CHAPTER

36 Blood-Borne Microparticles

JOSÉ A. LÓPEZ AND SWAMINATHAN MURUGAPPAN

This chapter concerns a blood element that has not been specifically addressed in previous editions of this textbook: blood-borne cell-derived microparticles. Although microparticles have been recognized for many years as important components of the procoagulant function of plasma, it is only in the past decade or so that they have emerged as important actors in many other biologic processes. Their roles are many and diverse. Besides procoagulant activity, they include cellular activation, signaling, endocrine functions, immune modulation, and transfer of biologically important molecules, including proteins, lipids, mRNAs, and microRNAs. The area of microparticle biology is fraught with controversy, owing in large part to the varied methods used to define microparticles, the difficulty in accurately measuring them, and the many artifacts associated with that measurement. Nevertheless, none of these factors justify ignoring them. In this chapter, we attempt to provide a useful way to think about this interesting biologic phenomenon.

DEFINITIONS

Several types of subcellular, membrane-bound particles are found in the blood. The most prevalent are exosomes, apoptotic bodies, and microparticles (FIGURE 36.1).

Exosomes

These particles range in diameter from 50 to 100 nM and are derived from the release of granules containing multivesicular bodies, each multivesicular body producing several exosomes.[1] Multivesicular bodies arise by invagination of granule membranes, producing vesicles whose outer membrane leaflets correspond to the inner membrane leaflet of the granule. Exosomes from immune cells have been the best studied and function in antigen presentation.[1–3] Conversely, exosomes derived from tumor cells can inhibit the immune response to the tumors by presenting tumor antigens to tolerogenic dendritic cells.[4,5] Exosomes can also activate the immune response against infectious agents by presenting pathogen-specific antigens.[1]

Exosomes can be detected by staining with antibodies against such antigens as CD63, CD81, CD9, and lysosomal-associated membrane protein-1 (LAMP-1), some of which are only found on internal membranes in intact cells.[6,7] Exosomes are distinguished from microparticles by both their smaller size and their failure to express phosphatidylserine (PS) and are best isolated by a combination of differential centrifugation and sucrose density ultracentrifugation.[8] They have been studied by a variety of techniques, including transmission electron microscopy (TEM), mass spectrometry, and immunoblotting after isolation by centrifugation.[8]

Apoptotic Bodies

These are membrane-bound cell fragments that arise as cellular blebs from cells undergoing apoptosis and range in size from 1 to 5 μm in diameter, thus overlapping platelets in size.[9] Like microparticles, they usually express PS on their external membrane leaflets, but unlike microparticles, they often carry DNA derived from the cell of origin.[10]

Apoptotic bodies are most commonly identified by flow cytometry, based on both surface antigen expression and annexin V staining (the latter being indicative of surface PS expression) and on their size characteristics. Protocols to isolate apoptotic bodies are lacking, in large part due to the overlap in size and antigen expression they share with other blood components such as microparticles and platelets.

Microparticles

Microparticles, also called microvesicles, are defined as membrane-bound cellular fragments that arise by blebbing from the plasma membranes of cells and range in size from 0.1 to 1.0 μm, with the majority being in the range of 0.2 μm.[11,12] Blood contains microparticles from a wide variety of cellular sources, including tissue cells and tumors, but the most abundant microparticles arise from blood cells or blood vessel cells in direct contact with the blood, endothelial cells.[6,13]

The most common method for measuring microparticles has been with flow cytometry.[14,15] With this method, it is possible to gauge the number and certain phenotypic characteristics of the microparticles, such as their cells of origin (Table 36.1). However, as will be discussed extensively later in this chapter, it is difficult by conventional flow cytometry to accurately count microparticles <500 nm in diameter,[16] unless those particles are stained for phenotype. Most microparticles also express PS on their external membrane leaflet, and this surface characteristic has been used in determining their number.

ORIGINS OF MICROPARTICLES

Blood-borne microparticles are highly heterogeneous with respect to their size and composition, in addition to their cellular sources.[13] By definition, their sizes span a range of diameters that varies by a factor of 10, from 0.1 to 1 μm. If the shape of a microparticle is assumed to be spherical, this size range translates to a 100-fold difference in surface area and a 1,000-fold difference in volume between the smallest and largest microparticles.

In addition to heterogeneity in size, their cellular sources are extremely varied. In the most common order of abundance

in human blood: platelets, megakaryocytes, endothelial cells, erythrocytes, lymphocytes, monocytes, vascular smooth muscle cells, dendritic cells, and, often, tumor cells.

Platelet and Megakaryocyte Microparticles

The existence of platelet microparticles was first inferred by Chargaff and West[17] in 1946, when they noted that there was a precipitable factor in plasma capable of supporting thrombin generation. In 1967, Wolf[18] described the source of this procoagulant activity as being the platelet and also identified the microparticles morphologically. He termed them "platelet dust." Wolf also demonstrated that there was a linear relationship between the number of platelets and the quantity of microparticles in the blood, with thrombocytopenic patients having low numbers of microparticles compared to normals and those with polycythemia vera having elevated microparticle numbers.

