen subjects achieved stable platelet counts >150,000/μL and 109 continued to have stable borderline thrombocytopenia. Platelet counts of 12 subjects declined to <100,000/μL, and these subjects met the study's criteria for ITP. Of the 11 subjects initially thought to have ITP, five subsequently developed autoimmune disorders. Overall, the probability of developing ITP in these subjects at 10 years was calculated to be 6.9%, and the probability of developing another autoimmune disorder at 10 years was 12.0%. However, the majority of subjects continued to manifest borderline thrombocytopenia without developing another disorder. Thus, it is likely that they simply represent the lower end of the normal platelet count distribution. Moreover, based primarily on the results of this study, as well as on the observations discussed above that platelet counts <150,000/μL are frequently found in apparently healthy individuals in some non-Western populations, the International Working Group of the Vicenza Consensus Conference set the threshold for the diagnosis of ITP at a platelet count of <100,000/μL.[16]

Table 60.1

Clinical implications of thrombocytopenia

Although the range of normal platelet counts in healthy individuals is 150,000–350,000/μL, the platelet counts of many individuals with borderline thrombocytopenia, that is, platelet counts of 100,000–150,000/μL, remain stable over time and most likely represent outliers of the normal platelet count distribution
The normal lifespan of circulating platelets is 7–10 d, but measured platelet lifespan decreases as the platelet count decreases
Most platelets are removed from the circulation because of senescence, but approximately 18% of platelet removal is random. It has been postulated that the function of randomly removed platelets is to support endothelial integrity
Approximately 30% of the normal platelet volume is present in the spleen. The amount of platelets sequestered in the spleen can increase with splenic enlargement
Platelets contain an endogenous apoptotic pathway that may be largely responsible for their senescence
Clinical experience suggests that a platelet count of 10,000/μL is a sufficient threshold for prophylactic platelet transfusions to minimize the risk of spontaneous bleeding in the absence of fever, infection, renal failure, and medications that impair hemostasis
Platelet counts of at least 50,000/μL are sufficient for most surgical procedures, but procedures involving the brain or eyes may require platelet counts >100,000/μL. Nonetheless, bleeding complications often do not correlate well with preprocedure platelet counts
Clinically relevant thrombocytopenia can result from decreased platelet production by bone marrow megakaryocytes, from accelerated platelet removal, or from platelet sequestration in an enlarged spleen

Nonetheless, we have encountered a number of patients with borderline thrombocytopenia who have either intermittently or progressively developed symptomatic thrombocytopenia consistent with a diagnosis of ITP. While it may be inappropriate to label all patients with borderline thrombocytopenia with a diagnosis of ITP when their thrombocytopenia is first discovered, these patients should be monitored to determine if ITP does eventually develop.

PLATELET KINETICS

Measurements of platelet survival in humans using autologous platelets labeled *in vitro* with either chromium-51[17] or indium-111[18,19] reveal that the lifespan of platelets in the circulation ranges from 7 to 10 days with a platelet turnover of 40,000 to 50,000/μL/day.[20] ^{111}In complexed with 8-hydroxyquinolone (oxine) is currently the preferred radionuclide for these studies because of its shorter half-life, higher γ photon yield, and the greater affinity of the oxine complex for platelets.[19,21] These features of ^{111}In-oxine have enabled the measurement of autologous platelet survival in patients with ITP who have platelet counts of <20,000/μL.[22] Estimating platelet lifespan from the decrease in circulating platelet-associated radioactivity is accomplished by fitting the survival curve into one of several platelet survival models.[23] The most commonly applied mathematical formulation is the multiple hit (or γ function) model developed by Murphy and Francis,[24] based on the hypothesis that a platelet is repeatedly subjected to multiple external environmental insults or "hits" before it is removed from the circulation. However, the validity of this hypothesis has been questioned because of the observation that platelets contain an internal apoptotic pathway that may be largely responsible for their senescence[25] (see below). Nonetheless, when the survival of autologous ^{51}Cr-labeled platelets was compared in normal subjects and patients with stable thrombocytopenia due to bone marrow failure, platelet lifespan correlated with the platelet count, decreasing as the platelet count decreased (FIGURE 60.1).[26] Based on a mathematical model in which a fixed platelet lifespan was reduced by a degree of random platelet destruction, the authors calculated that there was random destruction of approximately 7,100 platelets/μL/day.

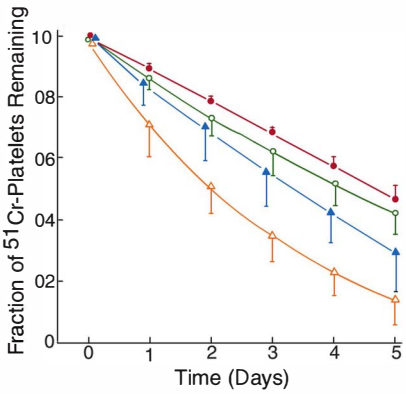

FIGURE 60.1 Effect of platelet count on the lifespan of platelets labeled with ^{51}Cr. Platelet lifespan was measured in normal individuals (*closed circles*, platelet lifespan 9.6 ± 0.6 days) and patients with bone marrow hypoplasia and stable platelet counts ranging from 50,000 to 100,000/μL (*open circles*, platelet lifespan 7.0 ± 1.5 days), platelet counts <50,000 (*closed triangles*, platelet lifespan 6.0 ± 1.7 days), and patients with more severe thrombocytopenia (platelet counts of 19,000 ± 6,000/μL) using labeled donor platelets (*open triangles*, platelet lifespan 3.4 ± 1.1 days). (Adapted from Hanson SR, Slichter SJ. Platelet kinetics in patients with bone marrow hypoplasia: evidence for a fixed platelet requirement. *Blood* 1985;66:1105–1109, with permission.)

This accounted for approximately 18% of the platelet turnover in normal individuals, while the remainder of platelet turnover occurred by senescent mechanisms. They also postulated that the shortened platelet lifespan they observed as platelet counts decreased resulted from an increase in the proportion of platelets removed by random processes and that the function of the randomly removed platelets is to support endothelial integrity.

Sixty to seventy percent of infused labeled platelets are recovered in the circulation of normal individuals, but this increases to nearly 100% when they are infused into individuals who have undergone splenectomy.[27–29,30] Thus, there is a splenic platelet pool that amounts to approximately 30% of the platelet volume in normal individuals. The splenic pool is in dynamic equilibrium with the circulating platelet pool. For example, the splenic pool is depleted in parallel with the circulating platelet pool during platelet apheresis.[31,32] Epinephrine infusions decrease splenic blood flow and the exchangeable splenic platelet pool and prolong the intrasplenic platelet transit time from its normal value of 10 to 12 minutes. This indicates that splenic blood flow is a major determinant of the size of the exchangeable splenic platelet pool.[33] Moreover, because the intrasplenic transit time of platelets is 5 to 6 times greater than that of erythrocytes, it is likely that by virtue of their smaller size, platelets are required to traverse a complex pathway through the splenic cords.[30]

PLATELET SENESCENCE

Analyses of measurements of platelet survival suggest that the platelet lifespan is determined by a combination of random platelet removal and a nonrandom aging mechanism that appears to result in the removal of senescent platelets by the reticuloendothelial (RE) system. Although the factors responsible for platelet aging are not known with certainty, there is accumulating evidence that the intrinsic apoptotic pathway may act as an "internal timer" that regulates platelet senescence.[25,34] Platelets contain several members of the antiapoptotic Bcl-2 family, as well as the proapoptotic proteins Bax and Bak.[34,35] Mason et al.[34] found that hypomorphic mutations of the antiapoptotic protein Bcl-x_L caused thrombocytopenia in mice due to increased platelet clearance, whereas inactivating other antiapoptotic proteins, Bcl-2, Bcl-w, and Mcl-1, in platelets did not. Furthermore, treating mice with the BH3 mimetic ABT-737, which antagonizes Bcl-x_L, caused acute thrombocytopenia. By contrast, absence of the proapoptotic proteins Bak and Bax was associated with a marked increase in platelet count and prolongation of the platelet lifespan.[36] Since the half-life of Bcl-x_L in platelets is shorter than Bak,[34,37] it has been proposed that as the inhibitory effect of Bcl-x_L declines, a threshold is reached, at which point uninhibited Bak is able to cause platelet apoptosis.[25] Nonetheless, how platelet apoptosis could cause platelet removal by the RE system is still unclear. Apoptosis causes phosphatidylserine (PS) exposure on cell surfaces, which can be a signal for phagocytosis of the apoptotic cells. Although apoptosis causes PS exposure on the platelet surface, agonist stimulation also exposes PS as a component of platelet procoagulant activity by a pathway that is independent of the apoptotic mechanism.[38] It remains to be established whether PS exposure plays a role in the clearance of senescent platelets, in addition to its role in supporting the formation of procoagulant complexes.

Supporting senescence as the major factor that determines platelet lifespan are purported decreases in platelet size, density, metabolic activity, and function as they age in the circulation.[39–42] Platelets contain a pool of mRNA that can be stained with thiazole orange ("reticulated platelets").[43] Because thiazole orange appears to preferentially label the youngest circulating platelets, and because the lifespan of "reticulated platelets" in mice is approximately one-third of the overall platelet survival, these findings support the notion that platelets age in the circulation.[43–45] However, others have studied the relationship between platelet size and platelet age, and while they confirmed heterogeneity in the size of circulating platelets and found a small correlation between platelet volume and lifespan, they could not confirm that platelet size decreases over time as they circulate. They concluded that the heterogeneity in platelet size results from factors related to platelet production, rather than aging.[46] This point is reinforced by the observations that patients with the Wiskott-Aldrich syndrome, and its variant X-linked thrombocytopenia, have small platelets with a shortened lifespan, whereas platelet survival in a kindred with inherited macrothrombocytopenia and megakaryocytic hyperplasia was normal.[47]

As noted above, the signals telling the RE system to remove senescent platelets are not known. However, studies of the mechanism responsible for the accelerated clearance of transfused platelets stored at cold temperatures revealed that desialylation of platelet surface glycoproteins occurred when the platelets were rewarmed prior to transfusion.[48,49] Loss of sialic acid results in the exposure of penultimate galactose residues, predominantly on platelet GPIbα and causes rapid platelet clearance, largely via hepatic asialoglycoprotein (Ashwell-Morell) receptors.[50] Whether these observations are relevant to the normal clearance of senescent platelets is not clear, in particular because clearance has been attributed to RE cells rather than to hepatocytes. However, it is noteworthy that the depletion of hepatic and splenic macrophages had little effect on the lifespan of freshly transfused platelets, suggesting that desialylation as platelets age could play a role in the recognition of senescent platelets.[51]

RISK OF BLEEDING DUE TO THROMBOCYTOPENIA

The number of platelets circulating in normal individuals is far in excess of the number required for normal hemostasis. Moreover, although meticulous cutaneous bleeding time measurements indicated that primary hemostasis is progressively impaired as platelet counts decline below 100,000/μL,[52] measurements of spontaneous fecal blood loss in patients with aplastic anemia revealed that blood loss did not substantially increase until platelet counts were <5,000/μL (FIGURE 60.2),[53] a number similar to the number of platelets thought to be required to maintain the integrity of the endothelium.[26]

Consistent with the latter observation, randomized and observational studies of patients treated with cytotoxic chemotherapy, undergoing bone marrow transplantation, or followed for aplastic anemia indicate that a threshold of 10,000 platelets/μL is sufficient for prophylactic platelet transfusion to minimize the risk of spontaneous bleeding in the absence of fever, infection, renal failure, and medications that impair hemostasis.[54–56,57] However, it may be best to avoid prophylactic platelet transfusions in patients with chronic stable thrombocytopenia, who have platelet counts as low as 5,000 to 10,000/μL, and who are free of serious bleeding to avoid alloimmunization and platelet refractoriness.[58] Issues that remain to be addressed are whether

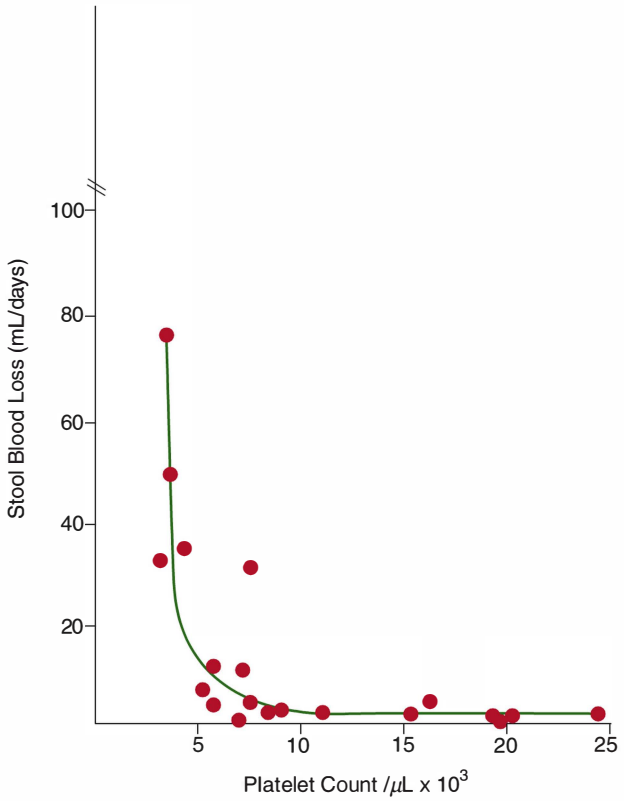

FIGURE 60.2 Relationship between stool blood loss and platelet count. Blood loss was measured using red cells labeled with ^{51}Cr in 28 patients with aplastic anemia. A threshold of increased blood loss was detected at a platelet count of approximately 5,000/μL. (Adapted from Beutler, E. 1993. Platelet transfusions: The 20,000/μL trigger. *Blood* 81:1411–1413, with permission.)

the platelet count trigger point for prophylactic transfusion can be safely lowered to 5,000/μL, and whether transfusion for clinical bleeding may be as effective as prophylactic transfusion.[59]

There is scant evidence upon which to base therapeutic decisions regarding platelet transfusion in other clinical situations. Guidelines have been proposed based on clinical experience and expert opinion.[55,58,60,61] Platelet counts of at least 50,000/μL are sufficient for most surgical procedures. However, procedures involving the brain or eyes may require platelet counts >100,000/μL. A bone marrow biopsy can be performed without platelet support. It has been reported that a lumbar puncture can be safely performed with meticulous technique at platelet counts >20,000/μL,[55,62] a liver biopsy at platelet counts >50,000/μL,[63] and gastrointestinal endoscopies and bronchoscopies at platelet counts >20,000/μL.[64,65] Platelets counts >50,000/μL have been recommended for dental extractions and central venous catheter insertions.[55] However, it should be noted that bleeding complications often do not correlate well with preprocedure platelet counts.[66,67]

MECHANISMS OF THROMBOCYTOPENIA IN CLINICAL DISORDERS

Thrombocytopenia can result from decreased platelet production by bone marrow megakaryocytes, from accelerated platelet removal, or from platelet sequestration in an enlarged spleen. A scheme for the systematic evaluation of patients who present with thrombocytopenia is shown in FIGURE 60.3. Since clinical disorders resulting in thrombocytopenia are described in detail in the subsequent chapters, they will only be briefly considered here.

Thrombocytopenia Due to Decreased Platelet Production

As discussed in Chapter 64, decreased platelet production occurs in diseases of the bone marrow, such as acute leukemia, aplastic anemia, myelodysplasia, and paroxysmal nocturnal hemoglobinuria; when bone marrow is replaced by metastatic carcinoma, fibrosis, or multiple myeloma; from the effects of chemotherapy, radiation therapy, or drugs that affect megakaryocyte number or function; from ethanol toxicity; and from infections with viruses such as HIV, measles, CMV, and varicella. Thrombocytopenia due to decreased platelet production is often accompanied by the perturbation of other blood cell counts, and thus, may be readily apparent after reviewing a peripheral blood smear. When thrombocytopenia in this setting is accompanied by bleeding, the bleeding usually requires treatment by platelet transfusion. Furthermore, when decreased platelet production cannot be readily reversed, prophylactic platelet transfusion to prevent bleeding is often considered. However, prophylactic platelet transfusion is complicated by the short platelet lifespan, the 5-day shelf-life of untransfused platelets, and platelet immunogenicity. As discussed above, the recommended threshold for prophylactic platelet transfusion is currently 10,000/μL, although it remains to be determined whether a threshold of 5,000/μL would be sufficient, and whether transfusion for bleeding rather than prophylaxis would be just as efficacious. In many patients with chronic stable thrombocytopenia, bleeding symptoms are minimal, even at platelet counts of 5,000 to 10,000/μL, so that prophylactic platelet transfusions may not be necessary. When they are transfused, using single-donor apheresis platelets and/or platelet donors who are human leukocyte antigen-identical to the recipient should be considered to minimize the risk of alloimmunization.

Thrombocytopenia Due to Increased Platelet Destruction

In the absence of splenomegaly, the presence of megakaryocytes in an otherwise normal bone marrow implies that thrombocytopenia is due to increased platelet destruction. Both nonimmune and immune processes can lead to a shortened platelet lifespan. Nonimmune causes, discussed in Chapter 64, include sepsis, disseminated intravascular coagulation, cardiopulmonary bypass, and giant cavernous hemangiomas (Kasabach-Merritt syndrome). The thrombocytopenia in these disorders resolves when the disorders resolve, and platelet transfusion is rarely necessary. As discussed in Chapter 99, the thrombocytopenia in patients with thrombotic thrombocytopenic purpura/hemolytic uremic syndrome is associated with thrombosis rather than bleeding, and platelet transfusion is only indicated in rare instances when significant bleeding occurs. Although there are reports of clinical deterioration, even death, following platelet transfusion, this remains a controversial issue.

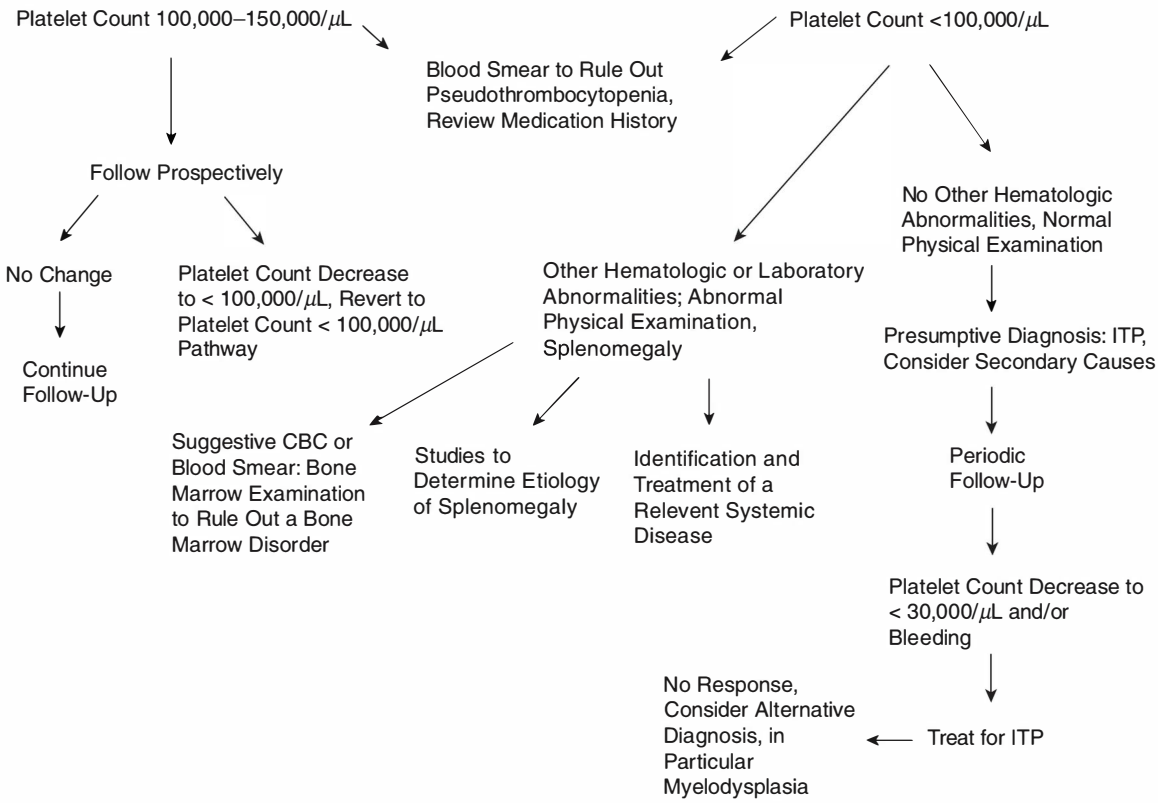

FIGURE 60.3 A scheme for the systematic evaluation of a patient with thrombocytopenia.

Immune-mediated platelet destruction can be due to medication, alloimmune sensitization following transfusion or pregnancy, and autoimmunity (see Chapters 61 and 62). As noted in Chapter 62, the list of medications reported to cause immune-mediated platelet destruction is long, but the most frequently implicated drugs include quinine and quinidine, sulfonamides, and gold salts. Nonetheless, medications should always be considered as a possible etiology for thrombocytopenia. Besides stopping the offending medication, emergent treatment for severe thrombocytopenia with bleeding includes platelet transfusion, as well as corticosteroids and intravenous immunoglobulin (IV IgG), which is similar to emergent treatment for autoimmune thrombocytopenia (see below).

Heparin-induced thrombocytopenia (HIT), discussed in Chapter 108, is a special case of drug-induced thrombocytopenia. HIT occurs in 1% to 4% of patients given unfractionated heparin for 5 to 10 days and is due to antibodies against a complex of heparin and the platelet α-granule protein platelet factor 4 (PF4). Patients with HIT rarely bleed, but rather the complex of heparin, PF4, and antibody activates platelets, causing thrombosis in both the arterial and venous circulations. HIT must always be considered when thrombocytopenia is detected in a hospitalized patient.

Alloimmune thrombocytopenia due to sensitization to alloantigens, such as Pl^{A1}, results from transfusion (posttransfusion purpura [PTP]) or from maternal sensitization during pregnancy (neonatal alloimmune thrombocytopenia [NATP]). PTP causes profound thrombocytopenia 7 to 10 days after transfusion and can be treated with IV IgG or plasma exchange. NATP can cause severe thrombocytopenia and bleeding in neonates, and it is treated with platelet transfusion, corticosteroids, and IV IgG.

Autoimmune thrombocytopenia, also known as idiopathic thrombocytopenic purpura (ITP), is due to circulating antiplatelet autoantibodies. An ITP-like picture can also occur in autoimmune diseases such as SLE, in patients with low-grade lymphoproliferative disorders such as chronic lymphocytic leukemia and well-differentiated lymphocytic lymphoma, and in patients with HIV infections. ITP can occur at any age, in either sex, and it presents with either spontaneous mucocutaneous bleeding or unexplained asymptomatic thrombocytopenia. Red cell and white cell counts are normal, splenomegaly is absent, and peripheral blood smears are only remarkable for a decreased number of platelets, some of which may be larger than normal. Although the presence of megakaryocytes in the bone marrow of patients with ITP confirms that their thrombocytopenia is due to accelerated platelet clearance, a bone marrow examination is rarely necessary in the absence of findings suggesting a bone marrow disorder such as myelodysplasia. Assays are available to detect antiplatelet antibodies, but they lack sensitivity and specificity, and they are rarely helpful diagnostically.

The diagnosis and treatment of ITP in children and adults is discussed in detail in Chapter 61. Suffice it to say, treatment is guided by symptoms and platelet count. Bleeding is usually minimal to absent until platelet counts decline to <30,000/μL. Thus, asymptomatic patients with platelet counts >30,000 can be followed without treatment. When bleeding is present and/or the platelet count is <30,000/μL, initial treatment is directed to inhibiting antibody-mediated platelet clearance

using corticosteroids and/or high doses of IV IgG or anti-D immunoglobulin. Most patients respond to this treatment, and platelet counts increase toward normal over days to weeks. Platelet transfusions alone are generally ineffective at increasing platelet counts in patients with severe ITP, because of antibody-mediated clearance of the transfused platelets, but the concurrent transfusion of high-dose immunoglobulin and platelets has been reported to rapidly increase platelet counts in most patients, and to control bleeding as well.[68,69] In adults with chronic ITP, splenectomy can produce long-term complete remissions in approximately 66% of patients, and some benefit in another 10% to 15%.[70]

Thrombocytopenia Due to Increased Platelet Sequestration

As noted above, approximately 30% of the circulating platelet mass is normally sequestered in the spleen.[30] Additional platelets may be sequestered when the spleen is enlarged due to portal hypertension or infiltrative diseases.[30] In general, patients with thrombocytopenia due to an enlarged spleen (hypersplenism) have palpable spleens, and there is a correlation between the degree of splenomegaly and the extent of thrombocytopenia. Platelet lifespan in patients with hypersplenism is normal or nearly normal.[30] Platelet counts in patients with hypersplenism are generally in the range of 40,000 to 50,000/μL, and bleeding due to thrombocytopenia alone due to platelet sequestration is unusual.

CHAPTER

61 Immune Thrombocytopenia and Posttransfusion Purpura

HOWARD A. LIEBMAN, DOUGLAS B. CINES, AND JAMES B. BUSSEL

IMMUNE THROMBOCYTOPENIA

Immune thrombocytopenia (ITP) is a heterogeneous autoimmune disorder characterized by thrombocytopenia with or without mucocutaneous bleeding manifestations. Because of its complex pathophysiology and association with a variety of other disorders, ITP is best characterized as a syndrome sharing the common clinical phenotype of immune-mediated thrombocytopenia.[1] While the clinical manifestations of ITP have been known for over a century, only in the last 20 years has our increased understanding of normal immune regulation led to better understanding of the pathophysiology of ITP involving aberrant interactions of antigen presenting cells, B lymphocytes, and regulatory thymic lymphocytes leading to increased platelet destruction and ineffective platelet production.[2,3] This new understanding has resulted in new therapeutic interventions with improved treatment outcomes, particularly for patients refractory to traditional therapies.

Definition and Epidemiology

ITP is an acquired disorder characterized by isolated thrombocytopenia with a peripheral blood platelet count $<100 \times 10^9$/L in the absence of any obvious other initiating or underlying cause, although ITP may be associated with other predisposing conditions (see "Secondary ITP").[4] This definition was the result of a recent consensus opinion by an International Working Group of ITP experts.[4] Therefore, the diagnosis of ITP is one of exclusion and is based principally on patient history, physical examination, complete blood count, and review of the peripheral blood smear.[5] Historically, the disorder was defined as either acute, with resolution of thrombocytopenia occurring within 6 months, or chronic persisting >6 months.[5] Acute ITP was a disorder observed predominately in children and chronic ITP (CITP) in adults. However, the recent International Working Group in ITP consensus report has divided the disorder into three phases: newly diagnosed ITP with a duration up to 3 months, persistent ITP 3 months to 1 year, and CITP >1 year.[4] During the time period encompassing newly diagnosed and persistent ITP, 85% of children and approximately 15% of adults will have a spontaneous remission. Spontaneous remissions are rare beyond a year.

ITP can be further characterized as either primary (idiopathic) or secondary to a number of associated disorders such as immunodeficiency diseases, autoimmune-rheumatologic disorders, lymphoproliferative diseases, and certain chronic infections.[4] It is estimated that approximately 20% of ITP cases in the United States are secondary to other disorders.[1] However, the incidence of secondary ITP worldwide may vary greatly, particularly in populations with high incidence of human immunodeficiency virus (HIV), hepatitis C virus (HCV), or *Helicobacter pylori* (*H. pylori*) infection. There are few data on the incidence or prevalence of ITP in populations other than in North America and Europe. The prevalence of ITP in adults is significantly greater than that of children due to the chronic nature of the disease in adults. The incidence of newly diagnosed ITP in adults ranges from 1.6 to 3.9 per 100,000 persons per year.[6–8] While older retrospective studies suggested a younger peak incidence for CITP in adult patients, more recent studies find an increased incidence and prevalence with advancing age.[6,7,9] In nearly all studies, the female-to-male ratio ranges from 1.2 to 1.9, with the female predominance more evident among young to middle age adults.[6–9]

Pathophysiology of ITP

Antiplatelet Autoantibodies

Harrington et al. were the first to provide experimental evidence that a plasma factor, later shown to be an antibody, was responsible for premature platelet destruction in ITP.[2,10,11] Early assays designed to detect platelet-bound antibodies were very sensitive, but had inadequate specificity. Using newer assays specific for platelet autoantibodies directed against specific platelet glycoproteins, such antibodies can be detected in 40% to 80% of patients with clinical ITP.[2,12,13] However, absence of detectable antibodies does not rule out a diagnosis of ITP, since many patients without detectable antibodies respond to traditional ITP therapies and antibodies may occur in patients with liver disease and other conditions without clinical ITP.

The antigenic target for these antiplatelet autoantibodies are prevalent platelet glycoproteins such as platelet GPIIb/IIIa in nearly two-thirds of patients, platelet GPIb/IX in approximately 20% of patients and in the remaining patients, antibodies are directed against both of these platelet glycoprotein complexes or other platelet antigens.[13] The B- and T-cell response against these common platelet glycoproteins can be directed against various antigenic sequences on same protein resulting in a polyclonal and polyspecific response. Also, antibodies against specific antigenic sequences on certain platelet glycoproteins may have different pathogenic properties. For example, a unique autoantibody observed in patients with HIV-associated ITP directed against platelet GPIIIa amino acid residues 49 to 66 appears capable of inducing platelet fragmentation by generating platelet superoxides, at least *in vitro*.[14] As stated above, some patients with assumed ITP may not have detectable antibodies due to a misdiagnosis such as early myelodysplasia in an older patient; antibodies directed against a less prevalent platelet antigen; low titer of antibody; clearance of the autoantibodies

with treatment; or the thrombocytopenia resulting from T lymphocyte–mediated platelet cytotoxicity.[15] In view of the variability of antibody detection in patients with suspected ITP, current guidelines do not recommend screening patients for platelet antibodies to make an initial diagnosis.

The spleen, in addition to being the major site of antibody-mediated platelet destruction, is a major site of autoantibody production as shown by *in vitro* studies where ITP splenic cells produced IgG that bound to platelets[16–18] and megakaryocytes.[19] Since in some ITP patients, autoantibody persists after splenectomy, there must be additional production sites, for example, bone marrow–derived B lymphocytes.[20]

Role of the Thymic Lymphocyte in ITP

Production of autoreactive IgG against a protein antigen, like all immunoglobulin isotype–switched IgG antibody responses, is initiated by activated T helper cells that recognize their antigens on antigen presenting MHC class II positive dendritic cells (DCs) or macrophages.[3,21–23] DCs from patients with ITP have upregulated costimulatory molecules enhancing autoreactive T- and B-cell responses against platelets.[3] The ongoing process of macrophage-mediated platelet destruction and further presentation of new platelet proteins to T and B lymphocytes contributes to the epitope spreading observed over time in patients with ITP and may contribute to a more refractory disease in patients with ITP of longer duration.[1]

Adults and children with CITP have a serum cytokine profile (IL2/IL10/interferon gamma) suggesting a Th0/Th1 activation pattern.[24–29] Oligoclonal accumulation of CD4+ T helper cells that frequently use Vβ3, 6, 10 and 13.1 to 14 genes for their T-cell receptors have been found in the peripheral blood of patients with CITP by some investigators.[30] These studies suggest that CITP is accompanied by a loss of T lymphocyte tolerance against platelet antigens with the accumulation of abnormal T lymphocyte clones that can direct autoreactive B cells to differentiate and secrete IgG autoantibodies.[30] Recent studies have clearly demonstrated that ITP patients have significant defects in immune self-tolerance.[1,3] Autoreactive cytotoxic CD8-expressing T lymphocyte clones capable of directly damaging platelets and possibly megakaryocytes have also been demonstrated[15] and are likely to proliferate under the influence of similar T helper lymphocytes.

A distinct population of T lymphocytes, essential to maintaining peripheral self-tolerance, preventing autoimmune disease, and limiting chronic inflammatory diseases,[31] termed Tregs, are usually reduced in number and/or function in patients with ITP.[32,33] Quantitative and qualitative defects in the Treg population appear to correlate with persistence of CITP. For example, an association between an improvement in the peripheral blood Treg number and function and remission induction with ITP treatment has been reported.[34]

One of the many factors responsible for maintaining proliferation of B lymphocytes is B cell–activating factor (BAFF).[35,36] BAFF is a member of the tumor necrosis factor family and binds to several receptors, one of which, BR3 is important for B cell–dependent Th1 responses. BAFF mRNA is increased in patients with active ITP compared to healthy controls, and values return to normal during remission. Addition of BAFF to cocultures of ITP lymphocytes and platelets reduced apoptosis of both B and T lymphocytes in patients with ITP, but not in normal subjects.[37] Apoptosis was prevented by the addition of a soluble decoy of the BAFF receptor. Also, in cocultures of ITP platelets and ITP B cells, addition of BAFF increased platelet apoptosis, which was again ameliorated using the decoy receptor.[37]

Suppression of Platelet Production

The dogma of ITP as exclusively a disorder of accelerated platelet destruction was challenged in the early 1980s by a number of investigators.[38–40] Using indium-111–labeled autologous platelets, these investigators found evidence not only of increased platelet clearance, but also impaired platelet production.[38–40] Recent studies have demonstrated inhibition of *in vitro* megakaryocyte growth and maturation by antibodies from some ITP patients.[41,42] Evidence that patients with ITP have autoreactive cytotoxic thymic (T) lymphocytes capable of directly lysing platelets suggests that these lymphocytes may also induce megakaryocyte injury and contribute to defective platelet production.[15] While megakaryocyte numbers and appearance in bone marrow specimens appear normal in most patients with ITP when viewed under light microscopy, electron microscope studies of bone marrows from ITP patients show extensive damage in the majority of megakaryocytes.[43,44]

Thrombopoietin (TPO) is the major physiologic regulator of megakaryocyte growth and differentiation.[45,46] TPO is synthesized and secreted by the liver and production is constant with no translational or posttranslational regulation.[47] When TPO is released into the circulation, most of the protein binds to TPO receptors on platelets and is cleared with the platelets with the remaining TPO binding to receptors on bone marrow precursors.[48] TPO levels are not increased above the normal range in the majority of patients with ITP and this observation provided the theoretical basis for treatment with TPO-receptor agonists.[45,48,49]

Clinical Presentation and Natural History of ITP in Adults

Adult patients with ITP are more likely to manifest disease with a chronic course. Overall, approximately 15% of patients remit within a year after disease onset, but rare late remissions occur, even among patients who have failed splenectomy.[7,50–52] While bleeding manifestations are the most common presenting symptoms in patients with ITP, the increased use of automated blood counts results in the frequent identification of asymptomatic patients or patients with minimal bleeding. Therefore, it is uncertain whether there is a period of mild-to-moderate thrombocytopenia in adults prior to the development of severe thrombocytopenia with bleeding. In a study of 217 healthy individuals with incidentally discovered thrombocytopenia and platelet counts between 100×10^9/L and 150×10^9/L, the 10-year probability of developing ITP as defined by platelet counts $<100 \times 10^9$/L was 6.9% (95% CI 4.0% to 12.0%). The 10-year probability of developing autoimmune disorders other than ITP was 12% (95% CI 6.9% to 20.8%).[53]

Bleeding manifestations vary widely among patients. Mucocutaneous bleeding, including petechiae, purpura, epistaxis, and gum bleeding, is the most common initial manifestation. The feared complications of internal bleeding or fatal intracranial hemorrhage are rare and more likely to occur in older individuals with additional comorbidities.[7,50–52] Symptomatic bleeding is to certain degree related to the platelet count, with nearly all major bleeding occurring with platelet counts under 30×10^9/L.

Only in patients with hepatitis C–related thrombocytopenia does major bleeding appear to occur with some frequency at higher platelet counts.[54]

The risk of bleeding and fatal hemorrhage in adults with severe CITP, defined as a platelet count of $<30 \times 10^9$/L at least 1 year following diagnosis, was analyzed in a pooled analysis of published clinical series comprising 1,800 patients.[55] The annual incidence of fatal hemorrhage was 1.6 to 3.9 cases per 100 patient years, with a lower risk in patients under 40 years of age (0.4% per year) compared to patients >60 years of age (13% per year).[55] The risk of nonfatal hemorrhage was estimated to be 3% per year in patients <40 years of age and 71% per year for patients >60 years of age. However, it should be noted that this case series dated from 1954 to 1991 and therefore, did not include patients treated with newer agents (rituximab, TPO receptor agonists) or managed with laparoscopic splenectomy that has a documented lower complication risk.

The prognosis of ITP in adults may be better than previously thought, with a majority of patients eventually obtaining a safe platelet count off treatment. In an Italian study of 310 children and adults (median age 40 years; range 8 to 87 years) with CITP, defined as a platelet count $<150 \times 10^9$/L 6 months after diagnosis, only 34 (11%) patients continued to have a platelet count under 30×10^9/L with a median follow-up of 121 months (range 7 to 434 months); 19 of the severely thrombocytopenic patients were receiving no treatment.[56] Major bleeding occurred in 9 (3%) patients with only 1 fatal intracranial hemorrhage.[56] While only 26 (8%) patients who received medical therapy alone achieved a sustained complete remission, 125 patients were able to maintain a platelet count over 50×10^9/L with low-dose prednisone or other treatments. Of the 109 patients who underwent splenectomy, 72 (66%) had a sustained response and 37 were either refractory or relapsed later.[56]

A single institution study of 152 adult ITP patients accrued over a 20-year period reported a complete response (defined as a platelet count over 100×10^9/L at 2 years off all treatment) in 90 (59%) patients and 114 (75%) had a platelet count $>30 \times 10^9$/L.[51] Among the patients who had a complete response, 46/90 (51%) underwent splenectomy to obtain remission. Only nine of these patients had a relapse during an extended follow-up. Four patients with severe thrombocytopenia died during the first 2 years of observation. Only one patient died of a bleeding complication (intracerebral bleed) and three from infectious complications (two with gram-negative sepsis and one with cytomegalovirus pneumonia); all four of these patients were older than 65 years. Compared to the age-matched general population, the mortality risk in adults with ITP was estimated at 1.5% (95% CI 1.1 to 2.2).[51] Patients with secondary ITP had a higher risk of dying of 6.0% (95% CI 2.5 to 14.5), most likely reflecting the morbidity and mortality associated with the underlying diseases. Patients with severe thrombocytopenia (platelets $<30 \times 10^9$/L) were more likely to require hospitalization, averaging 1.2 hospital admissions during the first 2 years following diagnosis.[51]

ITP diagnosed in elderly patients (age >65 years) is generally believed to be more refractory and associated with an increased risk of major bleeding, as well as higher mortality.[57] However, a recent retrospective single institution study of 178 consecutive elderly patients (age >65 years) presenting over a 17-year period appears to refute some of the earlier observations.[50] All patients had platelet counts $<150 \times 10^9$/L and clinical and bone marrow studies consistent with a diagnosis of ITP. One hundred twelve patients (63%) were not treated at presentation and 90 patients (50.6%), including 12 patients (6.8%) with platelet counts $<50 \times 10^9$/L, received no treatment for the duration of their follow-up.[50] Five untreated patients had a spontaneous complete remission. Eleven untreated patients developed other pathology during a median follow-up of 47 months (range 2 to 96 months). This included antiphospholipid antibody syndrome (APLS) (four patients); myelodysplastic syndrome (three patients); gastric lymphoma (one patient); rheumatoid arthritis (one patient); monoclonal gammopathy (one patient); and ovarian carcinoma (one patient). Therapy with low dose prednisone was initiated in 66 patients (37%) on presentation. The mean platelet count in these patients was 15×10^9/L (range $1–43 \times 10^9$/L). Within 1 month of treatment 49 patients (63.6%) increased their platelet count to over 50×10^9/L, with 16 patients attaining a complete remission. Eighteen of the 49 patients (36.7%) relapsed during the period of follow-up.[50] Only one nonresponding patient died of intracerebral bleed. As in other studies, the risk of bleeding appeared to be greatest among the patients with platelet counts persistently $<30 \times 10^9$/L.[34]

In a prospective analysis of 183 patients (25 children and 158 adults) treated with splenectomy during a 10-year period, 53 patients (29%) were refractory to this treatment.[58] The single significant clinical prognostic factor predictive of refractoriness to splenectomy was a platelet count below 50×10^9/L 10 days after surgery ($P < 0.001$). Of the 53 patients, 6 were lost to follow-up; there after, 47 refractory patients (26.6%) were followed prospectively for a median of 7.5 years (5 to 15 years). Thirty seven refractory patients (77%) achieved a durable platelet count $>100 \times 10^9$/L, 9 without treatment and 27 with low-dose corticosteroids or azathioprine. Six patients (13%) continued to have moderate thrombocytopenia with platelet counts of 35×10^9/L to 100×10^9/L and five patients failed to respond to any treatment and had platelet counts $<20 \times 10^9$/L. Three of the five severely refractory patients died of bleeding.[58]

McMillan and Durette[52] reported on the long-term outcome of 114 adult patients who failed to obtain a stable platelet count $>30 \times 10^9$/L after splenectomy; 105 patients were available for long-term follow-up. With a median follow-up of 110 months, a majority of patients (71.4%) achieved a complete or stable partial remission with a median of 46 months. Thirty patients (29.6%) remained unresponsive to treatment, failing to obtain a platelet count over 30×10^9/L. Eleven patients (10.2%) died of bleeding due to refractory thrombocytopenia. Six patients (5.6%) died of treatment-related complications, most often infection.[52]

A systemic review of the literature on the efficacy of splenectomy in ITP reported a 64% complete durable response with a mean follow-up of 7.25 years (range 5 to 12.75 years) with few late relapses.[59] Therefore, extrapolating from the studies of Bourgeois et al. and McMillan and Durette, an estimated 95% of adult patients with ITP can achieve a safe platelet count when splenectomy is incorporated into the ITP treatment algorithm. Except in the highly refractory patients (persistent platelet counts $<30 \times 10^9$/L), the risk of fatal hemorrhage is quite low and morbidity appears to reflect a combination of nonfatal hemorrhage and treatment-related toxicities.

Clinical Presentation and Natural History of ITP in Children

The peak age of presentation of ITP in children is between 5 and 6 years with 70% of cases presenting between ages of 1 and 10 years.[60] Approximately 50% to 60% of children will have a febrile illness that preceded the discovery of thrombocytopenia. Numerous viral infections, including rubella, varicella, mumps, rubeola, and Epstein-Barr virus, as well as immunizations with MMR vaccine have been associated with the subsequent development of ITP in children.[1,60–62] As with adults, review of the blood smear is essential. Signs of mucocutaneous bleeding most often occur without other systemic symptoms and the child frequently does not appear ill.[63,64] Bleeding manifestations vary from little or none, to the typical findings of purpura, petechiae, epistaxis, and menorrhagia in older females.[63–66] Most children present with platelet counts under 20×10^9/L.[66] In a study of 863 children with newly diagnosed ITP, no or mild bleeding manifestations were reported in 77% of patients, moderate bleeding occurred in 20%, and severe bleeding in 3%.[66] Life-threatening bleeding is rare and the estimated risk of intracranial hemorrhage is between 0.1% and 0.5% in newly diagnosed cases.[60,66,67] A retrospective systematic review of medical literature to ascertain the characteristics of children with intracranial hemorrhage in acute CITP found the median time to a hemorrhagic event from diagnosis was 32 days (range 0 to 8 years), with 72% occurring within the first 6 months and with 71.5% of the children having platelet counts $<10 \times 10^9$/L at the time of the bleed.[68]

Most children have a spontaneous resolution of thrombocytopenia within weeks irrespective of treatment.[69,70] However, therapy may shorten the duration of severe thrombocytopenia. Approximately 65% to 70% of children remit by 6 months and another 15% to 20% by 12 months.[60,71] Only 5% to 10% of children develop chronic disease. Children who develop CITP tend to be older, are more often female, and usually present with a higher platelet count.[69–73] Severe or life-threatening bleeding manifestations are rare in children with CITP.[69,73]

Diagnostic Approach to Patients with Suspected ITP

In almost all cases, a presumptive diagnosis of ITP can be made by a careful history, physical examination, complete blood count, and review of the blood smear.[5,74] Response to initial treatment with corticosteroids, intravenous immunoglobulin (IVIG), or anti-RhD supports the diagnosis and confirms the immune nature of the thrombocytopenia. However, additional investigation is necessary to exclude secondary ITP and provide additional information to assist with patient management.

Patient history should be directed toward excluding nonimmune disorders associated with thrombocytopenia, such as primary bone marrow disorders, active infection, cirrhotic liver disease with portal hypertension, drugs, and supplements. A careful drug history should be taken since a large number of medications have been associated with thrombocytopenia (see Chapter 62).[75] A family history of thrombocytopenia or a bleeding disorder may suggest inherited thrombocytopenia (see Chapter 63). A history of recurrent infections may suggest an underlying immune deficiency disorder that may be a contraindication to immunosuppressive therapy. A history of diabetes or psychiatric disorder may be a contraindication to high-dose corticosteroid treatment. Any constitutional symptoms such as fever, night sweats, or weight loss suggest an alternate diagnosis or a secondary cause of ITP.

Physical examination may reveal bleeding manifestations consistent with the severity of the thrombocytopenia, but should otherwise be normal. Finding splenomegaly, hepatomegaly, or adenopathy strongly suggests a diagnosis other than primary ITP. Some physical findings such as a malar rash or joint abnormalities may suggest that thrombocytopenia is secondary to an autoimmune-rheumatologic disorder.

A complete blood count should reveal isolated thrombocytopenia with normal white and red blood cell numbers. Anemia may exist if there has been significant bleeding and findings consistent with a microcytic anemia due to iron deficiency may exist in a female due to excessive menstrual blood loss. In patients with anemia, a reticulocyte count should be performed to determine whether anemia is due to recent blood loss or decreased red cell production. In some patients, concomitant autoimmune hemolytic anemia (Evan syndrome) may be diagnosed by finding an increased reticulocyte count, an elevated MCHC, and spherocytes on the peripheral blood smear.

A careful review of the peripheral blood smear is mandatory to exclude abnormalities in other cellular elements of the blood. Abnormalities in erythrocyte or leukocyte morphology may suggest an underlying bone marrow disorder, such as the myelodysplastic syndrome, or a congenital cause of thrombocytopenia. For example, the presence of a MYH9-related disorder may be suggested by finding leukocyte inclusion bodies. Many congenital thrombocytopenic disorders are associated with very large platelets (macrothrombocytopenia) that may also be reflected in an abnormally high mean platelet volume. Increased numbers of small lymphocytes may suggest a diagnosis of chronic lymphocytic leukemia (CLL) with secondary ITP. Increased numbers of lymphocytes with granular inclusions can suggest a diagnosis of large granular lymphocytic leukemia with secondary ITP. Pseudothrombocytopenia due to platelet clumping should be excluded: if platelet clumping is seen on the blood smear, a repeat platelet count using a blood sample collected in citrate or heparin rather than EDTA should be performed. Thrombocytopenia resulting from thrombotic thrombocytopenic purpura or hemolytic uremic syndrome must be considered if the blood smear shows significant numbers of schistocytes.

The International Working Group on ITP recommended a number of additional laboratory tests to further assist in the diagnosis and management of patients with primary ITP.[74] These recommendations are listed in Table 61.1. Bone marrow examination has been recommended in patients refractory to ITP-therapy or who relapse after an initial remission, patients with systemic symptoms or atypical physical findings, and prior to splenectomy.[74] A bone marrow aspirate and biopsy should be performed in patients older than 60 years and include cytogenetic studies and flow cytometry.[74]

Three chronic infections are commonly associated with the development of secondary ITP and their identification and treatment may affect the clinical outcome.[1,74,76,77,78] *Helicobacter pylori* infection, as detected by either the urea breath test or stool antigen, is recommended in all patients with a presumptive diagnosis of ITP. If these tests are unavailable or if patients are receiving proton pump inhibitors for ulcer treatment or prophylaxis, serologic detection can be considered if the patient has

Table 61.1

International ITP working group consensus recommendations for the diagnosis of ITP in children and adults

Basic Initial Evaluation	Addition Studies of Potential Value	Studies of Unproven Benefit
Patient history	APLAs (patients with history of thrombosis or fetal loss)	TPO assay
Family history	TSH or antithyroid antibodies	Reticulated platelets
Medication history	ANA in children	Platelet-associated immunoglobulins
Physical examination	Pregnancy test in women of child bearing years	Serum complement
Complete blood count	Viral PCR for parvovirus and CMV (selected refractory, febrile or leukopenic patients)	Bleeding time
Quantitative immunoglobulins	Platelet glycoprotein-specific antibodies	Platelet survival studies
Blood group (Rh)		
DAT		
Helicobacter pylori		
HIV		
HCV		
Bone marrow (in selected patients)		

Adapted from Glanz J, France E, Xu S, et al. A population-based, multisite cohort study of the predictors of chronic idiopathic thrombocytopenic purpura in children. *Pediatrics* 2008;121:e506–e512.

not received recent treatment with IVIG. Testing in children is not supported by the literature.[74]

Thrombocytopenia associated with infection with the HIV or the HCV can result in thrombocytopenia years before the development of viral-related symptoms. Thrombocytopenia associated with both viruses is indistinguishable from primary ITP and can response to standard ITP treatments. However, optimal treatment for HIV- and HCV-related thrombocytopenia should be directed toward treatment of the viral infection. Since both infections may be silent in early stages, screening for these infections is recommended regardless of patient background or reported lifestyle.[74] Patients should also be screened for hepatitis B infection since treatment with prednisone and/or rituximab may result in viral reactivation and fulminant hepatitis.

The international ITP working group recommends obtaining baseline immunoglobulin levels (IgG, IgM, and IgA). Low levels can be found in patients with common variable immunodeficiency, which is accompanied by a surprisingly high incidence of autoimmune complications including immune thyroid disease, autoimmune hemolytic anemia, and ITP.[79] Immune suppression in these patients should be avoided as should splenectomy, if possible. Selective IgA deficiency can also be associated with the development of ITP, with many patients lacking a history of recurrent or chronic infection. If required to treat ITP, these patients should receive IVIG preparations that are IgA depleted to avoid severe infusion reactions.

A direct antiglobulin test (DAT, direct Coomb test) should be considered if there is evidence of unexplained anemia associated with a high reticulocyte count. A positive DAT has been reported in up to 22% in patients with ITP, most often without overt evidence of hemolysis.[70] Therefore, it should also be performed along with red cell Rh typing in patients who are to be treated with anti-RhD, since the presence of a pretreatment antibody on the red cell could increase the risk of intravascular hemolysis.[74,80]

Several other tests have been suggested in the consensus reports that may be of clinical utility in some patients (Table 61.1).[74] Screening for antiphospholipid antibodies (APLAs) (lupus anticoagulant [LA], anticardiolipin [ACL] and anti-β_2-glycoprotein antibodies) should be considered in any patient with a prior history of thrombosis or fetal loss. While APLAs can be found in up to 40% of ITP patients, they have no apparent effect on the outcome of ITP treatment and the majority of patients with such antibodies do not develop clinical manifestations of the APLS.[76] Therefore, routine testing for these antibodies is not recommended unless there is a history suggestive of the APLS. A positive antinuclear antibody assay (ANA) may be present in 15% to 25% of patients with ITP, however independent of patients with clinical systemic lupus erythematosus, a positive test in primary ITP has not been shown to predict response to treatment or prognosis in adults.[81] Therefore, an ANA test is not routinely recommended in adults. However, a positive ANA test may be a predictor of chronicity in childhood ITP.[82]

Clinical hypo- and hyperthyroidism is reported in up to 20% of patients with ITP and antithyroid antibodies are present in nearly 40% of patients.[81,83] Mild to moderate thrombocytopenia has been reported in patients with both hypothyroidism and hyperthyroidism and platelet counts return to normal when patients become euthyroid.[83] Also, patients with ITP and clinical hypo- or hyperthyroidism maybe refractory to standard ITP treatment and only become responsive when their thyroid disease is treated.[83] Therefore, it can be useful to screen refractory patients with an assay for thyroid stimulating hormone (TSH)

to rule out associated thyroid disease.[74,83] In selected patient populations, testing for antibodies to thyroglobulin or other thyroid antigens may identify patients at risk of developing clinical thyroid disease.[74]

Secondary ITP

CITP has been classified either as a primary autoimmune disorder (idiopathic thrombocytopenic purpura) or as secondary to a number of underlying disorders.[4] Common conditions associated with secondary ITP include immunodeficiency disorders, lymphoproliferative disorders, and chronic infection with HIV, *H. pylori*, and HCV.[1,4,76,77,81] Other autoimmune rheumatologic disorders are associated with secondary ITP, of which systemic lupus erythematosus (SLE) and APLS are the most common.[1,4,76,77,81]

Systemic Lupus Erythematosus

Although laboratory evidence of autoimmunity, such as a positive ANA, is common in ITP, few patients are likely to develop SLE or related conditions.[1,84] The pathophysiology of ITP in SLE and APLS is similar to that of primary ITP and in most cases is mediated by antiplatelet glycoprotein autoantibodies. Decreased platelet production, as observed in primary ITP, may also be involved in the pathogenesis of ITP in patients with this secondary form of the disorder.[1,38]

SLE is a systemic inflammatory disease that can affect any organ system, including the hematologic system, which is 1 of 11 criteria for diagnosis.[84] Hematologic manifestations include leukopenia, hemolytic anemia, and thrombocytopenia, any or all of which can be present at the onset of the disease or can develop later. Twenty to twenty-five percent of patients with SLE have platelet counts $<100 \times 10^9$/dL, although <10% of patients have platelet counts $<30 \times 10^9$/L.[85,86] A recent study from China reported an incidence of significant thrombocytopenia in SLE of 24.2%.[87] In patients with SLE, thrombocytopenia with platelet counts $<100 \times 10^9$/L is more prevalent when patients have high titer ACL antibodies.[88] However, it is unclear whether these patients also fulfill criteria for APLS.

Potential mechanisms for the pathogenesis of thrombocytopenia in patients with SLE include antibody-mediated platelet destruction by anti-GPIIb/IIIa and anti-GPIb/IX antibodies or antiplatelet glycoprotein autoantibodies that induce megakaryocyte apoptosis.[2] Lupus vasculitis, thrombotic microangiopathy, and hemophagocytosis are immunopathologic disorders associated with SLE in which platelets are destroyed secondary to a microvascular inflammatory process. Thrombocytopenia in these disorders reverses with correction of the primary process. There are no studies of plasma TPO levels in patients with SLE and thrombocytopenia, but it can be assumed that they are similar to those reported in patients with ITP.[89]

A low platelet count in SLE can also result from mechanisms other than autoimmunity. These include drug-induced thrombocytopenia and infection. Antimalarial agents, commonly used to treat SLE, have been reported to induce thrombocytopenia, although recent data suggest improvement of platelet counts with hydroxychloroquine.[60,90] Infections with *H. pylori*, HCV, HIV, and other viral illnesses can further contribute to the risk of developing thrombocytopenia.[1] Two disorders associated with thrombocytopenia, Evans syndrome and Graves disease, are both reported to be more frequent in patients with SLE compared to the general population.[2,91] Thrombocytopenia in pregnant patients with SLE can result from the HELLP syndrome; in the postpartum period, SLE flares can add to the difficulty in diagnosis.[92]

When patients with SLE have associated ITP, corticosteroids remain the primary treatment modality, although every effort should be made to switch to a steroid-sparing therapy to minimize the long-term exposure. Immunosuppressive agents such as methotrexate, azathioprine, leflunomide, dapsone, cyclosporine, mycophenolate mofetil, and cyclophosphamide are often used as disease modifying and steroid-sparing agents in SLE.[93] Each of these agents has also been used to treat patients with CITP.[5,59] Several case series indicate that B lymphocyte depletion with rituximab, an agent with documented responses in refractory ITP, is also of clinical benefit in patients with refractory SLE.[94] Splenectomy, if possible, should be avoided, particularly in patients with active SLE who will require further immunosuppressive therapy and therefore be at risk of infection.

Antiphospholipid Antibody Syndrome

APLS is characterized by recurrent fetal loss and recurrent venous and/or arterial thromboembolic events.[95] In the most severe form, catastrophic antiphospholipid syndrome, multiple organ dysfunction occurs.[95] Although frequently associated with SLE, over half of the patients with APLS do not have clinical evidence of SLE.[96,97]

Thrombocytopenia in association with APLS is more common in patients with SLE than in primary APLS (PAPS), although it is well described in both.[98] The reported incidence of thrombocytopenia varies between 22% and 42%.[2,96–99] Thrombocytopenia in APLS tends to be less severe than that seen with ITP; platelet counts usually range from 70 to 120K and it does not usually require intervention.[99] Accordingly, it is less commonly associated with bleeding manifestations than ITP. APLS may present with isolated thrombocytopenia without other signs and symptoms. The presence of thrombocytopenia does not seem to affect the thromboembolic complications of the disorder, as rates of thrombosis are similar with and without thrombocytopenia.[96,100] While the findings of cardiac valvular vegetations and myocardial infarction are not associated with thrombocytopenia, there is a strong statistical association between valvular leaflet thickening and thrombocytopenia.[97] Chorea, arthritis, and livido reticularis, other clinical manifestations of APLS, are also associated with the presence of thrombocytopenia.[97]

The incidence of the LA, a defining characteristic of the disorder, is higher in APLS than in ITP. Antibodies to specific glycoprotein receptors such as GPIb/IX and GPIIb/IIIa are detectable in 40% of ITP patients with APLAs.[99–102] Godeau et al.[102] noted that in 11/15 patients with APLS and platelet counts <50K, antiplatelet antibodies to specific platelet glycoproteins could be identified. In patients with both PAPS and SLE-associated APLS, antiplatelet antibodies were found much more frequently in patients with thrombocytopenia compared to patients without thrombocytopenia. In addition, there was a strong association between PAPS with thrombocytopenia and ACL antibodies, the LA, and specific platelet glycoprotein antibodies.[103–105] It has been proposed that binding of antibodies to β_2 glycoprotein-1 induces dimerization of the protein, thereby stimulating phosphorylation of the abetalipoprotein E receptor. In turn, this results in activation of p38MAP kinase, generating

thromboxane A_2 as well as phosphatidylinositol-3-kinase and Akt and inducing platelet activation and sensitization to other agonists.[2,103] APLAs bind also to anionic phospholipids normally found on the inner platelet membrane. This implies that platelet activation or aggregation is needed to expose these phospholipids on the outer membrane surface, thereby enabling antibody binding.[104] The contribution of APLA *per se* to thrombocytopenia remains uncertain.

Thrombocytopenia in APLS rarely requires treatment unless the platelet count is below 30K. However, thrombocytopenia in patients with the APLS will respond to corticosteroid therapy and most other ITP treatments. In addition to prednisone, there are case reports indicating a response to rituximab with improvement in the platelet count as well as reduction or disappearance of ACL antibodies.[106–108]

Lymphoproliferative Disorders

Thrombocytopenia is a well-recognized complication of lymphoproliferative disorders. In addition to decreased platelet counts due to splenic sequestration in patients with splenomegaly and decreased production due to bone marrow replacement and/or systemic chemotherapy, immune platelet destruction can occur in 1% to 5% of patients.[109,110] While cases of ITP have been reported with nearly all lymphoproliferative disorders, the majority of cases are reported in patients with CLL, Hodgkin disease (HD), and large granular T-lymphocyte (T-LGL) clonal proliferations.

Retrospective studies have reported ITP in 1% to 2% of patients with CLL.[111–116] The incidence of ITP appears to be significantly less than that of CLL-associated autoimmune hemolytic anemia.[112,113,115] A multicenter study of 3,150 CLL patients found ITP in 35 patients (1%).[113] Older age and advanced CLL stage requiring therapy were found to be independent risk factors for autoimmune hemolytic anemia, but it is uncertain whether this is also true for ITP.[113] The presence of active CLL does not correlate with the onset or severity of ITP, which is distinctly different from autoimmune hemolytic anemia.[113,114] ITP may precede a diagnosis of CLL, and flow cytometry of bone marrow specimens from older patients with ITP may reveal small clones of monoclonal CLL phenotypic CD19/CD5 positive lymphocytes.[111,115]

A recent retrospective cohort study identified ITP in 69/1,270 patients (5%) with CLL.[114] ITP occurred at any time in the course of the disease with the median time to a diagnosis of ITP of 13 months (0 to 81 months). Laboratory characteristics of the CLL patients with ITP included a higher frequency of unmutated IgVh genes (54% vs. 18%), more frequent involvement of the Vh1 family (43% vs. 21%), and a lower frequency of the Vh4 family (4% vs. 22%).[114] The predominance of unmutated B lymphocytes and the unique Vh gene distribution may reflect a CLL subset with a greater propensity to autoimmune phenomena. As might be predicted by the greater frequency of patients with unmutated CLL, the patients with ITP had a lower 5-year survival (64% vs. 82%).[114] CLL patients with ITP were also less likely to respond to IVIG and prednisone treatment alone (19/35) when compared to the responses observed with the use of cytotoxic chemotherapy (27/41).

The reported prevalence of ITP in HD is estimated at 0.2% to 1%.[116–119] A review of 4,090 patients with HD in the British National Lymphoma Investigation (BNLI) registry identified only eight cases.[119] The majority of reported HD–ITP cases occur after the diagnosis of HD.[116–119] The median time to the development of ITP after the diagnosis of HD in the BNLI registry was 23 months (3 to 57), with six of the eight cases developing ITP while in remission.[119] However, a large population-based case-controlled epidemiologic study in Scandinavia found a statistically significant increased risk of Hodgkin lymphoma in patients with a personal history of ITP.[120]

T-LGL proliferation is a clonal proliferation of mature T lymphocytes that predominately express the CD8 phenotype.[121] T-LGL clonal proliferation is frequently found in patients with rheumatologic disorders such as rheumatoid arthritis, but can occur independent of other diseases.[121,122] Neutropenia and anemia are frequently reported in association with T-LGL.[121,122] Mild thrombocytopenia can occur in up to 20% of patients, but severe thrombocytopenia was observed in only 1% of patients.[122] The development of severe thrombocytopenia is most often due to suppression of megakaryopoiesis by cytotoxic T-LGL lymphocytes.[106–108] Amegakaryocytic thrombocytopenia frequently develops in conjunction with other cytopenias.[123–125] Treatment should be directed against the T-LGL clone employing cytotoxic therapy (cyclophosphamide) or cyclosporine.[123–125]

Human Immunodeficiency Virus Infection

Thrombocytopenia was first associated with the acquired immune deficiency syndrome (AIDS) before the discovery of the HIV virus.[126] Prior to the use of highly active antiretroviral therapy (HAART), thrombocytopenia (*HIV-ITP*, platelet count $<150 \times 10^9$/L) was identified in approximately 5% to 30% of HIV-1 infected patients.[77] Thrombocytopenia is more prevalent in patients with advanced HIV infection as defined by a CD4-lymphocyte count of $<200/\mu$L and clinical AIDS.[77] An increased incidence and severity of thrombocytopenia in HIV-infected intravenous drug users compared to HIV infected homosexuals has also been reported.[127,128] These differences may be explained, in part, by the higher incidence of coinfection with hepatitis C and underlying liver disease in HIV-infected intravenous drug users.[129]

Most data were obtained prior to the widespread use of HAART in patients with early HIV infection. There are few data on the current prevalence of thrombocytopenia in patients under active antiviral treatment. However, recent prospective data from the Women's Interagency HIV study have documented a reduction in the incidence of anemia and neutropenia in HIV-infected women on HAART therapy.[130,131] This is in accord with the impression that there has been a similar reduction in the incidence of thrombocytopenia, especially platelet counts $<50 \times 10^9$/L in compliant patients.

The pathogenesis of thrombocytopenia is partially dependent on the viral burden as defined by the severity of immunodeficiency. HIV-associated thrombocytopenia developing early after infection more often resembles classical ITP in which thrombocytopenia is mediated primarily by peripheral destruction, whereas thrombocytopenia in patients with immunologic AIDS (CD4 lymphocytes $<200/\mu$L) is predominately attributable to decreased platelet production and ineffective hematopoiesis.[132,133] While platelet counts may improve with antiretroviral therapy in both patient populations, patients with advanced disease are less likely to respond to classic primary ITP therapy such as corticosteroids, IVIG, or anti-RhD.

HIV-seropositive patients can develop thrombocytopenia several years before the development of overt AIDS, and the

early disease is clinically indistinguishable from classic ITP.[77] However, the clinical picture of HIV-ITP is often mild, with only a minority of patients having platelet counts $<50 \times 10^9$/L.[77] Major bleeding is rare and only a few cases of fatal hemorrhage have been reported. There has been greater variability in HIV-associated thrombocytopenia in patients with hemophilia A.[77] Severe thrombocytopenia in patients with advanced HIV infections is frequently associated with additional cytopenias.[77] HIV-infected drug users are also more likely to have antibodies to both hepatitis B and C and to have abnormal liver function studies.[129]

HIV-ITP is generally responsive to therapeutic interventions used in classical ITP. Therapy with prednisone produces a major hematologic response (platelet count $>100 \times 10^9$/L) in over half of patients, although only a minority will maintain platelets $>50 \times 10^9$/L after cessation of steroids.[134] No deleterious effect of short-term treatment with prednisone has become evident. However, long-term treatment with corticosteroids should still be avoided and other coinfections such as tuberculosis, cytomegalic virus, or hepatitis C should be excluded before initiating treatment with corticosteroids. IVIG and anti-RhD are equally effective in increasing platelet counts acutely in severely affected patients,[77] but a crossover study clearly demonstrated a longer duration of response with the latter agent.[135] Splenectomy has proven to be safe and effective in refractory patients with HIV-ITP.[77] After splenectomy, there is a transient increase in the peripheral blood CD4 lymphocyte count, which reflects redistribution from the splenic pool to the circulation, rather than an improvement in the patient's immunologic status.

HIV-related cytopenias have been found to correlate with plasma viral load.[136] Effective antiretroviral therapies (HAART) have resulted in improvement in several HIV-related cytopenias, including HIV-ITP.[136,137] Use of HAART in both *de novo* and zidovudine-refractory HIV-ITP has induced sustained platelet responses in association with effective viral suppression.[77,137]

Responses to zidovudine and HAART may be more limited in HIV-infected intravenous drug users, possibly reflecting the impact of associated liver disease and infection with HCV.[77] In a prospective placebo-controlled, double-blind, randomized trial, 12 of 14 zidovudine refractory HIV-infected intravenous drug users with elevated serum alanine aminotransferase suggestive of underlying liver disease and who were treated with interferon-α (IFN-α) had a statistically significant increase in their platelet counts by week 4 of therapy.[138] An unblinded open label trial of IFN-α in a cohort of predominately homosexual men documented responses in 9/16 patients, with responses occurring as early as 2 weeks after the initiation of treatment.[139] Such rapid responses preclude the possibility that improvement in the platelet count is due solely to suppression of concomitant HCV infection. There are no reported studies on the association of *H. pylori* infection and thrombocytopenia in HIV infected patients.

Helicobacter Pylori Infection

Helicobacter pylori is a gram-negative spiral-shaped bacterium that colonizes the mucous layer of the human stomach.[140] It has been causally linked with a diverse spectrum of gastrointestinal disorders, including gastritis, peptic ulcer disease, dyspepsia, gastric adenocarcinoma, and mucosa-associated lymphoid tissue lymphoma. Recent studies have provided strong evidence for an association between *H. pylori* infection and ITP in certain populations.[1,76,78]

A number of hypotheses have been advanced about the mechanisms by which *H. pylori* may cause ITP. One proposes molecular mimicry in which *H. pylori* induces antibodies that cross-react with epitopes on platelets proteins. The possible role of genetically and antigenically diverse cytotoxicity antigen A (CagA) gene products as candidates for evoking ITP antibodies was reported in two recent studies.[141,142]

No differentiating features have been identified in prospective series between the clinical presentation in patients with infection from those with classical ITP, aside from an older age in *H. pylori*–positive cases and in some studies higher platelet counts.[76] A uniform association has not been observed between *H. pylori* infection and symptoms of dyspepsia.[76] A cross-sectional study by Fukui et al.[143] did not find a correlation between *H. pylori* infection and thrombocytopenia during pregnancy.

A systematic review of studies on the treatment of *H. pylori* infection in 1,555 patients with ITP found a complete response (platelets $>100 \times 10^9$/L) and an overall response (platelets $>30 \times 10^9$/L or a doubling of the baseline platelet count) of 42.7% (95% CI 31.8% to 53.9%) and 50.3% (95% CI 41.6% to 59.0%), respectively.[78] Responses ranged from 0% in American series[144] to 100% in one Italian series.[145] In an Italian-English study, eradication therapy was administered to *H. pylori*–positive patients who either had a platelet count of $<50 \times 10^9$/L or symptoms of dyspepsia.[146] Platelet responses were observed in 17/52 patients (33%) who received treatment as compared with 0/12 patients who did not. Responders were younger than nonresponders (55 ± 8 years vs. 60 ± 14 years), had a higher baseline platelet count ($48 \pm 21 \times 10^9$/L vs. $31 \pm 20 \times 10^9$/L), a shorter disease duration (14 ± 7 months vs. 34 ± 23 months), and had either not received prior therapy for ITP or had received only prednisone or IVIG.[146] Platelet responses to eradication therapy appear to be sustained in the majority of successfully treated patients.[78] Adverse events from eradication therapy have been described as mild, usually consisting of abdominal pain and diarrhea, leading to discontinuation of treatment in <5% of cases. Patients who fail to respond to antimicrobial therapy should be retested to determine if eradication treatment was effective.

Hepatitis C Infection

HCV is the most common blood borne chronic viral infection in the United States. The third National Health and Nutrition Examination Survey estimated that nearly 3.2 million persons in the US population are infected with HCV.[147] Worldwide, an estimated 145 million individuals or 2.2% of the world's population are infected.[148] A significant proportion of HCV infected individuals are unaware of their illness and many only present to their physicians when they develop overt symptoms. In addition to cirrhotic liver disease, HCV is associated with the development of a variety of immune diseases and lymphoma.[1,76,77] Chronic HCV infection has also been associated with the development of thrombocytopenia.[1,76,77] Thrombocytopenia may be present even in the absence of clinically evident liver disease or splenomegaly and may be mistakenly diagnosed as primary ITP.[77]

Six cross-sectional studies have reported serologic evidence of HCV infection in 159/799 patients (20%) with ITP.[76,77] In the largest series published to date, HCV antibodies were identified in 76 of 250 patients (30%) fulfilling the American Society of Hematology guideline criteria for ITP.[54] There were significant differences in demographic characteristics of HCV-positive

compared with HCV-negative ITP patients. HCV-positive patients were older (54.9 ± 8 years vs. 40.3 ± 8 years) and there was no female preponderance as there is in HCV-negative ITP.[54] Pockros et al.[149] retrospectively identified 7 ITP cases among 3,440 new HCV patients seen over a 56-month period. They estimated that the prevalence of CITP among their HCV patients was much greater than would be expected by chance. Even in the presence of active liver disease, patients with HCV infection presented with lower platelet counts compared to patients with hepatitis B or alcoholic liver disease.[54,150]

There have been conflicting data reported with respect to the presence of specific antibodies in platelet eluates from patients with HCV-related thrombocytopenia.[76] In one report, 66% of HCV infected patients had detectable antiplatelet glycoprotein antibodies. However, their presence did not correlate with the patient platelet counts.[151] A similar frequency of antiplatelet glycoprotein antibodies was found in patients with alcoholic cirrhosis, indicating these antibodies are not necessarily specific for HCV infection.[151] In contrast, a cross-reactive antibody to an HCV protein and platelet GPIIIa has been described by Zhang et al.[152] that is capable of inducing peroxide-mediated platelet fragmentation, similar to an antibody found in patients with HIV-associated thrombocytopenia.

In one study from Japan,[153] platelet counts in HCV-positive patients were lower than in HCV-negative patients (26 ± 9 vs. 49 ± 30 × 10^9/L, respectively). Conversely, in an American series,[54] HCV-positive patients had less severe thrombocytopenia, as defined by a platelet count ≤10 × 10^9/L (4% vs. 46% for ITP). However, 74% had a platelet count ≤50 × 10^9/L. Symptoms and signs of thrombocytopenia were less frequent in HCV-positive ITP, but major bleeding was more frequent (25% vs. 10%,). Serum cryoglobulins and ACL antibodies were more frequent in HCV-positive ITP (90% and 62%) than in HCV-negative ITP (7% and 15%).[54] In another study, the characteristics of ITP in HCV-positive patients did not differ from those without a positive serology. However, this study evaluated only patients with platelet counts ≤25 × 10^9/L.[154]

A combined analysis of available studies indicates that responses to corticosteroids are significantly lower in HCV-positive than in HCV-negative patients (OR 0.39, 95% CI 0.17 to 0.86).[61] However, this result is entirely attributable to a single study from Sakuraya et al.,[153] in which none of the 10 HCV-positive patients treated with prednisolone achieved a response. Other case series have reported a >50% platelet response to steroids.[76] The response to splenectomy was not found to differ significantly between the HCV-positive and HCV-negative CITP patient populations (OR 0.84, 95% CI 0.19 to 3.61).[76]

Rajan et al.[54] noted that only a minority of HCV-positive patients received some form of treatment (29 [38%] vs. 158 [91%] for HCV-negative ITP).[54] Four of seven patients treated with prednisone responded, but six developed elevated hepatic transaminases of greater than twice pretreatment levels while on therapy and all six had a documented increase in HCV viral load. Two patients developed elevated serum bilirubin levels, with one patient developing overt jaundice. Treatment with either IVIG or anti-RhD IgG has proven to be effective in increasing platelet counts in both the HCV seropositive and seronegative patients.[54,76]

Approximately half of adult ITP patients with HCV and treated with IFN-α responded with a rise in platelet count.[76] Responders to IFN-α could be distinguished from the nonresponders by a decrease in HCV quantitative RNA, hepatic transaminases, and cryoglobulins.[54] Iga et al.[155] reported significant increases in the platelet counts of 12 HCV infected patients who were complete responders to IFN-α treatment, but no improvement in the platelet counts of 11 patients who failed IFN-α therapy as assessed by viral load.

IFN-α–based therapy can suppress platelet production. In a phase II study, Eltrombopag, an oral TPO receptor agonist, increased platelet counts in the majority of patients with cirrhosis associated with HCV infection to >100 × 10^9/L, permitting continuation of IFN-based therapy.[156] Response was dose dependent, with 9/17 responding to 30 mg/day, 15/19 to 50 mg/day, and 20/21 to 75 mg/day. None of the 17 patients treated with placebo increased their platelets to >100 × 10^9/L.[156]

Immune Deficiency

Immunodeficiency disorders are well known to be associated with ITP. The commonest form and best understood is common variable immune deficiency (CVID), also known as hypogammaglobulinemia. At least 10% of patients with CVID develop ITP and another 10% develop autoimmune hemolytic anemia.[157] Among patients with CVID, autoimmunity to platelets and red blood cells occurs more frequently in those with mutations in TACI, a B-cell growth factor receptor.[158] Furthermore, ITP does not appear to develop in patients with X-linked agammaglobulinemia (Brutons), presumably because there are no abnormal circulating B and T cells to instigate the autoimmune response to platelets. ITP is also common in patients with autoimmune lymphoproliferative syndrome (ALPS or Canale-Smith syndrome), an apoptosis defect in autoreactive T and B cells, although the pathophysiology has not been established.[159] Recent studies have suggested that overt or a "forme fruste" of ALPS may underlie a substantial fraction of pediatric cases of Evan syndrome (concurrent autoimmune hemolytic anemia and ITP).[160]

Management of Primary ITP in Adults

A number of important clinical factors must be considered before treatment is initiated in adults with primary ITP. Consideration must be given to the bleeding risk, toxicities of specific therapies, patient age and comorbidities, and patient preference and life style.[74] Management of adult CITP is different from that of ITP in children. For children with ITP, when treatment is given, it is initially aimed at rapidly increasing the platelet count to a safe level, then maintaining an adequate and safe count with the assumption that the child will have a spontaneous remission. For adults, most of whom will have CITP, the therapeutic goals are generally different. Therapies to increase the platelet count to a safe level and/or prevent further bleeding should be well tolerated and given over a limited period of time. More aggressive early intervention may be justified if proven to have curative potential. Since attaining a spontaneous remission becomes much less likely a year after diagnosis, short-term therapies, such as IVIG or anti-RhD infusions may be used to avoid severe thrombocytopenia while awaiting the response to a "curative" treatment. Also small changes in the platelet count may be clinically significant. An increase in the platelet count from 5–10 × 10^9/L to 20–25 × 10^9/L can have an important impact on the risk and occurrence of bleeding. Clinical experience and recent clinical trial data indicate that the risk of major bleeding is quite low at platelet counts of >30 × 10^9/L.

In some patients with thrombocytopenia without significant bleeding manifestations, observation alone with occasional "rescue treatment" with IVIG, anti-RhD, or pulsed steroids may be an appropriate choice. The obvious advantages of this approach are that there is less toxicity from therapy, patients have less frequent physician visits, spend less time focused on their disease, and the cost of treatment is reduced. The success of this approach is dependent upon the patient and the severity of disease. If patients have bruising, oral bleeding, or heavy menses, it may prove to be impossible to "ignore" their ITP and the patient may have heightened anxiety, restrict their social interactions, and return urgently to the hematologist for management. More serious bleeding may occur in the context of other illness or trauma; a low platelet count may prevent use of medications to treat other conditions, such as aspirin for coronary artery disease or pegylated interferons for the treatment of hepatitis C infection and could lead to the avoidance of other medical or dental care. For these reasons, periodic visits are optimal to maintain a patient–physician dialogue and prevent disease denial that may have serious consequences.

Therefore "observation and no treatment" is done with the understanding that the patient will have further follow-up and the physician is available to manage bleeding events should they arise. It is clear that if the platelet count is sufficiently low ($<20 \times 10^9$/L) and if there is bleeding, then the risk of serious hemorrhage is appreciable. Certain issues need to be considered at this juncture before discussing available treatments. First, what other reasons exist to treat patients even if they do not appear to be at immediate risk of life-threatening hemorrhage. Second, how completely has the patient been evaluated for secondary forms of ITP and what investigations are required to distinguish a case of "refractory" ITP from that of another etiology such as myelodysplasia. Third, where should the balance be between raising the platelet count in the absence of bleeding, side effects of therapy, improvement of health-related quality of life, and a policy of reasonable, cost-effective patient follow-up.

If a patient with CITP is being seen for the first time, it is worthwhile to review the items in the Table 61.1 to ensure the diagnosis of CITP is correct. Among the primary considerations is the exclusion of secondary ITP in which resolution of the primary, underlying disease would impact on the management of the thrombocytopenia.

The rest of this chapter is devoted to treatment of patients with CITP with the understanding that management paradigms are changing as new clinical trials and therapeutic agents are introduced. The consensus of ITP experts is that treatment should be considered when the platelet threshold is 20–30 $\times 10^9$/L, but occasionally it is appropriate to select a higher target count.[74] For secondary ITP, treating the underlying disease, such as infection or an immune defect, is usually the preferred approach. This section will assume that appropriate evaluation has been undertaken and patients with secondary causes of ITP will have been managed accordingly.

Corticosteroid Therapy

Corticosteroids are the standard initial therapeutic agents.[74] The corticosteroids used most often include prednisone, parenteral methylprednisolone, and dexamethasone. These medications are frequently used in combination with IVIG and IV anti-RhD to rapidly increase platelet counts in patients with significant thrombocytopenia ($<5 \times 10^9$/L) and extensive bleeding manifestations.[74]

Prednisone is the most frequently used corticosteroid. The drug is given orally at a dose of 0.5 to 2 mg/kg daily. Platelet counts will increase to $>50 \times 10^9$/L in a few days to several weeks in responders, depending upon the baseline platelet count and whether IVIG or anti-RhD is used in conjunction with the drug. Bleeding may cease before a rise in the platelet count is seen. When used alone, 65% to 70% of patients respond.[161–163] Responses in adults are rarely durable with only 13% to 17% of patients having an unmaintained normal platelet count at 1 year after treatment with prednisone alone.[161–163]

High dose methylprednisolone has been used to increase platelet counts more rapidly in patients not responding to oral prednisone.[164,165] There is no evidence that this improves long-term outcomes and most responding patients transition successfully to prednisone. Recent trials have shown significant efficacy for the initial treatment of ITP with pulse dexamethasone.[166,167] Previous studies on the use of high dose dexamethasone for the treatment of refractory ITP were abandoned due to significant toxicity and marginal efficacy.[168] A study of a single course of high dose dexamethasone (40 mg/day × 4 days) in newly diagnosed patients reported a high initial response (85%), with half of the responding patients maintaining their response at 6 months.[166] A multicenter trial of dexamethasone (40 mg/day × 4 days) repeated every 14 days for four courses produced at 86% response rate (platelets >50 10^9/L) and a 65% complete response rate (platelets $>100 \times 10^9$/L).[167] At 15 months median follow-up, 60% of responding adults had not relapsed and for both adults and children who obtained a complete response, 87% remained in remission at 15 months median follow-up.[167] However, a recently reported randomized trial comparing one or two cycles of the high dose dexamethasone to 1 mg/kg prednisolone failed to demonstrate superiority of the dexamethasone regimen.[169] Additional studies will be needed to prove this approach provides superior long-term benefit.

Intravenous Immunoglobulin

A number of controlled treatment trials have clearly demonstrated 65% to 80% of patients treated with IVIG show an increased platelet counts within 24 to 48 hours.[5,74,170,171] Duration of response is rarely >10 to 14 days. Initial treatment regimens, in which 0.4 g/kg was infused daily for 5 days have been supplanted by a higher dose regimen of 1 g/kg daily for 1 or 2 days. This latter regimen is associated with longer daily infusion time and greater toxicity, including infusion reactions, headaches, occasional aseptic meningitis, hemolytic anemia due to alloantibodies, acute renal failure, and rare thrombotic events primarily in the elderly. The concomitant use of corticosteroids may enhance the platelet response, reduce infusion reactions, and result in fewer headaches.

Intravenous Anti-RhD

Patients who are Rh positive, not significantly anemic, and who retain their spleens are candidates for treatment with anti-RhD. Before initiating treatment with anti-RhD, patients should be Rh typed and have a DAT performed. Treatment with the FDA-approved dose of 50 μg/kg can result in an increase in the platelet count to over 50×10^9/L in nearly 80% of patients, but requires 48 to 72 hours for a clinically significant response.[135,172,173] Infusions of 75 μg/kg have been associated with a more rapid

increase in the platelet count, equivalent to that reported with IVIG treatment.[173] Duration of response to anti-RhD therapy is usually greater than observed with IVIG treatment, averaging 21 days.[135] Treatment with anti-Rh immunoglobulin typically results in a mild hemolytic anemia with an average decrease in hemoglobin of 1 to 1.5 g. Occasional episodes of intravascular hemolysis resulting in renal failure and rare cases of disseminated intravascular coagulation have been reported,[174,175]. Because of these reactions, anti-RhD is no longer available in Europe for the treatment of ITP.

Splenectomy

Splenectomy is the historical "gold standard" for the treatment of CITP. A systematic review of the medical literature has clearly shown that 65% of patients will have unmaintained remissions lasting 10 years or longer. In these patients, the procedure appears to be curative.[59] However, outcomes beyond this time frame have not been well studied. The response rate in the 1st week is nearly 85%, with 20% of patients relapsing within weeks to years.[59] However, even after relapse, patients appear to be less refractory to medical treatment.[59] Patients older than 45 years appear to have a lower response to splenectomy.[59] At present there are no readily available clinical or laboratory markers that are predictive of response to splenectomy, although one report suggests that hepatic sequestration of autologous indium-111–labeled platelets maybe predictive of a poor response.[176]

Laparoscopic splenectomy is associated with lower complication rates and faster recovery, no greater need for accessory splenectomy, and no loss in efficacy. The efficacy of splenectomy decreases with increasing age above age 45 years; this means that the higher response rates to splenectomy are in patients with the greatest potential for late complications due to their longer lifespan postprocedure. The risk of postsplenectomy sepsis has been greatly reduced by immunization for pneumococcus, haemophilus influenza, and meningococcus.[59] Patients should have yearly influenza vaccinations and if a fever occurs, the patient should immediately receive parenteral broad spectrum antibiotics that are effective against pneumococcus. This is true no matter how many years postsplenectomy and despite immunization. Other long-term outcomes after splenectomy are unknown; particularly in regard to uncommon events such as pulmonary hypertension or vascular dementia.[177–179]

Anti-CD20 Therapy (Rituximab)

B lymphocyte depletion using rituximab, a humanized anti-CD20 monoclonal antibody, has shown limited, but reproducible efficacy in patients with CITP.[180,181,182] Nearly 60% of patients will have an initial increase in their platelet count, with an estimated one-third of patients obtaining an initial (1 year) unmaintained complete response (platelets $>100 \times 10^9$/L) with the use of the standard lymphoma regimen of 375 mg/m^2 rituximab weekly for 4 weeks.[180,181,182] Nearly all partial responders will relapse within 1 year, while nearly all complete responders will maintain their response for at least 1 year. Approximately one half of complete responders will relapse within 4 more years. Although repeat treatment of the relapsed complete responder can result in a high rate of response,[183] the safety of this approach has not been fully evaluated. Concerns with the use of anti-CD20 therapy include development of progressive multifocal leukoencephalopathy[184] and reactivation of hepatitis B, but the risk may be lower than reported in patients with lymphoma and other systemic autoimmune disorders since patients with ITP are generally not intrinsically immunosuppressed by their disease or receiving additional immunosuppressive therapies. Common, but less serious, toxicities include first infusion reactions such as fever and chills and serum sickness, the latter especially common in children.[185] Although total immunoglobulin levels rarely decrease, patients cannot mount a normal humoral antibody response to some vaccines for months after treatment. The optimal dose and frequency of rituximab administration for the treatment of ITP remains unknown.[186]

Other Second-Line Therapies with Documented Efficacy

Azathioprine has documented efficacy for ITP patients' refractory to first-line treatment. In one retrospective series, the overall response rate was 64% with 45% of patient obtaining a normal platelet count. The median time to response was 4 months. Responses tend to be maintained, but reported follow-up was short.[187] Toxicities can include nausea, leucopenia, hepatitis, and occasionally pancreatitis.

Cyclosporin A has been effective when given in combination with prednisone.[188] Improvement in platelet count occurred in 80% of patients with 42% of patients obtaining a complete response. Some remissions maybe durable even after the drug is discontinued.[189] Side effects include hypertension, neuropathy and renal toxicity.

Cyclophosphamide, given orally (1 to 2 mg/kg daily for at least 16 weeks) or intravenously (0.3 to 1 g/M^2 every 2 to 3 weeks) has demonstrated efficacy in the treatment of adults with refractory ITP who have failed splenectomy, with reported response rates ranging from 24% to 85%.[190–192] Toxicities may be significant, including severe leucopenia, hemorrhagic cystitis, possible sterility in men and the rare late complication of acute leukemia.

Danazol is an attenuated androgen analogue that is often effective as a corticosteroid-sparing agent when administered orally at doses of 200 to 800 mg daily.[193] Approximately 50% to 65% of patients respond, but nearly all relapse within 1 year of stopping the drug. Toxicities include virilism in women, elevated liver enzymes, skin rashes, myalgia, and rare hepatic adenomas. There may be an enhanced risk of venous thrombosis when higher doses are used.

Mycophenolate mofetil is an immunosuppressive agent predominately used to reduce the risk of solid-organ transplantation rejection. It inhibits inosine monophosphate dehydrogenase activity resulting in inhibition of T and B lymphocyte proliferation. Several case series have documented responses in refractory patients.[194,195] In one report, 7/18 refractory patients sustained an increased platelet count of $>50 \times 10^9$/L.[195] Treatment dose ranged from 250 mg twice daily to 500 mg twice daily in adults and 250 to 750 mg/day in children.[195] Toxicities include headaches, nausea, vertigo, and low white blood cell count.

Thrombopoietin Receptor Agonists: Romiplostim and Eltrombopag

Romiplostim was the first TPO receptor agonist to enter clinical trials.[196] Subsequently two randomized, placebo controlled studies were published, one in splenectomized patients and the other study in nonsplenectomized patients.[197] In both studies, the same dosing regimen was used with progressive weekly increases in dose depending on the platelet count, beginning at 1 μg/kg and increasing to 18 μg/kg. Rescue medications were allowed for overt bleeding or very low counts associated with a high risk of

bleeding. Concomitant medications such as prednisone could be decreased or stopped as the platelet count increased.

In both trials, unequivocal efficacy was demonstrated. Durable response (platelets ≥50 × 10^9/L for 6 of the last 8 weeks and no rescue therapy was seen in 38% of splenectomized patients and 61% in nonsplenectomized patients. The overall response rate (platelet counts ≥50 × 10^9/L on 4 of 24 weeks) was 79% in splenectomized patients and 88% in nonsplenectomized patients. There were no responses in the splenectomized patients and only 14% in nonsplenectomized patients taking placebo. There were statistically significant reductions in the use of concomitant medications such as prednisone and reduced use of rescue medications (IVIG, anti-RhD, or prednisone). No tachyphylaxis was seen over the 6 months of study and no important toxicities emerged, such as an increased incidence of thromboembolic events or malignancies. Rare instances of increased bone marrow reticulin were observed in patients at the higher doses: for this reason the upper dose recommended for treatment is now 10 μg/kg. "Rebound" thrombocytopenia with platelet counts decreasing to less than pretreatment baseline levels occurred in up to 5% to 10% of patients who stopped treatment abruptly. Romiplostim was licensed in August 2008 based on these two studies.

Patients who entered one of the two previous studies were eligible to enter a long-term maintenance study that validated the efficacy and safety of romiplostim use for up to 3 years of follow-up.[198] Overall, this study showed that long-term use of romiplostim as a maintenance therapy was feasible. Platelet counts could be maintained for years without a need to significantly increase the dose. Many patients learned to give weekly injections at home. No important new toxicities were identified with extended use. Nine cases of bone marrow reticulin fibrosis were identified, but no cases of myelofibrosis/myeloid metaplasia. Whether this incidence is significantly higher than occurs in patients with ITP successfully treated with other agents requires additional study.

An open-label 52-week randomized trial of romiplostim versus standard of care reported a higher rate of platelet response, lower incidence of treatment failure and splenectomy, and less bleeding in the romiplostim-treated patients.[199] However, utility beyond 52 weeks compared to patients who were treated with splenectomy is unknown. Another study has reported safety and efficacy in 22 children.[200]

Eltrombopag is the first oral TPO receptor agonist to complete clinical trials and to be licensed for use in the United States. In the initial published study, eltrombopag was given for 6 weeks in daily doses of placebo, 30, 50, and 75 mg and results were compared to patients given placebo.[201] Responses were seen in 70% to 80% of patients at the two highest eltrombopag doses compared to 11% in those receiving placebo.[201] No important toxicity was seen and bleeding decreased as the platelet counts increased. A second study reported similar results for thrombocytopenic patients with hepatitis C infection, allowing continued antiviral chemotherapy without dose reduction or interruption.[156]

A third confirmatory study was a 6-week randomized placebo controlled trial comparing 50 mg of Eltrombopag to placebo.[202] It demonstrated a 59% response rate in the Eltrombopag arm, based on an increase in platelet count to >50 × 10^9/L, compared to a 16% increase in platelet count in those taking placebo. Bleeding manifestations were decreased in responders, but returned to baseline levels after the medication was discontinued and platelet counts declined. In this study, rebound thrombocytopenia upon drug withdrawal was rare and no statistically significant organ toxicity was seen. However, some patients developed significant liver enzyme increases requiring cessation of medication. Accordingly, the FDA has required a black box warming concerning the need to monitor liver function in patients taking Eltrombopag.[202]

Other Eltrombopag studies have been reported in only abstract form. These include a 6-month randomized study trial comparing Eltrombopag to placebo with results comparable to the 6-month pivotal trial of romiplostim, as well as a long-term extension study.[203] Also long-term follow-up of all patients enrolled in the eltrombopag trial found a lower frequency of thromboembolic events than suggested in earlier reports.[204]

Single agent treatment of refractory ITP with azathioprine, danazol, cyclophosphamide, cyclosporine A, and mycophenolate mofetil has limited efficacy; no single agent induces unmaintained remission in more than 30% of refractory cases and this is particularly true in patients refractory to splenectomy.[205] Even autologous stem cell transplants have only been found to have a 25% to 33% response rate and are without multiyear follow-up.[206] Therefore, the higher response rates reported in postsplenectomy refractory patients treated with TPO receptor agonists suggest that these would be the drugs of choice for this group of patients. These agents also lessen the need for immunosuppressive drugs, thereby reducing the risk of infection in this high-risk patient population.

Combination chemotherapy has been utilized in some situations to increase response rate and decrease the toxicity of single agents. The first report involved a patient with HD and refractory ITP whose thrombocytopenia responded to six cycles of CHOP chemotherapy. Treatment of additional patients was associated with significant toxicity, but good responses were seen in some patients.[207] Long-term follow-up showed that all, but one responder, maintained the response over many years.[208] Boruchov et al. studied a multiagent therapy regimen in highly refractory patients using initial IVIG and methylprednisolone or intravenous anti-RhD and vincristine, or all four agents together, followed by danazol plus azathioprine in combination. The latter combination was effective in 13 of 17 patients, but the duration of response was brief in many patients.[209]

POSTTRANSFUSION PURPURA

Posttransfusion purpura (PTP) is a syndrome characterized by the development of severe thrombocytopenia 5 to 10 days following the transfusion of blood products. The vast majority of cases occur in women (90%), nearly all of whom have a history of multiple pregnancies or transfusion of blood product.[210,211,212] The initiating transfusion most often consists of red blood cells, but episodes of PTP have occurred after platelet transfusion and even plasma infusion.[210,211,212,213] In 80% of cases, the recipient of the transfusion is homozygous for the Pl^{A2} [HPA-1b] platelet GPIIIa polymorphism. In this case, patient serum is found to contain an alloantibody against the Pl^{A1} [HPA-1a] platelet antigen.[210,212,214] Alloantibodies against other platelet antigen polymorphisms, and occasionally HLA antigens, have been reported in other cases of PTP, though the latter remains controversial.[210,212,215–217] Prior sensitization in women occurs most frequently during pregnancy. Alloimmunization to the Pl^{A1}

antigen has been shown to occur in 1 of every 1,000 pregnancies in the white population or in approximately 6% of homozygous Pl^{A2} female carriers.[218] In a study of transfusion-induced platelet reactive antibodies, 8.1% of previously untransfused patients developed a mix of pan-reactive antibodies against the glycoproteins IIb/IIIa, Ia/IIa, and Ib/IX.[219] A conservative estimate is that PTP occurs after 1:50,000 to 100,000 transfusions, suggesting that many cases go unreported or misdiagnosed.[220] The lower than expected frequency of PTP may also be explained by genetic restriction on antibody production. PTP and neonatal allo ITP have been linked to the HLA B8 and DRB30101.[218,221,222]

Despite the clear serologic finding of platelet alloantibodies in the majority of cases of PTP, the pathophysiologic mechanism by which ITP develops in patients with PTP remains unknown. Although a number of hypothetical mechanisms have been proposed, none have been definitively demonstrated in the majority of patients. A hypothesis that PTP is initiated by the binding of antibody–antigen immune complexes to autologous platelets has never been convincingly demonstrated[223] nor has the proposal that Pl^{A1} antigen is absorbed by autologous platelets and platelets are subsequently destroyed *via* an innocent bystander mechanism.[224,225] Moreover, neither of these mechanisms account for the observation that prior to the use of plasmapheresis and IVIG therapy, thrombocytopenia in some cases of PTP has persisted for >30 days.[226,227] A more tenable hypothesis is that the infusion of foreign platelet antigens results in the transient development of a cross-reactive antiplatelet autoantibody.[228,229] Infusions of Pl^{A1}-negative (Pl^{A2} restricted) platelets did not increase the platelet counts in some patients with PTP, suggesting an antigenic target different from this polymorphism.[230,231] Moreover, in one report, reinfusion of plasma from a patient with PTP after platelet recovery failed to reinduce thrombocytopenia.[224] Also, repeat transfusion of Pl^{A1}-positive blood into a patient with a prior history of PTP has failed to induce a new episode of thrombocytopenia.[232]

Once thrombocytopenia develops in PTP, platelet counts rapidly fall to levels that are usually below 10×10^9/L.[210,211,212] Bleeding manifestations are common, including epistaxis, petechiae, ecchymosis, gingival bleeding and genitourinary bleeding.[210,211,212,227] Intracranial bleeding has been reported in 5% to 8% of patients.[210,211,212,227] The severity of bleeding appears to be greater than that observed with primary ITP or drug-related thrombocytopenia. This may be due in part to the fact that PTP frequently develops in the postsurgical setting following blood transfusion and in patients with significant comorbidities. A number of cases have been misdiagnosed as heparin-induced thrombocytopenia or other drug-induced thrombocytopenia based upon the time of onset of thrombocytopenia and the fact that many patients are simultaneously receiving medications associated with the development of thrombocytopenia.[233]

While the diagnosis of PTP is primarily based on patient history and clinical finding, serologic studies are required to confirm the presence of platelet alloantibodies and the absence of the corresponding antibody on the patient platelets following recovery.[210,211,212,215,216,223] International reference sera are now available to detect antihuman platelet alloantigens and alloantibodies and many referral centers have donors that are known to be HPA-1b homozygotes or that lack or possess other phenotypes occasionally implicated in PTP.[234,235] Patient platelet genotype can be determined with serologic or molecular methods.[240] Patient platelet genotyping may be of further value in family counseling regarding screening, for example, female siblings of child-bearing age.

PTP is self-limited. However, prolonged severe thrombocytopenia places patients at risk of potentially fatal bleeding. Therefore, PTP, though rare, should always be considered in the relevant clinical context and treated as an emergency. The efficacy of corticosteroids cannot be adequately determined due to the variable natural history.[210,211,212,236,237] Exchange transfusion appears to be effective in shortening the duration of severe thrombocytopenia. However, recurrent thrombocytopenia can occur once exchanges have been stopped and the procedure is both labor intensive and cumbersome.[210,230,238] IVIG, as used in the treatment of ITP, is highly effective and safe for the treatment of PTP and is the treatment of choice.[210,211,212,239] When given with corticosteroids, infusion reactions are rare and most patients respond by increasing platelet counts to a safe level within 2 to 7 days.[239] An occasional patient will relapse, but will respond to a second course of high dose immunoglobulin.[239]

CHAPTER

62 Drug-Induced Thrombocytopenia

RICHARD H. ASTER AND JAMES N. GEORGE

BACKGROUND

Drugs induce thrombocytopenia through various mechanisms. The inhibition of platelet production is an expected result of the dose-dependent toxicity of chemotherapeutic agents. Rarely, pancytopenia (aplastic anemia) results from idiosyncratic drug hypersensitivity. A few drugs suppress platelet production selectively. A much larger number cause thrombocytopenia by promoting platelet destruction that can be acute and severe and is usually caused by drug-dependent antibodies. Mechanisms by which drugs are known to cause thrombocytopenia are summarized in Table 62.1.

In this chapter, we consider drug-induced thrombocytopenia according to pathogenesis, clinical presentation, diagnosis, and treatment. The drug implicated most often as a cause of thrombocytopenia is heparin. Heparin-induced thrombocytopenia (HIT) has a unique pathogenesis, and thrombosis, rather than thrombocytopenia, is the major concern in patients with this condition. HIT is discussed in Chapter 108 and is mentioned here only briefly.

INCIDENCE

The annual incidence of drug-induced thrombocytopenia has been estimated in four studies to be approximately 1 case per 100,000 annually[1,2,3,4] (Table 62.2). However, these data are the result of reporting to national surveillance groups or reviewing hospital records. It can be reasonably assumed that many patients suspected of having drug-induced thrombocytopenia are not reported and that affected patients often do not require hospitalization. It is likely therefore that published estimates greatly underestimate the frequency of this condition. Another cause of underestimation may be the tendency to misdiagnose drug-induced thrombocytopenia as acute autoimmune thrombocytopenic purpura (AITP).[5]

SUPPRESSION OF PLATELET PRODUCTION BY DRUGS

Chemotherapeutic Agents

Thrombocytopenia is a common, dose-dependent side effect of chemotherapy used for treatment of cancer and for immunosuppression. All myeloid elements are likely to be affected, but thrombocytopenia is often dose limiting. Various cytokines and leukokines, including IL-6 and IL-11, have been used to reduce the severity of thrombocytopenia in patients receiving chemotherapy,[6] but only IL-6 has been approved for this purpose. Thrombopoietin receptor agonists are not yet approved but show promise and are in various stages of evaluation.[7] Profound thrombocytopenia sometimes occurs in patients treated with antiviral agents such as azidothymidine used to treat human immunodeficiency virus infection.

It should not be assumed a priori that thrombocytopenia associated with chemotherapy is caused by inhibition of megakaryocytopoiesis. Patients have been described who experienced an acute and very severe drop in platelet levels when treated with agents such as oxaliplatin, cyclosporine A, irinotecan, and suramin despite the demonstration of adequate numbers of megakaryocytes in aspirated bone marrow.[8] In such instances, appropriate serologic testing may demonstrate the presence of drug-dependent, platelet-reactive antibodies capable of causing platelet destruction when drug is administered. Systemic reactions such as chills, fever, and hypotension occurring at the time of drug administration can provide a clue to the presence of such an antibody.

Drug-Induced Aplastic Anemia

Numerous medications are thought to be capable of causing aplastic anemia on an idiosyncratic basis. Implicated drugs include anticonvulsants, nonsteroidal anti-inflammatory drugs, and sulfonamides. The pathogenesis of this complication is poorly understood,[9,10] and there is at present no means of identifying patients at risk to develop this complication.

Drugs that Selectively Inhibit Megakaryocytopoiesis

Alcohol

Thrombocytopenia, sometimes severe, is common in persons who ingest large quantities of alcohol for long periods of time.[11] Although vitamin deficiency and/or splenomegaly and cirrhosis contribute to the lowering of platelet levels in some cases, there is evidence that ethanol can directly affect megakaryocytopoiesis. In general, thrombocytopenia is mild in patients with chronic alcoholism, but very low platelet counts and bleeding have been described. After abstinence for a few weeks, platelet levels usually return to the normal range, but moderate thrombocytopenia persists for longer periods in some patients.

Estrogens

Large doses of estrogens adversely affect megakaryocytopoiesis, leading to profound thrombocytopenia in some species of animals, especially dogs.[12] Rare cases of thrombocytopenia associated with megakaryocyte dysplasia in humans treated

Table 62.1

Classification of drug-induced thrombocytopenia

Decreased Platelet Production
Generalized suppression of hematopoiesis (dose-dependent toxicity; e.g., chemotherapeutic agents)
Idiosyncratic aplastic anemia (e.g., anticonvulsants, sulfonamides, nonsteroidal anti-inflammatory drugs)
Selective suppression of platelet production (e.g., anagrelide, valproic acid)
Platelet destruction through nonimmune mechanisms (e.g., desmopressin, protamine sulfate)
Platelet Destruction Through Immune Mechanisms
Hapten-dependent antibodies (penicillin?)
"Quinine-type" immune thrombocytopenia (e.g., quinine, sulfamethoxazole, vancomycin, piperacillin
Drug-induced, platelet-specific autoantibodies (e.g., gold salts, procaine amide)
Thrombocytopenia in patients treated with ligand-mimetic platelet inhibitors (e.g., tirofiban, eptifibatide)
Abciximab-induced thrombocytopenia
Drug-induced immune complexes (heparin)

with estrogens have been described. It has been suggested that estrogens can exacerbate thrombocytopenia in women with autoimmune thrombocytopenia.

Histone Deacetylase Inhibitors

Histone deacetylase inhibitors (HDACi), a new class of chemotherapeutic drugs, regularly produce a degree of thrombocytopenia in treated patients, an effect that limits their use in some individuals.[13] Animal studies suggest that HDACi act directly on megakaryocytes to inhibit maturation and proplatelet formation[13] through a mechanism not fully understood. Preclinical studies provide evidence that HDACi-induced thrombocytopenia can be ameliorated by treatment with a thrombopoietin receptor agonist. Valproic acid, although mainly used as an anticonvulsant, is an HDACi and causes mild thrombocytopenia in up to one-third of treated individuals.[14] Rarely, thrombocytopenia is acute and severe.

Linezolid

Linezolid is an oxazolidinone antibiotic used for treatment of drug-resistant bacterial infections. Low-grade thrombocytopenia occurs in 30% to 40% of individuals treated with this drug for more than 10 days.[15] Patients with renal dysfunction and those given the drug intravenously[15] are more likely to experience a reduction in platelet levels. There is evidence that linezolid acts to suppress megakaryocytopoiesis through a dose-dependent mechanism.

Imatinib Mesylate

Thrombocytopenia, often accompanied by neutropenia, occurs in up to 70% of patients treated with imatinib mesylate for chronic myelogenous leukemia.[16] The mechanism of this effect is poorly understood. Responses to granulocyte colony stimulating factor and IL-11 have been described.

Anagrelide

The quinazoline compound anagrelide causes isolated thrombocytopenia with little effect on other aspects of hematopoiesis.[17] Animal studies suggest that anagrelide interferes with megakaryocyte maturation, possibly through the action of a metabolite, an effect that makes it useful for treating thrombocythemia in patients with myeloproliferative conditions. In rare cases, profound thrombocytopenia has occurred in patients given anagrelide for this purpose.

Table 62.2

Incidence of drug-induced thrombocytopenia

Country	Years	Method	Annual Incidence
Sweden[a]	1966–1970	Reports to Swedish Adverse Reaction Committee	1/100,000
Denmark[b]	1968–1991	Reports to Danish Committee on adverse drug reactions	1/100,000
USA[c]	1972–1981	Hospital records, Puget Sound Group Health Cooperative	0.6/100,000
USA[d]	1983–1991	Hospital records, case control study	1.8/100,000

Interferons

Low-grade thrombocytopenia is a common side effect of interferon therapy. Profound thrombocytopenia and bleeding have been described in patients with chronic hepatitis C given interferon α and pegylated interferon-2b.[18] Interferons α and γ inhibit megakaryocyte proliferation in cell culture models and stem cell differentiation in animals, but whether this is relevant to thrombocytopenia developing in patients treated with interferons is uncertain.

DRUG-INDUCED PLATELET DESTRUCTION THROUGH NONIMMUNE MECHANISMS

Leukokines and Hematopoietic Growth Factors

An acute drop in platelet levels has been described in patients treated with granulocyte–macrophage colony-stimulating factor. Activation of macrophages and monocytes in the liver and spleen has been implicated as a possible cause. Macrophage colony-stimulating factor may exert a similar effect in rare individuals.

Tumor Necrosis Factor α and Interferon γ

Acute, severe thrombocytopenia has been described in a small number of patients following treatment of Ewing sarcoma with tumor necrosis factor α combined with interferon γ. A direct effect of the cytokines on endothelium, leading to increased platelet clearance has been postulated as a possible mechanism.

Porcine Factor VIII

Patients given porcine factor VIII for treatment of hemophilia often experience mild thrombocytopenia. Occasionally, a profound drop in platelet levels occurs. Hypersensitivity symptoms such as chills, fever, and urticaria sometimes accompany these reactions. Bovine von Willebrand factor (vWF) contaminating the Factor VIII preparations has been implicated. Whether xenoantibodies specific for porcine factor VIII contribute to this effect has not been established.

Desmopressin

Desmopressin (DDAVP) is used for treatment of some patients with von Willebrand disease (vWD) because of its ability to induce vWF release from endothelial cells.[19] Patients with type 2B vWD, who possess a vWF mutant that binds to the platelet vWF receptor with high affinity, sometimes experience severe thrombocytopenia after treatment with DDAVP. Patients with "platelet-type" vWD, who have a mutant vWF platelet receptor, can also develop thrombocytopenia following DDAVP administration.

Protamine Sulfate

Protamine sulfate is widely used to neutralize circulating heparin following open-heart surgery. Mild thrombocytopenia often develops after protamine administration, but it can be difficult to ascertain whether this is a consequence of protamine infusion or is representative of low-grade thrombocytopenia routinely seen after this procedure. However, sequestration of indium 111–labeled platelets in the liver was demonstrated in a cohort of patients given protamine. Protamine is known to bind to chondroitin sulfate normally found on the platelet surface[20] but whether this interaction is related to transient platelet sequestration following protamine infusion is uncertain.

Amrinone

The pyridine phosphodiesterase-3 inhibitor amrinone is widely used for treatment of heart failure. Up to one-third of individuals given amrinone experience low-grade thrombocytopenia soon after starting the drug. The mechanism of this effect is uncertain, but the *N*-acetyl metabolite of the drug was implicated in one study.

DRUG-INDUCED PLATELET DESTRUCTION THROUGH IMMUNE MECHANISMS

Pathogenesis

As summarized in Table 62.3, drug-dependent, antibody-mediated immune thrombocytopenia is caused by several distinctly different mechanisms.

Hapten-Dependent Antibodies

It is generally thought that low molecular weight compounds like drugs induce antibodies only when they are covalently linked to a larger carrier molecule, usually a protein. Accordingly, it was assumed for many years that immune thrombocytopenia in patients sensitive to drugs is caused by antibodies raised against drug covalently linked to a platelet membrane glycoprotein. However, antibodies identified in such patients did not exhibit the behavior expected of a hapten-dependent immunoglobulin since they could not be inhibited by excess concentrations of drug and they failed to react with platelets pretreated with drug and then washed. It is now thought that classical "hapten-dependent antibodies" rarely, if ever, cause immune thrombocytopenia. However, penicillin and penicillin derivatives, which spontaneously form covalent linkages with cell membrane proteins, do on occasion induce true hapten-dependent antibodies capable of causing immune hemolytic anemia.[10] By analogy, it is possible that thrombocytopenia occurring rarely in patients treated with penicillin and structurally similar drugs is caused by this mechanism. However, this has not been confirmed experimentally.

"Quinine-Type" Immune Thrombocytopenia

Sudden and sometimes life-threatening thrombocytopenia following treatment with medication was described as a clinical entity more than 120 years ago. The responsible antibodies are unusual in that they are completely harmless in the absence of drug, but in its presence, bind tightly to specific platelet membrane glycoproteins and cause platelet destruction.[8,21] Several hundred different drugs have been implicated, but quinine, quinidine, various antibiotics, nonsteroidal anti-inflammatory drugs, and the chemotherapeutic drug oxaliplatin are among those that trigger this condition most often.[8,21,22] Since quinine is the prototypic drug associated with this condition, we will refer to it as "quinine-type" thrombocytopenia. Antibodies found in patients with "quinine-type" thrombocytopenia are unique among pathogenic immunoglobulins in several respects: (a) They bind tightly to epitopes on platelet membrane glycoproteins at the highest

Table 62.3

Mechanisms of drug-induced immune thrombocytopenia and commonly implicated medications[a]

Designation	Mechanism	Examples
Hapten-dependent antibody	Drug (hapten) links covalently to membrane protein and induces a drug-specific immune response.	Penicillin, cephalosporin antibiotics?
"Quinine-type" thrombocytopenia	Drug induces antibody that binds to membrane protein only in the presence of soluble drug.	Quinine, many antibiotics, nonsteroidal anti-inflammatory drugs, anticonvulsants
Autoantibody induction	Drug induces antibody that reacts with platelets in the absence of drug.	Gold salts, L-Dopa, procainamide
Fiban-induced thrombocytopenia	Drug (ligand) reacts with membrane glycoprotein IIb/IIIa and induces a conformational change recognized by naturally occurring antibody?	Eptifibatide, tirofiban
Drug-specific antibody	Naturally occurring or induced antibody is specific for the murine component of abciximab, a chimeric Fab fragment specific for GP IIIa.	Abciximab
Immune complex	Drug binds to PF4 to produce a complex for which antibody is specific. The resulting immune complex activates platelets via Fc receptors.	Heparin

[a]Adapted from Aster RH, Curtis BR, McFarland JG, et al. Drug-induced immune thrombocytopenia: pathogenesis, diagnosis, and management. *J Thromb Haemost* 2009;7:911–918.

achievable drug concentration, rather than being inhibited as might be expected of a "hapten-dependent" antibody. (b) They fail to recognize platelets pretreated with the sensitizing drug. (c) They recognize only glycoproteins found on human or primate platelets. (d) They dissociate from the target glycoprotein upon being suspended in buffer in the absence of drug.[8,23]

Various mechanisms have been postulated to explain how a soluble drug might promote high-affinity but reversible binding of this type of antibody to a target glycoprotein. This issue is not fully resolved, but it has been shown experimentally that the reaction is mediated by the Fab, rather the Fc, immunoglobulin domain, ruling out the possibility that the antibodies form some type of drug-dependent "immune complex" that reacts with platelets via Fc receptors as was formerly thought. An alternative concept advanced to explain this interaction proposes that the drug binds to a specific site on a membrane glycoprotein and somehow reconfigures it so that an epitope recognized by antibody is created. If this were the case, it would be expected that binding of drug to the target would be sufficiently stable to allow cells pretreated with drug to be recognized by antibody, but this does not hold for the great majority of drugs known to cause "quinine-type" thrombocytopenia. A recently advanced proposal supported by experimental data calls for drug to act by enhancing the "fit" between low avidity, naturally occurring immunoglobulins, and localized domains on platelet glycoproteins, especially GP IIb/IIIa and GP Ib/IX[8,21,24] (FIGURE 62.1). This concept proposes that one structural element of drug reacts with the antigen-combining site of antibody and another binds to the target glycoprotein, improving the fit between the two macromolecules sufficiently for binding to occur at concentrations of the three reactants achievable in the circulation when drug is administered. By analogy, it is possible that a drug-dependent fit between a B-cell receptor and a platelet glycoprotein is involved in the induction of "quinine-type" antibodies, but there is no direct evidence to support this.

Drug-Induced, Platelet-Specific Autoantibodies

About 1% of patients injected with gold salts, formerly used to treat rheumatoid arthritis and other inflammatory conditions, developed immune thrombocytopenia that behaved clinically like autoimmune thrombocytopenia unrelated to drug exposure. A condition resembling AITP clinically occurs occasionally in patients treated with levodopa, procaine amide, and other drugs.[25] Patients have been described who developed both drug-dependent antibodies and drug-independent autoantibodies simultaneously.[25] The mechanism by which drugs sometimes induce platelet-specific autoantibodies is not understood.

Thrombocytopenia in Patients Treated with Ligand-Mimetic Platelet Inhibitors

RGD (arginine-glycine-aspartic acid)-mimetic fibrinogen receptor antagonists (fibans) inhibit platelet function by binding to the RGD recognition site on the platelet GP IIb/IIIa glycoprotein complex and blocking its interaction with fibrinogen. The inhibitors tirofiban and eptifibatide are widely used to reduce posttreatment complications in patients undergoing percutaneous transluminal coronary angiography, and other drugs of this class are in development. Acute, severe thrombocytopenia

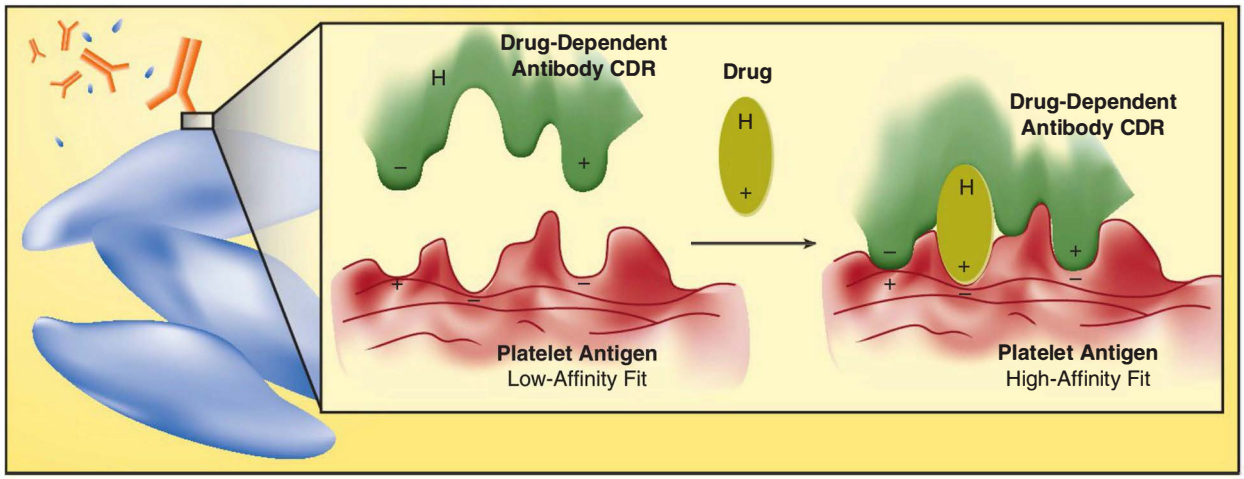

FIGURE 62.1 Model for the binding of a drug-dependent antibody to an epitope on a platelet glycoprotein. Antibodies capable of causing drug-dependent thrombocytopenia react weakly with an epitope on a target glycoprotein. The binding affinity (Ka) for this interaction is too low to allow a sufficient number of antibody molecules to bind in the absence of the drug ("low-affinity fit"). The drug contains structural elements that are complementary to a negatively charged site on the glycoprotein and a hydrophobic site (H) on the complementarity-determining region (CDR) of the antibody. The drug interacts with these sites to improve the fit between the two proteins, increasing the Ka to a value that permits binding to occur at levels of antibody, antigen, and drug achieved in the circulation after ingestion of the drug ("high-affinity fit") (From Aster RH, Bougie DW. Drug-induced immune thrombocytopenia. *N Engl J Med* 2007;357:580–587.)

occurs in 0.1% to 1% of patients given fiban-type platelet inhibitors, often within a few hours of the first exposure.[26,27] Although most affected patients recover uneventfully, fatal bleeding has been described. Paradoxical thromboembolic complications have occurred in some patients with fiban-induced thrombocytopenia and may be related to the tendency of some antibodies to activate platelets through Fc receptors, thereby inducing procoagulant activity.[28] When RGD and RGD-mimetic compounds bind to the RGD recognition site on GP IIb/IIIa, the integrin undergoes structural changes that are recognized by certain monoclonal antibodies specific for "ligand-induced binding sites." By analogy, it is possible that antibodies causing thrombocytopenia in patients treated with fiban drugs are specific for neoepitopes induced in the integrin by binding of the RGD mimetic. However, this has not been confirmed by direct experiment. Remarkably, antibodies capable of causing severe thrombocytopenia in patients treated with fiban drugs can be present in patients never before exposed to one of these agents.

Abciximab-Induced Thrombocytopenia

Abciximab is a "humanized" Fab fragment that inhibits platelet function by binding to a site on GP IIIa close to the fibrinogen recognition site.[29] About 2% of patients given abciximab for the first time and a higher percentage of those given the drug a second time experience acute thrombocytopenia within 6 to 12 hours of exposure. Most patients recover uneventfully but intracranial hemorrhage and deaths have been described.

Abciximab-induced thrombocytopenia following first exposure to the drug is caused by naturally occurring antibodies that bind to abciximab-coated platelets.[30] Evidence suggests that these antibodies recognize murine peptide sequences incorporated into the abciximab Fab fragment to confer specificity for GP IIb/IIIa. Thus, abciximab-induced thrombocytopenia appears to be the only known example of a drug-induced immune thrombocytopenia in which the responsible antibodies react directly with drug bound to a platelet membrane glycoprotein.

In some patients, thrombocytopenia develops 5 to 10 days after abciximab administration. It is known that abciximab remains detectable on circulating platelets for as long as 2 weeks after a single dose, indicating that the drug can transfer from one platelet to another. Delayed thrombocytopenia following abciximab treatment is caused by abciximab-specific antibodies newly induced by drug exposure that bind to abciximab-coated platelets persisting in the circulation.[31] Such antibodies are often very potent and can cause life-threatening bleeding, often after discharge from the hospital and while other platelet inhibitors such as clopidogrel are being taken. It is prudent to advise patients given abciximab about this possible complication.

Patients given abciximab sometimes manifest "pseudothrombocytopenia," the result of platelet clumping in a blood sample anticoagulated with ethylenediamine tetraacetic acid. The mechanism responsible for this phenomenon is not well understood. Pseudothrombocytopenia is an *in vitro* artifact that should be distinguished from true thrombocytopenia by performing a platelet count in blood anticoagulated with citrate or by examining a blood film prepared from a finger stick.

Drug-Induced Immune Complexes

In theory, immune complexes present in the circulation could bind to platelet FcγRII receptors, causing platelet activation and thrombocytopenia. However, the extent to which this actually occurs is uncertain because of competition for the receptor between immune complexes and the very high concentration of monomeric IgG normally present in the circulation. A clear

Table 62.4

Clinical criteria to document a drug-induced etiology for thrombocytopenia

Criterion	Description
1. Therapy with the candidate drug preceded thrombocytopenia and recovery from thrombocytopenia was complete and sustained after therapy with the drug was discontinued.	
2. The candidate drug was the only drug used before the onset of thrombocytopenia, *or* other drugs were continued or reintroduced after discontinuation of therapy with the candidate drug with a sustained normal platelet count.	
3. Other causes for thrombocytopenia were excluded.	
4. Reexposure to the candidate drug resulted in recurrent thrombocytopenia.	
Level of evidence	
Definite:	Criteria 1, 2, 3, and 4 met.
Probable:	Criteria 1, 2, and 3 met.
Possible:	Criterion 1 met.
Unlikely:	Criterion 1 not met.

exception is HIT in which antibodies react with the chemokine platelet factor 4 (PF4) when it forms a complex with heparin or with chondroitin sulfate, the major glycosaminoglycan on the platelet surface.[32] The resulting immune complexes activate platelets despite competition from normal plasma IgG because they are formed in close proximity to the Fc receptor. HIT is the most common form of drug-induced immune thrombocytopenia, but the reduction of platelet levels is rarely sufficient to cause bleeding. HIT is discussed in detail in Chapter 108.