Microparticles containing platelet markers account for 70% to 90% of circulating microparticles in healthy individuals.[19–21] Markers used to identify these microparticles by antibody staining and flow cytometry include CD41(the α subunit of the integrin $\alpha_{IIb}\beta_3$), CD42b (glycoprotein [GP] Ibα), CD42a (GPIX), CD61 (the β subunit of the integrin $\alpha_{IIb}\beta_3$), and CD62P (P-selectin).[13] Controversy exists over the extent to which platelet microparticles express PS, with some studies using the binding of annexin V as one of the defining characteristics of these microparticles[22] and one study finding that up to 80% of microparticles staining with platelet markers did not express PS.[23] This point is an important one, as some methods of microparticle quantification rely on annexin V capture of the microparticles[15] or base their definition of microparticles on the ability to bind annexin V. Despite these concerns, isolation by annexin V capture likely does give a reasonable estimate of the procoagulant capacity of the microparticles.[24]

Various stimuli are capable of eliciting microparticles from platelets, including thrombin, collagen, complement C5b-9,

Table 36.1
Cell-specific surface markers in microparticles

Cell of Origin	Surface Markers
Platelets	CD41 (αIIb) CD61 (beta3) Cd42b (GPIbα) CD62P (P-selectin)
Endothelium	CD31 (PECAM) CD54 (ICAM-1) CD62E (E-selectin) CD105 (endoglin) CD144 (VE-cadherin) CD146 (MUC18)
Red blood cell	CD235a (glycophorin A)
Monocytes	CD14
Lymphocytes	CD4 CD8 CD20 (B-lymphocyte antigen)
Neutrophils	CD66b (carcinoembryonic antigen-related cell-adhesion molecule 8)

high shear stress, and calcium ionophore.[25–35] Microparticle generation is coupled to externalization of PS on the platelet membrane and is a key component of the ability of platelets to support the enzymatic reactions of the coagulation system that eventuate in thrombin production and formation of insoluble fibrin clots.

Platelets also generate microparticles as they undergo apoptosis, albeit of a different nature than the microparticles produced by agonist stimulation.[36,37–39]

Numerous studies have reported elevated platelet microparticle concentrations in association with a variety of pathologic conditions, including acute coronary syndromes, atherosclerosis, hypertension, diabetes, venous thromboembolism, heparin-induced thrombocytopenia, antiphospholipid syndrome, thrombotic thrombocytopenic purpura, sickle cell disease, human immunodeficiency virus (HIV) infection, sepsis, malignancies, and several other conditions (Table 36.2).

Although it was initially believed that microparticle staining with platelet markers arose entirely from platelets, recent evidence by Flaumenhaft et al.[40] call this interpretation into question. Using videomicroscopy, these investigators demonstrated the capacity of cultured mouse megakaryocytes to vesiculate, the vesicles arising along the lengths of micropodia. These microparticles expressed CD41, CD42b, and PS. However, they were distinct from platelet microparticles in that they failed to express CD62P and LAMP-1 and they contained uncleaved filamin A, whereas filamin A found in platelet microparticles was uniformly proteolyzed to smaller fragments. In the blood of mice and healthy human volunteers, most of the "platelet" microparticles detected by these investigators did not express CD62P and LAMP-1, leading them to conclude that the microparticles were derived from megakaryocytes. Because both CD62P and LAMP-1 are membrane proteins restricted to granule membranes in unactivated platelets, this finding could also indicate that, in addition to a megakaryocyte source for these particles, they might also arise normally *in vivo* from platelets that have not been stimulated to release granules.

Endothelium

A second major source of microparticles in the blood is the endothelium. These microparticles arise by blebbing of the endothelial plasma membrane,[41] and they carry a wide variety of endothelial membrane proteins, including CD54 (ICAM-1), CD62E (E-selectin), CD31 (PECAM), CD105 (endoglin), CD144 (VE-cadherin), and CD146 (MUC1).[6] Because platelet microparticles also express CD31, endothelial cell microparticles are distinguishable by the absence of CD41 staining. A wide variety of stimuli have been reported to induce microparticle production by endothelium, including tumor necrosis factor (TNF)-α, interleukin-1, uremic toxins, oxidized low-density lipoproteins, oxidants such as superoxide and hypochlorous acid, and agents that uncouple nitric oxide synthase.[42–46] Endothelial cells undergoing apoptosis also elaborate microparticles. Microparticles released by cells undergoing apoptosis express more CD31 and less CD62E than those elaborated by cells exposed to activation stimuli.[47]

Endothelial microparticles are elevated in a number of conditions, all of which involve endothelial pathology. These include acute coronary syndromes, hypertension, metabolic syndrome, diabetes, chronic renal failure, systemic lupus erythematosus, sickle cell disease, pulmonary artery hypertension, malaria, and others (Table 36.2).

Erythrocytes

Erythrocyte microparticles make up only a small fraction of microparticles in the blood of normal individuals,[19] but their quantity can be increased considerably in a number of disorders that primarily affect the erythrocyte and other systemic disorders. Hemolytic anemias, both hereditary and acquired, are associated with increased blood microparticle levels, including paroxysmal nocturnal hemoglobinuria,[48] sickle cell disease,[49–51] the thalassemias,[52–54] autoimmune hemolytic anemia, malaria,[55,56] and disorders of the erythrocyte membrane skeleton.[57,58] Erythrocyte microparticle levels are also often elevated in systemic disorders such as atherosclerosis and chronic renal failure.[59,60]

In addition to conditions that increase erythrocyte microparticles *in vivo*, microparticles are also produced during extended red cell storage and by conditions that can affect the stored red cells, such as ATP depletion or low pH.[58,61–64] Exposure to agents that elevate intracellular calcium concentrations, such as the calcium ionophore A23187, also induces erythrocytes to produce microparticles. Erythrocyte microparticles are usually identified by staining for glycophorin A (CD235a).[54,65]