Drugs Implicated in Immune Thrombocytopenia

As noted, a large number of drugs has been implicated in immune thrombocytopenia. When the connection is supported only by one or two case reports, the relationship could well be coincidental. George et al. regularly monitor the English language literature for reports of drug-associated thrombocytopenia using a defined set of criteria to evaluate the likelihood of a cause-and-effect relationship between drug exposure and a drop in platelet count on a scale of 1 to 4 (Table 62.4). These criteria are structured so that a score of 3 makes drug-induced thrombocytopenia "probable" and a score of 4 makes it "definite." This database is periodically updated and is available on the internet at http://www.ouhsc.edu/platelets. George et al. recently undertook a comprehensive analysis of drugs implicated in the pathogenesis of thrombocytopenia utilizing three independent databases: (a) published case reports of drug-associated thrombocytopenia analyzed by the criteria shown in Table 62.4; (b) detection of drug-dependent, platelet-reactive antibodies in a laboratory having extensive experience with this type of testing; (c) analysis of the adverse event reporting system of the Food and Drug Administration using "data mining" algorithms.[22] Twenty-three drugs were identified as having a possible or probable cause-and-effect relationship with thrombocytopenia by all three methods (Table 62.5). An extensive summary of these analyses involving a total of 1,444 drugs can be accessed on line as an appendix to Reese et al.[22] or at http://www.ouhsc.edu/platelets.

Detection of an antibody that binds to platelets only in the presence of a drug implicated as a cause of thrombocytopenia provides strong evidence for a cause-and-effect relationship. In the decade 1998 to 2008, the Platelet Neutrophil Immunology Laboratory of Blood Center of Wisconsin identified drug-dependent, platelet-reactive antibodies specific for 64 different medications in patients suspected of having drug-induced immune thrombocytopenia (Table 62.6). Antibodies detected

Table 62.5

Drugs found to be significantly associated with thrombocytopenia by three independent methods: analysis of published case reports, detection of drug-dependent, platelet-reactive antibodies, and data mining of the adverse events reporting system of the U.S. Food and Drug Administration[a]

Abciximab	Piperacillin
Acetaminophen	Quinidine
Ampicillin	Quinine
Carbamazepine	Ranitidine
Eptifibatide	Rifampin
Ethambutol	Simvastatin
Haloperidol	Sulfisoxazole
Ibuprofen	Tirofiban
Irinotecan	Trimethoprim–Sulfamethoxazole
Naproxen	Valproic Acid
Oxaliplatin	Vancomycin
Phenytoin

Table 62.6

Drug-dependent, platelet-reactive antibodies detected 1998–2008[a]

Drug Category	#	Individual Drugs
ACE inhibitor	1–3	Lisinopril
Analgesic	1–3	*Acetaminophen*, propoxyphene
Antibiotic	>15	Sulfamethoxazole, vancomycin
	4–15	Ceftriaxone, levofloxacin, nafcillin, piperacillin, rifampin, trimethoprim
	1–3	Ampicillin, amoxicillin, cefazolin, cefadroxil, cefepime, cefpodoxime, ceftazidime, ceftizoxime, cefpodoxime, ciprofloxacin, ethambutol, lisinopril, loracarbef, metronidazole, nitrofurantoin, sulfisoxazole
Anticonvulsant	>15	Carbamazepine
	4–15	Phenytoin
	1–3	Lamotrigine, lorazepam, valproic acid
Antidepressant, antipsychotic	1–3	Amitriptyline, bupropion, Haldol, olanzapine, paroxetine, sertraline
Antithyroid	1–3	Propylthiouracil
Beta-blocker	1–3	Atenolol, propranolol
Cardiac	4–15	Amiodarone
	1–3	Dobutamine
Chemotherapeutic agent	4–15	Oxaliplatin
	1–3	Geldanamycin, irinotecan, suramin
Cinchona alkaloid	>15	Quinine, quinidine
Diuretic	4–15	Furosemide
GP IIb/IIIa inhibitor	>15	Abciximab, eptifibatide, tirofiban
	4–15	Orbofiban, xemilofiban
Histamine receptor antagonist	1–3	Fexofenadine, ranitidine
Narcotic	1–3	Fentanyl
Nonsteroidal anti-inflammatory	4–15	*Naproxen*
	1–3	Celecoxib, *ibuprofen*, oxaprozin
Proton pump inhibitor	1–3	Esomeprazole, lansoprazole, pantoprazole
Thrombin inhibitor	1–3	Argatroban
Vasodilator	1–3	Papaverine

#Indicates number of DDAbs identified. Italics = metabolite-specific antibodies
[a]Adapted from Aster RH, Curtis BR, McFarland JG, et al. Drug-induced immune thrombocytopenia: pathogenesis, diagnosis, and management. *J Thromb Haemost* 2009;7:911–918.

most often were specific for the cinchona alkaloids quinine and quinidine, 23 different antibiotics, particularly vancomycin, sulfamethoxazole, rifampin, piperacillin, and ceftriaxone, the anticonvulsants carbamazepine and phenytoin and the platelet inhibitors abciximab, eptifibatide, and tirofiban.[8]

Drug Metabolites as Triggers for Thrombocytopenia

Although detection of a drug-dependent, platelet-reactive antibody by a laboratory skilled in the required techniques provides strong evidence that the antibody caused thrombocytopenia, it is not unusual for negative test results to be obtained despite a history strongly suggestive of drug-induced immune thrombocytopenia. An important reason for this is that a drug metabolite formed *in vivo* can induce antibodies that are detectable only when the appropriate metabolite is used for testing. Since drugs often have numerous metabolites, many of which are not readily available, establishing that a drug metabolite caused immune thrombocytopenia is not a simple matter. However, it has been convincingly shown that two metabolites of acetaminophen (the glucuronide and sulfate conjugates), a metabolite of para-amino salicylic acid, the glucuronide conjugate of naproxen, and unidentified metabolites of ibuprofen and diclofenac can, when added to a reaction mixture containing serum from a patient with drug-induced thrombocytopenia, cause antibody binding to target platelets.[8,33,34] Further studies to define the range of drug metabolites causing sensitization leading to drug-induced thrombocytopenia

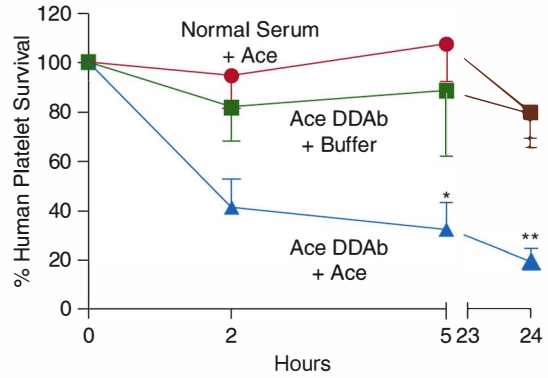

FIGURE 62.2 A drug metabolite produced *in vivo* promotes clearance of platelets by a metabolite-specific platelet antibody. Human platelets suspended in serum containing an antibody specific for acetaminophen glucuronide were transfused to NOD/scid mice. Acetaminophen was injected intraperitoneally at 0 and 5 hours. Platelet survival was significantly shortened in mice given both antibody and acetaminophen (*triangles*) but not in mice given antibody (*squares*) or drug (*circles*) with normal serum. Average of triplicate experiments 1 SEM. *$P < 0.05$, **$P < 0.01$, Ace, acetaminophen, DDAb, drug-dependent antibody. (From Bougie DW, Nayak D, Boylan B, et al. Drug-dependent clearance of human platelets in the NOD/scid mouse by antibodies from patients with drug-induced immune thrombocytopenia. *Blood* 2010;116:3033–3038.)

and other cytopenias could greatly improve laboratory diagnosis. Bougie et al.[35] recently adapted the NOD/scid mouse, in which human platelets circulate normally, to address this question. In this model, it was shown that following injection of the drugs acetaminophen and naproxen, metabolites were produced by the mouse that diffused into the circulation in quantities sufficient to cause destruction of platelets by a metabolite-dependent human antibody (FIGURE 62.2). Further use of this model may facilitate identification of other drug metabolites that cause sensitization leading to thrombocytopenia.

Clinical Presentation

Drug-induced immune thrombocytopenia is uncommon but should be considered in any patient who presents with unexplained acute thrombocytopenia. Patients should be asked specifically about exposure to quinine and sulfamethoxazole, which are among the most common triggers for immune thrombocytopenia. Nondrugs such as foods and herbal remedies have been shown to cause severe thrombocytopenia in rare instances. In seriously ill hospitalized patients who may have other causes for thrombocytopenia such as bacterial sepsis, it is easy to overlook a drug-induced etiology. In this situation, the antibiotics vancomycin,[36] piperacillin,[37] ceftriaxone, and rifampin should be given particular attention.

Patients with drug-induced thrombocytopenia are often considered initially to have autoimmune (idiopathic) thrombocytopenia (ITP). It is not uncommon for such individuals to be treated with corticosteroids, IV γ globulin, and platelet transfusions and for recovery to be attributed to these therapies rather than to withdrawal of drug. Extreme examples of patients, who presented as many as five times for acute "idiopathic" thrombocytopenia before a drug-induced etiology was documented, have been described.[5]

Patients presenting with acute, drug-induced thrombocytopenia have nearly always been exposed to the sensitizing drug during the preceding 24 hours. It has been noted that the platelet inhibitors abciximab, tirofiban, and eptifibatide are an exception to this rule, since "naturally occurring" antibodies capable of causing thrombocytopenia when these drugs are administered are present in a subset of normal persons.[26] Acute, immune thrombocytopenia after first exposure to piperacillin[37] and vancomycin[36] has also been described, but is rare. It is common for systemic symptoms such as flushing, chills, fever, and dizziness to occur soon after drug exposure. Severely affected patients often present with widespread cutaneous petechiae and ecchymoses as well as bleeding from the gums or the urinary or gastrointestinal tracts. Hemorrhagic bullae in the buccal mucosa indicate a very low platelet count. Some patients report to a dentist because of bleeding gums after brushing the teeth. When the responsible drug is discontinued, bleeding symptoms usually improve within 48 hours and the platelet count is restored to normal within 1 week. Occasionally thrombocytopenia persists for 1 or 2 weeks. In patients with vancomycin-induced thrombocytopenia, this may be a consequence of slow clearance of drug from the circulation, especially if there is renal dysfunction. Occasionally, patients present with coexisting immune hemolytic anemia and/or granulocytopenia; in such cases several different antibodies, each specific for one of the affected cell types, can sometimes be demonstrated.

Patients with thrombocytopenia caused by sensitivity to quinine and, rarely, other drugs sometimes present with profound renal failure and microangiopathic hemolytic anemia, a picture typical of the hemolytic uremic syndrome (HUS).[38] Why HUS sometimes accompanies drug-induced immune thrombocytopenia is unknown. Patients with this complication often require hemodialysis for several weeks before renal function is restored. HUS in patients presenting with drug-induced immune thrombocytopenia should not be confused with a similar condition seen after treatment with certain chemotherapeutic and immunosuppressive drugs in which spontaneous recovery is relatively uncommon. Patients treated with the platelet function inhibitors ticlopidine and clopidogrel for several weeks or longer occasionally experience severe thrombocytopenia together with other hematologic abnormalities and symptoms typical of thrombotic thrombocytopenic purpura (TTP) that often do not resolve spontaneously when drug is discontinued. The mechanism by which these drugs induce a TTP-like syndrome is not understood.

Laboratory Diagnosis

Drug-dependent antibodies capable of causing immune thrombocytopenia can often be detected by incubating normal platelets with the patient's serum in the presence and absence of the implicated drug and showing that antibody becomes bound to the target cell or glycoprotein when drug is present but not in its absence.[8,21] In patients sensitive to certain drugs such as vancomycin, quinine, and sulfamethoxazole, antibodies of this type can usually be detected and, when present, provide strong evidence that drug sensitivity is the cause of thrombocytopenia.

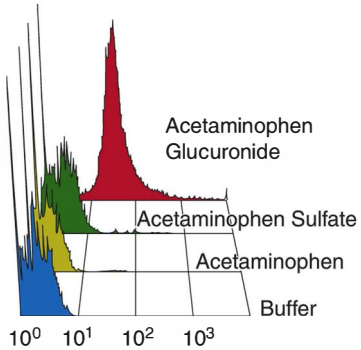

FIGURE 62.3 An antibody from a patient with acetaminophen-induced thrombocytopenia reacted with normal platelets in the presence of acetaminophen glucuronide, but not acetaminophen or acetaminophen sulfate. (From Bougie DW, Benito AI, Sanchez-Abarca LI, et al. Acute thrombocytopenia caused by sensitivity to the glucuronide conjugate of acetaminophen. *Blood* 2007;109:3608–3609.)

The most convenient, and probably the most sensitive method for antibody detection is flow cytometry (FIGURE 62.3). In general, such reactions are highly specific for the causative drug and it is usually safe to administer a pharmacologic equivalent possessing a different structure. When an antibody is not detected and the suspicion of drug-induced thrombocytopenia is very strong, a diagnostic challenge can be considered. However, it is important that very small amounts of drug, for example, 5 to 10 mg at most, be given initially and that the platelet count be carefully monitored. The potential risk of this procedure, although small, should of course be explained to the patient. If an *in vivo* challenge is to be undertaken, it should be done relatively soon after recovery of platelet levels since, although some drug-dependent antibodies persist for years, others decline and disappear over a period of several months. A recently described mouse model, in which drug-dependent platelet clearance by human antibodies can be demonstrated (FIGURE 62.2), may provide a useful surrogate for an *in vivo* challenge but requires validation in further studies.[35]

Prognosis and Treatment

For any patient suspected of having drug-induced immune thrombocytopenia, all drugs currently being taken should be discontinued and, where necessary, pharmacologic equivalents should be substituted. Patients with acute, profound thrombocytopenia and widespread petechiae and ecchymoses ("wet purpura") have a significant short-term risk of intracranial bleeding and should be treated aggressively. Whether glucocorticoids or intravenous immunoglobulin reduce the risk of serious bleeding is uncertain, but these therapies can be considered in patients with life-threatening hemorrhage. Platelet transfusions often fail to elevate the platelet count during the acute phase of thrombocytopenia, but can be given for their possible hemostatic effect. Plasma exchange has been used in severely ill patients, but whether this treatment accelerates the rise in platelet counts is unknown. Sensitivity to drugs that cause immune thrombocytopenia is usually permanent; patients should therefore be warned to avoid reexposure.

CHAPTER

63 Inherited Thrombocytopenias

PAQUITA NURDEN AND ALAN T. NURDEN

Bleeding syndromes arising from an inherited defect of platelet production are an important group of rare diseases with a variety of causes.[1,2,3,4] Some, such as the Bernard-Soulier syndrome (BSS) and Wiskott-Aldrich syndrome (WAS), associate a low circulating platelet count with a deficiency of a known functional protein. In others, platelet dysfunction has not been shown and bleeding arises from the inability of megakaryocytes (MKs) to produce platelets in sufficient numbers to ensure hemostasis. In some, there may be associated illnesses such as an increased risk for leukemia or β-thalassemia; sometimes, developmental changes result in profound skeletal defects. Haploinsufficiency of transcription factors can lead to decreased expression of multiple platelet proteins. In many cases, a low platelet count is accompanied by changes in platelet morphology with macrothrombocytopenias and enlarged or even giant platelets in variable numbers. Gene defects have been described for the major inherited thrombocytopenias and their characterization is providing basic knowledge of how MKs develop from the pluripotent hematopoietic stem cell (HSC) under the influence of thrombopoietin (TPO). Notwithstanding, the molecular basis for many moderate congenitally low platelet counts, often of mild clinical significance, remains to be elucidated. Our review deals with the biology, genetics, and clinical management of inherited thrombocytopenias. The fundamental aspects of megakaryocytopoiesis are dealt with in Chapter 23. Most important in this group of patients is the need to ensure correct diagnosis and to avoid inappropriate therapy such as steroid treatment and splenectomy. Where possible, a phenotypic approach has been taken to classifying the disorders (Table 63.1).

GIANT PLATELET SYNDROMES AFFECTING THE GPIb/VON WILLEBRAND FACTOR AXIS

In this group of disorders, the circulating platelet count is low and is accompanied by the presence of variable numbers of large platelets. Quantitative or qualitative defects of the GPIb-IX-V complex also result in defects of the platelet–vessel wall interaction (see Chapter 65); they also result in profound changes in megakaryocytopoiesis in the bone marrow.

(i) *BSS:* First reported in 1948, BSS associates macrothrombocytopenia with decreased platelet adhesion to subendothelium caused by an absence (or nonfunctioning) of GPIbα.[3,4,5] A simple diagnostic test is that the giant platelets fail to agglutinate with ristocetin, an antibiotic that promotes the binding of von Willebrand factor (vWF) to GPIbα. The products of four separate genes (*GPIBA*, *GPIBB*, *GP9*, and *GP5*) assemble in a 2:2:2:1 ratio within maturing MK to form the GPIb-IX-V complex, stabilized through cytoplasmic domains linked to the membrane cytoskeleton via filamin A (FlnA).[6] Generally inherited as an autosomal recessive trait, mutations within *GPIBA*, *GPIBB*, and *GP9* interfere with the biosynthesis, maturation, and/or trafficking of the complex through the endoplasmic reticulum and Golgi apparatus of MKs.[7,8] Recent data suggest that bleeding results from the loss of high shear- and vWF-dependent platelet-to-platelet interactions in thrombus formation, as well as a defective platelet adhesion and the low platelet count.[9] The additional absence of GPIbα-dependent binding of P-selectin, TSP1, factor VIIa, factor XI, factor XII, αMβ2, high molecular weight kininogen, and thrombin may also contribute to the phenotype (see Chapter 26A). Early reports of an increased phosphatidylserine (PS) exposure but decreased prothrombin consumption and a decreased platelet survival in BSS remain largely unexplained. Nonetheless, BSS platelets of all sizes readily expose PS and undergo apoptotic-like changes on platelet activation.[10]

Early studies showed that mature MKs isolated from the bone marrow of BSS patients had major changes in morphology with an altered organization of internal membranes, many vacuoles, and a disparate localization of α-granules.[11] Such changes lead to decreased platelet production with the formation of large round platelets having distinctive morphologic abnormalities (FIGURE 63.1). The macrothrombocytopenia in BSS is usually moderate but can be severe in some patients and lead to extensive, occasionally life-threatening, mucocutaneous bleeding. In rare variant forms, platelets express decreased to normal amounts of nonfunctional GPIbα. Mutations resulting in variant BSS have included three missense mutations in GPIbα: R41H, L73F, and A156V (so-called Bolzano mutation).[12–14] While the first two were heterozygous with autosomal dominant pattern of inheritance, the Bolzano variant was homozygous with autosomal recessive inheritance. Hemizygous mutations in *GPIBB* can also cause BSS when associated with the DiGeorge/velocardiofacial syndrome, a developmental disorder characterized by a hemizygous microdeletion at 22q11, the site of localization of *GPIBB*.[15]

Mice lacking GPIbα or GPIbβ have allowed evaluation of megakaryocytopoiesis in BSS and have confirmed aberrant membrane development early during MK maturation leading to a reduced demarcation membrane system (DMS), impaired proplatelet formation, and aberrant microtubule coil assembly.[16–18] Studies of platelet production *in situ* revealed large platelets being released from unusually short, broad, proplatelets protruding into vascular sinuses.[17]

Table 63.1

Inherited thrombocytopenias classified by gene mutation and associated phenotype

Syndrome	Gene Mutation	Chromosomal Location/Inheritance	Associated Phenotype
BSS	*GPIBA, GPIBB, GP9*	17, 22, and 3 Autosomal recessive	Deficient GPIb-IX-V, giant platelets, vWF-dependent adhesion defect
Platelet-type vWD	*GPIBA*	17p13.2 Autosomal dominant	Blocked GPIbα (vWF), platelet anisotropy
vWD2B (some families)	*vWD*	12p13.3 Autosomal dominant	Enlarged platelets, sometimes platelet agglutinates, blocked GPIbα
Mediterranean macrothrombocytopenia	*GPIBA*, possibly others	17p13.2 Autosomal dominant	Mild disorder, enlarged platelets
GT-like	*ITGB3, ITGA2B*	17q21.31/32 Autosomal dominant or recessive	Platelet anisotropy, defective platelet aggregation
MYH9-related thrombocytopenia May-Hegglin anomaly, Fechtner, Epstein & Sebastian syndromes	*MYH9*	22q11.21 Autosomal dominant	Giant platelets, various combinations of neutrophil inclusions, sensorineural hearing loss, nephritis, cataracts
β1-tubulin-related thrombocytopenia	*TUBB1*	20q13.32 Autosomal dominant	Altered organization of β1-tubulin into microtubules, enlarged platelets
FlnA-related thrombocytopenia	*FLNA*	Xq28 Autosomal dominant	PNHs and other defects, platelet anisotropy
DiGeorge/velocardiofacial syndrome	Hemizygous microdeletion including *GPIBB*	22q11 Autosomal dominant	Facial dysmorphology, cardiac and other defects of development
WAS	*WAS*	Xp11.23	Immunodeficiency, eczema, lymphoma, small platelets, defective platelet and lymphocyte function
XLT	*WAS*	Xp11.23	Small platelets, no immune problems
GPS	*NBEAL2*	3p21.1-3p22.1 (3p21) Autosomal dominant (rare) or recessive	Myelofibrosis, enlarged platelets (no α-granules), platelet dysfunction
Familial platelet disorder/acute myelogenous leukemia	*RUNX1 (CBFA2, AML1)*	21q22.12 Autosomal dominant	Myelodysplasia, acute myeloid leukemia, platelet dysfunction
Chromosome 10/ thrombocytopenia 2	*MASTL, ANKRD26*	10p12.1 (both) Autosomal dominant	Bleeding syndrome only
CAMT	*MPL*	1p34.2 Autosomal recessive	Low MK content in marrow, early development of pancytopenia (in most cases), elevated TPO
Thrombocytopenia with radio-ulnar synostosis	*HOXA11*	7p15.2 Autosomal dominant or recessive	Fused radius, incomplete range of motion, sometimes other defects
TAR	*RBM8A* null allele + low-frequency regulatory SNP	1q21.1 Autosomal recessive	Shortened/absent radii bilaterally, cardiopathy
Paris-Trousseau syndrome	Hemizygous microdeletion including *FLI1*	11q23/24 Autosomal dominant (or isolated)	Psychomotor retardation, facial anomalies (Jacobsen syndrome), enlarged platelets with abnormal granules
GATA-1–related thrombocytopenia with dyserythropoiesis	*GATA-1*	Xp11.23 X-linked	Dyserythropoiesis ± anemia, thalassemia in some patients Platelet dysfunction, enlarged platelets with few α-granules

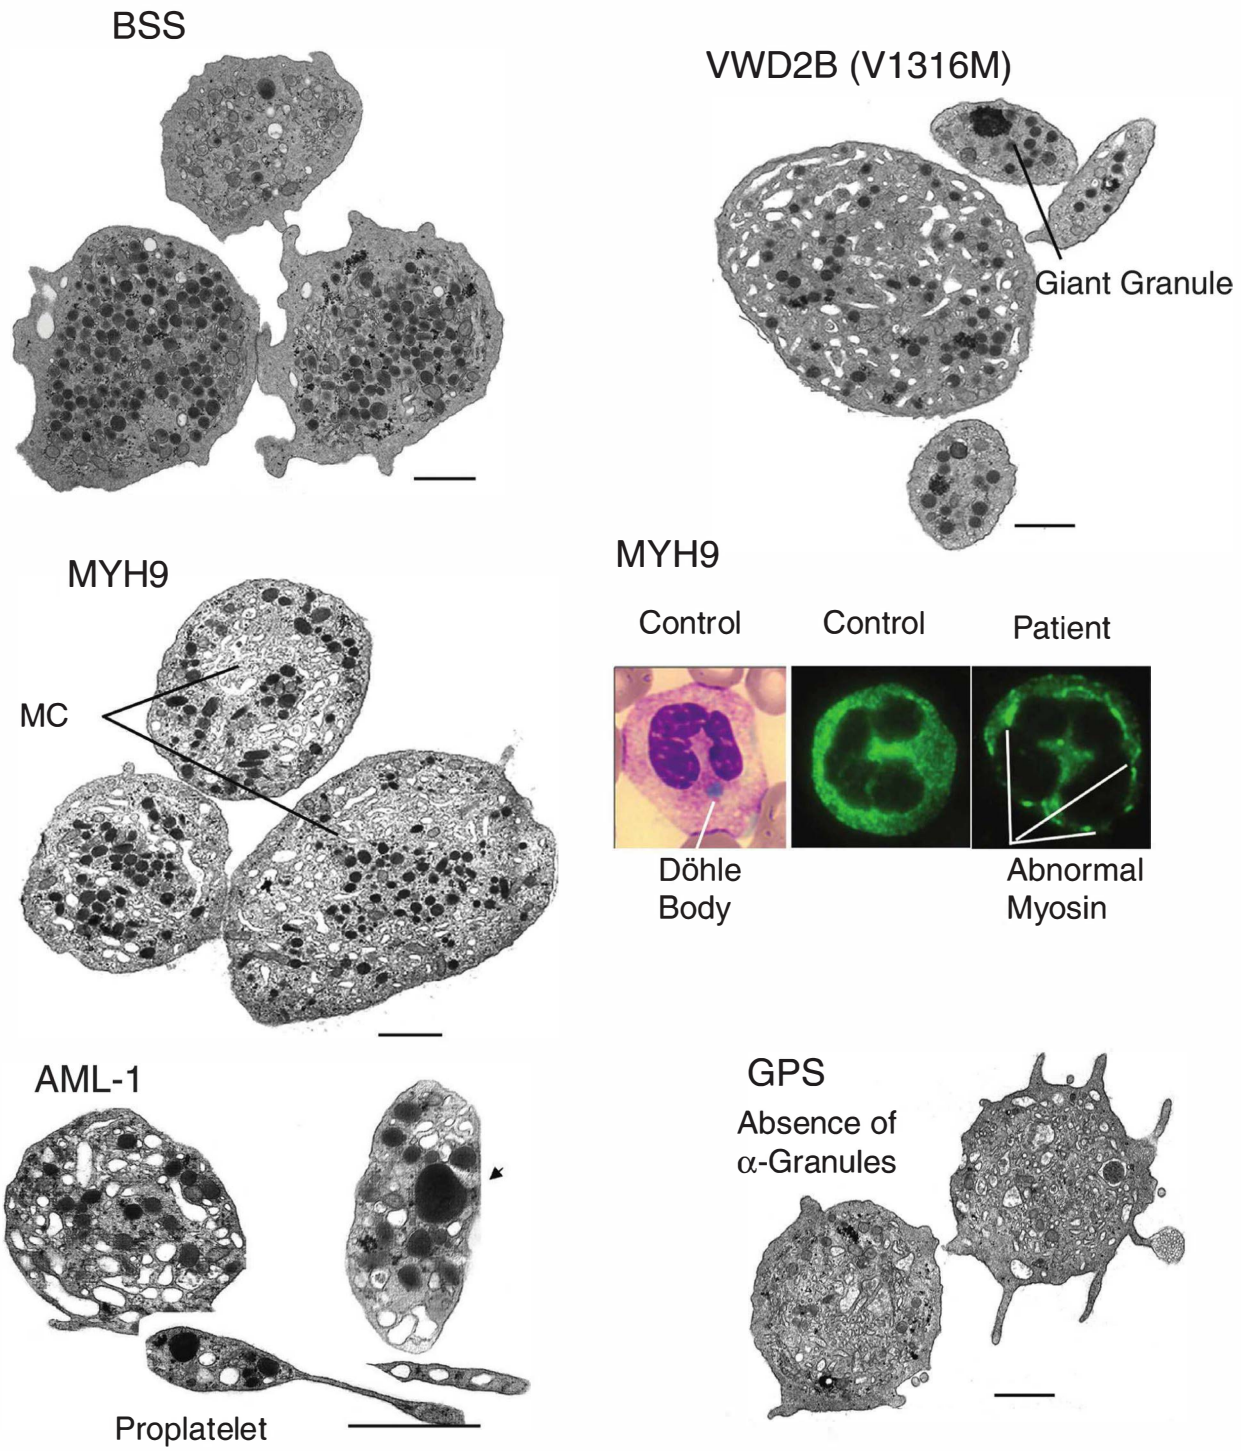

FIGURE 63.1 Composite illustration showing some of the striking ultrastructural characteristics of platelets in selected inherited thrombocytopenias. In the upper panels are shown the typical large round platelets of a patient with the BSS as seen by electron microscopy. Note the heterogeneous distribution of α-granules but the absence of large MC. Adjacent are platelets from a vWD2B patient showing size heterogeneity. An enlarged α-granule is highlighted. The middle panels first show electron microscope images of large round platelets from a patient with MYH9-related disease (May-Hegglin anomaly); note the large abnormal platelets with abundant MC. Also shown are a cytochemically stained Döhle-like inclusion and NMMHC-IIA immunoprecipitates detected by immunofluorescence in leukocytes from the same patient. In the lower panel is first shown platelet anisotropy in a patient with amegakaryocytic thrombocytopenia with predisposition to leukemia (AML-1). Platelets are immature and proplatelet fragments are present. Finally two platelets from a patient with the GPS are shown. These platelets are totally lacking α-granules. Bars = 1 μm

GPIbβ–/– MKs differentiated *in vitro* showed fewer proplatelet extensions with thicker shafts, fewer branches, and an increased diameter of terminal coiled elements that were enriched in tubulin fibers.[18] Significantly, the macrothrombocytopenia was much less severe in a novel murine model where platelets were engineered to express a GPIbα subunit in which the extracytoplasmic sequence was replaced by that of the α-subunit of the human interleukin-4 receptor; despite improvement in platelet production a severe bleeding phenotype persisted.[19,20] This suggests a role for the GPIbα cytoplasmic tail in signaling essential for normal MK maturation. Significantly, no correlations have yet been seen in BSS between phenotype (and bleeding severity) and genotype.[21]

(ii) *Mediterranean Macrothrombocytopenia*. In Mediterranean countries, patients manifesting a moderately low platelet count (70,000 to 150,000/μL), increased mean platelet volume, autosomal dominant inheritance with mild mucocutaneous or no bleeding, normal platelet function, and normal MK numbers are frequently observed. Linkage analysis and mutation screening of 12 Italian families identified a heterozygous A156 substitution in GPIbα in six with GPIb-IX levels comparable to those of BSS heterozygotes.[22] It is noteworthy that A156V is the same mutation as that causing the Bolzano variant of BSS (see above). Balduini et al.[23] cultured MKs from six patients and showed that proplatelet formation was much reduced compared to controls. Again, proplatelet tips were enlarged and α-tubulin distribution abnormal. Because the GPIbα mutation is heterozygous and occurs in the context of the wild-type protein, it must be exerting an as yet unexplained dominant negative effect, especially since obligate heterozygotes for classic BSS are largely asymptomatic.

(iii) *Platelet-type von Willebrand disease (platelet-type vWD)*. Platelet-type vWD is characterized by a gain of function phenotype with spontaneous binding of plasma vWF to platelets and increased platelet agglutination by low amounts of ristocetin in the presence of normal plasma. Platelet size can be increased in platelet-type vWD and there can be moderate thrombocytopenia. Selected heterozygous GPIbα substitutions with autosomal dominant inheritance cause platelet-type vWD, namely, G233V/S and M239V substitutions in the N-terminal domain; a 27-bp deletion in the macroglycopeptide-coding region of *GPIBA* implies that long-range conformational changes can also give rise to platelet-type vWD.[4,24,25] Mechanistically, the GPIbα mutations promote and stabilize platelet adhesion to vWF at low shear by enhancing formation and increasing longevity of the tether bond.[26] Interestingly, a knock-in mouse model with the G233V mutation not only had a phenotype mimicking the human disorder, but also showed increased bone mass.[27] In the same model, spontaneous binding of vWF blocked the capacity of platelets to bind fibrinogen when stimulated.[28] This probably contributes to the bleeding caused by an inhibited GPIbα although enhanced ADAMTS13 cleavage of the more stable platelet-bound vWF multimers may moderate the condition.[29]

(iv) *vWD2B*. Enlarged platelets with size heterogeneity (FIGURE 63.1) and thrombocytopenia can also occur in vWD, type 2B (vWD2B) where mutated plasma vWF spontaneously binds to a normal GPIbα.[30] As with platelet-type vWD, inheritance is autosomal dominant. In one such family with an R1308P vWF substitution, platelets showed signs of apoptosis and culture of CD34+ cells from the peripheral blood resulted in an increased surface expression of the mutant vWF on mature MKs that caused interactions between proplatelets.[31] This study was extended to nine patients with a total of seven different gain-of-function mutations and abnormal platelets typical of those seen in the circulation were produced *ex vivo* in MK cultures.[32] Circulating platelet clumps in rare patients with vWD2B prompted comparison with the previously described phenotype of the Montreal platelet syndrome (MPS); this was resolved when patients of the founder MPS kindred were shown to have the common vWF V1316M mutation.[33] Among the described characteristics of MPS were platelet calpain deficiency (probably due to autodegradation) and a reduced thrombin-induced aggregation; both findings are a consequence of the spontaneous binding of large vWF multimers to GPIbα. Significantly, lineage-specific mouse knock-in models of vWD2B show that abnormal plasma vWF (with a vWD2B mutation) can broadly reproduce the human vWD2B phenotype, emphasize its hemostatic variability, and suggest a possible role for ADAMTS13-dependent modulation of disease severity.[34,35]

PLATELET ANISOCYTOSIS AND THE αIIbβ3 INTEGRIN

Glanzmann thrombasthenia (GT), the principal disorder of platelet aggregation, is caused by quantitative and/or qualitative deficiencies of the integrin αIIbβ3 coded by the *ITGA2B* and *ITGB3* genes located at 17q21–23.[2,3] Although platelet count, volume, and morphology are normal in classic GT, several reports have inferred a role for αIIbβ3 in megakaryocytopoiesis because isolated point mutations in either of the *ITGA2B* and *ITGB3* genes combine an altered platelet production with selective deficiencies in platelet function.[36a,36b,37,38,39,40] This was brought to light by the discovery of R995Q/W mutations in αIIb and D723H in β3 that resulted in platelet anisotropy and thrombocytopenia.[37,38,39] R995 and D723, each located in the αIIbβ3 cytosolic tail, are thought to interact and aid in maintaining the integrin in its bent inactive conformation. Mutations weakening or abolishing this interaction increase the activation state of αIIbβ3 potentially changing the ability of MKs to interact with their environment and/or interfering with intracellular signaling pathways. Another mutation affecting platelet production is a heterozygous L718P substitution in the membrane-proximal extracellular domain of β3.[41] Finally, a genome-wide search in a large Italian family with an autosomal dominant trait combining thrombocytopenia, large platelets, defective platelet function, and moderate/severe mucocutaneous bleeding mapped the affected gene to chromosome 17q.[42] A novel heterozygous mutation (c.2134 + 1G>C) in the donor splice site of intron 13 of *ITGB3* resulted in an in-frame 120-bp deletion and loss of amino acids 647 to 686 within the extracellular membrane-proximal region of β3.

MYH9-RELATED SYNDROMES

May-Hegglin anomaly and the Fechtner, Sebastian, and Epstein syndromes constitute a group of disorders with autosomal dominant inheritance and macrothrombocytopenia; they are now generally referred to as MYH9-related disorders (Table 63.1).[1,2,3,4,43,44] Enlarged or giant platelets are a common feature (FIGURE 63.1).

Döhle-like inclusions in neutrophils, eosinophils, and some monocytes are diagnostic characteristics (FIGURE 63.1).[45] Thrombocytopenia is generally mild but can be severe; bleeding is infrequent and rarely life threatening. Other manifestations of these disorders include the progressive development of nephritis, sensorineural hearing loss, and cataracts. The Sebastian platelet syndrome associates macrothrombocytopenia with neutrophilic inclusions that differ in morphology from those in May Hegglin anomaly.[46] The Fechtner syndrome adds hearing loss, nephritis, and cataracts while in the Epstein syndrome only hearing loss and glomerulonephritis are present (Table 63.1).[47,48]

These syndromes result from heterozygous mutations in the *MYH9* gene encoding the nonmuscle myosin heavy chain IIA (NMMHC-IIA).[49–51] Class II myosins are hexameric proteins composed of two heavy chains and two pairs of light chains. A globular head binds to actin and ATP, has ATPase activity, and is required for motor activity. The C-terminal α-helical domain features a coiled-coil and a rod-like tail that allows the molecules to polymerize into bipolar filaments. NMMHC-IIA is found in platelets, monocytes, and granulocytes while its tissue distribution includes kidney, eye, and cochlea.[52] Immunofluorescence microscopy is now a diagnostic test with the mutated protein visualized in distinctive patches in granulocytes and platelets (FIGURE 63.1).[53] A wide range of heterozygous mutations have been identified, including substitutions, deletions or small insertions, frameshifts, and stop codons; these mutations mainly cluster in 9 of the 40 exons that encode the protein. The result is haploinsufficiency and/or a functionally defective protein.[54–56,57,58,59] The mutations may have a dominant effect, for example, on filament assembly; in this way they influence morphology of Döhle bodies and the nature of immunofluorescence staining (data reviewed in ref[14]). It is noteworthy that the same mutation can give rise to a variety of phenotypes; for example, a common D1424N substitution in the rod domain first described in May-Hegglin anomaly is also found in patients with various combinations of hearing loss, nephritis, and cataracts (data reviewed in ref[57]). In 20 families with the E1841K substitution, 15 had May-Hegglin anomaly and five Fechtner syndrome; in contrast, in families with R702C or R702H substitutions all developed the severe Fechtner or Epstein syndrome.[48,57] In a large family with Fechtner syndrome, only 5 out of 10 affected members showed renal lesions at the time of study.[49] Also, sequence analysis of *MYH9* in a family with nonsyndromic hereditary deafness showed that a R705H substitution cosegregated with the hearing loss phenotype, but giant platelets were not present.[60] Such findings suggest that the disease is not truly monogenic. Myosin molecules expressing mutations in the head domain had only 4% and 25% of the maximal ATPase activity and failed to translocate actin filaments in an *in vitro* motility assay.[54] *MYH9* mutations can affect myosin filament assembly or stability as well as function. *De novo* mutations may be the cause in sporadic cases.

Studies on MKs from patients in culture suggest that NMMHC-IIA negatively regulates megakaryocytopoiesis. In normal MKs, myosin light chain (MLC) kinase and Rho-associated kinase ensure the phosphorylation of MLC. Inhibition of this phosphorylation, possibly through the influence of stromal cell–derived factor-1, promotes proplatelet formation.[61] Perturbation of NMMHC-IIA levels and distribution in MYH9-related diseases potentially affects MK maturation, mobility, and the extent and timing of proplatelet production. MK-restricted *MYH9* inactivation in mice resulted in macrothrombocytopenia but conserved platelet aggregation and secretion as in the human disease. Nonetheless, bleeding times were prolonged, platelet shape change modest, and clot retraction defective; the latter linked to a defective αIIbβ3-outside-in signaling, a finding associated with an impaired thrombus formation under flow.[62] Mature MKs from these mice showed severe morphologic abnormalities with a poorly developed DMS and the absence of the peripheral zone that normally contains myosin filaments.[63] The MKs were unable to form stress fibers on adhesion to collagen. The number of cells extending proplatelets in culture was increased and the proplatelet tips were larger. The authors speculated that platelet release was premature, and that the decreased DMS contributed to a poor platelet production. Pecci et al.[64] supported premature release by showing that MKs cultured from MYH9-related disease patients lose the physiologic suppression of proplatelet formation exerted by type I collagen, an important extracellular matrix component and adhesive substrate for MKs as they migrate from the osteoblastic niche to the marrow vessels. These authors also showed a decreased branching of proplatelets and a lower number of proplatelet tips.

The basis for the phenotypic variability in MYH9-related diseases remains unclear and other genetic and/or environmental factors may intervene. A proposed explanation is that additional II-B and II-C myosin isoforms can compensate, at least in part, for the malfunction of defective *MYH9* A isoform when they are expressed in the same tissues.[53] Another gene, *FBLN1*, encoding fibulin-1, an extracellular matrix protein, has been proposed as a disease modifier.[65] Amino acid substitutions in the Ca^{2+}-ATPase-containing head domain appear more often to be associated with deafness and renal disease while those affecting the rod domain, and possibly myosin-IIA assembly, more frequently only have hematologic consequences.[57,66] But there are many exceptions. Missense mutations in the *APOL1* gene are highly associated with focal segmental glomerulosclerosis and end stage kidney disease risk previously attributed to *MYH9* SNPs in western African patients.[67] APOL1 is a neighboring gene to *MYH9* on chromosome 22. Such haplotypes should be studied in MYH9-related disease patients where renal disease develops often during adolescence.

The presence of functionally normal giant platelets has been speculated to compensate for the thrombocytopenia in MYH9 disorder in reducing bleeding risk and to also account for the risk of myocardial infarction in May-Hegglin anomaly patients.[68] Nevertheless because of the risk of hemorrhage, Pecci et al.[69] assessed the administration of eltrombopag, a new generation TPO mimetic.[70] Eltrombopag was able to increase platelet counts in MYH9-related disease and reduce bleeding over a 3-week test period. However, many patients with these disorders are asymptomatic and diagnosis may await adulthood or the occurrence of trauma-related bleeding. Often it is confused with immune thrombocytopenic purpura (ITP). Platelet transfusions are often given as a precaution prior to surgery, TPO mimetics may offer an alternative.

OTHER FAMILIAL THROMBOCYTOPENIAS WITH DEFECTS OF CYTOSKELETAL PROTEINS AND AN ALTERED PLATELET SIZE

Mutations of other genes encoding cytoskeletal proteins have resulted in the production of platelets in decreased numbers and of altered size.

(i) *Mutation of the β1-tubulin gene (TUBB1).* Microtubule assembly and function are key elements of proplatelet formation from MKs, trafficking granules and other organelles to the proplatelet tips where platelets are released by budding, and maintenance of the platelet discoid shape.[71,72] Freson et al.[73] found a heterozygous Q43P polymorphism in a highly conserved residue of β1-tubulin in 24.2% of 33 unrelated families with inherited macrothrombocytopenia of unknown cause. Electron microscopy showed enlarged spherocytic platelets with a disturbed marginal microtubule band and organelle-free zones. Decreased platelet reactivity to physiologic agonists was also noted. However the same mutation was also seen in approximately 10% of normal subjects. Kunishima et al.[74] studied a Japanese patient with the heterozygous Q43P mutation but found that it did not cause macrothrombocytopenia. Instead, these authors found a second heterozygous R318W mutation predicted to disrupt side chain interactions near the α and β intradimer interface of β1-tubulin. The authors found that R318W, but not Q43P, led to a 50% reduction in platelet β1-tubulin content. Cultured MKs from the patient showed morphologic changes consistent with a disturbed platelet production; the R318W β-tubulin was localized in punctate structures suggesting that it was forming aggregates. This unstable protein may be essential for the phenotype; while β1-tubulin (−/−) mice are thrombocytopenic and their platelets lose their discoid shape, heterozygotes do not show macrothrombocytopenia.[75]

(ii) *Mutations in the filamin A gene (FLNA).* Heterozygous mutations in the *FLNA* gene encoding the cytoskeletal protein FlnA are associated with a series of rare X-linked autosomal dominant diseases, the major feature being periventricular nodular heterotopia (PNH).[76] FlnA is the attachment site for GPIbα in the platelet cytoskeleton, helping to maintain thrombus stability at high shear.[77] Bleeding is an important feature for a cohort of patients with *FLNA* mutations as is thrombocytopenia and platelet anisotropy.[78] This was shown to be due to a defective megakaryocytopoiesis, a finding confirmed from studies on a conditional mouse model where FlnA null platelets also showed signaling defects and a reduced shear-dependent platelet accumulation on collagen.[79] Mice whose platelets possessed intermediate amounts of FlnA also showed macrothrombocytopenia.

(iii) *WAS.* This X-linked recessive disease combines thrombocytopenia and small platelets (microthrombocytopenia), recurrent infections due to immune deficiency, and eczema, autoimmune manifestations, and malignancy.[1,2,3,4,80,81] A milder form lacking the immune manifestations is known as hereditary X-linked thrombocytopenia (XLT). WAS platelets aggregate poorly and, due to their small size, have a reduced number of α-granules, δ-granules, and mitochondria. T cells, naturally occurring T regulatory cells, dendritic cells, and B lymphocytes also show defective function. The *WAS* gene is composed of 12 exons and encodes a 502–amino acid protein (WASP).[82] Genetic defects in *WAS* result either in the decreased expression of WASP or its absence. A secondary defect is abnormal expression of CD43 (sialophorin), a membrane glycoprotein of T lymphocytes. A wide range of genetic mutations occur in WAS; these are spread across the gene and result in the decreased expression or absence of WASP. For example, in a recent European demographic study, a total of 87 affected males and 48 carrier females were genotyped.[83] The most common sequence variations were missense mutations and small insertions, followed by nonsense and splice site mutations and insertions. Only one large deletion was identified. Generally, missense mutations accompanied by partially expressed and functional protein produce the milder XLT.[80,81,83] They most often affect exons 1 to 3. WASP-negative patients show a higher susceptibility to infection and eczema and have a greater tendency for malignancy. Rare mutations lead to spontaneously activated WASP with increased actin polymerizing activity and cause an X-linked form of neutropenia with variable myelodysplasia (in the absence of thrombocytopenia and T-cell immunodeficiency).[84] WASP is a multifunctional protein and is a key regulator of actin polymerization in hematopoietic cells. It is involved in signal transduction having tyrosine phosphorylation sites and adapter protein function; it acts through the Arp2/3 complex. Despite thrombocytopenia, MK numbers are normal, but the defect leads to premature proplatelet formation in the marrow where a lack of actin-rich podosomes slows MK migration to the vascular sinus.[85] Altered *in vivo* reactivity with immunoglobulin also contributes to decreased platelet survival, another characteristic of WAS. An autosomal dominant variant form of WAS has been described.[86] Although female heterozygotes for classic WAS have no clinical signs because of preferential selection of the normal nonmutated X chromosome in hematopoietic cells, X-linked WAS has been reported in girls, presumably due to coinheritance of a trait causing skewed X inactivation.[87] Infections (often bacterial) and malignancies are major causes of death in WAS and hemorrhage is also a problem. Overall, prognosis is poor and WAS remains primarily a disease of children. Antibiotic prophylaxis and IVIgG infusions can raise life expectancy while splenectomy can increase platelet numbers.[88] HSC transplantation is the optimal treatment as it remedies both immunologic as well as hematologic manifestations with a >80% survival using matched sibling donors.[89a] WAS is amenable to HSC gene therapy and genetically modified HSC have permitted its first successful use in 2 German patients with marked clinical improvement over 3 years.[89b]

GRAY PLATELET SYNDROME

Gray platelet syndrome (GPS) is usually a mild bleeding disorder with predominantly autosomal recessive inheritance and is characterized by the selective absence of α-granules and their contents.[90,91] The absence of α-granules gives the platelets a typical gray appearance on blood smears. The platelets are enlarged and often vacuolated, but not giant (FIGURE 63.1). Other clinical features are the early onset of myelofibrosis and splenomegaly. Patients with GPS can have moderate but progressive thrombocytopenia, likely due to negative regulation of megakaryocytopoiesis by spontaneously released cytokines/chemokines and other α-granule proteins. A novel recent finding is a high serum level of vitamin B_{12}.[91] Secretion-dependent platelet aggregation can be affected. In a French patient with GPS, collagen-induced platelet aggregation was accompanied by reduced GPVI expression.[92] Platelet α-granules contain biologically active proteins involved not only in hemostasis, but also in wound healing and tissue repair.[93] Pro- and antiangenic proteins are organized into different subpopulations of granules; both are affected in

GPS.[94,95] Vestigial granules may be seen and the basic molecular defect likely involves packaging or storage of proteins during α-granule biogenesis. Glycoproteins such as P-selectin, present in the α-granule membrane, are often retained in variable amounts distributed throughout the remaining membrane systems.

The genetic defect responsible for GPS has long remained an enigma. A report of X-linked GPS due to a GATA-1 Arg216Gln mutation is atypical since this and other related GATA-1 mutations also give rise to dyserythropoietic anemia, a finding not characteristic of GPS (see below).[96] Recently, genome-wide linkage analysis of a cohort of 25 GPS patients from 14 unrelated families spanning several continents localized the GPS gene(s) to a 9.4-Mb interval on 3p21.1-3p22.1 containing 197 protein-coding genes.[91] This approach was then used to make an even finer localization of the affected gene to 3p21.[97a] The affected gene has been identified as *NBEAL2* in 3 parallel studies using different molecular approaches including whole exome sequencing.[97b-d] *NBEAL2* is a member of the neurobeachin-like gene family and is likely a key element in α-granule biogenesis.

FAMILIAL THROMBOCYTOPENIA WITH A PREDISPOSITION TO ACUTE MYELOGENOUS LEUKEMIA

A large kindred with a bleeding tendency has been reported in which an autosomal dominant disorder of platelet production and function was linked to a propensity to develop myeloid leukemia.[98] The thrombocytopenia was moderate with considerable platelet size heterogeneity and structures resembling incompletely fragmented proplatelets (FIGURE 63.1). Linkage to markers on chromosome 21q identified an 880-kb interval containing the disease gene. Further analysis on this and other families confirmed the autosomal dominant pattern of inheritance and revealed heterogeneous germline nonsense and missense mutation, as well as intragenic deletions of the hematopoietic transcription factor *RUNX1 (CBFA2, AML1)* gene. Other developmental defects including mental retardation were present in some patients.[99–102] While haploinsufficiency of RUNX1 may be sufficient, a second genetic event and a biallelic alteration involving RUNX1 strongly favors disease progression to acute myelogenous leukemia (AML).[103] The latter may be aided by the presence of an expanded population of undifferentiated HSCs. RUNX1 is thought to have an important role in HSC differentiation and may also act as a tumor suppressor. The haplodeficiency and mutations interfering with DNA binding appear to lead to a decreased CFU-MK and decreased platelet production from birth. Mutated RUNX1 may heterodimerize with normal protein, leading to loss of function. Recently described interactions between RUNX1 and the GATA-1/FOG-1 and *FLI1* transcription factors could be causally related to the thrombocytopenia.[104] An altered regulatory interplay between miR-27a and *RUNX1* during megakaryocytopoiesis may also influence phenotype.[105] Impaired agonist-induced platelet aggregation, secretion, αIIbβ3 activation, and protein phosphorylation have all been described in patients with RUNX1 mutations. Recent elegant studies from Jalagadugula et al.[106] have shown that regulation of platelet MLC (MYL9) by RUNX1 has implications for both thrombocytopenia and platelet dysfunction; other platelet proteins for which gene transcription is under the control of RUNX1 include platelet 12-lipoxygenase (ALOX12), platelet protein kinase C-θ, and platelet factor-4.[107–109]

AUTOSOMAL DOMINANT THROMBOCYTOPENIA WITH PLATELETS OF NORMAL SIZE

There are rare reports of lifelong moderate to severe thrombocytopenia, but with normal sized platelets, in large kindreds with autosomal dominant inheritance. Clinical manifestations were a propensity to easy bruising and increased bleeding at times of hemostatic stress. Myeloid or erythroid cells were not affected and there was no progression to aplastic anemia. Linkage studies on large American and Italian families localized to chromosome 10.[110,111] Studies on cultured MKs from the American patients suggested a late block in terminal differentiation. A novel putative kinase, FLJ14813 (MASTL), was identified as a candidate gene mutated in the American family; a missense mutation encoding E167D segregated perfectly with the thrombocytopenia.[112] Knockdown of the MASTL kinase in zebrafish resulted in a deficiency of circulating thrombocytes as well as a decreased expression of the TPO receptor, c-Mpl, and αIIb encoding genes.[113] MASTL mutations were not found in the Italian family. Instead in this and eight other families, a series of mutations were clustered in a highly conserved 19-bp sequence located in the 5′ untranslated region of the *ANKRD26* gene (chromosome 10p12.1) encoding a proapototic protein whose function in megakaryocytopoiesis remains to be determined.[114] A mutation of human cytochrome c that enhances the intrinsic apoptotic pathway also causes thrombocytopenia with the release of "immature" platelets in a family with autosomal dominant thrombocytopenia.[115]

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

In congenital amegakaryocytic thrombocytopenia (CAMT), severe thrombocytopenia at birth often evolves into pancytopenia and severe aplastic anemia; occasionally, developmental decay, facial malformations, and neurologic problems are also present. CAMT has autosomal recessive inheritance and is a lifelong bleeding syndrome. Affected patients are born with low numbers of MKs in their marrow. Defects in the *MPL* gene that encodes the TPO receptor means that TPO is unable to fulfill its normal thrombopoietic role.[116] The fact that neither platelets nor haematopoietic progenitor cells show reactivity to TPO means that plasma TPO levels are greatly elevated (>10-fold above normal) and this is a diagnostic feature of CAMT along with a lack of c-Mpl expression on platelets. Ballmaier et al.[117,118] highlighted heterogeneity in CAMT, distinguishing patients with a severe form and early development into pancytopenia (type I disease) from others with mild thrombocytopenia in the first year of life but which then worsens over a 10-year period with pancytopenia in later life (type II disease). Frameshift or nonsense mutations predicting complete loss of c-Mpl led to severe disease; missense mutations in patients possessing residual c-Mpl were associated with slower progression of the phenotype. Rare mutations interfere with c-Mpl function rather than expression or even block receptor trafficking.[119,120]

The absence of c-Mpl function in HSCs cells leads to defective MK colony formation. Early exhaustion of multipotential progenitors may account for the pancytopenia. Mice that are genetically null for c-Mpl are thrombocytopenic, and although they

do not develop aplasia, marrow cell assays reveal severe reduction in precursors for all hematopoietic lineages.[121] Allogeneic bone marrow transplantation is a recommended treatment for CAMT, although potential donors among relatives need to be screened for mutations that may limit MK colony formation even in the heterozygous state. For some patients with expressed but nonfunctional c-Mpl, the possibility exists that they may react with TP-mimetics while not reacting with TPO itself.[122]

There are also activating mutations in the *c-Mpl* gene that give rise to familial essential thrombocythemia.[123] One example is a heterozygous S505N substitution inherited in an autosomal dominant manner and found in the transmembrane domain of c-Mpl. The result is spontaneous intracellular signaling, activated megakaryocytopoiesis, and excessive platelet production. The JAK2 kinase is critical for phosphorylation of c-Mpl and other signaling molecules, leading to activation of the Jak/signal transducer and activator of transcription and Ras/Raf/Mek1/2-Mapk-Erk pathways. Activating mutations in JAK2 and constitutive tyrosine kinase activities give rise to elevated blood cell counts in myeloproliferative disorders such as polycythemia vera.[124]

INHERITED THROMBOCYTOPENIAS ASSOCIATED WITH DISORDERS OF DEVELOPMENT

A series of thrombocytopenic disorders have been linked with severe defects in development with or without skeletal defects.

(i) *Amegakaryocytic thrombocytopenia with radioulnar synostosis*. Rare patients with what appears to be autosomal dominant inheritance, associated bone marrow failure with radioulnar synostosis and other skeletal abnormalities.[125,126] For some children, symptomatic thrombocytopenia with bleeding requires correction by bone marrow or umbilical cord stem cell transplantation. Marrow studies show few or no MKs and pancytopenia develops in some but not all individuals. A heterozygous mutation found in exon 2 of the homeobox gene, *HOXA1*, results in a stop codon in the third helix, a domain critical for DNA binding, and leads to a truncated protein in affected individuals. Studies on mice had previously shown that targeted disruption of the *HOXA10* and *HOXA11* genes affected forearm development in the embryo but did not result in thrombocytopenia (reviewed in[1]). Further studies have suggested that the *HOXA11* mutation inhibits MK differentiation.[127] It should be emphasized that radioulnar synostosis gives rise to mildly deformed forearms rather than their absence as in thrombocytopenia with absent radii (TAR, see below). The phenotype should also be distinguished from Fanconi anemia where skeletal abnormalities often affecting forearms, a predisposition to malignancies, and progressive pancytopenia are characteristic features.

(ii) *Thrombocytopenia with absent radii*. The TAR syndrome is a rare congenital defect with thrombocytopenia (often severe) and osteodysgenesis, namely shortened or absent forearms due to bilateral radial aplasia.[128,129] The inheritance is complex, with both autosomal recessive and autosomal dominant inheritance of various penetrance being reported. Other skeletal abnormalities as well as various developmental defects (e.g., facial dysmorphism, cardiac defects) can be present. Thrombocytopenia is often most severe at birth (most affected babies show purpura), but platelet numbers increase during childhood and platelet count can be near normal in adulthood. Platelet size is normal. MKs are reduced in number and appear small on biopsy smear. Serum TPO levels are elevated. Studies of MK differentiation *in vitro* in TAR syndrome patients showed a profound defect in MK progenitors.[130,131] MK differentiation is poorly stimulated by TPO or other cytokines and this is associated with a decrease in *c-Mpl* transcripts and Mpl protein. However, screening the *c-Mpl* gene has failed to show mutations and a defect in the early events of Mpl signal transduction has been proposed to explain the disorder. Furthermore, sequencing of the *HOXA10, HOXA11*, and *HOXD11* genes of 10 TAR syndrome patients revealed no mutations (see[128]). An interstitial microdeletion involving chromosome 1q was identified in a cohort of 30 individuals with TAR,[132] but was also seen in unaffected family members. More recently, the TAR syndrome has been shown to be given in 53 of 55 cases by compound inheritance of a low-frequency regulatory SNP and a rare null mutation in exon-junction complex subunit *RBM8A*.[133]

(iii) *Paris-Trousseau syndrome*. The Paris-Trousseau syndrome is a variant of Jacobsen syndrome characterized by haplodeficiency of chromosome 11q23-24.[134–137] This can give rise to growth and psychomotor retardation, facial dysmorphism, congenital heart defects, respiratory infections, and malfunction of multiple organs. Thrombocytopenia (or pancytopenia) affects approximately 90% of patients and distinguishes the Paris-Trousseau syndrome; the low platelet count can be chronic ($<50 \times 10^9$/L) and platelet function may be affected. However, the thrombocytopenia can correct within the first 2 years of life. Paris-Trousseau syndrome is said to have autosomal dominant inheritance, although several isolated cases have been described where *de novo* chromosome breakage may have occurred. Circulating platelets are often large and have giant α-granules visible on Giemsa-stained blood smears or by electron microscopy. Two morphologically distinct populations of MKs are present; one composed of normal cells and the other of small immature cells with hypolobulated nucleus and arrested maturation. The giant α-granules are a feature of platelets rather than MKs and may represent granule fusion after platelet production. Storage pool disease may also be present.

The chromosome 11 microdeletion is of variable length and includes two ETS transcription factor genes, *ETS-1* and *FLI-1*. A decrease in the *FLI1* protein results in reduced GATA-1/FOG-1–dependent transcription of MK-specific genes[138]; affected proteins can be downregulated (e.g., GPIba). Studies in mice favor a role for *FLI1* deficiency rather than ETS1 in the pathogenesis of Paris-Trousseau syndrome.[139] Lentivirus-mediated overexpression of *FLI1* in CD34+ cells from a Paris-Trousseau syndrome patient restores megakaryocytopoiesis *in vitro*, thereby confirming that *FLI1* hemizygous deletion contributes to the dysmegakaryocytopoiesis.[140] Furthermore a half-reduction in *FLI1* gene dosage generated a subpopulation of $CD41^+$ $CD42^-$ cells completely lacking *FLI1* transcription with a block in MK differentiation and the presence of a subpopulation of micromegakaryocytes that fail to reach the platelet production stage. Defects of other genes in the deleted region including *ETS-1* may contribute to the wide-ranging Jacobsen syndrome phenotype.[135,141]

(iv) *Other syndromes.* A moderately low platelet count is a feature of Ghosal syndrome, a rare autosomal recessive disorder characterized by progressive sclerosing diaphyseal dysplasia and refractory anemia. A genome-wide search in two large inbred families from Algeria and Tunisia first mapped disease gene to chromosome 7q33-34; it was subsequently identified as *TBXAS1* encoding thromboxane synthetase.[142,143] Noonan syndrome is a common, clinically and genetically heterogeneous condition characterized by distinctive facial features, short stature, chest deformity, congenital heart disease, and other comorbidities; thrombocytopenia is variable but often present.[144] The disease gene maps to chromosome 12q.24.1 and identified mutations in the Ras/MAPK (mitogen-activated protein kinase) signal transduction pathway including PTPN11 encoding the protein tyrosine phosphatase SHP-2 account for a majority of cases. Chronic thrombocytopenia and predisposition to AML associated with growth restriction, variable developmental delay, and facial dysmorphism has been associated with microdeletions at chromosome 21q encompassing the RUNX1 gene (see Section on AML).[145]

DiGeorge/velocardiofacial syndromes can have autosomal recessive inheritance but most often arise spontaneously.[146] They are seen in approximately 1:4,000 births. The phenotype arises from a microdeletion in chromosome 22q11.2 on one of a pair of chromosomes. Phenotypic features can include conotruncal cardiac abnormalities, learning disabilities, velopharyngeal insufficiency, immunodeficiency, facial dysmorphology, and thymic hypoplasia. A haploinsufficiency of a single gene, *Tbx1* (encoding a T-box containing transcription factor) largely accounts for the phenotype.[147] Surveys of DiGeorge syndrome suggest that mild thrombocytopenia and platelets of increased size affect about 20% of patients.[146,148] The gene encoding GPIbβ is adjacent to *Tbx1* (see Section on BSS). Bleeding is not a noted characteristic in DiGeorge syndrome patients, similar to the absence of bleeding in heterozygous BSS.

X-LINKED THROMBOCYTOPENIA WITH DYSERYTHROPOIESIS WITH OR WITHOUT ANEMIA

A special category of X-linked familial thrombocytopenia segregates dyserythropoiesis with or without anemia. Thrombocytopenia ranges from moderate to severe; splenomegaly may be present and platelet aggregation is affected. The gene responsible for this combination of defects was first mapped to the X-chromosome (Xp11-12) and identified as that encoding the transcription factor GATA-1 (reviewed in[149]). GATA-1 together with its cofactor FOG-1 (friend of GATA-1) plays a key role in both erythropoiesis and megakaryocytopoiesis. GATA-1 contains two zinc fingers, the C-terminal of which accounts for sequence-specific DNA binding and the N-terminal (N-f) for both stabilization of DNA binding and for the interaction with FOG-1. GATA-1 mutations give a wide range of phenotypic features besides thrombocytopenia, including mild β-thalassemia (XLTT), neutropenia, and congenital erythropoietic porphyria (CEP) in males. Mutations that give rise to thrombocytopenia all occur in the N-f domain; they interfere with the ability of GATA-1 to bind specific DNA sequences and/or to interact with FOG-1.

A small series of families have XLT without β-thalassemia. Typically, the marrow shows structurally abnormal MKs and an abundance of large multinucleated erythroid precursors. Circulating platelets are enlarged with few α-granules and contain an abundance of membrane complexes (MC). Erythrocytes are abnormal in size and shape and anemia may vary between mild and severe. Examples of GATA-1 mutations giving rise to severe XLT include V205M, G208R, and D218Y substitutions, while G208S and D218G result in milder phenotypes (reviewed in[149]). All appear to primarily affect GATA-1–FOG-1 interactions rather than DNA binding. Semiquantitative RNA analysis has revealed a low transcription of GATA-1 target genes such as *GPIbβ* and *GP9* and a reduced transcription of late MK maturation markers. Platelet function is affected with a poor response to ristocetin. Phenotypic variability is influenced by the nature of the substituted amino acid.[150–152] Skewed X inactivation in female carriers has also been reported.

Yu et al.[153] reported a R216Q substitution in the N-terminal finger of GATA-1 in the family that originally led to the description of XLT, but where red cell abnormalities were consistent with β-thalassemia (XLTT). The same mutation was subsequently found in an Italian family.[154] These were the first reports of β-thalassemia in man caused by a mutation in an erythroid transcription factor. The mutation allows programming of erythroid differentiation, though somewhat less efficiently than wild-type protein. Generally, XLTT results from mutations that affect the DNA binding face of the N-f domain of GATA-1 with the FOG-1 interaction conserved.[149] Thrombocytopenia is less severe than in XLT; again platelets contain few α-granules and have morphologic defects (see also Section on GPS). Platelet GPIb levels were higher than in controls whereas αIIbβ3 was lower. Not least, these studies confirm that the mutation changes rather than abrogates the expression of GATA-1–dependent target genes. Studies on marrow showed that mature MKs were often small and profoundly dysmorphic while immature cells retained a capacity to proliferate.

A GATA-1 mutation (R216W) that causes CEP has been described as has the association of GATA-1 with trisomy 21 (reviewed in[149]). Overall, a defective interaction of GATA-1 with either DNA or FOG-1 can disrupt hematopoiesis and give rise to disorders sharing common themes but with diverging phenotypes. The role of GATA-1 was confirmed by transgenic mouse models, with immature low ploidy MK progenitors proliferating profusely *in vitro* as a result of a unique MK differentiation arrest, a finding associated with dyserythropoietic anemia.[155,156] Recent biologic approaches have shown that in addition to FOG-1, the NURD complex, SCL/TAL-1, the zinc finger regulators GFI1B and ZFP143, and the compressor ETO2 all interact with GATA-1 to regulate terminal MK maturation.[157]

OTHER DISORDERS

Isolated reports of thrombocytopenia of unknown origin abound; often, insufficient evidence has been obtained to allow an understanding of the molecular cause. One example is a mild bleeding diathesis associating giant platelets with abnormal surface glycoproteins and mitral valve insufficiency.[158] Even more unusual is a report of hereditary macrothrombocytopenia with the atypical expression of the principal red cell glycoprotein, glycophorin A on the giant platelets.[159] Deafness developed in later life; no genetic defect has been described, although chromosomal crossover may be a possibility. A more complete case is that reported by Willig et al.[160] concerning a young boy with

macrothrombocytopenia and mild neutropenia. Morphologic abnormalities of MKs included an abnormal fragmentation of the cytoplasm and the presence of large MC. GPIb was selectively decreased but no sequence abnormalities were found in the genes encoding GPIb-IX-V. Significantly, there was a complete lack of sialyl-Lewis-X antigen on polymorphonuclear leukocytes from the patient and the authors concluded that a posttranslational modification of membrane glycoproteins was the origin of the defect. This was subsequently confirmed with inactivation of the Golgi CMP-sialic acid transporter through the combination of a heterozygous microdeletion and a heterozygous splice site mutation in the donor splice site of intron 6 of the *SLC35A1* gene.[161] Thrombocytopenia due to a defective O-glycosylation of GPIbα and expression of terminal *N*-acetylgalactosamine residues (Tn syndrome) is associated with somatic mutations in *COSMC* (*C1GALT1-specific chaperone*).[162,163] Here platelets are thought to have a reduced lifespan due to an accelerated clearance from the circulation; giant platelets are not present.

Platelets and MKs express the Gs-coupled VPAC receptor for which the pituitary adenylyl cyclase-activating peptide and the vasointestinal peptide are agonists. Patients with trisomy 18p and PCAP overexpression have mild thrombocytopenia and a reduced MK number with VPAC negatively regulating megakaryocytopoiesis via its control of cAMP levels.[164] Regulator of G-protein signaling 2 (RGS2) negatively regulates Gs signaling by inhibiting the activation of adenylate cyclase (AC). A heterogeneous mutation (G23D) in three related patients led to an enrichment of a large RGS isoform with strong AC inhibitor activity. Neurologic deficiencies and short fingers were among associated problems. Despite the absence of thrombocytopenia, platelets were enlarged and round with abnormal α-granules suggestive of changes in megakaryocytopoiesis.[165] An interesting situation whereby platelet production is influenced by a secondary gene defect is sitosterolemia (phytosterolemia). In this metabolic disease, there is an unrestricted gut adsorption of cholesterol and plant-derived cholesterol-like molecules. The disease is linked to mutations in the *ABCG5* and *ABCG8* genes. Patients are born with a normal platelet count and size, but rapidly develop macrothrombocytopenia.[166,167] Studies on *Abcg5*(−/−) mice showed a defective MK development with a deterioration of the DMS system and decreased polyploidy.[168,169] Platelet size was increased threefold and platelets showed a decreased lifespan as well as functional defects.

DIFFERENTIAL DIAGNOSIS

When a low platelet count is unexpected, it is first necessary to exclude artifacts and blood sampling errors (Table 63.2). With electronic counters falsely low platelet counts (and elevated leukocyte counts) often occur in giant platelet syndromes; platelet size should therefore also be examined on a blood film (reviewed in[43]). So-called pseudothrombocytopenia due to platelet clumping can occur in both healthy subjects and patients and is most often encountered in blood collected into ethylenediaminetetraacetic acid (EDTA) anticoagulant. Platelets may also show EDTA-dependent attachment to leukocytes (termed *platelet rosetting* or *satellitism*). Pseudothrombocytopenia is caused by naturally occurring agglutinins binding to an epitope exposed on αIIbβ3 after Ca^{2+} chelation.[170] Although platelet counts may be restored on using citrate anticoagulant, this is not always so and heparin or hirudin-based anticoagulants should also be tested.

Table 63.2

Causes to take into account when diagnosing patients with suspected inherited thrombocytopenia

Pseudoagglutination
ITP
Childhood acute
Adult chronic
Posttransfusion purpura
Drug-induced thrombocytopenia
Heparin-induced thrombocytopenia
Anti-GPIIb-IIIa drugs
Other medicaments
Antiphospholipid syndrome (SLE)
Evans syndrome
Paroxysmal nocturnal hemoglobinuria
Gestational thrombocytopenia during pregnancy
Preeclampsia and eclampsia
HELLP syndrome
TTP-HUS (Defect of ADAMTS13)
Viral and bacterial infections (and sepsis)
Increased platelet consumption
Splenomegaly
Disseminated intravascular coagulation and thrombosis
Liver and organ failure, vitamin B_{12} or folic acid deficiency
Myelodysplastic syndromes and myeloproliferative disease
Drug-induced marrow suppression and/or chemotherapy
Cancer and hematologic malignancy (leukemia)

In one large series of patients with EDTA-dependent thrombocytopenia, a majority also had anticardiolipin antibodies, and their removal by adsorption led to a loss in platelet clumping.[171]

When thrombocytopenia is severe and/or is associated with platelet dysfunction, bleeding is most often detected at birth. Mild thrombocytopenia may yield sporadic bleeding particularly at times of haemostatic stress; sometimes there is no past history and a low platelet count will only be detected in routine testing (e.g., prior to surgery or during pregnancy). A detailed family history helps determine the inheritance pattern; a questionnaire determining the duration and severity of symptoms may be useful to determine a bleeding score.[172] As we have illustrated, the coexpression of other phenotypic abnormalities will define clinically recognized syndromes. Platelet morphologic abnormalities will aid diagnosis as will elevated plasma TPO levels. Balduini et al.[43] working on behalf of an Italian study group and Bolton-Maggs et al.[2] on behalf of British organizations have published algorithms aimed at improving diagnosis of inherited thrombocytopenias and platelet function disorders. Analysis of the genetic defect is the final step, although this may requires the involvement of specialist centers.

Above all is the need to exclude an acquired cause. Among the many causes of acquired thrombocytopenia are autoimmune

diseases, increased platelet consumption, splenomegaly, marrow suppression, or failure (Table 63.2). Neonatal alloimmune thrombocytopenia and ITP must be excluded to avoid incorrect treatment (corticosteroids or even splenectomy). In the absence of a family history, it is necessary to know if the thrombocytopenia is persistent. Viral infection is a common cause of thrombocytopenia (particularly among children), bacterial infections, and sepsis in adults while drug-induced thrombocytopenia is an increasingly recognized cause. The list of drugs giving rise to drug-dependent antibodies is ever increasing.[173] The detection of plasma or serum alloantibodies and autoantibodies requires immunologic testing often only readily available in specialized centers. But in ITP, the detection of an antibody does not guarantee that it is responsible for the thrombocytopenia while the "nondetection" of an antibody does not rule out the presence of an antibody reacting with a minor component of platelets. In fact, ITP is largely diagnosed by exclusion leaving open the possibility that patients with familial thrombocytopenias are included within the diagnostic net of ITP (see[70]).

Systemic lupus erythematosus (SLE) is an often encountered but complex disease in which the detection of antinuclear antibodies is a sensitive diagnostic feature. Thrombocytopenia can be severe and is a risk factor for mortality while other organs can be affected. To complicate matters, thrombocytopenia in SLE can also have a severe familial phenotype with genetic linkages at 1q22 and 11p13.[174] Whether this linkage involves genetic polymorphisms or mutations directly implicated in the pathogenesis of the disease is unknown. Similarly, familial acquired thrombotic purpura has been reported with ADAMTS inhibitory autoantibodies in identical twins.[175] Antibodies associated with thrombocytopenia need not necessarily be directed against platelets. Neutralizing antibodies to granulocyte-macrophage colony stimulating factor (GM-CSF) or TPO have been detected in patients with amegakaryocytopenic purpura.[176,177]

PROGNOSIS

Platelet transfusions remain the most common treatment for severe spontaneous mucocutaneous bleeding in inherited disorders of platelet production, although DDAVP has been successfully used while recombinant human factor VIIa is now also widely used.[2] Isoantibody production is a risk in BSS after transfusion. When bleeding is moderate and superficial, then local measures can be applied.[2] The use of autologous platelet-rich plasma is a viable and inexpensive option for dental surgery.[178] Pregnancy and surgery represent special problems and are reviewed elsewhere.[2] An excellent systematic review of pregnancy in BSS has recently been prepared while menorrhagia in adolescents with inherited bleeding disorders has likewise been assessed.[179,180] The long-term treatment of CAMT and other severe thrombocytopenias of defined genetic basis is HSC transplantation with a matched donor. But the genetic basis of this disease suggests that it will be an excellent candidate for gene therapy for even a small population of targeted stem cells may be able to proliferate in response to TPO and repopulate the marrow. Whereas splenectomy may be an option in WAS, its efficacy in other inherited thrombocytopenias has been questioned, although it may be preferred in XLT where HSC therapy is not an option. Multidisciplinary management is required in WAS where life expectancy is low. Management of pregnancy needs to take into account that this is an X-linked disease. As stated earlier, gene therapy is now on the horizon for this disease.[89b]

Finally, it is now recognized that mean platelet volume and platelet count are highly heritable and regulated traits in a normal population. Whole-genome expression analysis and other approaches are starting to identify novel genetic markers of these parameters.[97b,181] Quite clearly, specific genetic traits and haplotypes will influence not only counts and platelet size in a normal population, but also the extent to which individual mutations responsible for inherited disorders of platelet production and/or function influence phenotype.

CHAPTER

64 Acquired Nonimmune Thrombocytopenia

ANDREAS GREINACHER AND THEODORE E. WARKENTIN

Acquired thrombocytopenic disorders can be divided into five categories, plus the spurious entity of pseudothrombocytopenia (Table 64.1): hemodilution, sequestration (usually due to hypersplenism), decreased platelet production, increased platelet consumption (by pathologically increased "physiologic" pathways of platelet activation and clearance), and platelet destruction (e.g., phagocytosis of antibody-coated platelets). This chapter summarizes the nonimmune differential diagnosis of acquired thrombocytopenic disorders. We also discuss thrombocytopenia in patients in intensive care units, as thrombocytopenia is very frequent in these patients, and provide an approach to separate the different causes of a low platelet count.

PERIOPERATIVE THROMBOCYTOPENIA

Early postoperative thrombocytopenia is a combined effect of hemodilution and platelet consumption. It is one of the most common events prompting consultation with a hematologist. A platelet count decline of 30% to 70% occurs universally following major surgery. Such hemodilution-associated thrombocytopenia is most prominent after cardiac surgery[1] and is roughly proportional to the amount of crystalloid, colloid, or blood products administered. Most of this platelet count decline is abrupt and occurs within a few hours following surgery. Dilutional coagulopathy generally accompanies the thrombocytopenia,[2] accounting for the minor-to-moderate increases in prothrombin time and activated partial thromboplastin time that are commonly seen immediately after surgery.

Perioperative hemodilution is accompanied by platelet consumption, an effect that correlates with the magnitude of tissue trauma. An important characteristic of the postsurgery platelet count is that it usually continues to decline over the next 1 or 2 days, with the postoperative nadir usually occurring at a median of postoperative day 2, with a range between postoperative days 1 and 4 (FIGURE 64.1A).[3,4] Subsequently, there is a rise in the platelet count to levels often two to three times the patient's preoperative baseline, peaking at approximately day 14, before it returns to baseline over the next 2 weeks (~day 28).

This platelet count profile can be explained by thrombopoietin physiology. Thrombopoietin, produced at a constant rate by the liver, is regulated by the circulating platelet mass. Platelets bind thrombopoietin, thereby decreasing the amount of circulating thrombopoietin. With perioperative platelet count declines, more thrombopoietin becomes available to stimulate megakaryocytes. However, there is a lag between megakaryocyte stimulation and release of new platelets. Studies of administering the thrombopoietin receptor analogue, romiplostim, to human volunteers showed an increased platelet count beginning after 3 to 5 days and peaking about 7 to 10 days later.[5] As platelet stimulation necessarily has an approximate 3-day lag, it would be expected that platelet counts reach a nadir as late as 3 or even 4 days after major surgery (SEE FIGURE 64.1B). This time course is the most important feature differentiating the normal platelet count decrease after major surgery from immune-mediated thrombocytopenias, especially from heparin-induced thrombocytopenia (HIT) where the platelet count decrease typically *begins* on or after day 5.[4,6]

This pattern can be changed by perioperative platelet transfusions that produce a transient increase in platelet count, with subsequently clearing of the transfused platelets over the next 2 or 3 days, resulting in a shift of the platelet count nadir to the right.

PLATELET SEQUESTRATION

Hypersplenism

Hypersplenism denotes the reduction in one or more of the peripheral blood counts due to sequestration within an enlarged spleen. Unlike postoperative hemodilution, hypersplenism is characterized by subacute or chronic, rather than acute, thrombocytopenia.

Normally, approximately one-third of the total body platelet mass resides within the spleen, even though the spleen receives only 5% of the cardiac output.[7] This discrepancy occurs because the transit time of a platelet through the spleen averages 20 minutes, much longer than the time required for a platelet to return to the heart after passing through other organs (~1 minute). In hypersplenism, the proportion of platelets within the spleen can be as high as approximately 90%.[7]

Characteristic clinical features of hypersplenism include splenomegaly (measured objectively as >11 cm by imaging studies) and mild-to-moderate pancytopenia. Often, the degree of anemia is not as marked as neutropenia and thrombocytopenia. In patients with advanced cirrhosis, thrombocytopenia is further aggravated by reduced platelet production due to decreased thrombopoietin levels[8] or the toxic effects of alcohol and/or increased platelet consumption due to enhanced thrombin generation and hyperfibrinolysis.

Table 64.2 lists various causes of splenomegaly.[9] In Western societies, cirrhosis (usually secondary to alcohol consumption or chronic viral hepatitis) is a common cause, whereas other explanations are more common elsewhere (e.g., schistosomiasis, malaria).

Treatment is usually not required, as thrombocytopenia rarely reaches clinically important levels and splenectomy is not without risk.

Table 64.1

Classification of thrombocytopenia

Six general explanations for thrombocytopenia, including pseudothrombocytopenia.

Explanation	Comment	Examples
Pseudothrombocytopenia	Antibody-mediated platelet clumping that occurs *ex vivo*, that is, spurious thrombocytopenia	EDTA-induced pseudothrombocytopenia; platelet satellitism (platelet binding to leukocytes)
Hemodilution	Abrupt platelet count fall due to administration of fluids or blood products	Early postoperative thrombocytopenia
Hypersplenism	Splenomegaly may require imaging studies to detect; concomitant leukopenia and (to lesser extent) anemia are usually present	Cirrhosis-associated portal hypertension
Decreased platelet production	Usually there is concomitant leukopenia and anemia (a notable exception is certain types of hereditary thrombocytopenia)	MDS; aplastic anemia; marrow infiltration by metastatic cancer; alcohol-induced thrombocytopenia
Platelet consumption	Accelerated platelet clearance due to pathologically increased platelet activation or other poorly defined mechanisms of increased platelet clearance	DIC; septicemia; multiorgan system failure; hemophagocytic syndrome
Platelet destruction	Accelerated platelet clearance due to pathological mechanisms that target platelets, especially due to platelet-reactive antibodies	Autoimmune thrombocytopenic purpura; HIT; drug-induced immune thrombocytopenia; TTP/HUS

EDTA, ethylenediaminetetraacetic acid; HIT, heparin-induced thrombocytopenia; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome.

Hypothermia

Hypothermia can be accompanied by mild-to-moderate thrombocytopenia.[10] The thrombocytopenia is transient and corrects with rewarming. Platelet kinetic studies in cooled dogs demonstrated reversible hepatic and splenic platelet sequestration.[11] Indirect evidence suggests that decreased platelet production may also contribute.[12]

DECREASED PLATELET PRODUCTION

Thrombocytopenia often is caused by decreased platelet production, which can be divided into three categories: acquired, generalized marrow disorders; acquired, isolated megakaryocytic disorders (e.g., alcohol-associated thrombocytopenia); and hereditary thrombocytopenic disorders.

Acquired, Generalized Marrow Disorders

By far the most common cause of decreased platelet production is acquired, generalized bone marrow disease. The pathologic process usually perturbs all cell lines, and pancytopenia typically results. Occasionally, however, isolated thrombocytopenia is the first abnormality detected during the early stages of a panmyelopathy, for example, myelodysplasia (MDS).

Nonneoplastic Hypoproliferative Stem Cell Disorders—Thrombocytopenia accompanies aplastic anemia, chemotherapy-induced pancytopenia, and idiosyncratic drug-induced aplastic anemia. Sometimes, isolated thrombocytopenia is a precursor of aplastic anemia.

Paroxysmal Nocturnal Hemoglobinuria (PNH)—PNH is a stem cell defect resulting in the loss of phosphatidylinositol-anchored proteins, resulting in intravascular hemolysis due to increased susceptibility of red blood cells to complement-mediated lysis; PNH is also associated with thrombocytopenia.[13] The low platelet count is a composite of a dysplastic platelet production defect, enhanced platelet consumption due to the higher susceptibility of PNH platelets to thrombin, and enhanced platelet destruction due to increased generation of lytic C5b9 complexes on platelet membranes.[14] Patients are at increased risk for thrombotic complications, perhaps induced by the production of procoagulant microparticles from affected blood cells. Diagnosis is made by showing by flow cytometry a population of blood cells with decreased/absent phosphatidylinositol-anchored proteins. A treatment option in severe PNH is the monoclonal antibody, eculizumab.[15,16]

Myelodysplasia—Isolated, refractory thrombocytopenia is the initial presentation of MDS in 1% to 3% of patients and can be confused with immune thrombocytopenic purpura (ITP).[17] Bleeding can result from thrombocytopenia or defective platelet function or from both. Findings that aid in differentiating MDS from ITP include red cell macrocytosis, a left-shifted white cell series, leukocyte morphologic abnormalities (e.g., hypogranular neutrophils and Pelger-Huët anomaly), and hypogranular, giant platelets. Marrow examination reveals dysmegakaryocytopoiesis in half of cases. Typically, the megakaryocytes are abnormally

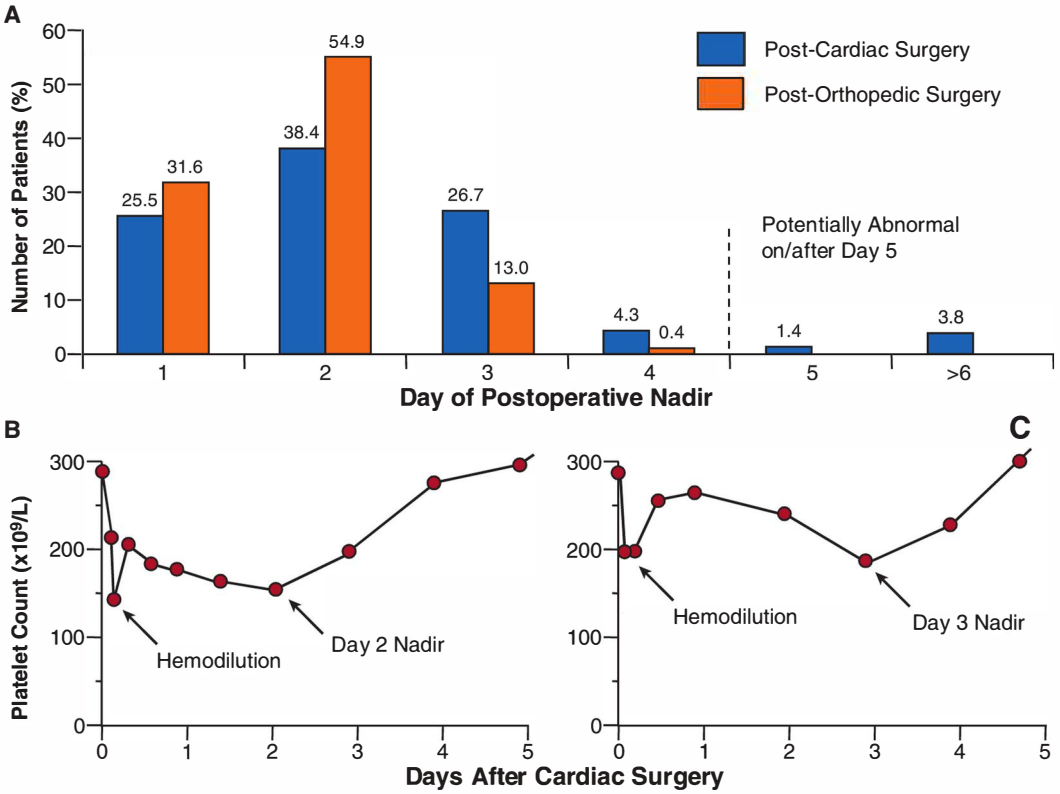

FIGURE 64.1 Early postoperative platelet count decreases. **A:** Distribution of early postoperative count nadirs. For both orthopedic and cardiac surgery patients, day 2 represents the most common day for the postoperative platelet count nadir to occur (data exclude day 0); beyond postoperative day 4, it is likely that a superimposed thrombocytopenic disorder is occurring. Orthopedic surgery data obtained from Warkentin TE, Levine MN, Hirsh J, et al. Heparin-induced thrombocytopenia in patients treated with low-molecular-weight heparin or unfractionated heparin. *N Engl J Med* 1995;332(20):1330–1335. and cardiac surgery data obtained from Greinacher A, Selleng K. Thrombocytopenia in the intensive care unit patient. *Hematology Am Soc Hematol Educ Program* 2010;2010:135–143. **B,C:** Representative postcardiac surgery platelet count decreases. Both patients illustrate early hemodilution effects (day 0) and subsequent additional early platelet count declines with nadirs of (**B**) day 2 and (**C**) day 3. Neither patient received platelet transfusions.

small, but large mononuclear and abnormal segmented megakaryocytes are found in some patients.[18] Megakaryocyte numbers are usually normal, but increased megakaryocytes (resembling ITP) or amegakaryocytic thrombocytopenia[19] have also been observed.

Neoplastic Stem Cell Disorders—Thrombocytopenia is common with primary neoplastic disorders of the bone marrow. Usually the presence of pancytopenia and circulating malignant cells points to the diagnosis; bone marrow aspirate and biopsy are confirmatory. These disorders include acute myeloid and acute lymphoid leukemia, as well as many chronic lymphoproliferative disorders, such as chronic lymphoid leukemia, hairy cell leukemia, non-Hodgkin's lymphoma, adult T-cell leukemia and lymphoma, multiple myeloma, and Waldenström's macroglobulinemia.

Infiltrative Bone Marrow Disorders—Thrombocytopenia can be secondary to infiltration of the bone marrow by nonhematologic metastatic malignancies, infectious organisms, storage-cell disorders, myelofibrosis, and osteopetrosis. When bone marrow replacement occurs from malignancies (e.g., breast cell carcinoma, prostate carcinoma), peripheral blood features include normoblasts (nucleated red cells), teardrop red cells, and leukopenia usually with leukocyte left shift. This constellation of findings is called a "myelophthisic" blood picture.[20]

Megaloblastic Anemia—Megaloblastic anemia, caused by vitamin B_{12} or folic acid deficiency, is often associated with mild thrombocytopenia. Vitamin deficiency–induced defective DNA synthesis results in megakaryocytes of low ploidy and small platelets.[21] Thus, the combination of large, heterogeneous red cells (oval macrocytes) together with small platelets (low mean platelet volume) is characteristic of megaloblastic anemia.

Isolated Thrombocytopenia Due to Drugs

Alcohol-associated thrombocytopenia is associated with heavy and prolonged alcohol consumption and can cause an acute, self-limited thrombocytopenia.[22] The platelet count increases 2 to 3 days after cessation of alcohol consumption, with "rebound" thrombocytosis. Bone marrow aspirates early in the course of the thrombocytopenia reveal reduced megakaryocyte numbers and sometimes vacuolation of normoblasts and promyelocytes.

Table 64.2

Causes of splenomegaly

Congestive Splenomegaly
Intrahepatic
Cirrhosis[a]
Extrahepatic
Portal vein obstruction
Splenic vein obstruction
Hepatic vein occlusion (Budd-Chiari syndrome)
Chronic passive congestion
Heart failure
Infections
Acute
Viral (viral hepatitis, infectious mononucleosis, cytomegalovirus infection)
Bacterial (septicemia, salmonellosis, brucellosis, splenic abscess)
Parasite (toxoplasmosis)
Subacute and chronic
Subacute bacterial endocarditis
Tuberculosis
Malaria
Kala-azar
Fungal disease
Inflammation
Felty syndrome
SLE
Serum sickness
Rheumatic fever
Sarcoidosis
Hematologic Disorders
Red cell disorders: hemolytic anemias, thalassemia, sickle cell disorders
Macrophage activation (hemophagocytic) syndrome
Neoplasia
Malignant
Myeloproliferative neoplasms
Myeloid metaplasia
Polycythemia rubra vera
Essential thrombocythemia
Chronic myeloid leukemia
Chronic lymphocytic leukemia
Hairy cell leukemia
Lymphoma
Acute leukemia

Hemangioma
Lymphangioma
Fibroma
Storage Diseases
Gaucher disease
Niemann-Pick disease
Miscellaneous
Amyloidosis
Cysts
Nontropical idiopathic splenomegaly (Dacie syndrome)

[a]The most common cause of hypersplenism in North America.

Interferon used for the treatment of hepatitis C causes a 10% to 50% drop in the platelet count in patients on combination therapy and 4% to 6% of patients require dose modification secondary to thrombocytopenia.[23] Interferon is thought to alter thrombopoietin production, thereby reducing platelet production. In most cases, thrombocytopenia is clinically insignificant, but reduction of the interferon dose is necessary when platelet counts decrease below 50×10^9/L and cessation of treatment is required if platelet counts decrease below 30×10^9/L.

Drugs targeting RUNX1, a transcription factor important in leukemia, have the potential to cause decreased platelet production,[24] as RUNX1 plays an important role in thrombopoiesis.[25]

Iron repletion: Mild-to-moderate thrombocytopenia can be observed also approximately 1 week after beginning iron replacement therapy[26]; this transient platelet count decline is most likely the result of a shift of stem cells to erythropoiesis.

Fatty acid–induced thrombocytopenia is most prominent in patients with adrenoleukodystrophy, who are treated with Lorenzo's oil (a mixture of glycerol trioleate and trierucate).[27] These oils change the composition of the platelet membrane, causing membrane anisotropy the production of enlarged and giant platelets, as well as platelet function defects.[28]

Viral Infections

Viral infections commonly cause thrombocytopenia, in part through decreased platelet production,[29] perhaps due to direct megakaryocyte infection as best illustrated by HIV infection.[30] In addition, viral infection can trigger platelet-reactive autoantibodies which can produce severe immune thrombocytopenia (see Chapter 61). Similarly, MMR (measles–mumps–rubella) vaccine results in acute immune thrombocytopenia beginning approximately 10 to 14 days—and up to 6 weeks—postvaccination in approximately 1/40,000 exposures.[31]

Miscellaneous Acquired Thrombocytopenia

Iron depletion—Mild-to-moderate thrombocytopenia can be observed at presentation of severe iron deficiency anemia.[32]

Acquired amegakaryocytic thrombocytopenia—Acquired amegakaryocytic thrombocytopenia is a rare disorder characterized by isolated thrombocytopenia associated with a total or marked reduction in megakaryocytes.[33,34] Sometimes, progression to aplastic anemia or MDS occurs. In other patients, there are autoimmune features (e.g., association with systemic lupus erythematosus (SLE) or a positive direct Coombs' test). Cyclic amegakaryocytic thrombocytopenia has also been observed.[35]

The pathogenesis of acquired amegakaryocytic thrombocytopenia is heterogeneous and at least three different mechanisms have been implicated: an intrinsic stem cell defect (defective growth of megakaryocyte precursors), autoantibodies directed against megakaryocyte precursors, and T-cell–mediated suppression of megakaryocyte development. Thrombopoietin levels are usually much greater than seen in patients with ITP.[36]

Treatment of these disorders have included corticosteroids, antithymocyte globulin, cyclosporine, cyclophosphamide, immunoglobulins, splenectomy, or allogenic bone marrow transplantation (BMT).[33,34]

Hereditary Thrombocytopenia

This topic is discussed in detail in Chapter 63; however, they are mentioned here because some hereditary thrombocytopenias with mild bleeding symptoms (e.g., MYH9-associated disorders) are often misconstrued to be an "acquired" disorder when previous platelet counts are not available and the associated macrothrombocytopenia suggests other diagnoses such as ITP or MDS.[37]

INCREASED PLATELET CONSUMPTION

Reduced platelet survival arising from platelet activation or accelerated platelet clearance can be represented as "consumptive" disorders. Pathologically increased thrombin generation as occurs with "disseminated intravascular coagulation (DIC)" or "consumptive coagulopathy" often produces thrombocytopenia and is discussed in Chapter 98. Decreased platelet survival (with or without overt DIC) due to enhanced macrophage-mediated platelet clearance is common in sepsis.

Septicemia

Thrombocytopenia occurs in 50% to 75% of patients with systemic bacterial or fungal infections, and in almost all patients with septic shock[38] (see Chapter 123). The thrombocytopenia is generally mild to moderate in severity and bleeding due to thrombocytopenia alone is infrequent. Thrombocytopenia in sepsis is associated with increased mortality. However, increased mortality is not attributable to thrombocytopenia-related bleeding, but rather as a marker of underlying disease severity, as exemplified by a study of post-liver transplant patients.[39]

The likelihood of laboratory evidence for DIC increases as the platelet count falls to $<50 \times 10^9$/L.[38] The mechanism of thrombocytopenia in septicemia in the absence of DIC is uncertain, but could include chemokine-induced macrophage ingestion of platelets (hemophagocytosis[40]) and platelet activation by endogenous mediators of inflammation (e.g., platelet-activating factor) or microbial products.[41] In rare situations, platelet-reactive autoantibodies have been implicated.[42] A diagnosis of sepsis-related thrombocytopenia is corroborated by a positive blood culture. Prompt recognition and treatment of the responsible infection is the most important therapy, as recovery of the platelet count tends to parallel the resolution of the infection. Prophylactic platelet transfusions are generally not required unless the platelet count falls to $<10 \times 10^9$/L, but bleeding might occur at higher platelet counts if comorbid clinical features are present (e.g., concomitant coagulopathy, an invasive procedure, renal failure). The use of heparin for patients with septic shock and DIC is controversial (see Chapter 98). However, heparin may benefit a subset of patients with clinical evidence of DIC and microvascular thrombosis (e.g., acral tissue ischemia or necrosis) if it can reduce progression of thrombosis.

Thrombocytopenia that occurs after 2 to 3 weeks of hospitalization, especially in a patient who has received antibiotics, suggests fungemia (e.g., candidemia). Worldwide, malaria is the most common parasite causing thrombocytopenia.

HIV Infection

Thrombocytopenia in patients infected with HIV poses a special diagnostic problem, because there are many potential and sometimes coexisting explanations for the thrombocytopenia.[43] These include immune-mediated platelet destruction, impaired platelet production secondary to HIV infection of megakaryocytes,[29,30] drug-induced myelosuppression (commonly implicated drugs include zidovudine, ganciclovir, and trimethoprim-sulfamethoxazole), HIV-associated thrombotic microangiopathy, hypersplenism, and marrow infiltration by tumor or opportunistic infections. Platelet kinetic studies have found a complex interaction of decreased platelet production, increased platelet destruction, and splenic platelet sequestration.[44] Immune mechanisms for platelet destruction include antibodies that cross-react with αIIbβ3 complexes ("molecular mimicry")[45] and induce platelet apoptosis,[46] as well as immune complexes containing IgM anti-idiotype antibodies (which could explain the paradox of high levels of platelet-associated IgG and IgM with low serum levels of platelet-reactive antibodies).[47] Anti-HIV chemotherapy (e.g., zidovudine, HAART) often raises the platelet count in patients with HIV-associated thrombocytopenia.[48] Most patients with HIV-associated thrombocytopenia respond to conventional treatments for ITP, including corticosteroids, splenectomy, intravenous immunoglobulin, and, particularly, anti-D.[49]

Macrophage Activation (Hemophagocytic) Syndrome

The macrophage activation (also known as the hemophagocytic) syndrome comprises a heterogeneous group of disorders characterized by fever, hepatosplenomegaly, elevated liver enzymes, cytopenias, and phagocytosis of red cells, granulocytes, and platelets by nonmalignant macrophages; hyperferritinemia, hypercytokinemia, weight loss, and sepsis-like features are characteristic, with high potential for fatal multiple organ failure or fatal complicating infections.[50,51] Table 64.3 lists various causes and diagnostic criteria.[52]

"Primary" hemophagocytic syndrome, also known as familial erythrophagocytic lymphohistiocytosis, is an autosomal-recessive

Table 64.3

Macrophage activation (hemophagocytic) syndrome: causes and diagnostic criteria

Primary
Familial
Secondary
Lymphoma (especially, certain T-cell or natural killer lymphomas)
Infection, especially, viral (e.g., Epstein-Barr virus, cytomegalovirus, HIV), bacterial (e.g., salmonella, brucellosis, mycobacteria, ehrlichiosis), or protozoal (e.g., plasmodia, babesiosis)
Immunosuppressive drugs (especially, transplant patients)
Autoimmune (especially, SLE, juvenile rheumatoid arthritis, ankylosing spondylitis)
Diagnostic criteria (five or more of the following)[a]:
Fever
Splenomegaly
Cytopenias (affecting two or more lineages in the peripheral blood): hemoglobin <90 g/L, platelets <100 × 10^9/L, neutrophils <1 × 10^9/L
Hypertriglyceridemia and/or hypofibrinogenemia triglyceride (fasting) ≥3 mmol/L (≥265 mg/dL) fibrinogen (≤1.5 g/L)
Hemophagocytic in bone marrow, spleen, or lymph nodes
Ferritin >500 μg/L
sCD25 (soluble IL-2 receptor) ≥2,400 U/mL
Low or absent NK-cell activity

[a] Adapted from Henter JI, et al. HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. *Pediatr Blood Cancer* 2007;48:124–131.

disorder that usually presents in infancy or early childhood. The high mortality rate associated with primary hemophagocytic lymphohistiocytosis in children warrants aggressive treatment, including antineoplastic chemotherapy and BMT.

"Secondary" hemophagocytosis affects adults and can be associated with lymphoma, infection (especially Epstein-Barr virus,[53] but also HIV[54]), immunosuppressive drugs (e.g., transplant recipients[55]), or certain autoimmune disorders.[56] Whether infection is the trigger or the consequence of macrophage activation is not always clear.

Thrombocytopenia is usually present, and may be complicated by bleeding, especially when there is concomitant hypofibrinogenemia with or without DIC. Anemia is often profound, reflecting the combination of erythrophagocytosis and the proinflammatory milieu (anemia of chronic disease).

Laboratory indicators of the macrophage activation syndrome include markedly elevated ferritin (often >10,000 μg/L),[57] soluble CD25 (interleukin-2 receptor α-chain), elevated levels of soluble CD163 (a member of the scavenger receptor cysteine-rich family of proteins, accounting for the clearance of hemoglobin–haptoglobin complexes), and morphologic evidence of hemophagocytosis.

Treatment should be directed at the underlying illness. Early administration of corticosteroids and high-dose gamma globulin appear to benefit some patients with the nonneoplastic syndrome.[58]

Envenomation

Snake bite frequently produces a profound consumptive coagulopathy that can be accompanied by thrombocytopenia.[59,60] The toxins present in snake venoms can be activators of the clotting cascade like thrombin-like enzymes (many vipers), prothrombin activators (*Echis* species, Australasian elapids), and factor X activators (Russell's viper), or they can activate platelets directly via the collagen receptor glycoprotein (GP) VI such as convulxin[61] or GPIb such as bilinexin.[62] However, unlike typical DIC, where microthrombosis and organ dysfunction are often present, venom-induced consumption coagulopathy is usually only complicated by bleeding. Nonetheless, a subgroup of patients develops a picture that resembles thrombotic microangiopathy, with renal failure, microangiopathic hemolysis, and thrombocytopenia that persists longer than the coagulopathy.[60] The most important treatment is to administer antivenom as soon as possible.

Pulmonary Embolism

Thrombocytopenia of variable severity can accompany pulmonary embolism. When the thrombocytopenia is severe, there is associated DIC.[63,64] The low platelet count presumably results from thrombin-induced platelet activation and/or platelet accretion within the thromboemboli.[65] Large thromboemboli within pulmonary vasculature may act as a reservoir for clot-bound thrombin that is relatively protected from inhibition by antithrombin-dependent inhibitors.[66] Thrombocytopenia commonly occurs with pulmonary embolism, but not with deep vein thrombosis alone.[67,68]

An important differential diagnosis in patients who develop pulmonary embolism or deep vein thrombosis associated with thrombocytopenia during treatment with heparin either in prophylactic or in therapeutic dose is HIT[68] (see Chapter 108).

Cardiovascular Disorders and Devices

Severe *congenital cyanotic heart disease* is often associated with moderate thrombocytopenia. Underlying mechanisms include a composite of increased platelet consumption due to hyperviscosity, thrombin generation due to venous stasis, and hypoxemia-related decreased platelet production. Reduction of the hematocrit to normal levels can improve hemostasis.[69]

Valvular heart disease can reduce the platelet count to some extent, especially aortic valve stenosis, most likely due to platelet activation. However, the major cause of increased bleeding in these patients is acquired von Willebrand syndrome due to shear-induced accelerated clearance of the largest von Willebrand factor multimers.[70] Endocarditis due to infected cardiac valves can cause severe thrombocytopenia through increased platelet activation, DIC, hypersplenism (subacute endocarditis), and, rarely, autoimmune mechanisms.

Artificial heart valve–associated thrombocytopenia is often caused either by infection of the valve or by a paravalvular leak produced by shear stress–induced platelet activation. However, paravalvular leaks most often produce red cell fragmentation without thrombocytopenia. One aortic bioprosthesis used in Europe is associated with a transient decrease in platelet counts in more than half the patients.[71] The platelet count decrease occurs soon after surgery, with 22% developing severe thrombocytopenia (platelet count $<30 \times 10^9$/L), but usually the platelet counts normalize within 2 to 3 weeks, without an apparent increased risk of thromboembolism or major bleeding. The responsible mechanism is unresolved.

Aortic aneurysms can cause thrombocytopenia because activation of coagulation by the abnormal vessel wall results in thrombin generation.[72] Imaging studies usually reveal adherent thrombus within the aneurysm.

Arterial Dacron vascular grafts can cause a mild decrease in platelet counts. The platelet life span improves over time, presumably because of progressive endothelialization of the implanted foreign material.[73]

Extracorporeal and intravascular devices. Extracorporeal and intravascular devices can induce thrombocytopenia for a number of reasons: their surface may be prothrombotic, causing platelet activation and thrombin generation; they may be located in areas of high shear stress, leading to shear-induced platelet activation; and they may mechanically alter platelets. The latter primarily occurs in intracardiac assist devices.

Cardiopulmonary bypass (CPB). During CPB, there is extensive contact between heparin-anticoagulated blood and the synthetic surfaces of the extracorporeal perfusion device (blood oxygenator). Generally, CPB-associated bleeding results from one or more of the following: thrombocytopenia and/or platelet dysfunction, surgical bleeding, and hyperfibrinolysis. Typically, the platelet count falls by 30% to 70% following CPB, initially due to hemodilution, aggravated by losses within the extracorporeal perfusion device, hypothermia-induced prolonged passage in the spleen, and consumption at sites of bleeding.[74] The thrombocytopenia persists for 3 to 4 days after bypass. Studies have described transient, *intrinsic* defects in platelet function. These include decreased *in vitro* platelet aggregation, decreased platelet surface membrane proteins, selective depletion of platelet α-granules,[75] and evidence of *in vivo* platelet activation and platelet vesiculation. The platelet dysfunction in heart surgery is also attributable to an *extrinsic* platelet defect resulting from thrombin inhibition by the high doses of heparin.[76] However, in most patients, the bleeding time, which rises markedly during heart surgery (>30 minutes), usually improves to <15 minutes shortly after surgery, and to normal within several hours.

Intra-aortic balloon pump. Intra-aortic balloon pumps result in a decrease of about 30% to 40% from the initial value in about half of the patients. Although thrombocytopenia may be caused directly by the device (as its removal often results in a rapid increase in platelet numbers), improved hemodynamic function may also alleviate platelet consumption.[77]

Cardiac (ventricular) assist devices. Various cardiac assist devices are designed to support left, right, or biventricular function. They differ in design (e.g., membrane pumps, roller pumps, high-speed propellors [Impella]) and flow characteristics (continuous, axial). All of these devices activate platelets and several destroy platelets mechanically as well.[78,79] Thrombocytopenia is very frequent in these patients, as are thrombotic and bleeding complications. The mechanisms by which the different devices cause platelet activation and alteration are only partly understood. Recently, acquired von Willebrand syndrome was reported with these devices.[80]

Other organ replacement devices. Hemodialysis, extracorporeal oxygenation, chronic venovenous renal replacement therapy, and plasmapheresis (with or without immunoadsorption) can all induce a mild-to-moderate decrease in platelet count.[81,82] A more pronounced decrease should prompt assessment of the anticoagulant regimen, as platelet consumption resulting from increased thrombin generation due to insufficient anticoagulation can occur. If platelet counts decrease abruptly by more than 50% within the second week after start of extracorporeal treatment devices, HIT should be considered, especially if new clots occur in the device.

Microangiopathic Hemolysis

This is characterized by anemia due to microangiopathic hemolysis (red cell fragments, increased lactate dehydrogenase, reticulocytosis) and thrombocytopenia.[83] Some disorders are well characterized, for example, thrombotic thrombocytopenic purpura (TTP) associated with autoantibodies against ADAMTS13 or hereditary deficiency of this enzyme.[84] The hemolytic–uremic syndrome (HUS, microangiopathic hemolysis and renal failure) is associated with verocytotoxin-associated diarrheal prodrome (typical HUS)[85] or hereditary abnormalities of complement (atypical HUS).[86] Others are associated with bone marrow and stem cell transplantation[87] or with medications.[88] This topic is discussed in detail in Chapter 99.

INCREASED PLATELET DESTRUCTION

Increased platelet destruction—as compared with platelet consumption—indicates reduced platelet life span caused by antibodies, such as autoantibodies, alloantibodies, or drug-dependent antibodies, which usually target platelet surface GPs. In contrast to most of the other causes of thrombocytopenia discussed above, platelet counts decrease significantly and severe thrombocytopenia ($<20 \times 10^9$/L) is often present.[89] With the exception of HIT (discussed in Chapter 108), platelets are not activated in the circulation. Mucocutaneous bleeding is the predominant complication. Immune-mediated thrombocytopenias are summarized in Table 64.4 and described in detail in Chapters 61 and 62.

SPECIALIZED TOPICS

Thrombocytopenia in the Intensive Care Unit Patient

The many comorbidities in the severely ill patient also make thrombocytopenia very common, occurring in 35% to 45% of patients in ICUs, although only 5% to 20% are severely thrombocytopenic.[4,90–95,96,97–104] About half of patients in ICUs have a low platelet count at admission ("prevalent" thrombocytopenia), the others develop thrombocytopenia during their ICU stay ("incident" thrombocytopenia).[96] This section provides a framework to differentiate among the various causes of acquired thrombocytopenia in this patient population.

Hemodilution and increased platelet consumption are very common causes of moderate thrombocytopenia after tissue

trauma, bleeding, or DIC. Severe thrombocytopenia with platelet counts <20 × 10^9/L can be due to bone marrow failure (e.g., acute leukemia), sepsis with severe coagulopathy, or immune-mediated platelet destruction. In particular, acute TTP (Chapter 99) needs to be recognized because these patients require plasma exchange. In endemic areas, malaria and viral hemorrhagic fever are important causes.

Thrombocytopenia is a marker of illness severity,[105,106] and an adverse prognostic marker predicting for prolonged ICU stay and mortality (mortality rate 31% to 46% in thrombocytopenic patients vs. 16% to 20% nonthrombocytopenic patients).[91–93,95,96,97,98,102] In contrast, it is unclear whether thrombocytopenia—other than very severe thrombocytopenia (platelet count, <10 × 10^9/L)—is a risk factor for bleeding.[107] Other factors that interfere with normal hemostasis, such as platelet function defects, hyperfibrinolysis, invasive procedures, or catheters, may be more relevant. Even if not associated with bleeding, low platelet counts often influence patient management and may prompt physicians to withhold or delay necessary invasive interventions, reduce the intensity of anticoagulation, order prophylactic platelet transfusion, or change anticoagulants inappropriately (e.g., due to unfounded fear of HIT).

When acute thrombosis complicates thrombocytopenia, one needs to consider the occurrence of severe pulmonary embolism with associated DIC,[63–65] diabetic ketoacidosis,[108] antiphospholipid syndrome (see Chapter 101),[109] and HIT (see Chapter 108).[1,6,89]

One approach to differentiating between different causes of thrombocytopenia in this setting is to consider the timing of onset of the platelet count changes (FIGURE 64.2).[4] In the vast majority of patients, the initial decrease in platelet counts within the first 2 to 4 days after trauma/surgery is transient and platelet counts reach the presurgery level at about postoperative day 5 to 7. A blunted or absent rise in platelet counts after day 4, however, is strongly associated with mortality and prolonged ICU admission and is a stronger predictor for mortality than the platelet count nadir during early ICU stay.[95,99,102,110] Prolonged thrombocytopenia is often caused by severe infection (e.g., bacterial sepsis, fungemia, endocarditis) or multiorgan failure. Moderate thrombocytopenia can be caused by sepsis alone, but when the platelets fall below 50 × 10^9/L, DIC is frequently present.[38]

A rare but important cause of severe thrombocytopenia manifesting at day 2 to 3 after surgery is *postsurgery TTP*.[111,112] Postsurgery TTP is presumably triggered by increased release of von Willebrand factor from endothelial cells as a response to major surgery on a background of low activity of ADAMTS13, either due to preexisting "compensated" anti-ADAMTS13 antibodies or due to mutations in the enzyme resulting in reduced activity. In contrast, a rapidly progressive platelet count decrease (e.g., occurring over a 1 to 3-day period) and that begins on day 5 or later (most often during the second week) strongly suggests an immunological cause (FIGURE 64.2). Relatively common examples include immune HIT (Chapter 108)[6] and drug-induced immune thrombocytopenic purpura (D-ITP), typically induced by drugs started within the last 2 weeks (Chapter 62).[113] Rare examples include αIIbβ3 inhibitor–induced thrombocytopenia of delayed onset in patients (see Chapter 62)[114] and post-transfusion purpura (PTP) (see Chapter 61).[115]

Occasionally, thrombocytopenia can begin abruptly within a few hours of the inciting event and can be due to passive alloimmune thrombocytopenia (PAT)[116] caused by transfusion of platelet-reactive alloantibodies, transfusion of bacterially contaminated blood products,[117] and rapid-onset HIT occurring in a patient with circulating HIT antibodies as a result of recent heparin exposure.[6] HIT is relatively rare in the ICU setting with an incidence of about 0.3% to 0.5%[96,118]. HIT usually features a platelet count fall >50% (from the highest value after day 4 of heparin treatment), most often to a nadir between 20 and 100 × 10^9/L, and can present with new thrombosis, typically occurring 5 to 14 days after start of prophylactic or therapeutic doses of heparin.[89] Timing of onset, the moderate nature of thrombocytopenia, and the common concurrence of thrombosis are very important factors differentiating HIT from other causes of thrombocytopenia in the ICU. Patients with early-onset thrombocytopenia or a platelet count <20 × 10^9/L usually do not have HIT.

Thrombocytopenia in Pregnancy

This topic is considered in detail in Chapter 118. Briefly, pregnancy-associated thrombocytopenia is a benign condition (gestational thrombocytopenia) that appears to be nonimmune in nature and is partly caused by dilution due to the increased plasma volume, although the exact cause is not well understood. Increased platelet consumption is the likely reason for thrombocytopenia associated with preeclampsia/eclampsia, the hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome, and in coagulopathies associated with a retained fetus, placental abruption, amniotic fluid embolism, endometritis, or severe hemorrhage. Pregnancy is also associated with an increased risk for autoimmune disorders such as ITP (Chapter 61) and HUS/TTP (Chapter 99).

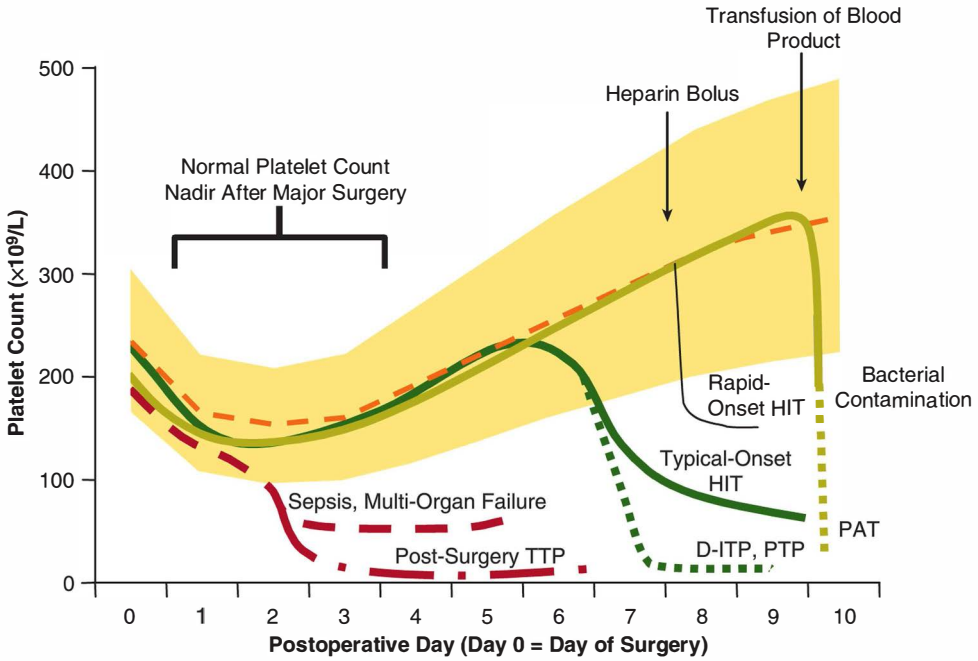

FIGURE 64.2 Timing of onset and severity of thrombocytopenia: implications for differential diagnosis. The usual postoperative platelet count nadir is seen between postoperative days 1 and 3 (inclusive). Early and progressive platelet count declines often reflect severe postoperative complications such as sepsis and multiorgan failure; severe thrombocytopenia can (rarely) indicate postsurgery thrombotic thrombocytopenic purpura (TTP). Thrombocytopenic disorders that begin approximately 1 week after surgery are often immune mediated: moderate thrombocytopenia can indicate heparin-induced thrombocytopenia (HIT), both "typical onset" and (if heparin is not being given) "delayed onset"; very severe thrombocytopenia can indicate drug-induced immune thrombocytopenic purpura (D-ITP) or (rarely) posttransfusion purpura (PTP). An abrupt decline in platelet count after receiving a heparin bolus in a patient who has received heparin within the past 7 to 100 days can indicate "rapid-onset" HIT; thrombocytopenia that begins abruptly after transfusion of a blood product can indicate sepsis from bacterial contamination or (rarely) passive alloimmune thrombocytopenia (PAT) due to transfusion of platelet-reactive alloantibodies.

CHAPTER

65 Inherited Disorders of Platelet Function

JOEL S. BENNETT AND A. KONETI RAO

Prolongation of the bleeding time in a patient with a normal platelet count suggests the presence of either von Willebrand disease (vWD) or impaired platelet function. vWD is discussed in Chapter 52, and acquired disorders of platelet function are discussed in Chapter 66. Inherited disorders of platelet function will be considered in this chapter. For the purposes of this discussion, these disorders will be classified into disorders of platelet adhesion, aggregation, secretion, or procoagulant activity according to the predominant aspect of platelet function affected.

DISORDERS OF PLATELET ADHESION

Bernard-Soulier Syndrome (Glycoprotein Ib-IX-V Deficiency)

The Bernard-Soulier syndrome (BSS), a rare hemostatic disorder characterized by a prolonged bleeding time, very large platelets, and thrombocytopenia, was described by Bernard and Soulier[1] in 1948. Patients with BSS bleed because their platelets cannot adhere to von Willebrand factor (vWF), a consequence of deficiency or dysfunction of the platelet membrane glycoprotein (GP) Ib-IX-V (GPIb-IX-V) complex.[2–4]

Following disruption of the vascular endothelium, circulating platelets can adhere to exposed subendothelial connective tissue components such as collagen, fibronectin, and laminins. However, at the higher shear rates present in arterioles and the microcirculation, platelet adhesion requires the additional presence of vWF.[5,6] vWF is an elongated multimeric GP, each monomer of which contains two motifs that interact with receptors on platelets[7] (see Chapter 52). One motif, located in the A1 domain of vWF, mediates transient vWF binding to the GPIb-IX-V complex on unactivated platelets. The second motif, located in the C1 domain, mediates the stable interaction of vWF with the integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) on activated platelets.[8] Although vWF in plasma cannot bind spontaneously to GPIb-IX-V,[9] exposing soluble vWF to the antibiotic ristocetin or the snake venom protein botrocetin *in vitro* enables it to bind to GPIb-IX-V.[10,11] The physiologic correlates for ristocetin and botrocetin are unclear. It is possible that the A1 domain of subendothelial vWF, but not soluble vWF, has a conformation allowing it to bind to GPIb-IX-V.[12] It is also that shear stress changes the conformation of the A1 domain, GPIb-IX-V, or both, enabling vWF binding to GPIb-IX-V.[13]

GPIb-IX-V is a noncovalent transmembrane heterotrimer consisting of the heavily glycosylated 165,000 mol. wt. protein GPIb,[14] the 20,000 mol. wt. protein GPIX,[15] and the 82,000 mol. wt. protein GPV.[16] The structure of GPIb-IX-V is discussed in detail in Chapter 26A. There are approximately 25,000 copies of GPIb and GPIX on the platelet surface but only half as many copies of GPV, suggesting that individual GPIb-IX-V complexes contain two copies of GPIb, two copies of GPIX, and one copy of GPV. GPIb itself is a heterotrimer containing one copy of a 143,000 mol. wt. α subunit (GPIbα) and two disulfide linked copies of a 22,000 mol. wt. β subunit (GPIbβ).[17] GPIbα can be cleaved by trypsin or a calcium-dependent platelet protease into a soluble 135,000 mol. wt. heavily glycosylated amino (*N*)-terminal fragment glycocalicin.[18] The *N*-terminal portion of glycocalicin contains binding sites for vWF and thrombin, while its *C*-terminal portion contains a variable number of tandem 13 residue mucin-like repeats to which multiple sialic acid-rich O-linked hexasaccharides are appended.[19,20] The cytosolic portion of GPIbα binds to the *C*-terminus of filamin A (actin-binding protein),[21,22] linking GPIbα to the platelet cytoskeleton.[23] It binds to the adaptor protein 14-3-3ζ as well, linking GPIbα to platelet signaling pathways.[24–26] The cytosolic portion of GPIbβ can be phosphorylated at Ser166 by cyclic AMP-dependent protein kinase A,[27] a reaction that inhibits collagen-induced platelet actin polymerization.[28] A role for GPV in GPIb-IX-V function is unclear. Although GPV can be cleaved by thrombin,[29] this is not required for vWF binding to GPIbα, nor does it activate platelets.[30]

The *N*-terminal portion of GPIbα, as well as GPIbβ, GPIX, and GPV, contain leucine-rich repeats (LRRs) with the consensus sequence L-L–N-L–LPPGLL-G—L-.[16,31] GPIbα contains eight LRR,[9] whereas GPIbβ and GPIX contain one each and GPV contains 15. The amino acids flanking the LRR are also conserved.[31] A crystal structure for the vWF A1 domain bound to residues 1 to 290 of GPIbα revealed that LRRs 1 and 5 to 8 of GPIbα bind tightly to the A1 domain.[9] Conformational changes in a flexible loop located near the C-terminus of the GPIbα fragment, termed the "β-switch"[9] or "R-loop,"[32] may be needed for vWF binding to GPIbα. This portion of GPIbα is the site of several gain-of-function mutations responsible for platelet-type vWD.[9] The function of the LRR in GPIbβ, GPIX, and GPV is unknown, but they do not participate in intermolecular interactions as "leucine-zippers."

Biosynthetic studies using recombinant GPIb-IX-V revealed that although small amounts of GPIbα can be detected on the surface of cells expressing GPIbα and GPIbβ, GPIbα expression is much more efficient when the cells coexpress GPIbα, GPIbβ, and GPIX.[33] Thus, mutations that result in the deficient expression of either GPIbα, GPIbβ, or GPIX can produce the BSS. On the other hand, GPV is not required for GPIb-IX-V expression and why it is absent from BSS platelets is not known.[34]

Clinical Manifestations

BSS presents in infancy or childhood with ecchymoses, epistaxis, and gingival bleeding.[16] Later manifestations include menorrhagia and postpartum, gastrointestinal, and posttraumatic

hemorrhage. Hemarthroses and expanding hematomas are unusual. Although the severity of bleeding is variable and may not always correlate with the extent of thrombocytopenia and the degree of GPIb-IX-V deficiency,[35] it can be severe enough to require transfusion and suppression of menses. In a review of 59 patients, for example, there were 10 deaths.[36] In some patients with BSS, the severity of hemorrhage inexplicably declines over the course of the disease.[36]

Laboratory Findings

The bleeding time in patients with BSS is markedly prolonged to >20 minutes.[16] Most patients are thrombocytopenic to some degree, and platelet counts <20,000/μL have been reported.[37] Nonetheless, platelet counts vary within kindreds and even in individual patients. BSS platelets are large when observed on peripheral blood smears[16]; 30% to 80% have mean diameters >3.5 μm, and occasional platelets are as large as 20 to 30 μm in diameter.[38] There is contradictory evidence about the size of BSS platelets in the circulation. It has been reported that circulating BSS platelets are normal in size[39] but have increased membrane, perhaps located in the surface-connected open-canalicular system that is extruded when platelets spread during the preparation of a blood smear.[40] Others have reported that the volume of circulating BSS platelets is increased[41] and that they have a more spherical shape[41] with a more deformable membrane.[42] The molecular basis for the macrothrombocytopenia of BSS is not known. However, amelioration of the macrothrombocytopenia when an IL4-GPIbα fusion protein was expressed in a murine BSS model suggests that absence of the GPIbα cytoplasmic domain contributes to this abnormality.[43]

Erythrocytes and white blood cells are normal in BSS. Distinctive abnormalities have not been observed in marrow megakaryocytes by light microscopy,[44] although demarcation membrane system abnormalities have been observed by electron microscopy.[45] The laboratory tests that distinguish BSS from normal platelets are the failure of BSS platelets to agglutinate in the presence of ristocetin or botrocetin and the failure of vWF to restore agglutination (FIGURE 65.1).[16] Aggregation of BSS platelets in response to ADP, collagen, and epinephrine is normal.[16] However, the rate of thrombin-stimulated aggregation can be reduced.[46]

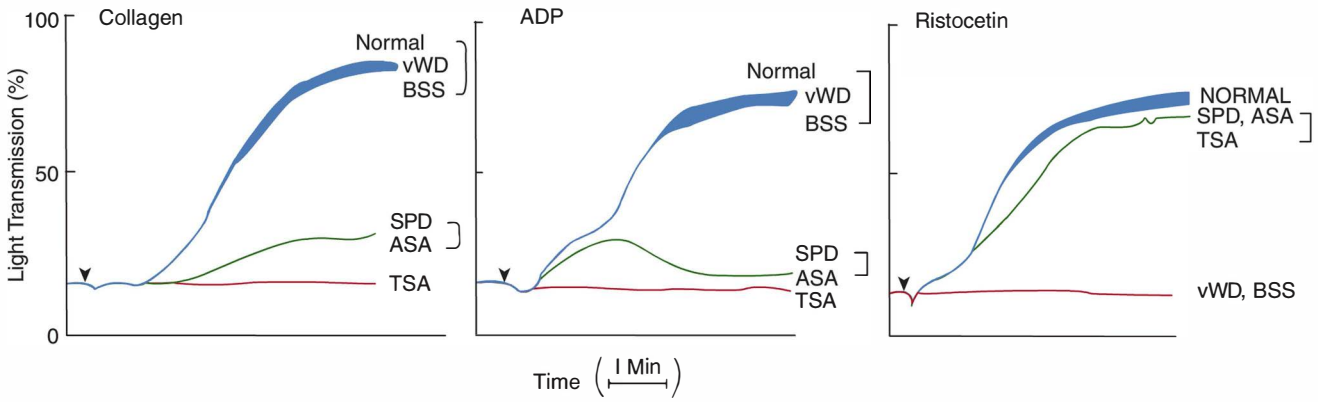

FIGURE 65.1 Platelet aggregation in various platelet disorders. Platelet aggregation can be studied *ex vivo* by a variety of techniques. Conventional turbidometric platelet aggregometry is performed in an "aggregometer" using stirred suspensions of either unwashed platelets in plasma or washed platelets in buffer. Immediately after the addition of all platelet agonists except epinephrine, there is a transient decrease in light transmittance that has been attributed to platelet shape change. This is followed by an increase in light transmission as platelet aggregates form. Two "waves" of platelet aggregation have been described. The "first wave" represents primary aggregation and is a direct consequence of agonist stimulation. The "second wave" represents secondary aggregation and is due to the formation of large irreversible aggregates when platelet secretion occurs. If the concentration of platelet agonist is sufficiently high, the first and second waves merge into a single continuous tracing. Measurements of platelet aggregation are expressed as either the extent or the rate of increase in light transmittance that occurs as platelet aggregates form.

The turbidometric aggregometer has been modified to simultaneously measure platelet aggregation and platelet dense granule secretion using the luciferin–luciferase reaction to measure secretion of dense granule ATP (lumiaggregometry). Platelet aggregation can also be measured in diluted anticoagulated whole blood based on the increase in electrical impedance (measured in ohms) that occurs as platelet aggregates accumulate on a pair of electrodes inserted into the suspension of aggregating platelets (impedance aggregometry). Impedance aggregometry tracings are similar to those obtained by the turbidometric method, except that shape change and two waves of aggregation are not seen. Lastly, because aggregometry is insensitive to the formation of small platelet aggregates, methods have been devised to measure the disappearance of single platelets immediately after platelet stimulation. Agonists are added to stirred platelet suspensions and after adding a fixative to stabilize the aggregates, their number and size are measured either visually with a hemocytometer or using an electronic particle counter or flow cytometer.

The platelet aggregation tracings shown in the figure were generated in a conventional turbidometric platelet aggregometer after the addition of collagen, ADP, and ristocetin to stirred aliquots of platelet-rich plasma. vWD, von Willebrand disease; BSS, Bernard-Soulier syndrome; SPD, storage pool disease; ASA, aspirin; TSA, Glanzmann thrombasthenia. (Adapted from Weiss HJ. Platelet physiology and abnormalities of platelet function (second of two parts). *N Engl J Med* 1975;293:580–588, with permission.)

Although the serum prothrombin time has been reported to be decreased in BSS[47] and both collagen-induced platelet procoagulant activity and factor XI binding to be absent,[48] prothrombin consumption has also been reported to be normal[49] and platelet procoagulant[49] and prothrombinase activity to be increased.[50] An unexplained decrease in thrombin-, trypsin-, and thromboxane-stimulated phospholipase C (PLC) activity has also been reported.[51] GPIb-IX-V can be a target for drug-dependent antiplatelet antibodies[52]; such antibodies fail to bind to BSS platelets.[53]

Genetics

BSS is an autosomal recessive disorder.[16] In most instances, GPIb-IX-V is not present on the surface of BSS platelets, but in a few cases, 7% to 47% residual GPIb or GPIb-IX has been detected.[54] Many, but not all, obligate BSS heterozygotes have platelets that are larger than normal and a content of GPIb intermediate between normal and affected individuals.[38,55] Consistent with its rarity, consanguinity has often been present in affected families.

The gene for GPIbα is located on chromosome 17p12-ter, the GPIbβ gene on chromosome 22q11.2, the GPIX gene on chromosome 3q21, and the GPV gene on chromosome 3q29.[16] Each gene has a compact "intron-depleted" structure; the genes for GPIbα, GPIbβ, and GPV each contain two exons and the gene for GPV contains three.[56] The open reading frame and 3′ untranslated region of each gene is encoded by a single exon except for GPIbβ where its single intron is inserted into the codon for the fourth residue of its signal peptide.[57] Like other genes expressed by megakaryocytes, the 5′ flanking region of each gene contains potential binding sites for the transcription factors GATA, Ets, and Sp-1.[58–60] In addition, polymorphic variation in the region surrounding the GPIbα translation initiation site appears to be a determinant of the level of GPIb-IX-V expression.[61]

As shown in FIGURE 65.2, at least 56 different mutations responsible for BSS have been identified in the genes for GPIbα, GPIbβ, and GPIX.[62] Most are missense mutations or nucleotide deletions and insertions resulting in frameshifts and premature stop codons. However, several unique mutations have been identified: deletion of the entire GPIbβ locus on chromosome 22q11.2, occasionally in the setting of the velocardiofacial syndrome[63,64]; a more circumscribed homozygous deletion of the *GPIBB* locus that included *SEPT5* gene resulting in the BSS, cortical dysplasia, developmental delay, and a platelet secretion defect[65]; a C to G transversion in the GATA binding site of the GPIbβ promoter resulting in decreased GPIbβ gene transcription[66]; and an Ala140Thr in the transmembrane domain of GPIX.[67,68] The latter is noteworthy because it is consistent with observations that transmembrane domain interactions

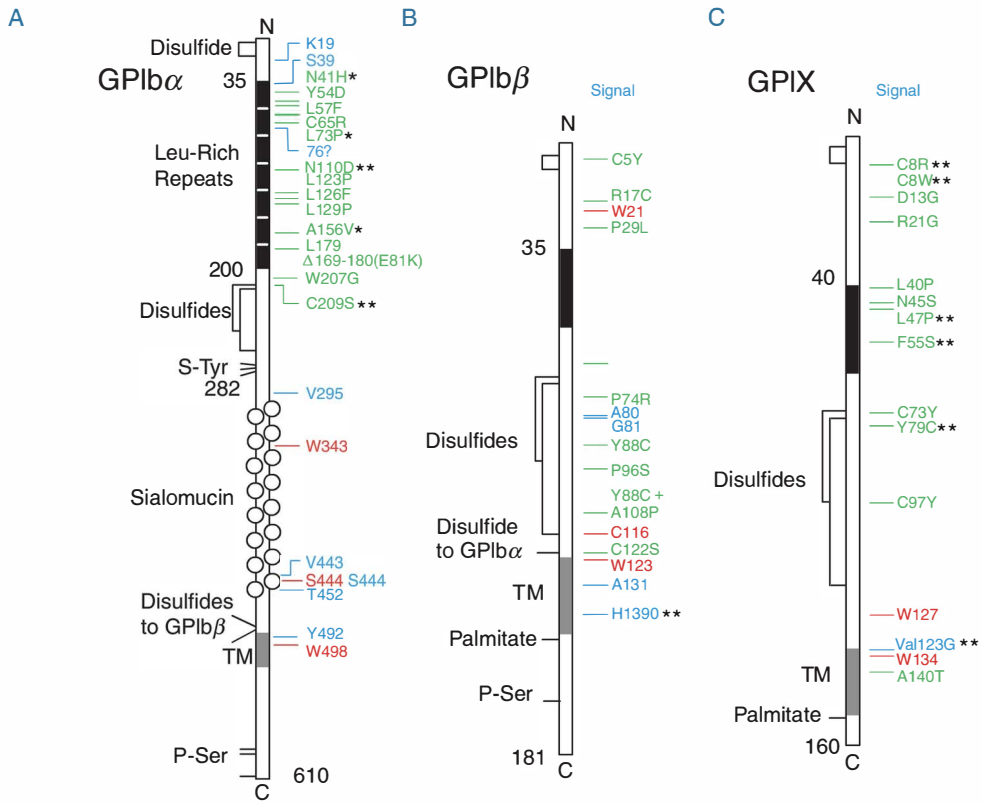

FIGURE 65.2 Mutations in the genes for GPIbα, GPIbβ, and GPIX causing the BSS mapped onto the structures of the mature proteins. *Green*, missense mutations and short deletions; *red*, nonsense mutations leading to premature stop; and *blue*, frameshift mutations leading to stop. *, autosomal dominant inheritance; **, mutations discussed in Savoia A, Pastore A, de Rocco D, et al. Bernard-Soulier syndrome. *Haematologica* 2011;96:355–359, with permission.)

Table 65.1

Differential diagnosis of inherited macrothrombocytopenia

Disorder	Ristocetin Response	Features	Bleeding Diathesis
BSS	No	GPIbα, GPIbβ, GPIX mutations	Yes
MHY9-related disorders	Yes	Leukocyte inclusions, deafness, nephritis, deafness, cataracts	Uncommon
Gray platelet syndrome (GPS)	Yes	Platelet α-granule deficiency	Yes
Montreal platelet syndrome	Yes	Heterozygous for V1316M mutation in exon 28 of vWF producing platelet type vWD	Yes
Mediterranean macrothrombocytopenia	Yes	Heterozygosity for BSS?	No
Mediterranean stomatocytosis/ macrothrombocytopenia	Yes	Phytosterolemia due to *ABCG 5* and *8* genes mutations	Yes
GATA-1 mutations	Decreased	X-linked inheritance, can be associated with dyserythropoiesis ± anemia	Yes
Sialyl-Lewis-S antigen deficiency	—	Progressive thrombocytopenia, hypogranular platelets, decreased GPIb, neutropenia	Yes
Paris-Trousseau syndrome	Yes	Part of Jacobson syndrome; caused by loss of the transcription factor FLI1 due to deletion of the long arm of chromosome 11	Yes
Filamin A mutations	Yes	X-linked disorder; usually associated with periventricular nodular heterotopia and the otopalatodigital syndrome	Yes
Platelet-type vWD	Yes	Hypersensitivity to ristocetin; GPIbα mutations causing spontaneous vWF binding to platelets	Yes
Type 2B vWD	Yes	Hypersensitivity to ristocetin; vWF mutations causing spontaneous vWF binding to platelets	Yes

are involved in efficient GPIb-IX-V expression[69] and with the impairment of GPIb-IX expression observed when the GPIbβ transmembrane domain was mutated *in vitro*.[70] The monoallelic GPIbα mutation Ala156Val, known as the "Bolzano mutation," has been reported to be the most common cause of inherited thrombocytopenia in Italy. It has been associated with a mild bleeding diathesis, a variable degree of thrombocytopenia, and a modest but consistent increase in platelet diameter and volume.[71] It is also noteworthy that many BSS mutations have been reported multiple times, suggesting that there may be "hot spots" for mutation in the GPIbα, GPIbβ, and GPIX genes.

Differential Diagnosis

BSS must be differentiated from other conditions that are associated with large platelets and thrombocytopenia (macrothrombocytopenia). Inherited disorders associated with macrothrombocytopenia are listed in Table 65.1 and can be readily differentiated from BSS because BSS platelets fail to agglutinate in the presence of ristocetin (FIGURE 65.1).[72] Many of these conditions are discussed in detail in Chapter 64.

Macrothrombocytopenia is a characteristic feature of mutations in the *MYH9* gene located on chromosome 22q12.3-q13.2 encoding the nonmuscle myosin heavy chain IIA (NMMHC-IIA).[73,74] Previously, these MYH9 disorders were segregated into four separate autosomal dominant inherited syndromes—the May-Hegglin anomaly and the Sebastian, Fechtner, and Epstein syndromes—based on the presence or absence of Döhle body-like leukocyte inclusions, hereditary nephritis, cataracts, and sensorineural deafness.[75] However, because each results from mutations in the *MYH9* gene, it now seems appropriate to consider them as a single entity whose variability results from the variable expression of *MHY9* mutations and whose common feature is macrothrombocytopenia. In general, the function of platelets affected by *MHY9* mutations is normal,[76–78] and if hemorrhage occurs, it is usually due to thrombocytopenia.[79]

Macrothrombocytopenia also occurs in the gray platelet syndrome (GPS), a disorder resulting from platelet α-granule deficiency[80] and due, at least in some cases, to mutations in the gene *NBEAL2* (see below).[81–83] In contrast to BSS platelets, GPS platelets are pale gray on Wright-stained blood smears and agglutinate normally in the presence of ristocetin.[84] In a reevaluation of the Montreal platelet syndrome, large platelets, thrombocytopenia, and spontaneous platelet aggregation were found to be due

to type 2B vWD caused by a heterozygous V1316M mutation in exon 28 of the vWF gene.[85,86] Mediterranean macrothrombocytopenia refers to putative differences in platelet count and size between Europeans of Northern and Mediterranean origin[87]; in Italy, this may be due to heterozygosity for BSS, in particular heterozygosity for the "Bolzano mutation" Ala156Val.[88] Mediterranean stomatocytosis/macrothrombocytopenia, the rare combination of stomatocytic hemolysis and macrothrombocytopenia, results from excess plant sterols in the blood and is caused by mutations in the *ABCG5* and *ABCG8* genes linked to phytosterolemia.[89] Several reported patients had significant bleeding histories. Sex-linked macrothrombocytopenia occurs in patients with GATA-1 transcription factor mutations,[90–92] and macrothrombocytopenia with dystrophic megakaryocytes and neutrophils lacking sialyl-Lewis-S antigen was described in an infant who died at 37 months due to hemorrhage.[93] In the Paris-Trousseau syndrome,[94] a part of the Jacobsen syndrome,[95] a deletion of the long arm of chromosome 11 at q23.3 containing the gene for the transcription factor FLI1 results in mild thrombocytopenia, subpopulations of large platelets and platelets containing giant α-granules, and the expansion of immature megakaryocyte progenitors.[96] Mutations in the filamin A gene located on chromosome Xq28 are responsible for periventricular nodular heterotopia and the otopalatodigital syndrome; macrothrombocytopenia and bleeding, misinterpreted as ITP, has been present in some patients.[97] In platelet-type vWD, mutations within the vWF binding domain of GPIbα induce spontaneous vWF binding to GPIbα and the clinical picture of type IIB vWD which itself can be associated with macrothrombocytopenia.[9,98–102] There are also anecdotal reports of thrombocytopenia and giant platelets, often associated with a mild bleeding diathesis but lacking the features of either BSS or the *MHY9* disorders.[103,104] In two other reports, macrothrombocytopenia was associated with the presence of large platelet granules whose origin was uncertain.[105,106]

Acquired BSS-like disorders can be differentiated from the congenital BSS by history. GPIb antibodies occur in some patients with idiopathic thrombocytopenic purpura[107]; whether the antibodies themselves are responsible for bleeding is not clear because of concomitant thrombocytopenia. Two patients with myelodysplasia and a BSS-like syndrome have been reported,[108,109] as has a patient with a lymphoproliferative disorder and a circulating IgG antibody that inhibited ristocetin-induced platelet agglutination, but was directed against an unidentified 210,000 mol. wt. platelet protein.[110]

Therapy

Treatment of hemorrhage in patients with the BSS usually requires platelet transfusion.[111] Hormonal control of menses has been effective in managing menorrhagia.[112] Splenectomy has been attempted to increase the platelet count[113] but has resulted in only transient increases and has not ameliorated the platelet function defect. Corticosteroids are not beneficial in this disorder. Desmopressin acetate (DDAVP) has been reported to shorten the bleeding time in some, but not all, affected individuals in whom it has been administered,[114–117] but its efficacy in patients with hemorrhage is unclear. Antifibrinolytics such as epsilon aminocaproic acid and tranexamic acid can be useful adjuncts to other therapy.[118] A number of anecdotal reports suggest that recombinant VIIa may be effective in the treatment of hemorrhage in BSS patients, although the degree of effectiveness has varied.[119–123] Lastly, bone marrow transplantation from HLA-identical donors has been performed successfully in patients with BSS.[124,125]

DISORDERS OF PLATELET AGGREGATION

Glanzmann Thrombasthenia (Integrin $\alpha_{IIb}\beta_3$ [Glycoprotein IIb-IIIa] Deficiency)

Thrombasthenia, described by Glanzmann[126] in 1918, is a rare bleeding disorder characterized by a prolonged bleeding time, a normal platelet count, and absent macroscopic platelet aggregation (see FIGURE 65.1).[127] Platelets from affected individuals are unable to aggregate because of a deficiency or dysfunction of the major platelet integrin $\alpha_{IIb}\beta_3$, also as known as GPIIb-IIIa.[128]

Platelet aggregation is essential for the formation of a hemostatic platelet plug.[129] In contrast to platelet adhesion, platelet aggregation is an active metabolic process, requiring platelet stimulation by agonists such as thrombin, collagen, and ADP and exposure of a binding site for fibrinogen or vWF on the integrin $\alpha_{IIb}\beta_3$.[130–132] $\alpha_{IIb}\beta_3$-bound fibrinogen or vWF then cross-links adjacent platelets into an occlusive plug. $\alpha_{IIb}\beta_3$, like other members of the integrin family, resides on the cell surface in an equilibrium between inactive (low affinity) and active (high affinity) conformations.[133,134] Platelet stimulation shifts $\alpha_{IIb}\beta_3$ to its active conformation, enabling it to bind ligands and mediate platelet aggregation.[134] Platelet stimulation also enables interaction of the $\alpha_{IIb}\beta_3$ cytoplasmic tails with submembranous actin filaments, providing a link between the force of cytoskeletal contraction and a fibrin clot, resulting in clot retraction.[135,136]

$\alpha_{IIb}\beta_3$ is a calcium-dependent heterodimer and dissociates into α_{IIb} and β_3 monomers in the presence of calcium chelators.[137] In rotary-shadowed electron micrographs, $\alpha_{IIb}\beta_3$ appears as a 12 × 8 nm globular head with two 18-nm stalks extending from one side.[138] When incorporated into phospholipid vesicles, the globular head extends ≈20 nm above the vesicle surface with the tips of the tails inserted into the phospholipid.[139]

α_{IIb} itself has an unreduced molecular weight of 136,000 and dissociates into a 125,000 mol. wt. heavy chain ($\alpha_{IIb}\alpha$) and 23,000 mol. wt. light chain ($\alpha_{IIb}\beta$) following disulfide bond reduction.[137] α_{IIb} is synthesized as single chain precursor (Pro-GPIIb) in the rough endoplasmic reticulum (ER)[140] where it associates with β_3. The resulting heterodimer is transported to the Golgi complex where Pro-α_{IIb} is cleaved into heavy and light chains.[141] In contrast to α_{IIb}, β_3 is a single chain protein containing 56 cysteine residues and 28 disulfide bonds[142]; its apparent molecular weight of 90,000 on unreduced sodium dodecyl sulfate gels increases to 110,000 following disulfide bond reduction.[137] The disulfide bonds in β_3 are concentrated in three regions of the extracellular portion of the molecule: a cysteine-rich, protease-resistant amino terminus (residues 1 to 62), a protease-sensitive central region (residues 101 to 422), and a disulfide-rich, protease-resistant core (residues 423 to 622).[143]

In the absence of heterodimer formation, α_{IIb} and β_3 monomers are retained in the ER and eventually degraded.[144] The factors responsible for the retention of uncomplexed monomers are unknown. However, it is clear from studies of various thrombasthenic mutants that formation of $\alpha_{IIb}\beta_3$ heterodimers alone is not sufficient to guarantee egress of $\alpha_{IIb}\beta_3$ from the ER.[144,145]

There are approximately 80,000 copies of $\alpha_{IIb}\beta_3$ on the surface of unstimulated platelets.[146] Glanzmann thrombasthenia

(GT) results when platelets lack sufficient numbers of functional $\alpha_{IIb}\beta_3$ to support platelet aggregation.[128] However, the platelets of obligate thrombasthenic heterozygotes aggregate normally, indicating that 50% of the normal amount of $\alpha_{IIb}\beta_3$ is at least sufficient to support platelet aggregation.[147]

Platelets express a second β_3-containing integrin, $\alpha_v\beta_3$, the vitronectin receptor.[148] There are 50- to 500-fold fewer copies of $\alpha_v\beta_3$ than $\alpha_{IIb}\beta_3$ on platelets.[149,150] While $\alpha_{IIb}\beta_3$ expression is restricted to cells of the megakaryocytic lineage,[151] $\alpha_v\beta_3$ is expressed by a variety of cells including endothelial cells, smooth muscle cells, and osteoclasts.[152]

Clinical Manifestations

The clinical manifestations of GT in a large cohort of patients have been described in detail.[127] GT typically presents with mucocutaneous bleeding during the neonatal period or infancy, occasionally with bleeding following circumcision. Spontaneous petechiae are uncommon and bleeding generally results from conditions that would also cause bleeding in an otherwise normal individual. Thus, epistaxis is a frequent type of bleeding, especially during childhood, as are gingival bleeding and menorrhagia. Bleeding at menarche may be severe and require transfusion. Similarly, parturition represents a severe hemorrhagic risk. Other hemorrhagic manifestations include gastrointestinal bleeding and hematuria, but hemarthroses and deep hematomas are unusual. Serious bleeding may follow trauma or surgery. However, the severity of hemorrhage in thrombasthenia is not predictable, even within single kindreds, and does not correlate with the degree of $\alpha_{IIb}\beta_3$ deficiency. The apparent decline in the clinical severity of GT with age is likely due to a decrease in the incidence of conditions such as epistaxis with aging.

Laboratory Findings

Platelet counts and platelet morphology on peripheral blood smears are normal. The bleeding time of affected individuals is markedly prolonged.[153] A diagnosis of GT is usually suspected when platelet aggregometry reveals absent agonist-stimulated platelet aggregation (see FIGURE 65.1). Platelet secretion induced by strong agonists such as thrombin is normal, but secretion in response to weak agonists such ADP and epinephrine which requires platelet aggregation does not occur. Coagulation tests, such as the prothrombin time and the partial thromboplastin time, are normal in GT, whereas clot retraction in the presence of GT platelets is absent or reduced.

In addition to their inability to aggregate, GT platelets do not spread normally on the subendothelial matrix because of an impaired ability to interact with fibronectin and vWF in the matrix.[154] The amount of fibrinogen in the α-granules of GT platelets is decreased to absent.[127] Human megakaryocytes do not synthesize fibrinogen, but rather, it is derived from plasma by an $\alpha_{IIb}\beta_3$-mediated endocytic process.[155–159] A number of biochemical reactions in platelets that require the presence of $\alpha_{IIb}\beta_3$ are impaired in GT platelets. For example, the tyrosine phosphorylation of multiple intracellular signaling proteins depends on ligand binding to $\alpha_{IIb}\beta_3$ and does not occur in GT platelets.[160] Calpain, a calcium-dependent thiol protease, is activated when stirred normal platelets are stimulated by thrombin, but not when GT platelets are treated in a similar manner.[161] The kinetics of calcium exchange in unstimulated GT platelets is inexplicably decreased[162] since it is not clear what role, if any, $\alpha_{IIb}\beta_3$ plays in calcium transport.[163,164] Clot retraction in blood containing GT platelets is either absent or reduced.[127,135]

Aspects of platelet function that do not depend on $\alpha_{IIb}\beta_3$ are normal in GT. GT platelets interact normally with collagen[153] and undergo secretion when stimulated by "strong agonists" such as thrombin.[165] Incubation of GT platelets with ristocetin induces vWF binding to GPIb-IX-V[10] and GT platelets adhere to vWF in the subendothelium.[154] GT platelets also express normal amounts of procoagulant activity following lysis.[50] However, agonist-stimulated prothrombinase activity varies and is influenced by the nature of platelet agonist.[50,166]

Genetics

The genes for α_{IIb} and β_3 are located on the long arm of chromosome 17 at q21→23[167] with the α_{IIb} gene at minimum distance of 365 kb downstream from the β_3 gene.[168] The α_{IIb} gene (*ITGA2B*) spans ≈18 kb and consists of 30 exons ranging in size from 46 to 220 bp.[169] Like the genes for other proteins expressed in megakaryocytes, its 5′ flanking region lacks TATA or CAAT boxes. Instead, it contains a linear array of regulatory elements that includes two motifs recognized by the GATA-1 transcription factor and its cofactor FOG[170,171]; sequences flanking each GATA-1 binding site are recognized by Fli-1 and perhaps other members of the Ets family of transcription factors[172–175]; and an Sp1-binding silencer element is located between the GATA-1 sites.[176] The gene for β_3 (*ITGB3*) spans 63 kb and contains 15 exons.[151,177] Like the α_{IIb} gene, the 5′ flanking region of the β_3 gene lacks TATA or CAAT boxes.[178]

GT is an autosomal recessive disorder with disease clusters in populations where consanguinity is common. It has been subclassified into three types based on the amount of $\alpha_{IIb}\beta_3$ present per platelet and the presence or absence of α-granule fibrinogen and clot retraction.[127] In type I, platelets contain <5% of the normal amount of $\alpha_{IIb}\beta_3$ and clot retraction and α-granule fibrinogen are absent. In type II, platelets contain 10% to 20% of the normal amount of $\alpha_{IIb}\beta_3$, clot retraction is decreased, and α-granule fibrinogen is present. In "variant" thrombasthenia, the platelet content of $\alpha_{IIb}\beta_3$ is ≥50% of normal, indicating that the $\alpha_{IIb}\beta_3$ abnormality is qualitative, rather than quantitative.

Because the expression of $\alpha_{IIb}\beta_3$ on the platelet surface requires the formation of correctly folded heterodimers,[179] mutations in the genes for either α_{IIb} or β_3 can produce GT. Approximately 200 different mutations responsible for GT have been identified[180] (FIGURE 65.3). The vast majority of these mutations consist of a mix of missense and nonsense mutations, nucleotide deletions and insertions, and alternative splicing, resulting in type I and type II GT. However, the most informative mutations have been qualitative $\alpha_{IIb}\beta_3$ abnormalities (variant GT) that primarily perturb $\alpha_{IIb}\beta_3$ function rather than the level of $\alpha_{IIb}\beta_3$ expression.

Mutations located in the extracellular portion of $\alpha_{IIb}\beta_3$ cause GT by either impairing fibrinogen or vWF binding to the active $\alpha_{IIb}\beta_3$ conformation or by paradoxically inducing constitutive $\alpha_{IIb}\beta_3$ activation but causing GT by concurrently decreasing the amount of $\alpha_{IIb}\beta_3$ expressed on the platelet surface. Six missense mutations (the α_{IIb} mutation Tyr143His[181] and the β_3 mutations Asp119Tyr,[182] Val193Met,[183] Arg214Trp,[184,185] Arg214Gln,[186] and Aspr217Val[187]) are located in regions implicated in ligand binding to $\alpha_{IIb}\beta_3$ and cause GT by preventing ligand binding.[188,189]

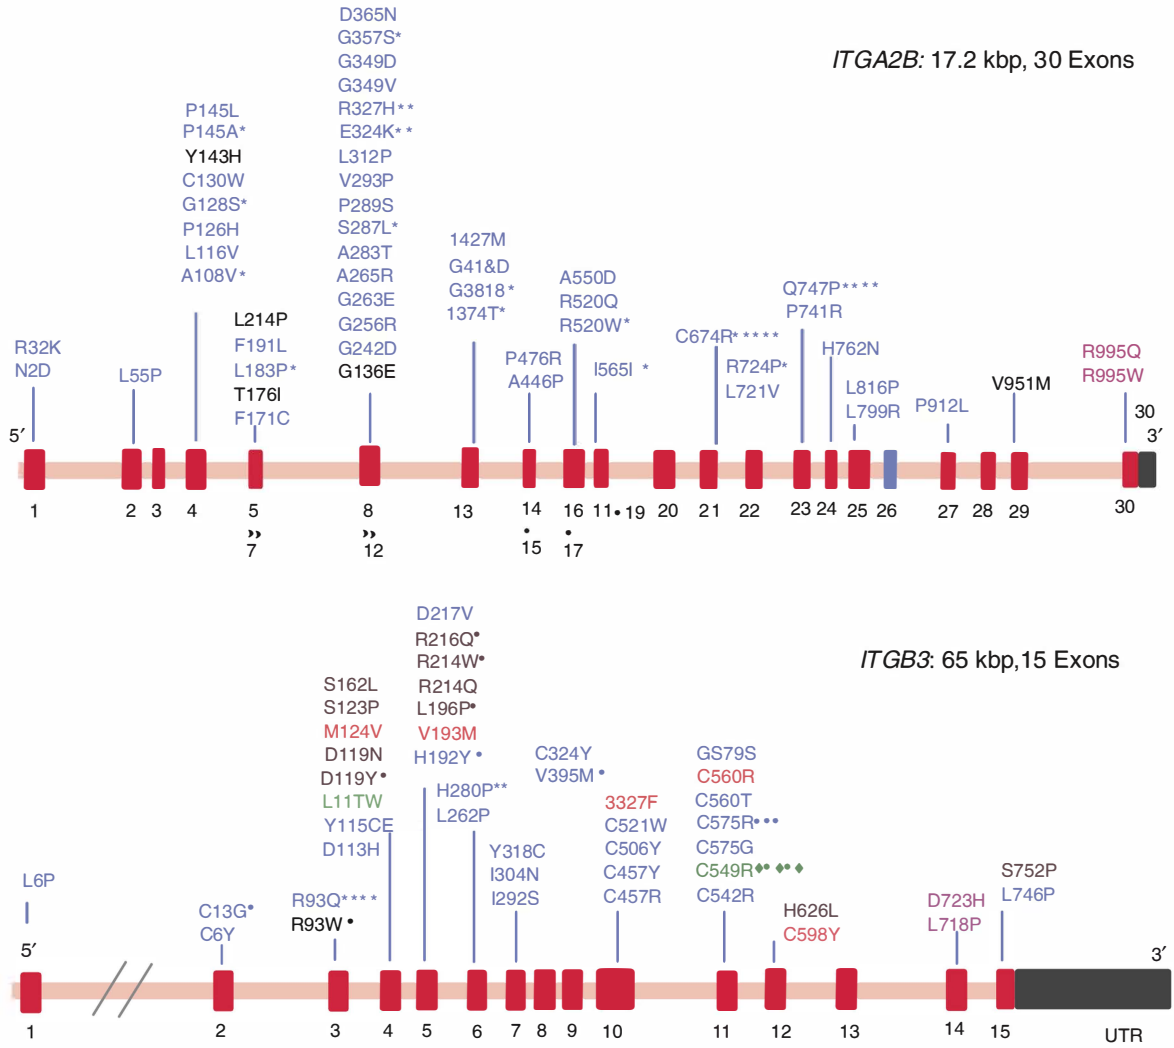

FIGURE 65.3 Missense mutations in the ITGA2B and ITGB3 genes resulting in GT. The exons in the ITGA2B and ITGB3 genes are shown schematically as *red bars*. Mutations shown in *black* are lack of function mutations, those shown in *blue* primarily impair $\alpha_{IIb}\beta_3$ expression, those in *green* are characteristic of particular ethnic groups, those in *orange* cause constitutive $\alpha_{IIb}\beta_3$ activation, and those in *rose* are associated with macrothrombocytopenia. *Asterisk* indicate the number of times the mutation has been reported. (Adapted from Nurden AT, Fiore M, Nurden P, et al. Glanzmann thrombasthenia: a review of ITGA2B and ITGB3 defects with emphasis on variants, phenotypic variability, and mouse models. *Blood* 2011;118:5996–6005, with permission.)

Similarly, an insertion of two amino acids (Arg–Thr) into the Cys146–Cys167 loop of α_{IIb} produced an inactive $\alpha_{IIb}\beta_3$ heterodimer.[190] An eighth mutation, β_3 Ser123Pro, did not impair $\alpha_{IIb}\beta_3$ expression or agonist-induced ligand binding but was associated with absent ADP- and collagen-induced platelet aggregation.[191] The β_3 mutation, Leu196Pro, was identified independently in two French patients and severely restricted $\alpha_{IIb}\beta_3$ expression.[192,193] However, the residual $\alpha_{IIb}\beta_3$ that made it to the platelet surface was unable to bind ligands, presumably because the mutation prevents $\alpha_{IIb}\beta_3$ from assuming its active conformation. By contract, the β_3 mutation Cys560Arg locked $\alpha_{IIb}\beta_3$ in a high-affinity conformation, but like Leu196Pro, it likely produced a GT-phenotype because the small amount of constitutively active $\alpha_{IIb}\beta_3$ on the platelet surface was insufficient to support platelet aggregation.[194]

The extracellular stalks of $\alpha_{IIb}\beta_3$ consist of the thigh, calf-1, and calf-2 domains of α_{IIb} and the epidermal growth factor (EGF)-like domains 1 to 4 and the βTD domain of β_3.[195] The distal portions of the stalks form an interface containing interacting energetic "hot spots" that are critical for maintaining $\alpha_{IIb}\beta_3$ in a stable, inactive conformation.[196,197] Thus, it is not surprising that four mutations involving cysteine residues located at the third and fourth EGF domains of β_3 (Cys49Arg,[198] Cys560Phe,[199] Cys560Arg,[194] and Cys598Tyr[199,199a]) as well as a Gly579Ser mutation, not only resulted in type II thrombasthenia but also induced constitutive ligand-binding activity in the residual $\alpha_{IIb}\beta_3$. Similarly, a Ser527Phe mutation detected in the third β_3 EGF domain of a patient who presented with a mild bleeding diathesis was found to cause constitutive activation of recombinant $\alpha_{IIb}\beta_3$ expressed in Chinese hamster ovary cells.[200]

Naturally occurring mutations involving the β_3 cytoplasmic domain have confirmed the singular importance of this structure in regulating $\alpha_{IIb}\beta_3$ function. The first mutation identified, a missense mutation that results in the substitution of Pro for Ser at residue 752, prevents $\alpha_{IIb}\beta_3$ activation by cellular agonists,[201–203] likely because it abrogates binding of the cytoplasmic protein kindlin-3 to β_3 (see below).[204] A second missense mutation, identified separately in two unrelated patients,[205,206] converts the Arg724 codon into a stop codon, resulting in the synthesis of a truncated β_3 molecule lacking 39 *C*-terminal amino acids. As a consequence, $\alpha_{IIb}\beta_3$ is unable to transduce both "inside-out" and "outside-in signals," likely because β_3 is now unable to interact with both kindlin-3 and talin.[204] A third mutation, identified in an Palestinian Arab with GT, produces aberrant mRNA splicing at the intron 14/exon 15 junction and replacement of the β_3 sequence distal to residue 741 with 40 unrelated amino acids.[207] This results in the absence of the distal talin binding site in the β_3 cytoplasmic domain, as well the binding site for kindlin-3, and an $\alpha_{IIb}\beta_3$ extracellular domain that appears to be "locked" in its inactive conformation.[208]

Lastly, several heterozygous mutations located in the highly conserved membrane-proximal regions of the α_{IIb} and β_3 cytoplasmic domains have been associated with GT-like phenotypes and macrothrombocytopenia.[209] Thus, replacement of α_{IIb} Arg995 with either Gln[209,210] or Trp[211] and β_3 Asp723 with His[212,213] results in decreased, but not absent, platelet aggregation, an approximate 50% decrease in the total amount of platelet $\alpha_{IIb}\beta_3$ predominantly affecting the surface—rather than the granule—membrane pool, a moderate degree of macrothrombocytopenia and platelet "anisocytosis," and partial $\alpha_{IIb}\beta_3$ activation when $\alpha_{IIb}\beta_3$ is expressed in tissue culture cells. A β_3 Leu718Pro mutation produced a similar phenotype,[214] as did a two residue deletion in the βTD domain of β_3.[215] How these mutations in $\alpha_{IIb}\beta_3$ produce this spectrum of abnormalities is not clear since "classic" GT is not associated with alterations in platelet number or size, but the association of macrothrombocytopenia with BSS and the MYH9 disorders suggests that perturbed $\alpha_{IIb}\beta_3$-cytoskeleton interactions could be involved.

Differential Diagnosis

A history of lifelong bleeding, a prolonged bleeding time, and absent platelet aggregation are diagnostic of GT and differentiate it from other disorders of platelet adhesion and secretion. Rare instances of acquired GT have been reported and can be differentiated from congenital GT by history. Although autoantibodies against $\alpha_{IIb}\beta_3$ are frequently detected in patients with idiopathic thrombocytopenic purpura,[216,217] they rarely induce a GT-like state.[218–221] There are anecdotal reports of autoantibodies producing acquired GT in patients with Hodgkin and non-Hodgkin lymphoma, hairy cell leukemia, and after an allergic reaction to diclophenac.[222–224] A patient with multiple myeloma has also been reported whose $IgG_1\kappa$ paraprotein was directed against β_3 and inhibited $\alpha_{IIb}\beta_3$ function.[225] Congenital afibrinogenemia may be associated with a prolonged bleeding time and decreased *in vitro* platelet aggregation due to the absence of sufficient fibrinogen to support normal platelet aggregation.[226]

In the LAD-III/LAD-1/variant syndrome, patients manifest mucocutaneous bleeding and absent platelet aggregation, despite normal or nearly normal $\alpha_{IIb}\beta_3$ expression.[227–229] Concurrently, they suffer from recurrent and severe bacterial infections due to defective leukocyte integrin function, implying that the syndrome results from a general defect in integrin activation. Although initially attributed to defective expression of the Rap-1 activator CalDAG-GEFI,[229–231] in several kindreds,[232,233] mutations have been identified in the *KINDLIN3* gene encoding the protein kindlin-3 that binds to β_1, β_2, and β_3 integrin cytoplasmic tails and is required for agonist-stimulated integrin activation.[204,234,235]

Therapy

The mainstay of treatment of bleeding in GT remains the transfusion of normal platelets.[111] Because bleeding is a lifelong problem, use of HLA-matched platelets should be considered to lessen the chance of refractoriness to transfusion due to platelet alloimmunization. Patients with GT, especially patients with null mutations, not infrequently develop alloantibodies against normal $\alpha_{IIb}\beta_3$ after transfusion, potentially limiting the effectiveness of transfused platelets.[236–239] Protein A-Sepharose immunoadsorption has been reported to restore the efficacy of transfused platelets in this situation.[240] Oral contraceptives have been useful in controlling menorrhagia. Regular dental care is essential in minimizing gingival bleeding, and fibrinolytic inhibitors, in addition to platelet transfusions, may be useful in controlling bleeding after dental extractions. Corticosteroids are not efficacious in managing bleeding in thrombasthenic patients,[153] and there is little evidence that desmopressin (DDAVP) is useful.[114,241] Recombinant factor VIIa has been found to be efficacious for the treatment of bleeding episodes and for obtaining surgical hemostasis in patients with GT, particularly in patients who have developed alloantibodies from prior platelet transfusions.[111,242,243] The GT phenotype of several severely affected individuals has been corrected by bone marrow,[244–247] stem cell,[248,249] and unrelated donor cord blood bone marrow transplantation.[250] Lastly, platelet gene therapy has improved hemostatic function in $\alpha_{IIb}\beta_3$-deficient dogs,[251] suggesting that at some point in the future, gene therapy could be used in humans.

DISORDERS OF PLATELET SECRETION

Platelets contain four types of granules: dense granules containing ADP, ATP, calcium, serotonin, and pyrophosphate; α-granules containing a variety of proteins, some derived from the plasma, others synthesized by the megakaryocyte; lysosomes containing acid hydrolases; and microperoxisomes containing a peroxidase activity. Following platelet activation, the contents of these granules are extruded in an exocytic process known as platelet secretion or the platelet release reaction.[252] Disorder of platelet secretion are heterogeneous and are generally manifest as decreased platelet aggregation and absence of the second wave of aggregation when platelets are stimulated with weak agonists like ADP and epinephrine. They can be due to a decrease in the number of granules, a decrease in granule contents, or perturbation of the mechanism of granule secretion.

The Gray Platelet Syndrome (α-Granule Deficiency, α-Storage Pool Disease)

The gray platelet syndrome (GPS), described by Raccuglia[80] in 1971, is a rare disorder that results from the specific absence of morphologically recognizable α-granules in the platelets of affected individuals.

Biology and Molecular Aspects of the Disorder

Normal platelets contain ≈50 spherical or elongated structures termed α-granules that contain a variety of proteins, some of which are specific or relatively specific for platelets and others that are also found in plasma.[253] The former include platelet factor 4 (PF4), β-thromboglobulin (βTG), platelet-derived growth factor, and thrombospondin (TSP), and the latter include fibrinogen, vWF, albumin, coagulation factor V (FV), IgG, fibronectin, and a number of protease inhibitors.[254] The platelet-specific proteins and several of the plasma proteins such as vWF[255] are synthesized by megakaryocytes, whereas others, such as albumin and IgG, reach the α-granules via endocytosis of circulating protein.[256] The α-granule membrane contains many of the same proteins present in the platelet plasma membrane ($\alpha_{IIb}\beta_3$[257] and GPIb-IX-V[258]) and others specific for α-granules (P-selectin[259,260] and osteonectin[261]). Each can be translocated to the platelet surface following platelet activation.

Pathogenesis

GPS is markedly heterogeneous.[262] Electron micrographs of megakaryocytes and platelets from patients with this syndrome reveal absence of normal α-granules[263] and the presence of vacuoles and small α-granule precursors containing material that stains for vWF and fibrinogen.[264] Other types of platelet granules are present in normal numbers. The vacuole membranes and small α-granule precursors contain P-selectin and $\alpha_{IIb}\beta_3$ that can be translocated to the platelet surface after thrombin stimulation.[257,265] This indicates that α-granules are present in gray platelets and suggests that the abnormality responsible for GPS is an inability to target proteins to these structures,[266] accounting for the elevated plasma concentrations of PF4 and βTG and the bone marrow fibrosis observed in patients with the syndrome.[267] The abnormality responsible for GPS appears to be restricted to megakaryocytes since electron micrographs of endothelial cells from affected patients reveal typical vWF-containing Weibel-Palade bodies.[268] However, there is a report of three children with GPS whose neutrophils had a gray appearance due to a decrease in secondary granules.[269] In a second report of five affected individuals, neutrophil granularity was normal,[270] consistent with the heterogenous nature of the disorder. Two macrothrombocytopenic disorders resembling GPS have also been described. In the White platelet syndrome, autosomal dominant macrothrombocytopenia was associated with mild-to-moderate bleeding, defective platelet aggregation, incomplete granule formation, and 30% or more gray-appearing platelets on blood smears.[271] In the Medich giant platelet disorder, macrothrombocytopenia was associated with a marked decrease in platelet α-granules, but in contrast to the GPS, empty vacuoles without granule contents were not present in the platelet cytoplasm but were replaced by membranous inclusions resembling cigars or scrolls.[272]

Clinical Presentation and Laboratory Findings

Patients with GPS present with a lifelong history of mild to moderate mucocutaneous bleeding.[273] Patients also exhibit variably prolonged bleeding times, moderate thrombocytopenia, reticulin fibrosis of the bone marrow, and large platelets whose gray appearance on a Wright-stained blood smear gives the name to the disorder.[80,84] Platelet counts vary from 25,000 to 150,000/μL but generally range between 60,000 and 100,000/μL. Platelet aggregation induced by ADP, epinephrine, arachidonic acid, and the calcium ionophore A23187 has generally been normal or nearly normal,[274] but collagen-induced aggregation has been decreased to absent in some, but not all, cases, perhaps due to an associated deficiency of GPVI.[84,275,276] Responses to thrombin have also been variable, with decreased aggregation and secretion in response to low thrombin concentrations in some cases.[84,274,277,278] Gray platelets agglutinate normally when exposed to ristocetin, and the content of their dense granules is normal.[279] As expected, the PF4, βTG, fibrinogen, vWF, FV, fibronectin, and TSP content of gray platelet α-granules is markedly decreased, but surprisingly in some patients, gray platelets contain substantial quantities of albumin and IgG.[280] The PF4 and βTG concentrations in the plasma of affected individuals are normal or elevated.[84,274]

Genetics

Genetic analysis of families with GPS suggests that platelet α-granule deficiency is a heterogenous disorder. Falik-Zaccai et al.[273] reported 59 GPS patients. The presence of GPS in males and females in the same family indicated that it is an autosomal disease, but its mode of inheritance was uncertain. On the other hand, a family has been reported in which GPS was inherited in an X-linked fashion and was associated with an Arg216Gln mutation in the *GATA1* gene.[281] A disorder resembling the GPS is present in the Wistar Furth strain of rat and is inherited as an autosomal recessive.[282] Studies from three separate groups have identified mutations in the *NBEAL2* gene as the genetic cause of GPS.[81–83] *NBEAL2* encodes a protein containing a BEACH domain that is predicted to be involved in vesicular trafficking and may be critical for the development of platelet α-granules. NBEAL2 localizes to the dense tubular system in platelets.[82] It is noteworthy that silencing *nbeal2* in zebra fish abrogates thrombocyte formation.[81]

Therapy

Treatment of severe bleeding episodes in GPS may require the transfusion of normal platelets. Desmopressin (DDAVP) was found to shorten the bleeding time in one patient and was used as successful prophylaxis for a dental extraction.[283]

The Quebec Platelet Disorder (Factor V Quebec)

Two unrelated families with an autosomal dominant bleeding disorder of moderate severity have been identified in Quebec.[284–286] Their disorder is characterized by mild thrombocytopenia, defective epinephrine-induced platelet aggregation, a decrease in the amount of multiple α-granule proteins due to degradation, and bleeding unresponsive to platelet transfusion but controlled by fibrinolytic inhibitors. Initially, the disorder was attributed to a decrease in platelet factor V, hence the name factor V Quebec.[287] In contrast to GPS, the α-granules in these platelets appear morphologically normal.[285] However, the amount of the α-granule proteins factor V, multimerin, fibrinogen, vWF, fibronectin, osteonectin, and TSP is decreased, and many are substantially degraded[285] due to the enhanced expression of urokinase-type plasminogen activator (u-PA) in α-granules.[288,289] This has been attributed to an increased megakaryocyte expression of the UPA gene (*PLAU*) due to an abnormality in a *cis* regulatory element.[290,291] A patient has also been reported whose platelets contained a reduced amount of factor V but no evidence of enhanced α-granule proteolytic activity, indicating that some other process reduced α-granule factor V.[292]

Dense Granule Deficiency (δ-Storage Pool Disease)

Normal platelets contain three to six 200 to 300 nm dense or δ-granules that are intracellular storage sites for ADP, ATP, calcium, polyphosphate, and serotonin.[293] Because of their high calcium content, δ-granules can be visualized in electron micrographs of unfixed, unstained platelet whole mounts.[293] They can also be visualized by electron microscopy of thin sections of fixed platelets after staining with uranyl ions (uranaffin reaction) and by fluorescence microscopy after staining platelets with mepacrine (quinacrine).[293] The δ-granule membrane contains a 40,000 mol. wt. protein named granulophysin (CD63) that is translocated to the platelet surface following platelet activation[294] and corresponds to the melanoma-associated antigen ME491, the lysosomal membrane protein-1 (LIMP-1), and the lysosomal membrane-associated protein-3 (LAMP-3).[295] The δ-granule membrane also contains P-selectin, GPIb, and $\alpha_{IIb}\beta_3$.[296] δ-granules undergo exocytosis coincident with the second wave of platelet aggregation (see FIGURE 65.1).

Platelet δ-granules are related to a group of lysosome-related granules including melanosomes, neutrophil azurophilic granules, the lytic granules of cytotoxic T lymphocytes and natural killer cells, basophilic granules in basophils and mast cells, and class II major histocompatibility complex compartments in antigen-presenting cells.[295,297] The biogenesis of δ-granules in megakaryocytes is poorly understood. However, δ-storage pool deficiency occurs in tyrosinase-positive albinism in humans,[295] pigment dilution syndromes in mice and rats,[295] and as part of a Chediak-Higashi-like syndrome in cattle, cats, mink, foxes and killer whales,[298] implying that the biogenesis of dense granules, melanosomes, and lysosomes is related. How dense granules accumulate ATP and ADP is also not known. One candidate for mediating ATP and ADP accumulation is MRP4 (multidrug resistance protein 4, ABCC4), a nucleotide transport pump, since it colocalizes with dense granules by immunofluorescence microscopy and its distribution is altered in dense granule-deficient platelets.[299] A second candidate is the gene *Slc35d3*, a nucleotide sugar transporter, that was identified in a strain of hypopigmented ashen mice (a model of the human Griscelli syndrome[300]) that independently developed platelet dense granule deficiency.[301]

Normal platelets contain two pools of adenine nucleotides that exchange very slowly, if at all.[302] One pool is a metabolic nongranule pool in which the ratio of ATP to ADP content is 8-10:1. The second pool is present in the δ-granules and contains 65% of the platelet adenine nucleotides with an ATP to ADP ratio of 2:3. Thus, in normal platelets, the whole platelet ATP to ADP ratio is <2.5. On the other hand, serotonin is not synthesized by megakaryocytes but is taken up from the plasma and stored in the δ-granules where it is protected from platelet monoamine oxidase.[303]

Etiology and Pathogenesis

δ-storage pool disorders are heterogeneous with δ-granule deficiency as the common feature. Storage pool disease (SPD) can be subdivided into deficiency states associated with albinism and those in otherwise normal individuals.[304] SPD has been reported in patients with the Wiscott-Aldrich syndrome/X-linked thrombocytopenia,[305,306] the syndrome of thrombocytopenia with absent radii,[307] the Ehlers-Danlos syndrome,[308] and osteogenesis imperfecta.[309] When SPD is associated with albinism, as in the Hermansky-Pudlak syndrome (HPS) (oculocutaneous tyrosinase-positive albinism, platelet dense granule deficiency, ceroid-like inclusions in cells of the reticuloendothelial system, progressive pulmonary fibrosis, and granulomatous colitis)[295] and the Chediak-Higashi syndrome (CHS) (partial oculocutaneous albinism, frequent pyogenic infections, and giant lysosomal granules in cells of hematologic and nonhematologic origin),[298] there is a quantitative δ-granule deficiency. In platelets of nonalbinos, however, the number of uranaffin- and mepacrine-positive granules is normal to only slightly decreased, suggesting an inability to package δ-granule contents in these patients.[310,311] The platelet granulophysin content also parallels the number of δ-granules in storage pool-deficient patients, being low in HPS and CHS, but normal in nonalbinos.[312] The δ-granule abnormality in some nonalbino is also associated with a variable of α-granule deficiency (αδ-SPD).[313,314] The content of lysosomal acid hydrolases in SPD platelets is normal, but thrombin-induced acid hydrolase secretion may be impaired in severely affected individuals, an abnormality corrected by the addition of ADP *in vitro*.[315]

Clinical and Laboratory Findings

Patients with SPD have a mild to moderate bleeding diathesis. Platelet counts and morphology are usually normal, but bleeding times are usually, but not always, prolonged.[316] Aggregometer tracings of SPD platelets stimulated by weak agonists such as ADP and epinephrine usually lack a second wave of aggregation (see FIGURE 65.1).[317] Responses to low concentrations of collagen are also diminished to absent, but responses to high collagen concentrations may be normal or nearly normal; aggregation response to arachidonic acid also may be normal.[318] On the other hand, patients have been reported with normal aggregation studies.[316] The steady-state serotonin content of SPD platelets is decreased, but the rate of uptake of serotonin is normal[302] because without storage sites, the serotonin either leaks out of the platelet or is metabolized by platelet monoamine oxidase. In SDP, the dense granule pool of ADP no longer contributes to the whole platelet ADP content and the ATP:ADP ratio of δ-storage pool deficient platelets is 3.0 or greater, a useful diagnostic finding.[316] Flow cytometry of mepacrine-labeled platelets may be a rapid method to detect δ-storage pool-deficient platelets.[319,320]

Genetics

HPS and CHS are autosomal recessive disorders.[295,298] There are at least 9 known human HPS genes and 15 genetically distinct strains of mice with phenotypes similar to human HPS.[321,322] Nine of the mutant mouse genes are orthologs of the human HPS genes. HPS-1, the HPS prototype, occurs with a frequency of 1 in 1,800 in northwest Puerto Rico[323,324] and is one of the most common causes of oculocutaneous albinism in Japanese.[325] In addition to SPD and tyrosinase-positive albinism, patients with HPS-1 suffer from decreased visual acuity, nystagmus, granulomatous colitis, and usually fatal pulmonary fibrosis.[326,327] HPS-1 results from mutations in a gene located on human chromosome 10q23.1-23.3 that encodes an 80,000 mol. wt. protein and corresponds to the gene responsible for the mouse mutant *pale ear*.[323,328,329] HPS-1 in Puerto Rico results from 16-bp duplication in the exon 15 of *HPS-1*[330] and at least 22 additional mutations have been identified in non–Puerto Ricans.[322] The HPS-1 protein is one component of a cytosolic and membrane-bound complex (BLOC-3, biogenesis of lysosome-related organelles complex 3)

that also contains the 77,000 mol. wt. protein that is mutated in HPS-4.[321] Thus, the phenotypes of patients with HPS-1 and HPS-4 are similar.[331] The gene mutated in HPS-4 corresponds to the gene involved in the mouse mutant *light ear*.[332] HPS-2 results from mutations in *ADTB3A*, the gene encoding the β_3A subunit of the adaptor complex AP-3; mutations in this gene are also responsible for the mouse mutant *pearl*.[333] Patients with HPS-2 have phenotypes ranging from mild to severe and are distinguished from other HPS mutants by the presence of neutropenia and recurrent childhood infections.[333–335] HPS-3, a relatively mild form of HPS,[336] is the human homologue of the mouse mutant *cocoa*[337] and results from mutation of a gene located on human chromosome 3q24 encoding a 113,700 mol. wt. protein of unknown function.[338] HPS-5 has been identified in five patients who manifested hypopigmentation and platelet SPD without colitis or pulmonary fibrosis and results from mutation of a gene located on chromosome 11p14.[339] HPS-6, detected in a single patient from Belgium[340] and 20 individuals from an extended Israeli Bedouin family,[341] produces a phenotype similar to HPS-5 and results from mutation of a gene located on chromosome 10q24.1-q25.1.[341] HSP-5 and HPS-6 correspond to the mouse mutants *ruby-eye 2* and *ruby-eye*, respectively.[340] Biochemical studies indicate that HPS-3, HPS-5, and HSP-6 interact to form a multisubunit complex called BLOC-2.[342] HPS-7, identified in a Portuguese woman with mild HPS, results from a mutation in the gene for dysbindin, responsible for the mouse mutant *sandy*.[343] Dysbindin is a component of the BLOC-1 complex that also contains the proteins pallidin, muted, and cappuccino associated with variants of murine HPS.[344,345] HPS-8, identified in a large consanguineous Pakistani family, is due to a frameshift mutation in the gene *BLOC1S3*, another component of the BLOC-1 complex.[346] HPS-9, discovered in a male child of Indian ancestry who presented at birth with generalized hypopigmentation and was found to be homozygous for a mutant gene located at chromosome 15q21.1 that encodes the BLOC-1 subunit pallidin.[347] Although the function of the BLOC-1, BLOC-2, BLOC-3, and AP-3 in the biogenesis of platelet δ-granules is not known, BLOC-1 and AP-3 have been shown to physically associate and to facilitate the trafficking of melanosomal membrane protein tyrosinase-related protein 1.[348] Similarly, BLOC-1 has been found to associate with BLOC-2 where it participates in a cargo transport pathway from early endosomes to melanosomes.[348,349]

CHS results from mutations in the gene *CHS1* (*LYST*) located on human chromosome 1q42-q43.[350,351] *CHS1* is the ortholog of the murine *bg* gene, mutation of which is responsible for the beige mouse.[351] *CHS1* encodes a 430,000 mol. wt. cytosolic protein whose role in normal lysosome development is unknown.[298]

Therapy

Bleeding in patients with SPD can be controlled not only by platelet transfusion but also, in some patients, by cryoprecipitate[352] or the vasopressin analog DDAVP.[353] DDAVP avoids transfusion of blood products and may be tried as the initial therapy of choice. The precise mechanism of its beneficial effect in patients with platelet defects is uncertain. However, DDAVP releases large vWF multimers and tissue plasminogen activator from endothelial stores.[241] In several series of patients with platelet disorders, DDAVP shortened the bleeding time in 43% to 100% of patients.[353–355] In some some patients DDAVP did not shorten the bleeding.[464] This variability in response indicates that if DDAVP is to be used for surgical prophylaxis in patients with SPD, it may be prudent to assess the effect of DDAVP on the bleeding time prior to surgery.

In an unconfirmed study, prednisone at doses of 20 to 50 mg for 3 to 4 days was used to improve hemostasis in patients with inherited platelet disorders.[356] However, prednisone was ineffective in patients with GT[153] or in normal individuals given aspirin.[357] There are also reports suggesting that recombinant VIIa can be effective in managing bleeding in patients with SPD.[120,358]

HPS-1 and HPS-4 are associated with progressive pulmonary fibrosis that is generally fatal by the fourth to sixth decades of life.[359] The drug pirfenidone, an antifibrotic agent, has been reported to slow the progression pulmonary fibrosis in patients with HPS.[360] One patient was treated successfully by bilateral lung transplantation.[361]

Bone marrow transplantation has been effective in reversing the immunologic and hemostatic manifestations of CHS,[362] but surviving patients later developed neurologic deficits.[298]

Disorders of Secretion Due to Defects in Platelet Signal Transduction

Platelet signal transduction is triggered by the interaction of agonists with specific surface platelet receptors, leading to the activation of specific platelet signaling pathways. Platelet signal transduction is discussed in detail in Chapter 33. Although the prevalence of inherited abnormalities in platelet signal transduction is unknown, these patients have been informative in understanding platelet physiology. [380]

Inherited Abnormalities in Platelet Agonist Receptors

Mutations in the TXA_2 Receptor

Patients have been identified with impaired platelet responsiveness to TXA_2.[363–365] Although the responsible mutations have not been identified in all patients, Hirata et al.[366] described a homozygous Arg^{60} to Leu mutation in the first cytoplasmic loop of the thromboxane A_2 (TXA_2) receptor in two unrelated patients. These patients had a mild bleeding disorder with an autosomal dominant pattern of inheritance. Although binding of TXA_2 analogs to platelets was normal,[367,368] TXA_2-mediated GTPase activity was diminished,[368,369] suggesting a defect in TXA_2 receptor-G-protein coupling. TXA_2-stimulated platelet aggregation was also impaired in the heterozygous family members.[366] Since half the normal number of TXA_2 receptors is sufficient to stimulate irreversible platelet aggregation,[370] it is possible that this mutation had a dominant negative effect. Absent TXA_2-stimulated platelet aggregation has also been observed in patients without detectable TXA_2 receptor abnormalities.[371]

ADP Receptor Mutations

Platelets express three ADP receptors: $P2Y_1$, $P2Y_{12}$, and $P2X_1$.[372,373] ADP binding to $P2Y_1$ induces PLC activation, intracellular Ca^{2+} mobilization, and platelet shape change, while ADP binding to $P2Y_{12}$ mediates or inhibits platelet adenylyl cyclase activity. ADP-induced platelet aggregation requires concurrent activation of both $P2Y_1$ and $P2Y_{12}$. $P2X_1$ functions as an ATP- and ADP-gated cation channel.

A number of patients presenting with mild to moderate mucocutaneous bleeding and platelet phenotypes that

included blunted ADP-induced platelet aggregation, impaired suppression of PGE_1-induced elevations in cAMP, and normal ADP-stimulated shape change were found to have mutations in the gene for $P2Y_{12}$.[374–379] Three patients were homozygous for a deletion in the $P2Y_{12}$ gene, resulting in premature termination and lack of $P2Y_{12}$ protein.[374,377,380] A fourth patient was homozygous for a missense mutation in the translation initiation codon of the $P2Y_{12}$ gene,[376] and a fifth had a two nucleotide deletion in one $P2Y_{12}$ allele, resulting in a frame shift and a premature stop codon.[375,381] However, a mutation was not detected in the other $P2Y_{12}$ allele. A sixth patient was found to be a compound heterozygote with one $P2Y_{12}$ allele containing an R256N substitution in the sixth $P2Y_{12}$ transmembrane domain, and the other, a R265W substitution in its third extracellular loop.[378] It is noteworthy that a seventh patient has been described whose bleeding diathesis was also associated with a heterozygous P258T mutation in the third extracellular loop.[382] Lastly, in a screen of 92 patients with type 1 vWD, a heterozygous mutation in the second extracellular loop of $P2Y_{12}$ was detected in one patient and several family members that was associated with decreased 2MeS-ADP binding and modest defects in ADP-induced platelet aggregation,[379] suggesting that mild platelet function defects could contribute to the variable severity of vWD.

Although $P2X_1$ is not thought to directly contribute to ADP-induced platelet aggregation, a heterozygous deletion of a single leucine in a stretch of four leucine residues in the second transmembrane domain of $P2X_1$ was detected in a 6-year-old child with a history of petechiae, ecchymoses, and severe expistaxis.[383] There was isolated impairment of ADP-induced platelet aggregation, raising the possibility that the mutant protein had a dominant negative effect on $P2X_1$-mediated calcium channel activity.

Platelet Collagen Receptor Mutations

Collagen plays an essential role in platelet function as a substrate for platelet adhesion, a binding site for vWF in the extracellular matrix, and an agonist for platelet aggregation and secretion (see FIGURE 65.1). As discussed in detail in Chapters 28 and 30, there are two receptors, GPVI[384] and the integrin $\alpha_2\beta_1$,[385,386] that mediate the interaction of platelets with collagen.

Glycoprotein VI

A 62,000 mol. wt. member of the immunoglobulin gene superfamily,[387,388] GPVI is associated with the Fc receptor γ chain in the platelet plasma membrane.[389] Exposing normal platelets, but not GPVI-deficient platelets, to collagen or collagen-like peptides results in γ chain phosphorylation on tyrosine residues, the phosphorylation of the proteins SLP-76, Syk, Lyn, LAT, and phospholipase Cγ2, followed by platelet aggregation.[390,391] Murine platelets lacking either the γ chain or Syk are unable to respond to collagen.[392] The interaction of GPVI-deficient human platelets with either immobilized and soluble collagen is markedly impaired.

There are at least five reports concerning patients with congenital GPVI deficiencies.[393–397] These patients manifest mild mucocutaneous bleeding and platelets that fail to aggregate following stimulation with collagen despite the presence of normal amounts of $\alpha_2\beta_1$, but retain some ability to adhere to collagen-coated surfaces. A sixth patient had more severe bleeding, including epistaxis requiring transfusion, severe bleeding after trauma, and significant postpartum hemorrhage.[398] This patient's platelets expressed GPVI and the FcR γ chain but aggregated poorly in response to collagen, convulxin, and collagen-related peptide, as well as to heparin-induced thrombocytopenia antibodies, implying a defect in collagen-induced signaling downstream of the FcR γ chain. GPVI deficiency has also been reported in conjunction with the GPS.[276] At least six patients have been described whose plasma contained autoantibodies against GPVI that inhibited collagen-induced platelet function.[399–404] Notable features of these patients include little or no detectable GPVI on the platelet surface, absence of detectable GPVI mutations, and, in several instances, restoration of GPVI following treatment of the immunologic disease.[403,404] It is likely that absence of platelet-surface GPVI in these patients was a consequence of antibody-mediated GPVI ectodomain shedding,[405] a phenomenon previously observed in mouse models.[406] Two patients have also been described, one with myelodysplasia and a second with chronic lymphocytic leukemia, whose platelets did not respond to collagen or convulxin but contained GPVI by flow cytometry.[407]

$\alpha_2\beta_1$

The widely expressed integrin $\alpha_2\beta_1$ (GPIa-IIa, VLA-2) binds with high affinity to type I collagen, as well as to collagen types II to V and to laminins 1 and 5, depending on the cellular context.[408] It is one of nine integrins whose α subunit contains a 200 residue I-domain that is largely, if not exclusively, responsible for ligand binding.[409] Besides platelets, $\alpha_2\beta_1$ is present on endothelial cells, fibroblasts, epithelial cells, Schwann cells, and activated T cells.[410] With regard to the relative contributions of $\alpha_2\beta_1$ and GPVI to collagen-initiated platelet function, current data suggest a model in which platelet tethering initiated by platelet GPIb-IX-V binding to collagen-bound vWF enables GPVI to bind to collagen and generate "outside-in" signals. In turn, these signals increase the affinity of $\alpha_2\beta_1$ for collagen, resulting in platelet adhesion to collagen that is sufficiently firm to resist the shear stress of flowing blood.[386,411,412]

Several patients have been reported whose platelets lacked $\alpha_2\beta_1$ and failed to interact normally with collagen. Of two patients with bleeding diatheses, platelets from one contained approximately 15% to 25% of the normal amount of α_2, failed to aggregate in response to collagen, and failed to adhere to collagen under both static and flow conditions.[413,414] Platelets from the second lacked α_2 as well as the α-granule protein TSP, failed to aggregate in response to low concentrations of collagen, and adhered to, but did not spread on, collagen-coated surfaces.[415] Platelets of two families with autosomal dominant thrombocytopenia and mild cutaneous bleeding were also found to express 38% to 63% of the normal amount of $\alpha_2\beta_1$ and to adhere poorly to collagen-coated surfaces, whereas collagen-induced platelet aggregation was either normal or only slightly perturbed.[416]

There are inherited differences in the density of $\alpha_2\beta_1$ on the platelet surface resulting from polymorphisms in the coding and promoter regions of the α_2 gene.[417–419] *In vitro* studies suggest a positive correlation between the extent of $\alpha_2\beta_1$ expression and platelet adhesion to type I and type III collagen.[420] In addition, some, but not all, epidemiologic studies have suggested that increased $\alpha_2\beta_1$ expression is a risk factor for myocardial infarction and stroke in younger individuals and for diabetic retinopathy in patients with type II diabetes mellitus.[421–427]

Mutations in Platelet Adrenergic Receptors

The response of platelets to stimulation of α_2-adrenergic receptors (α_2AR) by epinephrine is variable or may even be absent in otherwise normal individuals.[428] Nonetheless, a family with a history of easy bruising and minimally prolonged bleeding times has been described in which several members had impaired platelet aggregation and secretion solely in response to epinephrine and in which the number of platelet α_2AR was decreased.[429] It is noteworthy that inhibition of adenylate cyclase by epinephrine was normal, implying that the coupling of the α_2AR to aggregation and adenylate cyclase are different. Other families with defective epinephrine-induced platelet responses have been reported,[430] but the relationship of the functional defects to bleeding is unclear.

Inherited Abnormalities in Platelet GTP-Binding Proteins

GTP-binding proteins link surface receptors to intracellular signal transduction. Thus, they are a potential locus for mutations leading to platelet dysfunction. Abnormalities involving Gαq, Gαi_2, and Gαs have been described in human platelets. Although deficiency of Gαz in humans has not been reported, Gαz-deficient mice have impaired epinephrine responses.[431]

Gαq Deficiency

Gabbeta et al.[432] described a patient with a mild bleeding disorder, impaired platelet aggregation and secretion in response to several agonists, and diminished platelet GTPase activity. Binding of ^{35}S-GTPγS to platelet membranes was diminished, a result of the selective decrease in platelet membrane Gαq with normal levels of Gαi_2, Gα_{12}, Gα_{13}, and Gαz. Responses to the thrombin receptor agonist peptides SFLLRN and GYPGKF were impaired, demonstrating that Gαq is coupled to both the PAR 1 and PAR 4 thrombin receptors. Although the Gαq coding sequence in this patient was normal, Gαq mRNA levels were decreased in platelets but not neutrophils.[433] Thus, the responsible mutation remains to be identified.

Gαs Abnormalities

Gαs activation increases platelet cAMP levels and inhibits agonist-stimulated platelet responses. Two siblings and an individual have been described with inducible Gαs hyperactivity that was manifest as a bleeding diathesis, markedly prolonged bleeding times, variable mental retardation, and skeletal malformations.[428] Platelet aggregation was reportedly normal, but the platelets had increased sensitivity to inhibition by agents that elevate cAMP levels. The Gαs gene (*GNAS1*) has two extra promoters and a first exon that can be alternatively spliced, generating differentially imprinted transcripts. Use of an upstream promoter results in the paternal expression of a transcript for an extralarge form of Gαs, XLαs. Each of the patients was heterozygous for a 36-bp insertion, as well 2-bp substitutions, in the first exon of XLαs. The insertion and basepair substitutions were also detected in 6 of 276 normal controls. When they were present in the paternal allele, the control platelets also displayed inducible Gαs hyperfunction. Nonetheless, XLαs is not activated by Gαs-coupled receptors in platelets, so the mechanism leading to excessive cAMP in patient platelets is not apparent.

Conversely, Gαs deficiency associated with abnormal imprinting of the GNAS1 region was detected in the platelets of a patient with pseudohypoparathyroidism Ib.[430] The patient had decreased cAMP formation following Gαs-coupled receptor stimulation but apparently had no hemostatic or thrombotic phenotype.

Gαi_1 Deficiency

Gαi inhibits agonist-stimulated adenylyl cyclase activity in platelets. Thus, in a patient whose platelets expressed only 25% of the normal amount of Gαi_1, there was no inhibition of forskolin-stimulated cAMP synthesis when patient platelets were stimulated by ADP, thrombin, or epinephrine.[434] By contrast, Gαq-mediated responses were normal. The abnormalities in platelet biochemistry were accompanied by clinical bleeding and abnormal platelet aggregation and dense granule secretion, although the linkage between Gαi activation and the latter responses is not clear.

Inherited Abnormalities in Signaling Intermediates

Phospholipase C Abnormalities

Agonist-stimulated PLC activation results in the generation of the signaling intermediaries inositol triphosphate ($InsP_3$) and diacylglycerol, leading to an increase in the intracellular concentration of Ca^{2+} and protein kinase C (PKC) activation, respectively. Human platelets contain at least seven PLC isozymes in the quantitative order PLC-γ2 > PLC-β2 > PLC-β3 > PLC-β1 > PLC-γ1 > PLC-δ1 > PLC-β4.[435] Study of two related patients with impaired platelet aggregation and secretion revealed decreased agonist-stimulated $InsP_3$ and diacylglycerol formation suggesting a defect in PLC activation.[436–438] Subsequent study of one of the patients revealed decreased amounts of PLC-β2 mRNA and protein in platelets, but not in neutrophils, suggesting a megakaryocyte-specific defect in PLC-β2 gene regulation.[435,439]

Presumptive abnormalities in PLC related pathways have been suggested to explain the bleeding diatheses of a number of additional patients. In seven of eight patients with abnormal platelet aggregation and secretion, receptor-mediated Ca^{2+} mobilization and/or pleckstrin phosphorylation was also abnormal, but the defects were corrected using the direct PKC activator 1,2, dioctonoyl-sn-glycerol and the calcium ionophore A23187, suggesting defective PLC activation,[440] either at the level of PLC-β2,[435,438] Gαq,[432] or PKC-θ.[441] Study of eight other patients with decreased platelet aggregation in response to weak agonists[442] revealed decreased phosphatidylinositol hydrolysis and phosphatidic acid formation[443] and, in one, decreased pleckstrin phosphorylation.[444]

There are numerous reports of other patients with mild bleeding diatheses in whom platelet phosphoinositide metabolism was impaired.[368,380,440,442–448] However, the responsible biochemical abnormalities remain to be determined.

Protein Kinase C-θ Deficiency

PKC isozymes are serine/threonine-specific kinases whose activity has been linked to $\alpha_{IIb}\beta_3$ activation and platelet secretion. PKC-θ deficiency has been described in a patient with mucocutaneous bleeding, mild thrombocytopenia, abnormal platelet aggregation and dense granule secretion, and a heterozygous mutation in the transcription factor RUNX1.[441,449]

Impaired Liberation of Arachidonic Acid from Phospholipids

The initial and rate-limiting step in TXA_2 synthesis is the hydrolysis of arachidonic acid from membrane-bound phospholipids by PLA_2. Four patients have been described in whom thrombin-stimulated arachidonic acid mobilization from phospholipids was impaired.[450] In one of the patients, membrane and cytosolic PLA_2 were normal, but agonist-induced increments in cytosolic Ca^{2+} were impaired due to $G\alpha q$ deficiency.[432,437] On the other hand, a patient with recurrent small intestinal ulceration, markedly decreased eicosanoid synthesis, and platelet dysfunction was found to have two heterozygous missense mutations in the PLA_2 coding region.[451]

Defective Platelet Cyclooxygenase and Thromboxase Synthetase Activity

Malmsten et al.[452] reported platelet cyclooxygenase (COX) deficiency in a patient with a mild bleeding disorder and impaired aggregation responses to ADP, epinephrine, collagen, and arachidonic acid but with normal responses to PGG_2. Subsequently, other patients with defects in TXA_2 synthesis were reported.[453–458] In five such patients, Roth and Machuga[457] found normal amounts of COX enzyme, implying that the defect in the enzyme was qualitative, not quantitative. Similarly, of three patients whose platelets were able to convert the endoperoxide PGH_2, but not arachidonic acid, to TXA_2, protein corresponding to COX-1 was undetectable in two, but was normal in one, indicating that the latter was a functionally abnormal molecule.[458] Two patients have been described with thromboxane synthetase deficiency.[459,460] In a third patient, thrombin-induced TXA_2 synthesis was markedly diminished in platelet-rich plasma, but there was substantial TXA_2 production when the patient platelets were suspended in buffer containing no albumin, suggestive of a partial defect in arachidonic acid metabolism.[461]

Platelet Dysfunction Associated with Transcription Factor Deficiencies

Transcription factor abnormalities may be the basis for the platelet dysfunction in some patients. RUNX1 haplodeficiency is associated with thrombocytopenia and predisposition to leukemia;[462] abnormal aggregation secretion responses, and protein phosphorylation, dense granule deficiency, and alpha-granule deficiency;[441,463,464] and deficiencies of platelet PKC-θ,[465] PF4,[466] myosin light chain,[467] and 12-lipoxygenase.[468] Numerous genes are downregulated in platelets,[469] and are direct RUNX1 targets (MYL9,[467] ALOX12,[468] PF4,[466] and PRKCQ[465]). These patients have impaired megakaryopoiesis[470] and decreased platelet thrombopoietin receptors (Mpl).[471] Patients with GATA-1 mutations may have impaired responses to collagen and ristocetin,[90] diminished platelet GS[90] and gray platelet syndrome (R216N),[281] in addition to macrothrombocytopenia.

Therapy

Platelet transfusion is the mainstay of therapy for patients with platelet secretion disorders. However, the intravenous administration of DDAVP that shortens the bleeding time in a substantial number of patients with platelet function defects is a viable alternative.[472–475] Nonetheless, it is not clear whether DDAVP improves hemostasis in the absence of an effect on the bleeding time. Responses in patients with SPD have been variable with shortening of the bleeding time in some[353,475] but not others.[472,474] In uncontrolled studies, it has been possible to manage selected patients undergoing surgical procedures with DDAVP alone.[472,474] Abnormal *in vitro* platelet function is not corrected by DDAVP.[474]

Recombinant factor VIIa has been used successfully to manage bleed in patients with SPD.[120,242,358] Other approaches include a short 3- to 4-day course of prednisone (20 to 50 mg)[356] and administration of the antifibrinolytic agents epsilon aminocaproic acid or tranexamic acid.[118]

DISORDERS OF PLATELET PROCOAGULANT ACTIVITY

The plasma membrane of activated platelets provides a procoagulant surface for the assembly of the "tenase" and "prothrombinase" complexes that activate coagulation factor X and prothrombin, respectively (see Chapter 35). Although it is uncertain whether there are specific membrane protein receptors for this activity, it clearly results from the calcium-induced exposure of anionic phospholipids on the platelet surface.[476] The phospholipid composition of the platelet plasma membrane bilayer, like that of other cells, is asymmetric with phosphatidylcholine and sphingomyelin localized predominantly in the outer membrane leaflet and phosphatidylserine and phosphatidylethanolamine concentrated in the inner leaflet.[477] This asymmetry is established by at least two enzymatic activities: a "flippase," an ATP-dependent aminophospholipid translocase[478,479] that has been identified as a P4 ATPase[480] directing the inward transport of lipids, and a "floppase," an ATP-requiring transporter encoded by the gene ABCC1 that directs the transport of choline- and amino-phospholipids to the outer leaflet.[476] Following an agonist-stimulated rise in intraplatelet $Ca,^{2+}$ membrane asymmetry is lost with exposure of anionic phospholipids on the platelet surface,[481] as well as on the surface of shed platelet membrane vesicles or microparticles (see Chapter 36).[482,483] A similar response to increased intracellular calcium has been detected in erythrocytes[484] and lymphocytes.[485] Redistribution of membrane phospholipids also accompanies apoptosis, but the development of platelet procoagulant activity and apoptotic membrane changes operate through different pathways.[480,486] The Ca^{2+}-induced movement of phospholipids between membrane leaflets in platelets and other cells appears to be mediated by a membrane-associated phospholipid scramblase activity, an essential component of which is the protein TMEM16F.[487] TMEM16F is a member of a 10-member protein family in humans whose founding member is a calcium-activated chloride channel.[488,489] The decrease in Ca^{2+} ionophore-stimulated anionic phospholipid exposure when TMEM16F expression is knocked down in Ba/F3 cells supports its role as a component of scramblase.[487]

Isolated deficiency of platelet procoagulant activity is exceedingly rare. In addition to the one well-studied patient after whom the disorder was named (Scott syndrome),[490] three additional patients have been reported.[166,491,492] A recessive disorder identical to Scott syndrome has also been detected in a pedigree of German shepherd dogs and has been localized to canine chromosome 27.[493] The index patient for Scott syndrome, Mrs. Scott, presented with a history of a spontaneous retroperitoneal hematoma and bleeding after surgery and dental procedures.[490] Prothrombin and partial

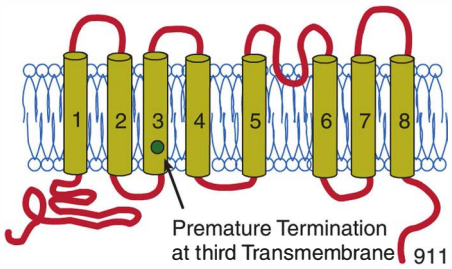

FIGURE 65.4 Schematic diagram of the TMEM16F protein showing the location of the mutation detected in the index patient with Scott syndrome. (Adapted from Suzuki J, Umeda M, Sims PJ, et al. Calcium-dependent phospholipid scrambling by TMEM16F. *Nature* 2010;468:834–838, with permission.)

thromboplastin times, bleeding times, and studies of platelet function were normal, but serum prothrombin times were short and the patient's platelets were unable to express normal procoagulant activity. Although the patient's platelets secreted normal quantities of factor Va, they expressed only 20% to 25% of the normal number of factor Xa binding sites.[494] In addition, factor X activation by factor IXa and factor VIIIa was impaired, suggesting a concomitant deficiency of factor IXa and/or factor VIIIa binding sites.[495] When her platelets were stimulated with the combination of thrombin and collagen, there was decreased exposure of anionic phospholipids on the platelet surface and decreased membrane vesiculation.[496–498] Similarly, there was decreased membrane vesiculation and procoagulant activity when the patient's erythrocytes were treated with the ionophore A23187.[484] In addition, membrane-associated phospholipid scramblase activity was impaired in the patient's platelets, erythrocytes, and lymphocytes.[477]

Recent evidence suggests that TMEM16F mutations are responsible for the Scott syndrome phenotype. A homozygous mutation at the splice acceptor site for intron 12 of the *TMEM16F* gene has been detected in DNA from Mrs. Scott.[487] This results in alternative splicing, a frame shift, and premature termination of protein translation in exon 14 (FIGURE 65.4). Analysis of genomic DNA from a second patient revealed compound heterozygosity for a mutation at the donor splice site of intron 6 and a single nucleotide insertion in exon 12 causing a frame shift and premature termination of translation.[499] Taken together, these data provide strong evidence that *TMEM16F* mutations can be causative in Scott syndrome; whether TMEM16F is the membrane scramblase itself remains to be determined.

CHAPTER

66 Acquired Disorders of Platelet Function

A. KONETI RAO AND JOEL S. BENNETT

Platelets are essential for normal hemostasis. Thus, defects in platelet function may lead to bleeding diatheses. Platelet function defects can be inherited or acquired, with the latter being far more common. Moreover, abnormalities are often observed in multiple facets of platelet function, including adhesion, aggregation, secretion, and procoagulant activity. Although it would be preferable to classify these disorders on the basis of specific biochemical or functional defects, this is often not possible because in many instances, the basis for the defective platelet function is poorly understood. In this chapter, acquired platelet function disorders are described in relation to the disease states in which the perturbed platelet function is observed (Table 66.1). In some disease states, such as the myeloproliferative disorders, intrinsically abnormal platelets are produced by the bone marrow. In others, platelet dysfunction results from the interaction of otherwise normal platelets with exogenous factors such as drugs, artificial surfaces, toxic metabolites, or antibodies. Acquired platelet dysfunction is a prominent feature of renal failure, liver failure, and cardiopulmonary bypass. The platelet dysfunction associated with these conditions is discussed specifically in Chapters 126, 127, and 129.

Bleeding due to acquired platelet dysfunction is usually mucocutaneous in nature. However, the impact of these disorders on clinical hemostasis is often unpredictable, and in some instances, perturbed platelet function can only be detected in the laboratory. When bleeding occurs, it is usually mild to moderate, although the potential for severe life-threatening bleeding exists. Acquired platelet function disorders can prolong the cutaneous bleeding time and perturb *ex vivo* measurements of platelet aggregation. For example, aspirin ingestion impairs platelet aggregation and secretion in response to weak agonists such as ADP and epinephrine in most individuals, but only prolongs the bleeding time in half of them.[1,2] Moreover, the correlation between bleeding time prolongation and clinical bleeding is weak. This also applies to other methods used to detect abnormal platelet function, including the platelet function analyzer (PFA), the VerifyNow rapid PFA, the Impact cone and plate(let) analyzer (CPA), and flow cytometry.

CHRONIC MYELOPROLIFERATIVE DISORDERS

Bleeding and thrombosis are frequent complications of the chronic myeloproliferative disorders such as essential thrombocythemia (ET), polycythemia vera (PV), and primary myelofibrosis (MF).[3,4] Factors that contribute to these hemostatic abnormalities include the increased whole-blood viscosity present in PV, intrinsic defects in platelet function, elevated platelet counts, as well as leukocyte and/or endothelial dysfunction.

Clinical Features

Large retrospective analyses have indicated that the frequency of thrombosis consistently exceeds the frequency of hemorrhage in these disorders.[5] Nonetheless, a wide range in the probability of major thromboses has been reported: 7.6% to 29.4% and 11.2% to 38.6% for newly diagnosed ET and PV, respectively.[5] By contrast, bleeding has been reported in 3% to 18% of patients with ET and 3% to 8.1% of patients with PV.[5] Most symptomatic patients experience either bleeding or thrombosis; however, some develop both complications during the course of their disease. Bleeding usually involves the skin or mucous membranes, but may also occur after surgery or trauma. Thrombosis can involve arteries, veins, and the microvasculature and may occur in unusual locations such as abdominal wall vessels or the hepatic, portal, and mesenteric circulations.[6–9] Indeed, full-blown or latent myeloproliferative disorders account for a substantial proportion of patients with the Budd-Chiari syndrome or portal vein thrombosis.[6,10–12] Individuals with ET may experience ischemia and necrosis of the fingers and toes due to digital artery thrombosis, microvascular occlusion in the coronary circulation, and transient neurologic symptoms due to cerebrovascular occlusion.[13] Erythromelalgia, characterized by redness and burning pain in the extremities, is strongly associated with ET and PV and is thought to be due primarily to arteriolar platelet thrombi.[14,15] It is difficult to predict the risk of bleeding or thrombosis in an asymptomatic patient,[16] but in a review of 891 patients with ET as defined by the World Health Organization criteria and followed for a median time of 6.2 years, 12% experienced arterial and venous thrombosis at a rate of 1.9% patient years.[17] A similar thrombosis rate was observed in the UK MRC Primary Thrombocythemia 1 study that compared treatment of high-risk ET patients with hydroxyurea/aspirin versus anagrelide/aspirin.[18] Predictors for arterial thrombosis in the former study were age >60 years, a history of thrombosis, cardiovascular risk factors, leukocytosis, and the presence of the JAK2 V617F mutation. This analysis is consistent with previous studies also showing that vascular complications are more likely to occur in patients older than 60, in patients with other risk factors for vascular disease, and when baseline leukocytosis is present.[19–23] By contrast, only male sex predicted venous thrombosis. Surprisingly, platelet counts $>10^6/\mu L$ were associated with a significantly lower risk of arterial thrombosis in both the JAK2 V617F-positive and -negative patient populations.

A major advance in understanding the pathogenesis of the myeloproliferative disorders was the identification of gain-of-function mutations in the *JAK2* or *MPL* genes in approximately 95% of patients with PV and approximately 50% to 60% of patients with ET and MV.[24–30] While it is plausible that

Table 66.1

Disorders associated with acquired defects in platelet function

Uremia
Myeloproliferative neoplasms
Essential thrombocythemia
Polycythemia vera
Chronic myelogenous leukemia
Primary Myelofibrosis
Acute leukemias and Myelodysplastic syndromes
Dysproteinemias
Cardiopulmonary bypass
Acquired von Willebrand Disease
Acquired Storage pool deficiency
Antiplatelet antibodies
Liver disease
Drugs and other agents

gain-of-function mutations in the protein products of these genes might influence hemostatic mechanisms, including the activation state of platelets,[31–33] their precise impact on platelet function and thrombotic risk remains unclear.[5,34–36] For example, some studies concluded that the presence of the *JAK2* V617F or a high *JAK2* V617F allele burden[37,38] confers increased thrombotic risk in ET, but others have failed to show such an association.[39–42] It may be useful in the future if such correlative studies were to focus on the *JAK2* V617F allele burden in platelets and granulocytes separately.[40,43]

Abnormalities in Platelet Function and Biochemistry

Under the light or electron microscope, platelets from patients with these disorders may be larger or smaller than normal, may be abnormally shaped, and may exhibit a reduction in the number of storage granules.[44] In ET, platelet survival may be modestly reduced.[45] In addition, a number of diverse functional and biochemical abnormalities have been described. The most frequently encountered abnormality is a decrease in platelet aggregation and secretion in response to epinephrine, ADP, or collagen.[46] The defect in epinephrine-induced aggregation often includes absence of the primary wave of aggregation. This is not simply due to an elevated platelet count, because it is not encountered in reactive thrombocytosis.[47,48]

The reduced platelet aggregation and secretion has also been associated with one or more of the following: decreased agonist-induced release of arachidonic acid from membrane phospholipids[49,50]; reduced conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products[51]; reduced platelet responsiveness to thromboxane A2[52]; deficiency of dense- or α-granules[53,54]; deficiency of the integrin $\alpha_2\beta_1$, resulting in variable changes in platelet responsiveness to collagen[55]; and decreased numbers of α_2-adrenergic receptors.[56,57] Similarly, a reduction in platelet procoagulant activity has been reported in some patients,[58] as have specific platelet membrane abnormalities, including decreased expression and activation of the integrin $\alpha_{IIb}\beta_3$[59]; decreased amounts of the glycoprotein Ib-V-IX complex, resulting in an acquired Bernard-Soulier syndrome[60]; decreased numbers of prostaglandin PGD2 receptors[61]; increased numbers of FcγRIIa receptors[62]; an increase in CD36 expression[63–65]; and decreased expression of Mpl receptors.[66,67] By contrast, spontaneous platelet aggregation, as well as increased thromboxane biosynthesis, has been reported for platelets from patients with ET and PV.[68–70] It has also been reported that Src kinase in unstimulated PV and ET platelets is present in a preactivated state (i.e., the inhibitory residue Tyr527 is dephosphorylated perhaps due to constitutive activation of the phosphatase SHP-2), perhaps causing these platelets to be hypersensitive to agonist stimulation.[71]

It is important to recognize that none of these biochemical and functional abnormalities are unique to a particular myeloproliferative disorder, their relative frequencies vary widely in reported series, and none are predictive of either bleeding or thrombosis. Since these disorders represent clonal abnormalities of hematopoiesis, megakaryocytes likely acquire these abnormalities as they develop from a clone of abnormal progenitors.

Treatment

Therapy should be considered for symptomatic patients, for patients >60 years of age, and for individuals about to undergo surgery.[20,22,34,72,73] Treatment includes correction of polycythemia and maintenance of a normal red cell mass, which may be approximated by a hematocrit <45% in males and <42% in females,[74] as well as treatment of the underlying disorder.[34,75–78] Platelet count reduction to <400,000/mm^3 in patients with thrombocytosis, either by plateletpheresis or by cytoreductive agents, has generally been considered to be the target value associated with clinical improvement.[21,42,77,79]

Effective cytoreductive agents include the ribonuclease reductase inhibitor hydroxyurea,[80] interferon-α, and anagrelide.[20,79,81,82] In a prospective, randomized trial of 114 "high-risk" individuals with ET who were either >60 years of age or had a previous history of thrombosis, hydroxyurea significantly reduced the incidence of new thrombosis from 24% to 3.6%.[80] Anagrelide, an imidazoquinazolin derivative, is thought to decrease platelet counts by specifically impairing megakaryocyte maturation.[83] Anagrelide has essentially no effect on red and white cell counts and is not known to be leukemogenic. Nevertheless, 10% to 20% of patients experience neurologic, gastrointestinal, and cardiac side effects, in particular fluid retention, often necessitating discontinuation of the drug.[82,84,85] When hydroxyurea and anagrelide were compared head-to-head in a randomized trial of 809 patients with ET, subjects in the anagrelide group showed an increased rate of arterial thrombosis, major bleeding, and transformation to MF compared to the group treated with hydroxyurea.[18] Progression to MF despite treatment with anagrelide was also observed in a phase II study.[86] During an episode of acute bleeding in the chronic myeloproliferative disorders, 1-desamino-8-D-arginine vasopressin (DDAVP) infusion may temporarily improve hemostasis if the patient has an acquired storage pool defect or acquired von Willebrand disease (AvWD).[54,87]

Low-dose aspirin (100 to 300 mg/d) may be useful in patients with ET and thrombosis, particularly those with erythromelalgia

or with digital or cerebrovascular ischemia.[15,34,78,88,89] In a recent double-blind, placebo-controlled study of 518 patients with PV who were judged to have no contraindications to daily low-dose (100 mg) aspirin, subjects in the aspirin arm exhibited a reduced risk of nonfatal arterial and venous cardiovascular endpoints. While aspirin was well tolerated, there was no effect of aspirin on overall and cardiovascular mortality.[90] However, aspirin can exacerbate a bleeding tendency in patients with myeloproliferative disorders.[20,91]

ET and PV in pregnancy pose special challenges because of an apparent increased risk of unsuccessful pregnancy, thrombotic or bleeding complications, and potential teratogenicity of hydroxyurea.[92] In ET, the risk of first-trimester miscarriages may be higher among women with the *JAK2* V617F mutation.[93] Barbui and Finazzi[94] have recommended a risk-stratified approach to management in pregnancy in which high risk is defined as either previous major bleeding or thrombotic episodes, previous pregnancy complications, or a platelet count >1.5 million/μL. Low-risk individuals are maintained at a hematocrit <45% and receive aspirin, 100 mg/d during pregnancy and low molecular weight heparin, 4,000 U/d for 6 weeks after delivery. Interferon-α is considered rather than aspirin if there has been previous major bleeding or if platelets are >1.5 million/μL. In addition, high-risk patients are recommended to receive low molecular weight heparin throughout pregnancy. However, in a retrospective analysis of 122 consecutive pregnancies in 92 women with ET, the risk of spontaneous abortion was 2.5-fold higher than in a control population and aspirin did not affect the live birth rate, but treatment with interferon-α was associated with better outcomes.[95] Consistent with previous reports, the presence of the *JAK2* V617F mutation was again found to be an adverse prognostic factor.

ACUTE LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Thrombocytopenia is the major cause of bleeding in acute leukemias and myelodysplastic syndromes (MDS). However, bleeding complications may occur in patients with normal platelet counts because of platelet dysfunction. Acquired platelet defects have been reported in acute myelogenous leukemia, as well as in acute lymphoblastic and myelomonoblastic leukemias and hairy cell leukemia.[96–101] The reported abnormalities in these patients include impaired platelet aggregation responses to ADP, epinephrine, and collagen and diminished nucleotide secretion, serotonin uptake and release, TXA_2 production, platelet PDGF and β-thromboglobulin levels, and platelet procoagulant activities. In patients with hairy cell leukemia, the platelet dysfunction appears to improve postsplenectomy.[102–104] Acquired forms of vWD[105] and Bernard-Soulier–like platelet defects have been described in hairy cell leukemia and juvenile MDS,[60] respectively. Decreased platelet aggregation in response to one or more agonists has been described in MDS.[106–108]

In acute leukemias and MDSs, platelets may be large and morphologically abnormal, with a balloon-like appearance. Ultrastructural studies have shown decreased microtubules, reduced number and abnormal size of dense granules, and excessive membranous systems[97–99]; megakaryocytes can have a dysplastic appearance.[97,98] Bleeding in acute leukemias and MDS usually responds to transfusion of platelets.

DYSPROTEINEMIAS

Bleeding in patients with dysproteinemias can result from multiple hemostatic abnormalities including platelet dysfunction, specific coagulation abnormalities, hyperviscosity, and amyloid deposition in vessel walls.[109,110] Qualitative platelet defects occur in 33% of patients with IgA myeloma or Waldenstrom macroglobulinemia, 15% of patients with IgG multiple myeloma, and infrequently in monoclonal gammopathy of undetermined significance. Several coagulation abnormalities have been reported in patients with dysproteinemias including factor X deficiency related to amyloidosis,[111] circulating heparin-like anticoagulants,[112] and impaired fibrin polymerization.[113] An acquired form of vWD has been described in some patients.[114–117] Platelets express Fc receptors, and it has been proposed that paraprotein binding to these receptors interferes with normal platelet membrane functions. In rare cases, paraprotein binding to platelet GPIIIa inhibited platelet aggregation or binding to GPIb interfered with its interaction of von Willebrand factor (vWF).[114–116,118]

Treatment

The platelet dysfunction in these diseases appears to correlate with serum paraprotein levels. Thus, acute bleeding episodes can be managed with plasmapheresis to lower the paraprotein levels and chronic bleeding may be controlled by chemotherapy aimed at reducing the concentration of the abnormal protein. DDAVP may be transiently effective in patients with AvWD.[114,116]

ACQUIRED vON WILLEBRAND DISEASE

AvWD is a bleeding disorder that is often unrecognized. Most patients with AvWD are older (median age 62 years) and have no previous personal or family history of a bleeding diathesis. Disorders associated with AvWD in these patients are diverse[119,120,121]; the major associations include lymphoproliferative or plasma cell proliferative disorders (50%), cardiac disease (20%), and myeloproliferative diseases (15%). AvWD has been reported in chronic lymphocytic leukemia, hairy cell leukemia, acute myeloid and lymphoblastic leukemias, and non-Hodgkin lymphoma. In patients with myeloproliferative diseases and in reactive thrombocytosis, there is a strong correlation between the plasma vWF abnormalities and elevated platelet counts.[122,123] AvWD has been observed in patients with autoimmune disorders, including systemic lupus erythematosus, scleroderma and mixed connective tissue disease, hypothyroidism, and the antiphospholipid antibody syndrome,[119,120] and following administration of ciprofloxacin,[124] valproic acid,[125] griseofulvin,[126] and the plasma expander hydroxyethyl starch.[127,128] AvWD has been reported in patients with solid tumors, most notably Wilms tumor, but case reports have noted an association with others as well (adrenocortical, lung, and gastric carcinoma).[119,129] Patients with severe aortic stenosis and congenital valvular heart disease may have excess bleeding (particularly gastrointestinal), and several reports have documented AvWD in these patients,[130–135] as well as in patient with left ventricular assist devices (LVADs).[136–138] Vincentelli et al.[131] studied 50 consecutive patients with aortic stenosis and found skin or mucosal bleeding in 21% of patients with severe aortic stenosis. Abnormal platelet function documented by the PFA-100, decreased vWF binding to collagen, and loss of the largest

vWF multimers, or a combination of these findings, has been reported in 67% to 92% of patients with severe aortic stenosis. These abnormalities were corrected following surgery.

AvWD arises from a variety of mechanisms.[119,121] Some patients (especially those with dysproteinemias or lymphoproliferative diseases) have antibodies directed against functional domains of vWF[119,121,132] that the antibodies that inhibit ristocetin cofactor activity or interfere with platelet or collagen binding. In some patients, antibodies enhances vWF clearance. Increased shear stress–induced proteolysis of vWF can produce AvWD, especially in patients with severe aortic stenosis,[131,133,134] congenital cardiac diseases,[130] and LVAD.[136–138] In some patients, cellular adsorption and removal of vWF by malignant or other cells is the responsible mechanism.[119,121] Nonimmunologic binding and precipitation of vWF has been noted following administration of hydroxyethyl starch.[127] Lastly, decreased vWF synthesis has been invoked in patients with hypothyroidism[139] and those receiving valproate.[125]

Laboratory findings in AvWD have included various combinations of a prolonged bleeding time, decreased plasma levels of vWF antigen and ristocetin cofactor activity and decreased factor VIII levels; most important is a selective reduction in large vWF multimers. Plasma levels of activated vWF, representing GPIbα binding form of vWF, are decreased in severe aortic stenosis.[134] vWF propeptide levels have been found to be elevated.

Therapy

The goals of treatment are first to raise plasma vWF levels to treat or prevent bleeding and second to address the underlying associated condition.[121] The first goal can be achieved by administration of DDAVP or factor VIII concentrates containing vWF.[119,121,132] Cryoprecipitate is also effective, but is associated with the risk of transfusion-transmitted diseases. Recombinant factor VIIa has also been used to control bleeding in patients with AvWD.[140] Several reports have found intravenous immunoglobulin to be effective, including in patients with plasma cell dyscrasias.[119,120,132,141,142] Other modalities include plasma exchange[116] and extracorporeal immunoadsorption.[143]

Treatment of the underlying disorder is an important component of managing patients with AvWD. In patients with elevated platelet counts due to myeloproliferative disorders, cytoreduction is effective in reversing the vWF abnormalities.[122,144] Remissions have occurred spontaneously or after therapy of the underlying disease, such as lymphoproliferative disease, Wilms tumor, multiple myeloma, hypothyroidism, chronic myelogenous leukemia (CML), or cardiac valve abnormalities.[119,131]

ACQUIRED STORAGE POOL DISEASE

Inherited deficiency of the platelet-dense granule pool of ATP and ADP (storage pool deficiency, SPD) is associated with impaired platelet function and a bleeding diathesis (Chapter 65). Several patients have been reported in whom SPD appears to have been acquired as a result of *in vivo* activation and release of platelet-dense granule contents or the production of abnormal platelets by the bone marrow. The presence of antiplatelet antibodies has been associated with acquired SPD.[145,146] It has also been reported in patients with disseminated intravascular coagulation, hemolytic-uremic syndrome, renal transplant rejection, multiple congenital cavernous hemangiomas, myeloproliferative diseases, chronic granulocytic leukemia, hairy cell leukemia, and acute nonlymphocytic leukemia.[50,98,147–152] Depletion of platelet granule contents has also been reported in patients with severe valvular disease and with Dacron aortic grafts, in patients undergoing cardiopulmonary bypass, and in platelet concentrates stored for transfusion.[153–156]

ANTIPLATELET ANTIBODIES AND PLATELET DYSFUNCTION

Antibody binding to platelets can lead to accelerated destruction, cell lysis, platelet aggregation and secretion, and expression of platelet procoagulant activity. Antibody binding can also impair platelet function by inhibiting platelet activation or by binding to surface glycoproteins. The overall impact may be thrombocytopenia and/or impaired platelet function, as noted in a wide range of autoimmune disorders, including primary immune thrombocytopenic purpura (ITP), collagen vascular diseases, and AIDS. In addition, these antibodies inhibit megakaryocytopoiesis and proplatelet formation.[157,158] Patients with ITP have decreased platelet survival with increased platelet-associated antibodies demonstrable in most patients. It has been generally considered that the circulating platelets in these patients are young and have enhanced function; for example, bleeding times have been reported to be disproportionately shortened in relation to the platelet counts in patients with ITP compared with those with regenerative thrombocytopenia.[159] However, the function of platelets in patients with ITP may also be impaired, even when platelet counts are adequate. In one study, defective *in vitro* platelet aggregation was observed in 9 of 11 patients with chronic ITP and normal platelet counts.[160] Serum globulin fractions from some of these patients were found to inhibit the aggregation responses of normal platelets to collagen and ADP. In another study, IgG and F(ab')2 fragments from some ITP patients inhibited responses of normal platelets.[161] Impaired platelet aggregation responses to agonists (ADP, epinephrine, and collagen) with and without prolonged bleeding times have been reported in ITP and in disorders such as systemic lupus erythematosus and Graves disease, diseases in which platelet-associated antibodies have been detected.[145,146,162–168]

Multiple mechanisms have been reported that produce antibody-induced platelet dysfunction. In some patients, the antibodies are directed against specific platelet surface membrane glycoproteins (GPIb,[169,170] $\alpha_{IIb}\beta_3$,[171,172] GPIa-IIa,[173,174] and GPVI[175,176]) or glycosphingolipids.[177,178] In others, antibody specifically blocked platelet aggregation induced by collagen through interaction with GPVI[175] or GPIa/IIa.[173,174] In one report, an anti-GPVI antibody induced selective clearance of the GPVI/FcR gamma chain complex from the platelet surface.[176] Antibodies against GPIb-IX and $\alpha_{IIb}\beta_3$ have been detected in 5% to 29% and 10% to 75% of ITP patients, respectively.[169,171,179] Rarely, these antibodies induce acquired forms of the Bernard-Soulier syndrome and Glanzmann thrombasthenia. One study noted that the severity of thrombocytopenia was not related to the glycoprotein specificity of the autoantibody.[180] Most of the platelet antibodies in ITP have been IgG, with IgM and IgA occurring less frequently.[181] Other functional defects in ITP platelets include impaired platelet arachidonate metabolism, as reflected by increased lipoxygenase activity and decreased cyclooxygenase (COX) products (TXA_2 and hydroxyheptadecatrienoic acid),[165] and deficiency of platelet granule contents.[145,146,182]

Table 66.2

Drugs that affect platelet function

COX Inhibitors
Aspirin
Nonsteroidal anti-inflammatory agents (indomethacin, phenylbutazone, ibuprofen, sulfinpyrazone, sulindac, meclofenamic acid, naproxen, diflunisal, piroxicam, tolmetin, and zomepirac)
ADP Receptor Antagonists
Thienopyridines: ticlopidine, clopidogrel, and prasugrel
Ticagrelor
GPIIb-IIIa Antagonists
Abciximab, tirofiban, eptifibatide
Drugs that Increase Platelet Cyclic AMP or Cyclic GMP
Prostaglandin I_2 and analogs
Phosphodiesterase inhibitors (dipyridamole, cilostazol, caffeine, theophylline, and aminophylline)
Nitric Oxide and Nitric Oxide donors
Antimicrobials
Penicillins
Cephalosporins
Nitrofurantoin
Hydroxychloroquine
Miconazole
Cardiovascular Drugs
β-adrenergic blockers (propranolol)
Vasodilators (nitroprusside and nitroglycerin)
Diuretics (furosemide)
Calcium channel blockers
Quinidine
Angiotensin-converting enzyme inhibitors
Anticoagulants
Heparin
Thrombolytic Agents
Streptokinase, tissue plasminogen activator, urokinase
Psychotropics and Anesthetics
Tricyclic antidepressants (imipramine, amitriptyline, and nortriptyline)
Phenothiazines (chlorpromazine, promethazine, and trifluoperazine)
Selective serotonin release inhibitors (fluoxetine, paroxetine, etc.)
General anesthesia (halothane)
Chemotherapeutic Agents
Mithramycin
1,3-bis (2-chloroethyl)-1-nitrosurea
Daunorubicin
Dasatinib
Miscellaneous Agents
Dextrans and hydroxyethyl starch
Lipid-lowering agents (clofibrate and halofenate)
e-Aminocaproic acid
Antihistamines
Ethanol
Vitamin E
Radiographic contrast agents
Food items and food supplements (ω-3 fatty acids, vitamin E, chocolates, onions, garlic, ginger, cumin, turmeric [curcumin], clove, black tree fungus, and Ginkgo)

LIVER DISEASE

The hemostatic defect in chronic liver disease is complex and results from deficiencies of blood coagulation factors and their inhibitors, disseminated intravascular coagulation, decreased fibrinolytic inhibitors and increased fibrinolysis, thrombocytopenia, and qualitative platelet defects (see Chapter 126). The overall contribution of platelet dysfunction to the hemostatic defect in severe liver disease is unknown; the major contributors are the changes in blood coagulation. Platelet abnormalities noted in patients with chronic liver disease of various etiologies include prolongation of the bleeding time, diminished platelet survival, and reduced platelet aggregation, platelet adhesiveness, and platelet procoagulant activities.[183–188] In some studies, platelet aggregation responses were normal.[189] Platelet TXA_2 production has been reported to be decreased, associated with a defect in the release of free arachidonic acid from phospholipids and in phosphatidic acid formation.[187,188,190] The platelet dysfunction in severe liver disease has been attributed to elevated plasma fibrin degradation products,[183,185] abnormal high-density lipoproteins,[191] and ethanol.[192,193] Therapy for the hemostatic defect in severe liver disease involves administration of products to correct the coagulopathy. Platelet transfusions are indicated in patients with serious bleeding and severe thrombocytopenia. Intravenous and subcutaneous DDAVP shortens the bleeding time of patients with cirrhosis[194–196] and may be useful in the treatment of some patients (Chapter 60).

MISCELLANEOUS CONDITIONS WITH IMPAIRED PLATELET FUNCTION

Platelet function abnormalities have been described in severe vitamin B_{12} deficiency,[197] eosinophilia[198–200], atopia,[201] asthma and hay fever,[201,202] and Bartter syndrome.[203] The clinical importance of these observations is uncertain.

DRUGS THAT INHIBIT PLATELET FUNCTION

Many drugs affect platelet function (Table 66.2), and the clinical relevance is the potential for either spontaneous or provoked

bleeding. However, for several drugs, the antiplatelet effects have been established largely *in vitro* and the clinical relevance of these findings is not clear. The impact on hemostasis is unknown for many drugs, even when they have been shown to decrease platelet responses *ex vivo*. Moreover, the impact of combined effects of multiple drugs, each with a mild effect on platelet function , is unknown even though this is a clinically relevant issue.

Aspirin (see Chapter 34)

Because of its widespread use, aspirin is an important cause of platelet dysfunction. Aspirin irreversibly acetylates and inactivates platelet COX-1 and inhibits endoperoxide (PGG_2 and PGH_2) and TXA_2 synthesis.[204] Much of the effect of orally administered aspirin on platelet COX occurs in the presystemic (portal) circulation.[205] As little as a single 80 mg tablet administered daily completely blocks platelet TXA_2 production.[206] The efficacy of aspirin in the primary and secondary prevention of arterial vascular events is well established.[204] Its effects as an antithrombotic agent and in impairing primary hemostasis are both related to the inhibition of platelet TXA_2 production, although aspirin has other effects, including acetylation of plasma proteins (prothrombin and fibrinogen).[204] In otherwise normal individuals, the overall result of aspirin ingestion is a mild impairment of hemostasis. Aspirin prolongs the bleeding time in many but not all normal individuals; this effect is influenced by the direction of the forearm incision and the venostasis applied during the procedure.[207–209] Aspirin ingestion results in inhibition of platelet aggregation and secretion following stimulation with weak agonists such as ADP, epinephrine, and low concentrations of collagen and thrombin, and in particular, when platelets are stimulated by arachidonic acid. Closure times in the PFA-100 are often prolonged using the cartridge coated with collagen and epinephrine but not collagen and ADP.[210] The bleeding risk with aspirin is dose related.[204,211] In a meta-analysis of 192,036 patients from 31 clinical trials, the risk of hemorrhage was lowest with aspirin dose <100 mg compared to higher doses.[211] The overall risk of a major bleed with aspirin is <1% per year.[204] Evidence for aspirin's adverse effect on hemostasis, particularly the risk of major extracranial and intracranial hemorrhages, comes from the larger aspirin trials. Several observations point to the clinical significance of the aspirin-induced platelet defect. Ingestion of aspirin during pregnancy has been reported to result in excessive bleeding at delivery in both the neonate and the mother.[212–214] In the Physicians' Health Study, 22,071 healthy, male physicians were randomized to receive placebo or aspirin (325 mg every other day); over a 5-year follow-up there was a significantly higher incidence of easy bruising, mucosal bleeding (including gastrointestinal bleeding), and blood transfusion requirements.[215] The rate of hemorrhagic stroke was higher with aspirin (0.04% per year) compared to placebo (0.02% per year, $P = 0.06$).[215] In the Nurses' Health Study cohort of 79,000 women (34 to 59 years of age), high frequency use of aspirin (>15 tablets per week) was associated with increased risk of subarachnoid hemorrhage, particularly among older or hypertensive women.[216] Preoperative aspirin increases blood loss, transfusions, and repeated operations in patients undergoing cardiac surgery.[217,218,219] The increased bleeding appears with aspirin doses >325 mg/d.[218] However, other studies have suggested that preoperative aspirin improves graft potency and survival.[218,220] Firm recommendations as to when to discontinue aspirin prior to coronary artery surgery (CABG) remain to be established. The American College of Cardiology and American Heart Association guidelines recommend that aspirin be stopped 7 to 10 days before CABG, while the American College of Chest Physicians recommends continuing aspirin up to and beyond the time of surgery.[219]

Gastrointestinal bleeding is a major adverse effect of aspirin.[204,215,221,222,223] Aspirin-induced gastrointestinal toxicity, but not its antithrombotic effect, is dose related in the range 30 to 1,300 mg daily.[204,221] However, even at low doses (30 to 50 mg daily), aspirin can cause serious gastrointestinal bleeding. The overall relative risks of gastrointestinal complications with the use of nonsteroidal anti-inflammatory drugs (NSAIDs including aspirin) have been estimated to be between 3.0 and 5.0 as compared to nonusers.[223]

Individuals with underlying hemostatic defects such as vWD, hemophilia, or mild platelet function defects, and those on oral anticoagulant therapy, may develop considerable postoperative or even spontaneous bleeding with concomitant aspirin therapy. In these patients, aspirin ingestion often leads to a striking prolongation of the bleeding time and an increase in bleeding manifestations and should be avoided. In otherwise normal subjects who are on aspirin and need to undergo elective surgery, aspirin should be discontinued 7 to 10 days prior to the procedure. If excessive perioperative hemorrhage is encountered, it is generally responsive to platelet transfusions. Moreover, DDAVP infusion shortens the aspirin-induced prolongation in the bleeding time.[224] In the context of spinal or epidural anesthesia, a large prospective study in 924 patients undergoing orthopedic procedures indicates that preoperative aspirin therapy is not a significant risk factor for development of neurologic dysfunction from spinal hematoma.[225]

Nonsteroidal Anti-Inflammatory Drugs

Platelet function is inhibited by NSAIDs that inhibit COX-1 and may prolong the bleeding time. These drugs include indomethacin, ibuprofen, sulfinpyrazone, diclofenac, meclofenamic acid, phenylbutazone, sulindac, naproxen, mefenamic acid, piroxicam, tolmetin, and diflunisal.[226–235] COX-1 inhibition by these agents is generally short-lived and reversible. For example, the effect of indomethacin is not detectable after 6 hours.[228] In contrast, the effect of piroxicam may last for several days because of its long half-life.[236] Exposure to NSAIDs other than aspirin is also recognized to increase the risk of upper GI bleeding and/or perforation. However, different NSAIDs vary in this effect.[222,223] In a meta-analysis,[222] the relative risk was lowest for ibuprofen and diclofenac; intermediate for aspirin, indomethacin, naproxen, and sulindac; and higher for azapropazone, tolmetin, ketoprofen, and piroxicam. Ibuprofen has been administered to hemophiliacs without a major increase in bleeding,[237] although enhanced bleeding was noted in HIV-infected hemophilic patients receiving ibuprofen and zidovudine.[238] These findings may be relevant to the choice of the drug for use in patients with impaired hemostasis. Concomitant administration of ibuprofen and aspirin antagonizes the irreversible COX inhibition of aspirin and may impact its antithrombotic efficacy.[239] Like aspirin, most of these NSAIDs inhibit both forms of cyclooxygenase (COX -1 and -2).[240] The selective COX-2 inhibitors, celecoxib, rofecoxib, and valdecoxib, do not have an antiplatelet activity.

Acetaminophen does not inhibit or impair platelet function at levels attained *in vivo*, although in some subjects, it may inhibit *in vitro* platelet responses as a weak COX inhibitor[241] and may even have anti-COX-2 activity.[242]

ADP Receptor Antagonists (see Chapter 111)

The thienopyridine derivatives, ticlopidine, clopidogrel, and prasugrel, inhibit platelet function by inhibiting ADP binding to the $P2Y_{12}$ receptor.[204,243,244,245,246,247] In patients treated with a thienopyridine, platelet aggregation responses to several agonists, including ADP, collagen, epinephrine, and thrombin, are inhibited to various extents depending on agonist concentrations. All three thienopyridines mediate their effects through active metabolites generated *in vivo* by cytochrome P450 in the liver. With repeated twice-daily dosing, plasma ticlopidine levels increase approximately threefold over 2 to 3 weeks because of drug accumulation; the elimination half-life is up to 96 hours after 14 days of repeated dosing. Clopidogrel differs from ticlopidine in pharmacokinetics. It is rapidly metabolized, and the main carboxylic derivative has a plasma elimination half-life of approximately 8 hours. With repeated daily dosing (50 to 100 mg) in healthy volunteers, ADP-induced platelet aggregation is inhibited from the second day, reaching a steady state after 4 to 7 days.[204] After a single dose of 400 mg clopidogrel, platelet aggregation is inhibited at 2 hours and inhibition persists for up to 48 hours. In patients receiving continuous therapy platelet inhibition persists for 7 to 10 days after these agents are discontinued. Both ticlopidine and clopidogrel prolong the bleeding time by 1.5- to twofold over control, although more striking prolongation has also been noted.[244,248,249] PFA-100 closure times are insensitive to therapy with these agents.[210] Because of prolonged pharmacologic activity, ticlopidine and clopidogrel must be discontinued for 7 to 10 days prior to elective surgery. Both drugs have been associated with thrombotic thrombocytopenic purpura.[250–252] Prasugrel, a newer thienopyridine prodrug, is a more potent and consistent inhibitor of platelet function than clopidogrel.[245,246,247] In the Triton-TIMI38 trial, prasugrel was superior to clopidogrel in acute coronary syndromes, but was associated with increased bleeding.[253]

Ticagrelor is a nonthienopyridine $P2Y_{12}$ antagonist. Unlike thienopyridines, it is not a prodrug and is a direct and reversible $P2Y_{12}$ inhibitor.[245,246] It is a more rapid and more potent inhibitor of platelets than clopidogrel.

GPIIb-IIIa Antagonists

Platelet activation results in a conformational change in the integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa), leading to fibrinogen binding to $\alpha_{IIb}\beta_3$ and platelet aggregation. Accordingly, $\alpha_{IIb}\beta_3$ antagonists inhibit platelet aggregation.[204,245] This class of drugs includes abciximab (Reopro), a humanized chimeric monoclonal antibody against the GPIIb-IIIa receptor; eptifibatide (Integrilin), a synthetic cyclic heptapeptide containing the KGD sequence; and tirofiban (Aggrastat), a nonpeptide arginine-glycine-aspartic acid (RGD) mimetic. These drugs are administered intravenously and are used in acute coronary syndromes and in the context of percutaneous coronary interventions. They are potent inhibitors of platelet aggregation in response to all platelet agonists, and they prolong the bleeding time.[204] As would be expected, bleeding is a complication of using these drugs. Acute thrombocytopenia occurring within 24 hours has been described with all three GPIIb-IIIa antagonists; it is mediated by naturally occurring antibodies and may occur even at the first exposure to the drug.[254]

Drugs that Increase Platelet Cyclic AMP or Cyclic GMP

Drugs that increase intracellular cAMP levels by activating adenylyl cyclase (e.g., PGI_2, PGE_1, PGD_2) or inhibiting the cyclic nucleotide phosphodiesterases inhibit platelet responses. Intravenous infusion of prostacyclin (PGI_2) and its stable analogs prolong the bleeding time.[255,256] Dipyridamole, a weak phosphodiesterase inhibitor, blocks adenosine uptake and does not inhibit platelet aggregation in response to collagen, epinephrine, and ADP at usual doses. It has a synergistic effect with aspirin in prolonging the shortened platelet survival in thromboembolic disorders.[257] The dipyridamole formulation currently used combines an extended-release form of dipyridamole with low-dose aspirin.[204] Cilostazol is a phosphodiesterase-3 inhibitor that suppresses platelet aggregation and is used for therapy of peripheral arterial disease.[245,258,259] It does not prolong the bleeding time.[249] Other weak phosphodiesterase inhibitors such as caffeine, theophylline, and aminophylline inhibit ADP-induced platelet aggregation *in vitro*, but this appears to have no clinical significance.[260]

Sildenafil (Viagra), a selective phosphodiesterase-5 inhibitor, increases platelet cyclic GMP levels, but does not have a direct effect on platelet function, although it potentiates the *in vitro* antiaggregatory effect of sodium nitroprusside[261] and may inhibit ADP-induced activation of $\alpha_{IIb}\beta_3$.[262] Some reports have associated sildenafil with epistaxis and hemorrhoidal and variceal bleeding. Nitric oxide (NO) and NO donors inhibit platelet activation and responses by elevating cyclic cGMP levels.[263–267] Elevated cGMP inhibits platelet cAMP phosphodiesterase, thereby elevating cAMP. NO administration is associated with a prolonged bleeding time.[263,265]

Antimicrobial Agents

β-lactam antibiotics, including penicillins and cephalosporins, inhibit platelet aggregation responses, and some induce a bleeding diathesis when given in high doses. These include carbenicillin, penicillin G, ticarcillin, ampicillin, nafcillin, cloxacillin, mezlocillin, oxacillin, and piperacillin.[268–278] The effects on platelet function are dose dependent, taking about 2 to 3 days to manifest and 3 to 10 days to abate after drug discontinuation.[268,273,274,277,278] Penicillins lacking an α-carboxy group (mezlocillin, piperacillin, and apalcillin) appear to adversely affect platelet function less often than carboxypenicillins or moxalactam.[277] Cephalosporins may also impair platelet function.[277,279,280] Moxalactam has been reported to induce platelet dysfunction associated with prolonged bleeding times and clinical hemorrhage.[277,280] However, other third-generation cephalosporins appear to show little effect on platelet function.[277] Some β-lactam antibiotics (i.e., moxalactam, cefamandole, cefoperazone, and cefotetan) may induce hypoprothrombinemia and thereby contribute to hemorrhage.[277,280] These compounds contain an N-methylthiotetrazole side chain, which inhibits vitamin K epoxide reductase, thus interfering with the carboxylation of the vitamin K–dependent coagulation factors.

Several generalizations may be made regarding the impact of β-lactam antibiotics on platelets. First, the effects on platelet

function and hemostasis are dose- and time-dependent, with effects discernible over several days.[268,273,274,277,278] Second, the patients at particular risk of bleeding appear to be those with concurrent illnesses including sepsis, malnourishment, thrombocytopenia, and malignancy. Third, the platelet inhibitory effect of β-lactam antibiotics is influenced by plasma albumin; binding of the antibiotic to platelets and the impact on platelet responses are inversely related to albumin concentration.[281] Last, with some cases, bleeding is related to a concomitant inhibition of synthesis of vitamin K–dependent coagulation factors.[277,279,280]

Multiple mechanisms have been invoked to explain platelet inhibition induced by β-lactam antibiotics. Some of the drugs inhibit platelet aggregation and secretion, as well as platelet adherence to subendothelial structures and collagen-coated surfaces.[272] However, these effects were often observed only *in vitro* and at concentrations well above those attained *in vivo*. Short-term *in vitro* exposure of platelets to penicillin has been reported to result in impaired aggregation responses and decreased binding of agonists to specific receptors (ADP, vWF, and α_2-adrenergic) on platelets.[282,283] Although the latter effect of penicillins was found to be rapidly reversible,[282,283] the platelet inhibitory effect of β-lactam antibiotics appears to persist for several days after the drugs are discontinued, indicating that other mechanisms underlie the sustained effect. Other reported effects of β-lactam antibiotics include inhibition of intracellular signaling events, calcium mobilization,[284] and TXA_2 synthesis,[283,284] and alterations in activation-induced changes in $\alpha_{IIb}\beta_3$ and GPIb-IX.[285]

The context in which the bleeding events are encountered in patients on antibiotics precludes clear definition of the role played by the antimicrobials because of the simultaneous presence of thrombocytopenia, disseminated intravascular coagulation, infection, and/or vitamin K deficiency. Discontinuation of a specifically indicated antibiotic may not be possible or necessary. Supportive measure using blood products and other interventions (correcting metabolic abnormalities, vitamin K deficiency) are indicated in the overall management.