Leukocyte Microparticles

Monocytes, neutrophils, and lymphocytes all produce microparticles.[65] Those derived from monocytes or tissue macrophages are identified by surface expression of CD14 and often are extremely procoagulant by virtue of carrying tissue factor (TF) in addition to expressing anionic phospholipids.[66] Neutrophils and lymphocytes also shed microparticles. Neutrophil microparticles are elevated in a number of inflammatory states known to be associated with neutrophil activation, including acute vasculitis, preeclampsia, rheumatoid arthritis, and meningitis.[67–72] Elevated neutrophil microparticle counts have also been reported in patients with extensive atherosclerosis and in those undergoing hemodialysis.[60,68]

Like monocytes, neutrophils have been reported to elaborate TF-bearing microparticles in response to activation with the anaphylatoxin C5a,[73–75] although this property might also be a consequence of fusion of TF-bearing microparticles with neutrophils, not from actual TF synthesis by the neutrophils themselves.[76]

MECHANISM OF MICROPARTICLE FORMATION

Several factors have led to platelets being the best studied cell for determining the mechanisms of microvesiculation. First, platelets were the first cell recognized to produce microparticles and for which microvesiculation was noted to be an important part of their physiology.[17,18,77] Second, microparticles containing platelet markers are the most prevalent type of microparticle in blood.[19–21,40] Finally, platelets are easy to isolate and produce microparticles rapidly when stimulated.[20,22]

Based on extensive research, it is clear that membrane remodeling and changes in cytoskeletal structure are both involved in the production of microparticles. A simplified illustration of the mechanism of microparticle formation resulting

from cell activation or apoptosis is shown in FIGURES 36.2 and 36.3, respectively.

Membrane Remodeling and Loss of Phospholipid Asymmetry

The plasma membranes of unstimulated cells are asymmetric with respect to their phospholipid content,[78] the inner membrane leaflets being relatively enriched in PS and phosphatidylethanolamine (PE) and the external leaflets having a much higher content of phosphatidylcholine (PC) and sphingolipids.[79,80] Loss of membrane asymmetry has been assumed to be a *sine qua non* requirement for plasma membrane blebbing of microparticles. In favor of this notion is the observation that patients with Scott syndrome, an extremely rare bleeding disorder in which cells are unable to expose PS and PE on their external membrane leaflet, have very low levels of microparticles in the blood and their platelets display defective microvesiculation following agonist stimulation.[33,77] Recently, the requirement for initial PS exposure in microparticle formation has been called into question, based primarily on the fact that endothelial cells can release PS-negative microparticles when undergoing apoptosis[47] and that in the plasma of healthy individuals, 80% of microparticles carrying platelet markers did not bind annexin V.[23] These findings have several potential interpretations: first, they may truly indicate that PS exposure on the parent cell is

(Text continued on page 485)