Other antimicrobials shown to inhibit platelet function include nitrofurantoin,[286] hydroxychloroquine,[287] and miconazole.[288]

Cardiovascular Drugs

Relatively high concentrations of propranolol *in vitro* inhibit the aggregation responses of normal platelets to ADP and epinephrine.[289–291] At lower concentrations, propranolol inhibits secondary aggregation and secretion in patients whose platelets are susceptible to a low threshold concentration of agonists, but not uniformly in all patients taking the drug.[289,292] At conventional doses, propranolol inhibits and normalizes the increased sensitivity to agonists of platelets from patients with angina pectoris.[293] The mechanism by which propranolol alters platelet behavior is probably unrelated to its β-adrenergic blocking effects and may be due to an effect on platelet membranes.[289,292] Propranolol inhibits the release of free arachidonic acid from phospholipids and TXA2 production during platelet activation.[294,295] Overall, propranolol is a weak inhibitor of platelet function and does not influence the bleeding time. Other β-blockers (pindolol, atenolol, metoprolol, and carvedilol) have also been reported to inhibit platelet responses when studied *in vitro*.[290,296] Other cardiovascular drugs known to inhibit platelet responses include furosemide,[297] nitroprusside,[298–301] nitroglycerin and isosorbide dinitrate,[298,302] and quinidine.[303,304] Although calcium channel blockers (nifedipine, verapamil, and diltiazem) inhibit platelet responses, this is only seen *in vitro* at drug concentrations higher than those achieved during therapy.[305–309] These agents inhibit platelet α_2-adrenergic receptors.[307,308]

The angiotensin-converting enzyme (ACE) inhibitors captopril,[310,311] perindopril,[312] and fosinopril,[313] but not quinapril,[312] enalapril,[314] and lisinopril,[315] have been reported to inhibit platelet aggregation in human studies.[316] Captopril[311,314] and fosinopril[314] decrease TXA_2 production. Interestingly, reduced circulating levels of plasma fibrinogen, factor XII, factor XI, tissue plasminogen activator, and plasminogen activator inhibitor-I have been observed with the use of ACE inhibitors.[316]

Anticoagulants and Thrombolytic Agents

Heparin–platelet interactions are clinically relevant, particularly because of the paradoxical antibody-mediated thrombocytopenia and thrombosis. Heparin binds to platelets[317] and enhances aggregation responses to platelet agonists *in vitro*.[318] On the other hand, a bolus injection of heparin into normal subjects prolongs the bleeding time[319] and heparin inhibits vWF-dependent platelet responses *in vitro* and *ex vivo*.[320] The impact of these disparate effects on hemostatic mechanisms during heparin therapy is complex and unclear. Interestingly, protamine sulfate, widely used to neutralize heparin, also inhibits thrombin-induced platelet responses *in vitro*.[321] The major complication following the administration of thrombolytic agents (streptokinase, urokinase, and recombinant tissue plasminogen activator [rt-PA]) is hemorrhage. This is a consequence of the effect of plasmin on the plasma coagulation system and platelets, but predominantly results from the dissolution of clots providing hemostasis at the site of vascular injury. The bleeding time in patients receiving rt-PA may be prolonged.[322] *In vitro*, plasmin induces several effects in platelets: initial platelet activation followed by inhibition; cleavage of membrane glycoproteins; inhibition of TXA_2 production; and disaggregation of platelet clumps.[323–327] Plasmin-induced platelet aggregation has been attributed to cleavage of protease-activated receptor-4.[328] Urinary metabolites of TXA_2 are increased during thrombolytic therapy with rt-PA or streptokinase, indicating *in vivo* activation of platelets.[329,330]

Psychotropic Drugs and Anesthetics

This heterogeneous group of drugs is generally thought to stabilize biological membranes by increasing their fluidity. Tricyclic antidepressants (imipramine, amitriptyline, and nortriptyline) inhibit platelet aggregation and secretion responses to ADP, epinephrine, and collagen.[331,332] Platelets incorporate serotonin into their dense granule by uptake from plasma. Selective serotonin reuptake inhibitors (SSRIs, e.g., fluoxetine [Prozac], paroxetine [Paxil]) are widely used antidepressants that cause an acquired but reversible serotonin deficiency in platelet-dense granules; this may be related to an apparent benefit of SSRIs in coronary artery disease.[333] Case reports indicate that fluoxetine can prolong the bleeding time, impair platelet aggregation, and cause excessive bruising.[334,335] Paroxetine prolongs the PFA-100 closure time and decreases thrombin-induced platelet surface expression of CD63.[336] As a group, SSRIs inhibit platelet function[337] and are associated with increased risk of GI bleeding, transfusions

during orthopedic surgery, and hospital admissions for bleeding manifestations.[338,339] A retrospective study found an increased risk of bleeding in patients taking an SSRI together with aspirin or aspirin plus clopidogrel compared to the antiplatelet regimen alone.[340] Phenothiazines (chlorpromazine, promethazine, and trifluoperazine) inhibit platelet responses to stimulation *in vitro* and perhaps *in vivo*.[341–345] Trifluoperazine may impair platelet responses by inhibiting calmodulin-dependent processes in platelets.[344] Halothane has been reported to increase the bleeding times during general anesthesia[346,347] but probably without effect on surgical hemostasis. Thiopental appears to inhibit platelet responses in surgery patients.[348,349]

Miscellaneous Drugs

Dextrans are branched polysaccharides of 40,000 or 70,000 kDa and have been used as antithrombotic agents. They prolong the bleeding time after infusion and inhibit platelet–factor 3 availability, glass bead retention, aggregation, and secretion.[350–355] Their effects on the bleeding time and platelet inhibition are most pronounced 4 to 8 hours after transfusion.[353] Dextran-induced platelet dysfunction has been attributed to their adsorption to platelets and to a decrease in plasma factor VIII-vWF.[354,356] It is unclear if their use, even in the perioperative state, leads to excessive hemorrhage.[357] In one multicenter study in surgical patients, prophylaxis with dextran-70 was associated with less bleeding than low-dose heparin.[358] Hydroxyethyl starch, another volume expander, may enhance bleeding and prolong the bleeding time,[359–361] as well as cause AvWD.[127,128]

Other drugs that impair platelet function include lipid-lowering agents (clofibrate and halofenate)[362,363]; chemotherapeutic agents such as daunomycin, mithramycin, and 1,3-bis (2-chloroethyl)-1-nitrosurea (BCNU)[364–369]; and antihistamines.[370,371] Dasatinib, a tyrosine kinase inhibitor used for the treatment of CML, has been associated with clinical bleeding symptoms[372]; it inhibits human platelet responses to collagen more effectively than responses to ADP and thrombin *in vitro* and following administration to mice.[373] The fibrinolytic inhibitor epsilon aminocaproic acid (EACA, Amicar) can prolong the bleeding time at the generally administered dose.[374] Ethanol inhibits platelet responses *in vitro*.[375–377] However, it does not prolong the bleeding time by itself. Nonetheless, acute ingestion of 50 g of ethanol potentiates the aspirin-induced prolongation of the bleeding time even in otherwise normal subjects.[378] Other agents reported to inhibit platelet function include radiographic contrast agents[379–381] (although some contrast agents activate platelets[382]), vitamin E,[383,384] fish oil with ω-3 fatty acids,[385,386], and food items and their extracts such as onions,[387–389] garlic,[389,390] ginger,[391] cumin,[392] turmeric,[392–394] clove,[395] flavanol-rich cocoa beverage and chocolates,[396–398] Chinese food, and black tree fungus.[399,400] Inhibition of eicosanoid synthesis appears to be the mechanism of action for several of the spices, although they have other effects, such as lowering of plasma lipids. For most of these agents, there is little evidence that they impair clinical hemostasis.

Herbal medicines, such as Ginkgo (*Ginkgo biloba*) and garlic (*Allium sativum*), inhibit platelet function and have been associated with increased bleeding, particularly when administered concomitantly with other medicines (warfarin and aspirin).[401] With the increasing use of herbal medicines and food supplements, their role and interaction with pharmaceutical drugs needs to be considered in the evaluation of patients with unexplained bleeding.

CHAPTER

67 Laboratory Markers of Platelet Activation

PAUL HARRISON AND ALAN D. MICHELSON

Prevention of platelet activation in the intact circulation is normally controlled by the antithrombotic nature of the endothelial cell surface, which exhibits a number of effective mechanisms for inhibiting platelets. Under normal conditions, platelets are therefore unable to form stable contacts on the vessel wall. Platelet adhesion, however, can occur upon vessel wall damage, on diseased/activated endothelial cells, or at sites of disturbed flow (e.g., atherosclerotic plaques). Exposure of the subendothelial matrix (e.g., collagen) initiates rapid platelet activation, which is then further amplified by the release of platelet-derived adenosine diphosphate (ADP), thromboxane, and serotonin, resulting in further platelet activation and recruitment of other platelets in the vicinity to rapidly form a hemostatic plug. The high shear stresses associated with mature atherosclerotic lesions can also initiate platelet activation.

Platelet activation results in a complex series of changes including a physical redistribution of receptors, changes in the molecular conformation of receptors, secretion of granule contents, cleavage and release of various glycoproteins (the "sheddome"), generation of thromboxane, development of a procoagulant surface, generation of platelet-derived microparticles, and formation of both platelet–platelet and leukocyte–platelet aggregates. All of these changes can potentially be used as markers of platelet activation (Table 67.1). Although platelet activation is usually initiated locally at the site of formation of the hemostatic plug or thrombus, it is possible to measure the consequences of these local events in the systemic circulation—in part because thrombi are very dynamic with transient adhesion, "rolling," and embolization of platelets often occurring. Also, in thrombotic disease, platelets may be "primed" or more reactive to agonists in the circulation or conversely "exhausted" (due to excessive activation) and less activatable *ex vivo*. This can be augmented by a genetic predisposition causing a preexisting reactive phenotype. However, individuals may also acquire a more reactive phenotype due to many environmental phenotypic factors including diet, lifestyle, ageing, various diseases, etc. Therefore, it is now possible to utilize a number of sensitive tools to measure inappropriate platelet activation and/or reactivity in health and disease and also to monitor various forms of antiplatelet therapy to potentially modify treatment and prevention strategies.

Whole blood flow cytometry[1] is now regarded as the research method of choice for the measurement of all these changes, except the secretion of soluble molecules and shed glycoproteins, which are now usually measured by ELISA. Whole blood flow cytometry has many advantages: (a) minuscule volumes (~5 µL) of blood can be used; (b) platelets are directly analyzed in their physiologic milieu of whole blood; (c) the minimal manipulation of samples prevents artifactual *in vitro* activation and potential loss of platelet subpopulations; (d) both the activation state of circulating platelets and the reactivity of circulating platelets can be determined; and (e) a spectrum of different activation-dependent changes can be determined.

METHODS AVAILABLE TO MEASURE PLATELET ACTIVATION

Biochemical Markers

Thromboxane generation provides one of the most important amplification loops in platelet biochemistry. This is exemplified by the widespread use of aspirin to target cyclooxygenase (COX)-1, resulting in irreversible inhibition of thromboxane A_2 generation for the lifespan of the platelet and partially explains why aspirin is such an effective antithrombotic therapy. Serum, plasma, and urinary assays for thromboxane B_2 (a stable metabolite of thromboxane A_2) and other metabolites have utility in the measurement of platelet activation and for monitoring aspirin therapy.[2,3,4] Modern assays are ELISA based and are normally performed on fresh serum samples that have been generated *ex vivo* under standard conditions of incubation (e.g., 1 hour at 37°C). The assays provide sensitive, specific, and relatively simple measurements of COX-1 inhibition, and samples can be stored and batched for analysis. Samples from aspirin-treated patients are unable to generate thromboxane. It is recommended that for monitoring aspirin it is important to measure the consequences of inhibiting the biochemical target of the drug, so these assays provide a simple means for monitoring compliance and effectiveness of aspirin therapy.[5] More recently, ELISAs of 11-dehydro thromboxane B_2 in stabilized and stored urine samples have also become popular and commercialized (AspirinWorks) and provide a simple noninvasive measurement of thromboxane generation that seems to correlate with aspirin efficacy.[4,5,6] The latter assays have the disadvantage that they are also more nonspecific to the platelet and can measure other sources of thromboxane generation.[7]

Another biochemical marker, the measurement of the phosphorylation status of vasodilator-stimulated phosphoprotein (VASP) by flow cytometry, is discussed in section II.C.5 below.

Soluble Markers

α-Granular Proteins

Providing there is a sufficient stimulus platelets secrete the contents of their granules into the plasma. Platelet α-granules contain a number of growth factors, clotting factors, and adhesion molecules, thus providing a way to release high concentrations of important mediators of inflammation, chemotaxis,

Table 67.1

Summary of laboratory markers of platelet activation

Biochemical markers
• Thromboxane (serum, urine)
• VASP
Soluble markers
• α-Granule releasates
• Dense granule releasates
• Platelet "sheddome"
Changes in platelet surface glycoproteins
Platelet surface exposure of granule membrane proteins
Platelet–platelet aggregates
Leukocyte–platelet aggregates
Platelet surface PS
Platelet-derived microparticles

and hemostasis within the local environment of the growing platelet thrombus. As some of these markers are also soluble and specific to the megakaryocyte–platelet lineage, their measurement provides a way to systemically and specifically measure the degree of platelet activation occurring in various disease states. Platelet-derived α-granular markers are now usually measured by ELISAs that have superseded radioimmunoassays. Of these molecules, the most commonly and traditionally measured markers of platelet activation are the α-granular soluble constituents, β-thromboglobulin (β-TG),[8,9] and platelet factor 4 (PF4).[8,9] More recently, some α-granular membrane proteins have been found to be expressed on the surface of activated platelets where they are rapidly cleaved by proteases and are shed into the plasma. These include soluble P-selectin[10,11] and soluble CD40 ligand (sCD40L)[12] (see the platelet "sheddome" section below). However, as a result of the obligatory plasma separation procedures, all of these assays are vulnerable to artifactual *in vitro* platelet activation.[8,9]

Dense Granular Proteins

Platelet-dense granules contain a unique pool of molecules (e.g., serotonin [5-HT], nucleotides, polyphosphate [Poly-P]) that can also provide a sensitive measurement of platelet activation. Lumiaggregometry can be used to measure the *ex vivo* release of adenosine triphosphate (ATP) from dense granules during the aggregation response to an exogenous agonist.[13] Levels of platelet-released ATP and ADP can also be measured by luminometry within standardized platelet-rich plasma preparations that have been activated and lysed.[14] These measurements are useful for the diagnosis of storage and release disorders. Circulating serotonin is actively taken up by platelets and packaged into the dense granules. Some *in vitro* platelet activation assays utilize the uptake of radio-labeled serotonin and measure its release after stimulation with different agonists. Dense granular Poly-P has recently been shown to be an endogenous activator of factor XII, a component of the intrinsic clotting cascade and proinflammatory pathways.[15,16] However, as none of these substances are exclusively synthesized and stored within platelets, their measurement within *ex vivo* blood samples is not as common as with some of the more specific platelet α-granular-derived or shed glycoproteins.

The Platelet "Sheddome"

It has become increasingly apparent that proteolysis of a large number of different platelet surface and granular membrane proteins during or after platelet activation results in the generation of a growing list of potentially useful plasma markers of platelet activation. These protein fragments have been given the collective term the platelet "sheddome" and are released from the platelet surface by proteinases such as ADAM17 or ADAM10.[17] Shedding tends to be slower than platelet activation and is a selective process rather than a wholesale loss of all surface glycoproteins. Among those proteins shed are glycoprotein (GP) Ib (glycocalicin), GPVI, GPV, P-selectin, endothelial cell–specific adhesion molecule, junctional adhesion molecule-A, semaphorin 4D, and CD40L.[17] Many of the shed protein fragments may play roles in platelet and vascular biology, although the full implications of this shedding process are still largely unknown. Nevertheless, measurement of components of the sheddome may prove to be useful as sensitive and specific biomarkers of platelet activation *in vivo*. For example, soluble GPVI is an excellent candidate for a specific biomarker of platelet activation as it is found in the plasma at relatively low levels in healthy subjects but is elevated in patients with thrombotic risk, heparin-induced thrombocytopenia, and immune thrombocytopenic purpura.[18,19] Exposure of platelets *in vitro* to high shear stress also results in increased soluble GPVI levels. Further work is required to determine the clinical potential of this unique marker. Platelet surface GPV is also cleaved by thrombin,[20–22] releasing a soluble form of GPV (sGPV) into plasma, which may serve as another biomarker of platelet activation.[23] A number of the shed glycoproteins (e.g., CD40L and P-selectin) are also present in α-granule membranes and are only detectable on the surface of activated platelets, where they can be cleaved and shed by the action of proteases. Release of sCD40L from the platelet surface is the predominant source of sCD40L.[24,25] sCD40L is thought to be prothrombotic by stabilizing $\alpha_{IIb}\beta_3$-dependent arterial thrombosis[26] but can also be proinflammatory[27,28] (although not all studies agree on this latter point[24]). sCD40L levels have been shown to be elevated in patients with acute myocardial infarction and other acute coronary syndromes. P-selectin (CD62P) is also externalized from the α-granules during platelet activation and is gradually cleaved and shed. Increased levels of soluble P-selectin have been found in many diseases and may predict major adverse cardiovascular events.[11]

An important practical point is that many published patient studies of shed glycoprotein levels were performed using serum. However, blood clotting results from thrombin generation and it is accompanied by platelet activation and the *ex vivo* release of large amounts of these markers into the serum. Therefore, accurate measurement of *in vivo* circulating molecules released from platelets requires assays performed using plasma rather than serum.[29] Platelets also have to be carefully removed during plasma preparation, without any significant activation; anticoagulants (e.g., citrate, theophylline, adenosine, and dipyridamole [CTAD]) containing some platelet inhibitory agents have

been traditionally used for measurement of PF4 and β-TG to help minimize any additional *ex vivo* platelet activation. Soluble P-selectin in plasma may also be of endothelial cell origin although it is thought that this is a predominant marker of platelet activation.[10]

Flow Cytometric Measurement of Platelet Activation

Introduction

Flow cytometry enables the rapid measurement of characteristics of a large number of individual cells.[30] For flow cytometric analysis, cells in suspension are fluorescently labeled, typically with a fluorescently conjugated monoclonal antibody. In the flow cytometer, the suspended cells pass through a focused laser beam at a rate of 1,000 to 10,000 cells per minute. After the laser light activates the fluorophore at the excitation wavelength, detectors process the emitted fluorescence and light scattering properties of each cell.[30] The intensity of the emitted light is directly proportional to the antigen density or the characteristics of the cell being measured.

Clinical studies utilizing flow cytometric assays of washed platelets or platelet-rich plasma are, like other assays of platelet function, potentially susceptible to artifactual *in vitro* platelet activation during obligatory separation procedures. The introduction of whole blood flow cytometry by Shattil et al.[31] was therefore a major step toward the application of flow cytometry to clinical settings.

A typical schema of sample preparation for whole blood flow cytometry is shown in FIGURE 67.1. The anticoagulant is usually buffered trisodium citrate (105 to 109 mmol/L or 129 mmol/L). Samples are then diluted (typically 1:10) in the presence of antibodies or agonists. The purpose of the dilution is to minimize the formation of platelet aggregates (see below). A minimum of two monoclonal antibodies is used, each conjugated with a different fluorophore. A wide variety of fluorophores are available for antibody conjugation (e.g., phycoerythrin, fluorescein, peridinin chlorophyll protein [PerCP], phycoerythrin-Cy5, phycoerythrin-Texas Red [Red-670], allophycocyanin [APC]). The "test" antibody (the monoclonal antibody recognizing the antigen to be measured) is added at a saturating concentration. The "platelet identifier" monoclonal antibody (e.g., GPIb, integrin α_{IIb}, or integrin β_3 specific) is added at a near saturating concentration. Physiologic agonists can be used in the assay, including thrombin, thrombin receptor-activating peptides (TRAPs), ADP, collagen, collagen-related peptide (CRP), the complement fraction C5b-9, and thromboxane A_2 analogs. Nonphysiologic agonists include phorbol myristate acetate and the calcium ionophore A23187. Samples are stabilized by fixation, typically with final concentrations of 0.2% to 1% formaldehyde or paraformaldehyde. Antibodies can be added after fixation, provided fixation does not interfere with antibody binding[32] (see below). Samples are then analyzed in a flow cytometer. After identification of platelets both by their characteristic light scatter and by the "platelet identifier" antibody, binding of the test monoclonal antibody is determined by analyzing 5,000 to 10,000 individual platelets. During *ex vivo* activation and labeling, the formation of platelet aggregates is minimized by using very gentle mixing (tapping of the tube) and dilution to minimize collisions between platelets.

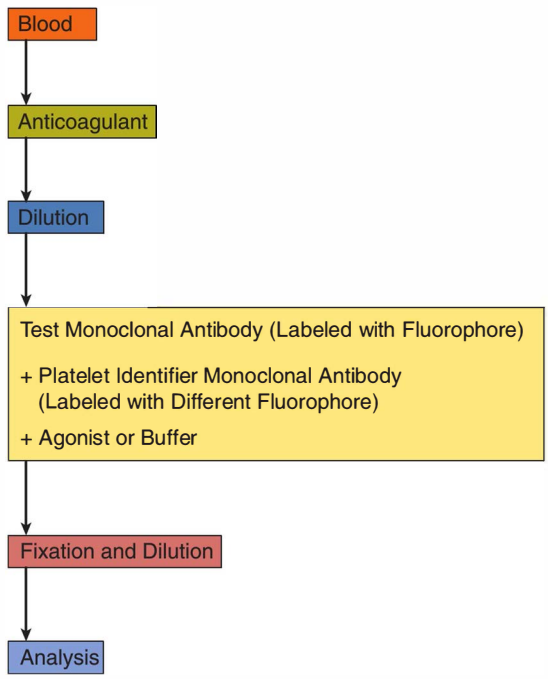

FIGURE 67.1 A typical schema of sample preparation for analysis of platelets by whole blood flow cytometry.

For specific protocols of whole blood flow cytometric assay of platelet function, the reader is referred to various references.[33,34] Laboratory markers of platelet activation include activation-dependent conformational changes in integrin $\alpha_{IIb}\beta_3$ (aka GPIIb-IIIa, CD41/CD61), exposure of granule membrane proteins, platelet surface binding of secreted platelet proteins, and development of a procoagulant surface (Table 67.2). The two most widely studied types of activation-dependent monoclonal antibodies are those directed against conformational changes in $\alpha_{IIb}\beta_3$ and those directed against granule membrane proteins.

Changes in Platelet Surface Glycoproteins

The integrin $\alpha_{IIb}\beta_3$ is a receptor for fibrinogen and von Willebrand factor (vWF) that is essential for platelet aggregation.[35] Whereas most monoclonal antibodies directed against $\alpha_{IIb}\beta_3$ bind to resting platelets, the monoclonal antibody PAC1 is directed against the fibrinogen-binding site that is exposed on $\alpha_{IIb}\beta_3$ by platelet activation (Table 67.1).[36] Thus, PAC1 only binds to activated platelets, not to resting platelets. Other $\alpha_{IIb}\beta_3$-specific activation-dependent monoclonal antibodies are directed against either ligand-induced conformational changes in $\alpha_{IIb}\beta_3$ (ligand-induced binding sites [LIBS])[37] or receptor-induced conformational changes in the bound ligand (fibrinogen) (receptor-induced binding sites [RIBS])[38] (Table 67.1). Rather than integrin $\alpha_{IIb}\beta_3$-specific monoclonal antibodies, fluorescein-conjugated fibrinogen can also be used in flow cytometric assays to detect the activated form of platelet surface $\alpha_{IIb}\beta_3$,[39,40] but the concentration of unlabeled plasma fibrinogen and unlabeled fibrinogen released from platelet α-granules must also be considered in these assays. $\alpha_{IIb}\beta_3$ is expressed at high copy number on the resting platelet surface, but as this protein is also distributed throughout the open canalicular system (OCS) and α-granular membranes, a significant increase in surface protein

Table 67.2

Activation-dependent monoclonal antibodies, that is, antibodies that bind to activated but not resting platelets

Activation-dependent Surface Change	Prototypic Antibodies	References

PS exposure	Annexin-V or lactadherin	59,64

copy density can also be detected on activated platelets. This is normally reflected as an increase in mean fluorescence intensity (MFI) with most fluorescent antibodies against this receptor. Although the vWF receptor GPIb is also expressed at high copy density on resting platelets, changes also occur after activation. As the protein can be internalized into the OCS and/or cleaved to form soluble glycocalicin, significant downregulation in the copy density of this receptor can occur with a decrease in MFI, although the percentage of positive platelets remains 100%.[41,42]

Granule Membrane Markers

The most widely studied types of activation-dependent monoclonal antibodies directed against granule membrane proteins are P-selectin (CD62P) specific. P-selectin is a component of the α-granule membrane of resting platelets that is only expressed on the platelet surface membrane after α-granule secretion. Therefore, a P-selectin-specific monoclonal antibody only binds to degranulated platelets, not to resting platelets. The activation-dependent increase in platelet surface P-selectin is not reversible over time *in vitro*.[43,44] However, *in vivo* circulating degranulated platelets rapidly lose their surface P-selectin, although they continue to circulate and function.[45,46] Platelet surface P-selectin is therefore not an ideal marker for the detection of circulating degranulated platelets, unless (a) the blood sample is drawn immediately distal to the site of platelet activation, (b) the blood sample is drawn within 5 minutes of the activating stimulus, or (c) there is continuous activation of platelets. The length of time that other activation-dependent markers remain on the platelet surface *in vivo* has not been definitively determined, but it is becoming clear that some of these are also shed from the surface (see the platelet "sheddome" section above). CD63 is a membrane protein of dense granules and lysosomes and, like P-selectin, it is only expressed upon the surface of activated platelets. However, unlike P-selectin, this glycoprotein is not prone to proteolysis and may provide a more stable marker of platelet activation.

Leukocyte–Platelet Aggregates

P-selectin mediates the initial adhesion of activated platelets to monocytes and neutrophils via the PSGL-1 counter-receptor on the leukocyte surface.[47] Monocyte–platelet and

neutrophil–platelet aggregates are readily and easily identified by whole blood flow cytometry.[34,48] These interactions are important in cardiovascular disease and many other clinical disorders in which platelets are activated (see section on platelet activation in clinical disorders below).[49,50,51]

Tracking autologous infused biotinylated platelets in baboons by three-color whole blood flow cytometry directly demonstrated *in vivo* that (a) platelets degranulated by thrombin very rapidly (within 1 minute) form circulating aggregates with monocytes and neutrophils (FIGURE 67.2, upper panel); (b) the percent of monocytes with adherent infused platelets is greater than the percent of neutrophils with adherent infused platelets (FIGURE 67.2, upper panel); and (c) the *in vivo* half-life of detectable circulating monocyte–platelet aggregates (~30 minutes) is longer than both the *in vivo* half-life of neutrophil–platelet aggregates (~5 minutes) and the previously reported[46] rapid loss of surface P-selectin from nonaggregated infused platelets (FIGURE 67.2, upper panel).[48]

These findings suggest that measurement of circulating monocyte–platelet aggregates may be a more sensitive indicator of *in vivo* platelet activation than either circulating neutrophil–platelet aggregates or circulating P-selectin-positive nonaggregated platelets. Indeed it has been demonstrated that after percutaneous coronary intervention (PCI), there is an increased number of circulating monocyte–platelet (and, to a lesser extent, neutrophil–platelet) aggregates, but not P-selectin-positive platelets, in peripheral blood.[48] Similarly in patients presenting to an emergency department with chest pain, those with acute myocardial infarction had more circulating monocyte–platelet aggregates than patients without acute myocardial infarction and normal controls. Furthermore, circulating P-selectin-positive platelets were not increased in patients with chest pain with or without acute myocardial infarction.[48]

Taken together, these studies indicate that circulating monocyte platelet aggregates are a more sensitive marker of *in vivo* platelet activation than platelet surface P-selectin.

Vasodilator-Stimulated Phosphoprotein

Measurement of VASP phosphorylation by flow cytometry can be performed by using a specific monoclonal antibody for VASP and fixed and permeabilized platelets in whole blood.[52] VASP is an intracellular platelet protein which is not phosphorylated under basal conditions. VASP phosphorylation is regulated by cAMP, and the assay is based upon stimulation/activation of *ex vivo* blood samples with prostaglandin E_1 (PGE_1) in the presence

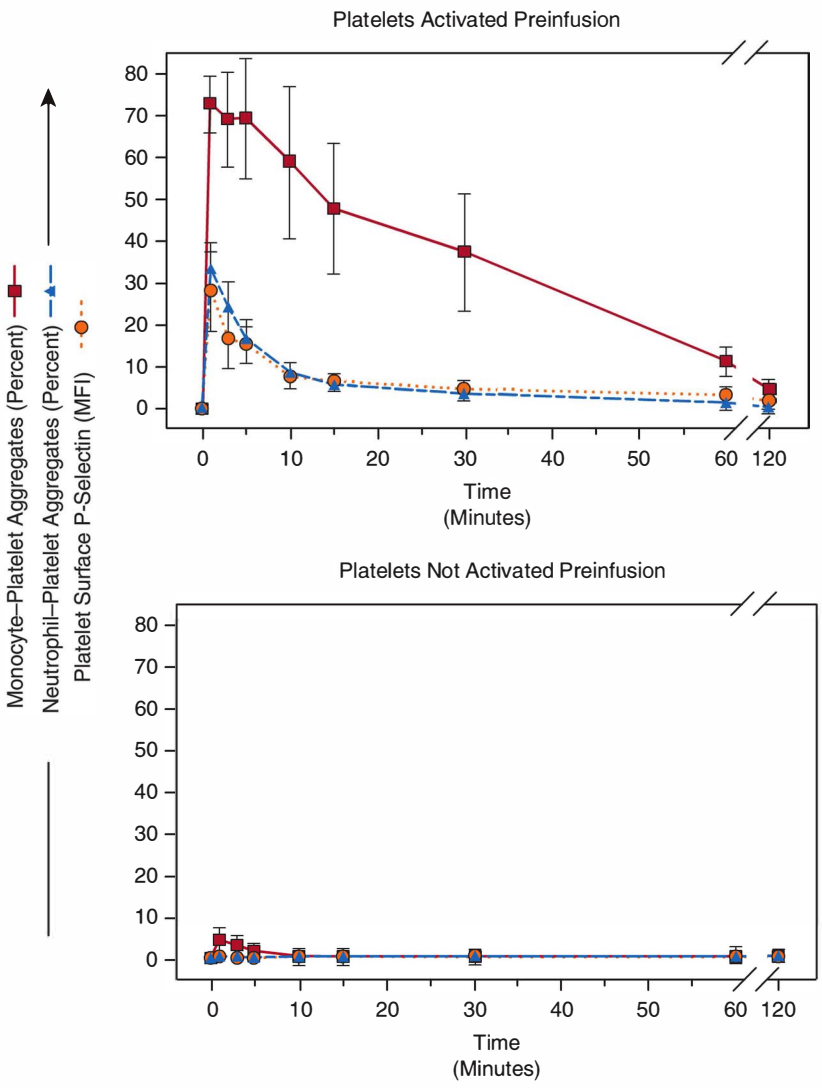

FIGURE 67.2 *In vivo* tracking of platelets. Baboons were infused with autologous, biotinylated platelets that were **(upper panel)** or were not **(lower panel)** thrombin-activated preinfusion. Surface P-selectin on the infused platelets and participation of the infused platelets in circulating monocyte–platelet and neutrophil–platelet aggregates was determined by three-color whole blood flow cytometric analysis of peripheral blood samples drawn at the indicated time points. The "0" time point refers to blood samples taken immediately preinfusion. Platelet surface P-selectin is expressed as mean fluorescence intensity (MFI), as a percentage of the fluorescence of a preinfusion maximally activated (10 U/mL) thrombin control sample. Monocyte–platelet and neutrophil–platelet aggregates are expressed as the percent of all monocytes and neutrophils with adherent infused platelets. Data are mean ± SEM. (Reproduced from Michelson AD, Barnard MR, Krueger LA, et al. Circulating monocyte-platelet aggregates are a more sensitive marker of *in vivo* platelet activation than platelet surface P-selectin: studies in baboons, human coronary intervention, and human acute myocardial infarction. *Circulation* 2001;104:1533–1537, with permission.)

and absence of ADP. PGE_1 and ADP (acting via $P2Y_{12}$) have opposite effects on VASP with either promotion or inhibition of phosphorylation respectively. Therefore the nonphosphorylated VASP correlates with the activity of $P2Y_{12}$. Interference with the activity of this receptor by the active metabolites of thienopyridines (e.g., clopidogrel or prasugrel) or direct antagonists (e.g., ticagrelor or cangrelor) results in persistent VASP phosphorylation induced by PGE_1 even when the platelets are stimulated with ADP. By comparing the level of VASP phosphorylation in whole blood samples stimulated with either PGE_1 or a combination of PGE_1 and ADP, it is possible to derive a platelet reactivity index (%).[53] The assay provides the most direct and specific measurement of the activity of $P2Y_{12}$ and can be used to monitor the efficacy of antiplatelet drugs that target this receptor.[54,55] Accordingly, the VASP phosphorylation assay has been used to monitor the effects of clopidogrel in humans, and an impaired restoration of VASP phosphorylation by clopidogrel has been shown to be associated with subacute stent thrombosis following PCI.[54,55] Further work is required to determine whether this indicates that a high level of receptor blockade is required to prevent stent thrombosis, particularly as the assay has been reported to be insensitive to low levels of $P2Y_{12}$ inhibition.

Phosphatidylserine

The distribution of phospholipids in the plasma membrane of resting platelets is asymmetric with the negatively charged phospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE) sequestered in the inner leaflet. The sustained increases in cytosolic calcium elevation that accompanies platelet activation by strong agonists result in the activation of scramblase,[56] and PS then provides a surface upon which the tenase and prothrombinase complexes can assemble, resulting in a burst of thrombin generation. It is possible to measure the extent of PS exposure by flow cytometry either *ex vivo* or *in vitro* after activation by using probes that bind to PS. Annexin-V is a high-affinity calcium-dependent probe for detecting PS and has been extensively used in platelet studies.[57] Recently, the calcium-independent probe lactadherin has also been utilized and shown to be more sensitive at detecting low levels of PS exposure.[58,59] Other probes based upon various clotting factors including monoclonal antibodies against factor V or factor VIII or directly labeled proteins have also been used.[60–62]

Platelet-Derived Microparticles

The sustained cytosolic calcium elevation that results in PS exposure also causes membrane blebbing and the release of microparticles, some of which are PS positive.[63] As determined by flow cytometry, *in vitro* activation of platelets by agonists such as C5b-9, collagen/thrombin, CRP, and the calcium ionophore A23187 in the presence of extracellular calcium ions results in the formation and release of platelet-derived microparticles. The microparticles are between 100 nm and <1 μm in size as determined by low forward-angle light scatter and binding of a platelet-specific monoclonal antibody and may be procoagulant as determined by binding of monoclonal antibodies to activated factors V or VIII or direct detection using the high-affinity probes annexin-V or lactadherin.[60,62,64] Procoagulant platelet-derived microparticles play an important role in the assembly of the "tenase" and "prothrombinase" components of the coagulation system *in vivo* as exemplified by the very rare inherited platelet disorder "Scott syndrome" where the patients present with a bleeding diathesis and cannot expose PS on cell surfaces or generate microparticles.[65] There are many methods available for measuring microparticles including ELISA, thrombin generation, and procoagulant assays but flow cytometry is regarded as the method of choice. Many flow cytometric methods for the direct detection of procoagulant platelet-derived microparticles in whole blood have been reported.[66,67,68,69] However, many flow cytometers are limited in their ability to detect particles below approximately 300 to 500 nm. The use of standardization beads (e.g., Megamix, Biocytex) facilitates optimal resolution of labeled microparticles from electronic noise and improves both within- and between-laboratory standardization.[68] Platelets can also release exosomes that are true nanoparticles formed within the α-granules from multivesicular bodies.[70] Platelet and other cellular derived microparticles are elevated in plasma in a wide range of disease including many thrombotic disorders where platelets are activated and thus may be novel disease biomarkers.[71]

Methodologic Issues

Preanalytical Considerations: Blood Drawing, Sample Handling, and Processing

It is imperative that any *ex vivo* artifacts are prevented during the processing and preparation of samples for the measurement of platelet activation markers. Some markers are sensitive to adrenergic stimulation and exercise, so subjects are often rested for at least 10 minutes prior to venipuncture. Platelet activation and aggregate formation can be minimized in the preparation of platelets for whole blood flow cytometry by a combination of the following methods: (a) preparing reagents in advance and avoiding delays in procedure; (b) using a light tourniquet and a needle not narrower than 21 gauge to collect blood; (c) smooth, easy flow from the blood draw; (d) discarding the first few milliliters of blood; (e) using polypropylene (or siliconized glass) tubes or syringes; (f) immediate mixing with the anticoagulant; (g) no washing, centrifugation, gel filtration, vortexing, or stirring steps; (h) reducing the platelet count by dilution of the samples; (i) if thrombin is the agonist, including the synthetic tetrapeptide Gly–Pro–Arg–Pro (GPRP) in the assay (see below); (j) mixing gently after addition of agonist, then incubating undisturbed; (k) fixation (see use of fixatives section below). RGD-containing peptides have also been used to prevent platelet aggregates,[72] but these peptides may interfere with the binding of detecting antibodies such as PAC1, and they can result in exposure of LIBS.[37,73]

Each sample should be monitored for evidence of platelet aggregation ("smearing" of the platelets into the upper right quadrant of the log side [orthogonal] light scatter vs. log forward light scatter histogram). After discarding the first few milliliters, blood should be collected into buffered 3.2% (105 to 109 mmol/L) trisodium citrate Vacutainer tubes (Becton Dickinson, Rutherford, NJ), which does not result in significant platelet activation.[74] However, each laboratory should determine whether their method of collection, including the drawing of samples through PCI and other catheters, results in artifactual *in vitro* platelet activation, as determined by the binding of activation-dependent monoclonal antibodies. To measure platelet activation markers, blood should be kept at room temperature and rapidly processed as *ex vivo* changes in various markers can occur rather quickly (e.g., 10 minutes).

Although the weak calcium chelator sodium citrate is the most commonly used anticoagulant, other anticoagulants have

been successfully used, for example, corn trypsin inhibitor (an inhibitor of activated factor XII).[75] The strong calcium chelator ethylenediaminetetraacetic acid (EDTA) should be avoided, because it can dissociate $\alpha_{IIb}\beta_3$. Nonchelating anticoagulants like PPACK (a direct thrombin inhibitor) or hirudin may be preferable for the monitoring of GPIIb-IIIa antagonist therapy.[76] Citrate has also recently been shown to interfere with *in vitro* but not *ex vivo* measurement of $P2Y_{12}$ inhibition by low concentrations of cangrelor and the prasugrel metabolite.[77] Another alternative anticoagulant available is EDTA-CTAD.[78] Platelet count, mean platelet volume (MPV), number of platelet clumps, mean platelet component, numbers of P-selectin-positive platelets, and platelet–leukocyte aggregates have all been shown to be stable for 360 minutes in blood samples kept at 4°C.

Flow Cytometric Methods

Use of Agonists in Whole Blood Assays

In the absence of an exogenous platelet agonist, whole blood flow cytometry can determine the activation state of circulating platelets, as judged by the binding of an activation-dependent monoclonal antibody. In addition to this assessment of platelet function *in vivo*, inclusion of an exogenous agonist in the assay enables analysis of the reactivity of circulating platelets *in vitro*. In the latter application, whole blood flow cytometry is a physiologic assay of platelet function in that an agonist results in a specific functional response by the platelets: a change in the surface expression of a physiologic receptor (or other antigen or bound ligand), as determined by a change in the binding of a monoclonal antibody. In addition, as discussed below, whole blood flow cytometric enumeration of monocyte–platelet aggregates and procoagulant platelet-derived microparticles are also sensitive markers of *in vivo* platelet activation. A large number of useful reagents now exist for the *in vitro* activation of platelets. These include ADP, thrombin, TRAPs, collagen and CRP, various snake venoms (e.g., convulxin), U46619, arachidonic acid, platelet activating factor (PAF), and the calcium ionophore A23187. It is possible to construct dose–response curves for each agonist to study their influence on different activation markers. One important consideration is to ensure that the agonists do not interfere with the eventual analysis of the platelets in diluted whole blood samples. Platelet activation by thrombin, a physiologically important platelet activator,[79–81] can be directly measured in whole blood in the presence of the synthetic peptide GPRP.[42,82,83] In the absence of GPRP, addition of thrombin to whole blood results in a fibrin clot. Furthermore, thrombin is a potent inducer of platelet-to-platelet aggregation, precluding analysis by flow cytometry of activation-dependent changes in individual platelets. However, GPRP inhibits both fibrin polymerization and, to a lesser extent, platelet-to-platelet aggregation, without affecting thrombin-induced platelet activation.[42,82,83] An alternative to the use of thrombin and GPRP in a whole blood flow cytometric assay is the use of TRAPs. There are now two TRAP agonists for the protease-activated thrombin receptors 1 and 4 (PAR1 and PAR4).[84] TRAP peptides directly activate platelets in whole blood without producing a fibrin clot.[85] However, the use of each TRAP individually may not mimic all aspects of thrombin-induced platelet activation, because PAR1 and PAR4 are not the only platelet receptors for thrombin.[86] CRP is a very useful reagent for specifically stimulating the GPVI activation pathway and provides a soluble, easy-to-use, reliable, and standardized alternative to collagen which can often be insoluble and prone to considerable variations between different preparations.

Detection of the Activation-Dependent Decrease in the Platelet Surface Expression of the GPIb-IX-V Complex

Whole blood flow cytometric assays frequently employ a GPIb- or GPIX-specific monoclonal antibody to identify platelets. Because GPIb and GPIX are not present on any circulating blood cell except platelets,[87,88] the activation-induced decrease in the expression of GPIb/IX on the platelet surface[41,42,89] generally does not result in fluorescence below the threshold used to distinguish platelets from other cells and debris.[31,83] Thus, no platelet subpopulations are excluded. A method of avoiding activation-induced decrease in binding of a GPIb-specific monoclonal antibody is to add a direct conjugate of the GPIb-specific antibody before addition of agonist ([90] and see below).

To specifically analyze the activation-induced decrease in the expression of the GPIb/IX complex on the platelet surface in whole blood, an α_{IIb}- or β_3-specific monoclonal antibody can be employed as the platelet-identifying reagent.[74]

There is an important methodologic point that needs to be emphasized with regard to the flow cytometric detection of the activation-induced decrease in the platelet surface expression of GPIb/IX.[90] If a fluorescein isothiocyanate (FITC)-conjugated GPIb/IX-specific test monoclonal antibody is added prior to the platelet agonist (as in the typical schema shown in FIGURE 67.1), the activation-induced redistribution of GPIb/IX to the surface-connected canalicular system[91] will not result in a significant decrease in platelet fluorescence because a flow cytometer can detect FITC fluorescence regardless whether the conjugated antibody is on the surface or within the interior of the platelet. Therefore, in flow cytometric assays examining platelet surface GPIb/IX modulation, GPIb/IX-specific antibodies that are directly conjugated (e.g., with FITC) must be added to the assay *after* the addition of the agonist.

Use of Fixatives

Sample fixation is very advantageous in a clinical setting where there may not be immediate access to a flow cytometer. Fixation prevents subsequent artifactual *in vitro* platelet activation. For most antibodies, the "antibody labeling before fixation" method described above, and shown in FIGURE 67.1, results in no significant differences in fluorescence intensity between samples analyzed immediately and samples analyzed within 24 hours of fixation.[42] A "fixation before antibody labeling" method also results in no significant differences in fluorescence intensity between samples analyzed immediately and samples analyzed within 24 hours of antibody labeling.[74] However, fixation is an important variable to be controlled for, especially in a "fixation before antibody labeling" method, because the binding of activation-dependent monoclonal antibodies to fixed platelets is often decreased compared to unfixed platelets.[32] Furthermore, the binding of some antibodies further decreases after fixation in a time-dependent manner. Therefore, the optimal fixation method for each new monoclonal antibody must therefore be defined by each laboratory.

A compelling argument in favor of immediate sample fixation is that activation-dependent changes are often time dependent, at least *in vitro*. For example, the platelet surface expression of the GPIb/IX/V complex decreases within 30 seconds of platelet activation, reaching a nadir at approximately 5 minutes, but over the next approximately 45 minutes, surface expression returns to normal.[43,85] The activation-dependent increase in the platelet surface expression of integrin $\alpha_{IIb}\beta_3$ and CD40 ligand (CD40L, CD154) is also reversible with time.[44,92] In contrast, although circulating degranulated platelets rapidly lose surface P-selectin *in vivo*,[46] the activation-dependent increase in platelet surface P-selectin is not reversible over time *in vitro*.[43,44]

A new closed system fixative (Platelet Solutions) is now available that stabilizes P-selectin measurements in whole blood samples for up to 9 days.[93] This facilitates standardized flow cytometry testing of remotely collected samples sent to a central testing facility.

Choice of Antibodies

Because exposure of different antigens reflects different aspects of platelet activation, it may be preferable to use a panel of monoclonal antibodies. Monoclonal antibodies are preferable to polyclonal antibodies in whole blood flow cytometry, because they (a) more reliably saturate all specific epitopes and (b) produce less nonspecific binding. Platelet-specific monoclonal antibodies are available from a wide variety of commercial sources and can often be purchased conjugated to fluorescein, biotin, phycoerythrin, PerCP, APC, or a tandem conjugate (e.g., phycoerythrin-Cy5 or RED-670). Alternatively, unlabeled antibodies can be FITC conjugated by the method of Rinderknecht[94] or more easily and rapidly using commercially available kits (Boehringer Mannheim, Indianapolis, IN; Molecular Probes, Eugene; and Sigma-Aldrich, St. Louis, MO). Antibodies can be biotinylated as described by Shattil et al.[31] or by following the manufacturer's directions. The use of antibodies that are directly conjugated with fluorescein, phycoerythrin, PerCP, APC, or tandem conjugates eliminates the requirement for the addition of secondary antibodies, thereby avoiding time-consuming additional incubations and washing procedures which, in unfixed samples, may result in artifactual *in vitro* platelet activation. Furthermore, the use of secondary antibodies is likely to result in increased background fluorescence and decreased assay sensitivity. Finally, the use of directly conjugated antibodies allows multiple color analysis with, for example, a number of differently conjugated murine antibodies.

F_{ab} fragments of monoclonal antibodies can be used to avoid F_c-mediated binding and the F_c-induced platelet activation that has been reported with some monoclonal antibodies.[95] However, the use of F_{ab} fragments is usually unnecessary, provided: (a) the absence of antibody-induced binding of other activation-dependent monoclonal antibodies is demonstrated in control samples, or the problem is avoided by fixation before test antibody binding; (b) the F_c-mediated and nonspecific binding obtained from parallel samples with isotypic species-specific immunoglobulin is subtracted from the binding of the test antibody, or (c) the FcγRIIa receptor-specific monoclonal antibody IV.3, immunoglobulins, or F_c fragments are used as blocking reagents.

Saturating concentrations of each antibody must be specifically determined by each laboratory. Concentrations are typically between 0.25 and 20 μg/mL. In addition, when more than one monoclonal antibody is used in the same assay (as is standard in whole blood flow cytometry), it is necessary to determine that the antibodies do not compete for binding to the platelet surface.

Platelets can be detected in whole blood by light scatter only. However, some of the particles falling within the light scatter gate for platelets may not bind any platelet-specific monoclonal antibody. Therefore, it is recommended that a minimum two-color/two-antibody technique be used for whole blood flow cytometry: one monoclonal antibody to identify a particle as a platelet; another monoclonal antibody to quantify the expression of the glycoprotein of interest.

Reporting of Results

Antibody binding can be expressed as MFI or as the percent of platelets staining positive for a particular antibody (based on a positive analysis region placed just to the right of the negative isotype control fluorescence histogram). Depending on the experimental conditions and the nature of the antigen being measured, either MFI or percent positive platelets may be more relevant. Unlike the MFI method, the "percent positive platelets" method is independent of variations in signal amplification (e.g., as a result of changes in photomultiplier tube [PMT] voltage or gain), because the negative control signal increases in proportion with the test sample. The "percent positive platelets" method may detect subpopulations of platelets arising from a local *in vivo* insult. However, it is important to realize that "antibody-positive" platelets may have very little antigen expressed on their surface. For example, in a given clinical setting, the data may be reported as 20% circulating activated platelets, based on P-selectin positivity. However, if each P-selectin-positive platelet expresses only 10% of maximal platelet surface P-selectin, then the overall average increase in platelet surface P-selectin is only 2%. If the goal is to determine the total amount of platelet surface antigen, MFI is therefore the preferred method of data presentation. For activation-dependent antibodies, inclusion of a control sample maximally activated by thrombin, TRAP, or phorbol myristate acetate assists in the quantification of the amount of surface antigen per platelet. The activation-dependent decrease in platelet surface GPIb/IX/V[42,85] should be quantified by MFI rather than by the "percent positive platelets" method, because the decrease in platelet surface GPIb/IX/V on each platelet is usually insufficient to result in a "negative" platelet.

Although standard flow cytometry does not produce a measure of the absolute number of binding sites, Shattil et al.[31] and Johnston et al.[96] used monoclonal antibodies double labeled with ^{125}I and biotin to demonstrate a direct linear relationship between the number of antibody binding sites per platelet as determined by ^{125}I-labeled and (after incubation with phycoerythrin–streptavidin) fluorescent-labeled antibody. Once this relationship is known for a given monoclonal antibody, it is possible to use subsequent batches of the biotinylated or FITC-conjugated antibody for binding site quantitation, provided that the molar ratio of fluorescein to antibody is known.

Commercial kits (e.g., Quantum, Sigma-Aldrich, and Biocytex) containing a set of calibrated fluorescent standards and software can be used to determine molecules of equivalent soluble fluorochrome (MESF). Use of these standards allows (a) quantitation of the fluorescence intensity of samples in terms of MESF, (b) determination of the fluorescence threshold of the instrument, (c) determination of the linearity and stability of the instrument, and, most importantly, (d) data comparison

over time and between different instruments and laboratories.[97] Flow cytometric methods are now available for quantitation of the number of antibodies bound per cell (e.g., Quantum Simply Cellular Microbeads Kit, Sigma-Aldrich; Platelet Calibrator & Platelet Gp Screen, BioCytex, Marseille, France). The lower limit of detection of antibody binding by flow cytometry is approximately 500 antibody molecules per platelet.

PLATELET ACTIVATION IN CLINICAL DISORDERS

Acute Coronary Syndromes

Platelets play an important role in the pathogenesis of coronary artery syndromes including unstable angina and acute myocardial infarction.[98,99] Angiography[100] and angioscopy[101] during acute coronary ischemic syndromes frequently reveal platelet-rich intracoronary arterial thrombi.[102] Whole blood flow cytometric studies have demonstrated circulating activated platelets in patients with stable angina, unstable angina, and acute myocardial infarction.[50,103–106] In addition, as determined by activation-dependent monoclonal antibodies, PCI results in platelet activation in coronary sinus blood.[107,108] Flow cytometrically detected exposure of LIBS is strongly associated with the development and progression of heart transplant vasculopathy.[109]

Circulating leukocyte–platelet aggregates are increased in stable coronary artery disease,[49,50] unstable angina,[103] acute myocardial infarction,[110,111] and cardiopulmonary bypass.[112] Circulating leukocyte–platelet aggregates also increase after PCI and to a greater extent in patients experiencing late clinical events.[113] As discussed above, circulating monocyte–platelet aggregates (but not neutrophil–platelet aggregates) are a more sensitive marker of *in vivo* platelet activation than platelet surface P-selectin in the clinical settings of stable coronary artery disease,[50] PCI,[48] and acute myocardial infarction.[48] Furthermore, circulating monocyte–platelet aggregates are an early marker of acute myocardial infarction.[114]

Platelet-derived microparticles are also increased in acute coronary syndromes[115] and after cardiopulmonary bypass.[116,117]

Elevated plasma levels of sCD40L have been demonstrated in unstable angina,[118] PCI,[118] and cardiopulmonary bypass.[119] GPIIb-IIIa antagonists inhibit the release of sCD40L from platelets both *in vitro*[120,121] and *in vivo*.[122] Measurement of sCD40L in the first 12 hours after the onset of ischemic symptoms in patients with unstable angina identifies a subgroup of patients that has a much greater clinical benefit from abciximab treatment.[123] High plasma concentrations of sCD40L may be associated with increased cardiovascular risk in apparently healthy women.[124]

Elevated plasma levels of sGPV have also been demonstrated in patients with coronary artery disease.[23]

In large clinical trials, antiplatelet agents have been shown to reduce the incidence of cardiovascular ischemic events, supporting the concept of an association between platelet activation and cardiovascular ischemia.[125] Furthermore, some investigators have found biochemical markers of platelet activation to be elevated during episodes of acute cardiac ischemia,[2,126] which may identify patients who could benefit from additional antiplatelet therapy.[126] Flow cytometric analysis of platelet activation-dependent markers can be used to determine optimal antiplatelet therapy in clinical settings, for example, in acute coronary syndromes[127,128] and after coronary stenting.[129,130] It is well known that thrombotic events still occur in coronary artery disease patients receiving aspirin therapy. Although there has been much interest in the phenomenon of aspirin "resistance," recent flow cytometric studies in 700 aspirin-treated patients using arachidonic acid stimulation of platelet activation markers (e.g., P-selectin and platelet–leukocyte aggregates) suggest that aspirin underdosing and noncompliance occurs in only a small minority of patients, and underlying platelet reactivity via a COX-independent pathway induced by ADP stimulation is responsible for residual arachidonic acid activation.[6] However, arachidonic acid-induced COX-1-dependent platelet activation measured by flow cytometry was not associated with poor clinical outcomes up to 2 years in contrast to a COX-1-independent assay.[131]

Flow cytometric analysis of platelet activation markers before PCI can predict an increased risk of acute and subacute ischemic events after PCI.[132–135] Clopidogrel is a widely used antithrombotic prodrug that inhibits the platelet ADP receptor $P2Y_{12}$. It is now clear that about 30% of whites cannot efficiently metabolize the drug and are at risk of increased thrombosis after PCI. There are a number of assays available for monitoring clopidogrel efficacy including flow cytometric measurement of VASP and measurement of various activation markers (e.g., P-selectin, platelet–monocyte complexes, and activated $\alpha_{IIb}\beta_3$) after *ex vivo* stimulation with ADP.[53] VASP offers the only relatively direct measurement of $P2Y_{12}$ blockade and has proven to be useful for identifying poor clopidogrel responders.[136] Despite evidence that decreased metabolism can result in decreased clopidogrel responsiveness, various flow cytometric studies suggest that preexistent variability in platelet ADP responsiveness can also partially account for the variability in clopidogrel response.[137] Therefore, posttreatment platelet reactivity may be a better predictor of ischemic events than measurement of clopidogrel nonresponsiveness. Flow cytometry has also been used to determine whether discontinuation of clopidogrel results in rebound platelet hyperreactivity and increased thrombotic risk.[138] A substudy of the TRITON-TIMI 38 trial also demonstrated that prasugrel results in greater inhibition of ADP-mediated platelet function than clopidogrel when measured by VASP.[139]

It is intriguing that platelet hyperreactivity also generalizes to multiple forms of stimulation including submaximal doses of epinephrine as measured by activation (surface P-selectin and PAC1 binding), aggregation (to multiple agonists ADP, arachidonic acid, collagen, etc.), and shear stress assays (e.g., PFA-100 and CPA).[140] Recent evidence suggest that platelet activation responses vary widely between individuals but are consistent within individuals with strong heritability.[141] Some, but not all, studies suggest that the Pl^{A2} polymorphism of GPIIIa is associated with ischemic coronary syndromes.[142] Indeed, flow cytometry has been used to demonstrate that (a) Pl^{A2}-positive platelets can display a lower threshold for activation and (b) platelets heterozygous for Pl^{A} alleles may show increased sensitivity to antiplatelet drugs.[143] The genetic basis of interindividual variability in platelet responsiveness has been recently explored in detail using flow cytometric measurement of consistent *ex vivo* responses to CRP and ADP in 500 healthy Northern European subjects. This resulted in the identification of 17 novel associations with platelet function, which accounted for about 46% of the variation in response.[144] Further studies in this cohort have identified novel proteins that regulate the platelet response including a novel variant on chromosome 7 that associates with MPV, platelet count, and function.[145,146]

Cerebrovascular Ischemia

Increased numbers of circulating P-selectin-positive, CD63-positive, activated $\alpha_{IIb}\beta_3$-positive platelets, monocyte–platelet complexes and platelet-derived microparticles have been reported in acute cerebrovascular ischemia.[147–155] Evidence of platelet activation can still be detected 3 months after the acute event, suggesting the possibility of an underlying prothrombotic state.[149,151,153] Furthermore, increased expression of surface P-selectin on platelets is a risk factor for silent cerebral infarction in patients with atrial fibrillation.[156] Flow cytometric measurements can also be used to monitor platelet activation markers in stroke patients receiving antiplatelet therapy.[157–160]

Platelet-derived microparticles are increased after transient ischemic attacks.[117,161] Increased platelet-derived microparticles and procoagulant activity occur in symptomatic patients with prosthetic heart valves and provide a potential pathophysiologic explanation of cerebrovascular events in this patient group.[162]

Peripheral Vascular Disease

Circulating activated platelets and platelet hyperreactivity (as determined by P-selectin expression, platelet aggregates, and platelet-derived microparticle formation) are increased in patients with peripheral arterial occlusive disease compared with healthy volunteers.[163,164] In addition, plasma levels of sCD40L[165] and sGPV[23] are elevated in peripheral arterial occlusive disease. Interestingly, platelet reactivity measured by ADP stimulation of P-selectin expression seems to be greater in patients who have more extensive distribution of atherosclerotic vascular disease than in those who have coronary artery disease and diabetes mellitus.[166] Soluble P-selectin and increased levels of platelet microparticles but not sCD40L are also associated with disease severity.[167,168] As the level of platelet activation seems to correlate with the severity of peripheral arterial disease, this suggests that new strategies for platelet inhibition are required in these patients.[169]

With regard to peripheral venous disease, Peyton et al.[51] demonstrated an increased number of circulating monocyte–platelet aggregates in patients with chronic venous stasis ulceration as compared to control individuals without venous disease. These changes were present not only in blood drawn from the lower extremity veins of affected individuals, but also in blood drawn from arm veins, suggesting that the changes are systemic rather than localized to the lower extremities.[51] Powell et al.[170] further characterized these findings as being related to the presence of chronic venous disease rather than the presence of venous ulceration since increased numbers of monocyte–platelet aggregates were noted in patients with all classes of venous disease, not just in patients with deep-venous valvular insufficiency. Furthermore, increased levels of monocyte–platelet aggregates were even observed in patients with only superficial venous stasis disease manifested by the presence of varicose veins. Even more intriguing is the fact that the number of monocyte–platelet aggregates remains elevated 6 weeks after total correction of the venous insufficiency by stripping of the abnormal veins, resulting in normal venous physiology as documented by postoperative duplex scanning.[171] This suggests an underlying predisposition to the development of chronic venous disease in these patients, perhaps mediated by monocyte–platelet interactions.

OTHER CLINICAL DISORDERS ASSOCIATED WITH PLATELET HYPERREACTIVITY AND/OR CIRCULATING ACTIVATED PLATELETS

Other conditions in which whole blood flow cytometric measurement of platelet hyperreactivity, circulating activated platelets, and/or circulating leukocyte–platelet aggregates may prove useful include diabetes mellitus,[172,173] the metabolic syndrome,[174] preeclampsia,[175,176] cystic fibrosis,[177] migraine,[178] placental insufficiency,[179] nephrotic syndrome,[180] inflammatory bowel disease,[181] inflammatory skin diseases,[182,183] hemodialysis,[184] glomerulonephritis,[185] sickle cell disease,[186] thalassemia,[187] systemic inflammatory response syndrome,[188] septic multiple organ dysfunction syndrome,[189,190] antiphospholipid syndrome,[191] systemic lupus erythematosus,[191] rheumatoid arthritis,[191] myeloproliferative disorders,[192,193] and Alzheimer's disease.[194] High levels of circulating monocyte–platelet aggregates can predict rejection episodes after orthotopic liver transplantation.[195] Uremic patients with thrombotic events have higher numbers of circulating platelet-derived microparticles than those without thrombotic events.[196]

QUALITY CONTROL OF STORED PLATELET CONCENTRATES IN THE BLOOD BANK

Many studies have provided evidence of significant changes in platelet activation markers associated with the "platelet storage lesion" in stored platelet concentrates.[197] As shown by flow cytometric measurements of P-selectin, CD63, PS, microparticle generation, and $\alpha_{IIb}\beta_3$, platelets stored in the blood bank prior to transfusion display time-dependent platelet activation and/or apoptosis.[198–203] These changes also seem to correlate with modifications in platelet morphology (decrease in swirling), leakage of lactate dehydrogenase, and release of soluble markers such as β-TG and P-selectin.[197,198] The expression of P-selectin has been proposed as a potentially useful quality control measurement, based on correlations between the platelet surface expression of P-selectin in stored blood bank platelets and (a) posttransfusion platelet counts,[204] (b) platelet survival determined by In^{111},[199,205] and (c) clearance of P-selectin-positive platelets from the recipient.[199] It has been recently proposed that a novel objective light scattering measurement of platelet aggregate and microparticle generation in response to temperature change could provide a simple way to assess platelet quality without the need for cytometry.[206,207,208] Preliminary evidence suggests that this measurement does indeed correlate with the *in vivo* clinical efficacy of platelet concentrates and could be potentially used as a simple quality assurance test by blood banks.[209] It has also been demonstrated that apheresis donors with the highest platelet reactivity as measured by flow cytometry produce concentrates with increased levels of platelet activation.[210] A planned clinical trial will reveal whether these platelets are more efficacious *in vivo*.

Platelet Hyporeactivity

Although there are currently few published studies in this area, whole blood flow cytometry could be useful in the clinical assessment of platelet hyporeactivity. For example, compared to adults, the platelets of very low-birth-weight preterm neonates are markedly hyporeactive to thrombin, ADP/epinephrine, and thromboxane A_2, as determined by flow cytometric

detection of (a) the exposure of the fibrinogen-binding site on integrin $\alpha_{IIb}\beta_3$, (b) fibrinogen binding, (c) the increase in platelet surface P-selectin, and (d) the decrease in platelet surface GPIb.[211–213] This hyporeactivity may contribute to the propensity of very low-birth-weight neonates to intraventricular hemorrhage.[214,215] Prediction of hemorrhage in severe thrombocytopenia is usually based on the platelet count. However, low levels of platelet P-selectin expression have been reported to be a prognostic marker for hemorrhage in acute myeloid leukemia.[216] This flow cytometric methodology has obvious advantages over other platelet function tests that require a near normal platelet counts and cannot be applied to patients with severe thrombocytopenia.

SUMMARY AND FUTURE PERSPECTIVES

The measurement of platelet activation has become established as an invaluable and reliable research tool for assessing *in vitro*, *in vivo*, and *ex vivo* platelet function in many clinical and research laboratories worldwide.[1] Flow cytometry has proven to be an excellent and sensitive method to measure platelet activation and, providing that careful quality control procedures are followed, it can be used to determine either the *in vivo* level and/or the *ex vivo* function of circulating platelets in a wide range of various clinical disorders. This, coupled with the discovery that platelets can release a much larger number of soluble proteins (the "platelet sheddome") than previously thought, may eventually translate into a large library of simple laboratory tests that may help to guide therapy for patients at high risk of bleeding or thrombosis.[17] Recent examples include the measurement of VASP and the remote collection of stabilized blood samples (for P-selectin measurement in a central laboratory) to monitor anti-$P2Y_{12}$ receptor therapy and the development of a new test of platelet quality to potentially ensure the *in vivo* efficacy of platelet transfusions.[93,136,209] With the complete definition of platelet genome and transcriptome, many more activation markers are likely to be discovered. Flow cytometry of classical activation markers after platelet stimulation has proven to be an important platelet function test in various genome-wide association studies and helped to identify significant genes and proteins associated with either platelet hyper- or hypofunction.[144,145] Understanding the genetic contribution to platelet function may elucidate the risks and possible benefits associated with specific genotypes and improve antiplatelet therapy in high-risk individuals. With advances in automation and flow cytometry technology, it is now possible to devise multicolor flow cytometry tests that measure a combination of platelet activation markers and to fully automate sample preparation and processing using 96- to 384-well plates. Such assays may prove useful for many types of large-scale studies to screen for and identify novel antiplatelet drugs and to study platelet function and *ex vivo* platelet activation in large numbers of samples simultaneously stimulated with multiple agonists. Some assays are now also fully automatable within full-blood counter instruments that also measure fluorescence, light scatter, and impedance parameters simultaneously.[217,218]

CHAPTER 68

Overview of Primary Disorders of Blood Vessels

WILLIAM C. AIRD

The cardiovascular system consists of a closed system or arteries, arterioles, capillaries, venules, and veins, in addition to an open system of lymphatic vessels, which connect to the blood circulation by way of the veins. Each blood vessel type, in turn, is comprised of cellular and noncellular components, the nature of which differs not only between blood vessel types (e.g., arteries and veins) but also between different organs (e.g., capillaries in the heart and brain). Blood vessels are highly dynamic entities; they participate in many different functions, including the control of vasomotor tone and maintenance of blood pressure, the selective permeability of cells and solutes between blood and underlying tissue, innate and acquired immunity, regeneration and repair, and the regulation of hemostasis. Thus, vascular pathophysiology may involve not only distinct vascular beds but also selected functions. The vascular wall is integrally linked to hemostasis and thrombosis, and the theme of vascular disease is weaved throughout all sections of this volume. In the current section, we have chosen to cover a few additional examples of such disorders.

Vascular disorders may be classified in a number of different ways. For example, they may be categorized according to whether they are congenital or acquired. Among the more prominent congenital disorders are connective tissue disorders, arteriovenous malformations, hereditary hemorrhagic telangiectasia, and cerebral cavernous malformations. As discussed in Chapters 69 to 71, recent studies have shed fascinating light on the molecular mechanisms underlying these defects. Vascular disease may be classified according to whether it involves primarily veins, arteries, small blood vessels, or lymphatics. Atherosclerosis is so common in the Western world that is often viewed synonymously with arterial disease. However, there are many other forms of arterial pathology, including arteriosclerosis, aneurysm formation (Chapter 72), and vasculitis (which is covered under the section on complex diseases). The most recognizable disorders associated with veins are superficial and deep thrombosis and varicose veins. Venous thromboembolism is discussed in detail in other chapters in the current volume. Another approach to vascular disease is to consider it from the perspective of the organ or vascular bed affected. For example, pulmonary vascular disorders, including pulmonary hypertension and diseases associated with the bronchial circulation, are considered quite separately from disorders of the kidney vasculature (e.g., renal artery stenosis and glomerulonephritis). Chapter 73 showcases how a specialist from a single discipline (neurology) approaches distinct vascular disease phenotypes in their organ of interest (subarachnoid hemorrhage and intracranial bleeding). Chapter 74 provides another example of how one approaches vascular disease from the perspective of a single organ, namely, the eye. In reading this chapter, we gain an appreciation for the complexity of the eye vasculature and the breadth of disorders that affect it. Indeed, in perusing the chapters in this section, it becomes clear that subspecialization in medicine, though a necessary development over the past 50 years, has limited our capacity to fully grasp the vasculature—warts and all—as an organizing principle in health and disease.

CHAPTER

69 Disorders of Connective Tissue and Extracellular Matrix

FRANSISKA MALFAIT AND ANNE DE PAEPE

THE CONNECTIVE TISSUE AND THE EXTRACELLULAR MATRIX

The connective tissue is the most abundant tissue throughout the body and serves both as a structural support and as a metabolic reservoir for tissue interactions. During recent years, the historical view on connective tissue as solely a supportive structure has been abandoned. It has become evident that the connective tissue actively participates in several important physiologic processes, including cell expression patterns and development, proliferation, differentiation, cell migration, and apoptosis, mainly acting through various cell signaling pathways. Three main connective tissues can be recognized: the loose or soft connective tissues (that embed organs and organ parts), the hard connective tissues (cartilage and bone), and blood. They consist of an extracellular matrix (ECM) and metabolically active cells that synthesize and maintain the ECM. Embryologically, connective tissue develops mainly from the mesoderm, the middle layer of the three-layered embryo. Mesodermal cells develop a loosely organized embryonic connective tissue, called mesenchyme, and differentiate further in specific cell types, including fibroblasts/fibrocytes, chondroblasts/chondrocytes, and osteoblasts/osteocytes. These cells synthesize and maintain the ECM in, respectively, the loose connective tissues, cartilage, and bone, according to the tissue's specific needs. The ECM consists of four main components: elastic fibers and microfibrils, collagen fibers, proteoglycans, and glycoproteins.

Elastic fibers provide elasticity and resilience to all deformable tissues. They are abundantly present in the aorta, arterial vessels, lung, and, to a lesser degree, skin. They are composed of two ultrastructurally distinguishable components: an amorphous component, "elastin", which contributes to the elasticity of the fiber, and a surrounding sheet of *microfibrils*. The microfibrillar component of the elastic fibers consists of fibrillin-rich microfibrils. Fibrillins are highly homologous glycoproteins, of which five isoforms have been described with the same overall arrangement of repetitive domains. Fibrillin-rich microfibrils interact with many other nonfibrillar components, which can be integral parts of the microfibrils or may associate with them. These microfibrils have a structural role and are functionally important in different processes such as microfibril assembly, elastogenesis, interactions with other ECM proteins, anchoring microfibrils to basement membranes and cell surfaces, and growth factor sequestration. For many of these molecules, however, the exact spatiotemporal relation and function still need to be addressed. Examples of nonfibrillar components include microfibril-associated glycoproteins, fibulins (a seven-member family of extracellular glycoproteins), and the latent transforming growth factor-beta–binding proteins (LTBPs), which are important players in the bioavailability of transforming growth factor-beta (TGF-β) in the ECM.

Collagens are the most abundant proteins in the body. They are trimeric proteins that are characterized by the presence of triple-helical domains. To date, 43 collagen genes have been described, the products of which combine to form at least 28 different collagen molecules. Most collagens form supramolecular assemblies, such as fibrils and networks, and the collagen superfamily has been divided in several subfamilies on the basis of their genomic structures, their assembly, and other structural features. The fibril-forming or fibrillar collagens, which include the collagen types I, II, III, V and XI, represent the most widespread and abundant class of collagens, and defects in these proteins are found in different heritable disorders of connective tissue (HCTD), such as osteogenesis imperfecta (OI), (type I collagen), Stickler syndrome (type II and XI collagen), and the Ehlers-Danlos syndromes (EDS) (type I, III, and V collagen). Fibrillar collagens are observed in tissues as long, highly ordered fibrils with a characteristic banding pattern. Type I collagen, a heterotrimer of two α_1-chains and one α_2-chain, is the major collagen type in the body and has a widespread tissue distribution. Type II and type XI collagens are predominantly found in cartilage. Type III collagen, a homotrimer consisting of three identical α_1-chains, is an essential component of stretchable tissues such as the blood vessel walls, the gastrointestinal tract, the uterus, and the skin. Type V collagen is a minor fibrillar collagen that coassembles with type I collagen, and acts as a regulator of collagen fibril diameter through the retention of a noncollagenous amino-terminal domain of the proα_1(V) collagen chain.[1] Each fibrillar collagen has a central uninterrupted triple-helical domain with short nonhelical domains at the carboxy- and amino-terminal ends. The presence of glycine, the smallest amino acid, in every third position of each chain is a prerequisite for the formation of a stable collagen helix. The biosynthesis of fibrillar collagens in the fibroblast is a complex process and starts with the synthesis of soluble precursor molecules, procollagens. These contain globular amino- and carboxy-terminal propeptide extensions, called the *N*- and the *C*-propeptide. Intracellular association of three proα chains occurs through interaction and disulphide bonding at the *C*-propeptide. In this way, correct alignment of the growing polypeptide chain is obtained as required for formation and propagation of the triple helix from the *C*- to the *N*-terminal end of the molecule. During helix propagation, the proα chains undergo extensive enzymatic modifications (e.g., hydroxylation of prolyl and lysyl residues), which cease when the helix is formed. Mature triple-helical procollagen molecules are secreted into the extracellular

environment where they are converted to collagen by enzymatic removal of the *N*- and the *C*-propeptides. Individual collagen molecules spontaneously assemble in a nonenzymatic process to form fibrils and fibers, which are stabilized by covalent cross-linking.

Proteoglycans consist of a core protein to which short oligosaccharides or longer chains of glycosaminoglycans (GAGs) are covalently attached. There is a large variety of proteoglycans based on the types and lengths of GAGs as well as the sequence and length of the protein core. Chondroitin sulfate, keratan sulfate, heparan sulfate, and dermatan sulfate are four different forms of GAGs that consist of repeating disaccharide units. The sulfates that are present on the GAGs create a highly negatively charged environment that is hydrophilic. In addition to water, proteoglycans also bind cationic proteins, such as growth factors, resulting in a mechanism by which tissues can store growth factors in the ECM.

A large group of noncollagenous matrix *glycoproteins* make up a substantial part of the ECM. Important members of this group include thrombospondins (TSP), fibronectin, tenascins, laminin, and osteopontin. As "ground substance" of the ECM, they display a variety of functions in tissue morphogenesis and remodeling, including cell adhesion, cell cycle regulation, cell–matrix interactions, and interactions with growth factors and various other matrix molecules.

HERITABLE DISORDERS OF CONNECTIVE TISSUE

The Ehlers-Danlos Syndrome

Epidemiology and Criteria for Diagnosis

EDS comprise a clinically and genetically heterogeneous group of HCTD, of which the principal clinical features are due to varying degrees of tissue fragility of the soft connective issues, including the skin, ligaments, blood vessels, and internal organs. The prevalence of EDS is estimated to be approximately 1 in 5,000 births, with no racial predisposition.[2] However, the incidence rises with increased physician awareness. The first attempts to classify EDS resulted in the Berlin nosology in 1986, in which 10 subtypes were recognized.[3] Elucidation of the molecular basis of several types of EDS resulted in revision of this classification, established in 1997 as the Villefranche nosology[4] that recognizes six subtypes, based on clinical characteristics, mode of inheritance, and the nature of the underlying biochemical and molecular defect(s). For each subtype, major and minor clinical diagnostic criteria were defined. Several EDS subtypes are caused by mutations in the genes for collagen type I (arthrochalasis type), type III (vascular type), or type V (classic type), or in the genes involved in the processing of type I collagen (kyphoscoliosis and dermatosparaxis type) (Table 69.1). In terms of management and counseling, it is very important to establish the correct subtype of EDS. Over the past few years, however, it has become clear that the Villefranche classification remains insufficient and that many patients present with overlapping forms of EDS, which cannot be classified unambiguously into one of the six recognized subtypes. Recent insights into the molecular and biochemical basis of some EDS variants call for a refinement of the Villefranche classification, which will likely improve genetic counseling of affected families.[5]

Clinical Characteristics

Cutaneous Manifestations

Cutaneous hyperextensibility (FIGURE 69.1) is one of the cardinal features of EDS in general, except for the vascular subtype. Skin extends easily and snaps back after release (unlike the lax and redundant skin observed in the cutis laxa (CL) syndromes). The skin is typically very smooth and velvety to the touch. It is also very fragile, as manifested by splitting of the dermis following relatively minor trauma. Wounds take a longer time to heal, and stretching of scars after apparently successful primary wound healing is characteristic. Scars become wide, with a "cigarette paper"–like or papyraceous appearance (FIGURE 69.2). Other dermatologic features in EDS include molluscoid pseudotumors, subcutaneous spheroids, and piezogenic papules. Less frequent cutaneous manifestations include acrocyanosis, chilblains, and, rarely, elastosis perforans serpiginosa.

Musculoskeletal Manifestations

Joint hypermobility (FIGURE 69.3) should be assessed using the Beighton scale (Table 69.2), the most widely accepted grading system for the objective semiquantification of joint hypermobility.[6] It may lead to major articular complications, such as habitual subluxation and dislocation of the joints most often affecting shoulder, patella, digits, hip, radius, and clavicles. When they occur, these dislocations usually resolve spontaneously or are easily managed by the patient. Many individuals with EDS suffer from chronic joint and limb pain, despite normal skeletal radiographs. Other problems related to the joint hypermobility are joint instability, foot deformities such as congenital clubfoot or pes planus, temporomandibular joint dysfunction, joint effusions, and osteoarthritis. At birth, uni- or bilateral dislocation of the hip may be present.

Bruising and Bleeding

The bleeding tendency primarily manifests itself as easy bruisability, bleeding of gums, prolonged bleeding after dental or surgical procedures, and prolonged menstrual episodes. Easy bruising is, to a variable degree, a common complaint in all subtypes of EDS. This bleeding diathesis is explained by an abnormal capillary structure with deficiency of normal perivascular collagen, resulting in poor support of cutaneous blood vessels that rupture when subjected to shearing forces. Laboratory investigation of platelet aggregation, clotting factors, and bleeding time in patients with EDS is usually normal. The Rumpel-Leede (or Hess) test may be positive, indicating capillary fragility.[7,8] To perform this test, pressure is applied to the forearm with a blood pressure cuff inflated to between systolic and diastolic blood pressure for 10 minutes. After removing the cuff, the number of petechiae in a 5-cm diameter circle of the area under pressure is counted. Normally, <15 petechiae are seen. Fifteen or more petechiae indicate capillary fragility. In children with EDS, excessive bruising is often the presenting complaint to the pediatrician. If pronounced, it can cause suspicion of a hematologic disorder, a malignancy, or child abuse. Careful evaluation of the medical and family history, and rigorous clinical examination with special attention to skin features that are characteristic for EDS, are mandatory to distinguish between a HCTD and other causes of bruising.

Spontaneous arterial rupture leading to life-threatening complications is a hallmark of the vascular subtype of EDS. It may also occur in the rare individual with a severe form of the classic or the kyphoscoliotic type of EDS. Rupture of middle-sized

Table 69.1
The Villefranche nosology for EDS

	Clinical Manifestations				
Type	**Major Criteria**	**Minor Criteria**	**IP**	**Protein**	**Gene**
Classic (gravis type I, mitis type II)	• Skin hyperextensibility • Widened atrophic scarring • Joint hypermobility	• Easy bruising • Smooth and velvety skin • Molluscoid pseudotumors • Subcutaneous spheroids • Muscular hypotonia • Complications of joint hypermobility • Surgical complications • Positive family history	AD	Type V procollagen	*COL5A1* *COL5A2*
Hypermobility (type III)	• Generalized joint hypermobility • Mild skin involvement	• Recurring joint dislocations • Chronic joint pain • Positive family history	AD	mostly unknown Tenascin-X (5%–10%)	mostly unknown *TNX-B*
Vascular (type IV)	• Excessive bruising • Thin, translucent skin • Arterial/intestinal/ • Uterine fragility or rupture • Characteristic facial appearance	• Acrogeria • Early-onset varicose veins • Hypermobility of small joints • Tendon and muscle rupture • Arteriovenous or carotid-cavernous sinus fistula • Pneumo(hemo)thorax • Positive family history, sudden death in close relative(s)	AD	Type III procollagen	*COL3A1*
Kyphoscoliotic (type VI)	• Severe muscular hypotonia at birth • Generalized joint laxity • Kyphoscoliosis at birth • Scleral fragility and rupture of the globe	• Tissue fragility, including atrophic scars • Easy bruising • Arterial rupture • Marfanoid habitus • Microcornea • Osteopenia	AR	Lysyl hydroxylase-1	*PLOD1*
Arthrochalasis (type VIIA&B)	• Severe generalized joint hypermobility with recurrent subluxations • Congenital bilateral hip dislocation	• Skin hyperextensibility • Tissue fragility, including atrophic scars • Easy bruising • Muscular hypotonia • Kyphoscoliois • Mild osteopenia	AD	Type I procollagen	*COL1A1* *COL1A2*
Dermatosparaxis (type VIIC)	• Severe skin fragility • Sagging, redundant skin • Excessive bruising	• Soft, doughy skin texture • Premature rupture of membranes • Large herniae	AR	Procollagen-*N*-proteinase	*ADAMTS-2*

IP, inheritance pattern; AD, autosomal dominant; AR, autosomal recessive.

FIGURE 69.1 Skin hyperextensibility in a patient with classic EDS.

arteries has also been observed in individuals with a classic/vascular EDS-overlap phenotype, which results from mutations causing specific arginine-to-cysteine substitutions in *COL1A1*, the gene encoding the proα_1(I) chain of type I collagen.[9]

Neuromuscular Involvement

Mild to moderate neuromuscular involvement is common in various types of EDS. Primary muscular hypotonia may cause delayed motor development and problems with ambulation. Muscle weakness, muscle cramps, musculoskeletal pain, and fatigue are frequent complaints. Muscle rupture can occur, especially in the vascular subtype of EDS.[10] Cerebrospinal fluid leak has rarely been reported to cause postural hypotension and headache in individuals with classic EDS.[11]

FIGURE 69.2 Atrophic scarring on the knees and shins in a patient with classic EDS.

FIGURE 69.3 Severe joint hyperlaxity in a patient with EDS arthrochalasis type.

Cardiovascular Manifestations

Structural cardiac malformations are uncommon in EDS. Mitral valve prolapse (MVP) and, less frequently, tricuspid valve prolapse may occur. Stringent criteria should be used for the diagnosis of MVP. Severe cardiac valvular anomalies necessitating surgery at young adult age are observed in a rare autosomal recessive form of EDS, caused by mutations that lead to a total absence of the α_2(I)-procollagen chain.[12,13]

Manifestations of Generalized Tissue Fragility

Manifestations of tissue extensibility and fragility may be observed in multiple organs. Patients with EDS may suffer from repetitive hernia, such as inguinal, umbilical, hiatal, or incisional hernia. In early childhood, recurrent rectal prolapse may be observed. Pregnancy-related manifestations include increased risk for extension of episiotomy incisions, tearing of the perineal skin, and prolapse of the uterus, and/or the bladder may occur after delivery. Prematurity, mostly due to premature rupture of the membranes, occurs more often than normal, especially in more severe forms of EDS and if the fetus is affected. Because of hypotonia, breech presentation is more frequent if the baby is affected and may lead to dislocation of the hips or shoulder of the newborn.

Vascular Ehlers-Danlos Syndrome

The vascular type of EDS is an autosomal dominant disorder that is caused by defects in the proα_1(III) chain of type III collagen, encoded by the *COL3A1* gene. Of all EDS subtypes, it has the worst prognosis because of the risk of potentially fatal vascular and intestinal complications.[14,15] Unlike other types of EDS, the skin is not hyperextensible, but rather thin and translucent, showing a visible venous pattern over the chest, abdomen, and extremities.[2,16] Excessive wrinkling and thinness of the skin over hands and feet may produce an old-looking appearance, referred to as "acrogeria."

Excessive bruising is the most common sign and is often the presenting complaint. Other early manifestations include premature rupture of the membranes, congenital clubfoot or congenital

Table 69.2

Beighton's criteria for joint hypermobility

Joint/Finding	Negative	Unilateral	Bilateral
Passive dorsiflexion of the fifth finger >90 degrees	0	1	2
Passive flexion of thumbs to the forearm	0	1	2
Hyperextension of the elbows beyond 10 degrees	0	1	2
Hyperextension of the knees beyond 10 degrees	0	1	2
Forward flexion of the trunk with knees fully extended and palms resting on the floor	0	Present = 1	
A total score of at least 5/9 defines hypermobility

hip dislocation, inguinal hernia, pneumothorax, and recurrent joint dislocation or subluxation.[17] Patients with vascular EDS often display a characteristic facial appearance, with prominent eyes (due to lack of subcutaneous adipose tissue around the eyes), a thin, pinched nose and small lips, hollow cheeks, and lobeless ears. Hypermobility is usually limited to the small joints of the hands.

The generalized vascular fragility largely dominates the clinical picture. Apart from excessive bruising and bleeding, it may cause precocious and severe varicosities and arterial rupture, potentially resulting in sudden death, usually in the third or the fourth decade of life. The vascular fragility affects large as well as small blood vessels, and bleeding may occur at every possible site in the body. The most common location of arterial bleeding is the abdominal cavity due to rupture of medium-sized arteries, such as the renal or splenic arteries, rather than of the aorta itself. Acute myocardial infarction due to coronary dissection or rupture is a rare complication. Some affected individuals may harbor predisposing lesions such as aneurysms or arteriovenous fistulae, but in other patients ruptures occur at locations that appear completely normal by angiography.[2] Besides the vascular ruptures, dangerous internal complications such as spontaneous rupture of the bowel (usually the colon, sometimes the intestine), the gravid uterus, and hemorrhagic pneumothorax may occur.[14,18–21]

Although uncommon, vascular EDS is a cause of stroke in young adults. The mean age of intracranial aneurismal rupture, spontaneous carotid–cavernous sinus fistula, and cervical artery aneurysm is 28 years.[22] Obstetrical complications are frequent and include vascular, intestinal, or uterine rupture, vaginal lacerations, prolapse of uterus and bladder, and premature delivery because of cervical insufficiency or fragility of the membranes. Patients with vascular EDS who are pregnant should be enrolled in a high-risk obstetrical program.

The clinical appearance of patients with vascular EDS may deviate from the typical picture, and especially the facial and cutaneous features, such as the acrogeria, may be very subtle or even absent. In the absence of a positive family history or a major vascular or intestinal complication, clinical diagnosis is difficult, especially in children.

From Genotype to Phenotype

EDS is extremely heterogeneous not only at the clinical but also at the molecular level. Abnormalities in the expression or structure of the fibrillar collagen types I, III, and V, as well as enzymatic abnormalities in the posttranslational modification and processing of these collagens, and more recently also in molecules involved in intracellular trafficking and extracellular organization of these molecules, have been identified in a number of EDS subtypes. Studies suggest that approximately 50% of individuals with classic EDS have an identifiable mutation in the *COL5A1* or *COL5A2* gene, the genes encoding the α_1- and the α_2-chain of type V collagen, respectively.[23] However, since no prospective molecular studies of *COL5A1* and *COL5A2* have been performed in a clinically well-defined patient group, this number may underestimate the real proportion of classic EDS patients harboring a mutation in one of these genes.[24]

The vascular type of EDS results from mutations in the *COL3A1* gene, encoding the proα_1 chain of type III collagen. A wide spectrum of *COL3A1* mutations has been identified, the majority of which are point mutations leading to substitutions for the obligatory glycine in the triple-helical region of the collagen molecule. Other types of mutations include splice-site mutations, partial gene deletions, and, rarely, mutations resulting in *COL3A1* haplo-insufficiency.[2,25] Parental mosaicism for *COL3A1* mutations has been documented in vascular EDS[26–29] and may explain unexpected recurrences in families in which a "new" dominant mutation has been identified.

Whereas defects in the genes encoding type I collagen generally result in different forms of OI, a subset of mutations in the *COL1A1* or the *COL1A2* gene result in specific subtypes of EDS. Mutations that cause loss of the *N*-proteinase cleavage site of either the proα_1(I) or the proα_2(I) collagen chain give rise to the arthrochalasia type of EDS. Mutations residing in the most amino-terminal part of the collagen type I triple helix result in a distinct EDS/OI overlap phenotype with variable joint hypermobility and bone fragility.[30] In addition, some of these patients display increased vascular fragility with bleeding diathesis (personal observation). These mutations have been shown to interfere with removal of the *N*-terminal propeptide, even though the *N*-proteinase cleavage site remains intact.[31] Specific arginine-to-cysteine (R-to-C) substitutions at different positions of the α_1(I) helical domain have been associated with a range of EDS phenotypes, including a classic EDS-like phenotype in childhood, and a vascular EDS-like phenotype with increased risk for spontaneous arterial rupture in young adulthood.[9,32,33] Finally, mutations leading to

total absence of the proα_2(I) chain, due to a homozygous or compound heterozygous *COL1A2*-mutation, can be associated with severe cardiac valvular anomalies necessitating surgery at young adult age.[12,13]

Homozygous or compound heterozygous mutations in genes encoding enzymes involved in collagen biosynthesis have been documented in several autosomal recessive forms of EDS. Homozygous mutations in *PLOD1* (procollagen-lysine, 2-oxoglutarate 5-dioxygenase or lysyl hydroxylase-1), the gene encoding lysyl hydroxylase-1, have been identified in patients with the kyphoscoliotic type of EDS.[34] Lysyl hydroxylase-1 is required for the hydroxylation of specific lysine residues to hydroxylysines, which act as precursors for the cross-linking process that is essential for the tensile strength of collagen. A deficient activity of procollagen-*N*-proteinase due to homozygous and compound heterozygous mutations in the *ADAMTS-2* gene is responsible for the dermatosparaxis type of EDS.[35]

Recently, several new EDS variants have been characterized, implicating genetic defects in molecules involved in processes as diverse as intracellular trafficking, enzymatic modification of ECM proteins, and cell–matrix interactions (Table 69.3). Total absence of tenascin-X (*TNXB* gene), a large ECM glycoprotein that plays a role in the maturation and the maintenance of the dermal collagen and elastin network, results in a classic EDS-like phenotype with extensive bruising, skin and joint hypermobility, and occasionally increased laxity of the genitourinary tract causing uterine and vaginal prolapse, increased risk for postpartum hemorrhage, progressive muscle weakness, and distal joint contractures.[36,37,38] Deficiency of SLC39A13 (*SLC39A13* gene), an intracellular zinc transporter, results in spondylocheirodysplastic EDS[39], and deficiency of Ras- and Rab interactor 2 (*RIN2*), which is involved in Rab5-mediated early endosomal trafficking, results in an EDS-like "RIN2 syndrome."[40,41] Deficiency of galactosyltransferase-I (*β4GALT7*) and of dermatan-4-sulfotransferase 1 (*CHST14*), two enzymes involved in dermatan sulfate biosynthesis, causes the progeroid and the musculocontractural subtype of EDS, respectively.[42,43,44] Furthermore, a zinc-finger protein (*ZNF469*), the exact function of which remains currently unknown, has been shown to be associated with brittle cornea syndrome, a condition with substantial phenotypical overlap with EDS kyphoscoliotic type,

Table 69.3

Newly identified subtypes of EDS, which are not present in the current Villefranche nosology, associated genes, and discriminating features

Gene	Protein	Disease Name	Discriminating Features	IP
COL1A1	Type I collagen (α_1(I) chain)	—	Aneurysm/dissection of middle-sized arteries	AD
COL1A2	Type I collagen (α_2(I) chain)	Cardiac valvular EDS	Cardiac valvular disease	AR
TNX-B	Tenascin-X	—	Skin hyperextensibility and easy bruising without atrophic scarring, laxity of GU tract, progressive muscle weakness, distal joint contractures	AR
B4GALT	Galactosyltransferase-I	Progeroid form of EDS	Progeroid appearance, radioulnar synostosis, short clavicle	AR
CHST14	dermatan-4-sulfotransferase 1	Musculocontractural EDS	Joint contractures, clubfeet, progressive muscle weakness, tubular fingers, multisystemic involvement	AR
ZNF469	ZNF 469	Brittle cornea syndrome	Brittle cornea, blue sclerae	AR
SLC39A13		Spondylocheirodysplastic EDS	Tubular fingers, distal joint contractures, platyspondyly, metaphyseal broadening	AR
RIN2	RIN2	MACS syndrome or RIN2 syndrome	Progressive craniofacial dysmorphism, progressive scoliosis, sparse hair/alopecia, macrocephaly, skin hyperextensibility/CL	AR
?	?	Periodontotic EDS	Severe early-onset periodontal disease, chronically inflamed pretibial plaques	AD
FLNA[93]	Filamin A	EDS with periventricular nodular heterotopia	Periventricular nodular heterotopia	X-linked dominant

IP, inheritance pattern; AD, autosomal dominant; AR, autosomal recessive; GU, genitourinary; MACS, macrocephaly, alopecia, cutis laxa, scoliosis

that is primarily characterized by fragility of the cornea, leading to corneal rupture.[45]

Diagnosis

The evaluation of the patient in whom EDS is suspected should start with a detailed clinical and family history and a thorough physical examination. Laboratory investigation of platelet aggregation, clotting factors, and bleeding time in patients with EDS is usually normal.

In certain EDS subtypes, ultrastructural, biochemical, and molecular analyses can be very helpful to confirm the diagnosis. To this end, a skin biopsy is required to obtain cultured skin fibroblasts.

Ultrastructural examination of the skin, performed by electron microscopy, usually reveals abnormalities of collagen fibrillogenesis. These include irregular, disrupted collagen fibrils ("collagen flowers") and variability in the diameter of the individual collagen fibrils. However, these abnormalities are found in several EDS variants and do usually not allow to discriminate between individual EDS subtypes, and cannot be used as a diagnostic test. Only in the dermatosparaxis subtype of EDS, ultrastructural examination of the skin is diagnostic, showing a pathognomonic "hieroglyphic" aspect of the collagen fibril architecture.[46,47]

Biochemical study of the collagen types I, III, and V includes SDS polyacrylamide gel electrophoresis of radiolabeled collagens extracted from the cultured fibroblasts, and can detect abnormalities of these proteins, regardless of the underlying cause. In the vascular subtype of EDS, biochemical analysis of type III procollagen is diagnostic in more than 95% of all patients. It allows to detect quantitative (reduced amounts of type III collagen) and/or qualitative (abnormal type III collagen with altered electrophoretic mobility) abnormalities of type III collagen. Biochemical analysis can also be helpful in the diagnosis of the arthrochalasis, kyphoscoliosis, dermatosparaxis, and some other rare subtypes of EDS, where distinct abnormal migration patterns of type I (pro) collagen chains are observed. For the majority of patients with the classic type of EDS, on the other hand, analysis of type V collagen is an ineffective method for routine diagnostic evaluation, since the chains of type V collagen are synthesized by fibroblasts at a low rate, causing poorly reproducible quantification and evaluation of alterations in electrophoretic mobility of this collagen.[23]

Molecular investigations usually start from genomic DNA and messenger RNA, extracted from cultured dermal fibroblasts. For the classic subtype of EDS, the majority of the mutations result in a nonfunctional *COL5A1* allele.[23] As a first step therefore, a *COL5A1* "null"-allele test is performed, using polymorphic markers in the expressed region of the genomic DNA, to determine if both *COL5A1* alleles have stable transcripts. This test determines if the individual is heterozygous for one of several *COL5A1* polymorphic exonic markers in genomic DNA and then establishes at the cDNA level whether both alleles are expressed. If only one of the two *COL5A1* alleles is present in cDNA, it is assumed that the absent allele is "null." Since it examines both genomic DNA and cDNA, *COL5A1* "null"-allele testing requires cultured skin fibroblasts. It does not identify mutations within the *COL5A1* gene.

Sequence analysis of the different genes involved in the various subtypes of EDS can be performed either on genomic DNA or cDNA. Once the mutation is known, its presence or absence can easily be verified on genomic DNA obtained from leucocytes from the patient and from relatives.

Prenatal diagnosis for pregnancies at increased risk is possible by analysis of DNA extracted from fetal cells obtained by amniocentesis usually performed at about 15 to 18 weeks' gestation or chorionic villus sampling at about 10 to 12 weeks gestation. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed. Requests for prenatal testing for conditions that (like classic EDS) do not affect intellect or life span are not common. Differences in perspective may exist among medical professionals and within families regarding the use of prenatal testing, particularly if the testing is being considered for the purpose of pregnancy termination rather than early diagnosis. Although most centers would consider decisions about prenatal testing to be the choice of the parents, discussion of these issues is appropriate. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified in an affected family member.

Guidelines for Management

As EDS affects many systems in the body, different medical specialists need to be involved in the management, depending on the extent and severity of the symptoms of the clinical phenotype. Each patient presents with a particular set of clinical problems, requiring a treatment plan that is tailored to his or her specific needs. Coordination of the multidisciplinary approach to ensure that all areas of the syndrome are covered is preferably done by a clinical geneticist, who will also provide genetic counseling. No causal therapy is available for EDS; however, a series of "preventive" guidelines are applicable to all forms of EDS. The key aspects of management include cardiovascular workup, physiotherapy, pain management, and psychological follow-up.

A baseline echocardiogram should be performed in all patients with EDS in order to evaluate aortic root diameter, as adjusted for age and body surface area, and to evaluate cardiac valvular abnormalities. Because longitudinal data on progression of aortic dilation are not available, specific recommendations for follow-up in individuals with a normal aortic diameter do not exist. However, if no abnormalities are found on echocardiogram in an adult, a follow-up echocardiogram is probably not necessary. For children and adolescents, it is reasonable to repeat the echocardiogram, approximately every 3 years until adulthood. Annual echocardiograms are warranted only if an abnormality such as aortic dilatation or MVP is present.

Children with pronounced skin fragility should wear protective pads or bandages over the forehead, knees, and shins in order to avoid skin lacerations. Dermal wounds should be closed without tension, preferably in two layers. Deep stitches should be applied generously. Cutaneous stitches should be left in place twice as long as usual, and additional fixation of adjacent skin with adhesive tape can help to prevent stretching of the scar.

Patients with pronounced bruising are advised to avoid contact sports and heavy exercise. Protective pads and bandages can also be useful in the prevention of bruises and hematomas. Drugs that interfere with platelet function, including aspirin (acetylsalicylic acid), dipyridamole, clopidogrel, and nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and diclofenac should be avoided where possible. Paracetamol (acetaminophen) and cyclooxygenase-1-sparing NSAIDs, such as celecoxib, do not influence hemostasis and can be

considered safe. By definition, anticoagulant drugs will increase the bleeding tendency, and should also be restricted to the minimum especially in the vascular subtype of EDS. These include the traditional oral vitamin K antagonists (coumarins) such as acenocoumarol, fenprocoumon and warfarin, heparin and low molecular weight heparins, and the newer oral thrombin inhibitors and pentasaccharides. There are currently no guidelines regarding the administration of anticoagulant drugs for the prophylaxis of deep venous thrombosis or pulmonary embolism in vascular EDS patients. Standard guidelines should be followed, but the treating physician needs to be aware of an increased risk for dramatic complications during anticoagulant treatment. Supplementation of ascorbic acid, a cofactor for cross-linking of collagen fibrils, can ameliorate the tendency toward bruising in some patients. The vasopressin analogue desmopressin acetate, 1-desamino-8-D-arginine vasopressin has been reported to reduce a bleeding tendency temporarily in subjects undergoing a dental or surgical procedure.[48] A case report describes the successful use of recombinant factor VIIa in a patient with vascular type EDS, in whom continued bleeding was successfully stopped after intravenously administered recombinant factor VIIa.[49]

In patients with hypotonia and delayed motor development, a physiotherapy program is important. Non–weight-bearing muscular exercise, such as swimming, is useful to promote muscular development and coordination. Sports with heavy joint strain, such as contact sports, are discouraged. Besides prescription of physiotherapy, the rheumatologist and/or physical therapist may also provide assisting devices such as braces, ring splints, and soft collar necks, while the occupational therapist may provide tools that make the living and working environment more user-friendly for the patient. Many patients will have undergone one or more orthopedic procedures prior to the diagnosis of EDS, such as arthroplasty and capsulorrhaphy. The degree of joint stabilization, pain reduction, and duration of improvement are usually far less in patients with EDS than in those without this disorder. It is often appropriate to delay surgery in EDS patients in favor of physical therapy and bracing.

Pain management is also very important. Pain medication should be tailored to the individual's subjective symptoms. Cognitive behavioral therapy can be beneficial in patients with hypermobility and chronic pain. Finally, psychological follow-up designed to explore coping strategies and to recognize and treat depression is of utmost importance.

For the vascular type of EDS, some prophylactic measures are of special importance.

Invasive vascular procedures to determine sources of bleeding such as arteriography and catheterization should be avoided because of the risk of vascular ruptures, which cause significant morbidity and may have fatal outcome.[50,51] They should rather be replaced by ultrasonography and/or subtraction angiography. Surgical interventions are generally discouraged because of increased vascular fragility, and conservative therapy is recommended. When surgery is required for the treatment of arterial or bowel complications or other health problems, thorough investigation of platelet function and clotting is appropriate, as affected persons are already subject to bleeding from ruptured vessels or organs and an intrinsic clotting defect (unrelated to EDS) may complicate clinical outcome. Surgical exploration and intervention should be minimized and manipulation of vascular and other tissues should be done with extreme care.[15]

Recently, a multicenter randomized trial showed that celiprolol, a long-acting β_1-antagonist with partial β_2-agonist properties, decreased the incidence of arterial rupture or dissection by three times in patients with the clinical diagnosis of vascular EDS. This study represents a substantial breakthrough in the evidence-based management of the syndrome.[52]

Pregnancy for women with the vascular type of EDS is a high-risk venture. The risk of maternal death is as high as 12% from uterine rupture or peripartum arterial rupture.[14] On the other hand, some women with vascular EDS have had one or several successful pregnancies prior to recognition of their underlying condition. It is prudent to follow pregnant women with the vascular type of EDS in a high-risk obstetrical program. It is not clear whether elective caesarean section is preferred to vaginal delivery.

The Marfan Syndrome

More than a century ago, the French pediatrician Antoine-Bernard Marfan described a 5-year-old girl, Gabrielle, with long slender digits, long-bone overgrowth, and muscle hypoplasia.[53] Clinical research further delineated this pleiotropic condition, known as the Marfan syndrome (MFS), as a systemic connective tissue disorder with severe manifestations mainly involving the cardiovascular, ocular, and skeletal systems and necessitating a multidisciplinary approach for diagnosis and management.

The estimated prevalence of this rather common disease is 1 in 5,000, affecting both sexes equally.[54] The disease demonstrates autosomal-dominant inheritance with high penetrance and marked inter- and intrafamilial variability. International criteria for diagnosis have been established and were recently refined in the revised Ghent nosology.[55] These criteria put much weight on the two cardinal features of MFS, namely, aortic root aneurysm/dissection and ectopia lentis (displacement of the eye's crystalline lens). In the absence of any family history, the presence of these two cardinal features is sufficient for the unequivocal diagnosis of MFS, irrespective of systemic involvement. In the absence of one of these two clinical manifestations, the presence of a bonafide *FBN1* mutation or a combination of systemic manifestations is required. For the latter, a new scoring system has been designed in which a score of seven or more indicates systemic involvement compatible with MFS (Table 69.4).

Clinical Characteristics

Cardiovascular System

A key diagnostic criterion for MFS is aortic root aneurysm or dissection. These cardiovascular manifestations are life threatening, with the majority of aortic dissections/ruptures occurring in early adult life if left untreated. The onset and growth rate of the aortic dilatation vary highly between individuals. Timely recognition and appropriate medical and surgical management of the disease have increased the mean survival age to 72 years.[56] Aortic dilatation is generally greatest at the sinuses of Valsalva. Aortic root measurements should be performed parallel to the plane of the aortic valve and perpendicular to the axis of the blood flow. The largest correctly measured root diameter obtained from at least three transthoracic images should be corrected for age and body size, and interpreted as a Z-score.[55] Aortic root dilatation is present when the Z-score is ≥2. MVP is also a common finding in MFS. There are no special criteria for diagnosing MVP in MFS and standard practices

Table 69.4

Scoring of systemic features for MFS

Clinical Sign	Points
Wrist and thumb sign	3
Wrist or thumb sign	1
Pectus carinatum deformity	2
Pectus excavatum or chest asymmetry	1
Hindfoot deformity	2
Plain pes planus	1
Pneumothorax	2
Dural ectasia	2
Protrusio acetabuli	2
Reduced US/LS and increased arm/height and no severe scoliosis	1
Scoliosis or thoracolumbar kyphosis	1
Reduced elbow extension	1
Facial features (3/5) (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia	1
Skin striae	1
Myopia >3 diopters	1
MVP	1
Maximum total: 20	
Score ≥7 indicates systemic involvement	

Modified from Loeys BL, Dietz HC, Braverman AC, et al. The revised Ghent nosology for the Marfan syndrome. *J Med Genet* 2010;47(7):476–485.

should be applied. Patients with MFS can develop aortic enlargement or dissection at segments distant from the aortic root. The frequency of this finding (particularly at the proximal descending thoracic aorta and in the abdomen) appears to be increasing with the prolonged survival due to improved management of disease at the aortic root. Descending aortic aneurysm/dissection is rare in the absence of aortic root enlargement.

Ocular System

The most prominent ocular features of MFS are lens dislocation (FIGURE 69.4) and myopia. Ectopia lentis reflects failure of the ciliary zonules, and the diagnosis is based on slit-lamp examination after maximal dilatation of the pupil. Myopia is very common in MFS, is usually early in onset, and can progress rapidly.

Musculoskeletal System

Long-bone overgrowth contributes to disproportionately long limbs and anterior chest deformities due to rib overgrowth. Pectus carinatum is believed to be more specific for MFS than pectus excavatum. Other major manifestations include arachnodactyly, limited extension of the elbows, scoliosis or spondylolisthesis, protrusio acetabuli (detected by X-ray), and hindfoot valgus in combination with forefoot abduction and

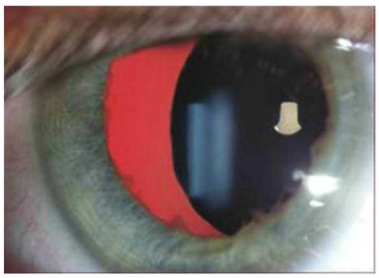

FIGURE 69.4 Ectopia lentis in a patient with MFS.

lowering of the midfoot. Arachnodactyly requires a positive thumb sign (when the entire distal phalanx of the fully adducted thumb extends beyond the ulnar border of the palm) and a positive wrist sign (when the tip of the thumb covers the entire fingernail of the fifth finger when wrapped around the contralateral wrist). Patients may present with typical facial characteristics including downslanting palpebral fissures, enophthalmia, retrognathia, and a highly arched palate with dental crowding. Joint hypermobility may predispose to ligamentous injury, dislocations, chronic joint pain, and premature osteoarthritis. Muscle hypoplasia and myalgia are often underrecognized and may result in fatigue and spinal pain.

Dura Mater

Dural ectasia (a gradual stretching and weakening of the dura mater) is a common observation, with a high prevalence in MFS patients. For the detection of dural ectasia, no preferred method (CT or MRI) or uniformly accepted cutoffs are available. It is a sensitive but not a specific sign of MFS, as it is commonly seen in other conditions, such as the Loeys-Dietz syndrome (LDS), or the EDS. It occasionally causes discomfort such as low-back pain, headaches, and irradiating leg pains.[57]

Skin/Pulmonary System

Cutaneous manifestations in MFS include striae atrophicae, which are not associated with weight changes or pregnancy, and which are present on uncommon locations such as the mid-back, lumbar region, upper arm, axillary region, or thigh. The most important pulmonary feature is spontaneously occurring pneumothorax.

Differential Diagnosis

The differential diagnosis of MFS is extensive, comprising other connective tissue disorders and metabolic diseases with skeletal, ocular, and/or cardiovascular involvement (Table 69.5).

Molecular Pathogenesis

MFS is caused by mutation in the *FBN1* gene, encoding fibrillin-1. Thus far, over 1,000 different mutations have been identified, dispersed all over the *FBN1* gene and often family specific. Until recently, it was believed that structural deficiency of the fibrillin-1 protein was the most important explanation for the weak connective tissues in MFS, a hypothesis based mainly on the microscopic observations showing rarefaction of elastic fibers. While this helped to explain the aortic pathology and ectopia lentis, it did not reconcile the observation of other clinical features such as long-bone overgrowth, thickening of

Table 69.5

Differential diagnosis of MFS, associated genes, and discriminating clinical features

Differential Diagnosis	Gene	Discriminating Features
MFS	*FBN1*	Aortic root dilatation, presence of ectopia lentis, systemic features (Table 69.4)
Loeys-Dietz syndrome (LDS)	*TGBR1/2*	Bifid uvula/cleft palate, arterial tortuosity, hypertelorism, diffuse aortic and arterial aneurysms, craniosynostosis, clubfoot, cervical spine instability, thin and velvety skin, easy bruising
Shprintzen-Goldberg syndrome	*FBN1* and other	Craniosynostosis, mental retardation, hypertelorism, proptosis
Congenital contractural arachnodactyly (CCA)	*FBN2*	Crumpled ears, contractures
Weill-Marchesani syndrome	*FBN1* and *ADAMTS 10*	Microspherophakia, brachydactyly, joint stiffness, short stature
Ectopia lentis syndrome	*FBN1, LTBP2, ADAMTS4*	Lack of aortic root dilatation
Homocystinuria	*CBS*	Thrombosis, mental retardation
Familial thoracic aortic aneurysm syndrome (FTAA)	*TGFBR1/2*	Lack of marfanoid skeletal features
	ACTA2	Levido reticularis, iris flocculi, CVA
	SMAD3	Osteoarthritis, arterial tortuosity, soft skin

the cardiac valves, or muscle hypoplasia. The study of fibrillin-1 mutant mouse lines that recapitulate human MFS has recently challenged this "mechanistic" view and show that structural fibrillin-1 deficiency leads to activation of the sequestered or latent cytokine TGF-β.[58,59] Dysregulation of TGF-β signaling, one of the major biologic pathways, has been shown to play a pivotal role in the development of aortic aneurysms, emphysema, and the muscle hypoplasia seen in MFS, and progression of aortic root enlargement can be effectively blocked with TGF-β antibodies.[58,60,61] In mouse models for MFS Losartan, an angiotensin II type 1 receptor blocker has been shown to stop aortic growth and reconstitute elastic fiber conservation.[61] Losartan directly blocks the effect of TGF-β, diminishes the expression of TGF-β receptors, and inhibits the activity of TSP, an ECM enzyme that enables the release of TGF-β.[62,63] This changing concept of MFS, from a syndrome characterized as a structural connective tissue disorder to a condition manifesting also perturbed cytokine signaling, has opened new and unexpected targets for drug treatment.

Guidelines for Management

Diagnosis and management require a multidisciplinary approach by geneticists, cardiologists, orthopedic surgeons, and ophthalmologists with experience in this field.[63] Cardiovascular follow-up should include yearly evaluation with echocardiography or CT/MRI angiography when visibility of the aortic root and

ascending aorta is limited. Evaluation frequency should be tailored according to aortic dimensions, rate of aortic growth, and family history. More frequent imaging should be performed if the aortic diameter is approaching the threshold for surgery (≥4.5 cm in adults, less well defined in children) or shows rapid growth (≥0.5 cm/y) or when there are concerns regarding heart or valve function.[55] Beta-adrenergic blockade, titrated to physiologic response, is a standard treatment to slow aortic growth, mainly by virtue of its antihypertensive and negative inotropic effects.[64] If beta-blockade is contraindicated (asthma, Raynaud phenomenon, psoriasis, depression, fatigue), calcium antagonists or angiotensin converting enzyme inhibitors may be used although no randomized studies currently exist. New therapeutic strategies, based upon the physiopathology in MFS, propose the angiotensin receptor blocker Losartan as an antihypertensive agent attenuating TGF-β signaling. Encouraging results were observed in a pilot experience in children with severe MFS, and several multicenter trials of Losartan versus or on top of beta-blockade in MFS are currently under way.[65–67]

Surgical repair of the aorta is indicated once the maximal diameter exceeds 5 cm in adults, when the rate of aortic growth exceeds >0.5 to 10 mm/y, or in the presence of significant aortic regurgitation. In cases where aortic valve function is preserved, the preferred technique is the valve-sparing procedure avoiding lifelong anticoagulant therapy, especially in females in their fertile period. Although the superiority of this technique in comparison with the composite graft has not definitely been established, the 10-year experience is very promising.[68] After surgical repair of the aortic root, imaging of the whole aorta is warranted for timely detection of aortic graft pseudoaneurysms, more distally occurring aneurysms, and coronary artery aneurysms.[63]

Pregnancy in women with MFS is associated with an increased cardiovascular risk, with the majority of aortic complications occurring in the third trimester or in the early postpartum period. The risk for aortic root complications is increased when the aortic root diameter is above 4 cm at the start of the pregnancy.[63] Therefore, pregnancy should be followed intensively, with special care in the peripartum period, through a high-risk obstetric clinic.

Orthopedic complications, mainly those involving deformities of the anterior chest and vertebral column, should be followed carefully, especially during and just after puberty. Since extreme pectus deformity has little impact on pulmonary function, surgery is considered as a cosmetic issue. Correction, preferably using the minimally invasive Nuss procedure, should not be done before the age of 11 years[69], as earlier intervention might lead to recurrent deformity due to continued rib growth. In contrast, severe (kypho-) scoliosis has a major impact on quality of life, needing surgical stabilization as bracing often remains inadequate.[70] Protrusio acetabulae is often asymptomatic in young adults, and the benefit of surgery is questioned.[71] Hormone therapy is indicated if predicted final height is unacceptable.[72]

Diffraction anomalies due to lens subluxation, flat cornea, or myopia can easily be corrected by eyeglasses or contact lenses. Lens extraction for manifest ectopia lentis or cataract severely increases the preexisting risk for retinal detachment and glaucoma, which causes significant visual impairment. Yearly examination by an experienced ophthalmologist is highly recommended for every Marfan patient.

Finally, lifestyle modifications may promote cardiovascular and psychosocial health, and prevent or relieve many locomotor inconveniences including fatigue, myalgia, osteoarthritis, and chronic joint pain. Patients should avoid competitive sport, straining, or isometric exercise as these increase blood pressure and cause considerable dynamic stress on the aortic root. Additionally, contact sports should be avoided as these may precipitate aortic dissection.[73]

Prenatal diagnosis for pregnancies at increased risk is possible by analysis of DNA extracted from fetal cells obtained by amniocentesis usually performed at about 15 to 18 weeks gestation or chorionic villus sampling at about 10 to 12 weeks gestation. The disease-causing allele of an affected family member must be identified before prenatal testing can be performed. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation has been identified in an affected family member.

Other HCTD that Can be Associated with Aortic Aneurysms

The Loeys-Dietz Syndrome

The LDS is an autosomal dominant aortic aneurysm syndrome characterized by a triad of hypertelorism, bifid uvula or cleft palate, and arterial tortuosity with ascending aortic aneurysm/dissection (FIGURE 69.5 shows bifid uvula). LDS is caused by heterozygous mutations in the TGF-β receptor 1- and TGF-β receptor 2-encoding genes *TGFBR1* and *TGFBR2,* resulting in perturbation of TGF-β signaling.[74] There is significant clinical overlap between LDS and MFS. However, LDS patients rarely satisfy diagnostic criteria for MFS. The main differences are the absence of long-bone overgrowth and lens dislocation, and the presence of multiple other findings, including the dysmorphic features, craniosynostosis, Chiari malformation, clubfeet, patent ductus arteriosus (PDA), and aneurysms and dissections throughout the arterial tree. In contrast to this typical presentation, which was later coined as LDS type I, some patients show less craniofacial abnormalities but more prominent joint and skin manifestations, reminiscent of vascular EDS. This subset of patients (referred to as LDS type II) is characterized by easy bruising, a velvety translucent skin, widened atrophic scars, uterine rupture, severe peripartal bleeding, and arterial aneurysm/dissection throughout the arterial circulation.

The natural history of LDS type I and II is far more aggressive than MFS or even vascular EDS, with a mean age of death of 26 years. Aortic dissections occur in young childhood and/or at smaller aortic dimensions, and the incidence of pregnancy-related complications is high.[75] However, the amenability to

FIGURE 69.5 Bifid uvula in a patient with LDS.

early and aggressive surgical intervention clearly distinguishes these patients from individuals with vascular EDS.

Arterial Tortuosity Syndrome

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive condition characterized by severe tortuosity, stenosis, and aneurysms of the large and middle-size arteries. Focal stenosis of the pulmonary and large systemic arteries can be associated. Patients usually present with characteristic dysmorphic features including elongated face, blepharophimosis and downslanting palpebral fissures, a beaked nose, highly arched palate, and micrognathia. Other connective tissue manifestations comprise a soft, hyperextensible skin and skeletal abnormalities such as arachnodactyly, pectus deformity, joint laxity, and contractures. Patients are prone to vascular complications including dissections and ischemic events. Although initially the prognosis was reported to be poor with mortality rates up to 40% before the age of 5 years,[76] more recent clinical studies and case reports have illustrated that the prognosis is better than previously thought, and that both aortic aneurysms and pulmonary hypertension due to peripheral stenosis are amenable to surgery. However, stroke remains a significant risk and progressive aortic root dilatation may occur.[77]

ATS is caused by mutations in *SLC2A10*, encoding a facilitative glucose transporter, GLUT10. Immunohistochemistry data suggest that the transporter resides on the nuclear membrane. Furthermore, similarly as in the clinically related LDS, vascular smooth muscle cells of ATS patients show enhanced TGF-β signaling.[78]

Cutis Laxa

The term cutis laxa, describing a clinical feature, is used as a common denominator for a heterogeneous group of rare connective tissue disorders, characterized by an increased number of inelastic skinfolds. Both hereditary and acquired forms can be distinguished. Acquired forms appear secondary to infections, administration of medications or as a paraneoplastic feature. Historically, classification of the hereditary forms is based on clinical grounds and mode of inheritance.

The X-linked recessive form, also known as occipital horn syndrome (OHS), includes hyperlaxity of skin and joints, bladder diverticulae, inguinal hernias, vascular tortuosity, and skeletal manifestations including the pathognomonic occipital horns (distinctive wedge-shaped calcifications at the sites of attachment of the trapezius muscle and the sternocleidomastoid muscle to the occipital bone).[79] OHS is caused by mutations in the copper-transporting ATPase gene (*ATP7A*), and affected individuals have low serum copper and ceruloplasmin concentrations.[80,81]

Autosomal dominant cutis laxa (ADCL) presents with generalized lax skinfolds resulting in a prematurely aged appearance. It is generally considered a mild condition without severe involvement of internal organs, although aortic and pulmonary abnormalities have been reported occasionally. In ADCL, heterozygous mutations are found in the elastin (*ELN*) and rarely in the fibulin-5 (*FBLN5*) genes.[82,83] Autosomal recessive cutis laxa (ARCL) comprises at least three subtypes, with typically severe emphysema, diverticulosis, disastrous vascular lesions, and a short life expectancy in ARCL type 1; developmental delay, microcephaly, and skeletal abnormalities in ARCL type 2; and corneal clouding, mental retardation, and athetosis in ARCL type 3, also known as de Barsy syndrome.

In ARCL type 1, homozygous or compound heterozygous mutations in *FBLN5*, *FBLN4* and *LTBP4* have been described.[84–86] Patients with *FBLN5* mutations encounter pulmonary emphysema as the most prominent systemic feature, while *FBLN4* mutations cause severe arterial tortuosity, aneurysm formation, and usually mild CL. Like in MFS, LDS and ATS immunostaining of aortic and lung tissue of patients with *FBLN4* mutations showed evidence of enhanced TGF-β signaling, revealing that this is a mayor player in the pathogenesis of aortic dilatation.[87] Mutations in *LTBP4* have recently been reported in a newly described type 1 ARCL constellation, eponymously named Urban-Rifkin-Davis syndrome, which includes craniofacial dysmorphism, short stature, severe bronchopulmonary dysplasia, emphysema, and marked genitourinary and gastrointestinal diverticulosis.[86]

For ARCL type 2, mutations in *ATP6V0A2* or *PYCR1* have been identified. This subgroup is characterized by CL, distinct facial features, skeletal abnormalities, and variable neurologic involvement. Mutations in *ATP6V0A2* and *PYCR1* were also found in some cases of wrinkly skin syndrome and gerodermia osteodysplasticum, two entities that share common features with ARCL type 2.[88,89] In rare sporadic cases, mutations in the gene *ALDH18A1* were identified in patients with CL, severe mental retardation, skeletal defects, and cataract.[90] Nonetheless, many cases of ARCL still remain molecularly unsolved.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is a HCTD characterized by progressive calcification of elastic fibers in the skin, retina, and the cardiovascular system. In general, the earliest clinical manifestations are dermal lesions that present as small yellowish papules primarily at flexural sites, such as the axillae, antecubital fossae, neck, and groin. These papules tend to coalesce into larger plaques, rendering the skin inelastic and redundant. Laxity of the affected skin causes the appearance of premature aging and may have an extensive cosmetic impact. The characteristic ophthalmologic finding in PXE is the presence of angioid streaks in the retina resulting from breaks in the calcified elastic lamina of the Bruch's membrane, which may trigger neovascularization and bleeding, and result in loss of visual acuity and central blindness. Cardiovascular complications arise from the progressive calcification of the elastin-rich arterial blood vessels. Clinical sequelae include intermittent claudication, arteriosclerosis that may lead to hypertension, internal bleeding from the gastric arterial blood vessels, and myocardial infarction at a relatively young age. The diagnosis of PXE is confirmed by histopathologic evaluation of dermal lesions using von Kossa and Verhoeff-van Gieson stains that demonstrate mineralization of elastic fibers. PXE is inherited in an autosomal recessive pattern, and mutations in the ATP-binding cassette (ABC) subfamily C member 6 (*ABCC6*) gene are the cause of PXE. The gene codes for the ABCC6 protein, also known as multidrug resistance–associated protein 6, which is expressed predominantly in the liver and kidneys and, to a lesser extent, in tissues clinically affected by PXE.[91] The precise physiologic function of ABCC6 and what molecule(s) this transmembrane protein transports *in vivo* are currently unknown. To date, close to 300 distinct *ABCC6* mutations associated with PXE have been disclosed in various populations.