tahir99-VRG & vip.persianss.ir

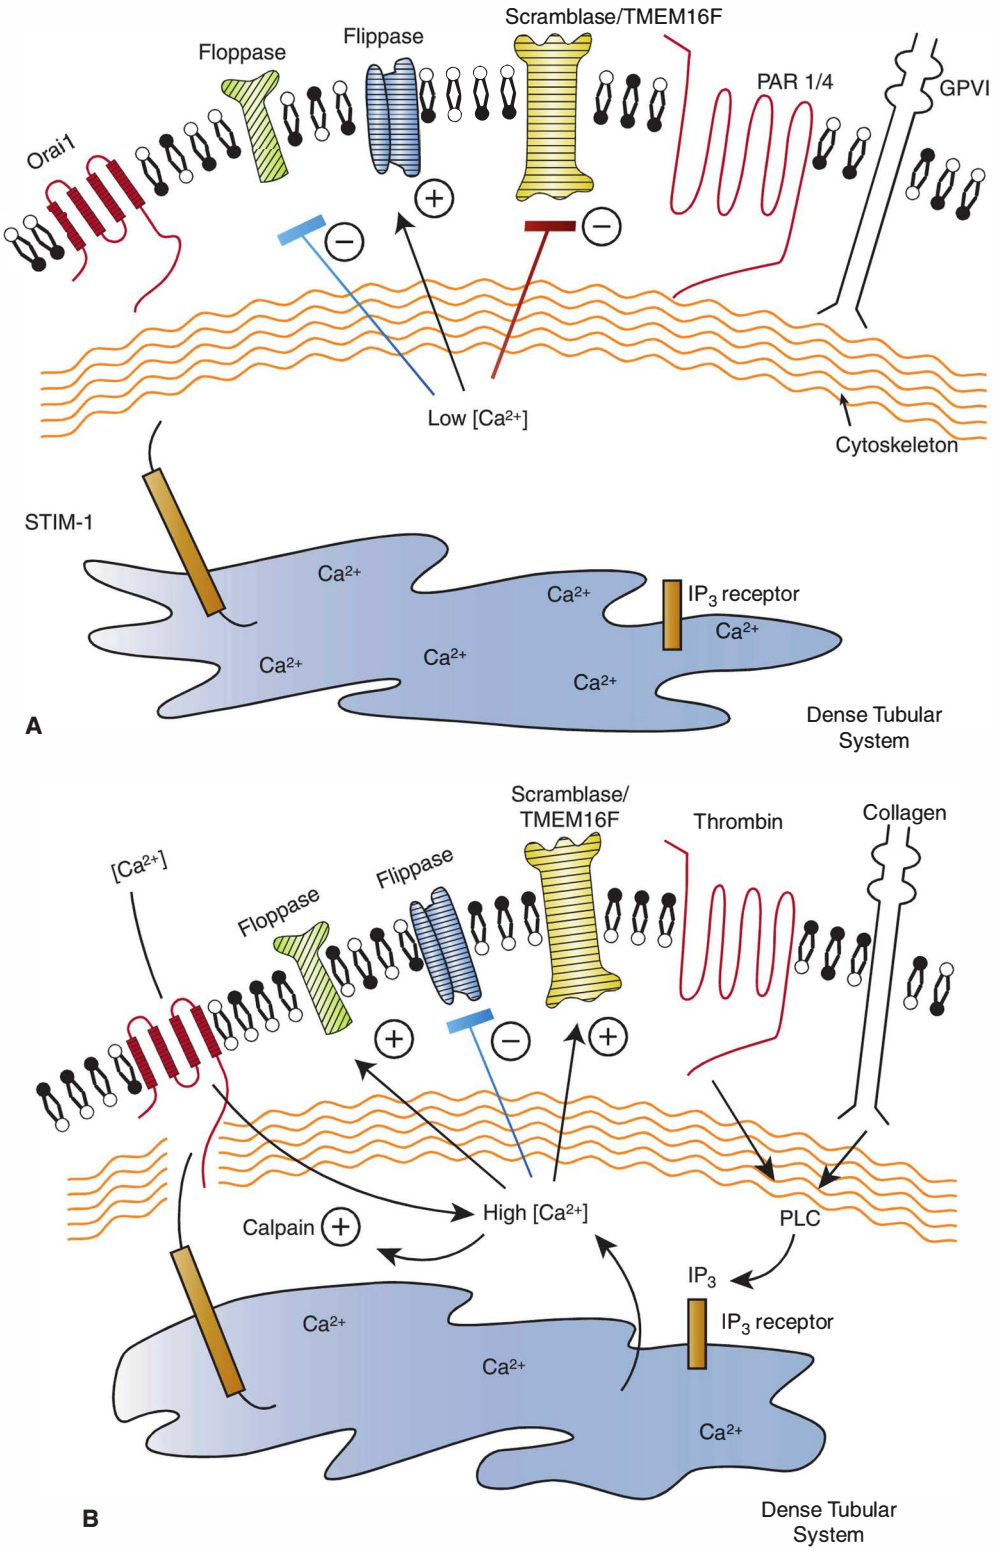

FIGURE 36.2 Proposed mechanism of cell activation–induced microparticle formation: **(A)** In the unactivated cell, the membrane asymmetry is maintained by the interplay between flippases and floppases, with flippases being more active in a low-calcium environment resulting in PS being sequestered in the inner leaflet of the plasma membrane. **B:** When the cell is activated, such as by thrombin or collagen in platelets, the intracellular calcium rises due to release of calcium from the intracellular stores. Increased calcium inhibits flippases and activates floppases and scramblases such as TMEM16F. These changes lead to externalization of PS. Emptying of the intracellular calcium stores also triggers Orai1/STIM1-mediated calcium influx.