While patients with PXE rarely have a bleeding diathesis, a recently described *pseudoxanthoma-like* condition was shown to be associated with a deficiency of the vitamin K–dependent

clotting factors.[92] Affected patients present clinical overlap with classic PXE, with manifestations of yellowish papules as observed in classic PXE; however, the severity of the skin symptoms, with spreading toward the trunk and limbs and the occurrence of thick, leathery skinfolds is also reminiscent of ADCL syndrome. Affected individuals may show a bleeding tendency, including epistaxis, gingival bleeding, vaginal or postpartum hemorrhage, and hematemesis. This condition is caused by specific mutations in the *GGCX* gene encoding a vitamin K–dependent carboxylase that is essential for γ-carboxylation of clotting factors, enabling them to attach to the phospholipid bilayer of membranes as a prerequisite for blood coagulation.

CHAPTER

70 Hereditary Hemorrhagic Telangiectasia

MICHELLE LETARTE AND CLAIRE L. SHOVLIN

Hereditary hemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome, was first recognized as a genetic disorder in the 19th century. HHT is inherited as an autosomal dominant trait, and its prevalence is now estimated at 1 in 5,000 people. Arteriovenous malformations (AVMs), representing direct connections between arteries and veins, are the distinguishing features of HHT. Small AVMs, or telangiectasia, give rise to frequent nosebleeds in most patients and to gastrointestinal (GI) bleeds in older individuals; they can also be present on lips, tongue, ears, and fingers and increase with age. Larger AVMs are found in internal organs, primarily in lungs, liver, and brain in a large number of patients, and can give rise to serious complications. Two genes are responsible for more than 80% of cases of HHT: *endoglin* (*ENG*) for HHT1 (OMIM #187300) and *ACVRL1 (activin receptor–like kinase 1,* or *ALK1)* for HHT2 (OMIM #600376). A third gene, *SMAD4* is mutated in 2% to 3% of HHT cases, co-presenting with juvenile polyposis (JP), a condition referred to as JPHT, OMIM #175050. These three genes code for members of the transforming growth factor-beta (TGF-β) superfamily involved in regulating multiple cellular functions. Endoglin and ALK1 are transmembrane proteins primarily expressed in the vascular endothelium, where they mediate the effects of specific TGF-β superfamily growth factors on endothelial function and vasomotor tone. Reduced functional expression of these specialized receptors leads to dysregulation of pathways essential for vascular homeostasis and the generation of AVMs.

CLINICAL MANIFESTATIONS AND DIAGNOSIS OF HHT

Clinical Manifestations of HHT

The spectrum of HHT encompasses multiple organ systems and within these, numerous forms of disease. Patients presenting to hematologists usually have iron deficiency anemia due to sustained and repeated nasal and/or GI bleeding, and are recognized by characteristic mucocutaneous telangiectasia (FIGURE 70.1A). The majority of HHT patients are also affected by pulmonary (~50%, FIGURE 70.1B) and/or hepatic (30% to 70%) AVMs, with cerebral and pancreatic AVMs affecting up to 20%.[1,2] These AVMs are characteristically silent unless detected by screening protocols. Non telangiectatic/AVM pathology in HHT includes pulmonary arterial hypertension[3] and pulmonary hypertension in the context of high-output cardiac failure secondary to hepatic AVMs,[2] JP,[4] and a prothrombotic state associated with elevated plasma levels of factor VIII.[5] Reduction in life expectancy has been observed in younger individuals.[6a,6b]

The spectrum of diseases associated with HHT has been reviewed recently.[2] In addition to age-related increases in the number of telangiectasia,[2,7] there are specific times in patients' lives when their HHT pathologies become more hazardous, the most important of which is pregnancy that results in a 1.0% risk of maternal death per pregnancy (due to pulmonary AVM [PAVM] hemorrhage, cerebral hemorrhage, and thrombotic complications), with all maternal deaths occurring in women previously considered well.[8a]

One of the emerging themes in HHT is the occurrence of pathologic thromboemboli in a condition that was formerly considered a purely hemorrhagic disorder.[8b] HHT patients are not protected from general venous thromboembolism (VTE) risks, and thromboembolic strokes affect a high proportion of HHT patients with PAVMs. Provision of anticoagulant/antiplatelet therapies in the setting of chronic HHT hemorrhage may therefore be required.

Diagnosis of HHT

The international consensus diagnostic criteria for HHT are nosebleeds, mucocutaneous telangiectasia, visceral involvement, and a family history[9] (Table 70.1). Anemia is not a criterion.[9] An individual has a clinical diagnosis of "definite HHT" if three criteria are present; "suspected HHT" if two are present; and "unlikely HHT" if only one is present.[9]

Clinical diagnosis is more difficult in younger individuals and those who are paucisymptomatic. Clinical diagnosis may be assisted by detection of visceral involvement either for management of clinical problems or as a result of screening protocols (see below). Outside of HHT centers, it is critical that non-HHT specialists be aware of potential pitfalls in diagnoses, particularly in inappropriate designation of a visceral vascular malformation that is not HHT associated as a diagnostic criterion (Table 70.1). It is also important that when patients receive a diagnosis of visceral AVMs, that they receive appropriate information about recommended management to reduce potential complications that extend far beyond hemorrhagic considerations: provision of such information may be challenging outside of specialized HHT units.

After passing through a clinical diagnostic screen, many patients will be left with a diagnosis of suspected or unlikely HHT. If the HHT mutation has been identified in their family, genetic testing can confirm or refute the diagnosis for the individual. Where a clinical diagnosis of HHT has been made, DNA testing is not required to "confirm" the diagnosis.

If a mutation is not found for a family where individuals have definite clinical HHT, the absence of a detected mutation should not affect the clinical diagnosis. Mutations are not found in approximately 15% to 20% of HHT families.[10–12] In addition, an estimated 10% to 20% of families have genetic variants of

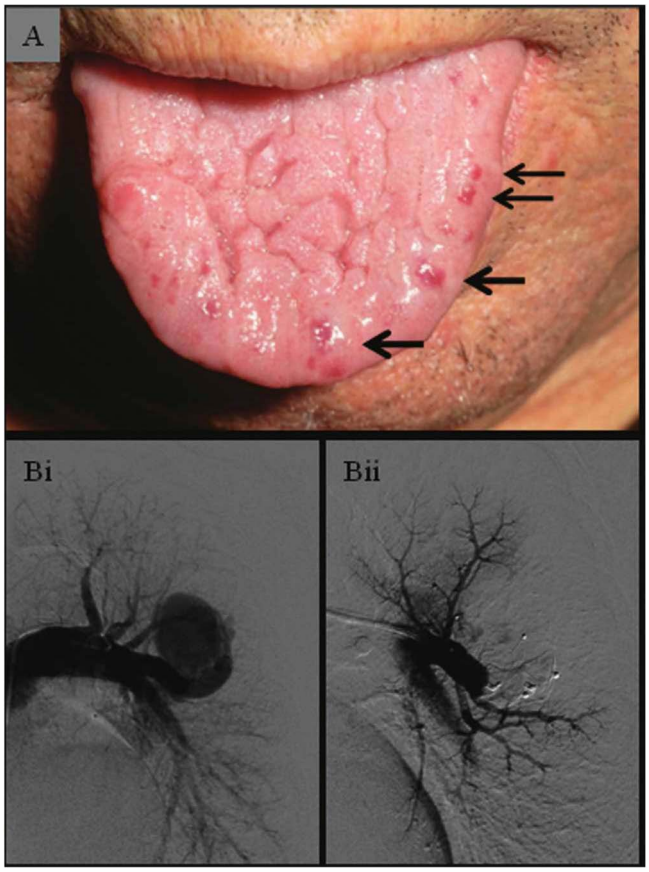

FIGURE 70.1 Clinical HHT. **A:** Tongue demonstrating typical florid telangiectasia. Note that these lesions increase with age and are often subtle or absent in younger individuals. **B(i):** Selective left pulmonary angiograms demonstrating large left lower lobe PAVM pretreatment, when it was associated with severe hypoxemia (SaO_2 85% at rest) and normal pulmonary artery pressure (27/9, mean 16 mm Hg). **B(ii):** Following embolization of separate feeding arteries using four Amplatzer plugs, the SaO_2 rose to 95% at rest, but the pulmonary artery pressure was unchanged (28/8, mean 15 mm Hg). *Angiograms courtesy of Dr James Jackson.*

uncertain significance, where a single-nucleotide change predicts an amino acid substitution that is not certain to sufficiently modify protein function to cause disease. Such "missense" changes have the potential to lead to misdiagnosis, as evidenced by families in which the alternate "real" mutation is also identified.[13,14]

Organ-Specific Screening Issues in HHT

Symptomatic patients will usually first undergo investigations performed by the relevant specialists. From a hematologic perspective, patients are often referred with iron deficiency anemia due to recurrent nasal and/or GI bleeding. In addition, a major component of management for the individual with suspected or proven HHT is screening, that is the investigation for a manifestation of HHT for which they were not previously aware, in order to improve their long-term health.

The international guidelines recommend clinical screens for pulmonary, cerebral, and hepatic AVMs, and genetic tests.[15] It is particularly in this context that overall management within, or in association with an HHT center, is recommended.[15] As discussed recently,[2] there are complex issues involved in screening for certain manifestations of HHT, particularly cerebral AVMs in which investigations and treatments carry substantial risks, and hepatic AVMs for which no treatments are currently recommended for asymptomatic patients. Assumptions that screening tests will be negative are misguided, and detailed prescreening discussions are advised.

Pulmonary

PAVM screening is recommended for all patients with possible or confirmed HHT, based on evidence of long-term efficacy of PAVM embolization resulting in improved oxygenation[15] and more recent evidence that PAVM embolization reduces stroke risk.[16] For sufficiently sensitive screening tests, the choice lies between thoracic CT scans and contrast echocardiography (CE), each of which, in dedicated HHT screening units, provides very high sensitivity as a first-line screen. The international guidelines committee recommended CE as the initial test, with 96% agreement,[15] but this may be reevaluated as the latest data manuscript calls into question the cost effectiveness of CE as the majority of contrast echocardiograms in HHT1 patients are positive, so the need for a subsequent CT scan may not be reduced.[17a] Conversely, in less experienced centers, if a negative echocardiographic study may be used to withhold a CT scan for an HHT patient undergoing PAVM screening, it is essential that methodologic reasons for a possible false negative are not overlooked.[17b] Where CT scans are ordered for PAVM screening, the rationale should be discussed with local radiologists, as use of standard protocols (CT-pulmonary angiogram and high-resolution CT scan) may miss clinically important PAVMs. This is because CT-pulmonary angiogram protocols do not image the lower part of the lungs, while high-resolution CT scans have substantial gaps between the thin slices imaged, and both can miss PAVMs.

Screening for pulmonary hypertension is not generally recommended, but for HHT patients whose impaired exercise tolerance and dyspnea appear to be out of proportion to the level of their anemia, consideration of this possible pathology is appropriate. First-line screening is by echocardiography.

Cerebral

The international guidelines recommend screening adults and children with possible or definite HHT by magnetic resonance imaging, followed by referral to centers with neurovascular expertise for invasive imaging.[15] This recommendation was made while recognizing the lack of evidence of treatment for asymptomatic individuals, and the risks of screening, stated as a 0.5% risk of permanent stroke per diagnostic angiogram.[15] However, the interpretation of the limited evidence base in HHT (as in the general population) differs between health care systems. In some countries therefore, screening is only recommended for patients who are considered at higher risk of cerebral hemorrhage, for example, in the setting of neurologic symptoms, or a family history of cerebral hemorrhage.

Hepatic

The guidelines recommend hepatic AVM screening using Doppler studies to assist diagnosis when there are fewer than three diagnostic criteria, and clinical genetics is unhelpful.[15]

Table 70.1

HHT diagnostic criteria

Curaçao Criterion	Diagnostic Issues	Specificity for HHT
1. Epistaxes (nosebleeds)	"Occur spontaneously on more than one occasion"[9]	Low[127] though likely to be enhanced if of higher severity[100]
2. Mucocutaneous telangiectasia	"Multiple, at characteristic sites—lips, oral cavity, fingers, nose"[9]	Not to be confused with actinic changes; spider naevi; Campbell de Morgan spots; or other cutaneous vascular lesions.[98,128]
3. Visceral lesions		
• *GI telangiectasia*	At endoscopy. With or without bleeding	Potential confusion with von Willebrands Disease, or other forms of angiodysplasia
• *Pulmonary AVM*	Diagnosis usually by CT or CE	Single PAVM may occur sporadically, and 8% of controls have a positive contrast echo[129] but HHT accounted for >90% of PAVM diagnoses in one center[130]
• *Hepatic AVM*		Full discussion of diagnostic issues in[131]
• *Cerebral AVM*		Does not include cavernous malformations or aneurysms (see[21,132] for spectrum)
• *Spinal AVM*		Spectrum of non-HHT disease discussed[133]
4. Family history	"A first degree relative with HHT according to these criteria"[9]	

New data suggest that where screening investigations have already identified abnormal liver function tests in an HHT family, Doppler studies may also be of value to predict a group with more severe disease who may require different follow-up regimes.[18]

Gastrointestinal

HHT patients with a *SMAD4* mutation, or a family history of GI cancer, require endoscopic investigations and management according to standard guidance for GI cancer screening in the non-HHT population.[19]

Specialized Screening Circumstances

Pregnancy

HHT centers have recommended for many years PAVM screening and treatment before pregnancy. Radiation assessment studies indicated that embolization may be undertaken during pregnancy,[20] and routine embolization in the later stages of pregnancy is performed in some centers where prepregnancy treatment was not feasible.[15] Spinal AVM screens form part of HHT pregnancy management in many units in order to facilitate the use of epidural analgesia if required during labor.[8a] No means of distinguishing a group of HHT women more likely to have significant pregnancy-related complications has been identified, and there are no data that specific screening or treatment modalities reduce pregnancy-associated risks. Importantly, prior awareness of the HHT diagnosis improves the outcome for women experiencing a life-threatening event, most likely by enhanced patients' awareness of significant symptoms, and obstetric preplanning in the event of major complications.[8a]

Children

The issues regarding screening of children are also controversial, as evidenced by the low rate of agreement for dedicated pediatric guideline recommendations.[15] There are clearly tragic cases of HHT-related deaths and disability in youngsters. Children with symptoms require specialist investigation and treatment guided by knowledge of HHT pathology. The most concerning pathology in childhood is a particular type of rare cerebrospinal arteriovenous fistula that appears to have a very high risk of hemorrhage, and high treatment-associated risks.[21] Current North American practice includes screening for these lesions from the age of 6 months, and repeating screens to capture AVMs that develop later in childhood.[21] Pediatric screening remains the matter of intense discussion in other health care systems.[2]

GENETICS OF HHT AND MOLECULAR DIAGNOSIS

HHT1 and HHT2

Mutations

ENG and *ACVRL1* mutations are responsible for >80% of cases of HHT. *ENG*, located on chromosome 9q34 and coding for the protein endoglin, was the first gene identified as mutated in HHT, resulting in HHT type 1 (HHT1).[22] *ACVRL1*, located on chromosome 12q31 encoding the ALK1 receptor, was then reported as mutated in HHT type 2 (HHT2).[23,24] Clinically, it is not possible to determine if a patient has HHT1 or HHT2, as there is extensive phenotypic heterogeneity among patients, even within the same family. A molecular diagnosis was developed and is now available in several countries, generally in association with

an HHT center, allowing for genetic counseling of the families, coordinated with patient care by expert physicians.

Results of research studies and diagnostic laboratories have led to the identification of hundreds of mutations in HHT patients.[10,25–35] The HHT mutation database (http://www.hht-mutation.org) currently lists 311 *ENG* mutations and 249 *ACVRL1* mutations. The *ENG* gene has 15 exons (including exons 9a and 9b), and mutations have been reported in all exons but 14, the latter coding for the intracellular region. All types of mutations are present in the *ENG* gene, with deletions and insertions (from single nucleotides to multiple exons, inframe, or causing a frameshift) accounting for the largest proportion. Single-nucleotide substitutions including missense, splice site, and nonsense mutations are also well represented (FIGURE 70.2). The *ACVRL1* gene has 10 exons, and the mutation frequency is highest in exons 3, 7, and 8. Single-nucleotide variants account for the majority with missense mutations being more numerous than stop codon and splice site mutations. Deletions and insertions are less frequent than in the *ENG* gene (FIGURE 70.2). Most mutations are unique but some have been reported in several families, such as in arginine codons 144, 374, 411, and 479 of *ACVRL1*. Therefore, mutation analysis requires the complete sequencing of both genes as well as the analysis of exon copy number.

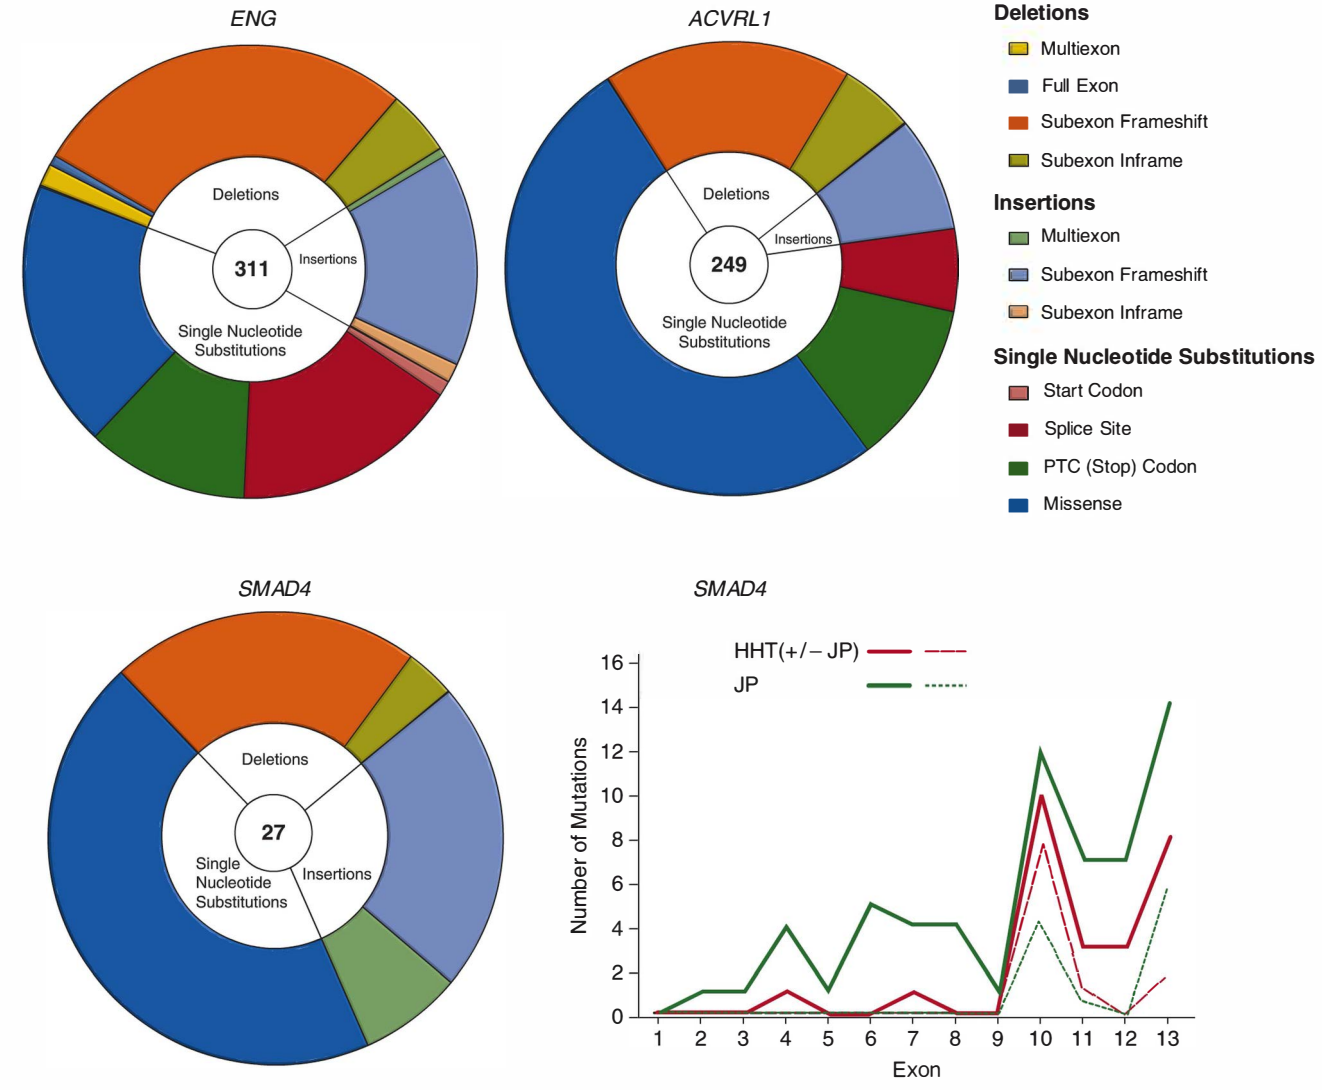

FIGURE 70.2 HHT mutations. Distribution of different types of mutations in *ENG*, *ACVRL1*, and *SMAD4* genes. PTC: premature termination codon generated directly, or by frameshift mutations. Note the higher proportion of missense single-nucleotide substitutions in *ACVRL1*. The graph illustrates the distribution of *SMAD4* mutations reported for HHT patients (*red lines*) and JP alone (*green lines*). Whereas for *ENG* and *ACVRL1*, mutations occur throughout the respective genes,[96] note the limited and highly comparable *SMAD4* mutational distribution for the two pathologies, for all mutations (*solid lines*), and missense substitutions affecting exons 10 to 13 (*dotted lines*). (Data derived from hht.mutation.org and Wooderchak WL, Zacary S, Crockett DK, et al. Repository of SMAD4 mutations: reference for genotype/phenotype correlation. *J Data Mining Genom Proteomics* 2010;1:101.) Ref.[126].

Mechanism of Disease

The underlying mechanism of HHT1 and HHT2 is haploinsufficiency, characterized by a lack of expression of the nonfunctional allele, as determined by protein quantification using metabolic labeling.[36,37] For example, in individuals with a molecular diagnosis of HHT1, the median level of endoglin was close to 50%, representing the normal allele only (in umbilical vein endothelial cells, median 45%, $n = 30$ newborns; peripheral blood–activated monocytes, median 48%, $n = 109$ patients).[31] In many cases, the absent protein will reflect absence of mRNA bearing the mutation due to nonsense-mediated decay of transcripts with premature termination codons.[38,39] The haploinsufficiency model is also supported by the distribution of mutations throughout both genes, deletions of the whole allele, and severity of the clinical phenotype not correlating with the type of mutation.

Genotype/Phenotype Correlations

Phenotypic studies in large groups of patients with identified HHT1 and HHT2 mutations indicate that the gene, rather than a particular mutation, influences the clinical phenotype.[10,40,41,42–44] The major findings in the multiple studies are that PAVMs are more frequent in HHT1 (ranging from 49% to 75%) than HHT2 patients (5% to 48%). Cerebral AVMs, despite an overall much lower occurrence, are also higher in HHT1 (8% to 20%) than HHT2 patients (0% to 2%). On the contrary, hepatic involvement, assessed by the presence of asymptomatic AVMs, is much higher in HHT2 than HHT1 patients.

JPHT

Mutations in the *SMAD4* gene, located on chromosome 18q21, are present in a subgroup of HHT patients (2% to 3%). Patients with *SMAD4* mutations, including those with HHT, are susceptible to JP.[4,45,46] Both JP and HHT are inherited as autosomal dominant traits with nonoverlapping clinical features, JP predisposing to GI tumors. *SMAD4* mutations associated with JPHT had been found mostly in the last four exons.[4,46] However, analysis of a larger number of patients has revealed mutations in other regions (FIGURE 70.2).[47] Thus, any JP patient with a *SMAD4* mutation is at risk for visceral manifestations of HHT and any HHT patient with such a mutation is at risk for early-onset GI cancer. Therefore, all patients with a *SMAD4* mutation should be monitored clinically for both HHT and JP.

HHT3

The large cohorts of patients analyzed for *ENG*, *ACVRL1*, and *SMAD4* mutations (including a search for large deletions and insertions not detected by sequencing) reveal up to 20% of patients with a convincing HHT clinical diagnosis have no identifiable mutation. This may be due in part to intronic mutations not resolved by current mutation detection strategies but also to additional genes that could be mutated in small subsets of HHT patients. Two loci have been reported: HHT3 on chromosome 5q31[48] and HHT4 on chromosome 7p14.[49] The HHT3 locus was identified in a single family with classical HHT, including PAVMs. The interval on chromosome 5 has recently been refined to 26 genes (including 10 pseudogenes) with fibroblast growth factor-1 and PPP2R2B at the centromeric and telomeric ends, respectively.[50] Both of these genes are relevant to angiogenesis and TGF-β signaling and remain candidates for HHT3; three genes in the interval are associated with known genetic disorders not related to HHT, leaving 11 other genes with no association with genetic disorders and no involvement in angiogenesis or TGF-β signaling.

HHT4

The locus for HHT4 maps to a 7-Mb region on the short arm of chromosome 7. It was identified in a four-generation family where PAVMs were detected in 50% of the 16 clinically affected individuals, who had fewer nosebleeds and telangiectasia than classical HHT patients.[49] This region covers 47 known genes, including seven implicated in vasculogenesis. However, DNA sequencing in the affected patients failed to reveal mutations in these genes. A strong candidate remains BMPER, expressed in endothelial cell precursors and which regulates duration and signaling by bone morphogenetic proteins (BMPs), having both pro- and anti-BMP activities.[51,52]

The identification of additional families with HHT3 and HHT4 should help in narrowing the loci and identify the relevant genes, their role in endothelial function, and their relationship to endoglin and ALK1.

MOLECULAR BASIS OF HHT

Endoglin and ALK1 Are Essential for Development of the Vascular System as Revealed by Mouse Models of Disease

Genetically modified mice that lack either endoglin or ALK1 are embryonic lethal at midgestation and display abnormalities in blood vessel development and maturation. *Eng* null mice die with numerous lesions in the cardiovascular tree including incomplete yolk sac vessel branching and remodeling, vessel dilation, hemorrhage, and abnormal cardiac morphogenesis.[53,54,55] *Alk1* null mice show severe vascular abnormalities such as hyperdilation of large vessels, excessive fusion of capillaries and of arteries and veins, and reduced recruitment of smooth muscle cells.[56,57] Endothelial-specific deletion of *Eng* or *Alk1* leads to AVM-like structures in several organs; furthermore, tissue wounding promoted the formation of AVMs in these *Alk1* mice.[58] Conditional knockdown of *Eng* led to the formation of AVMs in the retina, which were amplified by applying an angiogenic stimulus.[59] These findings support the concept that in HHT, expression of a single *ENG* or *ALK1* allele causes endothelial dysfunction that predisposes to AVM development upon exposure to a second hit such as wounding, increased blood flow, or angiogenic stimulus.

Heterozygous mouse models of disease have been generated. The $Eng^{+/-}$ mouse, particularly in early backcrosses, showed HHT-like clinical manifestations including nose and ear bleeds, hepatic and GI telangiectasia, stroke, and even cerebral AVMs.[60–62] Signs of HHT also develop in aged $Alk1^{+/-}$ mice.[63] In keeping with the notion of a second hit, injection of adenovirus-derived vascular endothelial growth factor (VEGF) in the brain of $Eng^{+/-}$ or $Alk1^{+/-}$ mice led to capillary dysplasia, but had no effect in control mice.[64,65] Furthermore, increasing cerebral blood flow using vasodilators had a synergistic effect on the VEGF stimulus, further promoting capillary dysplasia in genetically predisposed mice.[65]

Role of ALK1 and Endoglin in Mediating TGF-β Superfamily Signaling: Implications for HHT

There are numerous ligands of the TGF-β superfamily. In terms of HHT, the most relevant ligands are TGF-β1, TGF-β3, and BMP9. Therefore, our discussion is restricted to these growth factors and their receptors in endothelial cells. In most cell types, TGF-β mediates its effects through plasma membrane serine threonine kinase receptors type I (ALK5) and type II (TβRII) and the downstream canonical Smad pathway (FIGURE 70.3). TGF-β binds to the constitutively active TβRII, which phosphorylates ALK5 and leads to activation of Smad2 or Smad3. These so-called receptor Smads then recruit the common Smad4 and shuffle to the nucleus where they act as transcription factors to regulate expression of multiple genes. TGF-β generally inhibits endothelial cell proliferation and migration and regulates extracellular matrix synthesis, thereby maintaining quiescence and integrity of the vascular endothelium, via the ALK5 pathway.[66] Endothelial cells also express another TGF-β type I receptor, ALK1, which acts through a different set of receptor Smads, namely, Smads 1 and 5. These activated Smads also associate with the common Smad4 and shuffle to the nucleus where they regulate a different set of genes (FIGURE 70.3).

ALK1

The role of ALK1 in TGF-β superfamily signaling is still somewhat controversial. When first discovered, it was proposed as a receptor for TGF-β1.[67,68] ALK1 has been implicated in endothelial cell proliferation and migration and secondary formation of new blood vessels. In addition to angiogenesis, ALK1 also promotes vessel maturation via recruitment of pericytes and smooth muscle cells.[56,57,69] Two recent papers suggest that ALK1 stabilizes new blood vessels in human xenograft tumors implanted in mice and that targeting ALK1 reduces tumor growth and potentiates other antiangiogenic therapies.[70,71] Therefore, ALK1 and ALK5 have opposite effects on angiogenesis, and to attribute them to TGF-β1 responses, one has to argue that they are mediated by a different Smad pathway or that ALK1 directly inhibits the ALK5 pathway[66] (FIGURE 70.3). It was also reported that ALK5 is required for efficient TGF-β signaling via ALK1 and that the ratio of these two receptors on endothelial cells may determine whether TGF-β maintains quiescence or stimulates angiogenesis.[72] However, comparing the phenotypes of mice in which ALK1, ALK5, or TβR2 genes were conditionally deleted in the vascular endothelium revealed that only ALK1 deletion led to the formation of AVM-like structures.[73] These data suggest that ALK5 and TβR2 are not required for ALK1 signaling pertinent to the pathogenesis of HHT and that TGF-β signaling may be less relevant for this disease than previously thought.[73]

The observation that deficiency of TβR2 does not phenocopy that of ALK1 suggests that a non-TGF-β-ligand signals through ALK1 and/or that ALK1 interacts with another co-receptor. Indeed, recent studies have identified circulating BMP9 as a true physiologic ligand for ALK1,[74,75] raising the possibility that ALK1 haploinsufficiency as observed in HHT2, may be associated with defective BMP9 signaling. ALK1 binds BMP9 with high affinity, in the context of the BMP type II receptor (BMPRII) or activin type IIA receptor (ActRIIA), and triggers Smad1 and

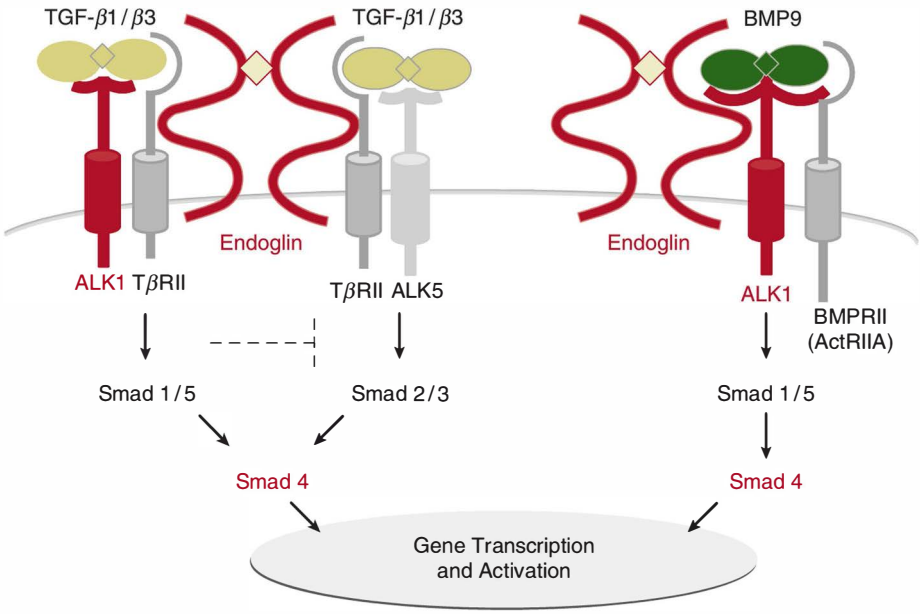

FIGURE 70.3 Role of ALK1 and endoglin in signaling for TGF-β and BMP9. In endothelial cells, TGF-β binds to TβRII, which then phosphorylates either ALK5 (the main type I receptor for this ligand) or ALK1 leading to Smad2,3 and Smad1,5 phosphorylation, respectively. These receptor Smads then interact with the common Smad4 and shuffle to the nucleus where they regulate gene transcription leading to multiple cellular responses. The ALK1 pathway is thought to inhibit the ALK5 pathway. Endoglin binds TGF-β1 and TGF-β3 isoforms in association with TβRII, thereby modulating responses. BMP9 binds ALK1 with high affinity, and its receptor complex includes either BMPRII or ActRIIA. Endoglin likely interacts more strongly with BMP9; it also binds ALK1. The BMP9 pathway is probably the pathway most affected in HHT.

Smad5 phosphorylation and transcriptional activation of several downstream genes[74–76] (FIGURE 70.3).

Endoglin

Endoglin (also referred to as CD105) is an integral transmembrane glycoprotein that was first identified in childhood ALL.[77] It was subsequently shown to be expressed in endothelial cells,[78,79] where it serves as an auxiliary receptor, or coreceptor, for TGF-β1 and TGF-β3,[80] as well as other members of the TGF-β superfamily.[81] It does not bind these growth factors on its own but via interaction with the ligand-binding receptor, and modulates multiple cellular responses. It interacts with TβRII, the receptor for TGF-β1 and TGF-β3, thereby affecting ALK5 signaling and Smad2,3 downstream pathways (FIGURE 70.3). It also forms complexes with ALK1 and promotes its signaling via the Smad1,5 pathways.[82,83]

Interestingly, when endoglin is transiently overexpressed, it can bind BMP9 in the absence of ALK1 and potentiate BMP9 responses.[75,76] Endoglin associates with ALK1 and BMP9 and mediates signaling in the presence of a type II receptor (either BMPRII or ActRIIA) (FIGURE 70.3). The observation that ALK1 and endoglin both interact with BMP9 with an apparent affinity higher than for TGF-β implicates a defective BMP9 pathway in HHT.

Endoglin has been studied more extensively in the context of its modulation of TGF-β-dependent cellular responses, as recently reviewed.[84] It generally opposes the TGF-β-induced inhibition of cell proliferation and adhesion, and the increased expression of extracellular matrix proteins. As recently reviewed,[85,86] endoglin plays an important role in angiogenesis, vascular development, and repair, and is implicated in several disorders, including HHT and preeclampsia. Endoglin is generally more abundant in proliferating endothelial cells and used as a functional marker of angiogenesis in human tumors, its level on the microvascular endothelium often correlating with a poor prognosis.[87]

A role for endoglin in the regulation of vascular tone has been identified.[88,89] Endoglin is localized to caveolae, where it binds endothelial nitric oxide (NO) synthase (eNOS). It acts as a scaffold protein, bringing the chaperone Hsp90 in close proximity with eNOS (FIGURE 70.4).[89] More recently, we have shown that ALK1 also interacts with eNOS.[90] TGF-β can increase eNOS expression[91,92] and stimulate dephosphorylation of eNOS at a specific site important for enzyme activation, leading to increased NO production.[90,93] We observed that in endoglin-deficient endothelial cells, the eNOS activation complex is impaired, producing superoxide instead of NO, due to an uncoupled state of the enzyme (FIGURE 70.4).[89,90] An eNOS-dependent rise in superoxide is also observed in the lungs of adult *Eng*$^{+/-}$ and *Alk1*$^{+/-}$ mice but not in 3-week-old mice.[90,94,95] *Eng*$^{+/-}$ mice also display an eNOS-dependent impairment in the myogenic response of resistance arteries.[89] Interestingly, treatment of *Eng*$^{+/-}$ and *Alk1*$^{+/-}$ mice with the antioxidant Tempol from the age of 3 weeks prevents the abnormal remodeling of the lung vasculature observed in the adult heterozygous mice.[90,95]

Thus, it appears that a major role of endoglin and ALK1 is to bring together TGF-β superfamily complexes and eNOS activation complex. Failure to do so leads to impaired vascular tone perhaps in response to an increase in blood flow, or an angiogenic stimulus, causing abnormally dilated capillaries, and eventually AVMs.

TREATMENT OF HHT

In HHT, management practice is guided by International Guidelines based on systematic assessments of HHT publications up to October 2006.[15] Thirty-three recommendations were

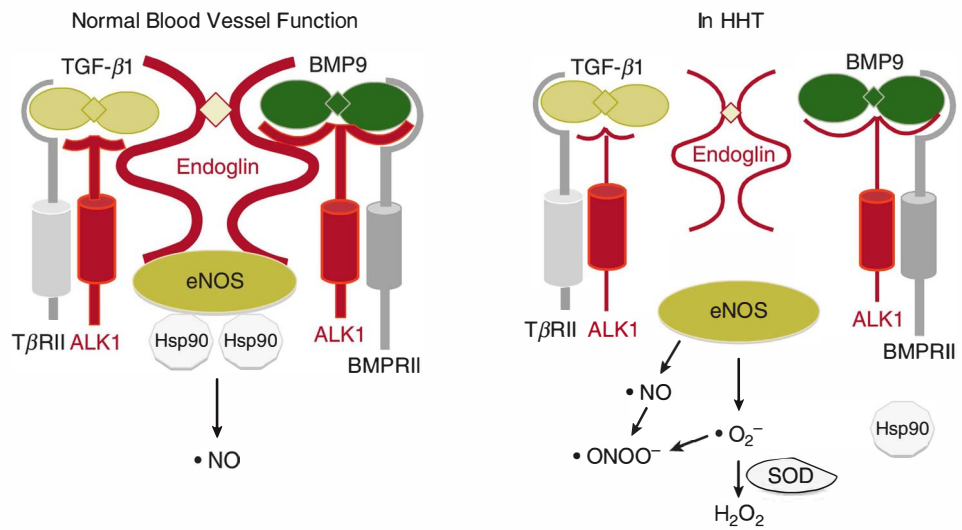

FIGURE 70.4 Model of the interaction of TGF-β and BPM9 receptor complexes with the eNOS activation complex in endothelial cells under normal conditions and in HHT. Endoglin and ALK1 can both associate with eNOS, in the caveolae of the endothelial cell and stabilize the enzyme during its activation.[89,90] In doing so, they can bring the TGF-β1 or BMP9 receptor complexes to eNOS and regulate NO production. Under normal circumstances, eNOS produces NO, which stimulates vasodilation. In HHT1 and HHT2, less endoglin and ALK1 (shown by *thinner molecules*) destabilize the eNOS complex, which generates reactive oxygen species that lead to vessel damage.

made based on a review process involving multiple experts.[15] The 2007 to 2010 data manuscripts and their recommendations are discussed in recent review articles,[96,97] but formal guidelines incorporating the post-2006 evidence base are not yet available.

Hemorrhage

The abnormal HHT vessels in HHT are prone to bleeding because of their inadequate blood vessel wall structures and high perfusion pressures.[2,98] At least one-third of HHT patients have iron deficiency anemia, with the proportion of patients on iron treatments increasing with age.[2]

Nosebleeds

Nosebleeds are a more common cause of blood loss in HHT than GI bleeding, but may not be readily stated by the patient as a clinical problem. Recommended strategies for acute management of nosebleeds include simple first aid and packing.[15] For recurrent nosebleeds, nasal humidification regimens and topical lubricants are recommended first line.[15] Dedicated expert ENT evaluation is recommended for second-line treatment (laser therapy), and third-line treatments such as septal dermatoplasty or Young's procedure.[15] The invasiveness of treatment should be proportionate to the severity of nosebleeds, with transfusion dependence suggested as a cutoff to indicate patients for whom third-line therapies may be appropriate.[99] A validated epistaxis severity score has been developed and found to be a significant predictor of invasiveness of therapy for nosebleeds.[100] Trials of topical and systemic treatments are currently recruiting (http://clinicaltrials.gov)

Gastrointestinal Bleeding

GI investigations are recommended if anemia is out of proportion to nosebleeds severity.[15] Numerous GI telangiectasias are identified in HHT patients, and evidence of bleeding (visible bleeding or associated thrombus) may help guide decisions regarding ablation treatments to specific lesions. HHT patients require more endoscopic treatments than non-HHT patients,[101,102] but the recent guidelines, recognizing procedural risks and limitations, cautioned against multiple procedures.[15]

Other Factors Contributing to Iron Deficiency Anemia

When evaluating patients with iron deficiency anemia, it is also important to consider non-HHT causes of blood losses such as menstruation and coincident (rare) coagulation disorders, as well as iron dietary intake. Patients should seek to meet more than the recommended daily allowance of dietary iron, in addition to using iron replacement strategies, transfusions if required, and specific HHT treatments outlined above. There are settings in which anticoagulants (and/or antiplatelet agents) are required in HHT [8b,15] in order to prevent major ischemic or thromboembolic sequelae. Prophylactic dose anticoagulation, for example, is required during high-risk periods for VTE, particularly for HHT patients hospitalized with PAVM-induced brain abscess.[5] Where a VTE occurs, treatment dose warfarin and heparin can be given, and in our experience, anticoagulation is tolerated surprisingly well by many patients.[2]

Arteriovenous Malformations

Ablative treatments for AVMs are beyond the scope of this chapter, but are mentioned briefly for completeness. PAVMs of any size amenable to embolization should be considered for this procedure,[15] as PAVMs below the former cutoff size of 3 mm have been associated with brain abscess and stroke.[16] The Amplatzer devices are now most commonly employed as they have more favorable profiles than the embolization coils and balloons utilized in earlier series.[103,104] Antibiotic prophylaxis is still recommended despite changes in recommendations for cardiac patients at risk of endocarditis.[105] Avoidance of intravenous air and scuba diving has also been recommended.[15] Cerebral AVM management involves complex decision making in selecting the most appropriate strategy for each patient, ranging from no therapy, through embolization,[21] microsurgery,[106] and stereotactic radiotherapy.[107] Multimodality treatments are often utilized.[108]

Hepatic AVMs that are asymptomatic are not treated, but due to the risk of catastrophic hemorrhage from hepatic AVM puncture, liver biopsies should be avoided in people with suspected or proven HHT.[15,109] For hepatic AVM patients who become symptomatic and fail to respond to intensive medical treatments, liver transplantation is the treatment of choice, with no role for hepatic artery embolization unless supported by a transplant program.[15] Excellent 10-year results are reported by the European liver transplant registry.[110]

General HHT Vascular Targeting Strategies

Hormonal Therapies

To date, the only randomized control trial (RCT) to prove efficacy in treatment of HHT bleeding relates to use of hormonal manipulations. The first RCT reported the use of high-dose estrogen–progesterone,[111] but it is poorly tolerated particularly in men, and there are concerns about thrombotic side effects. More recently, a double-blind, placebo-controlled trial of the antiestrogen tamoxifen[112] demonstrated a significant reduction in the frequency of epistaxis in the treated group, accompanied in many cases by either a rise in hemoglobin or reduction in transfusion requirements. The selective estrogen receptor modulator raloxifene[113] introduced to reduce the risks of tamoxifen side effects, particularly uterine hyperplasia, has recently been approved as an orphan drug for HHT. The mechanisms by which hormonal therapies act are incompletely understood. They are likely to include prothrombogenic effects (noting that pathologic thromboemboli are a recognized side effect of all such agents[114]) but there may also be direct modulation of endothelial cell and vascular function.[113]

Antifibrinolytics and Prothrombotic Agents

Therapeutic manipulation of coagulation and fibrinolytic pathways[115–118] has not yet been supported by data from RCTs. Recognition that venous thromboses occur in HHT, associated in many cases with coincidental inheritance of prothrombotic genetic variants such as FV Leiden, has raised concern regarding thrombophilic risk with these agents.[5] Routine measurement of FVIII, FV Leiden, and other thrombophilic markers in HHT patient assessments may assist individualized risk–benefit considerations before prothrombogenic systemic treatments are given.[5,96]

Antioxidants

There are recent uncontrolled short-term data demonstrating efficacy from oral *N*-acetylcysteine in a modest series of 43 HHT patients.[119] This specific drug is not currently licensed in many

countries but in general, antioxidants have favorable side effect profiles during long-term use.

Thalidomide

Thalidomide was considered in HHT following a chance observation in a patient undergoing treatment for cancer.[120] While efficacy in the clinical setting has not been substantiated (case reports[121] and small series,[122] have been published, but no RCTs), recent data highlight the potential for this type of drug to rescue the murine HHT phenotype.[122] Thalidomide appears to target mural cell recruitment to angiogenic sprouts, by increasing expression of platelet-derived growth factor (PDGF)-B at the endothelial tip cell, facilitating recruitment of pericytes that express PDGF receptor, increasing pericyte proliferation, and normalizing excessive sprouting in mice with HHT.[122]

Bevacizumab

Bevacizumab a recombinant full-length humanized antibody active against all isoforms of VEGF-A was also considered for HHT patients based on a chance observation in a patient with HHT undergoing treatment for malignancy.[123] A widely cited brief report of a patient whose hepatic AVMs initially responded[124a] has led to an encouraging trial reporting benefit in France in the setting of end-stage hepatic AVMs,[124b] though caution regarding side effects have been expressed,[125] and the results of RCTs are awaited. Topical approaches are being used to reduce the serious side effects associated with systemic treatments.

CONCLUSIONS

HHT is a vascular disorder affecting many organs, caused mostly by mutations in *ENG* and *ACVRL1* genes, coding for receptors of the TGF-β superfamily, and predisposing HHT patients to telangiectasia and AVMs and their associated clinical manifestations. A second hit in the form of an angiogenic stimulus such as VEGF, an increase in blood flow, or wounding is likely necessary to precipitate the vascular lesions. Although TGF-β plays an important role in regulating vascular proliferation, migration, and remodeling, we believe that BMP9, the physiologic ligand for ALK1, which also interacts with endoglin, is more relevant to HHT. Future studies will no doubt focus on this ligand and its role in endothelial function and vascular disorders. An emerging role of ALK1 and endoglin is their interaction with the eNOS activation complex, which implies that specific ligands of the TGF-β superfamily regulate NO production and vascular tone and that oxidative stress contributes to HHT.

The primary role of a hematologist reviewing a patient with known or suspected HHT is usually optimizing management of iron deficiency anemia, particularly for patients who are transfusion dependent, and/or under consideration for anticoagulant and antiplatelet therapies. Recognition of the crucial roles of ENT surgeons and gastroenterologists needs to be supplemented with knowledge of the emerging disease-modifying pharmaceutical agents. Clinical diagnostic and management pathways extend far beyond this particular specialty. Screening patients and their family members for other aspects of HHT may appear feasible, since the required investigative modalities are available in most institutions. The challenges arise, however, not with the ordering of these tests, but with the ability to provide informed pre- and post-test counseling in a field where evidence is still emerging. It is for this reason that referral to dedicated HHT centers is recommended.

Nevertheless, a striking observation for this disorder that so commonly presents with a chronic hemorrhagic state is that by 2012, only one of the 35 HHT Centers of Excellence was run by a hematologist. Since hematologic expertise is so critical for the long-term management of these complex patients and families, it is hoped that the specialty's interest in the wider aspects of HHT will increase.

CHAPTER

71

Arteriovenous Malformations and Hemangiomas and Cerebral Cavernous Malformations

KEVIN J. WHITEHEAD, DOUGLAS A. MARCHUK, AND MARK L. KAHN

The cardiovascular system is organized into a hierarchical, branching arrangement by which blood is distributed to, and collected from, organs through arteries, arterioles, capillaries, venules, and veins.[1] This arrangement is not merely an elegant example of biologic patterning; it is also essential for physiologic control of blood flow throughout the body. Loss of the normal vascular architecture may result in localized or generalized vascular malformations in humans.[2] Vascular malformations are descriptively categorized on the basis of the type of vessel that appears to be involved, for example, arterial, venous, or capillary. Most common vascular malformations, for example, arteriovenous malformations (AVMs) in which vascular connections link arteries and veins without an intervening capillary bed, arise spontaneously in affected individuals, but others arise in a heritable pattern that indicates contribution by germline mutations (e.g., cerebral cavernous malformation [CCM] and hereditary hemorrhagic telangiectasia [HHT], discussed further below).

Although many vascular malformations are not symptomatic, vascular malformations constitute an important component of pediatric and adult vascular disease. These vascular structures are fragile and frequently cause clinical disease due to hemorrhage in vulnerable sites such as the central nervous system (CNS) or the gastrointestinal (GI) tract. AVMs also come to clinical attention due to the cardiovascular effects of blood shunting such as high-output congestive heart failure. Since vascular malformations frequently arise in the skin, they are also an important component of dermatologic disease. The treatment of vascular malformations has improved in the past two decades but remains restricted to surgical and interventional vascular approaches to either remove them or block blood flow through them.

The lack of molecular pharmacologic therapies for vascular malformations reflects the fact that until very recently the pathogenesis of such lesions was virtually unknown. However, in the past decade, genetic studies of inherited human vascular diseases have intersected with developmental studies using model vertebrate organisms such as fish and mice to provide new molecular insights into the molecular and genetic basis for vascular malformations. These studies have revealed that many human vascular malformations arise because of loss of regulatory signaling pathways that participate in the development of the blood and lymphatic vascular systems. They have also produced useful animal models of human vascular malformations. Thus, there is hope that the new knowledge and biologic tools will enable the development of pharmacologic approaches to treat human vascular malformations. This chapter focuses on two common inherited vascular malformations, CCM and HHT (FIGURE 71.1).

CEREBRAL CAVERNOUS MALFORMATIONS

Clinical Presentation and Treatment

CCMs are thin-walled, dilated vascular malformations that present primarily in the CNS in early to mid adulthood.[3,4] The prevalence of CCM in the general population is relatively high, 0.1% to 0.5%, making this malformation a relatively common condition. While the clinical symptoms associated with CCMs vary with the size and location of the malformation, seizures, headache, and stroke with associated neurologic deficits are the most common. CCMs are diagnosed by MRI, and more sophisticated imaging technologies have revealed that a majority of these lesions are clinically silent. Although the number of longitudinal studies is limited, existing studies indicate that in the case of familial CCM, both the number and size of CCMs increase over time.[5] Presently, the treatment of CCMs is neurosurgical resection of symptomatic lesions. Histologic analysis of resected CCMs reveals vascular lesions with a thin endothelial lining that by transmission electron microscopy lack the typical number and quality of tight junctions between endothelial cells,[6] an ultrastructural feature that has been valuable for comparison to animal models.

Genetics of CCM

Approximately one third of CCMs arise in patients with a family history of this disease.[4] Familial CCMs are transmitted in an autosomal dominant pattern and are both more numerous and symptomatic than nonfamilial CCMs. Positional cloning studies have identified germline heterozygous loss-of-function mutations in three genes: KRIT1 (aka CCM1),[7–9] CCM2,[10,11] and PDCD10 (aka CCM3)[12] that encode intracellular adaptor proteins without enzymatic activity. The fact that CCMs arise in older individuals who are heterozygous for a loss of function allele has led to the hypothesis that these lesions are created by a "second hit" that confers a complete loss of function in the causal cell type. Surgically resected lesions from individuals harboring germline CCM mutations have revealed second site mutations in the remaining wild-type copy of the relevant CCM gene, lending support to the two-hit mutation mechanism for CCM pathogenesis.[13–15] Recent studies of mouse models also

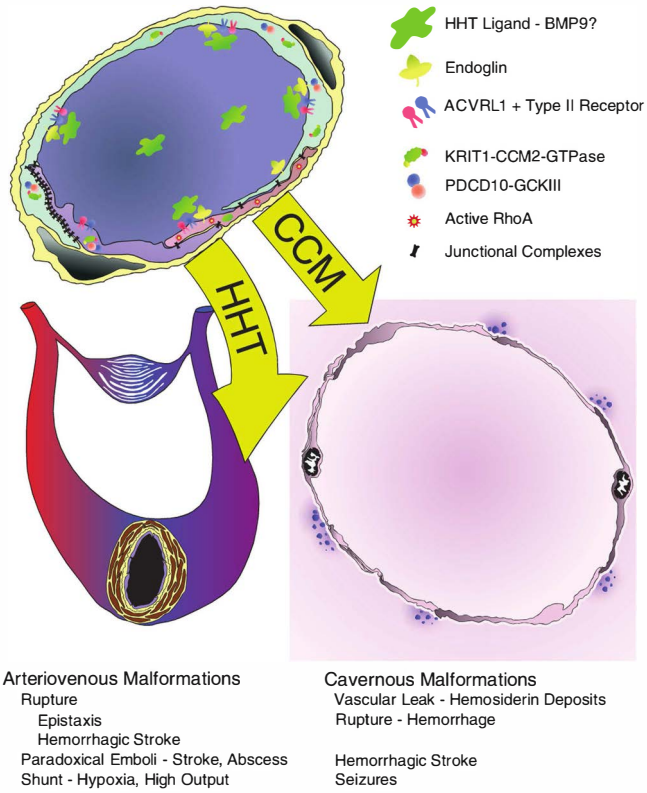

FIGURE 71.1 Pathogenesis of HHT and CCM vascular malformations. The endothelial cell signaling pathways that are affected in the pathogenesis of HHT and CCM are shown above. The resulting vascular malformations and their clinical manifestations are shown below.

support the two-hit mechanism and implicate the endothelial cell as the causal cell type.

Biology of the CCM Signaling Pathway

Genetic studies of mice and zebrafish have revealed that the CCM proteins function in a novel signaling pathway that is required for vertebrate cardiovascular development.[16,17–20,21–25,26] Despite the vascular phenotypes exhibited by deficient animals and humans, expression studies in mice have revealed that CCM1, CCM2, and CCM3 are broadly expressed genes and are particularly highly expressed in the CNS, a finding that has led to the hypothesis that this pathway regulates vascular function indirectly through signaling in neural cell types. Mice constitutively deficient in the CCM proteins die soon after the heart and vessels are formed due to defects in the formation of early vascular structures such as the branchial arch arteries that connect the heart to the aorta in the early embryo, so that these animals do not have circulating blood. Deficient zebrafish embryos exhibit similar branchial arch arterial defects, as well as a "dilated heart" phenotype conferred by deficiency of the type I transmembrane protein heart of glass (HEG).[23] Finally, biochemical studies have established that HEG, CCM1, CCM2, and CCM3 form a molecular signaling complex in which the HEG cytoplasmic tail binds CCM1, the CCM2 phosphotyrosine binding domain binds CCM1, and CCM3 binds CCM2 through an as yet unidentified mechanism.[23,27–29]

Electron microscopy of human CCMs, as well as studies in cultured endothelial cells and deficient mice and zebrafish suggest that one important endpoint of CCM signaling is positive regulation of endothelial cell–cell junctions.[6,21,23,25,30,31] However, precisely how CCM signaling regulates endothelial junctions is not completely understood. Two effectors of CCM signaling are RAP1 and RHO, proteins known to regulate cell junctions. RAP1 binds to the CCM1 FERM (4.1 protein, Ezrin, Radixin, and Moesin) domain and it has been proposed that CCM signaling is linked to RAP1 activity and localization in endothelial cells.[30,32] Several groups have demonstrated that loss of CCM proteins results in elevated levels of RHO-GTP and loosening of cellular junctions in cultured endothelial cells.[21,25,31,33,34] Thus, negative regulation of RHO may be a mechanism by which the CCM pathway regulates cell junctions. Biochemical studies and genetic studies in zebrafish have identified the GCK-III family of serine/threonine kinases as potential CCM3 binding and signaling partners *in vivo* that may regulate RHO and endothelial cell junctions.[19,25] In addition to regulating cell junctions, the CCM pathway may also maintain endothelial cell polarity and the formation of endothelial tubes.[35] Thus, the available evidence strongly supports a role for CCM signaling in positively regulating endothelial cell junctions and hint at other roles that may be connected to vessel formation and function.

CCM Pathogenesis: Insights from Animal Models

Sequence conservation and observations that zebrafish and mice lacking CCM proteins exhibit similar vascular phenotypes have suggested that the function of this pathway might be sufficiently conserved to permit in-depth investigation of human disease using genetically modified animals. Indeed, genetic studies using animal models have played a pivotal role in elucidating both the function of the CCM signaling proteins *in vivo* and the pathogenesis of human CCMs. Analysis of deficient zebrafish and mice have revealed that CCM signaling is required in vertebrates for early cardiovascular development,[16,17,23,25] a result that suggested a direct role in cardiovascular cell types such as endothelial cells. However, none of the CCM disease genes are highly or specifically expressed in cardiovascular cell types. Therefore, an early question was whether CCM proteins are required in vascular cell types such as endothelial cells or pericytes, or whether vascular CCMs arise due to loss of CCM signaling in adjacent tissues such as neural cells. Recent studies of mice in which CCM2 and CCM3 were conditionally deleted in neural, endothelial, and smooth muscle cells revealed that the defects in cardiovascular development observed in globally deficient animals arose because endothelial cells require these proteins.[21,24] These studies, as well as genetic studies of endothelial cells isolated from human CCMs, strongly suggest that human CCMs arise due to loss of this pathway in endothelial cells. The recent generation of mice carrying conditional CCM alleles has allowed this hypothesis to be directly tested using transgenic animals in which Cre recombinase can be inducibly expressed in endothelial cells and other cell types. However, results of these studies are controversial. It has recently been reported that deletion of CCM2 in endothelial cells after birth does indeed result in the formation of CCMs in the brain and retina,[22] providing strong evidence that human CCMs arise from loss of CCM function in endothelial

cells. However, deletion of CCM3 in neuroglia has also been reported to result in the formation of CCM in mice.[36] At this time, the weight of evidence favors an endothelial cell mechanism, but further studies addressing the cell specificity of CCM protein deletion in these studies will be required to definitively answer this question.

CCM Disease Mechanism: Future Directions and Unanswered Questions

Although research over the past decade has provided important insights into the genetic and molecular basis of human CCMs, it now seems likely that CCMs arise from loss of a previously unrecognized endothelial signaling pathway (SEE FIGURE 71.1). Nonetheless, numerous questions regarding the pathway and disease pathogenesis remain to be addressed. Loss of function phenotypes in mice and men reveals a remarkable conservation of function for CCM signaling, but why vascular malformations arise specifically in the CNS after deletion of endothelial CCM2 in all tissues in animal models and after stochastic endothelial loss of CCM proteins in humans is not clear. It seems likely that the CNS environment is one in which CCM signaling must be maintained at a higher level relative to other vascular beds. This could be related to maintenance of the blood–brain barrier and a role for CCM signaling in regulating endothelial cell junctions, but experiments to address this hypothesis have not yet been performed.

A clearer understanding of the molecular components of the CCM signaling pathway is also needed. Genetic and biochemical studies place the HEG receptor in the same pathway as CCM1, CCM2, and CCM3,[23] but HEG mutations have not been identified as a cause of human CCM. The identity of the HEG ligand will provide a major clue to the regulation of this pathway and its biologic function. Similarly, the nature of the downstream CCM signals required to prevent vascular malformations remain to be defined. Recent studies implicate the GCK-III family of serine/threonine kinases as downstream effectors of CCM signaling,[25] but their role in disease pathogenesis, like that of HEG, remains untested. Studies also implicate RAP1[30,32] and MEKK3[37,38] as CCM signaling effectors, but the role of these proteins in disease pathogenesis is not yet clear.

A major goal of future studies will be to use recently generated mouse models to better define the role of molecular CCM pathway components in disease pathogenesis, and to test potential therapeutic strategies. Potential therapeutic agents such as statins and fasudil that alter the levels of RHO-GTP can now be tested in animal models of CCM disease.[31] Moving from basic mechanisms of disease to the development of novel human therapies with these animal models will be very exciting and hopefully establish an important new paradigm for understanding and treating vascular diseases.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Clinical Presentation and Treatment

HHT is a syndrome characterized by hemorrhage-prone vascular AVMs that was recognized by the French physician, Henri Rendu,[39] as distinct from hemophilia in 1896. Sir William Osler and Frederick Parkes Weber then defined the clinical syndrome in the early 1900s,[40,41] accounting for the eponym, Osler-Weber-Rendu disease. The hallmark of HHT is telangiectasias representing abnormal connections between arterioles and venules that bypass intervening capillary beds and appear as small erythematous macules that blanch upon pressure as flow in the dilated channel is transiently occluded. Larger arteriovenous connections also occur with important clinical consequences. A diagnosis of HHT can be made on clinical grounds by the presence of at least three of the "Curaçao criteria": (a) a history of HHT in a first degree relative, (b) recurrent spontaneous epistaxis, (c) skin telangiectasias in typical locations, or (d) AVMs in viscera.[42] Using these criteria, HHT prevalence has been estimated at 1 in 5 to 10,000, with considerable geographic variation.[43] Unlike patients with CCM, the majority of patients with HHT are symptomatic. Spontaneous epistaxis results from telangiectasias of the nasal mucosa and is nearly universal, affecting over 90% of patients by age 30.[44,45] Telangiectasias of the fingers, lips, and oral mucosa are also extremely common (over 90% by age 30[46]), but rarely result in hemorrhage or symptoms. The consequences of visceral AVMs depend upon the affected vascular bed, with brain, lung, liver, and the GI tract as the most common clinically important sites. Brain AVMs are high-flow vascular lesions that are prone to rupture, resulting in hemorrhagic stroke and are found in approximately 10% of patients.[45,47] Lung AVMs are found in approximately 50% of patients[45,47] and result in shunting of deoxygenated blood directly into the systemic circulation, causing systemic hypoxemia and dyspnea as well as stroke due to paradoxical emboli. Like shunting in cyanotic congenital heart disease, there is a risk of systemic infections such as cerebral abscess as a result of bypassing the filtering effects of the pulmonary microvasculature. Hepatic AVMs are often clinically silent, but occasionally cause symptoms by significantly increasing the demand for cardiac output, resulting in high-output cardiac failure.[48] AVMs rarely occur in other vascular beds (GI tract, spinal cord) and screening is not generally performed unless the patient is symptomatic. A small number of patients with classic findings for HHT have an overlap syndrome with features of juvenile polyposis and a high risk for gastrointestinal malignancies.[49]

Genetics of HHT

The majority of patients with a clinical diagnosis of HHT have loss of function mutations in either the transforming growth factor-β (TGF-β) binding protein Endoglin,[50] or the type I TGF-β receptor activin receptor-like kinase-1 (ACVRL1 or ALK1,[51]). Patients with HHT and juvenile polyposis, as well as some patients with clinical features of only HHT, have mutations in the downstream TGF-β effector SMAD4 (also known as MADH4[49,52]). Two other loci on chromosome 5 and chromosome 7 are linked to HHT as well.[53,54] Disease is observed with high penetrance in patients heterozygous for a culprit mutation.

Biology of the HHT Signaling Pathway

The three known HHT genes all relate to the TGF-β superfamily of signaling proteins. This signaling pathway consists of families of ligands including TGF-β, activins, and bone morphogenetic proteins (BMPs). Ligand binding to a heteromeric

complex of type I and type II receptors leads to phosphorylation of type I receptors by the constitutively active type II receptors, recruitment and phosphorylation of the receptor-regulated SMAD proteins (R-SMAD), and downstream signaling. The type I receptor ACVRL1 phosphorylates R-SMADs −1, −5, and −8 that associate with SMAD4 and translocate to the nucleus to regulate transcription of target genes.[55] The downstream signal is potentiated by the activity of coreceptors such as Endoglin or betaglycan,[56] sometimes referred to as type III receptors. Recent work has suggested that BMP9 is a likely ligand for ACVRL1 present in physiologically relevant levels in human serum.[57,58]

HHT Pathogenesis: Insights from Animal Models

Animal studies demonstrate that *Endoglin, ACVRL1*, and *SMAD4* are all required for embryonic development.[59–64] Mice lacking *Endoglin* or *Acvrl1* die in midgestation at comparable time points and with similar defects. Both genes are required for establishing correct arteriovenous identity of the developing endothelial network in embryos.[60,65] The loss of either gene results in AVMs that profoundly disrupt circulation and perfusion. Studies of a zebrafish mutant for *acvrl1* confirm a role in preventing AVM formation, and suggest that AVMs develop from persistence of normally transient arteriovenous connections that form during angiogenesis.[66] An even earlier role for *SMAD4* in development is apparent from studies of gene-targeted mice that die very early in gestation and prior to the process of gastrulation.[64] Heterozygous mice that are the genetic equivalent of human HHT develop subtle features of HHT at a low frequency.[61,67] Careful study of these animals demonstrates that both genetic and environmental factors impact AVM formation. In mice lacking *Endoglin*, vascular malformations and hemorrhage can be observed, but are dependent upon the background strain.[68]

Mice with conditional alleles for *Endoglin* and *Acvrl1* allow for the inducible complete (homozygous) inactivation of the targeted gene after critical developmental angiogenesis has occurred. AVMs, hemorrhage, and death result from the complete loss of *Acvrl1* induced in adulthood.[69] AVMs also form in mature mice with complete loss of Endoglin in the endothelium.[70] The retinal AVMs that develop in this model differ from embryonic AVMs by expressing primarily venous markers in the smooth muscle-surrounded, enlarged vessels.[70]

As with familial CCM, the inherited mutant allele is present in all cells and all vascular beds, yet in both conditions the disease affects a characteristic subset of tissues. However, unlike CCM, protein expression is not absent in the endothelial cells of the HHT vascular lesions and loss of heterozygosity is not thought to be necessary for the creation of AVMs.[71] Telangiectasias are rarely present at birth, but develop with age. Most are found on the fingertips, lips, tongue, and sun-exposed skin of the face (such as the ears) in addition to the nasal mucosa. On the hands, the frequency of lesions tends to be higher on the dominant side. This characteristic distribution of telangiectasias suggests that trauma and subsequent vascular growth and repair is an important disease modifier, a hypothesis that is supported by studies in animal models.[69] Angiogenesis associated with inflammation may be a related physiologic stimulus of vascular malformation.[70]

HHT Disease Mechanism: Future Directions and Unanswered Questions

Angiogenesis is thought to underlie AVM development in patients with HHT. Increased levels of vascular endothelial growth factor (VEGF) have been observed in patient serum[72,73] and anecdotal reports of temporary improvement in epistaxis from patients who received bevacizumab, a monoclonal antibody directed against VEGF, have increased interest in antiangiogenic therapies for HHT.[74] Numerous case reports provide further anecdotal support for such antiangiogenic therapy,[75–80] and argue for a more systematic approach to testing such treatment using properly designed clinical trials. As with CCM, the availability of animal models of HHT is expected to facilitate preclinical studies of potential therapeutic agents. A preliminary series of studies have recently suggested that thalidomide might also carry promise in HHT as an antiangiogenic therapy.[81]

Despite its wide biologic use, the TGF-β family and its downstream signaling effectors may also prove to be tractable targets for HHT therapy. In addition, a number of genes and pathways downstream of this signaling pathway have been implicated in HHT animal and cellular models.[82,83] Whether such downstream pathways are central to disease pathogenesis or are merely epiphenomena, remains to be investigated using animal models. Although we assume that a common signaling pathway is disrupted in HHT (SEE FIGURE 71.1), there are important genotype–phenotype differences between these patients with different mutations, pointing to subtle but clinically relevant differences in the quantity or quality of downstream signaling alterations. While the association of juvenile polyposis and premature GI malignancy with SMAD4 mutations is an obvious example, the tissue distribution of AVMs differs significantly between Endoglin (more likely to have pulmonary AVM) and ACVRL1 (more likely to have liver AVM) families.[47] Targeted therapies that account for gene-specific unique mechanisms are an important clinical goal that is tied to a better understanding of the genetic and molecular basis of vascular malformations.

CHAPTER

72 Aneurysms (Large and Small Arteries)

CARLOS E. SANCHEZ, SANGITA KAPUR, AND NEAL L. WEINTRAUB

Aneurysms of the aorta and its branch vessels are a major health care concern; more than 15,000 patients die each year in the United States from aortic aneurysms, and the incidence and prevalence continue to rise.[1] Unfortunately, most aneurysms are asymptomatic, and their presentation is often acute with catastrophic complications.[2]

As the largest blood vessel of the body, the aorta serves as a conduit to deliver oxygenated blood from the left ventricle to the systemic circulation and all organs and tissues. The normal human adult aortic wall is composed of three layers. The intima is the innermost layer and consists of the endothelium residing on a basement membrane with subendothelial connective tissue; the media is a thick layer composed of layers of elastic fibers arranged concentrically with interposed smooth muscle cells bounded by an internal and external elastic lamina; and the outer layer, the adventitia, is composed of a loose collagen network containing the vasa vasorum and nerves. The aorta is divided into thoracic and abdominal portions defined by the location above or below the diaphragm. The thoracic aorta is subsequently divided into four parts: the aortic root, which consists of the aortic valve annulus, aortic valve cusps, and the sinuses of Valsalva; the ascending aorta, which begins at the sinotubular junction and extends to the brachiocephalic artery; the aortic arch, which begins at the origin of the brachiocephalic artery and gives rise to the neck and head artery branches; and the descending aorta, which begins at the isthmus between the left subclavian artery and the ligamentum arteriosum and ends at the diaphragm. Below the diaphragm, the abdominal aorta continues caudally, giving rise to mesenteric and renal arteries and ending at the bifurcation of the common iliac arteries. The abdominal aorta is divided into suprarenal and infrarenal portions based on the location relative to the takeoff of the renal arteries.

The normal size of the aorta varies by anatomical location, age, gender, body surface area, and imaging modality. On a study based on helical computed tomography (CT) in patients without cardiovascular disease, the mean thoracic aortic diameters were 2.98 cm at the aortic valve sinus, 3.09 cm at the ascending aorta proximal to the innominate artery, and 2.43 cm at the descending thoracic aorta at the level of the diaphragm. In general, the normal abdominal aorta exhibits a diameter of approximately 2 cm.[3] Aneurysms can develop in all portions of the aorta and in smaller arteries. The purpose of this chapter is to summarize the key aspects of aneurysm disease of the aorta and its major branches, focusing on pathogenesis, diagnosis, and management.

ABDOMINAL AORTIC ANEURYSM

Abdominal aortic aneurysm (AAA) is considered to be present when the anteroposterior diameter of the aorta is ≥3.0 cm[4] or when the vessel wall exceeds the normal diameter by 50%.[5] The infrarenal aorta is the most common site of AAA; population-based screening programs have demonstrated an incidence of up to 9% in asymptomatic adults.[6] The incidence and prevalence of AAA is on the rise, and whether this is related to the implementation of ultrasound screening programs, widespread use of CT, an aging population, or a true increase in the disease incidence is unclear. Despite advances in the treatment options for aneurysms, rupture continues to be the most widely recognized and feared complication with an overall mortality rate of up to 90%.[7]

Risk Factors and Pathophysiology

Multiple risk factors have been recognized to be associated with AAA. Smoking is strongly associated with the development of AAA; in particular, the duration of smoking, and not the number of cigarettes smoked per day, has been associated with the increased risk.[8] In addition, males exhibit a prevalence of AAA that is five- to sixfold greater than females.[9] The risk of rupture in women, however, is significantly higher than in men, and aneurysm rupture occurs at smaller aortic diameters in women.[10] The prevalence of AAA increases with age, with the highest rate in patients older than 65 years. Hypertension and having a first-degree relative with AAA have also been associated with increased risk for AAA. Family history of AAA also carries a greater risk of rupture, and aneurysms tend to occur at a younger age.[11]

Atherosclerosis is closely linked to the pathophysiology of AAA. Although AAA frequently occurs in patients with atherosclerosis, and both diseases share many of the same risk factors, they exhibit distinct pathologic features and anatomic predilection. The hallmark pathologic feature of atherosclerosis is foam cell formation, whereas aneurysms are typified by intense matrix degradation, inflammation, oxidative stress, and apoptosis of smooth muscle cells. Additionally, atherosclerotic lesions are predominantly intimal in location, whereas the media and adventitia are primarily involved in AAA. The media and adventitial layers contain large amounts of matrix structural proteins, particularly elastin and collagen, which impart strength to resist aortic expansion and wall tension.[6] Degradation of the extracellular matrix proteins weakens the aortic wall with subsequent remodeling and dilatation. Once the aorta dilates and an

tahir99-VRG & vip.persianss.ir

aneurysm is formed, tension in the aortic wall increases progressively based on Laplace law (tension is proportional to the product of pressure and radius), causing the aneurysm to enter a progressive and sustaining loop of enlargement.

One of the defining features of AAA is inflammation.[11] The inflammatory infiltrate is most prominent in the media and adventitia of the aortic wall and is composed predominately of macrophages and T lymphocytes, although neutrophils, B lymphocytes, NK cells, and mast cells are also present.[12] Activated macrophages are a major source of matrix metalloproteinases (MMPs), a group of structurally related, zinc-dependent endopeptidases that are also synthesized by vascular wall cells, particularly smooth muscle cells. In addition, macrophages secrete serine proteases and cysteine proteases that work in concert with MMPs to degrade structural proteins, thereby playing a key role in aneurysm formation.[13,14] MMPs are secreted as inactive zymogens (pro-MMPs) that require activation extracellularly. Among the numerous classes of proteases that can lead to tissue destruction, MMP-2 and MMP-9 have in particular been implicated in the pathogenesis of AAA. Deletion of either MMP-2 or MMP-9 prevented AAA formation in a mouse model.[15] Also, MMP-9 was reported to be the most abundant protease secreted by human AAA tissue explants *in vitro*.[16] Additionally, MMP-9 transcript levels were found to be higher in aneurysms measuring 5.0 to 6.9 cm compared to aneurysms measuring 3.0 to 4.9 cm.[17] In a study in ruptured AAA, MMP-8 and MMP-9 levels were increased at the aneurysm rupture site compared to the adjacent unruptured wall, suggesting that extracellular matrix breakdown may be the final mechanism causing AAA rupture.[18] Notably, systemic inhibitors of MMPs abrogated AAA in mouse models and are under study in humans with AAA.[13,19,20]

Lymphocytes, particularly $CD4^+$ T-helper cells, have a unique activated memory phenotype and produce proinflammatory cytokines (e.g., interleukin-6, tumor necrosis factor-alpha, interferon-gamma, and osteopontin), leading to further recruitment of immune cells and induction of apoptotic cell death. Apoptosis of smooth muscle cells within the aneurysmal wall is thought to contribute to aneurysm formation and progression, since smooth muscle cells are largely responsible for the production of elastin and collagen. The degradation of aortic extracellular matrix proteins by proteases, together with a reduced capacity to synthesize new matrix proteins due to smooth muscle cell apoptosis, may thus lead to impaired repair of the aortic wall resulting in weakening and dilatation.[21]

Oxidative stress induces MMP activation and smooth muscle cell apoptosis and is increased in the setting of AAA (reviewed in ref. [21]). A study of aortic tissue in patients undergoing surgical repair demonstrated that levels of reactive oxygen species (ROS) are increased locally in AAA tissue as compared with adjacent nonaneurysmal aorta, in part through the activation of NADPH oxidase, leading to marked increases in oxidative stress.[22] A subsequent study in mice demonstrated that deletion of $p47^{phox}$, a cytosolic subunit of NADPH oxidase, reduced aortic oxidative stress, macrophage infiltration, and MMP-2 activity and markedly attenuated AAA formation.[23] ROS also stimulate the secretion of cyclophilin A from vascular smooth muscle cells. Cyclophilin A, a member of the immunophilin family of proteins and a target of the immunosuppressive drug cyclosporine, binds to the highly glycosylated protein CD147 (also known as extracellular MMP inducer) on smooth muscle cells and induces its translocation to the cell surface, where it plays a critical role in stimulating MMP activity and matrix degradation. Absence of cyclophilin A reduced aortic inflammation, oxidative stress, and matrix degradation and prevented AAA formation and rupture in a mouse model.[24] An example of the typical pathologic features of human AAA is shown in FIGURE 72.1.

Mural thrombus is frequently present lining the walls of AAA and can be both prognostically and clinically significant. Although AAA size is the most commonly used determinant to predict the risk of rupture, some studies suggest that the presence of intramural thrombus portends a higher AAA expansion rate and risk of rupture.[25,26] The presence of a mural thrombus in AAA has been associated with a thinner arterial wall, lower density of smooth muscle cells in the media, and heightened inflammation and elastolysis in the aneurysm wall.[27] This might be caused by the increased production of proteases originating from neutrophils and other circulating cells trapped within the mural thrombus in the aneurysmal wall.[28] While intramural thrombus size and growth has been suggested to be prognostically significant in asymptomatic patients with aneurysms ≤5.5 cm in size, larger studies are needed to confirm this association before it is incorporated in the decision making of timing of aneurysm repair.

Diagnosis

AAAs are frequently asymptomatic and commonly detected as an incidental finding on imaging studies or, in the present era, through AAA screening programs. Multiple imaging modalities are currently available for diagnosing and monitoring AAA with excellent sensitivity and specificity. The indication of each type of imaging modality for AAA is determined by availability, cost/benefit ratio, and technical considerations. Ultrasonography is the preferred modality for screening AAAs, with the advantage that it is relatively inexpensive, noninvasive, and it does not require administration of a contrast agent or expose patients to radiation. The evaluation of AAA with ultrasound involves measuring the anteroposterior, longitudinal, and transverse dimensions of the aorta. The sensitivity, specificity, and accuracy to detect and quantify infrarenal AAA approaches 100%.[29] Limitations of this imaging technique are that it is technician dependent, difficult to implement in morbidly obese patients, associated with significant interobserver variability, and usually not able to visualize aneurysm extension to major branches (i.e., iliac arteries), which limits its utility for planning operative repair.

The use of routine ultrasound screening for AAA in asymptomatic patients is a controversial topic. The U.S. Preventive Service Task Force (USPSTF), in its 1996 report, found insufficient evidence to recommend routine AAA screening in asymptomatic adults. Since then, numerous randomized, controlled trials evaluating population-based screening for AAA have been published. The largest trial, the Multicenter Aneurysm Screening Study, randomized 67,800 patients aged 65 to 74 years to an invitation for abdominal ultrasound screening or to an uninvited control group. After 4 years of follow-up, the AAA-related mortality in ultrasound-screened patients was reduced by 42% compared to uninvited controls.[30] The trial also provided firm estimates of the cost-effectiveness of a screening program. At 4 years, the cost was 57,000 dollars per quality-adjusted life year, and when extrapolated to 10 years, the cost was estimated at 12,500 dollars. The authors concluded that at

tahir99-VRG & vip.persianss.ir

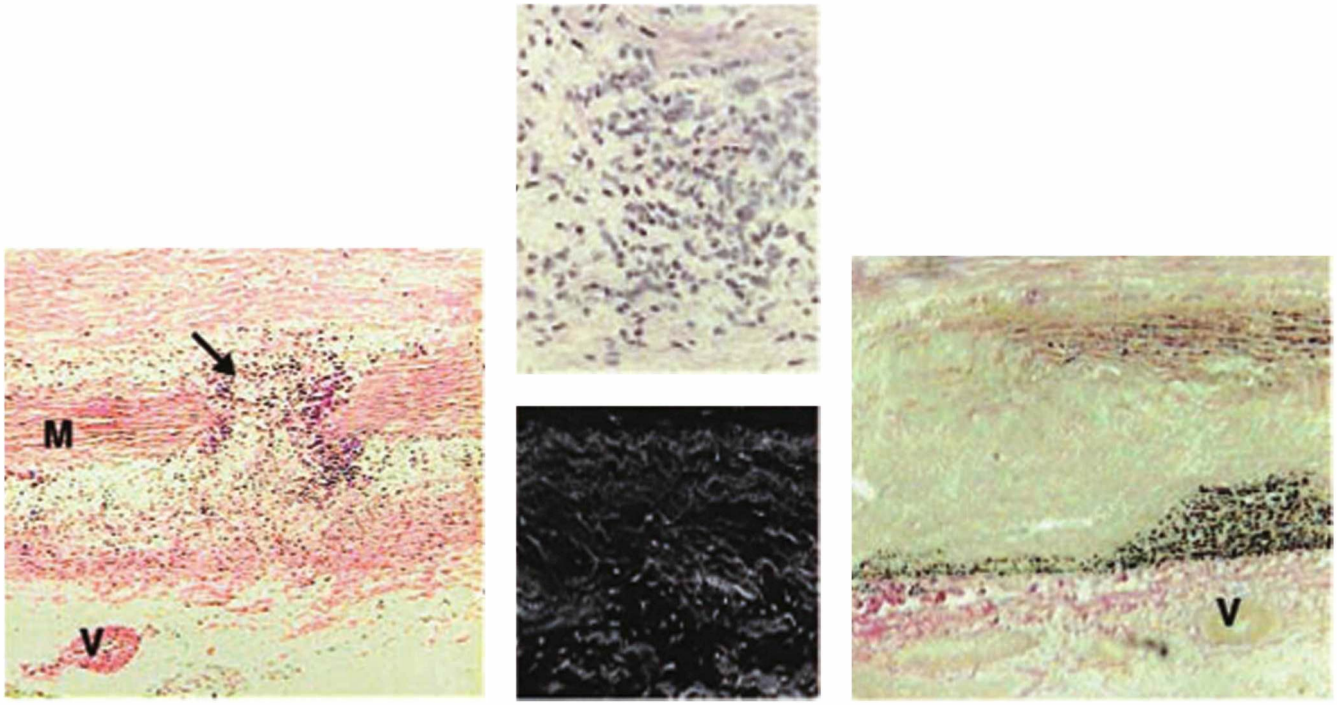

FIGURE 72.1 Inflammatory infiltrate (*left* and *upper middle panels*), focal oxidative stress (*lower middle panel*), and disruption of medial smooth muscle cells (*left panel*, *arrow*) and elastin (*right panel*) in human AAA. M indicates medial layer; V indicates vasa vasorum within the adventitial layer. (Reprinted from Miller FJ, Sharp WJ, Fang X, et al. Oxidative stress in human abdominal aortic aneurysms: a potential mediator of aneurismal remodeling. *Arterioscler Thromb Vasc Biol* 2002;22:560–565, with permission.)

4 years, the cost-effectiveness of screening for AAA is acceptable according to the current health services threshold.[31] Based on these data, and three other population-based studies, the USPSTF revisited the benefits and harms of population-based AAA screening in 2005, concluding that for men aged 65 to 75 years, an invitation to attend AAA screening reduces AAA-related mortality.[32] Unfortunately, these data do not specifically address AAA screening in women, who were underrepresented in the trials. The use of screening ultrasound for AAA in the United States is currently recommended for men aged 65 to 75 years who have smoked, and for both men and women in this age group with a family history of AAA.

CT is a well-established and widely used method for the diagnosis of AAA. The advent of multidetector CT, with its ability to perform volumetric imaging with isotropic voxels and a spatial resolution <1 mm, makes it an excellent modality for the diagnosis and follow-up surveillance of AAA. The multiplanar imaging ability of CT renders it an extremely accurate technique to serially evaluate changes in aneurysm size over time. In addition, CT permits better visualization of suprarenal aneurysms and improved assessment of the renal, mesenteric, and iliac arteries through axial images and three dimensional (3-D) reconstruction displays, thereby providing a complete description of the abdominal and pelvic vasculature prior to repair (FIGURE 72.2). An important use of CT is to measure the infrarenal neck of the aneurysm, the length of which is extremely important for endograft fixation during endovascular AAA repair. The infrarenal neck of the aneurysm is defined as the distance along the aorta from the renal arteries to the proximal origin of the aneurysm. Disadvantages of CT are its cost compared to ultrasound, exposure to radiation (particularly with repeated scans), and the use of intravenous contrast.

Noncontrast or contrast-enhanced magnetic resonance angiography (MRA) also clearly demonstrates the aortic anatomy, providing similar information to that of the CT scan. MRA is highly sensitive and specific at diagnosing and quantifying aortic diameter in AAA. In addition, MRA delineates the entire aorta and thus defines the anatomic relationship between the aorta and its principal branches for preoperative aortic aneurysm assessment. Advantages of MRA over CT scan in patients who need serial monitoring of aortic size are the absence of ionizing radiation and iodinated contrast; however, MRA is much more expensive and less widely available. Moreover, some patients cannot tolerate MRA due to implanted metal devices and/or claustrophobia and longer imaging times.

Management

Surveillance and Timing of Repair

Aneurysm size remains the single-most important predictor for aneurysm rupture and the main indication for repair in asymptomatic patients with AAA. The size of the aneurysm is directly related to the risk of rupture; however, the exact size upon which surgical intervention is justified remains a topic of debate. The optimal management and timing of surgical repair of AAA was addressed by two large randomized trials, the U.K. Small Aneurysm Trial and Aneurysm Detection and Management (ADAM) Veterans Affairs Cooperative Study. Both

tahir99-VRG & vip.persianss.ir

FIGURE 72.2 CTA volume rendered **(A)** and maximum-intensity projection (MIP) images **(B)** demonstrating a fusiform bilobed AAA with atherosclerotic calcifications (*arrow*).

trials randomized patients with small aortic aneurysm diameters (4.0 to 5.5 cm in U.K. Small Aneurysm Trial and 4.0 to 5.4 cm in ADAM Study) to undergo early elective surgery or follow-up surveillance. Collectively, there was no difference in survival between the early surgery group and the surveillance group after approximately 5 years of follow-up. The U.K. Small Aneurysm Trial extended their follow-up to 8 years, showing a slightly lower total mortality in the early surgery group. However, their 30-day surgical mortality rate was 5.8% compared to 2.1% in the ADAM trial.[33,34] The U.K. Small Aneurysm Trial also reported an annual risk of AAA rupture of 1.5% or less for aneurysms smaller than 5.0 cm in diameter and 6.5% for aneurysms 5.0 to 5.9 cm in diameter. Above 6 cm, the risk of AAA rupture rises sharply, with an annual risk of rupture of up to 33% in aneurysms 7.0 cm in diameter or larger.[10,35] These trials demonstrated that in patients with asymptomatic AAA, follow-up surveillance and deferment of repair until aneurysm diameter exceeds 5.5 cm is safe and associated with a very low rate of rupture. An important limitation is that female population was underrepresented in these trials; consequently, recommendations made for men may not apply stringently to women. Currently, the threshold for repair recommended by professional vascular surgery societies in women with AAA is 4.5 to 5.0 cm, based on the recognition that aneurysms tend to rupture at smaller sizes in women than in men.[36]

Rapid expansion rate is another important determinant that can also predict aneurysm rupture, with large aneurysms typically expanding more rapidly than small aneurysms in accordance with Laplace law. This hampers the exact prediction of aneurysm growth rate, even within the same individual over time. Based on multiple reports, however, the average annual expansion rates for AAA are 0.1 to 0.5 cm for aneurysms measuring <4.0 cm at the time of discovery, 0.4 to 0.5 cm for aneurysms 4.0 to 6.0 cm, and up to 0.7 to 0.8 cm for larger aneurysms.[37] In general, follow-up surveillance imaging is recommended every 12 months for individuals with AAA measuring 3.5 to 4.4 cm in diameter and every 6 months for those with an AAA measuring 4.5 to 5.4 cm in diameter, with a recommendation for elective aneurysm repair when diameter reaches 5.5 cm or increases by more than 0.5 cm within a given year.[38]

Endovascular versus Surgical Repair

Endovascular abdominal aortic aneurysm repair emerged almost two decades ago as an alternative approach to AAA repair in individuals not deemed to be surgical candidates. Endovascular aneurysm repair (EVAR) now has become the treatment of choice to repair infrarenal AAA, accounting for more than half of all AAA repairs in the United States.[39] The technique involves the use of a percutaneous stent graft, placed under fluoroscopy guidance to cover the aneurysm, excluding it from the circulation. It usually requires sufficient proximal and distal nonaneurysmal segments for adequate attachment of the stent struts to prevent distal migration. It is important to note that AAA endovascular repair has certain anatomical requirements for procedural success, and not all patients with AAA have suitable anatomy.[40] The implantation success rate, however, has approached 100% in recent years. Nevertheless, a common adverse effect continues to be the leakage of blood into the aneurysm, also called endoleak. Although they may spontaneously resolve, persistent endoleaks may lead to continual aneurysm expansion or rupture, requiring an additional intervention to repair either by endovascular implantation of a graft extension cuff or, less commonly, by conversion to open surgical repair.

Two randomized, prospective trials comparing AAA endovascular repair versus open surgical repair in individuals deemed healthy enough to undergo surgery have addressed the short- to late-term outcomes of EVAR. In the short-term outcomes, the Endovascular Aneurysm Repair trial 1 (EVAR-1), and the Dutch Randomized Endovascular Aneurysm Management (DREAM) trial, showed an almost identical improved 30-day mortality rate after EVAR compared to open surgical repair: 1.7% versus 4.7%, respectively, in the EVAR-1 trial and 1.2% versus 4.6% in the DREAM trial, respectively. Mid- and long-term data, however, have failed to demonstrate an all-cause mortality benefit, with overall survival rates converging after 2 years for both groups.[41,42] The role of endovascular repair in

tahir99-VRG & vip.persianss.ir

patients considered at high risk for complications or death with open repair has also been investigated in the United Kingdom Endovascular Repair-2 (EVAR-2) trial. The study randomized patients to elective endovascular AAA repair or no repair, with both groups equally treated medically. The study found no benefit of endovascular repair in patients who are deemed high risk for open aneurysm repair, even at long-term follow-up.[43] Therefore, the optimal indications for endovascular repair remain to be precisely defined. Patient preference is very important when making treatment decisions, and patients should be well informed about the pros and cons of each approach.

Medical Management

The cornerstone of medical therapy is risk factor modification. Current tobacco use has shown to be strongly associated with a significant increase in aneurysm growth rate. Hence, smoking cessation should be strongly encouraged in all patients with AAA and is likely the single-most important therapeutic intervention. Hypertension should also be controlled. Several studies have suggested that beta-blockers and angiotensin-converting enzyme inhibitors have a beneficial effect on aneurysm progression, but these data have been insufficient to make strong recommendations for their specific use to prevent aneurysm expansion.[44] Patients with AAA frequently have concomitant coronary artery disease, and beta-blockers are generally recommended for patients undergoing vascular surgery to reduce perioperative cardiac risk. Despite no clear relationship between cholesterol levels and AAA expansion rate, statin therapy has been shown in small studies to reduce infrarenal aneurysm growth rate and to reduce aortic MMP-9, which plays an important role in aneurysm formation and expansion.[45,46] In a recent study, the effects of statins on aneurysmal growth was examined in 150 patients with AAA over a median period of 3 years. Statin users averaged 2.0 mm/y aneurysm growth rate compared to 3.6 mm/y in nonusers.[47] A recent meta-analysis also suggested that statin therapy is associated with a lower rate of expansion in patients with small AAA.[48] Although these results are encouraging, larger trials are needed to confirm efficacy in order for statin therapy to be recommended for the treatment of AAA, in the absence of conventional indications.

Inflammatory AAA

Inflammatory AAA (IAAA) has been described as a variant of AAA defined by the presence of a thickened aneurysm wall, marked perianeurysmal and retroperitoneal fibrosis, and dense adhesions of adjacent abdominal organs.[49] IAAA account for 3% to 10% of AAA with a male-to-female predilection reported of up to 30:1 and with an age of occurrence 5 to 10 years younger than the mean age of patients with atherosclerotic aneurysms.[50] Unlike atherosclerotic AAA, symptoms of IAAA are common and highly suggestive of inflammation. Patients usually present with the triad of abdominal or back pain, weight loss, and an elevated sedimentation rate.[51] As with all AAA, inflammatory cell infiltrate is the pathophysiologic hallmark, but with a more pronounced inflammatory response in IAAA. Histologic features include internal elastic lamina disruption and loss of smooth muscle and elastic fibers of the media along with inflammatory infiltrates.[49] The exact etiology is unclear, but it has been hypothesized that enhanced inflammation might be related to infections such as Chlamydia and cytomegalovirus.[52,53] The rupture rate for IAAA has been suggested to be lower than noninflammatory AAA. CT scan is the gold standard diagnostic tool for IAAA, characterized by a thick inflammatory soft tissue rind around the aorta and demonstration of perianeurysmal fat stranding indicative of inflammation, which distinguishes IAAA from the more common atherosclerotic AAA.[51] More recently, increased metabolism in the AAA wall has been visualized by 18F-fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT. FDG uptake has been shown to correlate with inflammation, histopathologic characteristics of aneurysm wall instability, and clinical symptoms and may contribute in the near future to improved prediction of AAA rupture risk.[54] Surgical repair is the treatment of choice for IAAA, although EVAR has emerged as an option. Findings at operation include a thickened aortic wall and a shiny, white periaortic and retroperitoneal inflammatory reaction involving adjacent structures.[51]

Aortic Dissection

Aortic dissection is a tear of the intima layer with bleeding into the wall of the aorta resulting in separation of the layers and formation of a new lumen (false lumen). In 90% of patients, the dissection plane tracks within the media layer. Population-based studies have shown that the incidence of acute aortic dissection ranges from 2 to 3.5 cases per 100,000 person-years, twice that of AAA rupture.[55] The most common predisposing factor for acute aortic dissection is arterial hypertension, with a strong male predominance. Other predisposing factors include genetic conditions such as Marfan syndrome or Loeys-Dietz syndrome, nonsyndromic familial disorders, previous aneurysms, atherosclerosis, and inflammatory diseases. Underlying genetic disorders are particularly common in patients younger than 40 years of age who suffer aortic dissection, and only a small minority of these patients have a history of aortic aneurysm prior to dissection.[56] Thus, in most patients, aortic dissection represents a syndrome distinct from aortic aneurysm. For a comprehensive review on aortic dissection, please refer to ACC/AHA guidelines for the diagnosis and management of patients with thoracic aortic disease.[57]

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysm (TAA) is typically an indolent process, usually asymptomatic, and often diagnosed by an imaging modality performed for other indications. Hence, the true incidence of the disease is difficult to estimate, yet available data suggest it is increasing.[58] TAA involve different segments of the aorta and are usually classified based on the affected anatomical segment. The ascending aorta and/or aortic root is involved in 50% of TAA, followed by the descending aorta distal to the left subclavian artery in 40%, and the aortic arch in 10%.[59] TAA which extend below the diaphragm to the abdominal aorta are referred to as thoracoabdominal aneurysms, which constitute 10% of TAA.

Etiology and Pathophysiology

Classically, the hallmark pathologic feature of TAA is a degenerative process termed cystic medial necrosis, or more accurately, medial degeneration. The term cystic medial necrosis has fallen out of favor because histologically, there is neither necrosis nor cyst formation. In general, medial degeneration is characterized by disruption of the extracellular matrix proteins, apoptotic loss of

tahir99-VRG & vip.persianss.ir

vascular smooth muscle cells, and increased accumulation of proteoglycans. Inflammatory infiltration and upregulation of MMP in the aortic wall has been documented in TAA but is less pronounced than is typically seen in AAA.[60] Moreover, atherosclerotic lesion formation, which is common in AAA, is rare in TAA and extremely uncommon in cases involving the ascending aorta.[61,62]

The basis for pathologic differences of aortic histology in the thoracic versus abdominal aorta is not entirely clear. Historically, it was thought that the differences in atherosclerotic lesion formation between the atherosclerotic prone abdominal aorta and the atherosclerotic resistant thoracic aorta were due to turbulent hemodynamic flow patterns in the abdominal aorta.[63,64] However, this theory was dispelled by experimental studies demonstrating that transplanting abdominal aortic segments to the thoracic position, or thoracic aortic segments to the abdominal position, did not modulate atherosclerosis susceptibility.[64] The presence of medial degeneration without associated atherosclerosis in the thoracic aorta suggests that intrinsic abnormalities of smooth muscle cells may play a role, perhaps related to their unique embryologic origin. In this regard, smooth muscle cells in the ascending aorta arise from neural ectoderm-derived cells in the cardiac neural crest, whereas smooth muscle cells in the abdominal aorta originate from paraxial mesoderm-derived progenitors in somites.[63] Recent studies have elucidated fundamental differences in tissue growth factor beta (TGFβ) signaling in smooth muscle cells that may be pertinent to aneurysm susceptibility in thoracic versus abdominal aorta.[65] Under identical conditions, TGFβ-1 strongly induced cell proliferation, plasminogen activator inhibitor-1 expression, and DNA synthesis in neural crest–derived smooth muscle cells, whereas the same concentrations of TGFβ-1 inhibited these responses in mesoderm-derived smooth muscle cells. This may be pertinent to clinical and experimental observations, suggesting that TGFβ signaling differentially regulates TAA and AAA.[66,67]

Multiple underlying conditions have been associated with TAA, including congenital, hereditary, and acquired causes. Congenital causes include bicuspid aortic valve (BAV) disease and hereditary syndromic disorders such as Marfan syndrome, Loeys-Dietz syndrome, and Ehlers-Danlos syndrome. Although any segment of the aorta may become involved with these disorders, they typically involve the aortic root and ascending aorta. Aortic root aneurysms can cause aortic insufficiency from aortic valve annular dilatation, a condition commonly referred as *annuloaortic ectasia*[68] (FIGURE 72.3A,B). Hypertension is an important factor related to TAA. High blood pressure dilates and elongates the aorta and can hasten the process of medial degeneration that leads to weakening of the aortic wall. Other acquired disorders linked to TAA include infections such as syphilis and inflammatory diseases including giant cell arteritis (GCA) and Takayasu arteritis. An inflammatory variant has also been described in the ascending and descending thoracic aorta. Although inflammatory TAA is even more uncommon than its counterpart in the abdominal aorta, clinically and pathologically they behave the same and share similar radiologic features.

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of the connective tissue with a high penetrance but variable expression. The cause is a mutation in the *FBN1* gene that encodes fibrillin-1, a large extracellular matrix glycoprotein that is the major element of microfibrils, which form the elastic fibers in conjunction with tropoelastin.[69] Fragmentation of elastic fibers in the aortic media causes the histologic changes of medial degeneration, which is the main pathologic feature of TAA. A second locus was recently identified linked to mutations in the gene encoding the transforming growth factor-beta type II receptor (*TGFBR2*).[70] Mutations in *TGFBR2* can also be found in patients with different syndromes, including the Loeys-Dietz syndrome.[71] The diagnosis of Marfan syndrome is based on a combination of clinical criteria of typical phenotypic manifestations in the cardiovascular, ocular, and skeletal systems.[72] The most specific manifestations of Marfan syndrome are aortic dilatation/dissection (FIGURE 72.3C,D), ectopia lentis, and dural ectasia, with almost every patient having aortic disease at some point in their lifetime. In fact, patients who present with untreated ascending aortic aneurysm or aortic dissection account for most of the mortality of this syndrome.

Loeys-Dietz Syndrome

Loeys-Dietz syndrome is a rare autosomal dominant genetic disorder that shares various clinical manifestations with Marfan syndrome. Loeys-Dietz syndrome has been associated with mutations in the genes encoding the transforming growth factor beta receptors I and II (*TGFBR1* and *TGFBR2*). The syndrome is characterized clinically by the triad of arterial tortuosity and aneurysms, widely spaced eyes (hypertelorism) and a bifid uvula, cleft palate, or both.[71] The diagnosis is confirmed through genetic testing analysis for *TGFBR1* or *TGFBR2* mutations. Almost all affected patients have aortic root aneurysms that lead to aortic dissection at an early age and at aortic diameters <5.0 cm. Molecular characterization of 52 families with Loeys-Dietz syndrome found that the median survival age was 37 years, compared to 48 years in patients with vascular Ehlers-Danlos syndrome and 70 years in patients with Marfan syndrome.[73]

Vascular Ehlers-Danlos Syndrome

Also called Ehlers-Danlos syndrome type IV, this is an autosomal dominant disorder characterized by thin, translucent skin; easy bruising, characteristic facial appearance (thin lips, small chin, thin nose, and large eyes); and rupture of arteries, intestine, and uterus. Patients most commonly present with vascular rupture/dissection or perforation from the gastrointestinal tract. Arterial rupture may be preceded by aneurysm or dissection, but it may also occur spontaneously. Vascular complications are the most catastrophic complications, reducing median age of survival to only 48 years.[74] Mutation in *COL3A1* is the only genetic abnormality thus far linked to vascular Ehlers-Danlos. The diagnosis is based on clinical findings and confirmed by abnormal type III procollagen synthesis and/or molecular genetics testing.[74]

Bicuspid Aortic Valve Disease

BAV is one of the most common forms of congenital heart disease, affecting 1% to 2% of the adult population. BAV can follow an autosomal dominant pattern of inheritance and is associated with TAA formation; medial degeneration appears to be the underlying mechanism of TAA in patients with BAV. No

single gene mutation has been conclusively linked to BAV and TAA, although mutations in *NOTCH1* have been implicated.[75] Aortic dilation is often observed in individuals with BAV who lack aortic valve stenosis or insufficiency, implying that perturbed aortic flow is not responsible for the aortic pathology.[76] BAV disease has been associated with fibrillin-1 deficiency in the aortic media and increased MMP-2 activity independent of the presence or absence of aortic valve dysfunction, suggesting that congenital fibrillin-1 deficiency may play a role in aortic dilatation in patients with BAV.[77] About 40% of patients with BAV are affected by TAA, with the ascending aorta involved in 44% of cases, followed by aortic sinuses and sinotubular junction in 20% and 15% of cases, respectively.[78] Other aortic abnormalities associated with BAV include aortic dissection, aortic rupture, and coarctation of the aorta. It is important to point out that patients who have undergone repair of aortic coarctation may develop aortic aneurysms adjacent to the surgical site; serial imaging studies are indicated to address this possibility.[79]

Modified from Tromp G, Kuivaniemi H, Hinterseher I, et al. Novel genetic mechanisms for aortic aneurysms. *Curr Atheroscler Rep* 2010;12:259–266.

Familial TAA

Familial cases of TAA usually occur as a solitary manifestation not associated with other genetic syndromes or sporadic causes of aneurysms. They follow a familial pattern of inheritance, typically autosomal dominant or X-linked.[80] A recent analysis of more than 500 patients with nonsyndromic TAA demonstrated that about 20% exhibited a pattern of familial clustering.[81] Six different genetic loci have been identified in studies of familial TAA, with four genes found to harbor mutations linked to TAA[82] (Table 72.1). The most commonly identified mutation is in the *ACTA2* gene that encodes for smooth muscle alpha actin 2, found in 14% of unrelated families with TAA. This mutation has an autosomal dominant transmission pattern and can present with nonthoracic aneurysms, livedo reticularis, iris flocculi, and patent ductus arteriosus in addition to TAA.[83] The other three genes that have been identified are rare and encode for smooth muscle myosin heavy chain 11 (*MYH11*), *TGFBR1*, and *TGFBR2*. Mutations in the last two genes have also been linked to Loeys-Dietz syndrome, as previously discussed.[73]

Medial degeneration was considered the hallmark pathologic feature of Marfan syndrome; however, familial and syndromic disorders of TAA are also associated with similar pathology. The cascade of events that terminates in medial degeneration and aortic wall dilatation is not fully understood. Previous studies have shown the presence of inflammatory infiltrates, composed primarily of T cells and macrophages, in the aortic wall of TAA. Interestingly, this inflammatory component has been identified in patients with familial and syndromic TAA, as well as in nongenetic sporadic cases.[84] Furthermore, increased expression of MMP, in particular MMP-2 and MMP-9, has been consistently detected in the media of TAA associated with various disorders.[85–87]

Diagnosis

Most TAA are silent and are discovered incidentally. Symptoms, when present, usually result from a vascular complication or aneurysm expansion compressing an adjacent organ or bony structure. Similar to AAA, TAA can be diagnosed by multiple imaging modalities. Transthoracic echocardiogram (TTE) is an excellent modality to evaluate the aortic root important in patients with Marfan syndrome, who predominantly have dilatation of the proximal aorta. However, TTE can only image the first few centimeters of the aorta and may miss aneurysms in the mid and distal ascending aorta, as well as the descending aorta. Therefore, TTE should not be used to diagnose TAA in diseases other than Marfan syndrome. Transesophageal echocardiogram (TEE) allows clear visualization of the entire thoracic aorta, with exception of a blind spot in the ascending aorta close to the right main stem bronchus. However, TEE is an invasive procedure that can lead to significant complications, particularly in patients with compromised airway or respiratory function, and in those with esophageal disease. Also, accurate measurement of aortic diameter by TEE is challenging in the presence of aortic tortuosity. While TEE is a useful diagnostic tool for aortic dissection, it is not recommended to serially measure aortic diameters in patients with TAA.

Multidetector computed tomography angiography (CTA) is an excellent imaging modality to evaluate TAA (FIGURE 72.4A). Advantages of multidetector CTA include high spatial resolution of 0.5 to 0.75 mm and the ability to display the 3-D structure of the entire aorta, which makes it ideal for serial evaluation of TAA. Moreover, CTA can rapidly image the entire aorta and surrounding anatomical structures, including branch vessels, which is important in critically ill patients. CTA with prospective ECG gating, which limits pulsation artifact from cardiac motion, can accurately evaluate the aortic root and ascending aorta. Disadvantages of CT include the risk of contrast-induced nephropathy and the radiation dose, especially in patients who need follow-up surveillance over time.

MRA of the aorta also offers excellent visualization of the entire aorta and permits accurate measurement of aortic diameter, aneurysm extension, and its relation to aortic branches (FIGURE 72.4B). Advantages over CTA include the lack of ionizing radiation, which facilitates serial follow-up, particularly in younger patients. ECG-gated MRA can also evaluate aneurysms of the aortic root. When the aortic root is affected, a functional study can be performed with cine-MRI to evaluate the aortic valve for associated abnormalities. As previously mentioned, MRA requires a longer duration of scanning time, which limits its application in critically ill patients.

Management

Surveillance and Timing of Repair

The growth rate of TAA not associated with syndromes or other disorders is typically low, with a mean rate of 0.1 cm/y; the descending aorta expands faster at 0.19 cm/y compared to the ascending aorta at 0.07 cm/y. When rapid growth is reported, it usually reflects a measurement error, unless dissection is present.[58] Studies of the natural history of TAA have defined criteria when dissection and rupture are likely to occur, thus guiding the timing of repair. Surgical intervention in asymptomatic patients

tahir99-VRG & vip.persianss.ir

with aneurysms of the ascending thoracic aorta, aortic sinus, and descending thoracic aorta is indicated when the diameter is 5.5 cm or greater or a growth rate of more than 0.5 cm/y is documented in an aneurysm <5.5 cm in diameter. Although symptoms are rare with TAA, when present, repair is indicated regardless of size. In patients diagnosed with TAA who do not have indications for repair, follow-up surveillance with an imaging modality is recommended at 6 months and annually thereafter if stability is documented.[57]

In patients with Marfan syndrome, BAV, or a syndromic or familial form of thoracic aneurysm, the risk of rupture and dissection is higher at smaller diameters; thus repair is generally recommended when aortic diameter reaches 5.0 cm in size or earlier if rapid growth (>0.5 cm/y) is detected, if there is a family history of aortic dissection at an aortic diameter of <5.0 cm, or in the presence of significant aortic regurgitation.[88]

Patients with Loeys-Dietz syndrome should undergo aortic imaging examination at initial diagnosis and every 6 months thereafter; additionally, they should undergo yearly evaluation with MRI from the cerebral vasculature to the pelvis circulation. Prophylactic surgical repair of the aortic root/ascending aorta should be considered once the maximal diameter reaches 4.0 cm or greater.[57]

Surgical repair in patients with vascular Ehlers-Danlos can be challenging due to the extreme tissue fragility with poor wound healing and high risk of bleeding which may complicate the procedure. Therefore, it is important for the surgeon to know the diagnosis before the surgical procedure to optimize clinical outcomes by employing the least complicated technique for repair coupled with delicate handling of vascular tissues.[89] The role for prophylactic surgical repair of aneurysms in this syndrome has not been established, in part because of the heterogeneous spectrum of the disease, which ranges from excessive to near-normal tissue fragility. Noninvasive vascular imaging is the preferred method to evaluate the aorta and vascular structures due to the risk of major complications with invasive angiography.[74]

When the primary indication for surgery is aortic valve replacement, repair of the ascending aorta is recommended if the diameter is 4.5 cm or greater. Patients with BAV should undergo serial imaging to evaluate the size and shape of the aortic root and ascending aorta. It is important to visualize the ascending aorta distal to the sinotubular junction as aortic dilatation is common in this location. When treating patients with BAV, clinicians should be aware of the ongoing risk of aneurysm formation/aortic root dilatation even after surgical valve replacement, which necessitates the need for continued surveillance over time.[90]

Endovascular Repair

An alternative approach to surgical management of TAA is thoracic endovascular aortic repair (TEVAR), which currently is only approved for the management of descending TAA. Advantages over open surgical repair include avoidance of thoracotomy and aortic cross clamping, reduced morbidity associated with open surgery, and shorter length of hospital stay. Current indications for endovascular repair in asymptomatic patients with descending TAA are the same as for open surgical repair. It is important to recognize that not every patient is candidate for TEVAR. Patients with short aneurysm necks, aneurysms too wide to contain available devices, or poor vascular access are considered unsuitable for TEVAR. Although early effectiveness and high technical implantation success rate was demonstrated in a multicenter prospective nonrandomized phase II study,[91] long-term durability is largely unknown. In addition, prospective randomized trials have not been performed to compare endovascular versus open repair. Therefore, while TEVAR is a relatively new and appealing approach for the treatment of descending TAA, the decision to employ this approach must balance patient factors with the anticipated risks and benefits. For example, in young patients with descending TAA who are good candidates for open repair, the immediate benefits of stent grafting must be judiciously balanced against the proven efficacy and durability of open repair. On the other hand, in older patients with multiple comorbid conditions who are at increased risk for open repair, the immediate benefits of endovascular therapy likely overshadow concerns about its long-term durability.

Medical Management

Risk reduction measures, including hypertension control, lipid management, and smoking cessation, should be recommended for all patients with TAA, both before and after repair. Beta blockade has been shown to reduce the rate of thoracic aortic dilatation and aneurysm expansion in patients with Marfan syndrome and is currently recommended for all patients with this disease process who have TAA. These data were derived from an open-label study that randomized 70 patients with Marfan syndrome to propranolol versus placebo, which demonstrated reduced rate of aortic dilatation and risk of aortic dissection with propranolol treatment over a 10-year follow-up period.[92] Angiotensin II-receptor blockade (ARB) has also been demonstrated to reduce aneurysm expansion in animal models of Marfan syndrome.[93] More recently, in a small cohort study of pediatric patients with Marfan syndrome, the use of ARB slowed the rate of aortic root dilatation.[94] Further clinical trials are needed to determine the efficacy of ARB and beta blockade in patients with Marfan syndrome and TAA. Currently, there are no data to support the use of statins to prevent expansion in TAA; however, it is logical to use statins in patients with concurrent aortic atherosclerosis detected on imaging studies.

MYCOTIC ANEURYSMS AND OTHER INFECTIOUS DISEASES

Infection of the aorta, or infectious aortitis, is a rare cause of aortic aneurysms. The term *infected aneurysm* is now more commonly used than *mycotic aneurysm* because most of the infectious agents are nonfungal. Infected aneurysms occur through several mechanisms, including direct spread from contiguous structures (mediastinitis), septic embolization to the aorta (bacterial endocarditis), hematogenous dissemination (sepsis), or blood-borne vasa vasorum infection (syphilis).[95] Infection of the aorta is more common in regions of preexisting aortic wall disease, including aneurysms, extensive atherosclerosis, aortic trauma, or previous surgical sites. Bacteria such as *Staphylococcus aureus*, *Salmonella*, and *Clostridium* species are most commonly isolated. Although rarely seen at the present time, *Treponema pallidum* can cause syphilitic aortitis in 10% of patients with untreated tertiary syphilis, which most commonly occurs 10 to 25 years after the initial spirochete infection. The ascending thoracic aorta and aortic arch are most commonly involved. Other organisms, including fungi and mycobacteria,

tahir99-VRG & vip.persianss.ir

occasionally cause infected aneurysms, most often in immunologically compromised patients. Prompt surgical management with extensive debridement, along with antibiotic therapy, is recommended in patients with infected aneurysms. There are no data addressing the optimal duration of antibiotic therapy following surgical treatment for infected aneurysms.[95]

ANEURYSMS ASSOCIATED WITH SYSTEMIC INFLAMMATORY DISORDERS

Numerous systemic inflammatory disorders may cause inflammation of the aorta resulting in aneurysm, dissection, or rupture. It is very important to recognize these diseases given the benefit of immunosuppressive therapy to suppress the inflammatory cascade. GCA, also known as temporal arteritis, is a vasculitic syndrome that affects large- to medium-sized arteries, primarily in the elderly. It is estimated that GCA involves the aorta in up to 18% of cases, and patients with GCA are 17 times more likely to develop TAA and twice as likely to develop AAA as compared with age- and sex-matched patients without GCA.[96] The histopathologic process of GCA is manifested by granuloma formation in the aortic wall. This process is mediated by $CD4^+$ T cells and macrophages, which produce cytokines and MMPs. Although hyperplasia of the intima leading to arterial narrowing and ischemia is a more common presentation, GCA can affect the entire aorta and cause aneurysm formation many years after the diagnosis is originally made.[97] Patients with GCA have a significantly elevated erythrocyte sedimentation rate, and proof of giant cells by biopsy is diagnostic. Initial evaluation of patients with GCA should include CTA or MRI of the thoracic aorta and its branches to evaluate the possibility of aneurysms or occlusive disease. Imaging by PET with 18-fluoro-deoxyglucose (FDG) and CT allows the assessment of disease activity, vessel morphology, and localized inflammation in the same study.[98] Therapy is aimed at the inflammatory state with high-dose corticosteroids.

Takayasu arteritis is a large-vessel inflammatory vasculopathy that primarily affects the aorta and its major branches. Patients are usually females in their 2nd or 3rd decade of life. Arterial occlusion is more common than dilatation, and narrowing of the left subclavian artery is present in 90% of patients, making the left radial pulse weak or absent, hence the term *pulseless disease*.[99] The pathophysiology is poorly understood; however inflammatory mononuclear cells, primarily T cells, infiltrate the blood vessel wall through the vasa vasorum and invade the intima.[99] The inflammatory process may cause destruction or fibrotic repair of the aorta, leading to aneurysm formation or stenosis, respectively. Aneurysms are more common in the aortic root or arch, followed by the abdominal and thoracic aorta.[100] Initial evaluation of Takayasu arteritis should include assessment of the thoracic aorta and its branches with either MRI or CT scan. MRI is a good diagnostic tool to image aortic wall thickening, and MRA is useful to image the luminal appearance of the aorta and its branches. As in GCA, PET-FDG is a new imaging technique used in large-vessel vasculitis to detect increased aortic wall metabolism suggestive of inflammation and can be used in conjunction with CT to localize the disease process.[98] Initial treatment is directed to reduce inflammation with high-dose corticosteroids and other immunosuppressive agents as second line therapy.

Several other systemic inflammatory diseases, including Behcet disease, ankylosing spondylitis, rheumatoid arthritis, and Kawasaki disease, may be associated with aneurysm formation. No randomized trials exist to guide recommendations for detection or surveillance of aneurysms for these inflammatory diseases. Therefore, indications for aneurysm repair should be the same as in noninflammatory disorders.

ANEURYSMS OF OTHER ARTERIES

Coronary artery aneurysm (CAA) is an abnormal dilatation of a localized or diffuse segment of the coronary vasculature, with a diameter of ≥1.5 times the adjacent normal coronary artery. The incidence of this disease is 0.3% to 4.9%, with right coronary artery involvement in 68% of cases.[101] The most common etiology of CAA is atherosclerotic coronary artery disease, with a reported frequency of 50% to 90% depending on the series. Approximately 10% to 20% of cases are attributed to Kawasaki disease, infectious septic emboli, Takayasu arteritis, collagen vascular/connective tissue disorders, or as a complication of coronary stenting.[101–103] In rare instances, genetic predisposition to CAA has been reported.[104] The pathogenesis of this disease is poorly understood; an inflammatory process involving all layers of the coronary artery leading to medial elastin degradation may be a common pathway in the pathology of CAA.[101,103] This is supported by observations that patients with isolated CAA have higher levels of serum C-reactive protein and interleukin-6 than do patients with and without atherosclerotic coronary artery disease. In addition, elevated levels of plasma-soluble adhesion molecules, such as vascular cell adhesion molecule-1, intercellular adhesion molecule-1, and E-selectin, have also been detected in patients with CAA. Finally, activation of MMPs, particularly MMP-3, has been associated with CAA in humans.[101]

Multiple imaging modalities, including echocardiography, cardiac CT (FIGURE 72.4C), and MRI, can be used to confirm the diagnosis of CAA. However, the gold standard for diagnosis continues to be coronary angiography, which provides detailed anatomic information regarding the size, location, shape, and number of aneurysms.

The low frequency of the disease, and the lack of prospective randomized trials in patients with CAA, prohibits an evidence-based management protocol. However, CAA is clearly not a benign condition; the 5-year mortality rate in untreated CAA was reported to be 29%.[105] At present, options include medical therapy, stent insertion, or surgical excision. If a coronary aneurysm is three or more times greater than the reference vessel diameter, surgery is usually recommended due to the high risk for compression, rupture, or thrombosis.[101] Aneurysmal coronary arteries are susceptible to thrombus formation as a result of the loss of laminar flow in the dilated segment. This risk factor, along with the high concurrence of atherosclerosis in patients with CAA, makes antiplatelet therapy important in the overall management. Although anticoagulation therapy with warfarin would appear to be a reasonable approach for the management of CAA, there is no evidence to support this treatment option over aspirin; its use is based on the patients' clinical context and physician preference.[103]

Popliteal artery aneurysms (PAAs) are localized dilatations of the popliteal artery >2 cm in diameter or more than 1.5 times the reference artery caliber. PAAs are the most common extraaortic arterial aneurysms, accounting for up to 70% of peripheral aneurysms.[106] They have been documented in 55% of patients with AAA, with a male predominance of more than

tahir99-VRG & vip.persianss.ir

95%.[107] Unlike AAA, complications of PAAs are more related to thromboembolism than rupture. Patients usually present with acute or chronic ischemia of the lower extremity due to thrombus formation or distal embolization. Microembolic symptoms are manifested as "blue toes," and mortality and amputation rates with this condition may be as high as 20%.[108] The exact pathophysiology of PAAs is unknown; however, associated factors include atherosclerosis and hypertension, especially in the aging population. The etiology in a small minority may be attributed to trauma, infection or mycotic disruption of the arterial wall, fibromuscular dysplasia, or inflammatory arteritides such as Behcet disease or Takayasu arteritis. A congenital form has also been proposed in small series of young patients.[109] Diagnosis is suggested by popliteal pulse contour and confirmed by duplex ultrasound, CT angiography (FIGURE 72.4D), MRA, or invasive angiography. Repair of PAAs has been recommended for all symptomatic patients, and for asymptomatic aneurysms >2.0 cm in diameter.[110] Open surgical treatment with arterial bypass grafting has been the traditional method to treat PAAs. More recently, endovascular repair with stent grafting has become a reasonable treatment option in anatomically suitable patients, with patency rates comparable to surgical treatment in some studies.[110]

CHAPTER

73 Intracranial Hemorrhage and Subarachnoid Hemorrhage

TIMOLAOS RIZOS AND THORSTEN STEINER

INTRACEREBRAL HEMORRHAGE

Epidemiology, Risk Factors and Prognosis

Intracerebral hemorrhage (ICH) is an extravasation of blood into the brain parenchyma. Hemorrhagic stroke accounts for approximately 15% of all strokes.[1,2] Advances in treatment (in the context of specialized neurologic and neurosurgic intensive care units) have resulted in improved survival over the last decade.[3] However, the mortality rate in patients with ICHs remains high; approximately 50% of patients die in the first 3 months,[4–6] with half of these patients dying within the first 2 days after symptom onset.[4] Moreover, ICH is associated with significant morbidity. For example, after 6 months only 20% of patients are functionally independent.[4]

ICH is most common in elderly persons.[7] The crude risk ratio for age (every 10-year increase) was calculated to be 1.97.[7] The incidence of ICH is higher in African American and Asian populations compared with whites. The Northern Manhattan Study revealed that Hispanic adults from the Caribbean and Black adults have a higher risk for ICH than whites.[8] Especially in elderly patients, cerebral amyloid angiopathy (CAA) is an important risk factor for primary ICH.[31,32] Many modifiable risk factors for ICH have been identified and prevention of these factors may reduce the incidence of ICH. Arterial hypertension is one of the most important risk factors for ICH. In elderly patients and in patients with untreated or uncontrolled hypertension, the risk of ICH is doubled.[7,17,18] The frequency of arterial hypertension in ICH has been estimated at 70% to 80%[4] and the crude odds ratio (OR) for hypertension is 3.68.[7] Although hypertension is the most important modifiable risk factor for prevention of ICH recurrence, data on optimal blood pressure control are lacking.[19,20]

The use of oral anticoagulation with warfarin is associated with an 8- to 19-fold increase in the risk of ICH.[21,11] The risk of ICH in patients taking oral anticoagulants is estimated to be 0.3% to 3.7% per year (when the international normalized ratio [INR] is between 2.0 and 4.5).[15] Each increase in INR of 0.5 elevates the bleeding risk by a factor of 1.4. The risk is particularly high in patients whose INR exceeds 3.9.[22] Because of the rising prevalence of atrial fibrillation—which is the most frequent indication for long-term therapy with vitamin K antagonists—the burden of oral anticoagulant-associated ICH is expected to rise considerably over the next several years.[14,15,16] Although more studies are needed, newer oral anticoagulants, including factor Xa inhibitors may reduce the risk for ICH when used for prevention of stroke in patients with atrial fibrillation.[23,24] High-dose aspirin has also been implicated as a risk factor for ICH risk, particularly in elderly patients with untreated hypertension.[25] Aspirin use (at doses that reduce the risk of myocardial infarction and ischemic stroke) is associated with an absolute risk increase in ICH of 12 events per 10,000 persons.[25] In a pooled analysis from 21 cohorts, aspirin use at the time of ICH onset was independently associated with increased mortality, but not with poor functional outcome.[25] The combined use of aspirin and clopidogrel further increases the risk of ICH.[25] Other risk factors for ICH have been reported, including alcohol consumption,[26,7] cigarette smoking, cocaine use,[7] high cholesterol level,[27] Vitamin E intake, and racial variations.[28,29]

Age over 80 years represents a risk factor for unfavorable outcome. In addition, hematoma volume and hematoma location contribute to prognosis and outcome.[9,8] Specifically, large infratentorial and deeply located hematomas have unfavorable prognoses.[4] ICH associated with the use of oral anticoagulants accounts for 10% to 18% of all ICH and results in particularly high rates of secondary hematoma enlargement (up to 54% of patients) and mortality (up to 67%).[10–13]

Pathophysiology

The majority of ICH (80% to 85% of all ICH) occur following the spontaneous rupture of small arteries and arterioles that are damaged by chronic arterial hypertension (up to 70% cases) or amyloid angiopathy (up to 30% cases) (FIGURES 73.1 and 73.2).[17,33] These are termed "typical" or "primary" ICH. The location of the hemorrhages is usually deep, but they may also occur in the posterior fossa (brainstem and cerebellum).[4] In the case of CAA, hemorrhage is frequently located in the occipital or parietal region.[34] Miliary aneurysms (Charcot Buchard aneurysms) and lipohyalinosis, both associated with chronic arterial hypertension, have also been proposed as etiologic factors.