tahir99-VRG & vip.persianss.ir

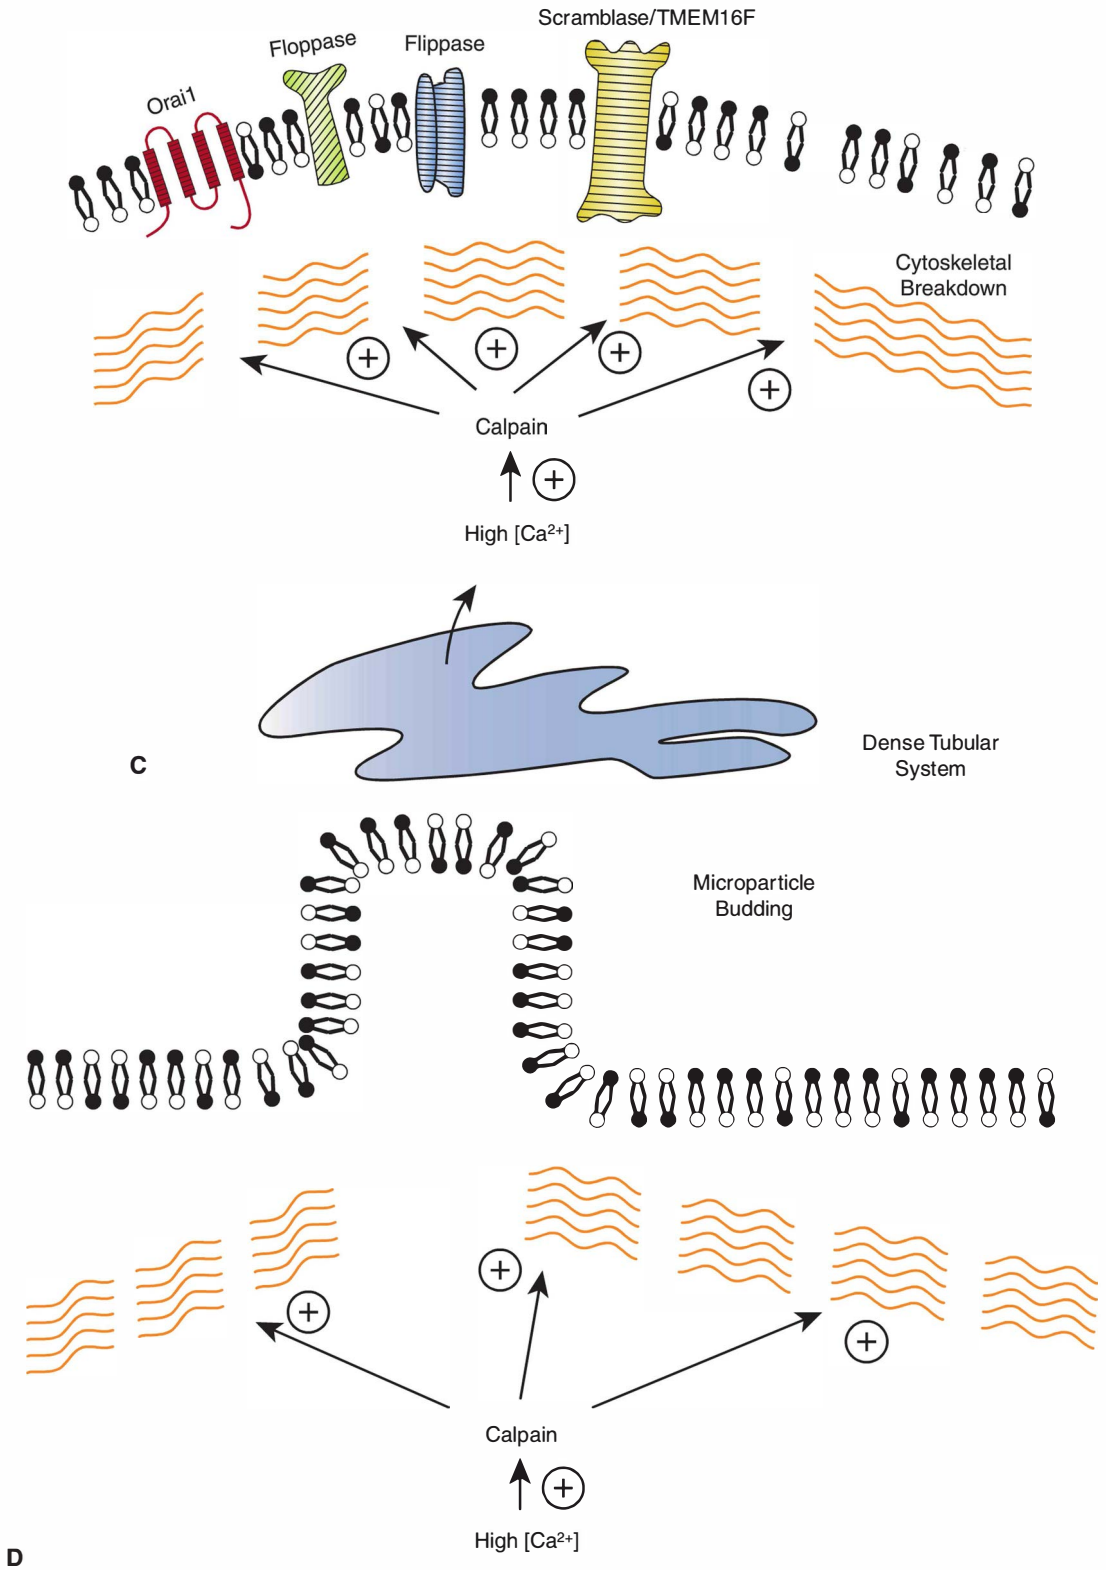

FIGURE 36.2 *(Continued)* **C:** Persistently high intracellular calcium levels also results in activation of calpain, which cleaves key cytoskeletal proteins. **D:** Calpain-mediated proteolysis of the cytoskeleton enables membrane budding and release of PS-exposing microparticles.