The remaining cases (15% to 20% of all ICH) are categorized as "atypical" or "secondary" ICH. These are related to multiple causes, including arteriovenous malformation (AVM), cavernoma, neoplasms, aneurysms, vasculitis, Moya-Moya disease, sinus venous thrombosis, eclampsia, and coagulopathies (e.g., liver malfunction and hemophilia). They also occur in the context of trauma or ischemic stroke, and in association with oral anticoagulation and/or antiplatelet treatment (particularly when given in combination), and drug consumption (i.e., amphetamines, cocaine).

Clinical Presentation

A frequent characteristic feature of ICH is the sudden onset of focal neurologic deficits during physical activity.[1] Presentations of neurologic deficits depend on the bleeding location and hematoma volume. For example, a small hematoma in

tahir99-VRG & vip.persianss.ir

FIGURE 73.1 "Typically" located primary ICH in the left basal ganglia.

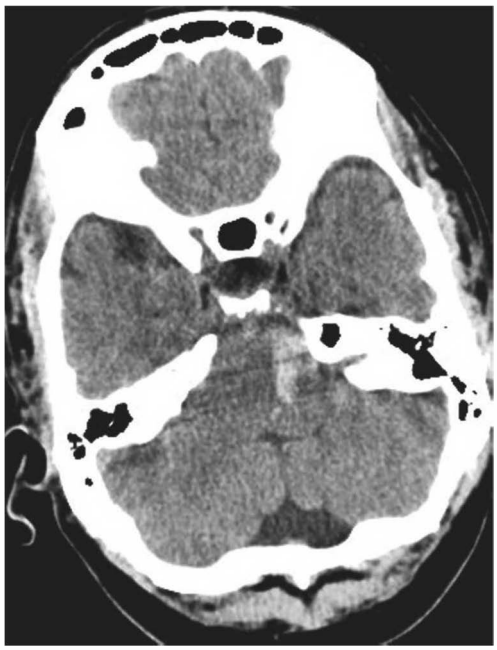

FIGURE 73.3 In this comatose patient, a brainstem hemorrhage was present. Though small in size, the bleeding caused severe symptoms including a high-grade right-sided arm paresis, ataxia, a complex oculomotoric dysfunction and dysphagia.

the brainstem (FIGURE 73.3) may produce profound neurologic deficits, whereas a similarly sized hematoma within supratentorial structures may cause only mild deficits. Bleeding in the basal ganglia may result in sensorimotor hemiparesis on the contralateral side. Bleeding in thalamic structures typically presents with paraesthesia or sensory loss. Symptoms of patients with lobar hematomas (~20% of ICH) include aphasia, neglect, hemiparesis, and hemianopia. Hematomas in frontal regions may lead to neuropsychological disorders. Brainstem symptoms, including diplopia, dysarthria, dysphagia, facial weakness, and cerebellar signs such as vertigo and ataxia can be observed in infratentorially located hematomas (see FIGURE 73.3). ICH in the brainstem or supratentorial ICH with impending or apparent herniation may lead to decreased consciousness and coma. In supratentorial ICH, unequal pupils with a dilated pupil on the side of the supratentorial hematoma (resulting from pinching the third cranial nerve to the clivus bone) indicates herniation of the temporal lobe (FIGURE 73.4). Clinical deterioration is frequent in ICH, often within the first 24 hours after onset of symptoms. Underlying mechanisms include hematoma enlargement, development of perihematomal edema, hydrocephalus, and seizures. As a result, continuous monitoring of vital parameters is indicated.

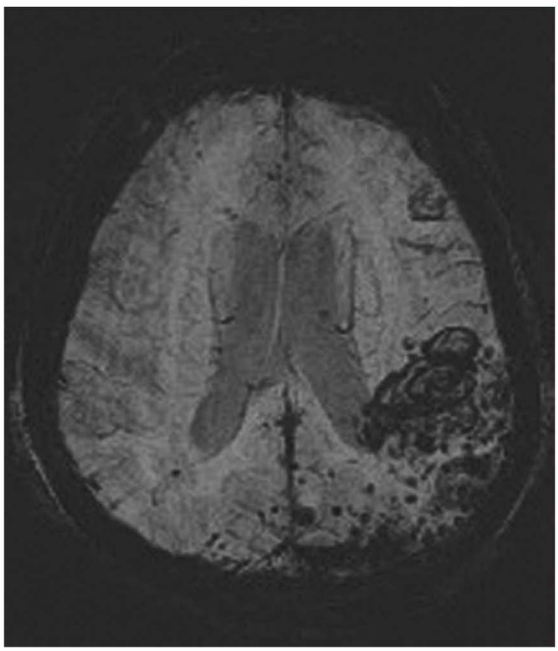

FIGURE 73.2 Cerebral amyloid angiopathy. In this patient, a left occipital ICH was seen on CT, subsequent MRI identified multiple CAA-related microhemorrhages (Susceptibility weighted images). In the CAA, depositions of b-amyloid in the media and adventitia of small- and mid-sized arteries can be found.

Diagnosis

It is important to distinguish between ICH, ischemic stroke, and subarachnoid hemorrhage (SAH). Despite efforts to establish clinical "rules" for differentiating ICH from ischemic stroke,[35] definitive diagnosis requires cranial imaging (cranial computed tomography [CCT] or magnetic resonance imaging [MRI]). The sensitivity for detecting acute ICH using noncontrast-enhanced CCT approaches 100%. Acute ICH presents as hyperdensity on computed tomography images (in patients with anemia, the hematomas may be isodense). During the course

tahir99-VRG & vip.persianss.ir

FIGURE 73.4 Large supratentorial ICH in a comatose patient presenting with a dilated pupil on the right side due to pushing of the Nervus oculomotorius to the clivus bone. Because of subsequent herniation of the temporal lobe, the patient died shortly after hospital admission.

of absorption, the hematoma becomes isodense, and finally hypodense. With the implementation of susceptibility-weighted T2* sequences in standard examination protocols, the sensitivity of MRI in detecting hyperacute and acute ICH is comparable to that of CCT.[36] In hyperacute hemorrhage, these sequences (for a 1.5-Tesla investigation) reveal characteristic hyperintense signals. In the chronic stage, hemosiderin causes a hypointense signal on T2- and T2*-weighted sequences. Whether further imaging studies (with the exception of a 24-hour scan to detect subclinical hematoma enlargement) are needed in patients with "typical" ICH (a previous diagnosis of arterial hypertension and localization of the hematoma in the putamen, pallidum, internal capsule, pons, or cerebellum) or with suspected CAA (periventricular white matter lesions) is controversial.[37] However, in younger patients without known arterial hypertension and in patients with suspected secondary bleeding (e.g., lobar bleedings or so-called "atypical" ICH) further diagnostic work-up is required to clarify the etiology of the hemorrhage. Computed tomography angiography (CTA), magnetic resonance angiography (MRA), and digital subtraction angiography (DSA) provide additional information in these patients. CTA provides a rapid and sensitive method for identifying vascular pathology, including aneurysms (>3 mm), and AVM. However, in patients with large ICH, hemodynamic changes may obscure detection of AVM by MRA or CTA. In these cases, DSA should be performed. MRA is the optimal technique for detecting underlying vascular malformations of low-pressure/venous systems (i.e., cavernoma and hemorrhagic tumors). Diagnosis of sinus venous thrombosis (which can cause secondary hemorrhage) requires venous MRA (contrast-enhanced) or DSA.

Complications

Hematoma Enlargement

The most important complication associated with ICH is enlargement of the hematoma (FIGURE 73.5). Hematoma expansion is frequently associated with neurologic deterioration and has an unfavorable outcome. The mechanisms of hematoma expansion are not fully understood. They may involve local tissue distortion, disruption of small vessels, blood-brain barrier disruption, and local coagulopathy due to the release of tissue thromboplastin.[30] ICH expansion may reflect continued bleeding or rebleeding. In approximately one-third of patients, the hematoma increases approximately 33% within the first 4 hours of onset. An additional 12% of patients suffer hematoma enlargement within the next 20 hours.[38] Different predictors of hematoma expansion have been identified: large initial hematoma volume, irregular hematoma contours, heterogeneity of density on CT images, spot signs on CTA within the hematoma, liver dysfunction, hypertension, hyperglycemia, and high alcohol consumption.[39–41,43] However, reliable radiographic predictors of ICH enlargement do not currently exist.[42]

Intraventricular Hemorrhage and Hydrocephalus

Concomitant bleeding into the ventricles (intraventricular hemorrhage [IVH]) is present in up to 40% of patients with ICH and portends a worse outcome.[30] Furthermore, IVH is frequently associated with obstructive hydrocephalus, which often requires temporary or permanent intraventricular drainage (FIGURE 73.6). Risk factors for further enlargement of IVH include baseline mean arterial blood pressure above 120 mmHg, larger baseline ICH volume, and existence of IVH on the baseline CT scan. Predictors of death or severe disability include older age, lower baseline Glasgow coma score (GCS), larger baseline ICH volume, IVH growth >2 mL, and existent IVH at baseline or at 24 hours.[44]

Perihematomal Brain Edema

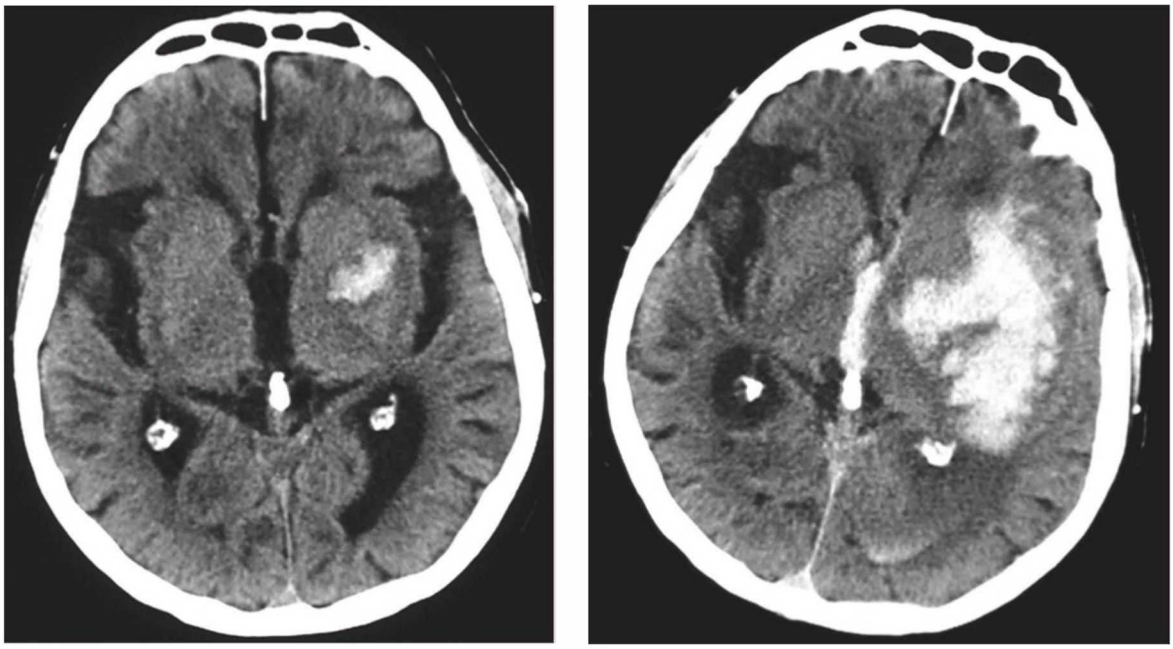
Perihematomal brain edema occurs is some patients with ICH. At one time, it was considered to represent ischemic penumbra (the term generally used to define ischemic but still viable cerebral tissue). However, the use of MRI has failed to confirm the existence of salvageable tissue. Indeed, perihematomal hypoperfusion has been shown to follow metabolic changes rather than true tissue ischemia.[47] A more likely mechanism for perihematomal brain edema is an underlying inflammatory response to the release of thrombin and other end products of coagulation from the hematoma, and secondary disruption of the blood–brain barrier.[45,46,48–50] Although studies are lacking, it is interesting to speculate that the use of anti-inflammatory drugs would mitigate this complication.[51]

Conservative Treatment

General Measures

ICH is an emergency and has to be treated as such. Although treatment options are limited, advances in supportive care have reduced mortality of these patients during the last several years. Indeed, previous studies have shown that treatment at specialized neurologic units can reduce mortality and improve functional outcome.[1] In these settings, patients may be continuously monitored for vital parameters and neurologic status using

tahir99-VRG & vip.persianss.ir



A B

Three hours after admission, the patient was found comatose with slight unequal pupils (**right < left**). The follow-up CT scan revealed massive expansion of the formerly relatively small hemorrhage **(B)**. The clinical condition further deteriorated and the patient died 26 hours after admission.

standardized scores (e.g., National Institutes of Health Stroke Scale, Scandinavian Stroke Scale, Hemphill-ICH-Score). Airway management including tracheal intubation and ventilation is frequently necessary in unconscious patients.[52] Elevated body temperature (>37.5°C) and hyperglycemia should be avoided and rapidly treated. Further aspects of general treatment are the prevention of decubital ulcerations and infections. Early mobilization and rehabilitation are recommended for clinically stable patients.[1]

Blood Pressure Management

Arterial hypertension is one of the most important risk factors for ICH and blood pressure monitoring and management is the most important aspect of ICH treatment. In ischemic stroke, aggressive lowering of the blood pressure is associated with increased neurologic deterioration.[53] However, small-volume ICH is not associated with detectable ischemic penumbra,[47] and thus the risk-benefits of treating high blood pressure in this patient population may favor such intervention. Indeed, The INTEnsive blood Pressure Reduction Trial[54] revealed that early intensive blood pressure-lowering treatment is clinically feasible, well tolerated, and seems to reduce hematoma growth in ICH. However, patients with severe injury (GCS 3-5) were excluded from this study, and it is still not known whether aggressive blood pressure reduction confers an improved clinical outcome. It is generally recommended that cerebral perfusion pressure (CPP) be monitored particularly in patients with elevated intracranial pressures, and CPP (mean arterial pressure minus intracranial pressure) should be kept above 60 to 80 mm Hg.

Hemostatic Therapy

Previous efforts have focused on the role of hemostatic agents in controlling bleeding and preventing hematoma expansion in ICH. Most of these strategies, including tranexamic acid, epsilon-aminocaproic acid, and aprotinin, have failed to demonstrate efficacy. However, the use of recombinant factor VIIa (rFVIIa) may hold more promise. A prospective randomized controlled phase IIB trial demonstrated the potential of rFVIIa to reduce hematoma expansion and to improve clinical outcome.[55] A subsequent phase III trial (FAST-Trial) confirmed that 80 μg/kg of rFVIIa IV reduced hematoma expansion significantly when given within 4 hours. However, in contrast to the Phase IIB study, rFVIIa did not improve clinical outcome,[56] and was associated with a dose-dependent increase of thromboembolic events.[57] Additional studies are needed to determine the risk-benefit profile of rFVIIa treatment according to patient age, time to treatment, volume of ICH, and presence of IVH.[58]

Treatment of ICH Related to Oral Anticoagulants

In patients with ICH associated with the use of oral anticoagulants, normalizing coagulation is of utmost urgency. Although fresh frozen plasma may be used, it requires large volumes (which increase the risk of congestive heart failure and pulmonary edema) and is associated with substantial time delays before normalization of the INR.[59,60] Thus, prothrombin complex concentrate (PCC) is preferred by many emergency physicians. PCC, a pooled plasma product containing factors II, IX, X, and (in some products) VII, can be stored in the emergency room, enabling prompt availability. However, plasma concentrations of the clotting factors can vary considerably between

FIGURE 73.6 ICH patient with isolated IVH. **A**: initial CT scan at presentation revealing a large left-sided IVH, the left ventricle is occluded by a blood clot. In this patient bilateral external ventricular drains (EVDs) were placed to anticipate obstructive hydrocephalus. **B**: Furthermore, the EVD can be used to perform intraventricular treatment with rt-PA to hasten clot lysis. Treatment with rt-PA was performed in this patient for 6 days, the CT scan on day 10 after the initial scan reveals only small blood clots in the posterior parts of both lateral ventricles **(C)**.

tahir99-VRG & vip.persianss.ir

different manufacturers and lots, and thus it is difficult to predict the dose needed to reverse the INR.[61] Though rFVIIa can rapidly normalize INR in subjects receiving anticoagulation treatment with warfarin, its effect on bleeding duration is unclear and thus routine use of rFVIIa is currently not recommended.[62,1] Treatment with coagulation factors should be combined with Vitamin K because the half-life times of coagulation factors are shorter than the half-life of warfarin. The exact time point at which the physician can safely continue oral anticoagulation after ICH in the individual patient remains unknown. It may depend on hematoma volume and location, but prospective studies with a high number of patients are needed. Given that the annual embolic risk in patients with mechanical heart valves is about 5% to 10%, discontinuation of anticoagulation for a period of 10 to 14 days seems to be an acceptable trade-off (translated 2-week risk of embolism: 0.2% to 0.4%).[63]

Treatment of ICH Related to Heparin

When ICH develops in patients being treated with unfractionated heparin, rapid normalization of coagulation (i.e., the activated partial thromboplastin time) with protamine sulfate (PS) is the treatment of choice. A relevant side effect of PS is hypotension; maximum infusion rate should not exceed 5 mg PS/min and the total dose should not exceed 50 mg of PS.[34]

Treatment of ICH Related to Fibrinolysis

Patients with ischemic stroke who have been received thrombolytic therapy with recombinant tissue-type plasminogen activator (rt-PA) may develop ICHs. While "any" hemorrhage after stroke treatment with rt-PA is found in approximately 30% of patients, symptomatic hemorrhage (as defined by the presence of clinical deterioration attributable to hemorrhage) occurs in 3% to 9% of cases.[64,65] Symptomatic hemorrhages in these patients are often serious and multifocal. Mortality at 30 days is 60% and above. To rapidly correct the systemic fibrinolytic state, platelet and factor VIII substitution is recommended.[1]

Management of Increased Intracranial Pressure

Increased intracranial pressure caused by cerebral edema and mass effects is frequently seen in patients with high-volume ICH and is associated with high morbidity and mortality. Because elevated intracranial pressure compromises CPP, it must be monitored for and treated in order to maintain a target CPP >60 to 70 mm Hg. Preventative measures include avoidance of situations that might increase the intracranial pressure (e.g., pain, fever, constipation, hyponatremia, and psychological/physical stress), treatment with sedation and analgesia, and maintenance of sufficient venous flow in the jugular veins (i.e., by positioning the head 30 degrees upright). Osmotic diuretics such as glycerol and mannitol (20%) can be used to lower elevated intracranial pressure. A risk of this approach, especially with mannitol, is excessive depletion of the intravascular volume, secondary renal failure, and rebound elevations in ICP. Therefore, serum levels of electrolytes, renal function, and osmolality must be carefully monitored (target osmolality: 300 to 320 mOsmol/L). Another approach is to administer hypertonic saline (Hyper-HAES: NaCl 7,5%; hydroxyethyl starch [HES] 6%). However, this treatment carries the risk of hypernatremia. In some patients, hyperventilation can rapidly reduce elevated ICP but the effect is transient and therefore this strategy is not useful for long-time therapy.

Management of Intraventricular Hemorrhage

Clots or compression from IVH may lead to obstruction of cerebrospinal fluid (CSF) outflow at the level of the 3rd and/or 4th ventricle and secondary hydrocephalus. In such cases, ventricular drainage may be required to prevent herniation. Ventricular drainage can also be used for administering rt-PA into the ventricles to hasten clot lysis. Indeed, preliminary data show that the use of low-dose rt-PA can be safely administered to stable IVH clots and may increase lysis rates[69] (FIGURES 73.6A-C). Although an increasing number of centers are using this approach, further studies are needed to demonstrate positive effects on clinical outcome.

Surgical Treatment

Supratentorial Primary ICH

There is little evidence that surgical intervention (beyond the placement of ventricular drains) improves patient outcome in primary ICH. The Surgical Trial in Intracerebral Hemorrhage, the largest multicenter randomized trial comparing hematoma evacuation with conservative treatment to date, failed to demonstrate an outcome benefit in the surgical group. However, *post hoc* analysis suggested that patients with superficial hematoma (<1 cm from the surface) might benefit from evacuation.[70] Based on these data, evacuation of the hematoma within 96 hours may be considered in patients with a superficial primary hemorrhage. However, very early craniotomy may be associated with an increased risk of recurrent bleeding. Although hemicraniectomy is feasible in certain patients with primary ICH,[71] its efficacy remains to be determined. Studies are currently in progress to determine the benefit of multimodality therapy, including minimally invasive surgery, clot aspiration, and local application of rt-PA.

Infratentorial Primary ICH

Little evidence exists for surgical evacuation and craniotomy in patients with infratentorial hemorrhage. Cerebellar (or brainstem) hematomas can result in serious and devastating compression of brainstem structures. At this location, hematomas may lead to compression of the 4th ventricle or the aqueduct with subsequent hydrocephalus and increased intracranial pressure. In these cases, clot evacuation or posterior craniotomy should be considered even in older patients.[1,2,72]

Other Treatment Options

Treatment options in patients with AVM and in patients with intracranial dural arteriovenous fistulae (FIGURE 73.7) usually include a combination of neurosurgery, radiotherapy, and endovascular approaches.[73] The choice of therapy depends on size, proximity to critical areas, venous drainage, and accessibility.[74] One approach that is frequently used is to reduce AVM size by endovascular embolization and radiotherapy before surgical excision. The risk of bleeding recurrence in AVM is about 18% within the 1st year.[75] The estimated annual bleeding rate for cavernoma bleedings of the low-pressure system is lower than for AVM and these bleeds are usually not life threatening. In patients with cavernomas, treatment varies from observation or radiotherapy (in patients with asymptomatic or inaccessible lesions) to surgical excision (in those with symptomatic and accessible lesions).

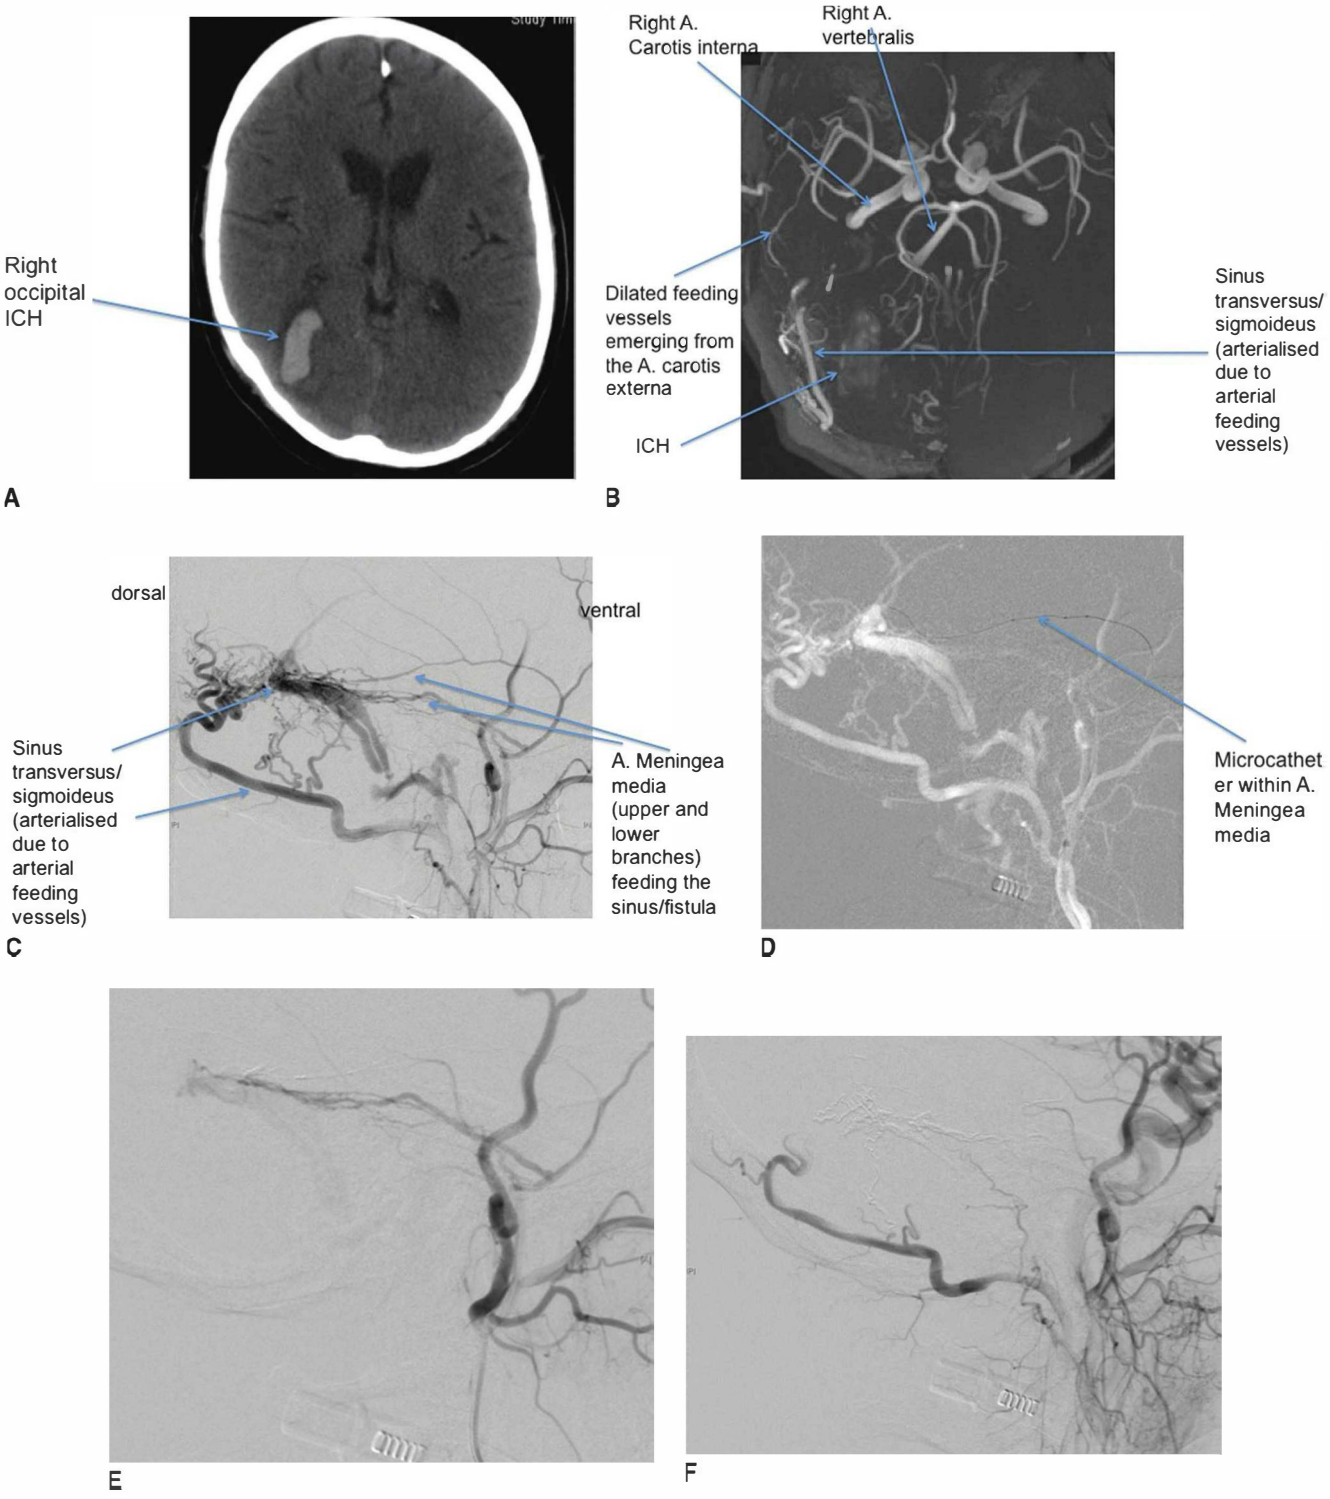

FIGURE 73.7 Series of a patient with dural arteriovenous fistula. **A**: Initial CT scan revealing an occipital ("atypical") ICH; **B**: Subsequent MRI-Angiography showing a intracranial dural arteriovenous fistula with feeding vessels from branches of the external carotid artery (A. meningea media and A. occipitalis). **C**: Initial vessel situation on angiographic images. **D**: A microcatheter placed within the A. meningea media to occlude the fistula using a liquid embolic agent. **E**: Situation after occluding the upper feeding part using a liquid embolic agent. **F**: Situation after complete occlusion.

SUBARACHNOID HEMORRHAGE

Epidemiology, Risk Factors, and Prognosis

In the majority of cases, SAH is caused by the rupture of an intracranial aneurysm. Cranial aneurysms are found in up to 5% of all autopsies. In asymptomatic individuals, MRI imaging detected an overall incidence rate of aneurysms in the general population of 6.8%, rising to 10.5% in persons with a family history of SAH.[76] However, rupture of an intracranial aneurysm causing SAH occurs in 6 to 7 per 100,000 person-years. Interestingly, the age-adjusted annual incidence of SAH considerably varies between countries: A multinational WHO study reported 2 cases per 100,000 persons in China and 22.5 per 100,000 in Finland.[77] SAH is often fatal; population-based mortality rates are as highs as 45% and the majority of deaths occur within the 1st few days after SAH.[78,79,80,81–83] Approximately 10% to 15% of patients die before reaching the hospital,[79,84] and one-third of surviving patients require lifelong care because of neurologic deficits.[84,79]

The incidence of SAH increases with age and occurs most commonly between 40 and 60 years of age (mean age 50 years).[85] Women over 40 years old are more likely to develop SAH, but under the age of 40 men are more often affected.[86,87] The risk for Africans Americans is 2.1 times that of whites[84] and the incidence of SAH increases with age, with a mean age at presentation being 55 years.[84] Modifiable risk factors include arterial hypertension, smoking,[95–98] heavy alcohol consumption,[99,33] and drug consumption.[79] Although hypertension control appears to reduce SAH severity,[100] the effect of treating modifiable risk factors on SAH occurrence has yet to be tested in randomized controlled trials.

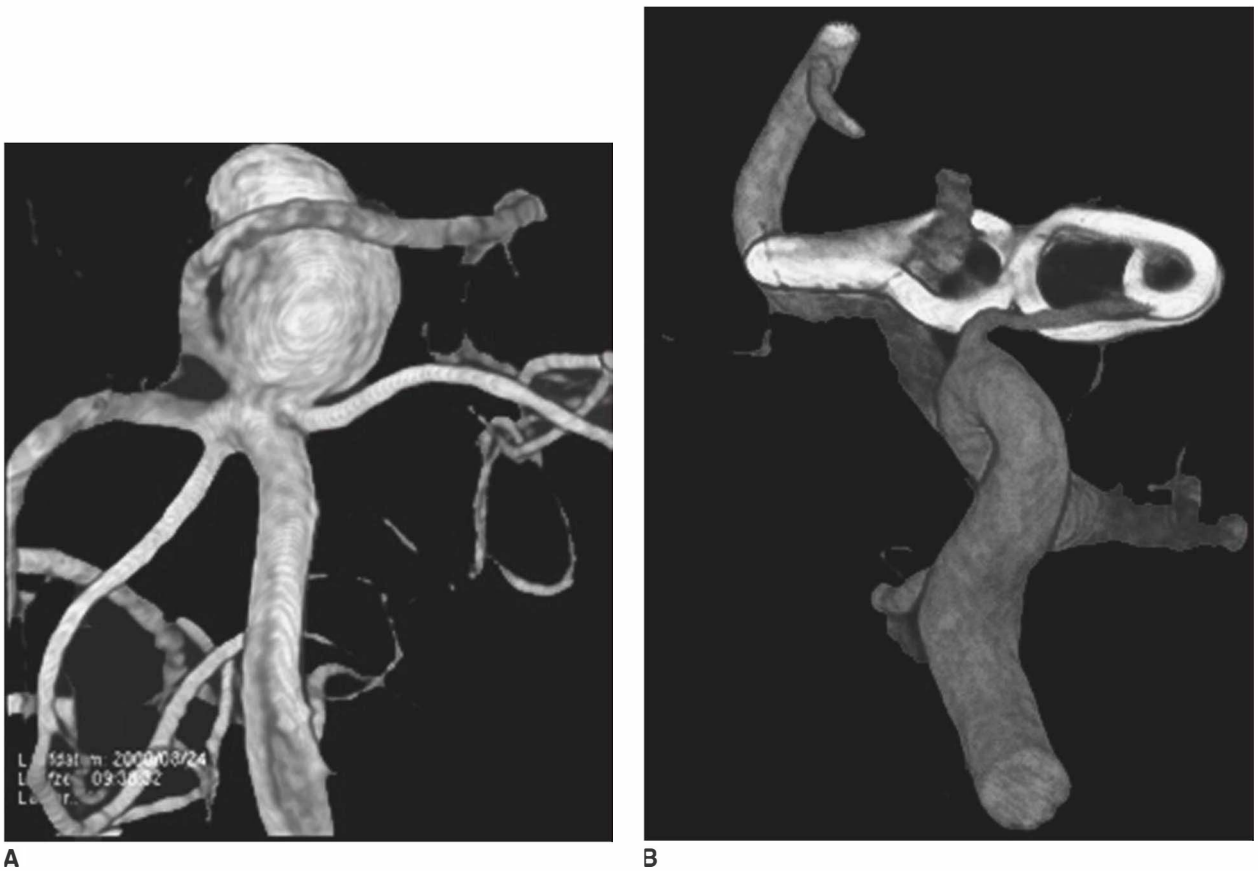
SAH is also associated with heritable disorders of connective tissue (Ehlers-Danlos disease IV, neurofibromatosis type I, Marfan syndrome) and with autosomal-dominant polycystic kidney disease.[79] Furthermore, aneurysms are frequently found on feeding vessels of AVMs.[103]

In patients with a history of a ruptured aneurysm, the annual rate of new aneurysm formation in about 1% to 2% per year[104–111] and patients with multiple intracranial aneurysms are perhaps more vulnerable to develop new aneurysms.[109,112,113] However, it remains unclear whether this is a consequence of genetic or acquired factors.

Unfavorable prognostic factors include older age, decreased level of consciousness at presentation, posterior circulation aneurysms, high quantity of blood in the subarachnoid space, and the presence of intraventricular blood.[84]

Pathophysiology and Location

Eighty five percent of all SAH are attributable to saccular aneurysms, the majority of which are located in the circle of Willis (FIGURE 73.8).[79] Approximately 10% of SAH are caused by nonaneurysmal perimesencephalic SAH (FIGURE 73.9).[79] The remaining



A B

FIGURE 73.8 **A**: Giant aneurysm of the basilar artery. **B**: Anterior communicans aneurysm after neurosurgical clipping

FIGURE 73.9 Typical prepontin SAH localization. No aneurysm was found on CTA, MRA, and conventional DSA.

5% are caused by AVM, dural arteriovenous fistula, dissection of intracranial arteries, septic aneurysms, or traumatic brain injuries (without contusion).[79] The most common sites for ruptured aneurysms are the posterior communicating artery (where it arises from the carotid artery; 41%), anterior communicating artery and anterior cerebral artery (34%), and middle cerebral artery (20%). Rupture in the posterior circulation (including the vertebrobasilar artery) is present in 15% of cases.[114] Importantly, in up to 20% of patients, multiple aneurysms can be detected.[115]

SAH can cause profound reduction in cerebral blood flow, reduced cerebral autoregulation, and acute cerebral ischemia.[124–128] Mechanisms of SAH-induced brain injury include increased intracerebral pressure with subsequent decreased CPP,[124,129,130] reduced availability of nitric oxide,[128,131] acute vasoconstriction,[125,132] microvascular platelet aggregation,[133] activation of collagenases and loss of microvascular collagen,[134] and decreased microvascular perfusion and increased permeability due to endothelial barrier antigen.[133,134] Unfortunately, advances in the understanding of the mechanisms of brain injury induced by SAH have yet to translate into therapeutic breakthroughs.

Clinical Presentation

Although the clinical presentation of aneurysmal SAH is one of the most striking and distinctive in medicine, many persons with SAH do not receive instant medical attention and many SAH cases are misdiagnosed.[88,89,90–94] Typically, patients with ruptured aneurysms report instantaneous onset of acute and severe headache ("thunderclap headache"),[116] often located in the neck and accompanied by acute nausea, vomiting, and neck stiffness. Reduced level of consciousness, hemiparesis, or other neurologic focal symptoms is common in severe SAH. In some patients, seizures or delirium are the first symptoms. Preretinal hemorrhages (Terson syndrome) may indicate an abrupt increase in intracranial pressure and is associated with increased mortality.[84] However, SAH might be missed when classic symptoms are absent. Sentinel thunderclap headaches may occur as the only symptom and reflect a "warning leak." Depending on the size and localization of the aneurysm, patients may present with single or combined cranial nerve palsy. For example, painful third nerve palsies are highly suspicious for aneurysm of the posterior communicating artery.[84] Several grading scores are available to evaluate the severity of SAH[117–121] (Table 73.1).

Diagnosis

Imaging

In almost all cases, diagnosis of SAH can be confirmed by CCT. Sensitivity of CCT decreases from 98% within the first 12 hours after onset of symptoms[79] to 50% on the 7th day.[84] Sensitivity of cranial MRI is comparable to that of CCT if performed on the 1st day.[79] CTA is the preferred tool for detecting aneurysms in SAH patients,[122,123] but additional DSA is frequently needed. Because of the possibility of three-dimensional visualization, CTA and MRA are often helpful for planning treatment especially in large or complex aneurysms.[84] However, conventional catheter angiography remains the gold standard for detecting aneurysms.[84] Because in many patients multiple aneurysms can be found, all cerebral vessels have to be carefully evaluated.[101] In patients with negative results in DSA, examination should be repeated 7 to 14 days after initial presentation if suspicion for the presence of aneurysms remains strong.[84]

Cerebrospinal Fluid

In patients with a typical clinical history of SAH and negative CCT, lumbar puncture (LP) is mandatory (presuming that no contraindications for LP are present). The CSF may be xanthochromic. Normal CSF excludes SAH within the prior 2 to 3 weeks. The value of the traditional "three tube test" whereby CSF is collected in three consecutive tubes for red cell count remains unclear.[79,84]

Complications

Vasospasm

Vasospasm of large cerebral basal arteries occurs in up to 70% of patients with aneurismal SAH. This complication typically begins 3 to 5 days after hemorrhage, peaks at 5 to 14 days, and gradually resolves over 2 to 4 weeks.[138,139] Transcranial sonography is commonly used for detecting and monitoring vasospasm.[84] Modalities such as MRI or CT with diffusion/perfusion sequences have also been shown to be advantageous in guiding the management of vasospasm.[142–144] Vasospasm is often associated with radiographic evidence of diminished brain perfusion and up to 20% of patients with vasospasm develop ischemic stroke or die despite maximal therapy.[140,141] Thus, these patients require aggressive treatment at experienced centers.

Hydrocephalus

Hydrocephalus is often observed in SAH patients. In up to 30% of cases, hydrocephalus occurs early in the course of the disease, and is more common in patients with poor clinical grade and large amounts of subarachnoid blood.[135,136] Occlusion develops when the 4th ventricle, the aqueduct, and/or the 3rd ventricle is obstructed

Table 73.1

Clinical classifications of subarachnoid hemorrhage

	WFNS		Hunt and Hess	Fisher	Modified Fisher
Grade	GCS	Focal deficit[a]		Appearance of hemorrhage	
0	N/A	N/A	N/A	N/A	No SAH or IVH
I	15	None	No symptoms, minor headache, minor neck stiffness	None evident	Minimal/thin SAH, no IVH in both lateral ventricles
II	13-14	None	Moderate to severe headache, neck stiffness, no neurologic deficit other than cranial nerve palsy	Diffuse deposition of subarachnoid blood, no clots, and no layers of blood >1 mm	Minimal/thin SAH with IVH in both lateral ventricles
III	13-14	Present	Somnolence, confusion, minor neurologic deficit	Localized clots and/or vertical layers of blood 1 mm or greater in thickness	Thick SAH[b], no IVH in both lateral ventricles
IV	7-12	Present/none	Sopor, moderate or severe neurologic deficit (hemiparesis)	Any thickness with IVH or parenchymal extension	Thick SAH[b], with IVH in both lateral ventricles
V	6-3	Present/none	Coma, signs of herniation	N/A	N/A

[b]Completely filling ≥1 cistern or fissure.

by intraventricular blood. On the other hand, hydrocephalus aresorptivus is a result of malfunctioning Pacchioni granulations, which normally reabsorb the CSF. Delayed hydrocephalus (up to weeks after onset of symptoms) is present in up to 25% of patients. Risk factors include older age, ventricular hemorrhage, poor clinical condition at presentation, and female gender.[137]

Other Complications

Additional complications in patients with SAH include seizures, pulmonary edema, cardiac malfunction, hyponatremia, inappropriate antidiuretic hormone secretion, and cerebral salt wasting.[84] The incidence of bleeding recurrence is particularly high within the first 2 weeks[84] and case fatality rates in these patients are up to 70%.[101] Thus, a critical therapeutic goal in all patients is to prevent rebleeding by early aneurysmal occlusion (by surgical or endovascular means).[101]

Conservative Treatment

General Measures

SAH is a serious medical emergency and patients should be treated in neurologic or neurosurgic critical care units at centers with neurovascular expertise. The main goal of treatment is to prevent medical and neurologic complications. Hypertension may increase the risk of rebleeding. Although controlled studies are lacking, monitoring and treating blood pressure to maintain CPP is recommended.[101] Antifibrinolytic therapy to prevent rebleeding in SAH has been investigated. Although older studies demonstrated overall negative effects of antifibrinolytic agents, recent evidence supports the use of an early, short course of antifibrinolytic agents in combination with other therapeutic modalities.[101] While oral treatment with the calcium antagonist nimodipine is indicated to reduce poor outcome in aneurysmal SAH patients,[145] treatment is recommended in all patients with SAH. The value of other calcium antagonists remains uncertain.[101]

Management of Vasospasm

Treatment of vasospasm starts with early management of the ruptured aneurysm.[101] If vasospasm is present, a reasonable approach is to employ the so-called triple-H therapy (hypervolemia, hypertension, hemodilution) to enable sufficient cerebral perfusion and oxygenation.[101] Catecholamines (e.g., dobutamine and norepinephrine) may be needed to achieve higher systolic pressures (up to 240 mm Hg). Because of the risks associated with aggressive therapy (e.g., pulmonary edema, cardiac failure, cerebral edema, rupture of aneurysm, and electrolyte imbalances), these patients should undergo occlusion of the aneurysm and be carefully monitored and followed in critical care units.[84] Another approach for controlling vasospasm is cerebral angioplasty and/or selective intra-arterial vasodilator therapy in combination with or alternatively to triple-H therapy.[101]

Management of Hydrocephalus

For acute chronic hydrocephalus, intermittent external ventricular catheter drainage is required to prevent increased intracranial pressure with subsequent brain tissue damage and herniation. In cases of chronic hydrocephalus, ventriculo–peritoneal or ventriculo–cardiac shunts are frequently necessary to prevent further brain damage.[84]

Surgical and Neuroradiologic Treatment

Because of the high risk of early rebleeding in aneurysmal SAH, which is often associated with fatal outcome, aneurysm occlusion should be performed early and is indicated as secondary prophylaxis in most cases.[101] Occlusion should be performed prior to the development of vasospasm (i.e., within the first 72 hours). Two types of treatment are available for patients with ruptured intracranial aneurysms: endovascular detachable-coil treatment and neurosurgical intervention with craniotomy and clipping. The multicenter international subarachnoid aneurysm trial reported that in patients who are suitable for both treatments, endovascular coiling is more likely to result in independent survival at 1 year than neurosurgical clipping.[146] However, the risk of late rebleeding was higher after endovascular coiling than after neurosurgical clipping.[146] While randomization of patients was based on the "uncertainty principle," older patients (>70 years) and patients with posterior aneurysms and aneurysms of the media cerebellar artery were underrepresented in the study. Therefore, the decision to use an endovascular or neurosurgical approach should be made on an individual basis.[101] Rebleeding is increased in incompletely wrapped, coated, clipped, or coiled aneurysms; aneurysms should be completely obliterated whenever possible.[101]

Primary Prophylaxis

While the prognosis of SAH is poor and the frequency of asymptomatic aneurysms is relatively high, elective screening has been discussed but is currently only recommended on an individual basis.[101] The management of patients with proven unruptured aneurysm remains controversial.[102]

CHAPTER

74 Retinopathy

JING CHEN, ANDREAS STAHL, AND LOIS E. H. SMITH

The eye is one of the most important sensory organs that enables us to perceive the environment to ensure species survival. The light-sensitive part of the eye, the retina, is composed of several transparent neuronal layers and functions similarly to a film in a camera. Light focused through the cornea and lens passes across the transparent retinal layers to interact with light-sensitive pigments in the photoreceptor outer segments, causing a signal transduction cascade. The signal generated in the photoreceptor ultimately propagates a series of action potentials across the retina, through the optic nerve to the neurons in the visual cortex of the brain, and results in the perception of an image (FIGURE 74.1). The essential function of the retina in light perception and processing is dependent upon a well-organized nonleaky vascular network that supplies vital oxygen and nutrients and clears waste. In retinal vascular diseases, the normal function of the ocular vasculature is disrupted, often leading to loss of barrier function with resulting plasma exudation and hemorrhage and, in most severe cases, disturbance of retinal neuronal function and loss of vision.

Epidemiologic studies have shown that proliferative diabetic retinopathy (PDR) accounts for the highest incidence of acquired blindness in the working-age population[1,2]; choroidal (subretinal) neovascularization in age-related macular degeneration (AMD) represents the leading cause of blindness in people over the age of 65[3,4]; and retinopathy of prematurity (ROP) is a major cause of acquired blindness in children[5] (FIGURE 74.2). In addition, there are many other ocular diseases that have a vascular component, such as retinal vein occlusion (RVO), Norrie disease, familial exudative vitreoretinopathy (FEVR), Coats disease, sickle cell retinopathy, retinitis pigmentosa, and others. This chapter summarizes our current knowledge of the physiology of the ocular vasculature and pathophysiology of several common vascular eye diseases, as well as cellular and molecular mechanisms that regulate the growth of ocular vessels.

OCULAR VASCULATURE IS COMPOSED OF THREE SEPARATE VASCULAR BEDS: HYALOIDAL, CHOROIDAL/UVEAL, AND RETINAL VESSELS

Hyaloid Vasculature

The hyaloid vasculature is a transient embryonic vascular bed that develops during embryonic and fetal stages to provide blood supply to the developing eye. The hyaloid vascular plexus originates from the optic nerve, extends through the primitive vitreous, and surrounds the developing lens. The hyaloid vessels eventually regress with completion of eye development, usually before 34 weeks of gestation in humans. In rare diseases such as Norrie disease and FEVR, the hyaloid vasculature fails to regress, resulting in persistent fetal vasculature, which is associated with poorly developed neural retina and impairment of vision.

Choroidal Vasculature

The choroidal vasculature is part of the uveal system of vessels that perfuse the iris, ciliary body, and choroid (FIGURE 74.1). During optic cup development, the primitive choroidal vascular system is formed from the surrounding mesoderm. Later, following the development of retinal pigment epithelium (RPE), this primitive vascular layer expands further,[6] until the capillaries completely encircle the optic cup. A definitive choriocapillaris layer appears at around 8 to 12 weeks of gestational age.

The choroidal vasculature consists of larger posterior vessels and a small-caliber anterior choriocapillaris (FIGURE 74.2), adjacent to the RPE. The choriocapillaris is a sinusoidal vascular plexus and is the site of the greatest blood flow (65% to 85%) in the eye.[7] The choriocapillaris provides oxygen and nutrients to the outer retina, particularly the RPE and photoreceptors that have the highest metabolic rate in the body and therefore have a very high oxygen demand. The choriocapillaris is highly fenestrated and allows blood flow beneath the basal surface of the RPE that digests shed photoreceptor outer segments and clears other photoreceptor waste. The RPE with tight junctions on the apical surface adjacent to the photoreceptors constitutes the outer blood retinal barrier (BRB). Similar to the blood brain barrier, the BRB is vital to preserve tissue integrity and function of the retina. The inner BRB is formed by vascular endothelial cells of the inner retina with tight junctions. The endothelial cells abut Müller cell endfeet and pericytes. This inner BRB is compromised in diabetic retinopathy, leading to retinal edema and often severe visual impairment. In exudative AMD in contrast, it is the outer BRB that is compromised when choroidal blood vessels (without tight junctions) grow through Bruch membrane and into the subretinal space, breaking through the RPE's BRB. This leads to edema of the macula, the part of the retina that is responsible for central vision and higher visual functions like reading or recognizing faces.

Retinal Vasculature

In the eye, 20% to 30% of blood flow is supplied by the retinal circulation, serving mainly the inner retina. In humans, retinal vascularization starts *in utero* at about 16 weeks of gestational age and is completed at approximately 40 weeks of gestation, right before birth. The retinal vessels develop as the hyaloid vessels regress. During development, retinal vessels grow first in the most superficial (i.e., innermost) layers of the retina and

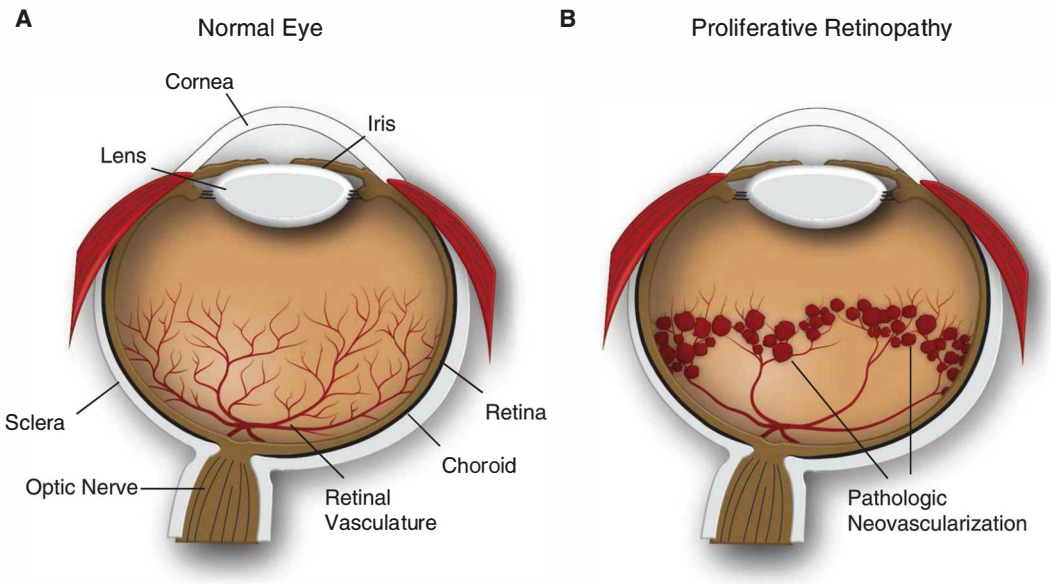

FIGURE 74.1 Schematic illustration of **(A)** normal eye and **(B)** proliferative retinopathy with pathologic neovascularization.

sprout radially from the optic nerve toward the ora serrata, the peripheral edge of the retina. They reach the nasal side of the ora serrata at about 36 weeks of gestational age, and the temporal retina at approximately 40 weeks of gestational age. As the superficial layer is almost completed, retinal vessels dive into the retina to form first a deep and then an intermediate layer along with a well-organized network of interconnecting vessels to complete three vascular layers: a superficial vascular layer that lies in the inner part of the nerve fiber layer, an intermediate layer in the inner plexiform layer, and a deep layer in the outer plexiform layer.[8] Similar to the RPE, the retinal vessels maintain BRB integrity.[9]

Under pathologic conditions when the BRB is disrupted, the retinal vessels become more permeable resulting in retinal edema and vision loss. This is seen with ROP and diabetic retinopathy, when retinal vessels proliferate to form fragile leaky neovessels. RVO is also a common retinal vascular disease. In the early stages of RVO, plasma leakage and hemorrhage is due to increased intraluminal pressure in the obstructed vein; in later stages it is due to vascular endothelial growth factor (VEGF)-induced proliferation of leaky neovessels and VEGF-induced increased permeability of normal vessels.

Among these three blood vessel systems in the eye, the inner retinal vasculature is the most extensively studied. The retina is an excellent model of vascular development, vessel remodeling, and vascular maturation. Studies of retinal vasculature have greatly expanded our basic understanding of the factors that regulate normal and pathologic vascularization including the relationship between oxygen and retinal vascular growth.

OXYGEN REGULATES BLOOD VESSEL GROWTH IN THE EYE

The hypothesis that oxygen-sensitive molecules control the development of retinal vasculature originates from early observations that capillaries grow more profusely near venules carrying oxygen-depleted blood than around arteries with fully oxygenated blood.[10–12] The vascular pattern of some eye diseases also supports the idea that oxygen (or lack of it) regulates blood vessel growth in the retina. Pathologic retinal angiogenesis in ROP and diabetic retinopathy is preceded by an initial loss of retinal vessels with resulting retinal ischemia, suggesting that hypoxia is an important stimulator of new blood vessel growth.[13] The timing and spatial pattern of normal retinal vascularization is coordinated with the differentiation, maturation and increasing metabolic demand of neural and glial cells. The wave of maturation of neural retina creates a moving wave of "physiologic hypoxia" that guides the development of new vasculature from the center toward the periphery of the retina.[14] VEGF, an essential growth factor for vascular growth and

survival is induced in a pattern that coincides with retinal blood vessel development both temporally and spatially.[15,16,17] As new vessels form, bringing oxygen and suppressing VEGF, the wave moves forward toward the developing retina.

Retinal Tissue Senses Oxygen Tension through Hypoxia-Inducible Factor

The increased expression of VEGF and some other blood vessel growth factors in response to low tissue oxygen levels is mediated in large part through the transcription factor hypoxia-inducible factor 1 (HIF1), which functions as a global regulator of O_2 homeostasis.[18–20] HIF1 is a heterodimeric protein composed of an oxygen-sensing α unit and a constitutively expressed transcription activating β subunit. Under normoxic conditions, a proline residue in HIF1α is hydroxylated by Egl9 enzyme, facilitating the interaction between HIF1α and von Hippel-Lindau protein, resulting in the ubiquitylation and proteasomal degradation of HIF1α.[21–23] Under hypoxic conditions, HIF1α escapes prolyl hydroxylation and dimerizes with HIF1β. The HIF1 heterodimer then translocates to the nucleus and activates target genes by binding to a hypoxia responsive element in the promoter region.[18] In addition to VEGF, erythropoietin (Epo) is an important target gene of HIF1 that plays an important role during retinal blood vessel homeostasis.[24,25,26] Epo is a glycoprotein hormone that is best known for its stimulation of erythropoiesis. However, Epo has also potent neuroprotective and proangiogenic effects. In the vitreous of patients with diabetic retinopathy,[26,27] ROP[28] or RVO,[29] Epo is upregulated along with VEGF, which is one of the master regulators of both normal retinal vessel development and proliferative retinopathies.[15,30,31]

VEGF Guides Retinal Vascularization Following an Astrocytic and Neuronal Template

Although tissue oxygen tension is an essential stimulus for retinal vessel growth, hypoxia alone does not generate the organized pattern of retinal vascularization and the structural alignment among retinal vessels, astrocytes and neurons that is seen during normal retinal development. It has been suggested that several other cellular guides contribute to this highly organized pattern of retinal vessel growth. Astrocytes grow along the inner surface of the retina preceding the vessels. It is assumed that this astrocytic template secretes VEGF and other factors in a tightly controlled manner to create a highly specialized micro milieu to guide the filopodia of sprouting endothelial cells in the right direction.[8,32–34] It is also postulated that the relative hypoxia of the deeper retinal layers during development results in a VEGF gradient that favors sprouting from the superficial layer downward, resulting in the formation of first the deep and then the intermediate layers of capillary networks.[15,16] If the astrocytic template guides vascular growth in the retina, what is it that guides the formation of the astrocyte template during retinal development? One theory postulates that astrocyte growth follows the radially oriented ganglion cell axons,[8,33] which synthesize platelet-derived growth factor (PDGF) to stimulate astrocyte growth and alignment.[35] The radial cellular pattern in the retina is likely to result from complex and highly regulated reciprocal cellular interactions: retinal neurons serve as the primary template and secrete PDGF to stimulate astrocyte growth and patterning; astrocytes in turn respond to increasing hypoxia during retinal maturation by increasing the synthesis and secretion of VEGF to induce and sculpt the formation of a retinal vascular plexus. When the vascular plexus becomes functional, it alleviates tissue hypoxia, decreasing VEGF expression and limits further excessive vascular growth.[36,37]

Remodeling of Retinal Vasculature Is Also Dependent on Oxygen

Once formed, the superficial layer of retinal vessels is remodeled before sprouting to the deeper layer,[38] which is regulated by the specific needs of the local tissue for oxygen and nutrients. Maturation of the superficial plexus leads to a less dense network with finer vessels compared to the structures formed during early development. Relative hyperoxia around arteries is considered an important factor for pruning of existing vasculature. Local hyperoxia would lead to local suppression of VEGF, which is an endothelial survival factor for immature capillaries. Reduction of VEGF leads to regression of these immature capillaries in areas with excess vasculature.[39,40] Leukocytes from the circulation also participate in vessel remodeling through induction of endothelial cell apoptosis, a process considered most relevant in the context of early vessel loss in diabetic retinopathy.[38]

VEGF during Development of the Choroidal Vasculature

Choroidal vascular development is less well studied than the development of the retinal vasculature. Clinically the retinal vasculature can be readily observed funduscopically in humans, while the choroidal plexus is blocked from view by a dense layer of pigmented RPE cells. Furthermore, in animal models, retinal vasculature development can readily be studied due to the postnatal development of retinal vessels in rodents. Retinal flat mounts expose retinal vessels well. The choroidal vasculature, in contrast, is less readily quantifiable during development. Nevertheless we know that formation and maturation of the choroidal vasculature is tightly associated with signals produced by RPE cells.[41] In particular, VEGF is highly expressed by RPE cells at the time of choriocapillaris formation,[42,43] suggesting involvement of RPE-derived VEGF in the development of choroidal vessels. Furthermore, in colobomas, failure of RPE differentiation results in defective development of the choroid and sclera,[44] and in patients with exudative AMD, degeneration of RPE cells and associated overproduction of VEGF leads to pathologic activation and sprouting of the normally quiescent choriocapillaries.

VEGF and Wnt Signaling during Formation and Regression of the Hyaloid Vasculature

The hyaloid artery penetrates into the optic cup in early development and extends through the vitreous to form branches that envelop the forming lens. Retinal vasculature development coincides with hyaloid vessel regression.[6,45] The mechanism governing both formation and regression of hyaloid vessels is still incompletely defined. VEGF was suggested to trigger the growth of hyaloid vessels because VEGF is expressed in the portion of the lens closest to the forming vessels.[42,46,47] In addition, patients

with VEGF-induced endothelial cell hyperplasia also have disorganized and persistent hyaloid vessels, further supporting a role of VEGF in hyaloid vessel formation.[48]

Interestingly, an entirely different process has been uncovered for hyaloid vessel regression (and retinal vascular formation) from studies investigating a group of rare hereditary eye diseases, Norrie disease, and FEVR. These diseases have in common persistent hyaloid vessels and incomplete formation of the retinal vasculature with a lack of a deep retinal plexus formation.[49] They arise from a number of mutations in the canonical Wnt-β–catenin signaling pathway: Wnt ligands Norrin or Wnt receptors Frizzled4 and Lrp5 are involved and mediated in part through macrophages.[50,51]

OCULAR DISEASES WITH VASCULAR PATHOLOGY

Many retinal eye diseases result from disruption of the normal blood supply. The subsequent hypoxia often triggers pathologic neovascularization. In diabetic retinopathy and ROP, abnormal proliferating retinal vessels extend into the vitreous. In AMD, choroidal vessels can proliferate pathologically into the normally avascular subretinal space. RVO is another common eye vascular disease, which in its late stages can lead to pathologic retinal vessel proliferation. The following sections discuss the clinical features of these common ocular vascular diseases and our current understanding of the pathogenesis and treatment options.

Retinopathy of Prematurity

ROP is a major cause of blindness in children in the developing and developed world despite current surgical and laser treatment in the late stage of the disease.[52] Formerly known as retrolental fibroplasia, ROP was originally described in the 1940s when the condition was first connected with oxygen supplementation after premature birth.[53] Initially, no treatment was available. Major advances came in the 1980s, when cryoablation of avascular retinal areas was shown to be partially effective in preventing blindness in ROP infants.[54] Laser photocoagulation soon supplanted cryotherapy.[55] However, although ablation treatment can reduce the incidence of blindness by approximately 25% in infants with late-stage disease, it does not improve the chances of good visual acuity. Preventive and less destructive therapies for ROP are thus highly desirable.

Risk Factors of ROP

ROP was associated with excessive oxygen use shortly after the initial description of the disease.[56,57] Controlled supplemental oxygen is now delivered to premature infants to maintain adequate blood levels of oxygen but at the same time limit the development of ROP.[58] However, even with monitored oxygen use, the incidence of ROP has increased over the last decades, probably due to the increased survival of infants with very low birth weight.[59] Oxygen use, early gestational age and low birth weight are major risk factors for ROP.[60–62] However, the postnatal factors of low postnatal weight gain, as well as low insulin-like growth factor (IGF)-1 blood levels are as important as gestational age and birth weight in determining ROP progression, as well as increased blood glucose level, which is also recognized as a risk factor.[63–69]

Pathogenesis of ROP: Two Phases

ROP is a biphasic disease consisting of an initial phase of impaired retinal vessel growth followed by a second phase of vascular repair that is—in severe cases—accompanied by pathologic vessel proliferation in the retina and often into the vitreous. Infants born prematurely have an incompletely vascularized retina at birth. During the first phase of ROP, the peripheral avascular zone of premature infants becomes vascularized too slowly to keep up with the rising metabolic demand of the maturing neurosensory tissue. The severity of ROP is to a large extent determined by the size of avascular retina (FIGURE 74.3), which in turn is dependent on gestational age at birth. The earlier an infant is born, the less vascularization of the retina has occurred. In addition to prematurity, a hyperoxic environment relative to that found *in utero* and additional oxygen treatment, which is often needed for survival of prematurely born infants, contributes to the slowing (or even cessation) of normal vascular growth. *In utero*, the normal PaO_2 is 30 mm Hg, compared to a PaO_2 of 60 to 100 mm Hg of an infant breathing room air.[70] As a consequence, *in utero* the blood is only approximately 70% saturated with oxygen compared to 100% in infants in room air. This first phase of impaired retinal vascularization signifies the first phase of ROP, which spans from birth to about 30 to 32 weeks of gestational age.

During the second phase of ROP, the retina changes from hyperoxic to hypoxic. It is believed that this change is induced by increased metabolic demand of the maturing neurosensory retina. During this phase neuronal and glial cells in the avascular areas of the peripheral retina are oxygen and nutrient deficient. This local tissue hypoxia leads to upregulation of proangiogenic growth factors that induce the ingrowth of new blood vessels. This second phase of ROP, characterized by hypoxia-triggered increased blood vessel growth, begins around 32 to 34 weeks of gestational age. However, in severe cases of ROP, with large avascular areas, the upregulation of angiogenic factors is excessive and induces not only organized growth of functional vessels but also uncontrolled sprouting of pathologic vessels in the retina and from the retina proper into the normally avascular vitreous. These preretinal neovessel proliferations are very similar to the pathologic neovascularization seen in other proliferative

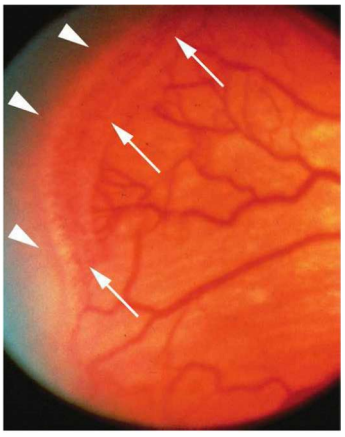

FIGURE 74.3 Fundus image from an infant with retinopathy of prematurity (ROP). *Arrows* indicate the prominent ridge demarking the vascularized retina from the avascular peripheral areas (*arrowheads*).

retinopathies such as diabetic retinopathy or the late stages of RVO. Several severe complications can arise from these pathologic neovessels: first, the preretinal nature of some of these neovessels exert tractional forces leading to detachment of the retina from the underlying RPE; second, the unorganized structure of these neovessels leads to plasma leakage and bleeding into retina and/or vitreous. These complications can lead to blindness or severe visual impairment. Even with treatment, patients who progress to these severe stages of ROP have usually extremely limited chances of developing normal or near-normal visual function.

VEGF in ROP

VEGF is an oxygen-regulated factor essential for normal retinal vascular development and important in ROP. As one of the most potent proangiogenic molecules, [71,72,73] VEGF can be secreted by a wide variety of cell types in hypoxic conditions.[74,75,76] Elevated VEGF levels are found in the vitreous of patients with retinal neovascularization,[75,77] including those with ROP.[78] In the neovascular second phase, antiangiogenic treatment using an anti-VEGF aptamer or anti-VEGF antibodies or antibody fragments might be beneficial. However, although anti-VEGF therapies have produced beneficial results in patients with neovascular AMD, the efficacy and safety of anti-VEGF treatments in ROP have still to be determined. As a consequence, anti-VEGF therapy in the second stage of ROP cannot be recommended at the time of writing as too little data exists on potentially severe side effects of anti-VEGF treatment in premature infants.

Growth Hormone and Insulin-like Growth Factor in ROP

The fact that prematurity is one of the most significant risk factor for ROP suggests that factors involved in growth and development are critical for ROP development. GH and IGF-1, which mediates many of the mitogenic aspects of GH, are both oxygen-independent growth factors. A pituitary hormone was associated with the development of retinal neovascularization after pituitary ablation was found to have an ameliorative effect on PDR.[79–81] Studies in animal models of ROP then found that GH mediated through IGF-1 is important in the development of retinal neovascularization. These studies identified a molecular mechanism by which IGF-1 modulates VEGF effects during retinopathy.[31,82]

IGFs (IGF-1 and IGF-2) are important in fetal growth and development during all stages of pregnancy.[83] Serum concentration of IGF-1, but not IGF-2, increases with gestational age and correlates with fetal size.[84,85] IGF-1 levels rise significantly in the third trimester of pregnancy.[83] After preterm birth of infants, IGF-1 levels fall from the *in utero* levels due to the loss of IGF-1 provided by the placenta and the amniotic fluid. In age-matched premature babies, mean serum levels of IGF-1 are directly correlated with the severity of clinical ROP[66–68,86] and low postnatal serum IGF-1 levels are at least as strong a determinant of risk for ROP as gestational age at birth and birth weight.[66,67] Low postnatal serum IGF-1 levels in preterm infants also correlate with slower brain growth and might account for abnormal neural retinal function in ROP.[68] In patients with genetic defects of the GH/IGH-1 axis, very low levels of IGF-1 directly cause decreased vascular density in the retina as evidenced by fewer vascular branching points.[87] This accumulated evidence suggests that early low serum IGF-1 levels are associated with vessel loss and may be contributing to early vessel degeneration in phase I of ROP that sets the stage for hypoxia leading later to proliferative retinopathy. Early restoration of IGF-1 to uterine levels might prevent ROP development by allowing normal retinal vascular development.

Based on the understanding of the roles of VEGF and IGF-1 in both phases of ROP, a rationale for the evolution of the disease has emerged (FIGURE 74.4). Retinal vessel growth requires both IGF-1 and VEGF. In premature infants, IGF-1, which is normally supplied by placenta and the amniotic fluid, is at very low levels after birth since the premature liver cannot replace the loss. Blood vessel growth therefore slows or stops since IGF-1 is needed to allow maximum VEGF signaling for vascular endothelial growth and survival. With oxygen levels higher than *in utero*, particularly with oxygen supplementation, VEGF is suppressed. Thus, both prematurity and oxygen contribute to the suppression of normal vessel growth and vessel loss in phase I of ROP. As the infant grows and the retina matures without an adequate vasculature to supply oxygen, it becomes oxygen starved, which increases expression of VEGF. In the meantime, as the infant's organs and systems continue to mature, IGF-1 levels rise slowly, eventually reaching a level that allows VEGF signaling to stimulate blood vessel growth. The result is the destructive neovascular proliferation in the phase II of ROP, with blinding consequences.

Current and Future Therapeutic Targets for Treating ROP

Although ROP in most infants regresses spontaneously, in severe cases ablation of avascular retina (which supplies angiogenic factors) is required to prevent loss of vision. This was achieved

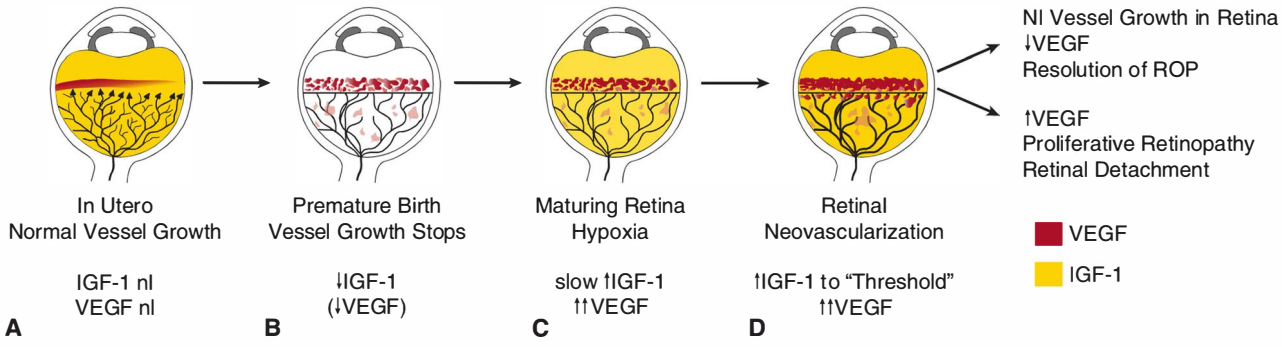

FIGURE 74.4 Schematic representation of IGF-I/VEGF control of blood vessel development in retinopathy of prematurity (ROP): **(A)** *in utero*, **(B)** premature birth, **(C)** retinal maturation, **(D)** retinal neovascularization. Nl: normal.

with cryotherapy in earlier years and has been replaced by laser photocoagulation, which is less invasive and can be more precisely controlled. Recent advances in ROP research suggest a number of new ways to medically intervene in ROP progression. The extent of the second destructive phase of ROP is determined by the amount of avascular retina in phase I. Therefore addressing the problem of persistent avascularity in peripheral retina by promoting increased functional vascularization of the postnatal retina is a very appealing approach to treat ROP. Systemic replacement of IGF-1 to those levels found *in utero* might prevent the disease by allowing normal vascular development after premature birth. This physiologic approach has been taken in a clinical trial to evaluate supplementation of IGF-1 (and IGFBP-3) to *in utero* levels with neurologic development and ROP severity in premature infants evaluated as primary outcomes.

The current understanding of ROP pathogenesis also makes clear that timing is critical in any medical intervention, since the two phases of ROP require very different approaches. Inhibition of either VEGF or IGF-1 in the second phase might prevent pathologic neovascularization while inhibition of either growth factor early after birth can—at least theoretically—severely impair normal blood vessel growth. On the other hand, providing VEGF or IGF-1 early might promote vessel growth, whereas late supplementation in the neovascular phase might exacerbate destructive neovessel formation. In the fragile neonate, any intervention must be made very carefully. Any approach to medically intervene in ROP must therefore be closely monitored and ideally should be guided by measurement of individual growth factor levels with a return to normal physiologic levels at each phase as the goal.

Diabetic Retinopathy

Diabetic retinopathy is one of the major complications of diabetes and in its late stages often progresses to proliferative disease.[88] It is the most frequent cause of legal blindness in the population of 30 to 70 year olds. Before the advent of intensive insulin therapy with the goal of near normalization of blood glucose levels, diabetic retinopathy afflicted over 90% of diabetic patients after 20 years of disease.[89,90] Despite the importance of tight glycemic control in the prevention of retinopathy shown in these clinical studies, it is not possible to achieve this goal in all patients. Diabetic retinopathy remains a persistent complication, especially with the increasing epidemic of obesity and type II diabetes.

Risk Factor of Diabetic Retinopathy

Both type I and type II diabetic patients are at risk of developing diabetic retinopathy. After 20 years of disease, nearly all type I diabetic patients and about 60% of type II diabetic patients develop some stage of retinopathy. Poor glycemic control, high cholesterol, and smoking are all associated with higher risk. In addition, pregnancy may also cause a rapid increase in progression of diabetic retinopathy. Genetic factors also play a role as diabetic patients with Down syndrome almost never develop diabetic retinopathy, possibly due to protection from elevated level of antiangiogenic endostatin.[91]

Pathogenesis of Diabetic Retinopathy

The development of diabetic retinopathy is a slow process that can occur over decades in two phases, nonproliferative retinopathy and proliferative retinopathy. Nonproliferative retinopathy or background retinopathy can be seen as early as 1 year after diabetes onset and begins with slow vessel destruction with vascular basement membrane thickening, pericyte loss, increased leukocyte adherence, and the development of microaneurysms and acellular capillaries. Visual loss is not usually associated with these early changes in retinal vessels. However, increased vascular permeability can lead to exudation of plasma into the retinal tissue and vision-distorting central macular edema. As the disease progresses, vascular occlusion is seen not only in retinal capillaries but also in larger venules and arterioles. The midstage of this disease is characterized by capillary nonperfusion, increased vessel tortuosity, leakage resulting in intraretinal exudates, retinal infarcts (cotton wool spots), as well as areas of hemorrhage (FIGURE 74.5). All these changes lead to vascular dysfunction and poor perfusion, resulting in retinal ischemia and hypoxia, which sets the stage for the second phase of the disease, abnormal vasoproliferation.

In patients with PDR, the nonperfused retina becomes hypoxic, which in turn leads to an increased expression of hypoxia-induced angiogenic growth factors including VEGF to trigger retinal neovascularization. The new vessels growing on the surface of the retina or into the vitreous are fragile and have increased permeability, increasing the risk of vitreous hemorrhage and retinal edema (FIGURE 74.5). Formation of fibrous membranes, associated with this preretinal pathologic neovascularization, can cause traction on the underlying retina and lead to retinal detachment and potential blindness. The proliferative stage of diabetic retinopathy is in many aspects similar to the proliferative stage of ROP. However, the underlying pathologies that initiate vessel loss in the first phase of each disease differ significantly. In ROP, premature birth with all its associated changes in oxygen and loss of factors normally provided *in utero* dictates progression of retinopathy; in diabetic retinopathy, progression in phase I is significantly determined by the quality of glycemic control, by dyslipidemia and by endocrine dysfunction.

High blood glucose levels (or rapid changes in glucose levels) are associated with many alterations in cellular metabolism, including vascular endothelial dysfunction.[92] Polyol accumulation in experimental hyperglycemia is associated with a thickened basement membrane, pericyte loss, and formation of microaneurysms.[93] This pathway converts excess intracellular glucose into sugar alcohols via aldose reductase, resulting in increased sorbitol level that in turn is hypothesized to damage vascular cells. Formation of advanced glycation end products, nonenzymatic binding of glucose to protein sides chains, is another well-characterized pathway linked with pericyte loss and microaneurysm formation in diabetic retinopathy.[94] Hyperglycemia can also lead to oxidative stress and increased formation of reactive oxygen species,[92] which may cause vascular damage. In addition, chronic activation of protein kinase C (PKC) in hyperglycemic conditions is associated with perturbed vascular cell homeostasis including increased vascular permeability, contractility, and apoptosis.[95] PKC is activated by the overflow of glycolytic intermediates into synthesis of diacylglycerol, which is a potent stimulus for PKC. Together these processes are thought to modulate diabetic retinopathy progression through their effects on cellular metabolism, as well as production and signaling of growth factors such as VEGF, GH, IGF-1, transforming factor β (TGF-β), and pigment epithelium-derived factor (PEDF) that can all modulate the angiogenic process in the retina.

Growth Factors in Diabetic Proliferative Retinopathy

Increased levels of angiogenic growth factors VEGF and Epo are found in the vitreous of patients with diabetic retinopathy.[75,77,96] Suppression of both factors in animal models of retinopathy suppresses retinal neovascularization illustrating their potential roles in retinal neovascular formation. GH and IGF-1 are also associated with diabetic retinopathy[80] and in animal models inhibiting GH or IGF-1 suppresses retinal neovascularization.[31,82] There is accelerated diabetic retinopathy progression in states of elevated IGF-1 during puberty, pregnancy, and upon rapid improvement of metabolic control.[97,98] Growth factors that may inhibit retinopathy are TGF-β and PEDF. TGF-β is produced by pericytes in the retina. Levels of TGF-β are usually high in normal eyes and may inhibit abnormal endothelial proliferation.[99] Patients with active PDR have lower vitreal levels of TGF-β, which may promote pathologic angiogenesis.[100] PEDF is expressed by RPE and is also an inhibitor of angiogenesis.[101] Systemic injection of PEDF reduces retinal neovascularization in the mouse model of retinopathy.[102]

Treatment of Diabetic Retinopathy

At present, tight glycemic control remains the most effective proven treatment to slow the progression of diabetic retinopathy.[103,104] However, with intensive insulin therapy also comes an increased risk of hypoglycemia, particularly for type I diabetic patients, affecting overall morbidity and mortality. Other therapeutic approaches are necessary. Tight control of dyslipidemia, often present in type II diabetic patients, also protects against progression of retinopathy.[105] In addition, intravitreal triamcinolone, a long acting steroid, decreases diabetic macular edema and increases visual acuity. Similarly, anti-VEGF compounds are currently under investigation for the same purpose. When the disease progresses to the proliferative stage, current standard treatment is ablation of avascular peripheral retina by photocoagulation. Through destruction of hypoxic tissue, the level of hypoxia-induced angiogenic growth factors is reduced and pathologic vessel proliferation is attenuated. However, this approach also irreversibly damages neuronal retina.

Age-Related Macular Degeneration

AMD is the primary cause of blindness in the elderly in developed countries. Because the pathology primarily affects the macula, the central retina associated with highest retinal sensitivity and visual function, AMD can cause severe visual loss (FIGURE 74.6A). In the late stages, AMD can progress into two forms: the nonexudative (dry) type and the exudative (wet) type.

Pathogenesis of AMD

The normal function of retinal photoreceptors is dependent upon a well-functioning adjoining RPE, which phagocytoses the spent photoreceptor outer segments, shed daily, to recycle photopigments (such as rhodopsin) and membrane lipids (such as docosahexaenoic acid). The RPE also transports nutrients and breakdown products between the photoreceptors and the adjoining choroidal vascular plexus, separated from the RPE by Bruch membrane. Therefore the photoreceptors, choroidal vessels, and RPE have an interdependent relationship, and loss of any one component causes dysfunction of the others. This dysfunction is often seen first in the macula because the densely packed photoreceptors here have the highest oxygen consumption and metabolic rate of any tissue in the body.[106]

Clinically, early dry AMD begins with the usually asymptomatic appearance of drusen, seen as white or yellow spots beneath the retina and the RPE on Bruch membrane (FIGURE 74.6B). These deposits increasingly separate the RPE from the underlying choroidal vasculature, interrupting normal function of the RPE and leading to photoreceptor dysfunction and degeneration, a hallmark of late-stage dry AMD. During progression from early AMD to later stages, patients with "wet" AMD develop pathologic blood vessels that sprout from the choroidal plexus, through Bruch membrane and sometimes even through the RPE layer into the subretinal space beneath the photoreceptors (FIGURE 74.6C). Increased leakiness from these neovessels can lead to accumulation of fluid or blood, resulting in detachment of RPE and/or neurosensory retina from the underlying Bruch membrane. Wet AMD is associated with rapid deterioration of visual function. In some cases the choroidal neovessels hemorrhage into the subretinal space, acutely blocking vision in the macula.

Several growth factors, including VEGF, basic fibroblast growth factor, and TGF-β, have been identified in human choroidal neovascularization at increased levels.[107,108] Although VEGF plays a central role in the development of choroidal neovascularization, development of invasive choroidal neovascularization (CNV) may require both elevated VEGF levels and defects in Bruch membrane,[109–114] as defects in Bruch membrane are visible in many ocular conditions with CNV, accompanied by varying degree of inflammation.[115] Increased oxidative stress, which is proinflammatory and can cause invasion of macrophages resulting in the local destruction of Bruch membrane, is another important mechanism in the pathogenesis of AMD.[116] The presence of macrophages has been demonstrated in the outer side of Bruch membrane in eyes with drusen, possibly attracted by RPE secreted monocyte chemoattractant proteins.[117] Increased oxidative stress can also lead to overexpression of many proangiogeneic growth factors by RPE that further exacerbates CNV.

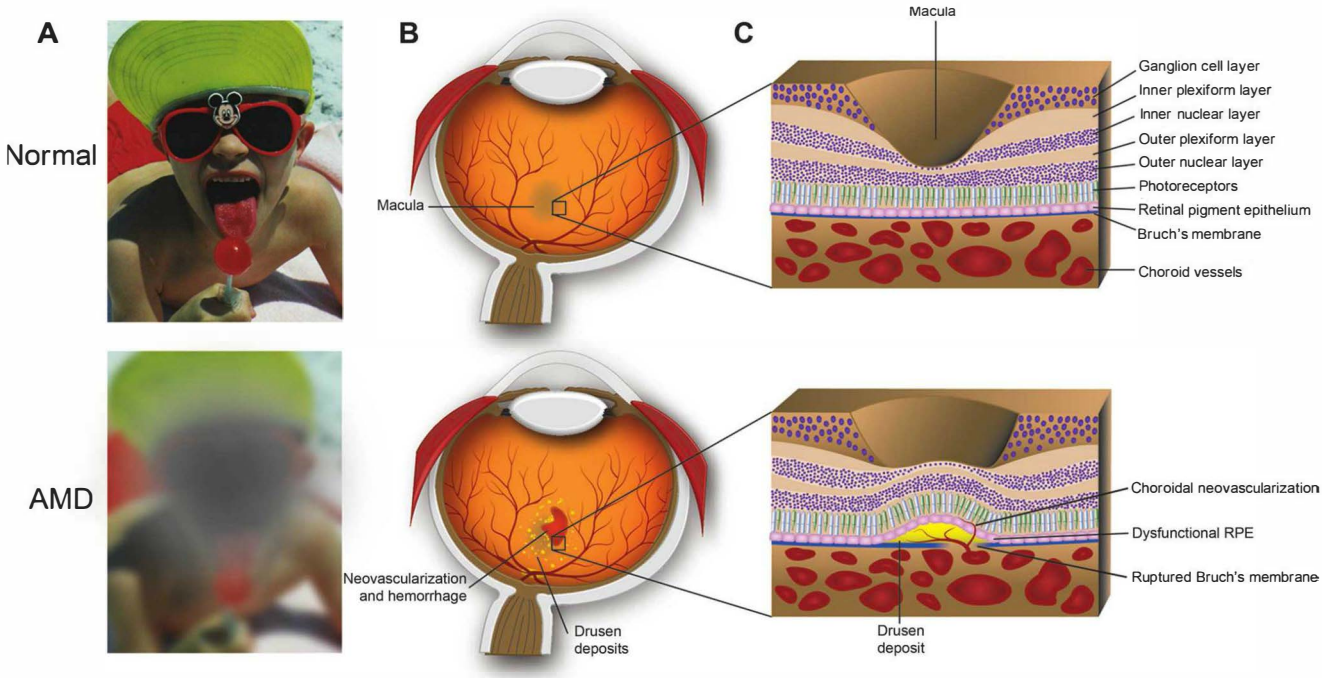

FIGURE 74.6 Loss of central vision in AMD patients. **A:** A representation of the visual field seen by a person with normal vision (**upper**) or seen by an AMD patient with a loss of central color vision (**lower**). **B:** A schematic drawing of a normal human eye (**upper**) compared with an eye with AMD (**lower**) depicting deposits of drusen (*yellow spots*) and choroidal neovascularization with subretinal hemorrhage in the macula (*red*). **C:** A schematic cross section of a normal eye through the macula, showing retinal neuronal layers, RPE, Bruch membrane, and choroid vessels (**upper**). In AMD, the intimate relation between photoreceptors, RPE, and choroid is disrupted by drusen (lipid and cellular debris-containing deposits) (**lower**). The formation of drusen separates RPE from Bruch membrane and the underlying choroidal vessels in association with RPE atrophy and photoreceptor degeneration (hallmarks of dry AMD). In wet AMD with choroidal neovascularization, abnormal leaky choroidal vessels proliferate and penetrate the altered Bruch membrane protruding into the subretinal space, causing hemorrhage and rapid loss of vision.

Hypoxia is also hypothesized to play a role in the development of CNV. Hypoxia-induced VEGF is secreted by RPE basally (toward the choriocapillaris). VEGF receptors are expressed on the choroidal endothelium facing the RPE, suggesting that VEGF is a survival factor for choriocapillaris in a hypoxia-driven feedback mechanism.[117] With age, especially in AMD, Bruch membrane is thickened and there is accumulation of lipids likely resulting in decreased permeability.[118,119] These changes may result in less efficient diffusion of VEGF across Bruch membrane to reach the choriocapillaris, leading to vascular atrophy and consequently hypoxia in the outer retina. In response, RPE would then increase the expression of VEGF, which would, in the presence of a rupture in Bruch membrane, attract invasive choroidal neovessels into the subretinal space. In addition to the upregulation of angiogenic factors such as VEGF, hypoxia also suppresses a potent antiangiogenic factor, PEDF. Therefore hypoxia leads to an inversion of the VEGF/PEDF ratio, which may promote pathologic choroidal angiogenesis.[120] In line with this pathomechanistic scenario, PEDF levels are decreased in the vitreous of patients with AMD and in animal models of CNV.[121,122]

Risk Factors of AMD

A twin study by Seddon et al.[123] found that genetic factors explain 46% to 71% of the variation in AMD disease severity, while environment explains 19% to 42%. Many of these risk factors for AMD are related to inflammation. These include environmental factors, such as smoking and low omega-3 fatty acid intake,[124] and genetic factors, such as polymorphisms in the genes for complement factor H,[125] other complement related genes such as C3, and the *ARMS2/HTRA1* gene.

Current Treatment of AMD

Currently there is treatment available only for the exudative form of late-stage AMD, consisting of anti-VEGF therapies to slow the activity of choroidal neovascularization.[126,127] In addition, progression of mid-stage AMD to late AMD can be slowed by dietary supplementation with vitamins and antioxidants,[128] which is consistentwith the role of oxidation stress in this pathologic process.[116] Higher intake of dietary lipids thought to be anti-inflammatory (omega-3 long-chain polyunsaturated fatty acids and fish) is associated with decreased likelihood of developing late stage AMD.[124]

Rare Inherited Vascular Eye Diseases

There are several rare hereditary eye diseases with similar retinal vascular defects as ROP. FEVR, Norrie disease, and Coats disease (also known as exudative retinitis) have in common incomplete and abnormal retinal vascular growth. Poor vascular growth results in retinal hypoxia, followed by hypoxia-stimulated abnormal proliferative vascular growth that can cause retinal

detachment and blindness. Persistent fetal hyaloid vessels are also a common clinical feature in FEVR and Norrie disease.

In FEVR as well as in Coats disease and Norrie disease, the pathologic process starts with incomplete vessel growth in the peripheral retina followed by abnormal vessel proliferation usually seen by age 10. The progression can continue into adolescence. The closer the child is watched and treated, the better the chances of preserving vision. FEVR progression usually stops by age 20. With a similar pattern but shifted timelines compared to FEVR, Norrie disease and Coats disease tend to present in early childhood often with more severe vision loss than in FEVR patients.

The prevalence of these complex diseases is unknown. FEVR can occur with all three forms of genetic inheritance: recessive, dominant, and X-linked. X-linked FEVR is clinically similar to Norrie disease, which almost always leads to blindness and is sometimes accompanied by hearing loss and mental retardation. Norrie disease in contrast is caused by the X-linked gene Norrin, a Wnt signaling ligand. Coats disease thought to be a result of somatic mutations is also linked to mutations in the Norrin gene. Some of the dominant and recessive FEVRs are caused by different genetic defects in the Wnt signaling receptors Frizzled4 and LRP5. These genetic links suggested that canonical Wnt-β–catenin pathway, a pathway fundamentally important for embryonic development and disease, is also critical for retinal vascular growth and hyaloid regression. Currently there is no treatment for these inherited vascular diseases. Further investigation of the Wnt/Frizzled pathway might lead to novel therapeutic approaches to treat or prevent these diseases as well as other ocular vascular diseases characterized by persistent hyaloid vessels and incomplete retinal vascularization.

Retinal Vessel Occlusion

Retinal vessel occlusions can affect both the arterial as well as the venous retinal vasculature. Retinal artery occlusions (RAOs) usually present with sudden, painless loss of vision, usually unilaterally. In most patients, the cause is embolism of a retinal artery by a dislodged thrombus from for example an atherosclerotic plaque. In that respect, RAOs resemble ischemic strokes where small brain arteries become blocked by embolic particles. Similar to ischemic strokes, revascularization attempts with recombinant tissue-type plasminogen activator have been tried in patients with RAO.[129] In addition, selective intra-arterial thrombolysis in the affected retinal artery has been proposed but has failed to yield superior results over standard care in the randomized, prospective multicenter EAGLE study.[130] One of the main limitations of lysis therapy in RAO patients is that therapy can usually only be initiated several hours after the occlusive event and can be associated with severe side effects like hemorrhage. For the highly metabolically active retinal tissue mere minutes of arterial nonperfusion might be enough time to undergo irreparable damage, irrespective of successful lysis or reperfusion in the later stages.

Retinal vein occlusion (RVO) represents a much more common entity where therapeutic intervention can in many cases successfully improve disease outcome. Pathophysiologically, RVOs are thought to differ from other venous occlusive diseases like deep vein thrombosis in that in most RVO patients the crucial changes appear to be in the vessel wall and not primarily in rheologic abnormalities. While in younger patients, RVO can sometimes occur as a result of genetically determined hypercoaguable states, for example, Factor V Leiden disease, in the large majority of patients above the age of 45, vessel wall alterations are thought to be the main risk factors for RVO. In that respect, RVOs share many of the risk factors of cardiac ischemic disease where small coronary arteries become occluded, also often due to primary vessel wall alterations[131] often but not only in veins. Due to the close proximity of arterial and venous vessels in the eye, alterations in the walls of retinal arteries can impact blood flow in the neighboring vein. This becomes especially apparent in branch retinal vein occlusions that almost exclusively occur at arteriovenous junction sites where the artery often appears to impinge the crossing vein (FIGURE 74.7).

Visual impairment in patients with both branch and central retinal vein occlusion is usually less acute than in arterial occlusion, and is to a large extent determined by secondary changes like retinal edema and/or macular ischemia. In the early stages, retinal edema is mainly the result of increased intraluminal pressure in the occluded vein. The occluded vein still receives unperturbed arterial and capillary inflow but is unable to drain blood through the occluded section, increasing pressure. Thus blood and plasma leak into the surrounding retinal tissue. In the later stages, hypoxia develops around the occluded area due to impaired blood circulation. Hypoxia-induced upregulation of VEGF then further increases leakage of plasma from the occluded vein into the retinal tissue through its permeability-enhancing properties. In severe cases of impaired circulation, macular ischemia can develop leading to severe and irreversible vision loss independent of macular edema.

It is important to distinguish between the causes of visual impairment in RVO patients. To date, no therapy exists that has proven reliably efficient in removing the venous obstruction.[132] Similarly, no recommendation can be provided on the use of systemic or locally applied fibrinolytic or anticoagulant therapies given the limited available evidence.[133] Anti-VEGF therapies, on the other hand, have had remarkable effects in patients with macular edema.[131,134–137] Different from wet AMD,

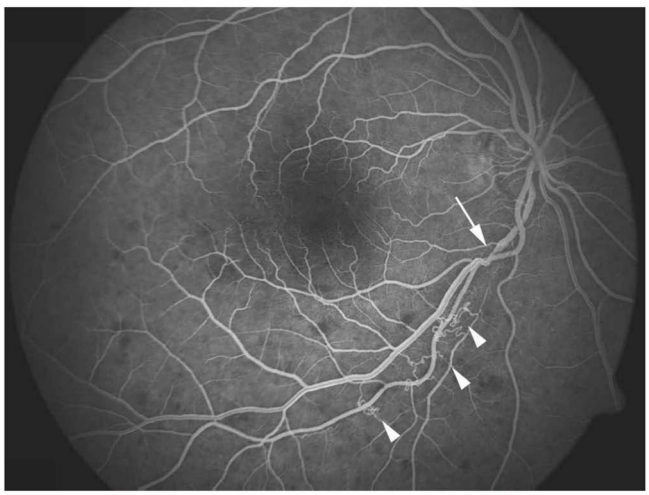

FIGURE 74.7 Fluorescence angiogram from a patient with RVO. The initial occlusion has resolved but the impingement of the retinal vein at the junction with a retinal artery is still visible (*arrow*). Collateral vessels (*arrowheads*) have formed to establish a new perfusion equilibrium. Image courtesy of Dr. Christoph Ehlken, University Eye Hospital Freiburg, Germany.

anti-VEGF therapy in RVO is not used to block the angiogenic properties of VEGF but the vasopermeability effects of VEGF leading to macular edema. It has been found that macular edema, even over relatively short time, leads to irreversible loss of photoreceptor cells.[138] Reduction of edema thus might have important implications in the long-term visual prognosis of RVO patients. As most RVOs eventually in later stages develop collateral circulation through newly-formed functional shunt vessels, limiting macular edema with anti-VEGF therapy in the earlier stages appears to be a sensible and promising strategy to increase final photoreceptor function. However, even (or especially) with anti-VEGF therapy it remains of utmost importance to continuously monitor RVO patients for the development of avascular and severely hypoxic retinal regions. If avascular regions develop, they might initiate—similar to diabetic retinopathy and ROP—a late stage of proliferative retinopathy with pathologic formation of preretinal neovascularizations and consequent complications like neovascular glaucoma and/or retinal detachments.

CURRENT AND FUTURE THERAPY FOR PATHOLOGIC ANGIOGENESIS

Pathologic retinal angiogenesis, which is morphologically distinct from normal retinal vessels often leads to blindness. When the vascular lesions have reached an advanced stage, aggressive measures are often required. Until recently the mainstay of treatment has been laser photocoagulation of the nonvascularized retina in diabetic retinopathy and ROP and photodynamic therapy in AMD.

The aim of laser photocoagulation is to induce the regression of new vessels, by obliterating ischemic areas to reduce expression of hypoxia-induced angiogenic growth factors.[139] Despite photocoagulation, however, retinopathy progresses in a significant proportion of patients. In AMD patients, the introduction of photodynamic therapy offered the first selective treatment for CNV, allowing for closure of choroidal neovessels with relative sparing of the overlying retina. However, the visual results still left room for improvement. With the advent of anti-VEGF therapies, visual function was for the first time improved in patients with late-stage AMD.[126,127] Several anti-VEGF therapies are currently in use or in late-stage clinical trials. Avastin (bevacizumab), a recombinant humanized monoclonal antibody against VEGF, was the first antiangiogenesis drug approved by FDA in 2004 for treatment of colon cancer. It was also the first anti-VEGF drug that was used to treat exudative AMD in off-label clinical application. Macugen (Pegaptanib), a 28-base oligonucleotide (aptamer) that binds VEGF,[140] was approved for the treatment of the wet AMD marking the official advent of anti-VEGF therapy for ocular disease. More recently, Lucentis (ranibizumab), a humanized monoclonal antibody fragment against VEGF, was also approved for the treatment of wet AMD.

Both Macugen and Lucentis are currently being investigated also for treatment of diabetic macular edema in large clinical trials. However prevention of vessel loss will be even more important in the treatment of retinopathy, as the extent of pathologic neovascularization depends in large part on the initial vascular loss and resultant tissue hypoxia. There are currently many active areas of research aiming at treating proliferative retinopathies in these early disease stages that are characterized by vascular loss and/or vascular dysfunction. Among these are dietary interventions with omega-3 polyunsaturated fatty acids that may help to alleviate ischemia by improving regrowth or sustainability of compromised retinal vasculature.[141] Neuroprotective agents may also play an important role by preventing degeneration of the neural retina to sustain functional vascular/neuronal cross-talk. Finally, anti-inflammatory agents may be important in curbing the inflammatory and often destructive activation of host defense cells that accompanies retinal (or subretinal) neovascularization.

CHAPTER 75

Overview of Therapy of Bleeding Disorders

GILBERT C. WHITE, II, SAM SCHULMAN, AND VICTOR J. MARDER

Historically, once it was recognized that blood clotting factors were components of plasma, the notion of treatment with plasma to correct deficiency states followed quickly. The decay of clotting factor activity in plasma that was stored led to the development of freshly frozen plasma. The problems encountered with fresh frozen plasma—fluid overload and the inability to achieve high clotting factor levels because of the fluid overload—led to efforts to concentrate the clotting factors. The terrible transmission of blood-borne viral illnesses by the concentrates, especially AIDS and hepatitis C, led to efforts to purify factors and develop recombinant products (FIGURE 75.1). Knowledge of the genes for clotting factors, generated by the efforts to develop recombinant products, now drives efforts aimed at gene therapy and proteins with improved function (Chapter 79). Along the way, additional treatments evolved. The discovery and characterization of fibrinolytic enzymes led to development of inhibitors of fibrinolysis, which are used as adjuncts for treatment of bleeding disorders, and profibrinolytics, which are used in the treatment of thrombosis. An analog of vasopressin, DDAVP (1-desamino-8-D-arginine vasopressin), used in diabetes insipidus, was discovered to induce secretion of von Willebrand factor and thereby increase von Willebrand factor and factor VIII levels in patients with milder forms of von Willebrand disease and hemophilia. As a result, the treatment of bleeding disorders has come a very long way from these initial treatments, and today's clinician caring for patients with inherited bleeding disorders now has a highly sophisticated panel of products that are biologically stable, effective, and safe. This section reviews the various products used in the treatment of hemorrhagic disorders and the approaches in specific situations. The treatment of specific inherited coagulation factor deficiencies, such as hemophilia and von Willebrand disease, is discussed in the chapters dealing with those inherited disorders.

Acute hemorrhage is often a medical emergency and the clinician must have an approach and treatment strategy in mind when called. Knowledge of the agents available, their action, and their toxicities are important in this decision. The clinician must be able to quickly assess the source and the cause of the bleeding. It is important to determine if there is a structural lesion, an acquired bleeding defect, and/or an underlying inherited disorder. Often the input of multiple specialists—surgeons, radiologists, gastroenterologists, and hematologists—is required. The formulation of a treatment plan may require both blood replacement and hemostatic agents. These issues are discussed along with specific approaches for particular situations in Chapter 76. For acute hemorrhage in hemophilia and in acquired inhibitors, the reader is also referred to Chapters 51 and 57. Additional approaches in bleeding disorders associated with disseminated intravascular coagulation and liver disease are referred to Chapters 98 and 126. Treatment of acquired and inherited platelet and vascular disorders is described in Sections III-B and III-C.

Chapter 77 describes the use of antifibrinolytic agents. These have become important adjunct therapies for either the treatment of acute or chronic hemorrhage or for the prevention of hemorrhage. Antifibrinolytics are especially useful in the treatment of chronic hemorrhage from tissues that contain high levels of fibrinolysis activators such as the gastrointestinal tract.[1–3] Antifibrinolytics have been used in combination with clotting factor concentrates to reduce factor administration in hemophilia and in combination with bypassing agents for dental work and other treatments in hemophilic individuals with inhibitors.[4–6]

An important question for the first quarter of the 21st century is, can we make even better products for hemorrhagic disorders? Given the discoveries over the past decade or more regarding the structure and function of clotting factors, the feasibility of making products that have altered properties is real. Products for hemophilia A and B are currently leading the way in this regard. Nevertheless, there remain significant knowledge gaps. One important gap is a lack of understanding of the mechanisms of clearance of the various clotting factors. In the case of factor VIII, for example, a number of candidate mechanisms have been proposed, including the low-density lipoprotein receptor–related protein on hepatocytes,[7,8] the high mannose receptor (CD206) on macrophages and other cells,[9] and the Gilbert-Ashwell asialoglycoprotein receptor on hepatocytes,[10] but none appear robust enough, at least in animal models. Most investigators in the field believe that von Willebrand factor is a key determinant of clearance based on the significantly shortened survival of factor VIII in the absence of von Willebrand factor. This would suggest that the approach to prolonging factor VIII survival may be to prolong that of von Willebrand factor. Another significant gap is the lack of structural information regarding clotting factor interactions and the residues that mediate the interactions. In the past decade, the structures of a number of individual clotting factors have been solved, but technology has not yet permitted determination of the structure of multiprotein complexes, such as the prothrombinase and tenase complexes. Knowledge of these interactions at the atomic level is important to developing ways to regulate the interactions.

Although clearance mechanisms for clotting proteins remain uncertain, efforts are going forward with attempts to develop products with a prolonged half-life, especially those used in the treatment of hemophilia. When one considers that the average hemophiliac treats himself about three times a month, even doubling the half-life would have a beneficial

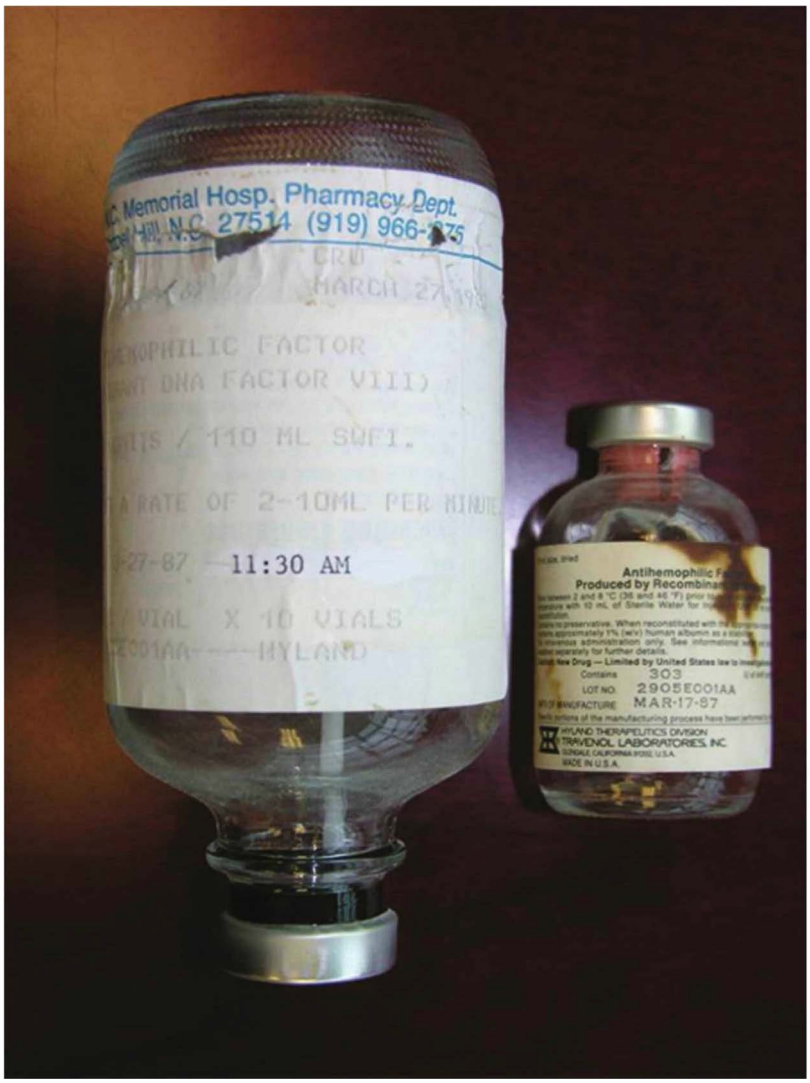

FIGURE 75.1 First vial of recombinant FVIII. Bottle on the right is the initial vial of antihemophilic factor (AHF) (factor VIII) produced by recombinant DNA technology to be infused into a human. The product was produced by Hyland Therapeutics Division, Travenol Laboratories, Inc. (Glendale, CA). The date of manufacture, indicated on the bottle, was March 17, 1987. The lot number was 2905EOO1AA and the vial contained 303 IU of AHF. The inverted bottle on the left is the infusion material reconstituted according to the manufacturer's specifications that was infused in the General Clinical Research Unit at the University of North Carolina on March 27, 1987 at approximately 11:30 AM.

effect. Studies are currently underway with various pegylated forms of factors VIII, IX, and VII and with factors fused to longer-lived proteins such as immunoglobulin fragments and albumin. The real problem with clotting factor therapy, though, is not the frequency of treatment *per se*; it is the intravenous nature of the treatment, the cumulative lifetime expense with insurance caps, and the long-term effect on venous access. For these reasons, the long-range goals of research should be the development of oral agents and more curative approaches such as gene therapy. These and other approaches are discussed in Chapter 79.

In the long term, better knowledge of coagulation biology might be expected to lead to more personalized treatment. Accumulating evidence suggests that individuals have a unique ability to form thrombin, a so-called thrombin potential, that can be assessed by *in vitro* testing.[11–14] Individuals at risk for thrombosis tend to have increased endogenous thrombin potential and individuals at risk for bleeding tend to have decreased endogenous thrombin potential. The actual amount of thrombin that is generated in plasma correlates well with clot structure *in vitro* (see Ref.[15]). For example, excessive generation of thrombin, as might occur with the G20210A mutation in the 3' untranslated region of prothrombin, leads to formation of relatively nonturbid, less permeable clots that are composed of a dense network of relatively thin fibrin strands. Such clots are relatively resistant to fibrinolysis. Conversely, inadequate generation of thrombin, as occurs in hemophilic plasma, leads to the formation of turbid, highly permeable fibrin clots that are composed of thick, loosely woven fibrin strands and are more sensitive to fibrinolysis. It has been suggested that the use of this type of *in vitro* endogenous thrombin generation assay can provide better assessment of thrombotic and bleeding risk and might be used to monitor therapy in bleeding or clotting patients, providing a more personalized approach to treatment.

CHAPTER

76 Management of Acute Hemorrhage

MICAH J. MOOBERRY, ROMMEL P. LU, AND NIGEL S. KEY

Evaluation and management of the acutely bleeding patient is a common encounter for the hematologist and is often fraught with innumerable challenges. It can additionally involve a wide variety of clinical scenarios, including pediatric, obstetric, surgical, and medical patients. These challenges are often further compounded by a paucity of clinical and laboratory information on which to base decisions. With these factors in mind, this chapter briefly discusses an approach to the initial evaluation of the acutely bleeding patient, including both clinical and laboratory assessments, followed by a discussion of specific therapeutic agents available for the treatment of acute hemorrhage. It concludes with a discussion of several specific bleeding situations and management of complications of antithrombotic therapy.

INITIAL EVALUATION

Clinical Approach

In the ideal setting, the evaluation of acute hemorrhage should be a multistep process beginning with a complete clinical history, followed by a focused physical examination and a directed laboratory evaluation. However, with the advent and now ubiquitous presence of more sophisticated medical diagnostic testing, the interview and examination of the patient often play a secondary role in the medical evaluation. Despite this trend, the clinical evaluation of the acutely bleeding patient is paramount and should be the foundation for further decision making regarding diagnostic testing, as well as possible intervention strategies. Contrary to outpatient bleeding evaluations, adherence to this algorithm may not always be possible in the setting of significant acute hemorrhage, and an abbreviated workup that focuses on pertinent exam and laboratory findings may be all that time allows.

When possible, a detailed history should be obtained, with particular attention paid to prior bleeding episodes, if present. The goal should be to answer several questions with reasonable certainty: (a) Is a bleeding disorder present? (b) If so, is it a disorder of primary or secondary hemostasis? (c) Is it acquired or hereditary in nature? To help make these determinations, the severity and nature (mucocutaneous, intramuscular, intra-articular, etc.) of each prior bleeding episode, as well as the number of bleeding episodes, should be assessed. Specific inquiries should also be made regarding menorrhagia, the presence of bleeding episodes during infancy and childhood, bleeding associated with dental procedures, peripartum hemorrhage, and excessive or unprovoked bruising.

A history of provoked versus spontaneous hemorrhage can offer additional insight. Bleeding events after a hemostatic challenge, such as trauma or surgery, could be indicative of an underlying mild bleeding disorder that had not manifested previously with spontaneous bleeding.[1] Conversely, the absence of bleeding despite the hemostatic challenge of multiple surgeries may suggest the absence of a longstanding bleeding disorder. Timing of bleeding with respect to the hemostatic challenge can also provide clues to whether there is a defect in primary or secondary hemostasis (e.g., immediate bleeding with disorders of primary hemostasis vs. delayed bleeding with disorders of secondary hemostasis) (see Table 76.1).

A thorough family history of bleeding symptoms should also be obtained, querying similar symptoms as those posed to the patient. It should be noted, however, that the absence of a family history of bleeding does not exclude the presence of a congenital bleeding disorder, as there may be no affected family members in the setting of spontaneous mutations or autosomal recessive disorders.[2,3] Obtaining a list of all comorbidities is also worthwhile, as numerous medical conditions are associated with specific coagulation disorders, which may or may not be realized by the patient. Finally, a full review of all current medications can aid in patient management, both from a diagnostic and a therapeutic perspective. This should include an inquiry into nonprescription compounds as well. Obvious culprits in the setting of acute hemorrhage include anticoagulants and antiplatelet agents; however, numerous over-the-counter medications contain nonsteroidal agents that exert antiplatelet effects and are often not considered "medications" by patients unless specifically addressed. Several herbal and nutritional supplements have also been implicated in hemorrhagic events and should be investigated, although they are unlikely to be the sole cause of bleeding complications.[4]

A focused physical examination is also prudent, as this can provide substantial insight into possible pathologic mechanisms and help guide management decisions. Bruises, petechiae, mucocutaneous bleeding, and menorrhagia are often seen in patients with platelet defects, von Willebrand disease (vWD), and other defects in primary hemostasis. In comparison, bleeding into muscles and joints is more characteristic of disorders of secondary hemostasis, such as hemophilia A and B and certain other coagulation factor deficiencies. The exam can also potentially lead to the discovery of previously undiagnosed comorbid conditions that may contribute to a patient's bleeding. Examples include gum hypertrophy in acute myelogenous leukemia (AML) (types M4 and M5); macroglossia, periorbital ecchymoses, and carpal tunnel syndrome in amyloidosis[5,6]; harsh systolic murmur in severe valvular disease; and jaundice,

Table 76.1
Classification of bleeding disorders

Disorders of Primary Hemostasis	Disorders of Secondary Hemostasis
von Willebrand disease	Hemophilia A
Platelet function disorders	Hemophilia B
Inherited	Other factor deficiencies: II, V, VII, X, XI, XIII
Acquired	Factor inhibitors
Drug induced	Fibrinogen abnormalities
Thrombocytopenia	Hyperfibrinolysis
Inherited	Inherited deficiencies
Acquired	Acquired
Drug induced	Connective tissue disorders
Immune mediated	

icterus, spider angiomata, and splenomegaly in severe liver disease, among others (see Table 76.2).

After the clinical assessment of the patient is complete, one should formulate a pretest probability as to whether a bleeding disorder exists or not, and if so, what type. Given the frequency with which "normal" subjects report bleeding symptoms, however, the ability to identify mild bleeding disorders can be challenging.[7–11] To that end, several attempts have been made to develop standardized screening tools that predict the presence of a bleeding disorder.[12–15] To date, however, no prospectively validated clinical tool exists to predict the presence of a bleeding disorder. Notably, the International Society on Thrombosis and Hemostasis recently proposed a Bleeding Assessment Tool consisting of a standardized questionnaire and well-defined interpretation grid to be used in any future studies aimed at description of bleeding symptoms or diagnosing bleeding disorders,[16] but this will need to be validated before it is adopted into clinical use.

Laboratory Evaluation

Evidence has shown that indiscriminate coagulation testing in patients undergoing surgery or other invasive procedures does not help predict risk of bleeding and is therefore not recommended.[17–19] In the setting of acute hemorrhage, however, laboratory testing is vital and should be pursued for several reasons: confirmation of a clinically suspected bleeding disorder, clearly defining the defect if present, and guiding treatment/intervention strategies.

Screening tests of coagulation that evaluate for both primary and secondary hemostatic abnormalities should be performed in all patients with acute hemorrhage. These include a complete blood count (CBC) and platelet count, peripheral blood smear, activated partial thromboplastin time (aPTT), and prothrombin time (PT). These tests are available in most settings, and due to their automated nature, provide reproducible results in a timely manner. In general, these basic tests in conjunction with the clinical assessment should be able to direct further evaluation toward defects of primary or secondary hemostasis. The details of the laboratory evaluation will not be fully covered here (see Chapter 50); however, it should be mentioned that preanalytical variables can have a profound effect on test results and therefore attention should be paid to proper collection and handling of specimens.[20,21]

If all testing for hemostatic defects returns normal, it should be remembered that up to 40% to 50% of suspected bleeding disorders yield a normal laboratory screening evaluation, particularly mild bleeding disorders that probably include heterogeneous platelet function defects.[22,23] Additionally, abnormalities on coagulation tests, particularly in the acutely ill patient, may

Table 76.2
Comorbid conditions and bleeding

Disease	Cause of Bleeding	Other Findings/Manifestations
Acute leukemia	Thrombocytopenia, hyperfibrinolysis in acute promyelocytic leukemia	Pallor, petechiae, gum hypertrophy
Amyloidosis	Acquired FX deficiency, other factor deficiencies (II, V, VII, VIII, IX), hyperfibrinolysis	Macroglossia, periorbital ecchymoses, carpal tunnel syndrome
Ehlers Danlos syndrome	Defect in collagen synthesis	Joint laxity, skin hyperelasticity
Hereditary hemorrhagic telangiectasia	Arteriovenous malformations of multiple sites, GI telangiectasias	Recurrent epistaxis, oral telangiectasias
Hypothyroidism	Acquired vWD	Thin hair, obesity, cold intolerance, dry skin
Liver disease/cirrhosis	Thrombocytopenia, factor deficiencies, hyperfibrinolysis	Hepatosplenomegaly, icterus, jaundice, spider angiomata
Scurvy	Defect in collagen synthesis	Corkscrew hairs, petechiae, perifollicular purpura
Severe valvular disease	Acquired vWD, thrombocytopenia	Harsh murmur
Wilms tumor	Acquired vWD	Flank mass

not be indicative of a primary coagulation defect, but instead be epiphenomena or the result of another acute medical process. Therefore, a suspected primary coagulation disorder should always be confirmed after the acute situation has resolved. In the event that exhaustive laboratory testing does not provide definitive answers as to the cause of the acute bleeding episode, empiric treatment based upon clinical findings and sound medical judgment is a reasonable choice and may be the only course of action available.

THERAPEUTIC APPROACH

Blood Component Therapy

Conservative approach to transfusion therapy has become the standard of care in most situations. In contrast to whole blood, which is utilized primarily in military settings,[24,25] red cell units contain negligible amounts of platelets and coagulation factors and are used to provide increased oxygen-carrying capacity. Plasma-containing blood products, including platelets, are conversely administered to correct hemostatic defects. The primary advantage of blood component therapy is the ability to allocate resources according to individual needs (see Table 76.3). The clinical decision to transfuse should be individualized and not simply based on a given blood count. The underlying mechanism causing the cytopenia or coagulopathy and its clinical risks must be considered as well. However, despite the potential transfusion-associated infectious, metabolic, and immunologic risks, it is important not to withhold blood products to anybody with a life-threatening hemorrhage. The management strategy for transfusion therapy that follows generally refers to adult patients. Guidelines for pediatric transfusion may differ.

Red Cell Transfusion

The decision to transfuse red cells requires a detailed analysis of clinical factors, with the primary goal of restoring tissue perfusion and reversing the effects of shock if already present. Generally, this decision is made on the basis of hemoglobin and hematocrit values in conjunction with the patient's physiologic response to anemia and coexisting medical condition. The administration of red cell transfusions in an actively bleeding patient is often lifesaving, but recommendations about when and how much to transfuse are unclear.[26] For many years, most clinical practices used a hemoglobin/hematocrit threshold of <10 g/dL/30% as transfusion trigger in numerous clinical settings. More recently, however, a pivotal controlled study evaluating transfusion strategies in critically ill patients provided new evidence to guide transfusion practices. This trial demonstrated that a restrictive transfusion approach (i.e., transfusing patients only with a hemoglobin <7 g/dL) was as effective as a liberal strategy (i.e., transfusing patients with a hemoglobin <10 g/dL) and had a lower in-hospital 30-day mortality, cardiac complication rate, and organ dysfunction.[27] However, patients with

Table 76.3

Blood component therapy

Component	Description	Volume	Dosing
Red cells	Prepared by removing plasma from whole blood or apheresis Transfused red cells have a half-life of ~30 d in the absence of processes that would result in red cell loss or premature removal.	200–350 mL	In average-sized adults, one unit of compatible red cells will increase hemoglobin by 1 g/dL and hematocrit by 3%, provided there is no ongoing hemolysis or bleeding. In neonates and older children, a transfusion dose of 10–15 mL/kg is generally given and results in hemoglobin rise of 2–3 g/dL.
Platelets	Collected as RDP or SDP RDPs are derived from whole blood and six units of RDPs constitute one adult dose. SDPs are apheresed platelets and are full adult doses.	One adult dose is 250–300 mL	In adults, expect an increment of approximately 30,000–60,000/μL for each SDP or pooled six units of RDP. In neonates and older children, a dose of 5–10 mL/kg generally results in 50,000/μL increment.
Plasma (FFP, FP24, thawed plasma)	Consists of non-cellular portion of blood. May be prepared from whole blood or collected by apheresis	150–300 mL	10–15 mL/kg (equivalent to 3–4 U in adult)
Cryoprecipitate	Prepared from plasma Each unit contains at least 80 IU of factor VIII:C and 150 mg of fibrinogen in 15 mL plasma.	One adult dose is ~150 mL	One dose (10 U in adult or 1 U per 10 kg body weight in neonates and older children) increases fibrinogen level by 0.5 g/L in the absence of continued consumption or bleeding

Modified from Brecher M, ed. *Technical manual*, 15th ed. Bethesda, MD: AABB press, 2005; Mintz P, ed. *Transfusion therapy: clinical principles and practice*, 2nd ed. Bethesda, MD: AABB Press, 2005.

ongoing hemorrhage were excluded from the study. Thus, it is important to realize the possible limitations of restrictive transfusion strategy in acute settings.