tahir99-VRG & vip.persianss.ir

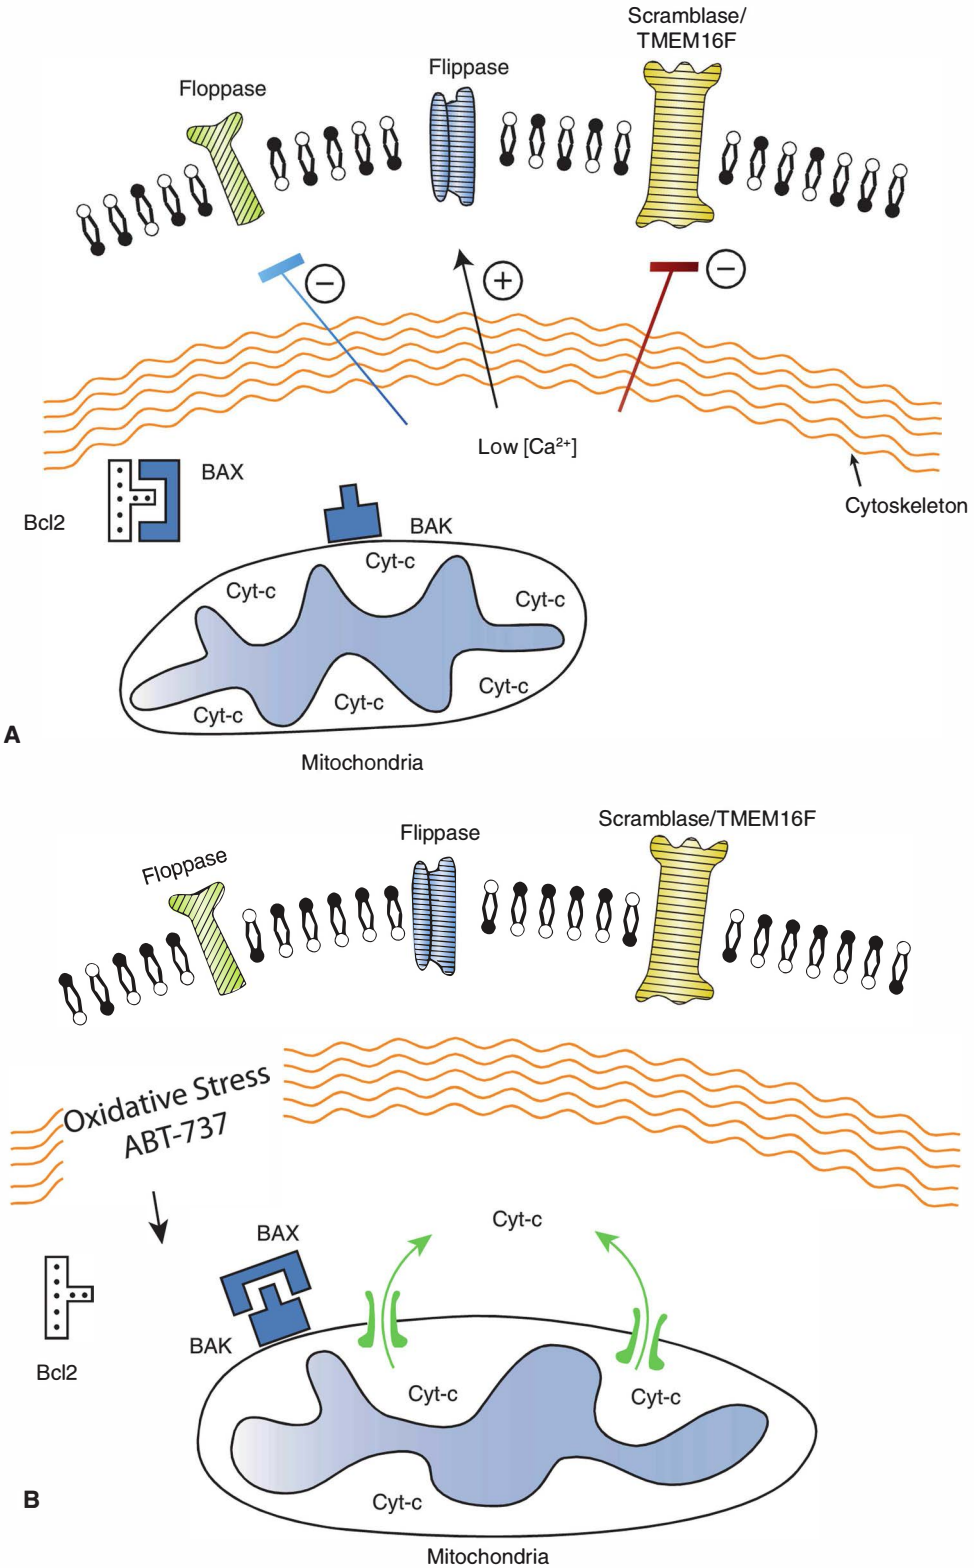

FIGURE 36.3 Proposed mechanism of apoptosis-induced microparticle formation: **(A)** In the unactivated cell, membrane asymmetry is maintained by the dominant action of flippases in a low-calcium state. Apoptosis is prevented by sequestration of Bax by Bcl-2 and Cyt c is sequestered in the intermembrane space of the mitochondria. **B:** When the cells experience an apoptotic trigger such as exposure to ABT737 or oxidative stress, Bax is released from Bcl-2 and is now free to bind to Bak present on the outer mitochondrial membrane. This binding leads to the formation of MOMP, which releases the Cyt c into the cytoplasm, where it contributes to the formation of the apoptosome.

tahir99-VRG & vip.persianss.ir

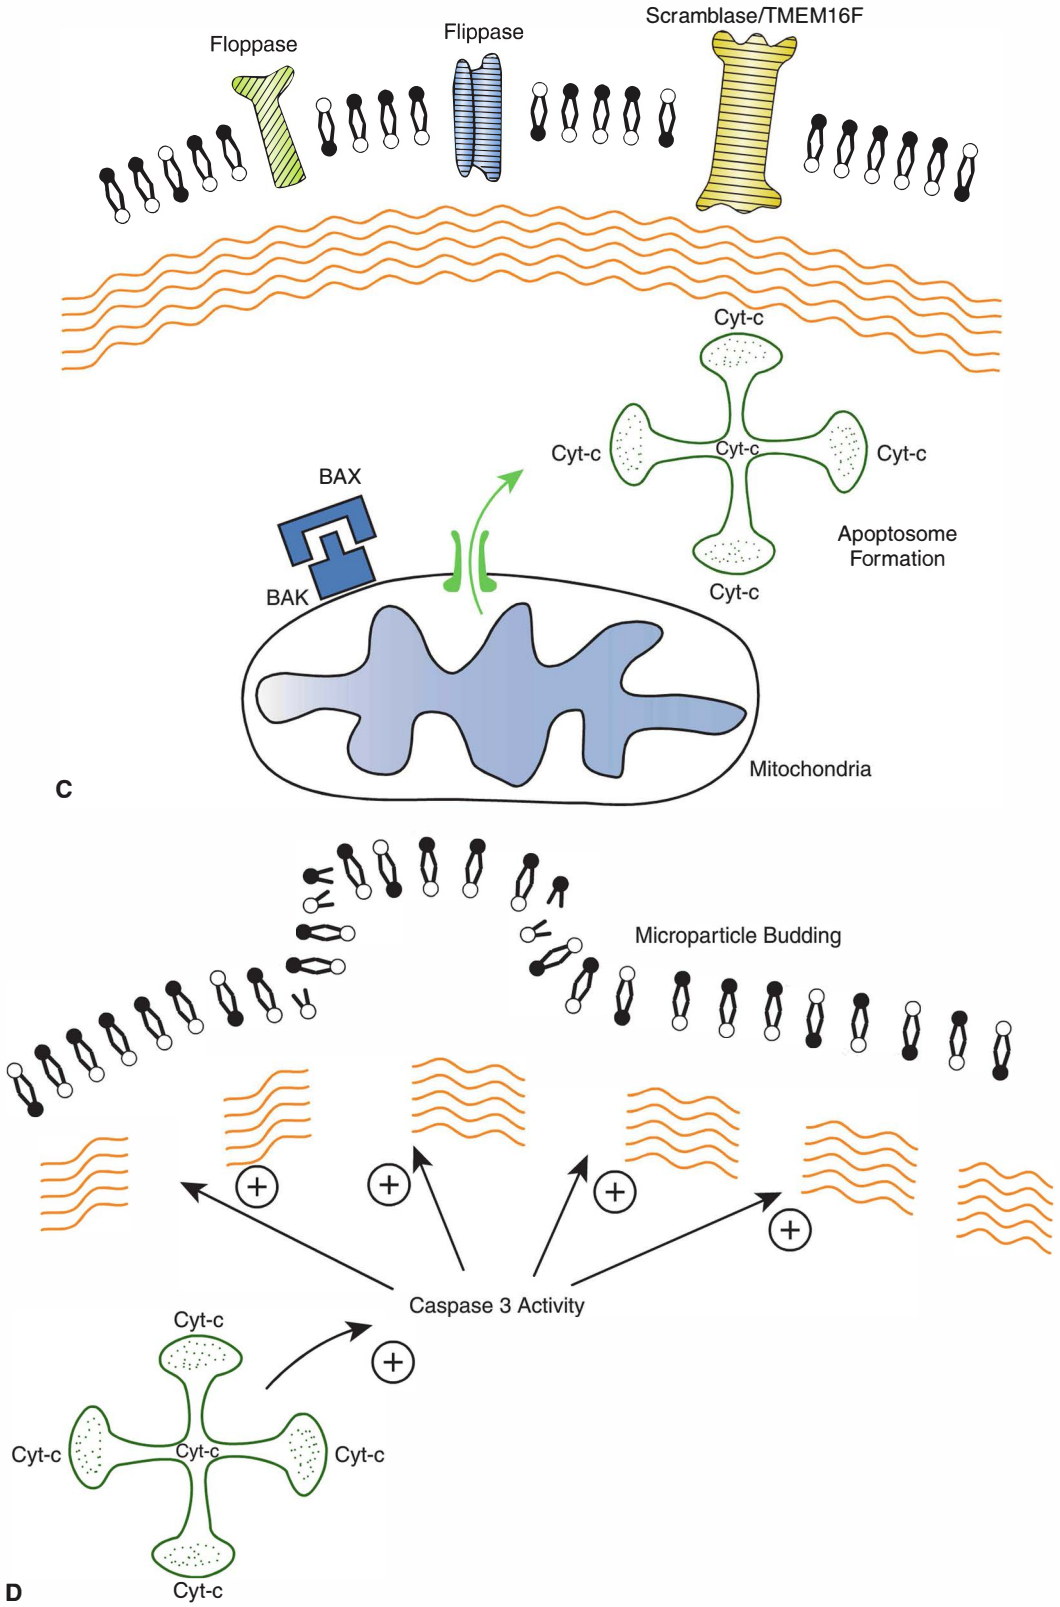

FIGURE 36.3 *(Continued)* **C:** Formation of the apoptosome results in the activation of executioner caspases such as caspase 3, which cleaves components of the cytoskeleton. **D:** Degradation of cytoskeletal elements aids in the budding of the membrane and subsequent release of microparticles. The exact mechanism by which PS is externalized in apoptotic cells is not known.

tahir99-VRG & vip.persianss.ir

not required for microparticle generation; second, the annexin V assay may be insufficiently sensitive to detect the quantity or arrangement of PS on the microparticle surface; or third, PS exposure on the parent cell is required for the formation of microparticles, but that this need not be reflected in enhanced PS on the microparticle.

Maintenance of plasma membrane phospholipid asymmetry requires energy expenditure, with ATP fueling the action of two phospholipid transporters, one that transports anionic phospholipids from the outer leaflet to the inner leaflet of the membrane, a so-called aminophospholipid translocase or flippase,[81–83] and one, a floppase, that transports PS to the outer leaflet from the inner leaflet, albeit much more slowly than the flippase.[83–86]

When cells are activated and the cytosolic Ca^{2+} concentration increases, the flippase is inhibited and another transporter is activated: a scramblase. Scramblase or scramblases transport aminophospholipids between the inner and outer membrane leaflets in both directions.[80,87] The unopposed activity of the floppase, coupled with the action of the scramblase, can rapidly increase the concentration of PS on the outer membrane leaflet.[80,83,87,88,89] At low intracellular Ca^{2+} concentrations, both the flippase and the floppase are active, with the scramblase being largely inactive. The threshold Ca^{2+} for activating the scramblase has not been determined.