The urgent need for transfusion is uniquely apparent in the operative and trauma settings. Significant hypotension occurs once more than 30% of blood volume is lost and is a late sign of internal hemorrhage. Frequently, red cells are transfused to improve blood pressure, hemoglobin concentration, or both before the cause of bleeding is identified. In the acute trauma setting, the rapidity and amount of blood loss may be inaccurately estimated by the hemoglobin/hematocrit values, thereby making it difficult to exclusively rely on these tests to determine the relationship between blood loss and transfusion requirement. A number of factors must be considered besides hemoglobin level, such as vital signs, oxygenation, and clinical status, to ensure tissue demands for oxygen are met. This is especially applicable in patients with limited cardiac reserve or significant atherosclerotic vascular disease, in whom the heart may be unable to increase total body oxygen delivery in the face of anemia, without risk of myocardial ischemia. A transfusion study in elderly patients with acute myocardial infarction showed a lower short-term mortality when patients were transfused to achieve a hemoglobin as high as 10 g/dL. Evidently, transfusion trigger for red cells must be customized to defined patient groups, and the decision to transfuse must be made on the basis of individual patient characteristics.[28]

Two of the recommendations of the American Society of Anesthesiologists Task Force with practical applications in the management of acute hemorrhage are:

1. Transfusion is rarely indicated when the hemoglobin level is above 10 g/dL and is almost always indicated when the hemoglobin level is below 6 g/dL.
2. The determination of transfusion in patients whose hemoglobin level is 6 to 10 g/dL should be based on ongoing indication of organ ischemia, rate and magnitude of any potential or actual bleeding, patient's intravascular volume status, and risk of complications due to inadequate oxygenation.[29]

Blood Substitutes

Biomedical advances have made the development of hemoglobin-based oxygen carriers (i.e., blood substitutes) possible, but due to safety concerns about increased rate of myocardial infarction, stroke, hypertension, and renal dysfunction in patients who have received them in clinical trials, they are still under development.[30–32]

Platelet Transfusion

Platelet transfusion is used to treat or prevent bleeding due to defect in platelet number or function. In general, most patients do not experience spontaneous bleeding at platelet counts of 40,000 to 50,000/μL unless there is a coexisting platelet dysfunction or other hemostatic defect. Studies indicate that achieving a platelet count of 40,000 to 50,000/μL with platelet transfusion in patients with severe thrombocytopenia might be sufficient to allow an invasive procedure to be safely performed. A threshold of 80,000/μL has been proposed for spinal epidural anesthesia. In those situations in which no excessive bleeding can be tolerated, such as central nervous system or retinal procedures, a platelet count of 100,000/μL is often used. In patients who are severely thrombocytopenic, such as those receiving myeloablative chemotherapy, it is a common practice to maintain a platelet count >10,000/μL in stable nonbleeding patients, and >20,000/μL in febrile nonbleeding patients, based on the observations that serious spontaneous bleeding is unlikely to occur at platelet counts >10,000/μL. When known platelet dysfunction results in microvascular bleeding or before anticipated major surgery, platelet transfusion may be required despite having a seemingly adequate platelet count. However, prophylactic platelet transfusion in patients with immune thrombocytopenic purpura based on platelet count alone in the absence of spontaneous bleeding is discouraged since bleeding is less frequent at equivalent platelet counts, and platelet transfusions are often ineffective. Similarly, prophylactic platelet transfusion practice is discouraged in cases of thrombotic thrombocytopenic purpura (TTP) and heparin-induced thrombocytopenia (HIT), unless there is life-threatening bleeding or in anticipation of major surgery. However, the reluctance to transfuse platelets in TTP and HIT may have been overemphasized, and it remains a controversial topic. In the presence of active bleeding, maintaining a platelet count of 50,000 to 100,000/μL with platelet transfusion support is often practiced. A platelet count threshold of 100,000/μL is often used in patients with severe, noncompressible bleeding such as in the gastrointestinal (GI) tract, intracranial, or intrathoracic areas, while a lower platelet count threshold is used in less severe bleeding. Overall, these guidelines tend to be based on expert recommendations rather than level I evidence.[29,33–38]

Practical issues regarding platelet transfusion include:

1. Response to platelet transfusion is adversely affected by the presence of fever, sepsis, splenomegaly, severe bleeding, consumptive coagulopathy, human leukocyte antigens (HLA) alloimmunization, and treatment with certain drugs (e.g., amphotericin B).[33,39,40]
2. Rh (D)-negative patients, especially women of childbearing age, should receive platelets from Rh (D)-negative instead of Rh (D)-positive donors because of the risk of alloimmunization and development of a clinically significant antibody to Rh (D) antigen, which can cause a hemolytic transfusion reaction from subsequent Rh (D) mismatched transfusions. However, this is not practically feasible at all times because of limited platelet inventory. If platelets from Rh (D)-positive donors are transfused to Rh (D)-negative recipients (especially women of childbearing age), consideration should be given to administering prophylactic Rh (D) immune globulin to prevent sensitization.[41,42]

Plasma Transfusion

Fresh frozen plasma (FFP) contains coagulation proteins involved in the maintenance of vascular integrity, anticoagulation proteins, and proteins involved in fibrinolysis. FFP is frozen at ?18°C or colder within 6 to 8 hours of collection and contains functional quantities of all coagulation factors. Plasma frozen within 24 hours (FP24) and thawed plasma may contain variably reduced levels of factors V and VIII. Despite these processing differences, FP24, thawed plasma, and FFP are generally used for the same indications.[43]

Current published guidelines by multiple organizations consider plasma transfusion appropriate only under specific circumstances. The definitive indications for FFP transfusion are replacement of coagulation factor deficiency in the event of

bleeding with certain coagulopathies (including patients with liver disease, isolated factor V deficiency, disseminated intravascular coagulopathy [DIC], or while on a vitamin K antagonist [VKA]) or TTP. Conditional uses of FFP include prophylactic use in patients with certain coagulopathies prior to invasive procedures, those undergoing cardiopulmonary bypass surgery, or children on extracorporeal membrane oxygenation.

When used to correct multiple coagulation factor deficiencies, the response to plasma transfusion should be closely monitored by follow-up laboratory tests and clinical assessment. A PT and/or aPTT >1.5 times the normal range are typically the recommended triggers for plasma transfusion, although this cutoff is being challenged by several groups.[29,44–46] Despite these guidelines, requests for FFP are the most frequent inappropriate orders received by the blood bank. The most frequent reason for these inappropriate orders is for correction of a prolonged international normalized ratio (INR) in the absence of bleeding. In clinical practice, prophylactic plasma transfusion prior to invasive procedures including neurosurgical interventions has become routine. It is suggested that inappropriate FFP orders occur because of three assumptions: (a) Elevation of the PT/INR will predict bleeding in the setting of a procedure. (b) Preprocedure administration of FFP will correct the prolonged clotting time results. (c) Prophylactic transfusion results in fewer bleeding events. However, these three assumptions about the relationship of FFP transfusion and decrease in INR, especially in patients with mildly prolonged INRs, are unproven. Studies in patients undergoing liver biopsies, bronchoscopic biopsies, renal biopsies, central line vein cannulation, thoracentesis, and angiography have repeatedly demonstrated that the PT and aPTT are not predictive of hemorrhage. Furthermore, plasma transfusion prior to an invasive procedure to correct a mild to moderately abnormal INR neither corrects the INR nor reduces the perceived bleeding risk.[47–50,51,52] Therefore, transfusion for patients not meeting current FFP guidelines does not reliably reduce the INR and exposes patients to unnecessary transfusion risk.

Practical issues regarding plasma transfusion include:

1. A significant degree of change in the INR following FFP transfusion may not be seen until the INR is >1.7, largely because the INR of donor plasma itself ranges between 1.0 and 1.3. Thus, the difference in coagulation activity between donor plasma and patient plasma is so small that plasma transfusions produce minimal demonstrable effect on the patient's INR.[51] Administering vitamin K may be a therapeutic option to consider in patients who have a presumed coexisting vitamin K deficiency.
2. If plasma is to be transfused, its timing should be carefully considered. If correction of a markedly abnormal PT or aPTT is required before surgery, FFP is better given just before the patient is called to the operating room, and not the night before. Several coagulation factors have very short half-lives, and if FFP is given 8 hours preoperatively, those factors will be cleared from the circulation by the time surgery begins.[53]
3. Many transfusion protocols suggest administering plasma after the patient has received 4 to 6 U of red cells, but recent studies in trauma are challenging this practice and are suggesting earlier rather than later plasma administration[54,55] (see section "Massive Transfusion Therapy").

Cryoprecipitate Transfusion

Cryoprecipitate is the precipitable protein fraction derived from frozen plasma thawed at 1°C to 6°C. It contains concentrated levels of fibrinogen, von Willebrand factor (vWF), factor VIII, factor XIII, and fibronectin in a small volume, but it is generally administered as a source of fibrinogen. Patients with hemophilia A or vWD disease should only be treated with cryoprecipitate when appropriate factor VIII concentrates or factor VIII concentrates containing FVIII: vWF are not available.[56]

Since FFP contains all coagulation factors, FFP transfusion should supply the depleted hemostatic proteins, although a large volume of plasma is usually required to fully replete significant deficiencies. This becomes a challenge in patients who are unable to tolerate larger intravascular volumes, such as those with significant cardiac, pulmonary, renal, and/or hepatic disease. In patients with ongoing bleeding with a fibrinogen level <0.8 to 1.0 g/L, cryoprecipitate transfusion is recommended.[29]

Massive Transfusion Therapy

Massive transfusion has been defined differently across studies, but in general it refers to transfusion of at least 10 U of red cells in the first 24 hours after trauma.[30] In lethal hemorrhagic shock, transfusion of blood products is performed empirically and is not guided by laboratory tests but is based on clinical parameters.[57] Hemorrhagic shock is a severe and life-threatening condition. Over 30% of military casualties receive blood transfusion and about 6% require massive transfusion.[58] In patients with severe traumatic injury, there is an association between rising transfusion requirements and increased risk of multiorgan failure and worsened clinical outcomes.[59–61] The increase in mortality is correlated with the number of red cell units transfused (22%, 30%, 50%, and 59% mortality in the groups receiving 1 to 10 U, 11 to 20 U, 21 to 40 U, and >40 U, respectively).[60] In the absence of timely and robust tests of coagulation during acute trauma, massive transfusion protocols were designed to provide rapid delivery of blood products to patients with life-threatening hemorrhage.

In the setting of exsanguinating hemorrhage, transfusion therapy is usually based on the number of red cell units administered and expressed as plasma to red cells (P:RBC) and platelets to red cells (PLT:RBC) ratios. Retrospective studies of trauma resuscitation protocols, especially from military experiences, indicate that traditional transfusion protocols do not achieve normal hemostasis and are designed to treat dilution, while earlier and aggressive treatment of coagulopathy with a P:RBC ratio of 1:1 to 1:2 and a PLT:RBC ratio of 1:1 (using random donor platelets [RDPs]) or 1:6 (using single donor platelets [SDPs]) have indicated a possible survival advantage compared to recommendations in existing transfusion guidelines. Currently, there is no standardized massive transfusion protocol in the United States but many trauma centers have their own protocols, with early use of blood type "O" Rh (D)-negative red cells and "AB" plasma in anticipation of further transfusion needs. These observations of RBC:P:PLT ratios of 1:1:1 (1 U red cell, 1 U plasma and 1 U RDPs), practically expressed as 6:6:1 (6 U red cells, 6 U plasma and 1 U single donor apheresed platelets), albeit retrospective, are paving the way to a changing paradigm of transfusion therapy in the military environment and are beginning to receive attention in the

civilian trauma setting.[62–65,66] Whether this high ratio of plasma to red cells would decrease mortality in nonmassively transfused patients is unknown.

Trauma-Induced Coagulopathy

The presence of a coagulopathy occurring early after traumatic injury is a well-recognized independent predictor of mortality.[67] The factors underlying the development of coagulopathy are multiple and traditionally were thought to include dilution of coagulation factors and platelets, compromise of the coagulation system by infusion of crystalloids and colloids, increased fibrinolysis and hypocalcemia.[68,69] The interplay between hypothermia, acidosis, and coagulopathy has been referred to as the "lethal triad." In patients who are already acidotic, massive transfusion of red cells increases acid load.[68,70] Trauma patients receiving large volumes of plasma may develop hypocalcemia due to the chelating citrate anticoagulant present in plasma. Liberal red cell transfusion, although improving oxygen transport, does not replace coagulation factors and platelets. All these factors, which may occur simultaneously, can potentially contribute to coagulopathic bleeding.[71]

Recent observational studies have described a distinct coagulopathy in trauma referred to as trauma-induced coagulopathy (TIC), Acute Traumatic Coagulopathy, or Acute Coagulopathy of Trauma Shock. TIC is a syndrome of "nonsurgical bleeding." The classic model of trauma coagulopathy occurring during resuscitation has been challenged by recent clinical observations, specifically studies showing that TIC may be present in 20% to 30% of patients upon arrival at the emergency room. This coagulopathy is present even prior to massive transfusion, fluid resuscitation therapy, or the development of hypothermia, and is independently associated with a four- to fivefold increase in mortality compared to patients who do not have coagulopathy upon initial presentation.[67,72,73] A combination of massive tissue injury and shock is believed to underlie the pathogenesis of TIC.[74] This situation is in contrast to the traditional understanding of posttraumatic coagulopathy in resuscitated patients that develops as a consequence of medical intervention. TIC is characterized by systemic anticoagulation and hyperfibrinolysis that manifests as a bleeding phenotype with mild prolongation of the INR (>1.3) and aPTT (>1.5 times normal) with preservation of fibrinogen levels and platelet counts.[75] Its mechanism is unclear but it does not appear to be a consumptive coagulopathy; instead, widespread activation of the protein C pathway has been implicated.[76] Recognition of this coagulopathy has stimulated revision of massive transfusion protocols. Early use of plasma, platelets, and cryoprecipitate together with red cells is advocated to reduce overall blood product use and potentially avoidable deaths from hemorrhage after trauma. This development in modern trauma care emphasizes the concept that not all bleeding can be controlled surgically.[74,77,78]

Pharmacologic Therapy

Prothrombin Complex Concentrates

Prothrombin complex concentrates (PCCs), otherwise known as intermediate purity FIX concentrates, were initially used primarily for the treatment of hemophilia B; however, they are rarely used for that indication now due to the availability of newer FIX preparations. Derived from pooled human plasma, these virally inactivated agents contain the vitamin K–dependent factors II, VII, IX, and X in varying amounts. Earlier preparations had considerable variability in their compositions;[79] however, this limitation has improved over the past 15 years with newer forms, and current composition is in line with levels listed by the manufacturer.[80] Due to increased thrombogenicity and risk of DIC seen with earlier forms, most agents now also contain varying levels of anticoagulants, including protein C, protein S, antithrombin, and heparin.[81] Earlier forms also contained variable amounts of activated factors,[82] particularly FVIIa and FIXa, which have been greatly reduced or eliminated in current preparations.[80] Although most current concentrates contain sufficient levels of all four vitamin K–dependent factors, several so-called three factor PCCs, which contain relatively low FVII levels, are also marketed, and are the only agents currently available in the United States.[83]

Although not licensed as such in the United States, the principal indication for PCCs currently is reversal of the effects of oral anticoagulation with VKAs (see section "Complications of Antithrombotic Therapy"). PCCs are also occasionally used as replacement therapy in patients with congenital or acquired deficiencies of FII or FX.[84,85] Although not licensed for this indication, PCCs have additionally been used in treatment of severe hemorrhage requiring massive transfusion,[86] but this practice is only widespread in certain European countries.[87,88] Other reported uses include treatment of bleeding due to vitamin K deficiency, severe liver disease[89,90] or after liver transplantation. In the latter two conditions, these agents are commonly used when volume status is of concern and the use of FFP risks volume overload. It should be noted, though, that PCCs do not contain all coagulation factors that are deficient in liver dysfunction, most notably FV and fibrinogen, and supplementation with FFP and/or cryoprecipitate may be needed to adequately treat active hemorrhage.

Potency labeling and dosing recommendations for PCCs are based on International Units (IUs) of FIX.[91] One IU of PCC per kg body weight generally increases the plasma activity of FIX by approximately 1 IU/dL. Doses are subsequently calculated based upon the goal FIX level, or in the case of VKA overdose, by INR. Typical doses are 25 to 50 IU/kg and can be repeated every 24 hours as needed. The most feared complication of PCC administration is thromboembolism, which has been reported in numerous case series.[92,93] With recent advances in preparation of these agents, including addition of anticoagulants and minimization of activated factors, it appears that thromboembolic events are relatively uncommon.[89,94] Despite this trend, however, PCCs should still be used with caution when the risk for thromboembolism is deemed to be high, such as in the setting of severe liver disease. PCC use is relatively contraindicated in the context of DIC due to thrombotic risk; however, this is less of a problem with the newer preparations that may be used in hemorrhagic forms of DIC when volume limitations preclude the use of FFP. Other adverse events reported include allergic, and even anaphylactic, reactions, although both are rare.[87]

Recombinant Factor VIIa

Recombinant factor VIIa (rFVIIa) was first introduced in the 1980s as a hemostatic agent for patients with hemophilia A and B with known inhibitors, and was approved for this indication in most countries by the late 1990s.[95] Since that time, its off-label use has become increasingly widespread, particularly in the setting of acute massive or life-threatening hemorrhage.

Its mechanism of action is thought to be related to enhanced platelet-surface thrombin generation.[96,97]

Recombinant FVIIa is currently approved for the prevention and treatment of bleeding in congenital hemophilia A and B with inhibitors, acquired hemophilia, and congenital FVII deficiency. Additional approved uses in Europe include bleeding in Glanzmann's thrombasthenia in the presence of antibodies to glycoprotein (GP) IIb–IIIa and/or HLA, with past or present refractoriness to platelet transfusions.[97] As mentioned above, off-label use of rFVIIa is widespread despite lack of definitive evidence regarding efficacy in most settings. Reported uses include bleeding due to anticoagulation, intracerebral hemorrhage, surgical bleeding, postpartum or obstetric hemorrhage, FXI deficiency, and liver disease, among others. Large-scale trials in these areas are limited, and additionally, results of existing trials have often resulted in conflicting data. In general, however, rFVIIa use is deemed appropriate by most experts when uncontrollable hemorrhage is encountered. Consensus panels in numerous countries have additionally made recommendations on appropriate use of rFVIIa, which are congruous with this approach.[98–100]

Another area of interest regarding the use of rFVIIa has been in the setting of civilian and military trauma, where uncontrolled massive bleeding contributes to up to 40% of early in-hospital deaths.[101,102] Several early phase trials appeared to demonstrate efficacy of rFVIIa in reducing bleeding and transfusion requirements.[103–107] This effect appeared to be more significant with blunt trauma, as opposed to penetrating trauma.[108] Data on mortality benefit were mixed, with several trials showing benefit in both early and overall mortality[103,109–111]; however, a recent phase III clinical trial was terminated prematurely due to low likelihood of showing improvement in primary endpoints of morbidity and mortality.[112] Overall, aggressive transfusion therapy remains the standard of care in trauma (see section "Blood Component Therapy"); however, rFVIIa continues to be used in cases where hemorrhage continues despite these measures. At this time, more trials are needed to further assess its efficacy in the setting of trauma.

Dosing regimens reported for rFVIIa in off-label uses vary tremendously by study, making interpretation of efficacy data difficult. Reported doses range from 5 to 200 μg/kg. In the setting of hemophilia, dosing regimens are more standard. Typical doses for bleeding in hemophilia are 90 μg/kg every 2 to 3 hours × three doses, however recent studies in hemophilia have shown that a single dose of 270 μg/kg is equally effective.[113,114] With no clear dosing guidelines in off-label uses, a reasonable starting point is 90 μg/kg, repeating doses every 2 to 3 hours if bleeding persists. Lower doses may be considered where there is heightened concern for thrombotic events. Of note, newer bioengineered forms of rFVIIa with greater potency and/or more rapid onset of action are in clinical development.[115–118]

Adverse events related to use of rFVIIa are mostly restricted to thrombotic events, including stroke and myocardial infarction. A recent review of safety data reported an incidence of <1% of serious thromboembolism in hemophilia patients treated with rFVIIa.[119] Thrombotic events have been reported with off-label use of rFVIIa as well; however, most placebo-controlled trials have not been powered to demonstrate a significant increase in thrombosis. To address this issue, a recent review evaluated 35 randomized, placebo-controlled trials where rFVIIa was used off-label to treat life-threatening hemorrhage. Results showed no difference in rates of venous thromboembolism; however, there was an increased rate of arterial events associated with rFVIIa use (5.5% vs. 3.2%). This effect was more pronounced in patients 65 years or older (9.0% vs. 3.8%), with particularly high rates seen in individuals 75 years or older (10.8% vs. 4.1%).[120] Thus, given the risk of thrombosis, caution should be taken when using rFVIIa in older patients or persons with known or high risk of atherosclerotic disease.

Antifibrinolytics

Antifibrinolytic agents include the synthetic lysine analogues ε-aminocaproic acid (EACA) and tranexamic acid (TXA), as well as the bovine-derived serine protease inhibitor aprotinin. The former two agents exert their pharmacologic effect by blocking the interaction between fibrin and plasminogen through reversibly binding to the lysine-binding site of plasminogen, subsequently preventing its activation and transformation to plasmin.[121–124] Aprotinin, on the other hand, is a nonspecific serine protease inhibitor of multiple enzymes, including trypsin, chymotrypsin, kallikrein, activated protein C, thrombin, and plasmin, and has effects on both coagulation and inflammation.[125,126]

Aprotinin has been primarily used in the setting of cardiac surgery, where it was initially shown to decrease blood loss and transfusion requirements with coronary artery bypass grafting.[127–133] Other perioperative uses have included prevention of blood loss in liver transplantation[134–137] and in orthopedic surgeries,[138] although both have been less well studied. Concerns about the use of aprotinin in cardiac surgery due to associated adverse events, including renal failure, myocardial infarction, stroke, and death, were raised after publication of results from several observational and cohort studies.[139–142] Subsequently, a large scale, prospective, blinded, randomized, controlled trial confirmed an increased risk of death with aprotinin as compared to EACA and TXA, and the study was prematurely terminated.[143] Based upon these results, aprotinin has now been removed from the market and is no longer available for clinical use.

The lysine analogues, EACA and TXA, are also used for prevention of blood loss in cardiovascular surgeries; however, they have been much less extensively studied.[144] Most studies have shown a reduction in perioperative blood loss with both agents, with mixed results regarding reduction in transfusion requirements and need for reoperation. Use of these agents has not been clearly associated with an increased risk of adverse events, including thrombotic events[145,146]; however, most of the studies have not been adequately powered to address this question conclusively. At this point, larger studies are needed to thoroughly assess their safety profiles in this setting. Both agents have also been evaluated in orthopedic and liver transplant surgeries and have been shown to reduce bleeding and transfusion requirements, albeit again with somewhat variable results.

In the setting of acute hemorrhage, lysine analogues have been used in a variety of situations to control bleeding. Both agents have long been used as adjuncts for the treatment of bleeding in patients with hemophilia and vWD undergoing dental extractions, in which setting they reduce the amount of coagulation factor replacement required.[147–151] In conditions associated with hyperfibrinolysis, such as liver disease, acute promyelocytic leukemia, and α_2-antiplasmin deficiency, they have also proven effective.[152–154] Other situations in which these agents are used include bleeding associated with

thrombocytopenia,[155–157] prevention of bleeding with oral surgery while on anticoagulation,[158–161] traumatic hyphema,[162–165] menorrhagia,[166–170] and postpartum hemorrhage (PPH).[171–173] Regarding the latter two indications, TXA has recently been Food and Drug Administration (FDA) approved for use in menorrhagia.[174] While data on the use of lysine analogues for PPH are relatively sparse at this time, efforts are currently underway to perform a large-scale, international, randomized, controlled trial assessing TXA in obstetric hemorrhage, particularly in low and middle income countries.[175]

Due to their ability to decrease blood loss and transfusion requirements in surgery, antifibrinolytics have also been evaluated in the trauma setting. A previous systematic review concluded that there were not enough data to support or refute the use of antifibrinolytics in the setting of trauma, based upon a small number of trials.[176] More recently, a large scale randomized, placebo-controlled trial evaluated TXA in trauma and found a significant reduction in bleeding as well as all-cause mortality when compared to placebo.[177] Based upon these results, the authors of the study concluded that TXA should be considered in all bleeding trauma patients as an adjunct to transfusion. Notably, despite the benefit seen in trauma in this large study, no benefit, and perhaps harm, has been shown with use of antifibrinolytic medications in the setting of isolated intracranial hemorrhage, where they are not routinely recommended.[178]

EACA and TXA are available in both intravenous (IV) and oral formulations. TXA is 7 to 10 times more potent than EACA,[179,180] which accounts for their different dosing regimens. Both agents have a half-life of approximately 1.5 to 2 hours, and dose reductions should be made for renal impairment, as both drugs are eliminated unchanged by the kidneys.[181] Typical EACA doses are up to 5 g orally or intravenously every 6 hours, with a maximum dose of 30 g/d. A continuous infusion of 1 g/h may also be used after a loading dose.[182] An oral solution is also available for swish/spit versus swish/swallow dosing with oral surgery. Typical TXA doses are 1 to 1.5 g orally three to four times daily or 500 to 1,000 mg IV three times daily.[183] Dosing regimens used in the setting of cardiothoracic surgery are highly variable for both medications and typically include a loading dose, maintenance infusion, and occasionally a pump priming dose.[184]

The side effects of EACA and TXA are typically dose-dependent and usually involve the GI tract. Symptoms include headache, nausea, vomiting, dyspepsia, and diarrhea, which are relatively more common with EACA and often subside with dose reductions. Hypotension and bradycardia may occur with excessively rapid IV administration of either agent. Hypersensitivity reactions, such as rash, and rarely anaphylaxis occur with TXA.[185–187] An increased incidence of seizures has also been documented with TXA, especially higher dosing regimens.[188,189] Rare reports of myopathies, including rhabdomyolysis, have been reported with EACA, particularly with extended use.[190–192] Despite the theoretical risk of thrombosis with both agents, there have only been isolated reports of venous or arterial thrombosis,[193–199] and no clear causal relationship has been established in meta-analyses and other reviews of the literature.[146,200,201] Few prospective safety data, however, exist on the use of these agents. Therefore, it is recommended to avoid their use in DIC, concurrently with PCCs (particularly activated forms), with thrombotic disorders, or with estrogen use due to the increased potential for thrombotic events. These agents are also relatively contraindicated in the setting of upper urinary tract bleeding due to the risk of ureteric obstruction.[150,202–204]

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP) is a V2 synthetic analogue of vasopressin that works, at least in part, by promoting release of ultralarge vWF multimers from endothelial cell Weibel-Palade bodies via a cyclic-adenosine monophosphate mediated pathway, resulting in a three- to five-fold increase in circulating levels of vWF and FVIII.[205–209] Other potential mechanisms for its hemostatic effects are likely and have been explored, but the full extent of its *in vivo* effects are yet to be established.[210–213] Its primary use is in the management and prevention of mild to moderate acute hemorrhage in type 1 vWD and mild hemophilia A[214,215] (see Chapters 51 and 52). It has also proven to be effective in managing acute bleeding in acquired platelet function defects, as well as certain inherited platelet disorders, although with variable outcomes depending on the type of defect.[216,217] Other reported uses include Ehlers-Danlos syndrome,[218–220] factor XI deficiency,[221,222] uremia,[223–225] liver disease,[226] and bleeding associated with antiplatelet agents.[227,228]

Dosing is available in intravenous, subcutaneous, and intranasal forms. The typical IV dose is 0.3 μg/kg, infused over 15 to 30 minutes, and it can also be given subcutaneously. Peak vWF and FVIII levels are reached 30 to 60 minutes after IV administration and 60 to 90 minutes after subcutaneous administration, and remain elevated for 6 to 10 hours after infusion.[229,230] Doses can be repeated as clinically indicated every 12 to 24 hours; however, tachyphylaxis typically occurs after three to four doses, reducing its efficacy with repeated use.[231,232] An intranasal form (Stimate) is also available, with recommended dosing of 150 μg (patient weight <50 kg) or 300 μg (patient weight > 50 kg) and similar pharmacokinetics to that seen with subcutaneous dosing.

Common side effects are typically mild and include tachycardia, flushing, and headache. Given its antidiuretic effect, hyponatremia and resultant seizures have been documented, but more commonly occur in children <2 years of age.[233,234] Care should be taken to avoid aggressive hydration with hypotonic solutions in patients receiving DDAVP, and serum sodium levels should be monitored if repeated doses are given. A rare but serious side effect includes arterial thromboses, particularly acute stroke and myocardial infarction,[235–238] and for this reason caution should be used when treating the elderly or persons with known atherosclerotic disease.

MANAGEMENT OF BLEEDING IN SPECIFIC SITUATIONS

Medical Bleeding

Acute hemorrhage outside of the surgical setting is often encountered and may be due to numerous factors, including mechanical, pharmacologic, or hematologic perturbations. Specific management decisions are, in large part, based upon the underlying cause of the bleeding. For example, hemorrhage due to esophageal varices is most definitively treated by local measures such as banding or sclerotherapy, although adjunctive treatment with transfusions or pharmacologic agents may also be indicated if an underlying coagulopathy exists.

Conversely, other medical conditions are commonly associated with a bleeding tendency due to specific underlying hemostatic abnormalities, several of which warrant further discussion.

Renal Disease

Bleeding is a common and potentially serious complication of acute and chronic renal failure. Although multifactorial in etiology, the pathogenesis of hemorrhage in uremia is largely due to numerous platelet abnormalities,[239] which are at least in part caused by dialyzable uremic toxins.[240,241] Other contributing factors include abnormal nitric oxide production, as well as anemia and the consequences thereof. As this population is also at heightened risk of atherosclerosis and thrombosis, medications such as aspirin and others with anticoagulant properties often further contribute to bleeding susceptibility.

Historically, DDAVP has been the primary pharmacologic agent for treatment of acute bleeding with uremia, where it has been proven to shorten bleeding times and prevent bleeding complications with renal biopsy.[223] Its utility, however, has declined recently due to the widespread use of recombinant erythropoietin, which has made the hemostatic abnormalities associated with uremia much less prevalent due to increased red cell mass, thereby leading to improved blood rheology and increased interaction of platelets with the vessel wall.[242] Due to the delayed hematologic response to erythropoietin, however, it is also reasonable to transfuse red cells to the acutely bleeding uremic patient to improve these rheologic factors quickly and thus improve hemostasis, with a goal hematocrit >30%. Additionally, consideration should be given to urgent dialysis to facilitate improvement in hemostatic parameters, although this should not be the only intervention pursued.[243] Finally, attention should be given to the potential contribution of medications affecting hemostasis, such as aspirin or heparin, and appropriate interventions taken to counteract these effects (see section "Complications of Antithrombotic Therapy").

Liver Disease

Chronic liver disease is characterized by numerous abnormalities in hemostatic parameters, and has classically been considered a substantial risk for bleeding complications. More recently, a view of a fragile balance in coagulation between deficiencies in both procoagulant and anticoagulant pathways, leading to both increased bleeding and thrombotic risk, has emerged.[244] Contributors to the bleeding risk in liver disease may include decreased procoagulant clotting factors,[245] thrombocytopenia secondary to both hypersplenism and decreased thrombopoietin synthesis,[246] platelet dysfunction,[247] dysfibrinogenemia secondary to abnormally glycosylated fibrinogen,[248] hyperfibrinolysis secondary to impaired hepatic clearance of plasminogen activators and/or reduced hepatic synthesis of inhibitors of fibrinolysis,[249] and vitamin K deficiency secondary to decreased enterohepatic recirculation of bile salts.[250]

Due to the complexity of the coagulopathy observed in liver disease, as well as the limited prospective, evidence-based data regarding therapeutic interventions, specific universal recommendations for acute bleeding management are not possible. In general, however, hemostatic abnormalities should be identified and corrected, if possible, typically through the initial use of transfusions, though this practice has undefined efficacy. Platelets should be given for profound thrombocytopenia, with goal platelet level of >50,000[251]; however, platelet recovery to this level may not be possible if there is coexistent splenomegaly. Although indiscriminate attempts at correcting the PT and aPTT in nonbleeding patients is not recommended due to their poor correlation with bleeding risk,[252] FFP infusions are usually given in the event of acute hemorrhage. The utility of FFP is impaired due to the substantial volumes required to improve and correct hemostatic defects, the concomitant risk of volume overload in this susceptible patient population, and lack of clearly defined thresholds in coagulation parameters for which administration is indicated.[253] Finally, cryoprecipitate is commonly given for fibrinogen levels <100 mg/dL[254] and should be considered as well.

Alternative interventions for persistent bleeding or as adjuncts to transfusion therapy may be useful but should be tailored to the specific clinical situation and coagulation defect present when possible. Antifibrinolytic agents such as TXA and EACA[255] should be considered when hyperfibrinolysis is present, although this distinction may be difficult to make due to the current lack of validated assays of global hemostasis/fibrinolysis. PCCs may be useful when tenuous volume status precludes the use of aggressive FFP administration, although it should be remembered that these agents only contain the vitamin K–dependent factors and may not be sufficient alone to achieve hemostasis. Furthermore, there have been no controlled trials using PCCs in this patient population, and therefore they should be used with caution.[256] Finally, rFVIIa has been used to manage acute hemorrhage in liver disease, albeit with mixed results,[257,258] and data from prospective, well-designed trials are generally lacking. Despite this lack of clear evidence, it is generally thought to be a reasonable "rescue" treatment when there is ongoing hemorrhage despite aggressive therapy based upon anecdotal reports of successful administration.[259,260] In addition to the scant data regarding efficacy of these adjunctive therapies, there are even fewer data regarding their safety in the setting of liver disease. Therefore, the use of antifibrinolytics, PCCs, and rFVIIa should take into account their potential thrombotic risk and be avoided in circumstances where risk of thrombosis is deemed to be high.

Obstetric Bleeding

PPH is generally defined as blood loss >500 mL following vaginal birth, or >1,000 mL following cesarean section,[261] though this definition has limitations due to inherent inaccuracies with blood loss measurement. There are numerous potential causes for PPH, with uterine atony being the most common.[262–264] Other local causes may include tissue injury, ruptured uterus or vessels, and abnormal placentation.[265] Initial management options include emptying the uterus, stimulating the uterus to contract with massage or uterotonics, uterine tamponade or compression, and potentially uterine devascularization (via surgical ligation or embolization of uterine arteries) or hysterectomy if warranted.[266]

In addition to local causes of bleeding, a systemic coagulopathy may also contribute to PPH. Causes of coagulopathy in the peripartum period include DIC secondary to placental abruption, retained products of conception, hypertensive complications of pregnancy, HELLP syndrome (hemolysis, elevated liver enzymes, low platelets), septic complications, or amniotic

fluid embolus, as well as coagulopathy secondary to massive hemorrhage itself and/or hemodilution.[267] As with other forms of DIC, any underlying pathology should be identified and treated promptly, if present (i.e., delivery of retained products). In addition to local measures performed by the obstetrician, volume resuscitation and transfusion support are the initial mainstays of therapy. Although not yet largely accepted, some centers are moving toward transfusion protocols similar to those being utilized in trauma settings, with early and aggressive use of plasma components and platelets in addition to red cells[268] (see section "Massive Transfusion Therapy"). Data from clinical trials to guide management of transfusion in obstetrics, however, are lacking. Some advocate assessing the role of early fibrinogen replacement as a first step[269] based upon existing evidence that fibrinogen levels are the only coagulation parameter independently associated with worsening PPH.[270] Despite the lack of clear transfusion guidelines, however, most would advocate transfusing platelets for a platelet count > 50,000; FFP for a PT and/or aPTT >1.5 times the normal range; and cryoprecipitate or fibrinogen concentrate for fibrinogen levels <100 mg/dL, though 150 to 200 mg/dL may be a more useful threshold.[271] As with trauma, attention should also be paid to correction of hypothermia, acidosis, and hypocalcemia.

If hemorrhage is unresponsive to maximal blood component therapy and local measures, off-label use of rFVIIa has been shown to be efficacious in retrospective, cohort, and case–control studies,[272–274] and should be considered. No prospective, randomized studies have been published to date, however, assessing either its efficacy or safety in obstetric hemorrhage. With regards to timing, most recommend using rFVIIa only after failure of other conventional therapies, including invasive therapies, but prior to hysterectomy if possible. Furthermore, its use should not delay or be a substitute for a potentially life-saving procedure.[265,271,275,276]

Even fewer data are available regarding the use of antifibrinolytics for PPH, although one prospective, randomized trial did show a modest reduction in acute blood loss with TXA compared to placebo.[277] More prospective studies are needed to validate the efficacy and safety of antifibrinolytics and rFVIIa before they should be considered for routine use in PPH, though both agents appear promising. Finally, both rFVIIa and antifibrinolytics may increase risk for thrombosis; therefore, caution should be used when using these agents where thrombotic risk is deemed high, such as in the setting of overt DIC.

Surgical Bleeding

Hemorrhage in the surgical setting can be challenging both from both a diagnostic and therapeutic standpoint. When confronted with the bleeding surgical patient, the first step should be to determine whether the bleeding is "surgical" in nature or due to a defect(s) in hemostasis. "Surgical" bleeding is the most common cause of bleeding, and is best controlled with local measures by the surgeon. In addition to operative techniques, numerous topical agents are available to help control bleeding and promote hemostasis in the surgical setting. Mechanical hemostats that form barriers to bleeding include gelatin-based, collagen-based, cellulose-based, polysaccharide-based, albumin-based, and inorganic agents. Potential adverse effects include compression of adjacent structures due to swelling, infection, adhesion formation, and foreign body reactions.[278] Two active hemostatic agents are currently in use. Topical thrombin from bovine, human-pooled plasma, and recombinant forms are marketed. All three have been compared and are functionally equivalent in terms of efficacy, with 95% of patients achieving hemostasis within 10 minutes of application.[279] Fibrin sealant, or fibrin glue, is a two-component hemostat and sealant composed of fibrinogen and thrombin. Certain preparations also contain FXIII and/or antifibrinolytic agents such as aprotinin or TXA.[280] Hematologists should be aware of potential adverse events related to the use of agents containing bovine thrombin, as coagulopathy due to development of cross-reactive antibodies to bovine FII and FV has been reported.[281–284] Although the development of antibodies is relatively common, they do not result in clinical coagulopathy in most patients.[285]

Nonsurgical causes of bleeding should be suspected when there is slow, diffuse bleeding at the surgical site or when there is evidence of bleeding outside of the surgical site. Common causes of coagulopathy in the perioperative period include consumption of platelets and coagulation factors, as well as dilutional coagulopathy secondary to crystalloid and blood product administration during the surgery. Routine laboratory assays such as CBC, PT, and aPTT can help guide decisions to transfuse platelets, FFP, and/or cryoprecipitate; however, it should be noted that routine coagulation studies may not be entirely reliable in this setting.[286] Other secondary causes of coagulopathy should also be entertained, such as DIC, and the underlying conditions be treated, if present. Further interventions beyond transfusion support should be based upon the clinical context, with therapies directed at the underlying hemostatic defect (e.g., antifibrinolytics for mucosal hemorrhage posttonsillectomy). Finally, rFVIIa may be given off-label if there is continued life-threatening hemorrhage despite maximum surgical and medical therapy.[287]

Complications of Antithrombotic Therapy

Antiplatelet Agents

Antiplatelet agents are commonly used in both primary and secondary prevention of atheroembolic disease. Aspirin, one of the most widely used agents in the Western World, works by irreversibly binding to cyclooxygenase-1, thereby inhibiting thromboxane A2 production in all exposed platelets and subsequently causing mild to moderate platelet dysfunction.[288,289] Aspirin use increases the risk of major hemorrhage, typically in the form of GI and intracranial hemorrhage, although the absolute annual increased risk is quite modest (0.13%).[290] The mainstay of reversing aspirin effect in the setting of acute hemorrhage is platelet transfusion. Given the rapidity with which aspirin is metabolized to an inactive form, this strategy is appropriate as long as aspirin has not been taken in the last hour.[291] DDAVP is another therapeutic option shown to reverse the effect of aspirin, although large clinical studies in this area are limited.[292,293]

Thienopyridine derivatives, such as clopidogrel and ticlodipine, are antiplatelet agents that exert their effects through blockade of the platelet adenosine diphosphate (ADP) receptor ($P2Y_{12}$). These agents are frequently used for secondary prevention in coronary artery disease and cerebrovascular disease, and are often used in conjunction with aspirin. Not surprisingly, combined use of aspirin and thienopyridines is associated with higher risk of bleeding.[294] Transfusion of platelets has been shown to reverse the antiplatelet effect seen with clopidogrel

use,[295] and is probably the best management option in acute hemorrhage. DDAVP has also been shown to improve platelet reactivity and hemostatic parameters *in vitro* when administered to subjects receiving clopidogrel,[296] as has rFVIIa[297]; however, little clinical evidence exists for their use in this setting. Newer thienopyridine derivatives have recently come on the market as well, such as prasugrel and ticagrelor, but little evidence regarding bleeding management is available at this time.

GP IIb/IIIa inhibitors are commonly used, and have shown considerable efficacy in improving outcomes in patients with acute coronary syndromes and in percutaneous coronary intervention.[298,299] Management of bleeding complications with these agents varies based upon which agent is used due to major differences in their respective pharmacokinetics. Eptifibatide and tirofiban are similar in that they rapidly bind and dissociate from GP IIb/IIIa receptors, thus requiring increased serum levels.[300] Transfusion of platelets is therefore ineffective due to the fact that the number of drug molecules present in plasma overwhelms the number of GP IIb/IIIa receptors by several orders of magnitude.[301] Both agents are renally excreted, with half-lives of 2.5 hours and return to baseline platelet function in 4 to 8 hours of discontinuation.[302,303] Therefore, discontinuation of the drug is the most important factor in acute hemorrhage. Both agents can be removed with hemodialysis[304] as well, making this a viable option in the setting of renal insufficiency. *In vitro* studies have additionally shown that fibrinogen and platelet supplementation in combination,[305] or desmopressin,[293] may help to restore platelet function in patients treated with these agents, although clinical data are lacking.

Contrary to the above agents, abciximab binds with high affinity to platelet GP IIb/IIIa receptors with little free drug in plasma.[306] Despite its short half-life of 15 to 30 minutes, abciximab has a prolonged biologic half-life with 50% inhibition of platelet function still present 48 hours after drug discontinuation.[307] Because little free drug circulates in the plasma compartment, platelet transfusion can reverse the hemostatic defect by replenishing the number of viable GP IIb/IIIa receptors,[308] and should be used whenever emergent reversal is required due to hemorrhage. With regard to adverse effects related to GP IIb/IIIa inhibitors in general, thrombocytopenia has been reported with all agents and should additionally be evaluated if a patient receiving these medications has bleeding complications.

Vitamin K Antagonists

VKAs have been the mainstay in oral anticoagulants for >60 years and are commonly used in the setting of venous thromboembolism, mechanical heart valves, and atrial fibrillation. VKAs exert their anticoagulant effect by inhibiting vitamin K epoxide reductase, an enzyme that regenerates vitamin K back to its active, reduced form. This reduced form of vitamin K serves as a cofactor in the γ-carboxylation of the vitamin K–dependent factors II, VII, IX, X, protein C, and protein S, a step necessary to promote their coagulant activities.[309] Several preparations exist, including acenocoumarol, warfarin, and phenprocoumon, which differ mainly with regards to their half-lives (9 hours, 36 to 42 hours, and 90 hours, respectively),[310] directly impacting management of treatment-associated bleeding.

Bleeding is not an uncommon clinical scenario in patients receiving VKAs, with risk of major bleeding reported to be between 0.9% and 1.4% annually with warfarin.[311] Factors associated with increased risk of bleeding include intensity and duration of anticoagulation,[312,313] recently initiated anticoagulation,[314,315] older age,[314,316] unstable INRs,[317] comorbid conditions such as hypertension[318] or chronic renal disease,[315] concomitant aspirin use,[319] among others. Per American College of Chest Physicians (ACCP) guidelines, asymptomatic elevation in INR and mild warfarin-associated bleeding can typically be managed with lowering and/or omitting a dose(s). In this setting, vitamin K is also typically recommended, however, only if the INR is >5. For INR 5.0 to 9.0, vitamin K at a dose of 1 to 2.5 mg orally may be used if there is mild bleeding or in the asymptomatic patient with a presumed increased risk of bleeding. For INR > 9.0, vitamin K 2.5 to 5 mg orally is recommended in both scenarios.[320]

With serious or life-threatening hemorrhage, the goal is rapid reversal of anticoagulation with vitamin K and FFP or PCCs. Intravenous vitamin K has been shown to correct the INR more rapidly at 6 and 12 hours, with similar correction at 24 hours, when compared to oral vitamin K.[321] Therefore, vitamin K 5 to 10 mg IV by slow infusion is recommended for severe hemorrhage to promote more rapid improvement in coagulation parameters. Although the risk of anaphylaxis with IV vitamin K exists, it is quite low and has been described in only 3 per 10,000 doses with the more modern micelle preparations.[322] Intramuscular vitamin K should be avoided due to the risk of intramuscular bleeding, and subcutaneous administration has been shown to be inferior to IV administration[323] and should not be used.

Although FFP contains all the coagulation factors needed to correct the INR, its use in rapid reversal of anticoagulation due to warfarin is hindered due to the large volumes required, time needed to crossmatch and prepare the plasma, and inability to infuse rapidly.[324] Subsequently, PCCs are typically recommended over FFP, when available, in the setting of severe hemorrhage, although prospective trials comparing them with FFP are currently lacking. The optimal dose of PCCs has not been clearly established; however doses of 25 to 50 U/kg have been proven effective.[325,326] Tailored dosing based upon INR at presentation has been shown to have similar efficacy as well.[327] It should be noted that "three factor" PCC use may result in inadequate correction of the INR, which can be improved with the addition of several units of FFP, based upon a retrospective case series.[83] This has, however, recently been challenged in a prospective cohort study.[328] Therefore, supplemental FFP administration should be considered when using "three factor" PCCs, particularly if the INR does not adequately correct with PCC alone. Finally, rFVIIa has been used to treat warfarin-associated bleeding; however, data are mainly limited to *in vitro* changes in coagulation assays or clinical outcomes in retrospective, nonrandomized studies in which most subjects also received FFP.[329] A recent prospective, placebo-controlled, exploratory phase I trial additionally showed no improvement in a skin punch biopsy bleeding model with rFVIIa, although there was improvement in coagulation parameters.[330] Further studies are needed in this area; however, at this time rFVIIa cannot be recommended as frontline therapy for warfarin-associated bleeding. It may be considered in the setting of refractory bleeding despite standard therapy, or in low dose as an adjunct to vitamin K and PCCs, particularly "three factor" PCCs.

Heparins

Unfractionated heparin exerts its anticoagulant effect by binding to antithrombin and augmenting its inhibition of certain coagulation factors by 1,000-fold. It inhibits FIIa to a much

greater extent than FXa and has a half-life of 1 to 2 hours.[331] Given its short half-life, minor bleeding may be managed by simply discontinuing heparin. In cases of severe hemorrhage, protamine can be used as an antidote to rapidly reverse its anticoagulant effect. Protamine doses of 1 mg for every 100 U of heparin administered over the last several hours should be given to attempt complete reversal.[331] The maximum dose of protamine is 50 mg, and infusion should be done slowly (5 mg/min) to decrease the risk of histamine-associated hypotension and bronchoconstriction.[332] Due to its short half-life of 10 minutes, repeat dosing may be needed to reverse therapeutic doses of subcutaneous heparin.[310] It should be noted, however, that protamine has an anticoagulant effect of its own and excess administration can lead to increased bleeding.

Low molecular weight heparins (LMWHs) are derived from heparin, generally have longer half-lives, and exert their anticoagulant effects primarily through antithrombin-mediated inhibition of FXa. Protamine neutralizes the anti-IIa activity of LMWHs, and only partially affects the predominant anti-Xa activity of these drugs.[333,334,335] Recommended doses of protamine for LMWH-associated bleeding are 1 mg for every 100 anti-Xa U of anticoagulant given within the last 8 hours. A second dose of 0.5 mg protamine for every 100 anti-Xa U can be administered if bleeding persists.[331] Data regarding the effectiveness of this intervention are mixed and mainly limited to case reports.[336–338] No proven antidote is available for newer agents, such as fondaparinux, idraparinux, and danaparoid; however, *ex vivo* data suggest that rFVIIa may reverse the anticoagulant effects of some of these agents, including LMWHs.[339] Clinical results are again limited to case reports that showed mixed results, but this approach is reasonable in the setting of life-threatening hemorrhage or persistent bleeding despite conservative measures.

Other Anticoagulants

Direct thrombin inhibitors (DTIs), including lepirudin, bivalirudin, and argatroban, are typically administered via continuous infusion and have relatively short half-lives.[340] Thus, prompt discontinuation of the drug with acute hemorrhage is an important factor and may be all that is necessary with less serious bleeding. No clearly proven reversal agent exists for this class of medication, which presents a serious challenge in the setting of acute bleeding. Activated PCC and rFVIIa can improve coagulation *ex vivo*[339] as well as bleeding in animal models,[341] but their clinical utility remains to be seen. Recombinant FVIIa has been evaluated in several case reports, albeit with mixed results.[342] DDAVP has also been shown to improve bleeding time in animal models[343]; however, it has not been evaluated fully in humans. Finally, hemodialysis can remove all three DTIs and is another management option,[331] particularly with renal impairment and the associated toxicity with the renally eliminated preparations lepirudin and bivalirudin.

New oral anticoagulants have either recently become available or are expected to be available shortly, including the IIa inhibitor dabigatran, and the Xa inhibitors rivaroxaban and apixaban. No antidote exists for these agents, which is a cause for concern in the setting of acute hemorrhage, particularly as they become more commonly used. As with the DTIs, discontinuation of the medication is an important factor with associated bleeding. *Ex vivo* data suggest that rFVIIa may antagonize the anticoagulant effect of some of these agents; however, no clinical data exist at this time.[344] Further studies are needed to better guide management of bleeding with these newer agents.

CHAPTER

77 Therapy with Antifibrinolytic Agents

DAPHNE B. STEWART AND VICTOR J. MARDER

After hemostasis is established in an injured vessel, a highly orchestrated process follows to heal the vessel and to reestablish blood flow. To a large extent, this process is mediated through locally controlled fibrinolysis by activation of the plasminogen–plasmin enzyme system (see Chapters 20 and 21). Briefly, plasminogen binds to lysine residues on fibrin and is converted to plasmin by plasminogen activators (PAs) released by endothelial cells, through cleavage of the heavy chain at Arg560-Val561.[1] Trace amounts of plasmin liberate an amino-terminal 76-residue portion of plasminogen,[2] converting glu-plasminogen to lys-plasminogen, which binds to fibrin more efficiently[3] and is more sensitive to PA activation,[4–6] thereby promoting further conversion of plasminogen to plasmin.[7,8] Just as coagulation inhibitors such as antithrombin and tissue factor pathway inhibitor limit the initial hemostatic process to the site of vessel injury, fibrinolytic inhibitors such as plasminogen activator inhibitors, α_2-antiplasmin, and α_2-macroglobulin contain the fibrinolytic reaction to the site of injury.

Antifibrinolytic agents (AFs) are best viewed as prohemostatic drugs that act in two situations. The first is to prevent bleeding caused by an excess of plasmin activity (see FIGURE 77.1), such as in the setting of primary menorrhagia.[9,10] The second situation is to retard physiologic fibrinolysis following slow or ineffective hemostasis (see FIGURE 77.1), such as may occur in a hemophiliac.[11,12] AFs may improve hemostasis in a wide variety of bleeding states, reducing blood loss and transfusion. Useful properties of AFs are ready whole body distribution following oral or intravenous administration, potent inhibition of plasmin, and no associated tachyphylaxis. When used appropriately to diminish an exuberant fibrinolytic response, these agents do not induce or potentiate coagulation. Thus, lower levels of D-dimer were present in patients treated with ε-aminocaproic acid (EACA) (vs. placebo) before, during, and after cardiac surgery, demonstrating inhibition of fibrinolysis, but levels of thrombin–antithrombin complexes and soluble fibrin were the same as in placebo-treated patients, indicating no activation of coagulation.[13] However, AF agents have the potential to unmask subclinical thrombosis, such as in a patient with unrecognized, compensated, disseminated intravascular coagulation (DIC) (see Chapter 98).

There are three distinct clinical situations in which antifibrinolytic therapy has been proven to be useful: (a) systemic hyperfibrinolysis, (b) hypocoagulability, and (c) localized lesions in the absence of systemic hyperfibrinolysis or hypocoagulability.[14–17] The field has undergone a sea change due to two significant circumstances:

1. Withdrawal of the preeminent AF agent, aprotinin, from the market due to evidence of increased mortality following its use
2. The expansion of the indications for AF agents to the treatment of trauma-induced hemorrhage, an indication that will likely dramatically increase the number of patients treated

MODE OF ACTION OF ANTIFIBRINOLYTIC AGENTS

The AF agents fall into three categories:

1. Natural plasma inhibitors of plasmin and of PAs,[18,19] which are not the subject of this chapter (see Chapter 21)
2. Synthetic lysine analogs, such as *trans-p*-aminomethylcyclohexane carboxylic acid (tranexamic acid, TXA) and 6-aminohexanoic acid (EACA)[21–24]
3. Aprotinin (Trasylol, bovine pancreatic trypsin inhibitor), a 58-residue polypeptide (M_r = 6,500) isolated from bovine lung, parotid gland, or pancreas,[20] is a dose-dependent inhibitor of plasmin[17] and at higher concentrations of other serine proteases (trypsin, kallikrein, chymotrypsin).[14,16,17] Recent studies show an increased risk for death and renal failure after treatment with aprotinin, so this drug is no longer marketed for use in the United States or Europe, although it remains available for research.

Biochemistry

The lysine analogs (TXA and EACA) prevent excessive plasmin formation by occupying plasminogen's lysine-binding site (LBS) for fibrin, thereby precluding plasminogen localization to fibrin for activation by PA (see FIGURE 77.2). Lysine analogs also bind to tissue plasminogen activator (tPA) kringles, interfering with plasminogen activation.[18,21] *In vitro*, these agents bind to the LBS of plasminogen, resulting in a conformational change that may actually accelerate activation,[19,21,22,25] and binding to plasmin kringles reduces the binding by plasmin inhibitors, which could theoretically increase fibrinolytic activity.[26,27] Yet, the major action of these compounds *in vivo* is antifibrinolytic, primarily by blocking the association of plasminogen and tPA on the fibrin surface.[28,29] Although plasmin may still be generated, fibrinolysis is prevented.

The seemingly disparate effects may be explained by the two-step process required for binding of plasminogen to fibrin (see FIGURE 77.2). Plasminogen is activated by proteolytic cleavage that exposes the serine–histidine catalytic site, a cleavage that also promotes binding to fibrin[30] between LBSs on plasminogen and lysine residues on fibrin. Without proper binding, proteolysis cannot proceed. This two-step requirement explains the seeming discrepancy of *in vivo* inhibition[29,31–36] and *in vitro* activation.[22,25–38] *In vitro*, EACA and TXA accelerate plasminogen activation by altering plasminogen's conformation and making it more susceptible to proteolytic action by activators. However, lysis of a fibrin substrate is inhibited because the same binding phenomenon also blocks the LBS. Therefore, plasmin may be

	Normal Response to Injury	Bleeding Tendency	
		Abnormal Hemostasis, Normal Fibrinolysis	Normal Hemostasis, Excessive Fibrinolysis
Injury Incurred	Platelet Adhesion, Aggregation, Formation of Primary Plug	Delayed Plug Formation	Normal Primary Plug Formed
	↓	OR	↓
Hemostasis	Thrombin Burst, Fibrin Formed and Cross-Linked	Inadequate Plug Reinforcement	Fibrin Formed and Cross-Linked
	↓	↓	↓
Fibrinolysis	Delayed Clot Resolution	Normal Rate of Clot Resolution	Accelerated Fibrinolysis
	↓	↓	↓
Net Effect on Bleeding	Bleeding Resolves, Vessel Patency Re-Established	Prolonged Primary Bleeding or Late Rebleeding	Delayed Rebleeding

FIGURE 77.1 Schematic of body's hemostatic response to vascular injury and effect of imbalances between hemostasis and fibrinolysis. Under physiologic conditions, when an injury is incurred, hemostasis proceeds culminating in fibrin generation and reinforcement of the platelet plug, followed by delayed clot resolution through fibrinolysis. A bleeding tendency arises when either arm is disrupted. If hemostasis is inadequate, normal fibrinolysis will occur and cause premature clot resolution with bleeding. As well, if hemostasis is normal, yet balanced by enhanced fibrinolysis, a clot will dissolve prematurely and result in bleeding.

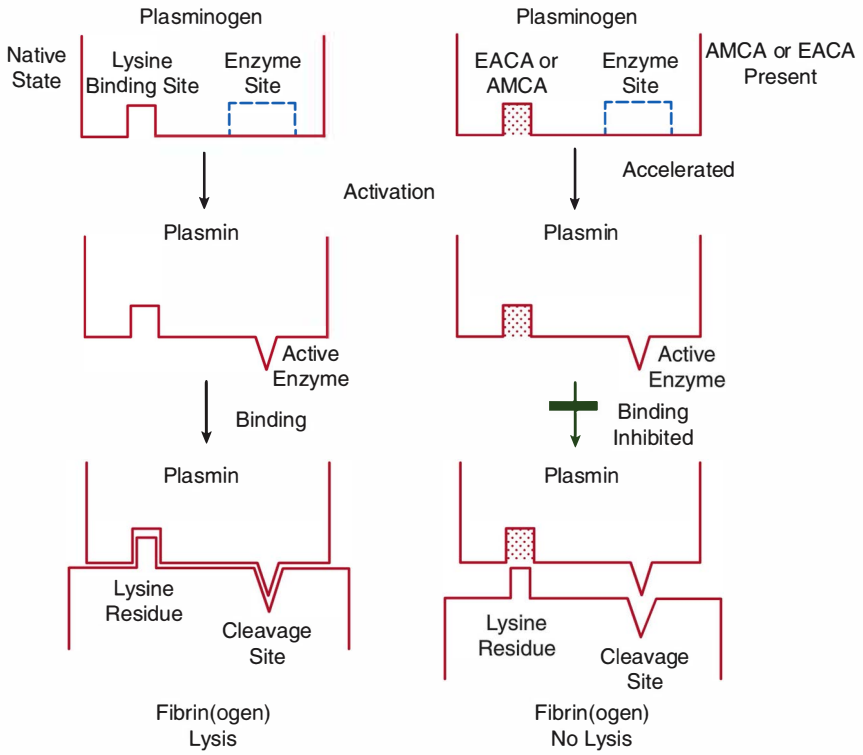

FIGURE 77.2 Schematic diagram of the *in vitro* mode of action of synthetic lysine analogs on plasminogen activation and plasmin proteolysis of fibrin(ogen). ε-aminocaproic acid (EACA) and *trans-p*-aminomethyl-cyclohexane carbolyxic acid (TXA) accelerate plasminogen activation by inducing a conformational change in the molecule; however, they inhibit fibrinolysis by blocking the lysine binding site necessary for the binding of plasmin(ogen) to its substrate. Therefore, even though plasmin may be rapidly formed, it cannot reach the fibrin substrate because its binding site is occupied by the synthetic inhibitor. The accelerated activation as shown in the figure is from the *in vitro* experiments; it remains to be demonstrated *in vivo*.

produced, even rapidly, but without binding to fibrin; there is no proteolytic fibrinolysis by the serine enzyme site.

EACA and TXA are structurally similar to lysine and inhibit the interaction between fibrinogen lysine residues and plasminogen LBSs, especially those located on kringle 1.[39–42] Subtle differences in the synthetic analogs markedly affect their inhibitory potential, as exemplified by the approximately 6- to 10-fold higher molar potency of TXA in comparison with EACA[43] and the ineffectiveness of the *cis* form of TXA in comparison with the *trans* form.[43] Other active analogs of lysine include *p*-amino methylbenzoic acid and 4-amino ethylbicyclo-[2.2.2]-octane-1-carboxylic acid, which are 5- to 10-fold and 100-fold, respectively, more potent than EACA.[44]

Aprotinin is a nonspecific serine protease inhibitor of the Kunitz family. Its active residue, 15-lysine, binds reversibly to its target's catalytic site and inhibits numerous serine proteases, including trypsin, plasmin, chymotrypsin, kallikrein, elastase, urokinase, and thrombin.[17] *In vivo*, aprotinin binds directly to plasmin at 137 kallikrein inhibitor units (KIU) per mL, whereas it binds to kallikrein at >250 KIU per mL. Side chain Lys15 of aprotinin binds to the aspartate side chain in the specificity pocket of plasmin. Aprotinin blocks activation of protease-activated receptor-1 on platelets, preventing thrombin-induced platelet aggregation, a mechanism thought to be particularly important in the platelet dysfunction acquired during exposure to cardiopulmonary bypass circuits.[45] Aprotinin inhibits the inflammatory cascade at multiple levels, protects against kallikrein-induced generation of bradykinin, decreases neutrophil degranulation and extravasation at inflammatory sites, decreases expression of proinflammatory glycoproteins (CD11b) on neutrophils, and attenuates complement generation.[46,47]

Pharmacology

TXA and EACA are rapidly absorbed from the gastrointestinal (GI) tract, allowing oral or intravenous administration,[48–50] with peak plasma levels at 1 to 2 hours after oral dosing. Elimination is primarily via renal excretion and metabolism, approximately 65% excreted in the urine unchanged and 10% as an inactive metabolite, adipic acid. Approximately 85% of an intravenous dose is cleared within 3 hours, but because EACA penetrates the entire extravascular space, urinary excretion may be detected for 12 to 36 hours.[49] The drugs cross the blood–brain barrier,[51] enter joint fluid and synovial membranes,[52] are excreted at low levels into breast milk, and pass through the placenta.[53]

The recommended dose for EACA has been derived from *in vitro* studies and shown to be effective for the treatment of hyperfibrinolytic states; however, the minimal dose required to inhibit normal or enhanced local fibrinolysis is not known. EACA is usually administered as an intravenous priming dose of 0.1 g/kg over 20 to 30 minutes, followed by a continuous infusion of 0.5 to 1 g/h or an equivalent intermittent dose every 1, 2, or 4 hours, generally until acute bleeding is controlled.[35] Continuous intravenous infusion of 0.5 g/h may be a useful regimen for serious acute bleeding (personal observation). Plasma levels of at least 0.001 M (13 mg/100 mL) are adequate to inhibit *in vivo* fibrinolysis.[29,33,43,54] Urinary concentration is generally 75- to 100-fold higher than plasma[49]; therefore, much lower doses may be used to control urinary tract bleeding (3 g EACA per day). As renal clearance approximates endogenous creatinine clearance,[48] patients with renal insufficiency should have their doses reduced according to creatinine clearance.

The serum half-life of TXA is similar to EACA, 1 to 2 hours, and it is also rapidly excreted unchanged in the urine, more than 90% in 24 hours.[50,55] Compared with EACA, TXA is much more potent, inhibiting fibrinolysis at much lower plasma concentrations, with inhibitory effect lasting for 7 to 8 hours. The recommended oral dose is 25 mg/kg, three times daily. Intravenous infusion is delivered at a dose of 10 mg/kg, three times per day, or if used for surgical prophylaxis of bleeding, 10 mg/kg loading dose followed by continuous infusion of 1 mg/kg/h. Although studies with aprotinin have demonstrated a clear dose–response curve with regard to reduction in fibrinolytic bleeding, assessment of a dose response among lysine analogs is limited by a lack of randomized, placebo-controlled trials.[56]

Unlike the orally bioavailable lysine analogs, aprotinin must be administered parenterally. Following its distribution phase, the plasma half-life of aprotinin is 150 minutes, and its terminal half-life is 5 to 10 hours. Aprotinin is primarily reabsorbed in the proximal tubules, with only approximately 10% excreted unchanged in the urine. Ultimately, the drug is taken up by tubular endothelium, stored in phagolysosomes, and slowly degraded by lysosomal enzymes.[20] Aprotinin dosing is measured as KIU, or the amount of aprotinin to decrease two biologic units of kallikrein activity by 50%. Aprotinin is associated with a risk for anaphylaxis, so an intravenous test dose of 10,000 KIU must be given to exclude hypersensitivity at least 10 minutes prior to the loading dose.[20] Clinically significant decreases in surgical blood loss and transfusion requirements correlate with higher doses of aprotinin.[57–60]

Side Effects and Complications

EACA and TXA are associated with nasal stuffiness, conjunctival injection, skin rash, and dose-related GI discomfort, including nausea, vomiting, and diarrhea.[35,50] A literature review of EACA use between 1972 and 1995[61] found 33 cases of clinically significant myopathy, notably with prolonged administration of high doses (16 to 36 g/d for >28 days) and that patients recovered after discontinuing the medication.

Aprotinin, a bovine-derived protein, is associated with hypersensitivity reactions, including skin eruption, pruritus, dyspnea, and fatal anaphylactic shock in 0.3% to 0.6%.[56] Although exceedingly rare with first exposure, the incidence of anaphylaxis may be as high as 2.7% upon second exposure.[62] A pretreatment test dose must be given to exclude those at risk for hypersensitivity, although anaphylaxis has occurred following a nonreactive test dose.[62] Efforts to decrease incidence of anaphylactic shock have not proven effective. Aprotinin is associated with dose-related renal dysfunction and increased need for dialysis,[63,64] with higher risks in patients with baseline renal impairment or those taking renal toxic medications. When combined with off-pump bypass surgery and angiotensin converting enzyme inhibitor (ACEI) use, aprotinin nearly tripled the risk for postoperative renal dysfunction.[65] Additional side effects of aprotinin include vasodilation, generally transient and preventable with slow drug administration, and prolongation of the partial thromboplastin time and activated clotting time due to inhibition of the intrinsic clotting cascade.

Serious systemic thrombotic complications have been reported following the use of antifibrinolytic therapy, although these complications are most clearly associated with a concurrent thrombogenic stimulus, and case reports of devastating, systemic thrombotic episodes following antifibrinolytic therapy are reported,[61–73] generally in association with conditions predisposing to coagulopathy. Central venous catheter thrombosis may occur more commonly following antifibrinolytic therapy,[74–77] and prophylactic antifibrinolytic therapy used during joint replacement or prostate surgery is associated with an increased risk of venous thrombosis.[60,78,79] Lysine analogs have been used successfully to treat postpartum hemorrhage and hemorrhage associated with *abruptio placentae*, and a retrospective analysis of 2,102 pregnant women showed only 2 of 256 TXA-treated patients versus 4 of 1,846 matched controls developed thrombotic complications,[80] and the authors concluded that there was no thrombogenic effect of TXA in this high-risk group. Clots in the urinary tract have been noted following AF therapy in hemophilic and hemoglobinopathy patients with active genitourinary bleeding, explained as inhibition of urokinase allowing the generation of lysis-resistant clots.[81,82,83,84–93] AF therapy is best reserved for patients with excessive, protracted genitourinary bleeding for whom surgical intervention is contemplated.

Recent retrospective analyses of over 60,000 patients treated with AF agents during cardiac surgery suggest an increased risk of all-cause mortality associated with aprotinin use,[81,82,83] (relative risk 1.32 to 1.64 versus lysine analog or placebo), although thrombotic disease has not been clearly implicated to explain the mortality excess. Five studies evaluating cardiac graft patency after cardiopulmonary bypass grafting surgery, comparing aprotinin-treated patients with controls, included more than 1,300 patients and demonstrated no increased rate of graft occlusion among those treated with aprotinin.[84–88] Secondary thrombotic outcomes following treatment with AF agents during cardiac surgery show variable results. In the Cochrane Systematic Review of 2007, aprotinin use did not affect the incidence of myocardial infarction, stroke, or renal dysfunction following cardiac surgery,[89] and there was no association between treatment with TXA or EACA and increased thromboembolic events. An observational study of more than 4,000 patients comparing adverse outcomes following exposure to aprotinin or the lysine analogs suggests a significantly increased incidence of myocardial infarction (55% increase), stroke (181% increase), and renal failure requiring dialysis (more than 200% increase).[83] In contrast, the meta-analysis by Brown et al. reported no difference between aprotinin, TXA or EACA, or placebo in the risk of myocardial infarction or stroke.[94] More recent trials utilizing aprotinin have reserved the drug for patients with higher risk of bleeding, limiting the retrospective comparison to patients treated without the drug.[95] These observational studies led to the randomized blood conservation using antifibrinolytics in a randomized trial (BART) comparing aprotinin to TXA and EACA, which found a 50% increase in death at 30 days among aprotinin-treated patients.[96] The data suggest that among patients undergoing cardiac surgery without concurrent thrombogenic stimulus, aprotinin confers a greater risk for adverse outcomes compared with the lysine analogs, and although no definitive evidence exists, suggests a greater tendency to thrombosis.

CLINICAL APPLICATION

Indications for AF therapy include interventions for ongoing hemorrhage or prophylactic administration to prevent bleeding, for which systemic or local fibrinolysis plays a contributory role (Table 77.1).

Fibrinolytic Hemorrhage

Systemic Hyperfibrinolysis

Many pathologic states may generate hyperplasminemia through the release of endothelial stores of tPA in sufficient quantities to overcome fibrinolytic inhibitors and convert plasminogen to plasmin (see Chapters 77 and 98). Plasmin, in turn, degrades fibrinogen and fibrin, and previously stable or new hemostatic sites are at risk of bleeding. Acute conditions that may induce systemic hyperfibrinolysis include heat stroke, hypoxia, hypotension, cardiothoracic surgery, and treatment with thrombolytic agents. Chronic diseases (neoplasm, cirrhosis) may be associated with a systemic hyperfibrinolytic and hemorrhagic state characterized by a shortened euglobulin lysis time, elevated levels of plasma tPA, decreased plasminogen and fibrinogen, and elevated D-dimer. In most cases, tPA release is of limited duration, and an essential therapeutic consideration is directed to the underlying condition.

Acute, systemic hyperfibrin(ogen)olytic states responding dramatically to EACA have been reported in portal hypertension following bowel surgery, a plasminogen-activator–secreting tumor, and with amyloidosis.[97–99] Chronic hyperfibrinolysis may exist with some neoplasms and with the rare congenital α_2-antiplasmin deficiency, and is manifest as a bleeding tendency effectively controlled with chronic antifibrinolytic therapy.[100] Acquired α_2-antiplasmin deficiency may be seen in acute promyelocytic leukemia, systemic amyloidosis, and metastatic adenocarcinoma, and hemorrhagic complications may be successfully controlled by treatment with AF agents[101–104] Bleeding may accompany treatment with systemic thrombolytic therapy. Because the lysine analogs inhibit plasminogen-activator–mediated fibrinolysis, these agents are reasonable antidotes for acute bleeding attendant PA treatment, although efficacy has not been documented by clinical trial.

Cardiac Surgery

Cardiopulmonary bypass is associated with significant perioperative bleeding, on average ranging from 750 to 1,250 mL and requiring median transfusion of 1.5 to 2.2 U of packed red blood cells.[105] The extracorporeal bypass circuit and the surgical wound both induce thrombin and plasmin generation, continuing for up to 24 hours postoperatively.[106] Laboratory findings of thrombosis and fibrinolysis, namely, high prothrombin fragment 1 + 2, high plasma D-dimer, shortened clot lysis time, and increased tPA levels,[107,108] are demonstrated in blood collected from the chest wound[109–125] helping to explain the significant blood loss. Perioperative bleeding leads to a high rate of cardiac reoperations[126] and patients requiring blood transfusion during cardiac surgery have a significantly decreased life expectancy.[127,128] Concern for the morbidity of significant bleeding and laboratory evidence supportive of a state of hyperfibrinolysis, have led to the extensive prophylactic use of AFs during cardiac operations to block the physiologic manifestations of hyperfibrinolysis and thereby minimize perioperative blood product transfusions.[109]

Table 77.1

Clinical application of antifibrinolytic therapy

Bleeding State	Clinical Association	Use of Antifibrinolytic Therapy	Comment
Systemic hyperfibrinolysis	Spontaneous plasminemia or following therapeutic thrombolysis	Rare, since hyperfibrinolytic state usually self-limited	If DIC present, AF therapy is contraindicated
	Cardiac surgery, with or without cardiopulmonary bypass	Prophylactic administration indicated to lessen blood loss, particularly in high risk circumstance, for example, repeat sternotomy, prolonged pump time, preoperative aspirin use	TXA, EACA decrease blood loss and transfusions vs. placebo. Aprotinin is modestly more effective than TXA/EACA in decreasing transfusions, but increases all-cause mortality
	Liver transplant	Prophylaxis useful prior to graft reperfusion to reduce perioperative bleeding and transfusion requirements	Adults with hepatocellular dysfunction more prone to hyperfibrinolytic bleeding; case reports of thrombotic events suggest use may be best guided by coagulation testing
	α_2-antiplasmin deficiency	Lysine analogs indicated for acute bleeding and prophylaxis	Chronic administration controls lifelong bleeding state in congenital deficiency
Defective hemostasis, followed by normal fibrinolysis	Hemophilia, von Willebrand disease	Indicated to control mucosal bleeding and as adjunctive prohemostatic treatment postoperatively or following acute bleed	Reduces blood loss and use of factor concentrates after dental extraction, synovectomy, joint replacement; likely useful in all postoperative settings
	Chronic anticoagulation	Indicated to prevent interruption of therapeutic anticoagulation during dental procedures	May be useful in treatment of minor bleeding episodes in chronically anticoagulated patients
	Thrombocytopenia or qualitative platelet dysfunction	Indicated for acute bleeding episodes to reduce platelet transfusions	Less effective if platelet count $<10{,}000/\mu L$
Normal hemostasis, followed by enhanced local fibrinolysis	Upper urinary tract	Indicated to control bleeding from essential hematuria, renal disease postrenal biopsy, and prolonged, spontaneous hematuria in sickle cell disease or hemophilias	Higher risk for obstructive clot formation in hemophiliacs treated simultaneously with factor replacement
	Lower urinary tract	May be useful in patients undergoing prostatectomy who have high risk of bleeding	Studies with lysine analogs demonstrate reduced blood loss, without effect on transfusion rate
	Dysfunctional uterine bleeding	Indicated for treatment of essential menorrhagia, menorrhagia due to IUD use or cervical conization	Underlying uterine pathology must be excluded Role in treatment of postpartum hemorrhage undergoing study
	Subarachnoid hemorrhage	Reduces incidence of rebleeding, but currently, AF treatment not indicated	Treatment associated with higher rate of vasospasm and ischemic events
	GI bleeding	Indicated to treat acute bleeding episodes from gastric erosions, ulcers, varices	Proven to decrease rate of rebleeding, need for surgical intervention, and mortality
	Traumatic hyphema	Indicated in patients with high risk for rebleeding (e.g., aspirin use)	Lysine analogs decrease rate of rebleeding without vision improvement
	Mucous membranes	Indicated for recurrent epistaxis; may be useful for excessive bleeding following tonsillectomy or sinus surgery	May be given orally or topically as packing component

(Continued)

Table 77.1

Clinical application of antifibrinolytic therapy *(Continued)*

Bleeding State	Clinical Association	Use of Antifibrinolytic Therapy	Comment
	Cavernous hemangioma	Used to reverse consumptive coagulopathy prevalent in large lesions	Lysine analog therapy leads to tumor shrinkage and improved symptoms
	Chronic urticaria	Indicated for cases resistant to standard therapy	Effective in subset with enhanced local fibrinolysis; elevated D-dimer may predict response to AF treatment
	Hereditary angioedema	Long-term prophylaxis against attacks	No effect on symptoms during acute episode
Blood conservation	Orthopedic surgery	Indicated to reduce blood loss in total knee replacement and total hip arthroplasty	Reduces total blood loss and blood transfusion requirements
	Neurosurgery	Indicated for multilevel spinal surgery and meningeal procedures with systemic bleeding	AF therapy reduces blood loss and transfusion
	Trauma	Indicated in patients presenting after traumatic events with significant bleeding	Associated with decreased mortality and decreased death due to bleeding

DIC, disseminated intravascular coagulation; TXA, *trans-p*-aminomethyl-cyclohexane carboxylic acid; EACA, *ε*-aminocaproic acid; IUD, intrauterine device.

Prior to 2006, aprotinin was the most widely used AF agent for cardiac surgery. Its use was first described in 1987 in a trial of 22 patients undergoing repeat sternotomy.[110] A Cochrane Database Systematic Review in 2001 evaluated 61 trials of aprotinin in cardiac surgery involving over 7,000 patients and concluded that aprotinin use decreased the rate of red blood cell transfusion by 30% and decreased the need for reoperation due to bleeding by 60%.[89] However, the risk of hypersensitivity reactions led the American College of Cardiology and the American Heart Association to restrict the use of aprotinin in primary cardiac surgery for patients at high risk of blood loss,[111] but as aprotinin showed greater benefit in patients undergoing repeat sternotomy procedures,[112,113] its use was routinely recommended for these patients.[114] Although less well studied, two randomized trials of aprotinin in patients undergoing lung resections, who were deemed at high risk for bleeding, demonstrated significantly reduced blood loss, need for transfusion, and need for re-exploration due to bleeding in the treated group versus placebo.[115,116] A randomized, double-blind, placebo-controlled trial of 70 patients undergoing myocardial revascularization by total arterial grafting showed that aprotinin reduced the proportion of patients requiring transfusion (39% vs. 77%) and significantly decreased the number of units transfused (0.8 vs. 2.6).[117]

A study of 56 patients undergoing cardiac surgery found lower blood loss over the first 24 hours postoperatively among patients treated with EACA, an effect that was more marked in patients with cyanotic heart disease or on cardiopulmonary bypass for longer than 1 hour.[118] The largest trial of EACA prophylaxis randomized 350 patients undergoing elective cardiac surgery to EACA or placebo and found that patients treated with EACA had significantly less postoperative blood loss, fewer red blood cell transfusions (2.8 U vs. 4.2 U), and fewer reoperations for bleeding,[119] without an increase in thrombotic complications. Early reports exploring the use of EACA reported rare adverse events, including DIC unmasked by therapy,[67] and significant intracavitary bleeding with the formation of lysis-resistant clots.[11,107]

Toward finding the optimal dosing schedule, one trial of 90 patients undergoing primary cardiopulmonary bypass surgery randomized three groups: TXA administered prior to bypass, TXA after bypass, or saline placebo. The number of units of transfused blood was significantly less in the TXA pre-bypass group versus control (0 vs. 4.5).[120] A larger trial of 210 randomized patients undergoing primary or repeat sternotomy procedures or valve operations to prophylactic treatment with high-dose TXA prior to initiation of bypass or saline placebo, and found a smaller proportion of patients treated with TXA required blood product transfusion support (13% vs. 31%),[121] without an increase in thrombotic events. In two similar trials of prophylactic TXA in pediatric cardiac surgery, one trial of 41 patients undergoing repeat sternotomy treated with high-dose TXA had significantly decreased transfusion support,[122] whereas another study of 85 patients showed decreased blood loss without a difference in transfusion versus placebo.[123] A trial that compared patients with on-pump (n = 51) versus off-pump (n = 51) procedures, randomized to prophylactic treatment with high-dose TXA or placebo found reduced perioperative blood loss in both on- and off-pump groups, greater with on-pump procedures, with TXA use.[124] Prior to elective cardiac surgery, aspirin use is typically discontinued to prevent excessive bleeding, but continuing aspirin may be beneficial by improving survival.[129] A meta-analysis by McIlroy et al.[130] of trials of prophylactic AF agents in patients receiving aspirin within 7 days of cardiac surgery found no effect of aspirin coadministration on the benefit of AF agents to reduce bleeding.

Topically applied AF therapy has been utilized as a prophylactic measure to reduce postoperative bleeding following cardiac surgery, the hypothesis being that the pericardium is an important site of fibrinolytic activity[131] and that the pericardium is a barrier to absorption of medications.[132,133] In a meta-analysis of topical AFs[134] administered directly into the sternal wound and into the pericardial cavity, the data suggest that topical AF agents reduce postoperative chest tube drainage (by a mean of 220 mL) and postoperative red blood cell transfusions (by 1 unit per patient), compared with placebo. These data are similar to results after systemic antifibrinolytic therapy.[94]

The trials cited above all utilized blood loss and transfusion requirements as the primary study outcomes. Head to head trials comparing aprotinin with the synthetic lysine analogs in cardiac surgery show a modest hemostatic advantage for aprotinin,[96] and a meta-analysis of 211 trials (21,000 patients) showed a small reduction in red blood cell transfusion (relative risk 0.83).[135] Although aprotinin was widely adopted for its slight superiority over the synthetic lysine analogs in terms of blood loss and blood transfusions, recent trials have found aprotinin use to come at a substantial cost in increased mortality and postoperative renal insufficiency[136] (see Table 77.2). Three observational cohort studies published between 2007 and 2008 suggested a higher risk of mortality associated with aprotinin exposure during cardiac surgery.[81,82,83] From prospectively collected observational data on more than 4,300 patients, Mangano et al.[83] found a 48% increased risk of mortality at 5 years in aprotinin- versus placebo-treated patients, with no such effect on mortality associated with TXA or EACA (vs. placebo). Schneeweiss et al.[81] analyzed a European database including patients undergoing cardiac surgery and receiving prophylactic treatment with aprotinin (n = 33,517) or EACA (n = 44,682), and found a 64% increase in the risk for death following treatment with aprotinin. The BART trial of 2,331 high-risk patients undergoing cardiac surgery found aprotinin was associated with a lower rate of massive hemorrhage (9.5% vs. 12.1% for EACA or TXA), but there was a 6% risk of death at 30 days versus 3.9% and 4% amongst patients treated with EACA or TXA (relative risk = 1.53).[96] The conclusion of the study was that the modest benefit of aprotinin in terms of bleeding was offset by increased mortality and that aprotinin should not be used in high-risk cardiac surgery.

Given the discordance between hemostatic effectiveness and survival outcomes, future trials of AFs must address clinical endpoints, not just blood loss and transfusion requirements. Although specific patients may derive benefit from aprotinin, at present, this agent is not used in the United States, Canada, or Europe. Concerns remain regarding the safety of the synthetic lysine analogs, for example, TXA is associated with more seizures compared with aprotinin.[137]

Table 77.2

Antifibrinolytic therapy in cardiac surgery and effect of mortality

	Study Type	Study Population	Outcome	Conclusion
Fergusson et al.[96]	Double-blind, randomized, controlled	N = 2,331 High risk cardiac surgery	Massive bleeding: Aprotinin 9.5% TXA 12.1% EACA 12.1%	RR massive bleeding: 0.79 (0.59–1.05)
	Aprotinin vs. TXA vs. EACA		Mortality at 30 days: Aprotinin 6% TXA 3.9% EACA 4%	RR mortality: 1.55 (1.06–2.22) Aprotinin use not justified in cardiac surgery
Mangano et al.[362]	Multicenter, observational, prospective trial	N = 3876 undergoing CABG and CPB	Mortality at 5 y: Aprotinin: 20.8% TXA: 14.7% EACA: 15.8%	HR for death after Aprotinin: 1.48 (1.19–1.85)
	AF or no antibleeding agent		Control: 12.7%	No increased risk of death with TXA or EACA.
Schneeweiss et al.[81]	Prospective, multicenter cohort Aprotinin vs. EACA	N = 78,199 undergoing CABG	Mortality prior to hospital discharge: Aprotinin 4.5% EACA 2.5%	RR of death after Aprotinin: 1.64 (1.50–1.78)
Shaw et al.[82]	Prospective, single center cohort Aprotinin vs. EACA vs. control	N = 10,275 undergoing CABG	Mortality at 30 days: Aprotinin: 6.4% EACA: 2.4% Control: 2.2%	HR for death after Aprotinin: 1.32 (1.12–1.55)

TXA, tranexamic acid; EACA, aminocaproic acid; RR, relative risk; AF, antifibrinolytic agent; CABG, coronary artery bypass grafting; CPB, cardiopulmonary bypass; HR, hazard ratio.

Liver Transplantation

Many coagulation defects are present in the setting of end-stage liver disease, including increased fibrinolytic activity due to impaired hepatic clearance as well as enhanced endothelial release of tPA. The central role played by the liver in clearing circulating tPA was demonstrated by Illig et al. in a study of patients undergoing aortic clamping during repair of abdominal aortic aneurysms.[138] Patients who underwent supraceliac clamping of the aorta compared to those requiring infrarenal clamping experienced a reversible primary fibrinolytic state manifest by a shortened euglobulin lysis time, increased circulating tPA, and decreased α_2-antiplasmin concentration, likely caused by hepatic hypoperfusion. Orthotopic liver transplantation is associated with still increased fibrinolytic activity related to ischemic insult to the mesenteric vascular bed and release of activators from the transplanted graft during the anhepatic and reperfusion phases of transplantation.[139] To reduce hemorrhage associated with hyperfibrinolysis, an AF agent is commonly administered just prior to graft reperfusion.[140] In the study by Segal et al.,[141] patients treated with aprotinin during liver transplantation had a blunted increase in circulating tPA, prolonged euglobulin lysis time, decreased peak D-dimer levels, and increased circulating α_2-antiplasmin concentration during the reperfusion phase compared with control subjects, consistent with reduced systemic fibrinolytic activity.

Prophylactic treatment with AF agents during orthotopic liver transplantation shows variable results. The European Multicenter Study on the Use of Aprotinin in Liver Transplantation trial, a randomized, double-blind, placebo-controlled study of 137 patients undergoing liver transplantation, demonstrated lower intraoperative blood loss as well as considerably reduced transfusion requirements in patients treated with aprotinin versus placebo, although no differences occurred in 30-day mortality or incidence of thrombotic events.[142] Low-dose (2 mg/kg/h), continuous TXA during transplantation demonstrated decreased laboratory parameters of fibrinolysis, but no effect on blood loss or transfusion requirement versus placebo.[143] A prospective, placebo-controlled study of 132 patients comparing prophylactic treatment with high-dose TXA (10 mg/kg/h) and EACA (16 mg/kg/h) to placebo demonstrated significantly reduced transfusion requirements for patients treated with TXA, but not for EACA, versus placebo.[144] Blinded comparison of TXA and aprotinin in 127 patients showed no difference in blood loss, transfusion requirements, mortality, or thrombotic events between groups.[145] Prophylactic AF agents may not be useful in all clinical situations, and may even lead to adverse events.[114,140] Coagulation changes and excessive intraoperative bleeding due to hyperfibrinolysis are less common in children undergoing liver transplant, possibly because most are being treated for cholestatic rather than hepatocellular liver failure,[146] and adults with primary biliary cirrhosis have less laboratory evidence of hyperfibrinolysis than patients with cirrhosis due to hepatocellular disease.[147] A meta-analysis of 23 studies including 1,400 patients undergoing liver transplantation and treated with aprotinin or TXA found that both drugs significantly decreased the transfusion rate with no difference in rate of hepatic artery thrombosis, venous thrombotic events, or 30-day mortality.[148] Retrospective analysis of nearly 1,500 patients transplanted for liver disease who were exposed to aprotinin or no AF agent showed an increased risk for reversible renal dysfunction with no difference in the rates of hepatic artery thrombosis, venous thrombosis, or long-term mortality.[149,150] A review of prophylactic administration of AFs during orthotopic liver transplantation reviewed by the Cochrane Database in 2009 concluded that there is no effect on perioperative morbidity or long-term mortality, although the review cautioned that its findings are not robust.[151]

α2-Antiplasmin Deficiency

α2-antiplasmin deficiency may be a congenital condition associated with a severe, lifelong bleeding tendency in homozygotes,[152,153] as well as an acquired deficiency seen in settings of severe liver disease, DIC, and myeloproliferative disorders.[154] The bleeding clinically seen in deficiency is due to premature dissolution of hemostatic plugs by robust, unimpeded plasmin activity.[155] Both lysine analogs, EACA and TXA, are used to treat acute bleeding episodes. They may also be employed in prophylactic doses prior to invasive procedures.[156]

Localized Fibrinolysis with Defective Hemostasis

The formation of a stabilized and solid hemostatic plug is dependent on a maximal thrombin "burst,"[157] allowing activation of factor XIII to cross-link fibrin polymers and attenuate local fibrinolysis by activation of the thrombin-activatable fibrinolytic inhibitor.[158,159] Therefore, any state in which full thrombin generation is impaired, as in hemophilia and other hereditary coagulation disorders, is prone to hemorrhage due to fibrinolytic dissolution of inadequate hemostatic plugs.[160,161] Although systematic trials of AF agents have been tested predominantly in hemophiliacs, results are reasonably generalized to patients with other congenital or acquired hemostatic defects.

Hemophilia

Thrombin generation is considerably decreased in hemophilia because feedback amplification of the clotting cascade requires factor VIII and factor IX.[162,163] Accordingly, fibrin clots formed in patients with hemophilia are sensitive to accelerated fibrinolytic degradation. *In vitro* study of factor VIII-deficient plasma shows that the presence of TXA increases clot stability fourfold.[164] AF therapy has been used in hemophilia (a) as prophylaxis to prevent hemarthrosis; (b) for treatment of hematuria; (c) for treatment of gum bleeding and epistaxis; (d) as adjunctive, prohemostatic treatment during and following surgery and (e) in patients with factor VIII inhibitors. Although some studies have concluded that a combination of factor concentrate and AF agent produces an enhanced therapeutic effect,[165,166] the weight of evidence indicates that EACA and TXA may be useful for treatment of individual bleeding episodes but are not effective for prophylaxis against hemarthrosis.[167–169]

Treatment of intractable *hematuria* due to bleeding from the upper urinary tract may lead to renal functional impairment or extrarenal obstruction in hemophiliacs treated with factor replacement.[170] However, additional risk probably occurs with the use of AF agents because they prevent or retard dissolution of clots, which may lead to frank renal obstruction[92,93,171,172,173,174–196,197,198–208] that may contribute to mortality.[209–224] An early review of 66 patients with hemophilia treated with EACA for severe hematuria reported improvement in symptoms in 52 patients, but with renal obstruction in 10.[93] A recent report of four cases of children with protracted hematuria due to hemophilia or sickle cell trait described complete cessation of bleeding with oral EACA every 6 hours without complications.[174] Therefore, upper urinary tract bleeding should be managed conservatively

unless bleeding is protracted, requires transfusion, or if surgical intervention is considered.

The addition of AF agents to cryoprecipitate in 10 hemophilic patients with *gum bleeding*[175] improved hemostasis and recovery. A case report describes a patient with an acquired factor VIII inhibitor and severe *epistaxis* who was successfully treated with oral EACA.[176] Combined prophylaxis with EACA or TXA and factor IX in eight patients with hemophilia B permitted dental extractions without bleeding.[177] A single center report of 534 dental procedures, including 288 oral surgeries performed using EACA adjunctively, reported only a 1.9% incidence of severe bleeding complications..[178]

Although factor replacement therapy is effective in providing normal hemostasis after all types of major surgical procedures in hemophiliacs,[179] the addition of AFs reduces blood loss and the amount of factor VIII or factor IX concentrate required by an average of more than 80%.[177,180–184] It seems reasonable to suggest that patients with hemophilia undergoing other surgical procedures can be similarly supported by jointly administered AF and factor replacement therapy, as seen, for example, in synovectomies.[185,186] Among patients with acquired hemophilia, TXA and EACA are useful adjuncts to factor bypassing agents and recombinant factor VIIa for nonelective surgery[187] and for acute bleeding episodes.[188]

Chronic Anticoagulation

AF use has proven effective as a hemostatic agent in patients on chronic warfarin anticoagulation. A randomized trial of aTXA mouthwash after oral surgery in patients on chronic anticoagulation for a prosthetic cardiac valve was effective in reducing the incidence of bleeding episodes, as compared to the saline control group.[189] A meta-analysis of eight trials found that patients receiving continuous anticoagulant therapy and using AF mouthwashes had no greater bleeding than patients treated with interrupted anticoagulation or reduced anticoagulation.[190]

Thrombocytopenic and Thrombocytopathic States

Because qualitative and quantitative platelet deficiencies lead to fragile hemostatic plugs, AF therapy should be useful in these settings. A hemostatic effect of EACA has been demonstrated in patients with bleeding due to immune thrombocytopenia or thrombocytopenia due to induction chemotherapy for leukemia[191–194] and in Bernard-Soulier (giant platelet) syndrome[195,196] in the control of obstetric bleeding. In a single-center series of 77 patients with chemotherapy-induced severe thrombocytopenia and hemorrhage, treatment with EACA resulted in complete resolution of hemorrhage in 66% of patients, and a 17% rate of partial response or 50% decrease in platelet transfusion requirement.[197]

Normal Hemostasis with Localized Fibrinolysis

Bleeding can result from a localized fibrinolytic effect caused by an imbalance between heightened local lysis and normal hemostasis.[10,97] Tissues that are rich in PA might be more likely to be affected by such imbalances, for example, in the uterus, which increases PA concentration during menstrual bleeding.[198] Important sites of heightened fibrinolytic activity include the vascular endothelium; cells that line glands, ducts, tubules, or body spaces (kidney, prostate, endometrium, meninges, pleura, pericardium, and peritoneum); invasive tumors and cells; and fluids exposed to or draining such sites. In fact, the earliest clinical applications of AF therapies were for bleeding at sites of known, enhanced fibrinolytic activity: prostate, bladder, uterus, and uterine cervix.

Upper Urinary Tract

The renal pelvis is rich in urokinase, which may be the underlying defect in essential hematuria. Andersson et al.[199] reported the successful treatment of 13 patients with "*essential hematuria*" with EACA and TXA, and others have demonstrated that AF therapy can be dramatically successful for prolonged upper urinary bleeding in sickle cell disease.[200–206] However, there is an increased risk of clot formation in the renal collecting system when AF agents are used.[207] This complication is usually of minor importance, but in some patients, the clot is large enough to impair renal function,[91,92,173] appearing as an abrupt clearing of blood from the urine and flank pain, with radiologic evidence of hydroureter or hydronephrosis. Such clots may be treated with intraureteral urokinase,[208] but their size may be minimized by a high urine output before and during AF therapy. Posttransplantation or postrenal biopsy hematuria has been treated with EACA.[209–212]

Lower Urinary Tract

Bleeding after *prostatectomy* is enhanced by urokinase, which diffuses into the operative site to dissolve newly formed hemostatic plugs.[10,11,15,16,97,199,213–215] Eight randomized trials in the 1960s and 1970s evaluating EACA therapy after prostatectomy demonstrated a significant decrease in blood loss when compared to placebo[214,216–223]; a ninth study found similar results with TXA treatment.[224] In these trials, there was a twofold to fivefold reduction in urinary tract blood loss during the postoperative period, but no effect on the volume of intraoperative blood loss. Although the difference was statistically significant, the findings were not as relevant clinically, because the bleeding in control patients rarely required transfusion. Thromboembolic side effects of treatment were no greater than in control groups and were not reduced by the concomitant use of prophylactic heparin.[225] A prospective, double-blind study of EACA versus placebo administered immediately following prostatectomy in 61 patients failed to demonstrate any effect of EACA on blood loss,[223] leading the authors to conclude its use was not warranted, and a trial of prophylactic TXA in 136 men undergoing elective transurethral resection of the prostate demonstrated decreased operative blood loss in the treatment group, but without an effect on transfusion requirements.[226] AF agents have been used to control lower urinary tract bleeding associated with benign prostatic hyperplasia or prostatic carcinoma,[35,215] but Smart suggested that EACA- and TXA-associated clots in the lower urinary tract pose a problem after prostatectomy.[227] Interestingly, although aprotinin is a potent *in vitro* AF agent, it was not beneficial in a single study of lower urinary tract bleeding.[228] Given the lack of efficacy in preventing transfusion, it has been suggested that AF therapy should be reserved for those patients who demonstrate excessive bleeding at the time of prostatectomy.[97]

Dysfunctional Uterine Bleeding

Higher uterine PA activity is present during the secretory phase when compared with the proliferation phase of the menstrual cycle,[229] and higher mean PA levels on the first day of menses are demonstrated in patients with primary menorrhagia than in those with normal menstrual blood loss.[230] Treatment of

essential menorrhagia has been studied by several groups,[35,231,232] and the efficacy of AFs was clearly demonstrated by Nilsson and Rybo[233] in a double-blind clinical trial. In the latter study, 37 women received EACA or placebo during two successive menstrual cycles, with the menstrual blood loss significantly different, 120 mL for placebo-treated patients and 52 mL for EACA-treated patients. Later studies of EACA and TXA[234–237] confirmed these data, especially when AFs are taken during the first 3 days of menstrual bleeding.[10,97] No benefit was seen in women with bleeding secondary to uterine fibroids who were treated with TXA.[238] Patients with von Willebrand disease–associated menorrhagia responded to chronic TXA with reduced blood loss.[239] A systematic review published in the Cochrane database in 2000 concluded that AF therapy leads to a reduction in blood loss compared with placebo or other medical therapies such as oral progestogens or nonsteroidal anti-inflammatory drugs.[240] Concern for thrombotic complications with chronic use has not been borne out.[241]

Whether increased bleeding secondary to the placement of an intrauterine device (IUD)[242] is caused by the higher fibrinolytic activity in the endometrium[243] or by edema, inflammation and necrosis, AF therapy decreases the menstrual blood loss. In an uncontrolled study before and after IUD placement, Kasonde and Bonnar[244] noted that menstrual blood loss increased from 43 to 82 mL in 28 untreated women, whereas there was a diminished increase (from 43 to only 54 mL) in patients treated with EACA. A double-blind study in 65 women showed a similar increase in blood loss from 36 to 65 mL in control patients but no increase (mean <4 mL) in patients treated with TXA.[245–277]

The cervix contains a high concentration of PA, which contributes to excessive bleeding in some patients after *cervical conization*. In a double-blind study by Rybo and Westerberg[245] treatment with TXA beginning after surgery and continuing for 12 days, led to significantly reduced blood loss (from 79 to 23 mL). 7 of the 23 women treated with placebo had unexpected severe bleeding after the fifth postoperative day, requiring resuturing of the operative site, a complication that was not seen in the TXA-treated group. Similar findings were reported by Grundsell et al.[246]

Given the high concentration of PA in the female genital tract, recent interest in the use of AFs in the prevention and treatment of maternal hemorrhage has launched the World Maternal Antifibrinolytic Trial, a randomized, placebo-controlled trial to evaluate the role of TXA for the treatment of postpartum hemorrhage.[247]

Although providers must rule out underlying pathology in patients with menorrhagia or postoperative bleeding,[248] it would not be unreasonable to attempt to control excessive uterine bleeding from any cause in the absence of DIC with AF therapy while the diagnostic workup is proceeding, and it may be useful as an adjunctive therapy once treatment of the underlying disorder has been initiated.

Subarachnoid Hemorrhage and Intracranial Surgery

Although cerebral tissue is not rich in tPA activity,[198] there are localized regions of high concentration in the meninges and the choroid plexus,[249] and measurable amounts of PA present in the cerebrospinal fluid after cerebral injury[250,251] may contribute to lysis of fragile intra-aneurysmal thrombi and contribute to "rebleeding" following the initial event in 6% to 20% of the at-risk population.[252–255] The data from clinical trials employing AF therapy in the setting of *ruptured intracranial aneurysm* is conflicting. Although the initial, uncontrolled studies suggested that therapy after subarachnoid hemorrhage was useful in preventing recurrent hemorrhage,[256,257–266] controlled trials of EACA or TXA are discordant.[267–273] Three small controlled studies failed to show benefit with AF therapy.[270–272] Concern regarding increased thromboembolic complications[274] inspired two large multi-institutional studies.[275,276] The Cooperative Aneurysm Study[254,255,275] was based on 672 patients and showed rebleeding in 11.7% of 467 patients receiving AF treatment, compared with 19.4% of 205 patients without AF therapy. However, the rate of focal ischemic events was higher in the AF group (32.4% vs. 22.7%), as was the incidence of hydrocephalus (14% vs. 7%). The incidence of clinical venous thromboembolic complications and the overall mortality rates were not different. A second large trial comprising 479 patients was organized as a randomized, double-blind, placebo-controlled trial[276] and showed essentially the same mortality rates at 3 months for TXA and placebo (35% vs. 37%). Although the rate of rebleeding was significantly lower in the TXA group, the incidence of cerebral infarction was higher. Thus, although AFs probably decrease rebleeding, they do so at the cost of an increase in cerebral ischemia and infarction, leading to an unchanged mortality rate with treatment.[278] In an effort to exploit improved methods to control cerebral vasospasm, Roos et al. undertook a randomized, placebo-controlled trial of TXA in 462 patients with aneurysmal hemorrhage in which all patients were treated with calcium antagonists to minimize vasospasm. Although TXA considerably reduced the incidence of rebleeding, there was no effect on primary functional outcome at 3 months.[279] A recent case–control study by Starke et al. addressed the question of early use of EACA to prevent rebleeding, with required discontinuation of the drug by 72 hours from symptom onset to avoid exposure during the period most associated with ischemic injury. The results showed a significant decrease in rebleeding (2.7% vs. 11.4% in untreated patients), no difference in ischemic complications, and a trend toward improved mortality.[280] Interestingly, all patients were evaluated with lower extremity Doppler ultrasound, and the EACA-treated patients had an eightfold increased risk of developing deep venous thrombosis (DVT).[280]

Gastrointestinal Tract

Certain pathologic lesions that cause upper and lower GI bleeding have been associated with increased fibrinolytic activity, either within the tissues themselves or in veins draining the affected organ.[281] Six prospective, controlled clinical trials[281–286] used TXA in patients with upper GI bleeding and demonstrated significant benefit. The study by Cormack et al.[282] conducted in the early 1970s demonstrated that treatment with TXA was superior to placebo in patients with undiagnosed bleeding distal to the esophagogastric junction in terms of a fatal outcome, the need for surgery, or continued bleeding that required blood transfusion. There was, however, no difference in the failure rate in patients with bleeding secondary to esophageal varices. A prospective, double-blind study comparing TXA and placebo in 154 patients with upper GI bleeding from verified, benign lesions, demonstrated a significantly decreased need for blood

transfusion or surgical intervention after TXA treatment.[286] In the study by Biggs et al.[283] of 200 randomized patients with acute upper GI hemorrhage, there was a significant difference in the requirement for surgical intervention to control bleeding, occurring in 23 of 97 control patients but in only 7 of 103 TXA-treated patients. Unlike the study by Cormack et al.,[282] this study showed benefit in patients with esophageal varices as well as in those with gastric ulcers and gastric erosions. Barer et al.[285] randomly assigned 775 patients with acute upper GI bleeding to TXA, cimetidine, or placebo, and showed a reduced mortality from 13.5% in the control group to approximately 7% in either of the treatment groups. Meta-analysis of the effect of fibrinolytic inhibitors on mortality from upper GI hemorrhage included six randomized, controlled trials involving 1,267 patients and concluded a short-term course of TXA (2 to 7 days) resulted in a 20% to 30% reduction in the rate of rebleeding and a 30% to 40% reduction in mortality.[287] Other upper GI lesions improved by antifibrinolytic therapy are giant hypertrophic gastritis (Ménétrier disease) and gastric antral vascular ectasia, through a reduction in incidence of rebleeding.[288,289]

Patients with cirrhosis often have laboratory evidence of a chronic, systemic lytic state, with elevated D-dimer and tPA concentrations in the blood. Although the incidence of bleeding is higher in those patients with more advanced cirrhosis and with higher circulating D-dimer and tPA levels,[290] clinical efficacy of AFs may be attributable more to inhibition of local fibrinolysis at lesions prone to bleed than to correction of the systemic fibrinolytic state.[291] Evidence for this hypothesis is provided by the work of Cox et al.,[281] who found a high level of plasmin activity in gastric veins of patients with peptic ulcers when compared to a control population, and by Oka and Tanaka,[292] who demonstrated increased fibrinolytic activity in the mucosa of the esophagus and stomach in patients with cirrhosis and upper GI bleeding. The use of AF therapy in bleeding complicating portal hypertension and cirrhosis deserves further clinical study.

Increased amounts of PA have been demonstrated in the rectal mucosa of some patients with active ulcerative colitis.[288,293] Although an uncontrolled study[294] suggested that the bleeding in such patients was controlled with AF therapy, two controlled trials[295,296] give conflicting results. Alternative approaches such as direct administration of agent by enema may prove more useful,[297,298] but trials have not been performed.

Traumatic Hyphema

Increased local fibrinolytic activity is present in circumscribed areas of the eye, specifically in the canal of Schlemm, ciliary body, iris, and proximal scleral vascular plexus.[299] This fibrinolytic activity presumably prevents obstruction of intraocular fluid drainage and glaucoma, and may be responsible for clot lysis following ocular trauma, but on the other hand, such fibrinolytic activity may also contribute to rebleeding after blunt eye trauma. Therapy with AFs has been attempted as a prophylactic measure against such rebleeding,[300,301] which occurs in as many as 30% to 40% of patients, approximately 2 to 6 days after the injury. A favorable effect of AF therapy in preventing secondary bleeding after traumatic hyphema was reported in studies based on historical controls[300,302–305] and in three controlled trials.[301,306,307] In a controlled study of 238 patients, oral TXA decreased the incidence of secondary hemorrhage from 26% in those receiving placebo to only 10% ($P = 0.008$).[308] A similar benefit has been noted in a study of 118 patients in which topical TXA was as effective as oral TXA in reducing secondary hemorrhage (2 of 64 vs. 12 of 54 patients receiving placebo).[309] A 5-day course of topical EACA versus placebo decreased the rate of rebleeding in 51 patients presenting with traumatic hyphema, and there was a nonsignificant trend toward more rapid improvement in vision in the treatment group.[310] Yet the study by Taboul et al.[311] suggests that the incidence of secondary hemorrhage after traumatic hyphema is quite low in patients without added risk factors such as aspirin ingestion and, therefore, that routine use of EACA (or any antifibrinolytic) is not warranted. Taken together, the data seems to indicate that on balance, AF therapy is a reasonable approach in preventing rebleeding following traumatic hyphema, at least in those who do have added risk factors for hemorrhage.

Mucous Membranes

AF therapy has been studied in patients undergoing tonsillectomy and adenoidectomy,[312–314] demonstrating a significant decrease in blood loss when compared with other treatment modalities, although the amount of blood loss may not suffice to recommend such agents for routine use. AF therapy has been a useful adjunct to control bleeding after minor oral surgery for tonsillectomy in von Willebrand disease.[315,316] A randomized blinded trial of 30 patients treated with topical TXA or EACA versus placebo administered by spray at the conclusion of endoscopic sinus surgery demonstrated topical TXA to be superior to EACA or placebo in promoting hemostasis at the surgical site.[317] A trial of TXA for patients with epistaxis showed a significant decrease in the number and severity of bleeding episodes.[318] AF treatment might reasonably be attempted in patients with unexplained serious postoperative mucosal bleeding that requires unsuturing or packing or in those with recurrent, unexplained epistaxis.

Cavernous Hemangioma

Patients with multiple giant hemangiomata (Kasabach-Merritt syndrome) present a clinical dilemma particularly resistant to medical therapies, with progressive enlargement of vascular tumors that often require extensive surgery. Ongoing consumption of platelets and fibrinogen suggests that thrombi are continually formed and dissolved within the hemangioma. This led Neidhart and Roach[319] and, later, Warrell and Kempin[320] and Ortel et al.,[321] to apply the novel approach of inducing *in situ* thrombosis by the administration of EACA, either alone[319] or with concomitant cryoprecipitate infusion.[320] Tumor shrinkage, symptomatic improvement, or improvement of laboratory evidence of consumption were obtained in all cases. A similar approach has been applied successfully in a reversal of a consumption coagulopathy associated with Klippel-Trenaunay-Weber syndrome.[322,323] Variable success has been achieved using AF agents in hereditary hemorrhagic telangiectasia,[324] but, as noted in an editorial,[325] systematic studies are needed to establish this therapy as definitely effective.

Chronic Urticaria

Chronic urticaria is a rare condition, generally managed with antihistamine and steroid therapy, which, when severe, can activate the coagulation and fibrinolytic systems. A pilot study demonstrated that patients with chronic, therapy-resistant

urticaria respond to combination therapy with low molecular weight heparin and TXA, in particular those patients with D-dimer elevation.[326]

Hereditary Angioedema

The syndrome of hereditary angioedema, with recurrent attacks of swelling of arms, legs, abdomen, or oropharynx, is due to mutations in the C1 inhibitor gene leading to an abnormal protein, incapable of inhibiting complement proteases, kallikrein, and plasmin.[327] Although ineffective for the management of acute symptoms, the lysine analogs are effective in long-term prophylaxis. One crossover trial of TXA and placebo in 18 patients with hereditary angioedema demonstrated complete cessation of attacks in 7 of 18 patients during the TXA treatment period, with recurrence during the placebo crossover.[328] Another report cited long-term benefit of EACA prophylaxis, with 90% decreased frequency of attacks in two patients.[329]

Applications to Reduce Blood Loss

Given their role in promoting hemostasis, AF agents have been employed in surgical settings to control bleeding and reduce patient exposure to allogeneic blood products. In conjunction with desmopressin and technical approaches such as hypotensive anesthesia or hypothermia, they may reduce hemorrhage.[330]

Orthopedic Surgery

Three placebo-controlled trials have demonstrated that TXA significantly decreases perioperative blood loss and transfusion requirements associated with primary total knee replacement surgery.[331–333] Hiipala et al.[331] randomized 75 patients undergoing total knee replacement to TXA or placebo and demonstrated that fewer patients required perioperative transfusion (17/39 vs. 34/38, $P < 0.00003$) as well as a lower mean number of transfused units (1 vs. 3.4, $P < 0.0001$). A randomized, double-blind trial in 127 patients undergoing bilateral total knee replacement treated with TXA, EACA, or placebo showed that 7.5% of treated patients required blood transfusion compared with 38% of placebo-treated patients ($P < 0.001$).[334]

Similar benefit has been shown for patients undergoing primary total hip arthroplasty. Husted et al.[335] randomized 40 patients to TXA or placebo, and demonstrated a significant decrease in postoperative blood loss, decreased proportion of patients receiving transfusions ($P = 0.04$), and no difference in thrombotic events. Rajesparan et al.[336] randomized 73 patients to bolus TXA given at anesthesia induction versus placebo and showed that TXA significantly reduced total blood loss and transfusion rate without affecting the incidence of venographically documented DVT. Claeys et al.[337] demonstrated the efficacy of preoperative bolus injection of TXA over placebo in reducing total blood loss and transfusion volume, although there was a higher rate of DVT in the treatment group (3 vs. 0 events). Bolus TXA (20 mg/kg) prior to orthognathic surgery significantly improved total blood loss versus placebo use (878 mL vs. 1,287 mL, $P < 0.001$).[337,338] Meta-analysis of trials of prophylactic TXA in orthopedic surgery evaluated 12 trials and concluded that treatment with TXA significantly reduces total perioperative blood loss and the proportion of patients requiring transfusion (odds ratio 0.26).[60]

Placebo-controlled trials evaluated aprotinin prophylaxis during hip replacement surgery and generally have demonstrated a reduced rate of allogeneic blood transfusion (vs. placebo), without an increased incidence of thrombotic events. Janssens et al.[339] evaluated 40 patients and demonstrated a reduction from 3.4 transfused units in the placebo group to 1.8 in the treatment group ($P < 0.001$). Murkin et al.[340] randomized 225 patients undergoing hip replacement surgery to treatment with high-dose versus low-dose aprotinin or saline placebo, and demonstrated that a significantly lower proportion of aprotinin-treated patients required allogeneic blood transfusion (6% vs. 12%). Samama et al.[341] found no dose-related effect on transfusion requirements in high versus low-dose aprotinin treatment. Jeserschek et al.[342] demonstrated that high-dose aprotinin versus placebo significantly reduced the requirement for intraoperative blood transfusion (1.4 U vs. 3.1 U). Confirming the importance of delivering aprotinin continuously, a randomized study of 40 patients undergoing hip replacement surgery who received a single prophylactic injection of aprotinin did not demonstrate any benefit in reducing blood loss.[343]

Neurosurgery

Spinal surgery is associated with significant blood loss and transfusion support.[344] A randomized trial comparing TXA and placebo in 64 patients undergoing spinal surgery showed TXA had a 49% decrease in total blood loss and 80% decrease in the rate of transfusion ($P < 0.007$ and $P < 0.008$).[345] Among 182 patients treated with EACA or placebo, the rate of RBC transfusion was lower in patients receiving EACA (2 U vs. 2.8 U), although the amount of allogeneic blood transfused was the same.[346] A trial comparing intermediate-dose aprotinin with EACA or placebo demonstrated significantly decreased blood loss after aprotinin, less so with EACA, compared with placebo (3,628, 4,056, and 5,181 mL, respectively).[59] The results of a meta-analysis of 18 clinical trials utilizing aprotinin, TXA, or EACA in spinal surgery, confirmed all three agents decreased total blood loss and transfusion volume. However, aprotinin and TXA were associated with the greatest effects, while the effect of EACA became significant as the complexity of the spinal surgery increased.[344]

AF therapy may reduce blood loss when administered into the surgical field. In a pilot trial to evaluate topical AF therapy, 30 patients were randomly assigned to TXA or placebo administered directly into the spinal wound; those treated with topical TXA had a 50% decrease in postoperative blood loss.[347]

The endothelium lining the meninges is a rich source of tPA and fatal episodes of systemic hyperfibrinolysis have been reported following surgical resection of benign lesions.[348,349] One patient with life-threatening perioperative bleeding associated with elevated levels of circulating tPA was successfully resuscitated with high-dose aprotinin.[350] In a study of 100 patients undergoing craniotomy for an intracranial meningioma or vestibular schwannoma, randomized to low-dose aprotinin versus placebo, intraoperative blood loss was reduced by 50% in the group treated with aprotinin (1,014 to 508 mL, $P = 0.028$).[351]

Trauma

Given the efficacy of AF therapy to reduce blood loss and transfusion volume in patients undergoing surgery, its utility to moderate the bleeding and coagulopathy that occurs with trauma has been explored. Over 20,000 adult trauma patients with clinical evidence of hemorrhage or deemed to be at risk for significant bleeding were randomized to treatment with TXA versus saline placebo. [352] Treatment with TXA was associated with a modest reduction in all-cause mortality at 4 weeks (relative risk 0.91, $P = 0.0035$) and a decreased risk of death due to bleeding

(RR 0.85, $P = 0.0077$). The deceased mortality was independent of blood loss and the study's design did not permit conclusions to clarify the mechanism by which TXA reduced mortality.

Pediatric Surgery

Results in pediatric patients are comparable to those in adults. One randomized trial of 41 pediatric patients undergoing repeat cardiac surgery received either high-dose TXA or placebo and showed a 24% decrease in blood loss in the TXA-treated group (26 mL/kg vs. 34 mL/kg, $P = 0.03$).[122] In pediatric cardiac surgery, a randomized, double-blind trial of high-dose aprotinin in 60 patients demonstrated decreased perioperative blood loss as well as a significantly reduced proportion of patients requiring blood transfusion support (13% vs. 47%).[353]

In a study of pediatric posterior spinal fusion surgery for scoliosis, TXA was compared to placebo in a randomized, double blind trial, and showed a significantly decreased rate of RBC transfusion.[354] One randomized trial of 59 anterior or posterior spinal fusion procedures demonstrated decreased blood loss and RBC transfusion (1 vs. 2 U, EACA vs. placebo).[355] In 44 pediatric patients undergoing spinal fusion surgery, aprotinin decreased blood loss and transfusion requirements compared with placebo (1.1 U vs. 2.2 U).[58] As a hemostatic adjunct for patients requiring surgical intervention while on extracorporeal membrane oxygenation, a retrospective analysis at a single center demonstrated a decreased incidence of surgical site bleeding with no adverse thrombotic events in 298 treated patients.[356] A meta-analysis of AF therapy in pediatric patients at high risk for bleeding while undergoing major surgery included five studies of patients undergoing scoliosis surgery and 23 trials of cardiac surgery, treated with either TXA or aprotinin, and found both agents significantly reduced red blood cell transfusion compared to placebo (4 and 7 mL/kg respectively).[357]

Fibrin Sealants

Fibrin sealants containing fibrinogen, thrombin, and factor XIII have been used to enhance local hemostasis and adhesion during surgical procedures, and some commercially available fibrin sealants contain an AF agent (bovine aprotinin, TXA) as well.[358] Although these agents have been used effectively in uncontrolled trials in hemophiliacs undergoing dental extractions, hypospadias repair, endonasal surgery, and tracheoesophageal fistula repair,[359–361,171] there are no randomized trials comparing the efficacy of fibrin sealant products with and without AF additives.[358] Among children treated with aprotinin containing fibrin sealant during cardiac surgery, 40% exhibited circulating, aprotinin-specific antibody 6 weeks postoperatively, suggesting that a test dose remains imperative to avoid anaphylaxis even with topical application.[172,359–362]

CHAPTER

78

Platelets, Plasma, and Specialized Coagulation Concentrate Therapies

THOMAS S. KICKLER

The biggest driving force in improving the safety of transfusion therapy in bleeding disorders has been the concern by patients of disease transmission. Safety has been accomplished not only by improved donor screening and testing but also through technologic improvements of blood product production and recombinant production of clotting proteins. The purpose of this chapter is to review the properties and clinical indications of platelets, plasma, and coagulation factor concentrates.

PLATELET TRANSFUSION THERAPY

Platelet Concentrates and Pheresis Platelets: Platelet transfusions are available as platelet concentrates or as apheresis units,[1] the former prepared from whole blood by centrifugation and the latter collected by pheresis devices. Platelet concentrates are separated from whole blood by first preparing platelet-rich plasma, from which the platelets are centrifuged. The contents of the platelet concentrates are highly variable, but 50 mL of platelet concentrate has at least 5.5×10^{10} platelets. A buffy coat method uses centrifugation to prepare a buffy coat, from which platelets are separated by an additional centrifugation. The white cell contamination is approximately 10^8 per bag using the platelet-rich plasma method of concentration, but considerably lower (10^6 per bag) for platelets prepared by the buffy coat method. Lower white blood cell (WBC) content in buffy coat platelet preparations may be advantageous in reducing alloimmunization and febrile transfusion reactions.[1,2,3] Platelet concentrates obtained from platelet-rich plasma method versus the buffy coat method do not show any functional difference *in vitro*, and comparative clinical trials have not been done.

Pheresis platelets are collected from donors by continuous processing of large volumes of blood and removal of platelets using an automated system. Most devices have WBC contamination of $<10^6$ per bag.[1] An advantage of pheresis platelets is that enough platelets can be derived from a single donor to provide a therapeutic dose, in contrast to platelets prepared from whole blood collection that requires pooling of platelets from four to six donors, which increases donor exposure risk.

Platelet Storage Lesion: In the United States, platelet blood components are licensed for a storage time of 5 days at room temperature, a limitation that constrains inventory control and can lead to wastage of this resource and periods of platelet shortages. Two factors lead to the short shelf life, first the risk of bacterial contamination and second the deterioration of platelet function. Platelets are stored at room temperature, as storage at 6 to 10°C leads to loss of function and viability, but room temperature (22°C) storage promotes bacterial growth of that may have been introduced at the time of blood collection. The risk of bacterial contamination is decreased by shortening storage time and by bacterial testing and pathogen inactivation procedures.[4]

The platelet storage lesion is characterized by (a) irreversible change in platelet shape from discoid to spherical, (b) generation of lactic acid from glycolysis, with an associated decrease in pH, (c) release of cytoplasmic and granule content causing a decrease in *in vitro* measures of platelet function and ADP-induced shape change, and (d) reduction in *in vivo* recovery and survival. Many of the biochemical changes are related not just to the active metabolism of platelets but to preparation technique and storage conditions. Consequently improvements in bag composition and platelet additive solutions that maintain platelet metabolism during storage are under evaluation.[2,4,5]

Clinical Applications of Platelet Transfusions

Thrombocytopenia: Platelet transfusions in thrombocytopenic patients enhance endothelial support functions by plugging fenestrations between endothelial cells. Table 78.1 outlines platelet transfusion guidelines for clinical situations, including issues of long-term support.[6,7,8] There has been considerable interest in defining the lowest safe platelet concentration at which bleeding is unlikely, so that fewer transfusions are consumed. Investigators have now shown that a prophylactic platelet transfusion threshold of 10,000/μL in adult patients with acute leukemia is safe,[9,10,11] thereby decreasing platelet utilization, with only a small adverse effect on bleeding and with no effect on mortality. Thus, prophylactic transfusions should be given to patients with amegakaryocytic thrombocytopenia if the count falls below 10,000/μL, and at values between 5 and 10,000/μL, transfusion can be held if the patient is stable and if no other conditions make spontaneous bleeding likely. These conditions include blast crisis, anticoagulation with heparin for disseminated intravascular coagulation (DIC), drugs that affect platelet function, uremia, and recent invasive procedures, including lumbar punctures or placement of central venous catheters. A study in patients after autologous peripheral blood stem cell transplantation demonstrated the safety and feasibility of therapeutic platelet transfusions, with one-third of transplants performed without platelet transfusions, reducing platelet transfusion by 50% compared with historical controls when the practice of prophylactic transfusions was in place.[11]

Platelet Dosing: While there have been a few small studies addressing platelet dosing,[12,13,14] a well-designed dose-ranging study was recently completed.[15] In this large study by Slichter et al., 1,351 adult and pediatric hematology–oncology patients were randomized to receive low (1×10^{11}), medium (2.2×10^{11}), and high dose (4.4×10^{11}) platelets per m^2 body surface area. Among the 1,272 evaluable patients, WHO grade 2 or higher bleeding was not significantly different between the three groups. This study suggests that fewer transfused platelets can

Table 78.1

Platelet transfusion guidelines

Prophylactic Platelet Transfusion Thresholds:

- Acute leukemia: For adult patients, a threshold of 10,000/μL is recommended; transfusion at higher levels may be necessary in the newborn or in patients with hemorrhage, high fever, hyperleukocytosis, rapid fall in platelet count, or coagulation abnormalities
- Hematopoietic cell transplantation: Same as for acute leukemia, with similar exceptions
- Chronic stable severe thrombocytopenia: Many patients can be observed without prophylactic transfusion, reserving transfusion for episodes of hemorrhage or during times of active treatment
- Solid tumors: Evidence supports the benefit of prophylactic transfusion at a threshold of 10,000/μL or less; a threshold of 20,000/μL should be considered for patients receiving aggressive therapy for bladder cancer, as well as for those with demonstrated necrotic tumors
- Surgical or invasive procedures: A platelet count of 40 to 50,000/μL is sufficient to perform major invasive procedures safely, in the absence of associated coagulation abnormalities; certain procedures, such as bone marrow aspiration/biopsy, can be performed safely with counts <20,000/μL; lumbar puncture in children is safe at platelet counts >10,000/μL
- Prevention of alloimmunization using leukoreduced blood products: It is appropriate to provide leukoreduced blood products to patients with acute myelogenous leukemia from the time of diagnosis to ameliorate the problem of alloantibody-mediated refractoriness to platelet transfusion; currently, this is not indicated in patients with cancer RBCs or treatments that do not produce significant and sustained thrombocytopenia
- Diagnosis of refractoriness to platelet transfusion: A CCI of 7,500/m²/μL is recommended as a definition of a satisfactory response; a diagnosis of refractoriness should be entertained only when at least two consecutive ABO-compatible transfusions, stored <72 h, result in poor increments
- Management of refractoriness to platelet transfusion: Patients with alloimmune refractory thrombocytopenia (i.e., poor increments in association with alloantibody detected using lymphocytotoxicity or antiplatelet antibody assays) are best managed with HLA-A and HLA-B antigen–selected donors or from compatible donors identified using platelet crossmatching techniques. Alloimmunized patients do not benefit from unmatched prophylactic platelet transfusions that fail to raise the platelet count, Such patients should be transfused only for hemorrhagic events

RBC, red blood cells; CCI, corrected count increment; ABO, blood group system; HLA, human leukocyte antigen.

prevent clinically relevant bleeding. It should however be noted that the total number of platelets transfused ended up being higher in the low-dose platelet group who received a median of five transfusion events versus three in the other two groups. Thus while the dose may be decreased it is not apparent that the total number of platelets needed to sustain a patient through a period of aplasia will be decreased.[15]

Platelet Transfusion in Specific Disorders

Consumptive Thrombocytopenias: Thrombocytopenia may develop on the basis of increased consumption, for example, autoimmune or drug-induced thrombocytopenia, DIC, and thrombotic thrombocytopenic purpura (TTP). Thrombocytopenia in these conditions can be quite severe, and profound bleeding is not uncommon, so platelet transfusions may be considered necessary in such patients. In the immune-mediated thrombocytopenias, the destruction of allogeneic platelets is as likely as are autologous platelets, and platelet transfusion is not the only therapeutic means to treat this form of thrombocytopenia.[16] There has been no documentation of increased morbidity from using platelets in DIC despite some concern that their use may increase disease severity by fueling the ongoing activation of coagulation. In TTP, the use of platelet transfusions has been said to provoke acute clinical deterioration[17] but there are also cases in which patients received platelet transfusions without difficulty, although they were already undergoing plasma exchange therapy.[18]

Qualitative Platelet Disorders: The most common acquired qualitative platelet abnormalities are either drug-induced or caused by uremia, others occurring in patients with myeloproliferative disorders, dysgammaglobulinemias, or secondary to mechanical cardiac assist devices. No controlled trials have been conducted to determine what an appropriate platelet dose should be, but one recommendation is for at least 10 platelet equivalent units of platelets should be given for severe bleeding or for extensive surgery.[19] Platelet transfusions can improve the bleeding time in patients taking aspirin if the transfused platelets constitute 10% of the platelet population,[20] an observation of importance in cardiac patients who require emergency intervention. Whether one can extend this observation to other antiplatelet drugs such as clopidogrel is unclear. In those patients where clopidogrel cannot be stopped preoperatively within 72 hours of surgery, blood loss is higher and platelet transfusions are frequently given.[21]

Inherited qualitative platelet disorders such as Glanzmann thrombasthenia and Bernard-Soulier syndrome can be manifest by severe bleeding, particularly following trauma. Platelet transfusions are effective in these disorders until the patient becomes alloimmunized to human leukocyte antigens (HLAs)

or to a platelet glycoprotein receptor such as the IIb/IIIa or Ia/IX complex, after which platelet transfusions are ineffective. In this situation, recombinant factor VIIa has been used successfully.[22]

Platelet Transfusion Refractoriness: Failure to achieve an expected increment to a platelet transfusion (refractoriness) may be caused by immune or nonimmune processes, most commonly due to HLA alloantibodies.[23,24] Before labeling a patient as being refractory to platelet transfusions, one should document low platelet recovery after using ABO identical platelets on two sequential transfusions.[25] The platelet count increment is calculated using the following formula:

$$\text{Corrected platelet count increment} = \frac{(\text{Posttransfusion} - \text{pretransfusion platelet count}) \times 10^{11} \text{Body surface area } (m^2)}{\text{Number of platelets transfused}}$$

This formula takes into account the dose of platelets given in total number of platelets and is corrected for the body surface area of the patient. Facilitating this calculation is the labeling of the platelet bag with the number of platelets in the bag by the facility producing the platelet transfusion. An acceptable corrected platelet count increment should be >7,500 platelets per $m^2/\mu L$ within 1 to 60 minutes after the transfusion, and >4,500 platelets per $m^2/\mu L$ if measured 18 to 24 hours later.

Immunologic Basis of Platelet Transfusion Refractoriness: Serial platelet transfusions result in decreasing platelet count increments. These transfusion failures result from the induction of alloantibodies to HLA-A and -B locus antigens.[6] Antibodies to human platelet alloantigens such as HPA-1a (PLA1) are only rare causes of platelet transfusion refractoriness. ABO compatible transfusions are associated with about a 20% greater increment than those that are not compatible. Some patients with blood group O who have high isoagglutinin titers to group A or group B antigens present on platelets may also fail to achieve adequate platelet increments.[25]

HLA antibodies are measured using lymphocytotoxicity or enzyme-linked immunosorbent assay (ELISA) testing. Some patients may have decreases in or a loss of HLA antibody, either permanently or transiently, yet still be successfully transfused with platelet concentrates. HLA antibodies may be transient, and after their disappearance, patients are not refractory to platelets, even though they are not HLA matched. Some patients may have antibodies to HLA class I and yet not have platelet transfusion failures, because these HLA antigens may not be well expressed on platelets.[26–28]

There are two broad types of HLA antibodies produced in response to platelet transfusions. The first type recognizes epitopes unique to a particular HLA allele, referred to as antibodies to private specificities and including A2 or B12. The second type of HLA antibodies recognize more than one gene product. These antibodies recognize structural similarities between gene products (cross-reactive epitopes) or identical epitopes present on different gene products of different alleles, and are referred to as antibodies to public epitopes. Traditionally, HLA serology has placed the greatest emphasis upon classifying the private antigens, although more attention has recently been given to the clinical importance of public HLA specificities, the best known examples of which are Bw4 and Bw6. These antigens are encoded by a diallelic system and are associated with two different groups of HLA-B class I antigens. Other public antigens carried by HLA-B class I antigens have been divided into four cross-reactive groups, B5, B7, B8, and B12. The observation that the specificity of HLA antibodies in multiply transfused individuals is generally against private epitopes suggests that matching for these public antigens is not necessary.[29–31]

Table 78.2 outlines alternative approaches to selecting platelets for an alloimmunized patient. In patients with an unusual HLA type, such as in some ethnic groups, HLA matching may be difficult. Relying only on HLA matching may have shortcomings and in some cases it is overly restrictive, in that some HLA-B loci antigens are not located on platelets. Therefore, in addition to antigen matching there has been interest in adopting an approach to red cell compatibility. In this paradigm, one first selects a red cell phenotype that matches the patient's phenotype, and then performs a major crossmatch. This same approach can be used for platelets by also performing a platelet crossmatch. Unlike red cell pretransfusion testing, there are no accepted standards for selecting platelet transfusions in patients with alloantibodies to platelets.[23,24]

Table 78.2

Two approaches to selection of platelets for alloimmunized patients

Approach A
Determine HLA phenotype and ABO type of the recipient
Screen patient's serum for (a) HLA antibodies typically done by ELISA testing, or (b) antibodies to human platelet antigens (if there is a history of poor response to HLA-identical platelets)
Select from the donor pool those units with the most compatible HLA antigens and, if possible, ABO systems
Or
Approach B
Crossmatch available platelet units without regard to patient or donor HLA type (circumvents the need for HLA typing and provides a means of finding compatible platelets when antibodies to human platelet antigens are present); then obtain 10-min and 18–24-h posttransfusion platelet counts, not only to assess transfusion outcome but also to guide the selection of donors for future transfusions

Nonimmune Refractoriness: Platelet transfusions may not result in an increment if the stored platelets are defective. Splenomegaly is a major cause of platelet transfusion failure. Normally, approximately 30% of a patient's platelet mass is contained within the spleen, but with increases in splenic size, up to 90% of circulating platelets can be sequestered. Characteristically, splenic sequestration is associated with a reduced 1-hour platelet recovery but a normal survival. Fever and infection also cause decreased platelet survival. One study noted that platelet transfusion requirements were increased by 50% in febrile patients, even more so in patients with major infections and DIC. Medications may cause platelet refractoriness, including amphotericin, vancomycin, antithymocyte globulin, granulocyte-macrophage colony-stimulating factor, granulocyte colony-stimulating factor, and interferons.[32–34] Gamma radiation of platelet transfusions either prior to transfusion or prior to storage period does not affect platelet transfusion survival.

Management of Platelet Transfusion Refractoriness and Bleeding: When no compatible platelets can be found for an alloimmunized patient who is bleeding, or may be undergoing invasive procedures, therapeutic modalities have included splenectomy, corticosteroids, plasmapheresis, administration of intravenous gamma globulin, and repeated platelet transfusions. Except for intravenous immunoglobulin, there is little evidence that any of these work.[23,24,35] Kickler et al.[35] performed a randomized, placebo-controlled clinical trial, investigating the use of intravenous immunoglobulin (400 mg/kg for 5 days) in patients with alloimmunized thrombocytopenia. An incompatible platelet transfusion from the same donor was used before and after the patient received study drug or placebo. Although platelet recovery at 1 to 6 hours was satisfactory in five patients after intravenous immunoglobulin treatment, 24-hour survival was not improved in most of these patients. This small study suggests that the kinetics of platelet destruction may be improved by intravenous immunoglobulin to an extent to permit the performance of invasive procedures. When all conventional methods fail to increase the platelet count to hemostatic levels, an alternative is continuous platelet transfusion. Although this approach does not result in an increased platelet count, transfused platelets may permit platelet plug formation or help to maintain endothelial integrity, but clinical trial has not tested this assumption.

Prevention of Alloimmunization: Animal studies show that depletion of contaminating leukocytes from donor blood components is effective in prevention of alloantibody response to major histocompatibility complex.[36] In the Trial for the Reduction of Alloimmunization to Platelets, 534 leukemic patients receiving induction chemotherapy were studied during an 8-week period for the development of platelet alloantibodies. HLA antibodies developed in 45% of patients in the control group, compared to 18% in the filtered platelet concentrate group and 17% in the filtered apheresis group.[37] Not all patient groups may benefit from leukoreduction, for example, cardiac surgery patients who are not immunosuppressed may still develop HLA antibodies even with leukoreduced platelet transfusions.

PLASMA THERAPY

Table 78.3 lists plasma products and their properties. Clinicians are often aware of only fresh frozen plasma (FFP), whereas in reality, many transfusion services rely on plasma frozen within 24 hours, rather than 8 hours; plasma frozen within 24 hours has approximately 15% lower levels of factors V and VIII. Coagulation factor activity is well maintained in thawed plasma stored at 1 to 6°C for up to 5 days. An average unit of plasma has a volume of about 300 mL. Today, clinicians use plasma primarily for replacement therapy when a specific clotting concentrate is not available and for patients undergoing therapeutic plasma exchange for TTP.[38,39] Because plasma can be frozen for up to 1 year, some blood centers release the plasma for use when the donor returns at least 112 days later, and the infectious disease tests are found negative for hepatitis B, C, and human immunodeficiency virus (HIV). The 112-day release date for retested plasma was chosen because it exceeds the period during which virally transmitted diseases can occur despite negative infectious disease testing.

Methods for pathogen inactivation include solvent detergent treatment and photoinactivation using either psoralen or methylene blue. Solvent detergent plasma has lower levels of protein S and there is concern about increasing thrombosis in patients with TTP.[38]

Indications for Plasma

When plasma was first introduced, it was used as a plasma expander, promoter of improved wound healing, and nutritional support for correcting hypoalbuminemia, but safer and more effective means are available using nonblood products such as crystalloid with dextran. Plasma therapy is a poor method for nutritional support,[39] and there is no evidence that plasma improves wound healing. Frozen plasma carries the risk of viral disease transmission, similar to that associated with the use of red cell transfusions. Allergic reactions to plasma are common, as high as 3%, the most serious complication being transfusion-related acute lung injury (TRALI). In some locales, plasma from multiparous women is not used to make plasma, so as to circumvent the passive transfusion of white cell antibodies that provoke the potentially fatal TRALI syndrome. There is no single test or intervention that cannot be done to prevent TRALI. Most important strategy is preventive, where donors implicated in TRALI can no longer donate plasma or platelets by pheresis.

Congenital or Acquired Coagulation Factor Deficiencies: Patients with hemophilia with factor VIII levels of 5% to 10% rarely have spontaneous bleeding, and with factor VIII levels >50%, effective surgical hemostasis is anticipated. Therefore, the volume of transfused plasma should be sufficient to achieve approximately 30% coagulation factor levels, approximately 10 to 15 mL/kg of body weight. One of the limiting factors in dosing plasma is how well the patient can accommodate the increased plasma volume. In surgery where there is active bleeding, volume overload may not be an issue, whereas in a patient with severe liver disease, volume overload is a limiting factor.[38,39,40] FFP is used for correcting congenital or acquired coagulation deficiencies of factors II, V, VII, X, XI, and XIII, and adequate hemostasis occurs at factor concentrations of 0.2 to 0.3 U/mL (20% to 30%). Depending upon the half-life and extent of injury or surgery, additional treatments with FFP or factor concentrates may be needed.

Reversal of Warfarin: In the setting of active bleeding, emergency surgery, cardioversion, or invasive procedure where there is inadequate time to wait for vitamin K reversal, plasma is used to correct a prolonged international normalized ratio >1.6. Reversal may require 5 to 8 mL of plasma per kilogram body weight,[38,39] but prothrombin complex concentrates (PCCs) can be utilized for this purpose. PCCs achieve more rapid and

Table 78.3

Plasma products and their properties

Plasma Type	Preparation Characteristics	Composition	Comment
FFP	Separated from whole blood and frozen at –18°C or colder within 8 h of collection	Volume varies between 180 and 300 mL and plasma proteins and all coagulation factors	A 200-mL bag of FFP would contain approximately 200 U of each coagulation factor
Plasma frozen within 24 h of collection	Frozen within 24 h of whole blood collection	Levels of factors V and VIII are reduced approximately 15% compared to FFP	
Liquid plasma	Liquid plasma is separated no more than 5 d after the expiration date of whole blood	Stable coagulation factors are equivalent to FFP, but the labile factors of V and VIII are significantly reduced	Rarely should this product be used for replacement therapy in massive transfusion or severe liver disease and associated bleeding
	The supernatant plasma after the removal of cryoprecipitate material	Deficient in fibrinogen, factor VIII, and von Willebrand multimers	Has been used in therapeutic pheresis, and in TTP
Cryoprecipitate	Cryoprecipitate is prepared by thawing FFP at 1–6°C and recovering the precipitable material and then stored at 18°C or colder for up to 1 y	Contains more than 150 mg of fibrinogen, more than 80 U of factor VIII, von Willebrand multimers, and factor XIII in 15 mL of volume	Used in replacement therapy of hypofibrinogen, in preparation of fibrin sealants used in surgery, and in uremic platelet dysfunction

complete warfarin reversal than FFPs, but they carry the risk of thromboembolic complications. FFP when given in sufficient amount to correct hypoprothrombinemia may result in volume overload that may end up putting the patient in the intensive care unit. It should be noted that FFP contains citrate that when given rapidly in large volume may induce tetany by reducing ionized calcium, but not to an extent that affects coagulation. A systematic review of the use of recombinant factor VIIa (rFVIIa) to reverse warfarin provided no quality evidence for its use in this situation, so FFP still has a role.[38,41,42]

DIC: In many patients with DIC, severe hypofibrinogenemia may be present, but FFP alone may be insufficient to raise the fibrinogen to hemostatic levels of 100 mg/dL. Fibrinogen is concentrated 15-fold or greater in cryoprecipitate, which is the blood component of choice for correcting acquired hypofibrinogenemia. Transfusion of cryoprecipitate in doses of 1 bag per 5 kg of body weight will increase the fibrinogen levels by 80 mg/dL. The half-life of fibrinogen is 3 to 5 days,[43] and additional cryoprecipitate should be given on the basis of fibrinogen concentration.[43–45,46]

Massive Transfusion: Several factors contribute to bleeding in the setting of massive transfusion, including transfusion of packed red cells without clotting factors, large volumes of crystalloid leading to clotting factor dilution, and development of concurrent bleeding diathesis from DIC. Monitoring of coagulation should guide transfusion therapy, noting that thawing of plasma may take up to 1 hour, so empiric therapy based on clinical judgment may be the best approach in the face of serious bleeding.[43–45] Chapter 129 contains further description of transfusion therapy in surgical situations.

SPECIALIZED COAGULATION CONCENTRATES

Plasma Clotting Factor Concentrates

Tables 78.4A to 78.4K lists all the Food and Drug Administration (FDA) licensed blood product derivatives or recombinant therapies used for treating hemostatic disorders. Lyophilization of factor concentrates was introduced in the 1970s, leading to the widespread availability of a stable transfusion product that could be kept without freezing and permitted the introduction of home therapy by many patients with hemophilia. The introduction of viral inactivation and enhanced donor screening, along with the avoidance of paid plasma donors have resulted in highly safe plasma derivatives. The development of recombinant concentrates has provided for the safest possible form of factor replacement.[46,47,48] Since the introduction of recombinant clotting factors, clinical experience has shown that they are similar in efficacy as agents purified from plasma.[47]

Gel and ion exchange chromatography were used to increase the specific activity of factor VIII preparations to approximately 100 U of factor VIII per mg of protein. Polyethylene glycol precipitation followed by affinity chromatography of factor VIII/von Willebrand complex using heparin agarose columns is one method used to obtain relatively high purity concentrate of factor VIII and von Willebrand protein; other manufacturers employ monoclonal antibodies directed to factor VIII, producing a product of factor VIII that has >3,000 U of factor VIII per mg of protein. These affinity chromatography products

are referred to as very high purity, in contrast to gel and ion exchange products, which are referred to as high purity.[48,49,50,51]

Viral inactivation steps were developed in the 1980s to prevent hepatitis and HIV. Careful longitudinal studies were performed to document the safety of this approach and the pitfalls, namely, the inability to inactivate nonenvelope viruses by detergent.[50,51] Dry heat activation concentrates heated at 68°C for 32 to 72 hours are partially effective for HIV, but not for hepatitis. Prolonged dry heating at 68°C for 144 hours is used for some products, moist heating under pressurized vapor at 60°C for 10 hours for others, the latter appearing to prevent transmission of hepatitis C or HIV, but not parvovirus. A newly available human fibrinogen concentrate is heated and undergoes glycine precipitation to inactivate or remove viruses. Solvent detergent treatment of concentrates to disrupt viral lipid membranes is used in conjunction with chromatographic purification, and no cases of hepatitis C or B, or HIV have occurred with this approach. Most of the currently available factor concentrates are treated with solvent detergent.[50,51,52]

Recombinant-Derived Factor VIII and IX Concentrates

Several recombinant coagulation formulations are available for the treatment of hemophilia A.[46,47] A larger treatment of inherited and acquired hemophilia is in Chapter 51. B-region deleted recombinant factor VIII product is more stable than the natural full-length rFVIII, making production in mammalian cell culture less difficult, but it may be less bioactive than the other recombinant factor VIII products. One product was stabilized through coexpression of von Willebrand factor, and another through supplementation of the culture medium with small synthetic compounds. The first generation of recombinant FVIII were full length copies of VIII and had either human- or animal-derived protein exposure. The second generation of recombinant VIII was either B-domain deleted or full length and also had human- or animal-derived protein exposure. The current third generation recombinant FVIII have no human or animal protein exposure and are full length. Whether

Products licensed in the United States to treat rare bleeding disorders

Recombinant Factor VIIa Concentrate for Treatment of Factor VII Deficiency

Product Name	Manufacturer	Method of Viral Depletion or Inactivation	Stabilizers in Final Vial	Heparin in Final Vial (U/mL)	Human or Animal Plasma-Derived Protein Used in Culture Medium	Generation	Viral Safety Studies in Humans with This Product?
NovoSeven RT	Novo Nordisk	1. Affinity chromatography 2. Solvent/detergent (TNBP/polysorbate 80)	1. Mannitol, 25 mg/mL 2. Sucrose, 10 mg/mL	None	Newborn calf serum	Second	Yes

Table 78.4J

Products licensed in the United States to treat rare bleeding disorders

PCCS Derived from Human Plasma for use in Patients with Deficiencies of Factors II and X

Product Name	Manufacturer	Method of Viral Inactivation	Heparin in Final Vial (U/Unit Factor IX)	Specific Activity of Final Product (Iu Factor IX/mg Total Protein After Addition of Stabilizer)	Relative Content of Factors (FIX = 100)	Viral Safety Studies in Humans with This Product?
Bebulin VH	Baxter	1. Vapor heat (10 h, 60°C, 190 mbar pressure plus 1 h, 80°C, 375 mbar)	<0.15	2.0	X > II > IX > VII	Yes
Profilnine SD	Grifols	1. Solvent/detergent (TNBP/polysorbate 80)	None	4.5	II > IX = X > VII	Yes

Table 78.4K

Products licensed in the United States to treat rare bleeding disorders

Factor XIII Concentrate

Product Name	Manufacturer	Method of Viral Inactivation	Heparin in Final Vial (U/unit Factor XIII)	Specific Activity of Final Product (IU Factor XIII/mg Total Protein After Addition of Stabilizer)	Relative Content of Factors (FXIII = 100)	Viral Safety Studies in Humans with This Product?
Corifact, factor XIII concentrate	CLS Behring	$Al(OH)_3$ adsorption/ Vitacel defibrination, ion exchange chromatography and heating to 60°C	None	Stated on vial	Not available	No

recombinant VIII versus plasma-derived VIII promotes inhibitor formation with greater frequency is still an active question of investigation.[50,51]

Structurally and therapeutically, recombinant factor IX is comparable to monoclonal plasma-derived factor IX.[53,54] The only observed difference is the recovery recombinant factor IX at approximately 72% that of a plasma factor IX product, due to minor differences in the posttranslational modifications.

Prothrombin Complex Concentrates: Anti-inhibitor coagulant complex is a freeze-dried sterile human plasma fraction with Factor Eight Inhibitor Bypass Activity, hence the trade name FEIBA. FEIBA contains factors II, IX, and X, mainly nonactivated, and factor VII, mainly in the activated form, as well as 1 to 6 U of factor VIII coagulant antigen per mL, and traces of factors of the kinin-generating system.[46] FEIBA is indicated for the control of spontaneous bleeding episodes or to cover surgical procedures in hemophilia patients with inhibitors.[55] Other prothrombin complexes contain variable amounts of vitamin K dependent clotting factors and one has been tested for reversing the anticoagulant effect of warfarin and for severe surgical bleeding where platelet and plasma infusions were ineffective.[56]

Recombinant Factor VIIa: Production of recombinant human factor VIIa requires a mammalian expression system. The gene for human FVII, isolated from chromosome 13, is transfected into a baby hamster kidney cell line that secretes factor VII into the culture medium in its single chain form. The product is purified with murine monoclonal antifactor VII antibodies and is subjected to treatment with 0.1% Triton X-100 to inactivate enveloped viruses. Subsequent ion exchange chromatography further purifies the product and causes autoactivation, producing the activated form.[57]

Administration of rFVIIa enhances thrombin generation through direct activation of FX independent of FVIII or FIX, on thrombin-activated platelet surfaces, ensuring a full thrombin burst needed for formation of a fully stabilized fibrin plug.[57,58] rFVIIa is approved by the U.S. Food and Drug Administration for treating bleeding episodes in patients with hemophilia A or B when inhibitors to these factors are present. In Europe, rFVIIa is approved for use in alloimmunized patients with Glanzmann thrombasthenia, who are bleeding. Experimental evidence of rFVIIa for warfarin reversal in normal volunteers has not demonstrated that its use reduces blood loss.[41] In one randomized placebo controlled trial after cardiac surgery, rFVIIa showed benefit for treating bleeding, but this was at the expense of serious adverse events, including stroke.[52]

Activated Protein C (Drotrecogin-Activated): Drotrecogin α (activated) is a recombinant form of human-activated protein C (APC) that is manufactured as an inactive zymogen, enzymatically activated by thrombin cleavage and purified using monoclonal antibodies.[59] APC exerts an anticoagulant effect, along with its cofactor protein S, by inactivating factors Va and VIIIa, two critical cofactors that promote thrombin formation. APC is approved for use in severe sepsis, on the basis of decreased mortality in high-risk patients with sepsis. APC therapy increases the risk of bleeding and is contraindicated in patients with active internal bleeding, recent spinal or cranial surgery or trauma, presence of an epidural catheter, or an intracranial neoplasm or mass lesion.[59] There are no recommendations for individual dose adjustments on the basis of laboratory studies.

Antithrombin: There are two forms of antithrombin concentrate: (a) a lyophilized preparation isolated from pooled plasma by a modification of the Cohn fractionation technique with viral attenuation achieved by heat treatment at 60°C for at least 10 hours, with some products also nanofiltered, and (b) a recombinant harvested from transgenic goat milk, further purified by flow filtration, heparin affinity column, and nanofiltration, and with specific measures taken to ensure the absence of prions.[60] Antithrombin serves as a control mechanism for coagulation activation in the circulation, inhibiting thrombin, factor Xa, and other serine proteases much more efficiently than when those factors are bound to platelets or fibrin. Antithrombin is approved for use in the treatment of patients with hereditary antithrombin deficiency, as prophylaxis against thrombosis following surgery or obstetric procedures, and for therapeutic use when such patients have thrombosis. Debate continues about the use of antithrombin concentrates in patients with "acquired" antithrombin deficiency, such as in cases of sepsis and DIC, or in those with relative heparin resistance during surgery and extracorporeal circulation.[60] The product is not approved for pediatric use. Replacement therapy is designed to achieve levels of 120%, with subsequent doses administered empirically to keep levels

at 70% to 120%. In stable antithrombin-deficient patients, the half-life of infused antithrombin is 60 to 90 hours after an initial half-disappearance time of 22 hours. In acute DIC, the half-life is usually 50% that of stable patients, and may be as short as 4 hours.

CHAPTER

79

New Approaches for the Therapy of Bleeding Disorders, Including Gene Therapy

GILBERT C. WHITE, II AND HAROLD R. ROBERTS

Better understanding of the molecular mechanisms of blood coagulation and the structure and function of blood clotting factors, along with advances in recombinant DNA technology have placed us on the threshold of remarkable new approaches to the treatment of bleeding disorders. Gene therapy is the most visible of these new approaches, but mechanisms now exist to actually make coagulation factors that are better than the native proteins. Some of these new approaches are the subject of this chapter.

HISTORICAL PERSPECTIVE

The treatment of bleeding disorders has traditionally been through the use of fresh frozen plasma or plasma-derived coagulation factor preparations. The first of these coagulation factor preparations was cryoprecipitate, which was developed by Judith Graham Pool in 1964. Cryoprecipitate was enriched in factor VIII, as well as fibrinogen, von Willebrand factor, and fibronectin, and for the first time provided a method of increasing factor VIII levels with less volume overload. Later came other coagulation factor preparations, including glycine-precipitated purified factor VIII and barium sulfate–purified prothrombin complex concentrates containing factors II, VII, IX, and X. These were produced commercially and revolutionized the treatment of hemophilia A and B, leading to home treatment. The prothrombin complex concentrates were also effective in the treatment of patients with coagulation factor inhibitors, allowing treatment of these individuals for the first time. The mechanism of action was uncertain, but activated clotting factors in the concentrates were thought to "bypass" the inhibitor block in the coagulation cascade. Although these crude plasma-derived concentrates changed the treatment of hemophilia, they contained blood-borne viruses that were transmitted to hemophiliacs. By the early and middle 1970s, hepatitis B and a new non-A, non-B form of hepatitis, later renamed hepatitis C, were becoming epidemic in the hemophilic population. Even worse, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) appeared in the hemophilic population in the early 1980s and eventually led to the untimely death of thousands of patients with hemophilia. In response to these blood-borne infections, the academic–industry complex developed physical and chemical methods for inactivating hepatitis, HIV, and other blood-borne viruses, used monoclonal antibodies to factors VIII and IX to generate antibody affinity-purified ultrapure forms of both factors, and developed recombinant DNA techniques for producing factors VIII and IX, resulting in synthetic forms of both factors that were essentially free of blood-borne contaminants. As a result of these and other advances, current products used to treat hemophilia are the safest ever developed.

Despite their safety, the current products have some drawbacks. They are expensive, require intravenous administration, and must be administered frequently because of the short biologic half-life of the normal coagulation factor proteins. For the average hemophiliac, who might bleed as many as 50 times a year or more, the cost of replacement therapy with current products can be as much as $50,000 per year. Prophylaxis, the treatment to prevent bleeding and the damage to joint and tissues, requires treatment two to three times a week or 100 to 150 times a year, with costs in excess of $50,000 and considerable damage to veins from frequent venipuncture. Developing technologies to make clotting factors that are cheaper, last longer after infusion into patients, or those that could be administered by alternative routes (including oral) would be advantageous. Gene therapy is another approach that has received considerable attention. This chapter reviews these new approaches to the treatment of bleeding disorders. The focus of the chapter is primarily on hemophilia A, but the concepts can be applied broadly to all bleeding disorders.

GENE THERAPY APPROACHES

Gene therapy is literally the use of genes, DNA or RNA, as treatment of a particular condition or disorder. In most cases, it is the proteins produced from the genes that have the intended effect in gene therapy, although DNA itself can have effects. For monogenic disorders like hemophilia or cystic fibrosis, the intent of gene therapy is curative. The aim is to use normal genes to express enough normal protein to correct the abnormality. One of the great promises of gene therapy is the potential ability to cure monogenic disorders such as hemophilia. For complex multigenic disorders, such as atherosclerosis, diabetes, or cancer, the aim of gene therapy is modification of the disease process. The goal might be to express a protein or gene that is toxic to a cancer cell or inhibits smooth muscle proliferation in atherosclerosis.

The origins of gene therapy lie in the remarkable advances in recombinant DNA technology that occurred in the middle and latter half of the last century. The ability to isolate and manipulate DNA, and the development and use of viral and nonviral plasmid vectors to introduce DNA into cells where the DNA products could be expressed were critical developments. In one

of the early reports using direct injection of DNA into cell nuclei, Jaenisch and Mintz reported injecting SV40 DNA into mouse blastocysts and finding SV40 gene sequences developing from the blastocysts in the animals.[1] The notion of using viruses as vectors to introduce new genetic information into cells evolved very quickly. By 1979, several laboratories were employing the SV40 virus, using viral promoter, splicing, and polyadenylation sequences in plasmid vectors to introduce β-globin sequences into cells and drive transgene expression.[2,3,4] Retroviruses, which are adept at gaining entry into cells and inserting their genetic material into the host genome, soon followed. Defective retroviruses in which the malignant transforming gene region was eliminated, were shown to retain the ability to transduce cells.[5–7] The first gene transfer experiments in humans were carried out by Cline in 1980 in two subjects with severe β thalassemia.[8] Nucleated cells, obtained by bone marrow aspiration, were transfected *in vitro* using a pBR vector containing a herpes simplex virus thymidine kinase (*HSVtk*) marker gene, and then returned to the subject intravenously. HSVtk sequences were detected at low levels 1 to 2 weeks after transfection and lasted 3 months in one subject and 9 months in the second.

Hemophilia A is a monogenic disorder which, like sickle cell disease, cystic fibrosis, and muscular dystrophy, has historically been considered as an attractive target for treatment using gene transfer approaches. Primary prophylaxis studies in which clotting factor concentrates have been administered to maintain low levels of factor VIII have shown that near-continuous correction of the clotting factor defect prevents bleeding in unaffected joints and delays progression in diseased joints.[9–11] Logically, more continuous levels of factor VIII, as might be anticipated with gene therapy, provide the rationale for the enthusiasm for this approach in hemophilia A.

Other aspects of hemophilia A add to its attractiveness as a candidate disorder for gene transfer (see Table 79.1). As a monogenic disorder, correction of the factor VIII defect should correct the phenotype. Furthermore, unlike monogenic inborn errors of metabolism, levels of factor VIII are not regulated in any way and do not require feedback or other control as, for example, insulin requires regulation by blood glucose levels. Another important feature is that complete correction of the factor VIII level is not absolutely necessary in hemophilia for gene transfer to be effective. For example, an increase in plasma levels of factor VIII by even as little as 1% to 2% could have a beneficial effect, especially in patients with severe hemophilia. Persistence of expression after gene transfer might also have beneficial effects. Given the biological half-life for current plasma products of approximately 12 hours, expression of factor VIII for even a month would change patients' lives. Factor VIII message is detected in a number of tissues,[12] but as long as the factor VIII that is expressed after gene transfer is processed correctly and has access to blood, it does not matter where the protein is produced. There is no current evidence that synthesis of factor VIII in tissues outside its site of normal synthesis is detrimental to that tissue. Therefore, it is not necessary to target the factor VIII to a particular tissue or to its tissue of natural synthesis. In addition, factor VIII is a secreted protein that would be expected to gain easy access to blood. The gene for factor VIII is well characterized and, based on homology modeling, much is known about the structure of the factor VIII protein and the function of the various structural domains.[13] A low-resolution crystal structure of factor VIII is available.[14] Good clinical and laboratory parameters of efficacy are available. Large and small animal models of hemophilia are available for preclinical trials.[15,16] Finally, safe and effective treatments for hemophilia currently exist, and so subjects can make appropriate decisions about participation in clinical trials without the pressure engendered by the lack of adequate treatment.

Table 79.1

Hemophilia as a target for gene transfer

Monogenic disorders; correction of factors VIII or IX will correct the phenotype
Complete correction of factors VIII or IX is not required; any level of factor VIII will have a clinical effect
Production of factors VIII or IX can occur in any tissue that has access to blood
The genes for factors VIII and IX are well characterized and protein structure is understood
Large and small animal models of hemophilia A and B exist
Safe and effective treatments for hemophilia A and B exist

Gene Transfer Vectors*

Viral Vectors

Viruses have evolved highly efficient mechanisms for entering human cells and using the DNA/RNA replication machinery of the cell to produce viral products.[17] By replacing viral coding sequences with genes of particular interest (e.g., the cDNA for factor VIII) one can use viruses as agents to introduce the gene into cells where they use the cellular machinery to produce therapeutic quantities of the protein. The obvious advantage of viruses as vectors is their native ability to get into cells; the general disadvantage is their toxicity.

Retrovirus Vectors

Retroviruses are enveloped RNA viruses that use reverse transcriptase to convert virion RNA into double-stranded DNA; the DNA is subsequently integrated into the genome of the cell. The surface of the retrovirus consists of a lipid bilayer with protruding membrane proteins, GP41 and GP120, both encoded by the *env* gene. The tropism of the virus, that is the host cell that is targeted by the virus, is determined by these surface proteins. For example, for HIV-1, GP120 mediates the interaction of HIV-1 with CD4 lymphocytes. For gene therapy vectors, it is common to replace the retroviral *env* gene with other sequences that change the tropism of the vector. This can be done to either target a particular tissue or cell or to broaden the tropism of the vector to increase the number of cells that are transduced. Two sequences that are frequently used to broaden the tropism of retrovirus vectors are the amphotropic envelope gene of

*Sections of text on gene transfer vectors and phase I gene transfer trials in hemophilia A and B have also been used by G. C. White in the first edition of the *Textbook of Hemophilia*, eds. Lee, C., Berntorp, E. and Hoots, W. K., Blackwell Publishing, Oxford, UK.

murine leukemia viruses, which is able to interact with a widely expressed phosphate transporter on human cells, and the glycoprotein of vesicular stomatitis virus, which interacts with a ubiquitous receptor on cells. Current retroviral vector production is through a three-part packaging system, consisting of a genome vector that contains the packaging signal and the cDNA of interest, an expression vector that contains the pseudotyped envelope glycoprotein, and an expression vector that expresses the viral *gag* and *pol* genes. These are assembled into vector particles in a packaging cell. The retroviral packaging systems in current use appear safe and are designed to prevent the generation of replication-competent virus. In addition, sufficient modifications are made in the viral sequence to minimize the possibility of homologous recombination with retroviral sequences in target cells. Self-inactivating ("sin") vectors are ones in which the long-terminal repeats (LTRs) have been removed to prevent activation of downstream cellular genes.

Vectors derived from the Moloney murine leukemia virus (MoMLV) were the first retroviral vectors used for gene transfer. MoMLV has a 9-kb cDNA expression cassette and is therefore able to accept the entire 7.1-kb factor VIII cDNA or 1.9-kb factor IX cDNA. Although MoMLV can be produced in large quantities and is able to efficiently gain entry into cells, it only transduces dividing cells,[18] a disadvantage for many tissues such as liver where the rate of cell replication is low. Strategies for inducing cell division in the liver using partial hepatectomy,[19,20] chemical injury,[21] or hepatocyte growth factor[22–25] have been proposed to increase retrovirus-mediated transduction.

More recently, vectors derived from lentiviruses, including HIV-1, have been developed.[26,27] Members of this family of retroviruses include feline immunodeficiency virus, simian immunodeficiency virus, and equine infectious anemia virus.[28–30] Like MoMLV, lentiviral vectors have a 9-kb cDNA expression cassette. These vectors retain some of the attractive features of the Moloney-based retroviral vectors, such as stable integration into the host chromosome and targeted cellular uptake through coat proteins, and they are able to infect nondividing and dividing cells.[26,31] More recent observations provide greater understanding of the mechanisms of nuclear import by lentiviruses and may lead to improvements in cell transduction. During reverse transcription (RT) of HIV-1, a three-stranded DNA flap is formed that is composed of the central polypurine tract from the *pol* gene and central termination sequences. This flap functions as a cis-acting element to enhance nuclear import and improve gene transduction in nondividing cells.[32–35] Other cis-acting DNA elements that enhance transgene expression, perhaps through a mechanism like the DNA flap, have been identified, including the matrix attachment region from immunoglobulin κ[36] or from β interferon.[37,38]

Although retroviral integration is not sequence-specific, there is increasing evidence that it is also not completely random, as was once thought. The ability of retroviruses to successfully replicate themselves depends on integration of the viral DNA into transcriptionally active areas of the host cell chromosome. Integration into silent areas would prevent expression of viral proteins and inhibit replication. Studies to map the site of retrovirus integration demonstrate that different viruses have different patterns of integration.[39–41] With murine leukemia viruses (MLV), for example, transcriptional start sites are favored targets. For HIV-1, active genes are preferential integration targets, especially genes that are activated by infection of the cell by the retrovirus. Regional hotspots also exist.[39] Whether the predilection for active genes results from increased chromatin accessibility, locally bound transcription factors, or some other influence is not clear. In contrast, for avian sarcoma leukosis virus, an avian retrovirus, the virus does not prefer transcription start sites or active genes,[41] a feature that might confer an advantage with regard to gene therapy and the risk of insertional mutagenesis (see below).

Retroviruses insert their DNA into the host chromosome and are therefore termed *integrating vectors*. Because of their integrating properties, insertional mutagenesis is a concern with some retroviruses. Integration of retroviral sequences near protooncogenes has been known to be capable of activating their expression, contributing to tumorigenesis in animal models.[42,43] A report of T-cell leukemia in subjects with X-linked severe combined immunodeficiency syndrome treated by MLV-mediated gene transfer[44] shows that insertional mutagenesis occurs in man. The subjects were among 10 receiving *ex vivo* retrovirus-mediated gene transfer into autologous $CD34^+$ bone marrow cells. Approximately 3 years after treatment, the subjects developed acute T-cell lymphocytic leukemia. The leukemic T-cells showed evidence for retroviral insertion near the LMO2 proto-oncogene promoter. Because of the survival advantage that the cells expressing the retroviral γC-transgene had over the normal T-cells, it has been suggested that the insertional mutation in the LMO2 promoter region resulted in uncontrolled clonal expansion of the corrected T-cells, initially correcting the severe combined immunodeficiency and then resulting in T-cell leukemia.

Adenovirus Vectors

Adenoviruses (Ads) are linear, double-stranded DNA viruses that infect a wide variety of human cells, both dividing and nondividing, including lung, liver, heart, and brain. The 36-kb viral genome consists of a number of early and late genes. Transcription and translation of the early genes modulates cell function to facilitate replication of the viral DNA, whereas the late genes are involved in the structural aspects of viral replication. The icosahedral adenoviral capsid is composed of three major components: the hexon, penton base, and knobbed fiber. Viral entry into cells is accomplished through an initial high-affinity interaction between the knobbed fiber[45,46] and a widely expressed, 46-kDa coxsackie-adenovirus receptor (CAR) on the surface of cells.[47] After the initial interaction with CAR, entry of the virus into the cell proceeds through clathrin-mediated endocytosis, by an interaction between the penton base and $\alpha_V\beta_3$ and $\alpha_V\beta_5$ integrins on the cell surface. Disruption of the viral capsid occurs in the endocytic vesicle and the viral genome enters the nucleus through nuclear pores. In the nucleus, the adenoviral genome does not integrate into the chromosomes of the host cell, functioning instead from an extrachromosomal or episomal template.

Adenoviral vectors characteristically elicit an intense inflammatory response. This is due in part to capsid proteins, which provoke a brisk humoral and cellular immune response.[48] At the same time, Ad is designed to evade the immune response that it elicits.[49,50] Products of the *E1A* gene interfere with nuclear factor κB (NFκB) which is a key regulator of the innate antiviral response by cells. Products of the *E3* gene are also known to subvert the host immune response. Other gene products play a role, as well. One of the goals in the generation of adenoviral vectors

is to retain the high degree of efficiency that these vectors have with respect to cell infection while moderating or eliminating the inflammation that they cause. First-generation adenoviral vectors were deleted in E1 and E3, removing some of the primary mediators of the immune response while increasing the expression cassette to 6.5 kb. The *E2* genes were removed in the second-generation vectors and, in recent vectors, all of the viral coding sequences have been removed, rendering the vector "gutless."[51,52] Although preclinical studies indicate that removing these proteins may reduce the cellular immune response,[53–55] there is also evidence that the virion shell alone elicits substantial cellular responses.[56]

There are at least 47 different adenoviral serotypes, each immunologically distinct. The development of an immune response to one vector serotype generally precludes readministration of that vector. Adenoviral vectors for gene transfer are primarily Ad2 or Ad5.

The only death that was directly attributable to a gene transfer trial occurred with an adenoviral vector in an 18-year-old subject with ornithine transcarbamylase deficiency.[57] The second-generation vector used in this study was based on human Ad5 and was deleted in E1 and E4. Following administration of the vector in the right hepatic artery, altered mental status and jaundice were noted 18 hours later, and the ensuing clinical course was marked by a systemic inflammatory response syndrome with high levels of interleukin-6 (IL-6) and IL-10, biochemically detectable disseminated intravascular coagulation, and multiple organ system failure, leading to death 98 hours following gene transfer. The story of Jesse Gelsinger has been well-chronicled in the news media.[58]

Adenovirus-Associated Virus Vectors

Adenovirus-associated viruses (AAV) are small, nonenveloped, single-stranded DNA viruses, which require helper virus to facilitate efficient replication. In the absence of helper virus-mediated replication, the wild-type virus persists in the host cell in a latent state. The 4.7-kb genome of AAV consists of two inverted terminal repeats (ITRs) and two open reading frames that code for the rep and cap proteins. There are four rep proteins that function in regulating AAV replication and three cap proteins that form the protein coat of the virus. Wild-type AAV stably integrates into the host genome at the AAVS1 region of chromosome 19q13.3-qter.[59] Two of the *rep* gene products, rep68 and rep78, are believed to direct integration to the AAVS1 site.[60] Nine different AAV serotypes have been identified, AAV1 to 9, each with distinct tissue tropism.[61] AAV8 targets primarily liver, whereas AAV1 and AAV7 transduce muscle with high efficiency. The cellular receptor for AAV2, the serotype most commonly used for gene transfer studies, is heparan sulfate, a glycosaminoglycan that is variably present on the surface of most cells.[62] Slow-twitch (slow myosin-expressing) skeletal muscle fibers have higher concentrations of heparan sulfate proteoglycan on their surface and are better transduced by AAV2 than fast-twitch fibers.[63] Interestingly, AAVS1, the site of integration, is closely linked to the slow skeletal troponin *T* gene, TNNT1,[64] raising an interesting correlate with the preference of AAV for slow myofibers. The integrin $\alpha_v\beta_5$ and fibroblast growth factor receptor 1 are coreceptors for AAV2.[65,66]

Typical AAV gene transfer vectors have been derived from AAV2. The ITRs are retained but the rest (96%) of the viral genome has been removed, including the *rep* gene. As a result, AAV vectors currently in general use are unable to integrate into the host chromosome in a site-specific manner, and persistence as integrated sequences appears to be a low-frequency event, if it occurs at all. Efforts to quantify *in vivo* integration in skeletal muscle and liver suggest that at least 99.5% (skeletal muscle) or at least 90% (liver) of persisting AAV vector DNA was episomal, present in large concatemers.[67,68]

The AAV expression cassette is approximately 5 kb, too small to accommodate the whole factor VIII cDNA but large enough to accommodate the factor IX cDNA. Several groups have separately packaged factor VIII light and heavy chain sequences under the control of minimal transcriptional regulatory elements into AAV vectors and demonstrated expression *in vivo* after coinfection.[69–72]

AAV are not associated with any known disease and are not pathogenic.[73] On the basis of this nonpathogenicity, the toxicity associated with AAV has been expected to be low. In preclinical studies, AAV has been well tolerated with no effects on hematopoiesis, liver function, or other organs. Reports of late tumors in mice treated with AAV vectors[74] have not been confirmed and the chromosomal breaks that have been observed in cells following AAV integration[75] are of uncertain significance, especially because integration by AAV vectors lacking the *rep* gene is infrequent. However, in liver-directed human trials for hemophilia B, transient liver enzyme abnormalities have been reported and were associated with loss of transgene expression.[76]

Recent advances in AAV technology include the production of self-complementing (sc) forms of the vector that overcome the rate-limiting complementary-strand DNA synthesis step that is the primary barrier to transduction *in vivo* and lead to faster onset of protein expression and higher transduction efficiency.[77,78] This is accomplished through deletion of the terminal resolution site from one of the AAV terminal repeats (TRs) thereby enabling, after entry into the cell and uncoating, intramolecular base pairing of the viral DNA within the mutant TR that then proceeds to formation of a double-stranded molecule. The disadvantage of scAAV is the reduced insert size. A second advance has been the continued evolution of the identification of naturally occurring AAV serotypes and the idea of cross-packaging vector genomes from one AAV serotype into the capsid proteins of other AAV serotypes, generating "pseudotyped" vectors. This pseudotyping permits novel targeting strategies and can be used to reduce immune neutralization of vector.[79,80,81]

Plasmid Vectors

Nonviral approaches for delivering therapeutic genes as naked plasmid DNA are attractive because plasmid DNA is relatively simple and inexpensive to produce, does not engender cell-mediated immune responses, and does not result in humoral immune responses against the DNA vehicle that would limit the opportunity for repeated delivery. Until recently, most plasmid DNA applications have resulted in short-lived (days to weeks) transgene expression. Recent attempts to use electrical[82] or hydrodynamic[83] approaches to augment target cell uptake of plasmid DNA have resulted in expression of clotting factors lasting months after delivery. By rapidly treating mice through the tail vein with factor VIII expression sequences under the control of transcriptional regulatory elements optimized for liver expression, in large fluid volumes, supraphysiologic factor VIII levels were obtained.[83] Immune responses that are species independent have been reported.[84] Despite the attractive features of

nonviral approaches, current technical limitations reduce the likelihood of human use in the near future.

Spliceosome-Mediated Pre-mRNA Transsplicing

A specific repair mechanism that may be especially applicable to the common inversion mutations that cause approximately 30% of hemophilia A is an approach termed *spliceosome-mediated mRNA transsplicing*.[85] This method is used to repair messenger RNA, rather than DNA. In the final steps of transcription, introns are removed and exons are spliced together to form mature, functional mRNA. The site of splicing is directed by 30 to 40 nucleotides at each end of the intron that form consensus binding sites for the spliceosome, a large ribonucleoprotein complex composed of small nuclear ribonucleoprotein particles that catalyze the splicing reaction. Spliceosome-mediated pre-mRNA transsplicing takes advantage of this normal cellular process to effect RNA repair. The method involves synthesis of a pretranssplicing molecule (PTM) that contains the corrected mRNA fused to a 30 to 40 nucleotide sequence that targets a specific pre-mRNA. The PTM binds to the pre-mRNA, allowing specific transsplicing of the corrected mRNA through normal mechanisms.

Chao et al.[86] used a transsplicing approach to correct the hemophilic defect in factor VIII knockout mice. The repair PTM consisted of a 125-nucleotide binding domain that was complementary to intron 15 of the gene, a spacer sequence, and a strong 3′ splice acceptor site, linked to exons 16 to 26 for the mouse factor VIII cDNA. Correctly transspliced factor VIII was detectable genetically and functionally in the treated mice, with up to 17% factor VIII activity observed. It was estimated that conservatively between 1.6% and 6.3% of mutant transcripts were being repaired.

Enhanced Translational "Read Through"

In prokaryotes and eukaryotes, aminoglycoside antibiotics cause ribosomes to read through stop codons during translation.[87,88] As a result, these antibiotics can suppress nonsense genotypes, increasing expression of the full-length protein and partially restoring the normal phenotype. In tissue culture cells, restoration of gene expression to as much as 20% of wild-type levels has been observed after aminoglycoside treatment.[87] Clinical trials of gentamicin in cystic fibrosis showed that translational "read through" could be obtained in patients who were both homozygous and heterozygous for stop mutations with a reduction in basal potential difference in nasal mucosa and an increase in response to chloride-free isoproterenol solution.[89] Approximately 9% of hemophilia A and hemophilia B mutations are nonsense mutations that might respond to aminoglycoside treatment. Several small preliminary studies have examined the responses to aminoglycoside antibiotics in patients with hemophilia A and B and nonsense mutations with inconsistent results.[90,91,†]

Gene Editing

Cells possess normal DNA repair mechanisms that edit or correct mistakes that can occur during DNA replication. Li et al.[92] took advantage of this gene editing process to correct factor IX expression in a murine hemophilia model. A site-directed zinc finger nuclease that induced double-stranded DNA breaks at a targeted region of the *F9* gene together with a promoterless wild-type cDNA cassette containing *F9* exons 2 to 8 as a corrective donor template were codelivered to liver with an appropriately designed AAV8 vector. With this approach, they were able to achieve partial correction of the gene defect, with expression of up to 6% to 7% functional levels of factor IX for an extended time. Although the levels achieved were only a fraction of what has been achieved in mice with more traditional gene transfer approaches, the study demonstrated the ability to use a targeted gene editing approach to correct gene defects. The potential advantage of this approach is the ability to correct multiple defects, from small deletions to point mutations, over a large segment of the *F8* or *F9* gene using a single system. The key to successful gene editing will be the ability to improve the targeting efficiency, which was only 1% to 3% in the study.

Induced Pluripotent Stem Cell Approach

A number of laboratories have explored the use of induced pluripotent stem (iPS) cells to effect gene transfer. The general idea is to take an accessible tissue, skin being most accessible, extract fibroblasts or keratinocytes from the skin and grow them in tissue culture. The differentiated fibroblasts are reprogrammed to a pluripotent state by the simultaneous expression of four transcription factors: Oct3/4 and Sox2 plus either Nanog and LIN28 or KLF4 and c-Myc.[93–95] The normal *F8* or *F9* gene is then inserted *in vitro* into the iPS cells by homologous recombination, the cells expressing the transgene selected, differentiation initiated under growth factor guidance, and the cells then inserted into the patient. The obvious advantage of this approach is the transplanted cells are immunologically identical with the host, so immune responses other than to the transgene should be nonexistent. Another advantage is that the site of gene insertion in the transduced iPS cells can be determined and cells with insertions in tumor suppressor genes can be eliminated. The highest expressing cells can also be selected for transplantation. Several labs have explored this approach in preclinical models.[96,97] Factor levels of 8% to 12% were observed for out to 3 months.

Codon Optimization

Codon optimization through protein sequence-conserving changes in the DNA codons has evolved as a method to improve the efficiency of gene expression.[98–101] Practically, there are several ways to achieve this, including increasing the guanine-cytosine content (GC content) of the transgene, which increases mRNA stability, removal of cryptic splice sites, removal of RNA instability elements, and utilizing the most frequently used codons for a given amino acid, which typically have high concentrations of tRNAs and therefore have the fastest rates of and most accurate translation. For example, CTC is the most frequently used codon for leucine in man, and human cells generally have developed higher concentrations of tRNA for this codon than for less frequently used codons for leucine. The higher concentrations of tRNA for CTC results in more efficient translation. Doing this for the whole transgene improves gene expression. Current gene therapy trials in hemophilia use codon-optimized *F9* and *F8*.

Phase I Gene Transfer Trials in Hemophilia A and B‡

Before gene transfer trials can be carried out in humans, clinical grade vectors—viral, plasmid, or naked DNA—must undergo rigorous testing. Vectors driving expression of factor VIII or factor IX are first tested in tissue culture systems, then in small animal models, usually mice, in large animal models, usually dogs or monkeys, and in factor VIII– or factor IX–deficient models, usually knockout mice and/or hemophilic dogs. These studies test the safety and efficacy of the vectors. Current U.S. National Institutes of Health (NIH), U.S. Food and Drug Administration (FDA), and the European Agency for the Evaluation of Medicinal Products (EMEA) regulations for gene transfer trials are available at http://www4.od.nih.gov/oba/rac/guidelines/guidance.html, at http://www.fda.gov/cber/genetherapy/gtpubs.htm under guidance, and at http://www.emea.eu.int/index/indexh1.htm, respectively. Safety must be rigorously demonstrated before initiating human trials.

Clinical trials have been performed in hemophilia A and B (see Table 79.2).[102,103–107]

Chinese Trial in Hemophilia B

The initial clinical trial in hemophilia was undertaken at Fudan University in China in 1991.[102] This was a phase I trial in hemophilia B using *ex vivo* retrovirus-mediated gene transfer in autologous skin fibroblasts.[108] Two vectors were used: XL-IX, a MoMLV -based vector containing human factor IX cDNA under control of the retroviral LTR, and N2CMV-IX, a Moloney-based vector containing human factor IX cDNA under control of the cytomegalovirus (CMV) promoter.

Two brothers with moderately severe hemophilia B, ages 9 and 13, were studied. Baseline factor IX activity and antigen levels were 2%. Skin fibroblasts obtained by biopsy and maintained in culture were transduced with XL-IX or N2CMV-IX. Following demonstration of *in vitro* synthesis of factor IX, the resulting HBSF-IX cells were injected subcutaneously into multiple sites in the wall of the abdomen and the back at approximately monthly intervals. A total of 6.6 to 11 $\times$ 10^8 cells were injected. No treatment-related side effects were observed. An increase in factor IX was observed in both subjects, as early as 15 to 20 days after the first set of injections. Although the pretreatment variation in factor IX levels was not reported, plasma factor IX antigen and activity following treatment was increased to more than twofold in both subjects and was reported to persist for more than 420 days. There was also a reduced tendency to bleed. One subject received an additional set of injections of HBSF-IX cells at 16 months after factor IX levels had diminished and demonstrated another increase in factor IX levels in response to the injections.

Transkaryotic Therapy (TKT) Inc. Trial in Hemophilia A

In overall design, this trial employed an *ex vivo* approach,[109] similar to that employed in the initial Chinese trial in hemophilia B, except that the TKT trial used a nonviral, plasmid vector rather than a viral vector and the target disorder was hemophilia A rather than hemophilia B. The plasmid used for the TKT trial contained the cDNA for the B-domain-deleted form of human factor VIII under control of the CMV promoter.

A total of 12 subjects, ranging in age from 19 to 71 years, were studied, 9 in a dose-escalation trial, and 3 in a comparison of sites of intraperitoneal injection. Seven of the twelve were HIV-seropositive without AIDS and all were hepatitis C virus (HCV)-seropositive with stable liver function. Dermal fibroblasts obtained from the subjects by excisional skin biopsy were electroporated with the plasmid containing the B-domain-deleted human factor VIII cDNA. Fibroblasts expressing the factor VIII gene were clonally expanded, characterized for the stability of the integrated gene sequences and production of factor VIII, and administered by laparoscopic intraperitoneal injection, either into the fat of the greater omentum, or into the fibrofatty tissue that bound the lesser omentum. Laparoscopy was performed under general anesthesia. A total of 100, 400, or 800 million autologous clonal cells were injected in three cohorts of three subjects per cohort. Follow-up was up to 24 months. There were no serious adverse events related to the study material, the skin biopsy, or the intraperitoneal injection. No inhibitors to factor VIII were reported. Seven of the twelve subjects demonstrated a decreased bleeding frequency and/or factor VIII use following cell transfer, with low levels of factor VIII detected transiently in plasma, up to 1% to 2% of normal, with a maximum of 4%. Injection of cells into the lesser omentum appeared to be less effective than injection into the greater omentum. The first six subjects in this study were reported by Roth et al.[103]

Chiron Trial in Hemophilia A

The Chiron study was designed as a phase I, open-label, multi-institution, single-dose, dose-escalation trial in volunteers with severe hemophilia A using a replication-deficient MoMLV-derived vector to deliver B-domain-deleted human factor VIII cDNA (hFVIII[V]). The vector was complement-resistant and employed a human packaging cell line system with reduced homology between the retroviral vector and the packaging components, thereby allowing production of high-titer virus production without the generation of replication-competent retrovirus (RCR).[110] Expression of the B-domain-deleted factor VIII was driven by the retroviral LTRs.

The study was undertaken in subjects over the age of 18 with severe hemophilia A and no inhibitor.[104] Subjects could be HIV seropositive or seronegative, but were required to have stable CD4 counts over 400 per mm^3 and were excluded if taking RT inhibitors because of their effect of the (hFVIII[V]) on RT. Five doses, 2.2 $\times$ 10^7, 9.2 $\times$ 10^7, 2.2 $\times$ 10^8, 4.4 $\times$ 10^8, and 8.8 $\times$ 10^8 transduction units per kg, were administered in divided daily doses by peripheral vein injection. A total of 13 subjects were enrolled, three at each of the first four doses and one at the highest dose. The infusion of (hFVIII[V]) was well tolerated, with no serious adverse events. There was no acceleration of chronic HIV or HCV disease and all tests for RCR were negative. No factor VIII inhibitor activity was detected in any subject. Although no subject had sustained levels >1%, six patients showed factor VIII levels of more than 1% on at least two occasions, 5 or more days after infusion of exogenous factor VIII. Most elevated levels were in the range of 1.0% to 1.8%, although isolated levels of 2.3%, 3.0%, 4.3%, and 6.2% were reported for three subjects. Elevated levels of factor VIII were detected as early as 8 days following treatment. Peripheral

‡Sections of text on gene transfer vectors and phase I gene transfer trials in hemophilia A and B have also been used by G. C. White in first edition of the *Textbook of Hemophilia*, eds. Lee, C., Berntorp, E. and Hoots, W. K., Blackwell Publishing, Oxford, UK.

Table 79.2

Gene therapy for hemophilia clinical trial summary

	Subject	Age	Dose	Inhibitor	Semen PCR	Peak Factor[a]
Chinese study[102]—hemophilia B *ex vivo* transduction	1	9	11×10^8 cells	No	Unk	5.92%
	2	13	6.6×10^8 cells	No	Unk	4.13%
TKT study[103]—hemophilia A *ex vivo* transfection	1	Unk	1×10^8 cells	No	Neg	<0.8%
	2	Unk	1×10^8 cells	No	Neg	<0.8%
	3	Unk	1×10^8 cells	No	Neg	2.0%
	4	Unk	4×10^8 cells	No	Neg	<0.8%
	5	Unk	4×10^8 cells	No	Neg	1.0%
	6	Unk	4×10^8 cells	No	Neg	4.0%
	7	Unk	4×10^8 cells	No	Neg	<0.8%
	8	Unk	4×10^8 cells	No	Neg	<0.8%
	9	Unk	4×10^8 cells	No	Neg	<0.8%
	10	Unk	8×10^8 cells	No	Neg	<0.8%
	11	Unk	8×10^8 cells	No	Neg	1.1%
	12	Unk	8×10^8 cells	No	Neg	1.0%
Chiron study[104]—hemophilia A retrovirus	2–1	50	2.8×10^7 TU/kg	No	Neg	1.8%
	5–1	33	2.8×10^7 TU/kg	No	Neg	6.6%
	5–2	30	2.8×10^7 TU/kg	No	Neg	3.0%
	3–1	51	9.2×10^7 TU/kg	No	Neg	1.7%
	3–2	55	9.2×10^7 TU/kg	No	Neg	1.3%
	5–3	50	9.2×10^7 TU/kg	No	Neg	6.2%
	2–2	20	2.2×10^8 TU/kg	No	Neg	1.1%
	3–3	43	2.2×10^8 TU/kg	No	Neg	<0.1%
	5–4	18	2.2×10^8 TU/kg	No	Neg	2.6%
	1–1	52	4.4×10^8 TU/kg	No	Pos	<0.1%
	5–5	48	4.4×10^8 TU/kg	No	Neg	1.4%
	5–6	18	4.4×10^8 TU/kg	No	Neg	4.4%
	5–7	20	8.8×10^8 TU/kg	No	Neg	2.1%
Avigen study[105]—hemophilia B muscle-directed AAV	1	38	2×10^{11} vg/kg	No	Neg	3.7%
	2	23	2×10^{11} vg/kg	No	Neg	0.8%
	3	67	2×10^{11} vg/kg	No	Neg	<0.3%
	4	29	6×10^{11} vg/kg	No	Neg	<0.1%
	5	44	6×10^{11} vg/kg	No	Neg	<0.1%
	6	43	6×10^{11} vg/kg	No	Neg	1%
	7	38	1.8×10^{12} vg/kg	No	Neg	<0.1%
	8	30	1.8×10^{12} vg/kg	No	Neg	<0.1%
Genstar study—hemophilia A "gutless" Ad	1	23	4.3×10^{10} vg/kg	No	Unk	N/A
Avigen study[106]—hemophilia B liver-directed AAV	1	63	2×10^{11} vg/kg	No	Pos	<0.1%
	2	49	2×10^{11} vg/kg	No	Pos	<0.1%
	3	20	1×10^{12} vg/kg	No	Unk	<0.1%
	4	22	1×10^{12} vg/kg	No	Unk	<0.1%
	5	31	5×10^{12} vg/kg	No	Unk	11.8%
	6	28	5×10^{12} vg/kg	No	Unk	3%
	7	20	1×10^{12} vg/kg	No	Unk	<0.1%
St Jude's study[107]—hemophilia B liver-directed AAV	1	63	2×10^{11} vg/kg	No	Pos	<0.1%
	2	49	2×10^{11} vg/kg	No	Pos	<0.1%

	4	22	1×10^{12} vg/kg	No	Unk	<0.1%
	5	31	5×10^{12} vg/kg	No	Unk	11.8%
	6	28	5×10^{12} vg/kg	No	Unk	3%

PCR, polymerase chain reaction; AAV, adeno-associated virus; TU, transduction units; vg, vector genomes; Unk, unknown.
[a]Peak factor levels. In the Chiron study, this was defined as the highest level observed in those individuals who demonstrated levels >1% on at least two occasions, 5 or more days after infusion of exogenous factor.

blood mononuclear cells demonstrated the presence of vector gene sequences by polymerase chain reaction (PCR) testing to 6 months in all 10 subjects tested and to 1 year in three of four subjects tested, indicating long-term persistence of vector sequences even at the lowest dose. Pharmacokinetic examination following the infusion of exogenous factor VIII 13 weeks after vector infusion showed a statistically increased half-life (T1/2) and area under the curve compared to prestudy values. Bleeding frequency was decreased in six subjects compared to historical rates. A single, transient, low-level positive signal was detected in a single semen sample from one subject at week 9; no other unusual events or complications were observed.

Avigen Trial in Hemophilia B

The Avigen trial was a prospective, multi-institution, single-dose, dose-escalation, phase I trial to examine the safety of an adeno-associated virus vector to deliver human factor IX to skeletal muscle in subjects with severe hemophilia B.[105,111] Coagulin-B, the recombinant AAV produced by Avigen, which was used in the study, was derived from serotype AAV-2.

A total of seven subjects were enrolled in the trial, three at 2×10^{11}, three at 5×10^{11}, and one at 2×10^{12} vg/kg. Vector was administered under general anesthesia through ultrasound-guided injections in the *vastus lateralis* muscle of the leg. The number of injections ranged from 10 to 72, depending on the dose administered. Muscle biopsies performed 8 to 12 weeks after vector administration showed immunohistochemical evidence for factor IX in the extracellular space in a pattern similar to that observed in preclinical studies. There was no muscle injury or inflammation. Although subjects had detectable pretreatment titers of neutralizing antibodies against AAV that were as high as 1:1,000, gene transfer and expression was demonstrated in each subject by Southern blot on DNA extracted from muscle and by RT-PCR. No antibodies against factor IX were detected. There were no detectable vector sequences in semen at any time. Increased plasma levels of factor IX were observed on multiple occasions beginning approximately 8 weeks after vector administration in one subject with cross-reacting material positive severe hemophilia B receiving 2×10^{11} vg/kg. The highest level was 1.6% at week 10 and increased levels were detected up to at least 22 weeks. A second subject had levels up to 0.8%. Both subjects had reduced requirement for replacement factor.

Genstar Trial in Hemophilia A

The aim of the Genstar trial was to examine the safety of MaxAdFVIII, a "gutless" Ad vector derived from Ad5.[112] The vector was devoid of all viral genes except essential cis-elements and carried a 27-kb expression cassette that contained the full-length factor VIII cDNA under the control of the human 12.5-kb albumin promoter.

The Genstar trial was designed as a phase I, multi-institutional, single-dose, dose-escalation study in subjects with severe hemophilia A with normal liver function. One subject was enrolled in the trial. Infusion of MaxAdFVIII in that subject was associated with high fevers at the time of injection. There was an approximately 50% decrease in platelet count, starting posttreatment day 1 with a return to normal by day 7, and a 10-fold increase in alanine aminotransferase starting on posttreatment day 2 and returning to normal by approximately day 20. The reduction in platelet count and increase in liver enzymes constituted serious adverse events and the trial was placed on hold by the FDA and eventually discontinued.

Avigen Liver-Directed Trial in Hemophilia B

The AAV2 vector used in the second, liver-directed Avigen trial was similar to that used in the initial muscle trial but contained the α_1-antitrypsin promoter and apolipoprotein E-enhancer/hepatic control locus region to drive liver-specific factor IX expression.

The trial was a phase I, single-dose, dose-escalation study to examine the safety of liver-directed AAV-AAT-FIX in severe hemophilia B.[106] A total of seven subjects were enrolled, ranging in age from 20 to 63 years. Three cohorts of two patients each received doses of 2×10^{11}, 1×10^{12}, or 5×10^{12} vg/kg by injection directly into the liver via cannulation of the hepatic artery. The liver-directed injections were well tolerated. Two subjects at the highest dose achieved significant increases in factor IX level, one to 11.8% and the second to 3%. However, expression in both subjects was transient and the loss of expression was accompanied in the subject with the highest expression level by significant liver enzyme abnormalities starting approximately 3 weeks after vector administration.[81,106] A third subject treated with 1×10^{12} vg/kg also developed transient asymptomatic transaminitis. T-cell immune responses to two conserved AAV-2 capsid peptides were identified in this subject. Because of the grade 3 liver toxicity and the lack of persistent effect, the trial was discontinued.

No inhibitors to factor IX were detected. The first two subjects developed PCR-positive signals in sperm. Both subjects cleared vector signal over time and all subsequent subjects were advised to use contraception until the semen was negative.

St. Jude AAV Trial in Hemophilia B

A third AAV trial sponsored by St. Jude's Children Hospital utilized a pseudotyped, scAAV8-based vector containing codon-optimized FIX under control of a liver-specific LP1 promoter (scAAV8-LP1-FIXco).[107] Vector was administered by peripheral vein injection.

A total of six patients with severe hemophilia B have been treated in three dose cohorts. AAV-mediated gene expression was observed in all six subjects, with FIX levels of 2% to 11%. Two subjects in the high dose cohort developed asymptomatic elevation of liver enzymes, one associated with AAV8 capsid protein positive T cells. Treatment with steroids resulted in normalization of liver function and maintenance of FIX expression levels. No inhibitors have been detected.

NEW APPROACHES TO THE SYNTHESIS OF COAGULATION FACTOR CONCENTRATES

Despite intense interest in gene transfer approaches, coagulation factor concentrates continue to be the mainstay of treatment in hemophilia and other bleeding disorders. In the developed world, approximately 85% of patients with hemophilia are treated with recombinant concentrates, either factor VIII, factor IX, or factor VIIa. The commercial synthesis of these factors has not changed substantially since the initial products were introduced in 1990, although the promise of recombinant technology has always been the ability to use it to make better products. With increasing knowledge of the three-dimensional structure of coagulation proteins and better correlates between structure and the function of these molecules, it becomes more feasible to use recombinant technology to make proteins that have improved function. Some of the current directions in developing improved coagulation factor proteins are described here.

Current recombinant clotting factor concentrates are synthesized in well-characterized mammalian cells such as Chinese hamster ovary and baby hamster kidney cells. The proteins synthesized in these cells are fully active and are identical with purified plasma-derived proteins in their ability to participate in blood coagulation. There are six wild-type polymorphic forms of factor VIII (H1-H6), but only two, H1 and H2, are produced recombinantly for clinical use (Recombinate and Advate from Baxter are H1; Kogenate and Kogenate FS from Bayer are H2).[113] There are minor differences between recombinant and plasma proteins that are due in part to differences in the posttranslational modifications that take place in tissue culture cells compared to human cells. All three plasma proteins contain complex *N*- and *O*-linked carbohydrates. In the recombinant proteins, the carbohydrates are attached normally, but the complex structure of the *N*-linked carbohydrates in the recombinant proteins differs from that in the native molecules. Although the carbohydrate changes do not appear to affect the function of the recombinant molecules, it is possible that other unknown functions may be affected. Plasma factor VIII contains six sulfated tyrosine residues at positions 346, 718, 719, 723, 1,664, and 1,680[114] and these appear to be present and fully modified in recombinant factor VIII. Plasma factors IX and VIIa each contain 12 γ-carboxylated glutamic acid (Gla) residues in the amino-terminal portion of the molecule that are important for binding of the proteins to phospholipid surfaces and therefore for the coagulant activity of the proteins. Recombinant factor IX is less than fully γ-carboxylated, with approximately 60% of the recombinant molecules containing 12 Gla residues, 35% containing 11 Gla residues, and 5% containing 10 Gla residues.[115,116] The less than fully modified proteins demonstrated a specific clotting activity that was indistinguishable from the fully modified form. Plasma factor IX contains a single β-hydroxylated aspartic acid residue, which appears to be comparably modified in recombinant and plasma factor IX. In addition, factor IX contains a sulfated tyrosine at amino acid 155 and a phosphorylated serine at amino acid 158 in the activation domain that appear to be important for the distribution of the protein in the circulation. In plasma factor IX, these two residues are fully modified. In recombinant factor IX, Ser158 is not phosphorylated, and Tyr158 is only 15% sulfated.

Synthesis of Properly Modified Proteins

One major area for improvement in the production of recombinant clotting factor proteins is better control of the posttranslational modification of proteins to more closely approximate plasma proteins. For example, the recent identification of the genes for vitamin K carboxylase and vitamin K epoxidase /reductase[117–119] potentially permit better control of the carboxylation process during the tissue culture synthesis of the vitamin K-dependent proteins. More importantly, full sulfation of Tyr155 and phosphorylation of Ser158 in the activation domain of factor IX would be expected to improve the recovery of factor IX and have a beneficial effect in the treatment of hemophilia B. Because changes in the conditions of synthesis or structure of recombinant coagulation factors require extensive preclinical and clinical testing to compare the new product with the old before the changes can be approved by the FDA, the cost of modification can be very high. As a result, the improvement in molecular function must be considerable to make the cost worthwhile.

Active forms of factors VIII and IX have been synthesized in transgenic livestock.[120–123] Velander et al. showed that the factor VIII and IX produced in mammary epithelium is catalytically active and can be easily purified from endogenous milk proteins. Expressed under control of the whey acidic protein or β-lactoglobulin promoter, factor VIII or IX concentration in bovine or porcine milk is over 10-fold to 200-fold higher than in plasma.[121] The porcine mammary gland has been shown to carry out the posttranslational processing necessary for full biologic activity and normal half-life in the human circulation. The advantage of the transgenic approach in milk is the large volume of protein that can be produced and the ease of purification because of the small number of admixed endogenous proteins. In addition, it has been suggested that the large amount of protein that can be produced from transgenic animals makes alternative delivery methods, including oral methods, feasible.

Super-Molecules

One of the promises of recombinant technology is the ability to make proteins that have enhanced functions. In the case of coagulation factors, this might be increased coagulant activity, or an increased half-life in the circulation, or reduced immunogenicity. As the structure and function of clotting factors become better defined, it may be possible to synthesize coagulation factor molecules that are actually better than the native proteins. Early attempts to make such molecules are underway.

Coagulation Factors with Improved Coagulant Function

Proteins with increased coagulation factor activity have been achieved by a number of laboratories. In some cases, this has been accomplished by an actual improvement in the catalytic efficiency of the molecule. For example, the catalytic efficiency of factor IX was increased by the replacement of selected sequences in the catalytic domain of factor IX with the corresponding sequences from factor X.[124] Substitution of selected sequences from the catalytic domain of factor X for the corresponding sequences in the catalytic domain of factor IX resulted in a 56-fold increase in the amidolytic activity of factor IX. There was no significant change in inhibition by *p*-aminobenzoic acid (PABA), an S1 pocket–directed reversible inhibitor of serine proteases, demonstrating that the integrity of the active site was unchanged. Further modifications, including alterations in the 99-loop, a structure unique to factor IX which is believed to shield the active site prior to assembly of the tenase complex, led to more impressive increases in the amidolytic activity of factor IX.[125] Building on these observations, Milanov et al. showed that a triple mutant factor IX (V181I/K265T/I383V—termed ITV) exhibited almost 16% the activity in factor VIII-deficient plasma that wild type factor IX exhibited in normal plasma.[126] In other words, the mutant ITV factor IX was able to by-pass the need for factor VIII. Chang et al.[127] showed that the apparent activity of factor IX could also be enhanced by replacing the epidermal growth factor (EGF)-1 domain of factor IX with the corresponding domain from factor VII. The increased factor IX activity was demonstrated both *in vitro* and in a canine model. The EGF-1 substitution increased the rate but not the extent of factor Xa generation, suggesting that the EGF-1 domain of factor VII was more efficient in promoting assembly of the tenase complex. Although the immunogenicity of the chimeric factor IX-VII molecule was not examined in the canine model, the

substitution of whole domains may preserve the tertiary structure of the domain but the altered protein might be immunogenic. Factor IX with increased activity occurs through a natural mutation, too,[128] an observation that may be of use in gene therapy.

Although factor VIII does not have intrinsic protease activity, the cofactor function of factor VIII in generating tenase activity can be similarly enhanced. Substitution of the factor VIII sequences that direct thrombin cleavage to a site between the A2 and A3 domains with sequences that direct thrombin cleavage of heparin cofactor II, increased factor VIII cofactor activity.[129] The increased factor VIII activity is believed to result from improved cleavage at a critical site in thrombin-induced activation of factor VIII.

Factors with Increased Survival

Another approach to generating improved forms of factor VIII has been to synthesize molecules that have prolonged activity in the circulation. Factor VIII circulates as an inactive procofactor that must be activated by thrombin to participate in the activation of factor X. Factor VIII is then rapidly inactivated by either spontaneous dissociation of the A1 and A2 domains or by further proteolytic cleavage by activated protein C. A critical event in the inactivation of factor VIII is the dissociation of the A2 domain from the light chain and A1 domain (see Chapter 12). The A2 domain exists in a metal-ion complex with the other domains and either falls apart spontaneously or during cleavage by activated protein C. By linking the A2 domain to the light chain, the activity of factor VIII can be considerably prolonged *in vitro*.[130,131] This inactivation-resistant factor VIII shows persistence for up to 40 minutes after activation, a marked increase compared with native factor VIII. The rapid inactivation of factor VIII activity under normal physiologic conditions suggests that there may be biologic advantages to limiting the presence of activated factor VIII in the circulation. Persistence of activated factor VIII might lead to more generalized generation of thrombin and an increased risk of thromboembolism. Modifications of factor VIII that increase its activity—either by decreasing the inactivation of activated factor VIII or by increasing the intrinsic catalytic activity of the protein—must be examined carefully in *in vivo* models before clinical trials proceed in humans.

Interfering with the interaction of factor VIII with receptors involved in the clearance of clotting factors from the circulation constitutes another method to prolong the survival of factor VIII in the circulation. The advantage of this approach is that one does not have to worry about the effect of increased circulation of an activated clotting factor. The low density lipoprotein-related protein (LRP) receptor, a hepatic protein that has been implicated in the clearance of low-density lipoproteins and other proteins from the circulation, has been shown to interact with and bind factor VIII through cysteine-rich low-density lipoprotein receptor class A repeats in the LRP extracellular domain.[132,133] Heparin sulfate proteoglycans may also participate in the clearance of factor VIII by LRP. Conditions that inhibit the interaction of factor VIII with LRP prolong the survival of factor VIII in hemophilic mice.[134] More general approaches to prolong clotting factor half-life include modification with polyethylene glycol (PEG). PEG has been used to prolong the half-life of a number of molecules, including interferon and erythropoietin. Preclinical studies and initial human trials with PEG-factors VIII, VIIa, and IX are currently underway.[135–139]

Another approach to prolong the half-life of clotting proteins is the creation of fusion proteins with long-lived plasma proteins such as immunoglobulin and albumin. Both of these proteins are cleared from the circulation by neonatal Fc receptors (FcRn) on endothelial cells that recirculate the proteins through an endocytic pathway.[140] Clinical trials of factor IX (rFIXFc–B-Long) and factor VIII (rFVIIIFc–A-Long) fused to an Fc molecule are currently underway (see www.clinicaltrials.gov[141,142]) and albumin-fused factor VIII, factor IX, and factor VIIa molecules are in various stages of development.[143–145]

Immunologically Altered Proteins

Inhibitors in hemophilia A are a common and serious complication that renders normal therapy with replacement factor VIII ineffective. Forms of factor VIII that evade or prevent an immune response would be advantageous for patients with inhibitors. One approach to generate antigenically altered factor VIII, based on the observation that porcine factor VIII is able to substitute for human factor VIII in coagulation but is poorly recognized by antibodies to the human protein, has been to engineer chimeras of human and porcine factor VIII.[146,147] The substitution of porcine sequences, either entire domains or selected sequences, into human factor VIII significantly reduced recognition of the molecule by inhibitor antibodies while preserving participation in thrombin generation *in vitro*. Nevertheless, although the porcine/human hybrids were not well recognized by established human inhibitor antibodies, it remains to be determined whether the hybrid molecules are immunogenic themselves. Porcine factor VIII is variably immunogenic in humans and the hybrid sequences might be capable of generating an immune response in some individuals. Despite this, the concept of engineering factor VIII genetically to reduce antigenicity would seem to be a viable approach as we learn more about inhibitor epitopes and the three-dimensional structure of factor VIII. The critical question with this approach is whether we can understand the antigenicity and immunogenicity of proteins well enough to engineer molecules that lack both.

Improved Synthesis of Coagulation Factors

Another area for improvement is in the efficiency of protein synthesis in mammalian cells (see Chapter 5 for general background). The endoplasmic reticulum (ER) is a major site for the folding and assembly of secretory proteins such as factor VIII and factor IX (FIGURE 79.1A).[148] Proteins destined for the cell surface are cotranslationally translocated into the lumen of the ER where the proteins undergo various posttranslational modifications and proper folding.[148,149] These reactions and the orderly movement of proteins through the ER and the Golgi apparatus are facilitated by enzymes and molecular chaperones present in the various compartments of the ER and Golgi. Two homologous protein chaperones that regulate transport of improperly folded glycoproteins through the ER are calnexin, a conserved integral ER membrane protein, and calreticulin, an ER lumenal protein. Calnexin and calreticulin associate transiently and selectively with newly synthesized glycoproteins in the early stages of folding and are thought to promote the interaction of misfolded proteins with disulfide isomerases that enhance proper folding.[150] The oxidizing environment of the ER facilitates the action of these disulfide isomerases to catalyze and monitor disulfide bond formation in an ordered manner.

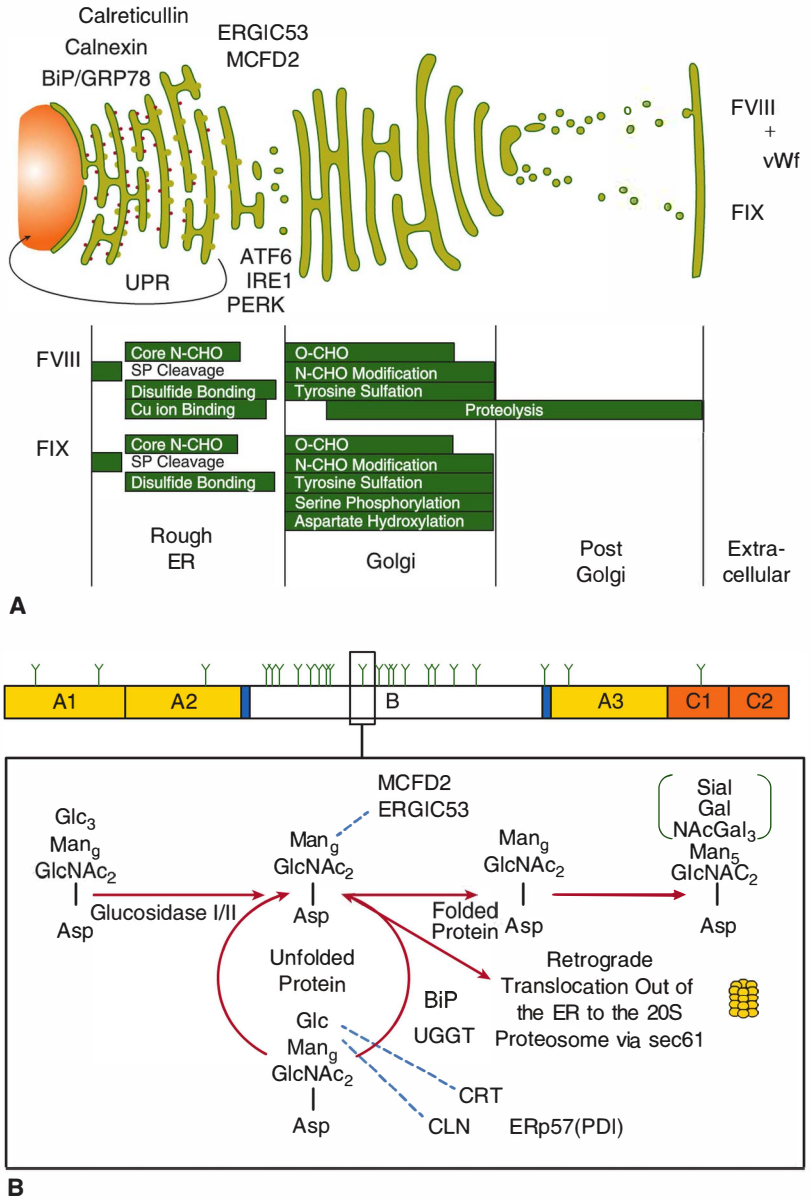

FIGURE 79.1 Cellular biosynthesis and assembly of factor VIII and IX. Secretory proteins like factors VIII and IX undergo complex intracellular processing. **Panel A:** Factors VII and IX are cotranslationally translocated into the lumen of the endoplasmic reticulum (ER) where they undergo various modifications and folding. After cleavage of the signal peptide, factor VIII and factor IX undergo specific posttranslational modifications. Copper atoms are bound to factor VIII in the rough ER. Protein folding begins and disulfide bonds are formed, providing stability to the tertiary structure of the protein. These changes are monitored by chaperone proteins, calnexin, calreticulin, and BiP/GRP78, which provide "quality control" to the folding process. The presence of unfolded protein in the ER leads to an integrated signaling response that transmits information from the ER to the nucleus to affect protein synthesis. ATF6, IRE 1, and PERK are ER transmembrane proteins that initiate transduction of the UPR. Also in the ER, *N*-linked carbohydrates are added to target asparagine residues, a process that is thought to be critical to the monitoring process by chaperone proteins. Once the protein is properly folded, it can bind to the ERGIC53/MCFD2 complex and transit to the Golgi apparatus. In the Golgi, the *N*-linked carbohydrates are modified, *O*-linked carbohydrates are added, and target tyrosine residues are sulfated. Like factor VIII, factor IX undergoes extensive posttranslational processing in the ER and Golgi, but the secretion of factor IX is more efficient than that of factor VIII and there does not appear to be the same critical monitoring of factor IX structure that occurs for factor VIII. In particular, the ERGIC53/MCFD2 complex is not involved in factor IX movement through the ER-Golgi. **Panel B:** The folding cycle for factor VIII. The *N*-linked carbohydrates in factor VIII play an important role in proper folding of the protein in the ER. Following the addition of carbohydrates, the terminal-glucose residues are sequentially removed by glucosidases. A UGGT in the ER senses improperly folded proteins by an unknown process and is activated by the unfolded protein to transfer glucose to the carbohydrate. Calnexin and calreticulin bind to the monoglucosylated protein, leading to an interaction with ERp57, a protein disulfide isomerase that stimulates disulfide bond formation. The protein undergoes another cycle of deglucosidation and, if still improperly folded, interaction with UGGT, monoglucosylation, binding to calnexin and calreticulin, and disulfide bond formation. Once properly folded, the factor VIII binds to the ERGIC53/MCFD2 complex to transit to the Golgi. Conversely, if the protein fails to fold properly, it is eventually translocated out of the ER through an ATP-dependent interaction with BiP. (Adapted from Kaufman RJ. Orchestrating the unfolded protein response in health and disease. *J Clin Invest* 2002;110:1389–1398.)

Prolonged association of calnexin or calreticulin is observed when proteins are misfolded or unable to oligomerize. The calnexin or calreticulin recognition motifs are at least partially determined by the structure of asparagine-linked oligosaccharides. Another resident ER protein, immunoglobulin-binding protein (BiP)/glucose-regulated protein (GRP78), uses energy from adenosine triphosphate (ATP) hydrolysis to promote folding and prevent aggregation of protein in the ER.[151] Feedback mechanisms exist in the ER that also promote proper folding. There is an unfolded protein response (UPR) that senses excess unfolded protein in the ER and generates signals to the nucleus to upregulate chaperone proteins such as calnexin, calreticulin, and BiP to increase proper folding.[148] Amino-terminal fragment (ATF)6, IRE1, and protein kinase-like ER kinase (PERK) are three proteins in the ER that signal to bZip transcription regulators in the nucleus to synthesize new chaperone proteins.

The synthesis of factor VIII has been studied intensely. At a molecular level, glucosylation controls factor VIII transit through the ER–Golgi (FIGURE 79.1B). In the ER, factor VIII undergoes *N*-linked glycosylation. After translocation into the lumen of the ER, a core unit of 14 saccharides (GlcNAc2Man9Glc3) is added to targeted Asp residues. The terminal-glucoses are trimmed, first by glucosidase I, which cleaves the first glucose, and then by glucosidase II, which cleaves the second and third glucoses. If the protein is properly folded, the deglucosylated protein is able to interact with the ER–Golgi intermediate compartment (ERGIC53)/multiple coagulation factor deficiency 2 (MCFD2) complex, probably through the terminal mannose groups on the proteins, and factor VIII is transferred through the intermediate compartment to the Golgi apparatus.[152] If the protein is not folded properly, it is recognized by a UDP-glucose:glycoprotein glucosyl-transferase (UGGT), which transfers a single glucose to the high mannose containing side chains. The activity of the UGGT to add this single glucose is stimulated by the unfolded protein although the sensing mechanism is uncertain. The monoglucosylated protein interacts with calnexin and calreticulin, which direct the interaction of factor VIII with ERp57, a protein disulfide isomerase that stimulates disulfide bond formation, leading to increased protein folding. The protein then undergoes another cycle of deglucosylation by glucosidase I/II, interaction with UGGT, interaction with calnexin and calreticulin, and disulfide bond formation. Once the protein is properly folded, it is no longer recognized by UGGT and is not glucosylated. The high mannose protein is then able to interact with ERGIC53, a mannose-binding cargo protein in the intermediate compartment that transfers the protein to the Golgi apparatus. The interaction with ERGIC53 is facilitated by MCFD2, a calcium BiP that forms a complex with ERGIC53.[153] In the Golgi, the mannose groups are trimmed to a core of GlcNAc2Man5, knocking off ERGIC53, which recycles to the ER to transport more protein to the Golgi. If, despite maximal folding, the protein remains misfolded, it is removed from the ER. This degradative pathway is through a transport protein called sec 61 to the 20S proteasome and is facilitated by BiP.

The synthesis of factor VIII, in particular, is inefficient compared with factor IX, factor VII, or even factor V, which is highly homologous with factor VIII. Studies by Kaufman, Pipe et al.[149] have shown some of the reasons for the inefficient production of factor VIII. First, factor VIII secretion from cells is affected by its interaction with the chaperone protein BiP/GRP78 and subsequent ATP-dependent release. The requirement of ATP hydrolysis by BiP/GRP78 is unique for factor VIII and is not required for release of factor V. Binding of factor VIII to BiP/GRP78 occurs through Phe309 in the A1 domain and mutation of this residue results in improved factor VIII secretion efficiency.[154] Interestingly, Phe309 is adjacent to Cys310, which is a site of copper binding in factor VIII (see Chapter 12). It has been suggested that binding of copper to factor VIII stabilizes the factor VIII structure and BiP/GRP78 may monitor this stability. Second, the B-domain of factor VIII is important for efficient secretion. The B-domain-deleted form of factor VIII is 10 times less efficiently secreted than full-length factor VIII. The important sequences in the B-domain for this are the amino-terminal 226 amino acids of the B-domain, which contain six asparagine-linked glycosylation sites. Mutation of these asparagines residues to glutamine reduces the efficiency of factor VIII secretion, perhaps by reducing the interaction of factor VIII with ERGIC53/MCFD2.[155]

The increased understanding of the transport of secretory proteins like factor VIII through the ER and Golgi will have its greatest application in the synthesis of recombinant proteins for clinical use, not as a method for treatment of hemophiliacs, although methods of increasing protein production in mild hemophilia might be useful. In the manufacture of recombinant clotting factor proteins, any enhancement in the amount of protein synthesized per cell would reduce the cost of production and result in cheaper products for patients, allowing more frequent treatment and prevention of bleeding.

SUMMARY

The treatment of hemophilia and other bleeding disorders is on the threshold of a new era. Clinical trials of gene transfer approaches have been started and although continued advances in the field promise to impact hemophilia in the future. Current understanding of the structure and function of factors VIII, IX, VII, and other clotting factors also promise to lead to the development of new and better proteins. We are at a point in time where we can truly consider the possibility of making proteins that are potentially better than those that exist in nature. However, the pursuit of making such molecules must be done carefully, and with circumspection.

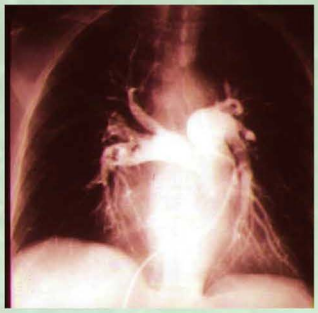
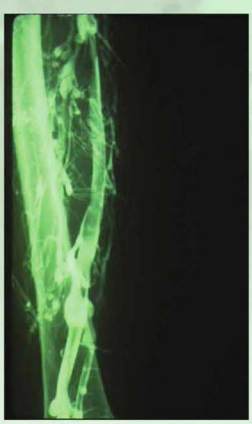
PART IV





THROMBOTIC DISORDERS

CHAPTER 80

Overview of Venous Thromboembolism

SAM SCHULMAN, VICTOR J. MARDER, AND GILBERT C. WHITE, II

HISTORICAL BACKGROUND

Thrombosis as a clinical condition was probably described almost 5,000 years ago, when the Chinese emperor Huang Ti wrote of a likely arterial event, "when it coagulates within the pulse the blood ceases to circulate beneficially; when the blood coagulates within the foot it causes pains and chills."[1] The Greek physician Claudius Galen (131 to 201 AD) coined the term "thrombosis," which means curdling, but the first thorough analysis of the pathogenesis of thrombosis was described by the German pathologist Rudolf Virchow (1821 to 1902).[2] He concluded that "consequences" (rather than causes) "of the obstruction could be grouped into three categories," (a) irritation of the vessel and its surroundings, (b) blood coagulation, and (c) interruption of the blood stream,[2] the combination of which was later named Virchow's triad.

RISK FACTORS FOR VENOUS THROMBOEMBOLISM

Research during the past 3 to 4 decades has identified abnormalities that are etiologic factors for venous thromboembolism (VTE).[3] These abnormalities can be categorized as hereditary or acquired, or, alternatively, as increased coagulation factor activity (factor V Leiden, prothrombin G20210A mutation), decreased coagulation inhibitor levels (antithrombin, protein C, endothelial protein C receptor, protein S), or antiphospholipid antibody disruption of hemostasis. In addition, abnormalities of the fibrinolytic system and protective mutations of coagulation factors (e.g., factor XIII Val34Leu) may have roles in thrombosis. The hereditary thrombophilias (see Chapter 81) mainly contribute to VTE, but there is controversy as to their importance in arterial thrombosis.[4,5] On the contrary, the antiphospholipid syndrome is associated with both venous and arterial thromboembolism (see Chapter 101).

The need for investigation of thrombophilia in patients with VTE is controversial. Screening for thrombophilia in patients without previous VTE, but who are at increased risk (estrogens, pregnancy, major surgery), is hardly ever cost-effective.[6] Acquired risk factors can be temporary, chronic, or permanent. Temporary risks include surgery, immobilization, estrogen exposure, L-asparaginase treatment, long-haul travel, infection, heparin-induced thrombocytopenia, and indwelling catheters. Long-distance travel may or may not present a need for prophylactic therapy; for example, if deep-vein thrombosis (DVT) after an 8-hour car trip 1 month earlier is the only identifiable risk factor, one may be hesitant about the association and whether the thrombosis is provoked or unprovoked. Chronic or permanent risk factors include immobilization such as after spinal cord injury or stroke, inflammatory bowel disease, systemic lupus erythematosis, nephrotic syndrome, cancer, myeloproliferative disorders, and paroxysmal nocturnal hematuria (see FIGURE 80.1 for more information).

The reported incidence of VTE varies from 104 per 100,000 in a study of medical records in Worcester, Massachusetts,[7] to 387 per 100,000 in a cohort study in Sweden.[8] Differences relate to methodology for data capturing, selection of population, and diagnostic techniques. There is a definite need to establish trends accurately in order to show when implementation of preventive measures has had any impact and also to determine how changes of patient demographics (age, body weight) play out in the disease panorama (see Chapter 82).

DIAGNOSIS OF VENOUS THROMBOEMBOLISM

Clinical symptoms and signs of DVT or pulmonary embolism (PE) are not sufficient for diagnosis, but the combination of risk factors and select symptoms and signs is used in clinical prediction, for example, with the Wells score for DVT or PE[9,10] or the Geneva score for PE.[11] The revised Wells scores for DVT and PE allow one to utilize low, moderate, or high probability of VTE for assessing unlikely or likely outcomes.[12,13] Patients with unlikely or low probability of VTE can be assessed with a D-dimer test, which, if negative, allows for a highly negative predictive value for VTE. This strategy allows for a 50% reduction of expensive imaging for VTE diagnosis.

The "gold standard" of imaging of the leg veins using venography has been almost entirely abandoned in favor of noninvasive compression ultrasound. Similarly, computed tomography of the pulmonary arteries (chest CT) for imaging of PE is utilized more often than ventilation–perfusion lung scanning (see Chapter 83). In spite of progress in diagnostic approach, there are unresolved issues, for example, the extent of ultrasound examination, DVT recurrence, diagnosis of PE in pregnancy, and VTE assessment of suspected PE in hospitalized patients with elevated D-dimer levels. The PIOPED III study demonstrated that gadolinium-enhanced magnetic resonance angiography has a sensitivity of 78%, which is suboptimal, and many centers have a high proportion of technically inadequate images.[14] Conversely, multidetector chest CT may be too sensitive, identifying subsegmental filling defects of questionable clinical significance.

The assessment of the emergency room patient with possible VTE requires not only a correct diagnosis but also an assessment of risk. This is of particular importance for patients with PE, for whom there is no high-quality evidence for the safety of outpatient treatment. The Pulmonary Embolism Severity Score, based on identifying risk strata that allow prognostic accuracy,[15,16] describes 30% of patients with low risk who have

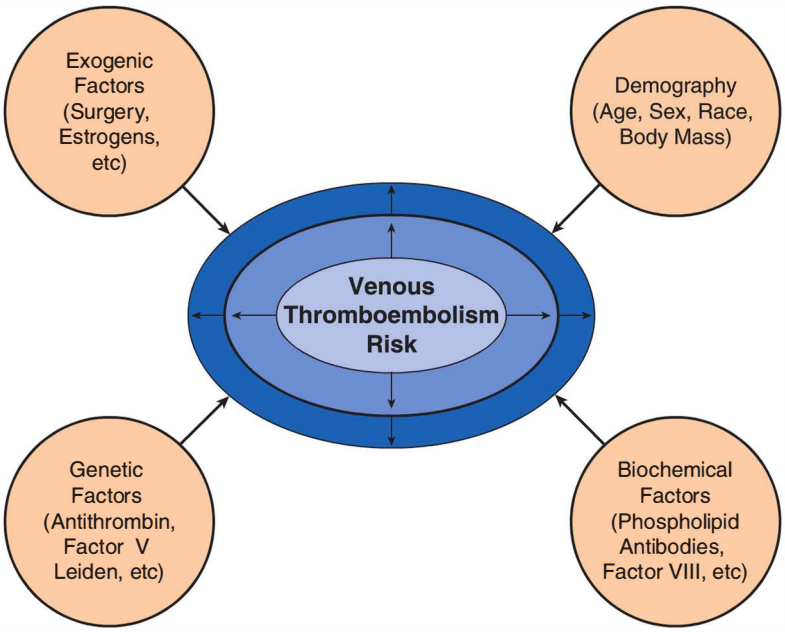


FIGURE 80.1 Risk factors for VTE.

a 30-day mortality of 1% and can be treated as outpatients. For the remaining 70% of patients, cardiac biomarkers (troponin, brain natriuretic peptide [BNP], pro-BNP, and heart-type fatty acid–binding proteins) combined with clinical score may be useful to identify additional patients for home treatment.

LOCATION OF VENOUS THROMBOEMBOLISM

Most DVT occurs in the lower extremity, and consequently almost all randomized controlled trials on management are based on this thrombus location. Upper extremity thrombosis of the brachial, axillary, and subclavian veins constitutes 4% to 10% of DVT,[17] and chronic sequelae with venous insufficiency are not uncommon (FIGURE 80.2). The basilic and cephalic veins are superficial, not deep veins.

Superficial phlebitis is mainly an inflammatory process secondary to chemical or mechanical irritants or in varicose veins with very slow blood flow. It is often complicated by a self-limited clot formation. It is difficult to find any data on the incidence of superficial (thrombo-) phlebitis, but in an Italian study of 15,000 patients seeking advice from their general practitioner for any medical condition, there was a history of this disorder in 10.8% of the women and 4.9% of the men.[18] It is unclear how patients should be selected for 4 to 6 weeks of treatment with low molecular weight heparin (LMWH) or fondaparinux versus short-term anti-inflammatory therapy.[19]

The most common acquired cause for upper extremity DVT is an indwelling catheter; thoracic outlet syndrome accounts for 30% of upper extremity DVT (2 events/100,000/year).

Cerebral vein or sinus thrombosis is diagnosed in two persons per million each year.[20] Patients can present with headache, papilledema with blindness, seizures, hemianopsia, aphasia, hemiparesis, or cognitive disorders, depending upon thrombus location and infarct extension. Nowadays, the diagnosis is usually obtained early with MRI or CT, and appropriate treatments can be started to reduce intracranial hypertension, avoid seizures, and control the clot size (FIGURE 80.3). The prognosis has improved compared to a few decades ago; the ISCVT study of 624 patients showed 80% recovery with fatal outcome in 8%.[21] Residual headache is usually related to chronic intracranial hypertension, and continuing seizure activity occurs in 10% of patients, less so after the first year.

Splanchnic vein thrombosis includes mesenteric, portal, and hepatic (Budd-Chiari syndrome) vein thrombosis. The incidence of Budd-Chiari syndrome or isolated mesenteric vein thrombosis is <1 in a million per year, whereas extrahepatic portal vein thrombosis occurs in at least 4 per million.[22] The majority of mesenteric or portal vein thrombosis occurs in the presence of other disorders, mainly cancer but also chronic myeloproliferative disorders, hepatic cirrhosis, pancreatitis, inflammatory bowel disease, or as a postoperative complication. Hypercoagulability plays an important role with inherited thrombophilia identified in one-third of the patients.

Among patients with thrombosis associated with myeloproliferative disease, the JAK2 V617F mutation is highly prevalent,[23] present in up to 96.5% of patients. There is no controversy regarding the need for anticoagulant therapy, but the duration of secondary prophylaxis must balance the risks of recurrence against that of bleeding.

Renal vein thrombosis is a rare complication in severely ill neonates, often with poor prognosis for the renal function.[24] It also occurs in adults associated with renal transplantation, with nephrotic syndrome with urinary loss of antithrombin and possibly free protein S, or with severe thrombophilia. The condition is best diagnosed with CT angiography.[25]

Retinal vein occlusion (RVO) differs from the other types of unusual-site thrombosis in that it is largely a primary vascular disease, associated with systemic atherosclerotic risk factors such as hypertension, diabetes, and hyperlipidemia. RVO occurs in 5.2 per 1,000 individuals who are 30 or older[26] and 2.1% over 10 years among patients with ocular hypertension.[27] There is controversy regarding the importance of traditional risk factors for DVT, the highest yield provided by tests for antiphospholipid

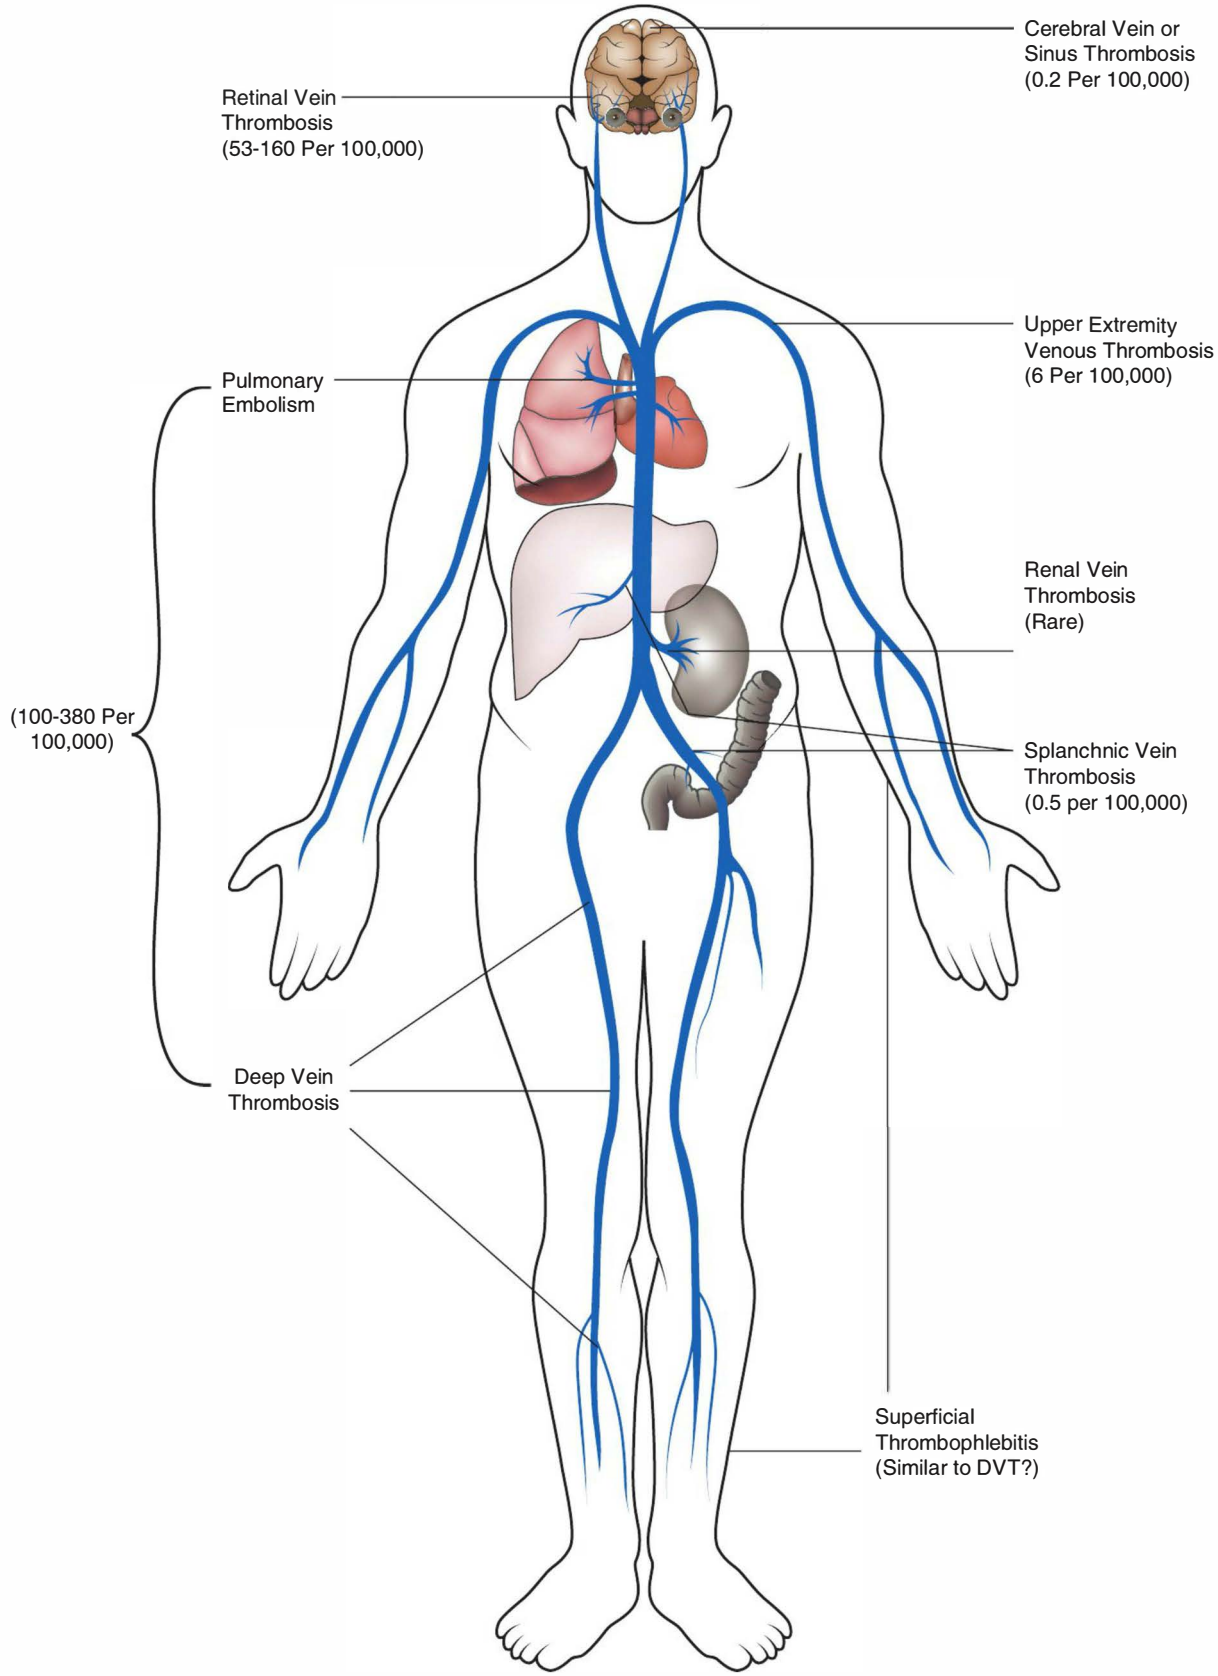

FIGURE 80.2 Locations and annual incidence of VTE.

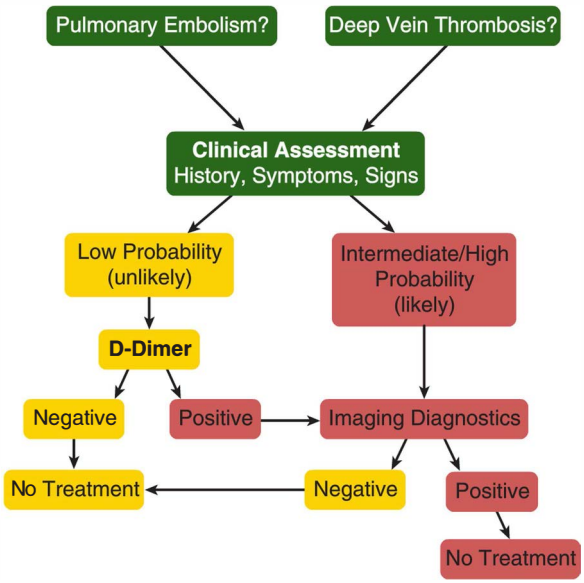

FIGURE 80.3 Simplified diagnostic algorithm for VTE.

syndrome.[28] A randomized study comparing LMWH with aspirin in 58 patients with RVO showed better functional long-term results with anticoagulation, but this result requires confirmation.[29] Unusual sites of DVT are described in Chapter 84.

LONG-TERM CONSEQUENCES OF VENOUS THROMBOEMBOLISM

Patients with DVT have a high risk of recurrence as well as chronic venous insufficiency, the postthrombotic syndrome (PTS) (FIGURE 80.4). The main cause of PTS is damage to the delicate venous valves, with resulting reflux and increased venous pressure in the affected extremity. The clinical findings range from mild swelling in the evening, often combined with symptoms of heaviness or tiredness in the leg, or skin discolorations due to telangiectasia and malleolar flare, to severe edema, iron deposition with hyperpigmentation, lipodermatosclerosis, and, ultimately, venous stasis ulcers[30]; the latter present in 5% of patients after 10 years.[31] The Villalta score has been recommended for quantifying the syndrome.[32] Patients with PE without symptomatic DVT also have an increased risk of developing PTS, 41% at 10 years.[31] Compression stockings should be used to reduce the risk of PTS,[33] but there are some controversies. Once severe PTS has occurred, treatment is challenging. Some relief may be gained with intermittent pneumatic compression,[34] pentoxyphylline,[35] or rutosides.[36]

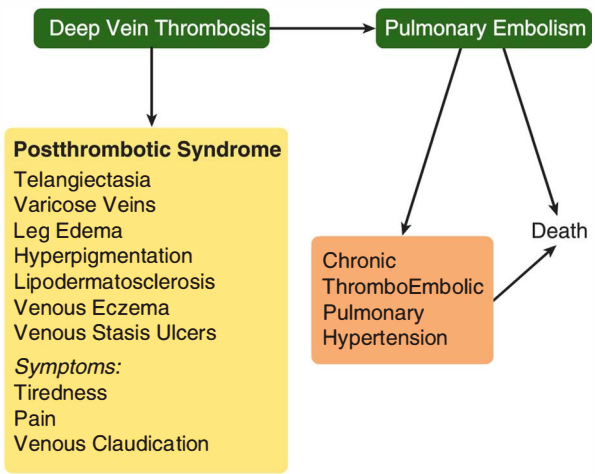

FIGURE 80.4 Sequelae of VTE.

Pulmonary hypertension (mean pulmonary artery pressure ≥25 mm Hg) is an incapacitating long-term sequel that has been reported in 0.8% to 3.8% of patients 2 years after PE.[37,38] It is unclear what transforms the original fragile emboli into fibrotic, endothelialized obstructions that are tightly attached to the arteries. The condition must be suspected when the dyspnea persists or recurs without evidence of new emboli. A screening program with echocardiography several years after an episode of PE was not useful due to a low yield of only 0.57% with chronic pulmonary hypertension.[39] Right heart catheterization is required to assess the pulmonary artery pressures accurately, and central venous saturation and cardiac output are needed to understand prognosis and decide on medical therapy.[40] Pulmonary endarterectomy is the treatment of choice but should only be performed at highly specialized centers. The long-term consequences of VTE are reviewed in Chapter 85.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

Prophylactic regimens against VTE have been most extensively evaluated in major orthopedic surgery, notably hip or knee replacements, with primary efficacy being asymptomatic DVT documented by venography and surgical wound bleeding serving as a sensitive safety outcome. Recently, there has been intensive debate around these outcomes. The value of asymptomatic DVT as a surrogate outcome for fatal PE has been questioned.[41] The European Medicines Agency has since 2007 recommended a composite of (a) symptomatic or asymptomatic proximal DVT, (b) symptomatic nonfatal PE, and (c) VTE-related death or any death as the primary outcome;[42] so asymptomatic distal DVT may not be an acceptable surrogate outcome. Variations in the definition of major bleeding have been used during the past two decades,[43] and attempts have been made to harmonize this definition, published as recommendations by the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis.[44,45] The European Medicines Agency refers to this definition in their recommendations.[42,46]

In major orthopedic surgery, prophylaxis against VTE is today given to a high proportion of patients, although the recommended duration and start time are not followed for over 60% of patients.[47] Overall compliance with guidelines in surgical patients is 58.5%, and only 39.5% for medically ill patients, according to the ENDORSE survey.[48] Collins et al.[49] showed in a meta-analysis of more than 70 randomized trials that prophylaxis with low-dose unfractionated heparin (LDUH) reduces fatal PE in the surgical setting from 0.81% to 0.26%. In the studies in medical patients, death was not significantly affected.[50,51] The duration of high VTE risk was recently addressed by the EXCLAIM trial by evaluating extended prophylaxis with LMWH in medically ill patients. Although prolongation of prophylaxis to 28 days reduced the incidence of VTE, this occurred at the cost of a significant increase in major bleeding,[52] a phenomenon

that did not occur in patients receiving extended prophylaxis after hip replacement[53] or hip fracture surgery.[54] Although there are many "excuses" for abstaining from prophylaxis against VTE in medically ill patients, almost as many patients who do not qualify for prophylaxis ended up receiving treatment as did the eligible patients who were not given prophylaxis.[55] Education, local protocols, and national/international guidelines are not sufficient to maintain an acceptable standard,[56] but computer-driven electronic alerts resulted in more frequent use of prophylaxis with a concomitant reduction of VTE (8.2% to 4.9%) in medical patients with a high proportion of cancer (80%).[57]

LDUH, LMWH, and fondaparinux are well-documented prophylactic agents for patients with medical illness or following orthopedic or general surgery.[56] For patients requiring extended prophylaxis, vitamin K antagonists may be utilized, but they are not effective and are challenging for obtaining and maintaining a stable therapeutic level.[58] In medically ill patients or high-risk surgical patients, LDUH (5,000 U) needs to be administered every 8 hours to have a comparable effect with LMWH.[56,59,60] Mechanical prophylactic methods should be combined with pharmacologic prophylaxis for patients at very high risk of VTE or given alone when there is a high risk of bleeding. See Chapter 86 for more details regarding VTE prophylaxis.

During the past 5 years, several new, specific, orally available anticoagulants have been investigated in large programs. The direct thrombin inhibitor dabigatran and the direct factor Xa inhibitors rivaroxaban and apixaban have been approved in some countries for use in patients undergoing hip or knee arthroplasty (see Chapters 86 and 110).

TREATMENT OF ACUTE AND CHRONIC VENOUS THROMBOEMBOLIC DISEASE

The most important advance in VTE treatment during the past two decades has been the change from inpatient to outpatient management of most patients with DVT and some patients with PE. This change was possible with the shift from required monitoring of intravenous unfractionated heparin to the use of subcutaneous LMWH, which does not require routine laboratory monitoring (FIGURE 80.5). Subcutaneous LMWH seems more effective and safer than unfractionated heparin when given intravenously or subcutaneously,[61] and outcomes are similar when LMWH is given in the hospital compared with outpatient administration.[62] The same quality of evidence is not available for outpatient therapy of PE, but with risk stratification, ever more patients at low risk are treated as outpatients.

Promising results of the new anticoagulants from the orthopedic VTE prophylaxis studies are now being replicated in patients with VTE. Oral thrombin inhibitors ximelagatran (withdrawn from the market in 2006) and dabigatran showed similar efficacy as warfarin with seemingly less bleeding.[63–65] The factor Xa inhibitor rivaroxaban demonstrated similar safety and efficacy as a regimen of LMWH followed by vitamin K antagonists,[66] and none of these new agents require laboratory monitoring of coagulation. These agents will simplify treatment and may allow for longer treatment durations to prevent VTE.

There is uncertainty as to whether patients with unprovoked VTE with a 30% risk of recurrence over 10 years[31,67] should be treated for 3 to 6 months or indefinitely. The PROLONG trial showed that 6.2% of patients with a normal D-dimer level at 1 month after stopping warfarin had recurrence, compared with 15% among those with increased D-dimer.[68] However, a 6.2% recurrence rate over 1.4 years may still be higher than acceptable, and a follow-up study demonstrated that with repeated negative D-dimer tests at 1 and 3 months after discontinuing anticoagulation allowed for selection of a population with a 2.9% risk of recurrence.[69] This low rate must be balanced by the risk of bleeding with continued anticoagulation.

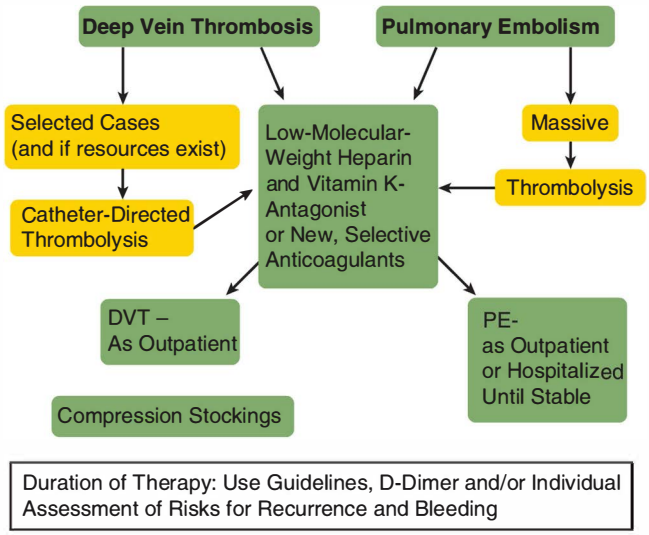

FIGURE 80.5 Treatment of VTE.

Major questions remain regarding the optimization of initial treatment in order to minimize long-term sequelae. Can catheter-directed thrombolysis or pharmacomechanic combinations effectively remove the DVT before the delicate venous valves have been damaged to avoid the PTS[70]? Should other patients with PE than those with hemodynamic instability receive treatment with thrombolysis? Within the next few years, we should have answers to these questions.

CHAPTER

81 Thrombophilia Genetics

JOSEPH EMMERICH, MARTINE AIACH, AND PIERRE-EMMANUEL MORANGE

Each year, approximately 1 in 1,000 individuals in industrialized countries develops deep-vein thrombosis (DVT) of the lower extremities.[1,2] Between 1% and 2% of these patients die from pulmonary embolism, and as many as 25% suffer the chronic effects of the postthrombotic syndrome. It is therefore important to identify high-risk patients with a genetic predisposition to thrombosis, particularly among those who have recurrent DVT. The terms "hypercoagulability" and "thrombophilia" refer to situations in which constitutional or acquired risk factors for thrombotic events are present.[3]

Hereditary thrombophilia is associated with a higher risk of thrombosis (mainly venous thrombosis) and is the antithesis of hemophilia, a disease associated with a high risk of spontaneous hemorrhage. Female carriers of hemophilia have clotting factor levels approximately 50% of normal and have a reduced risk of thrombosis.[4] In contrast, thrombophilia is mainly an autosomal dominant trait linked to heterozygous loss-of-function mutations affecting inhibitors of coagulation or gain-of-function mutations affecting coagulation factors. Interestingly, half-normal coagulation factor levels are not associated with a bleeding tendency, whereas half-normal levels of coagulation inhibitors are associated with an increased risk of thrombosis.

As far back as 1856, Virchow postulated that thrombosis could be due to "changes in the composition of blood," yet it was only in 1965 that Egeberg[5] published the first case of inherited antithrombin (AT) deficiency, and this was followed by similar reports of protein C (PC) and protein S (PS) deficiency.[6–8] Hereditary thrombophilia was initially considered as a rare monogenic disorder, but this view was challenged in the mid-1980s.[9,10] With the discovery of activated protein C resistance (APCR), a frequent factor V (FV) mutation known as FV_{Leiden} became a change of paradigm of genetic risk factors for thrombophilia and paved the way for studies of gene–gene and gene–environment interactions.[11,12] The main risk factors for venous thromboembolism (VTE) can be divided into acquired factors, genetic factors, and other factors that may vary due to genetic variations yet to be identified[13,14] (see Table 81.1). This chapter focuses on genetic risk factors, the main features of which are summarized in Table 81.2.

COAGULATION INHIBITOR DEFICIENCY

Antithrombin Deficiency

Biochemistry

AT is a 58-kDa plasma protein that regulates coagulation by inhibiting procoagulant serine proteases such as thrombin, activated (a) factor X, and factor IXa (see Chapter 18). AT belongs to the serpin family, members of which share structural features that allow them to form a stable stoichiometric complex with their target serine protease. The reaction between AT and thrombin involves the reactive center loop and the protease active site serine and is increased approximately 1,000-fold by heparin and other glycosaminoglycans (e.g., heparan sulfate) that are present on the endothelial surface. Heparin binding to AT involves amino-terminal amino acids 1 to 47, the A helix, and the D helix.[15] AT is synthesized by the liver and circulates at a concentration of approximately 2.5 μM; levels are decreased by estrogen and heparin therapy.

Clinical Manifestations

AT deficiency is transmitted as an autosomal dominant trait (0.02% prevalence in the general population) and is associated with a high risk of VTE (~1% per year).[16–19] It is prevalent in <2% of unselected patients with a first VTE event, and it confers a higher risk of thrombosis than other thrombophilia. Homozygous AT deficiency may cause death *in utero* or severe, life-threatening thrombotic problems in the perinatal period.[20]

Laboratory Diagnosis

There are two types of hereditary AT deficiency. Type I is the most frequent and is characterized by decreased activity in a heparin cofactor assay and a decreased protein concentration by immunoassay. Type II deficiencies are caused by functional defects, protein concentrations being normal or near normal in immunoassays. The dysfunction may affect the reactive site (II_{RS}) or the heparin-binding site (II_{HBS}) or both (II_{PE}) (pleiotropic effect).[21] Homozygosity is mostly present in patients with type II_{HBS}, with the exception of one patient with type II_{PE} deficiency.[20] Venous and arterial thrombosis may occur during infancy in such patients.[22,23]

The ability of plasma to inhibit bovine thrombin and human FXa in the presence of heparin is the foundation for chromogenic heparin cofactor assays. Concentrations <80% (without heparin or estrogen treatment) call for further investigation, although only patients with severe deficiencies (<60%) are at high risk of thrombosis. Chromogenic assays distinguish type II deficiencies, in that type II_{HBS} has normal activity whereas type II_{RS} has low activity; the risk of VTE is very low in type II_{HBS} deficiency.[24]

Molecular Basis

The human *AT* gene (SERPINC1—GenBank X68793.1) is located on chromosome arm 1q23–25 and it comprises seven exons spanning 1.3 kb and containing 10 Alu repeats.[25] A leader sequence of 32 amino acids is encoded by exon I and by the 5′ end of exon II. The mature secreted polypeptide (432 amino acids) is encoded by exons II to VI. The reactive site, an Arg393–Ser394

Table 81.1

Main risk factors for venous thrombosis

Acquired Risk Factors	Genetic Risk Factors	Other Risk Factors[a]
Age	AT deficiency	Hyperhomocystinemia
History of venous thrombosis	Protein C deficiency	High levels of factor VIII
Surgery	Protein S deficiency	High levels of factor XI
Cancer	Factor V_{Leiden}	High levels of factor IX
Hormonal treatment	Factor II G20210A	High levels of factor VII