Full phospholipid scrambling requires that the elevation in intracellular Ca^{2+} be sustained[90] as a rapid return of Ca^{2+} to baseline decreases scramblase activity, restoring phospholipid asymmetry.[91] In some situations, phospholipid asymmetry may be maintained even with a fairly rapid return of Ca^{2+} to baseline because the flippase may be irreversibly inactivated through proteolysis by calpains.[91]

The identity of the scramblase has been mysterious and highly sought after for many years and several candidates have been proposed. These include the ATP-binding cassette lipid transporter ABCA1[92] and phospholipid scramblase-1 PSCLR1, also called scramblase 1.[93] The case for ABCA1 seemed strong when a mutation in the transporter was discovered in a patient with Scott syndrome.[94] However, subsequent studies in deficient mice failed to demonstrate a defect in phospholipid scrambling.[87,95] PSCLR1 was also ruled out as the platelet scramblase when normal levels and functions of the transporter were detected in the lymphocytes of Scott syndrome patients.[96] In addition, PSCLR1-deficient mice do not manifest hemostatic defects.[97]

Another strong candidate was recently proposed. Suzuki et al.[98] identified a mutant mouse B-cell line that constitutively expressed PS on the surface, constructed a cDNA library from the cell line, and isolated a cDNA that could confer constitutive PS surface expression on other cell lines. The cDNA encoded a constitutively active mutant of a protein called TMEM16F, which has eight putative membrane-spanning helices. The case for its role as the scramblase defective in Scott syndrome was made when the investigators found a mutation in a splice-acceptor site of the gene encoding TMEM16F in a patient with Scott syndrome, leading to premature termination of translation of the encoded protein. Of interest, Scott syndrome lymphocytes undergoing apoptosis express PS normally, suggesting that the activation-depending increase in external leaflet PS occurs by a different mechanism than that occurring with apoptosis.

PS Exposure and Microparticle Release

The mechanism by which membrane phospholipid redistribution induces blebbing and microparticle release is unresolved. Changes in the shape of membranes (bending and puckering) can be induced by altering the composition or quantity of phospholipids; in isolated membranes, this is largely a consequence of energy minimization.[99] Unilamellar membranes with high local concentrations of PS form concave structures owing to the fact that PS assumes a cone-like shape by virtue of its small head group and relatively wider acyl chains. Such a configuration favors invagination rather than blebbing of membrane bilayers with increased external leaflet PS. However, it is also possible that the invagination can assume the form of a stalk at the base of the emerging microparticle.

Curvature of membranes can also be induced by an imbalance in the areas of the inner and outer membrane leaflets.[100] Thus, it is possible to envision that sudden local increases in the external membrane leaflet PS concentration could produce local areas of high convexity in the membrane, essentially producing a bleb. This mechanism may account for the observation that PS added to erythrocyte ghosts replete with ATP formed cytosolic inside-out vesicles resembling endocytic vesicles.[101] Presumably, the added PS was transported inward through the action of a flippase, producing a relative excess of PS in the internal leaflet. In intact cells, however, changes in membrane shape or composition can also trigger chemical changes in the cytoskeleton, for example, the polymerization of actin in platelets.[102]

Finally, proteins are likely to have large influences on the curvature of membranes, and on the formation of microvesicles. Negatively charged phospholipids, including PS and phosphatidylinositol 3,4 bisphosphate (PIP_2), interact with proteins containing clusters of basic residues (Lys and Arg), which in many cases facilitate membrane anchoring of the protein and also serve to fix the location of the acidic phospholipids on the inner leaflets. A subgroup of these proteins, known as BAR domain proteins (BAR for *B*in/*A*mphiphysin/*R*vs), are able to induce membrane curvature through their interactions with acidic phospholipids, in particular PS. Proteins with BAR domains are responsible for such membrane remodeling functions as formation of T-tubules in muscle and recycling of synaptic vesicles.[102,103] It remains possible that related proteins carry out similar functions in the generation of microparticles.

Role of the Cytoskeleton

The cytoskeleton has also been implicated in microparticle generation. Several reports indicate that cytoskeletal integrity is essential for maintaining the shape of cells and the asymmetry of their membranes.[78,104,105] This suggests that loss of the plasma membrane's cytoskeletal attachment could facilitate membrane blebbing.

Cytoskeletal disruption can be tied to increased Ca^{2+} through the activation of the calcium-dependent proteases known as calpains.[104,106–108] Activation of calpains requires high and sustained calcium levels, derived from influx and internal stores.[106] These thiol proteases are able to degrade several components of the cytoskeleton, including adducins, spectrin, actin, filamin A, talin, and α-actinin.[104,106–108] These changes are associated with increased microparticle release[109–111] but may not be a prerequisite for it, as calcium-driven PS exposure[112] and vesiculation[39] can occur even in the presence of calpain inhibitors, although

tahir99-VRG & vip.persianss.ir

one study did show a decrease in agonist-induced microparticle formation in platelets when calpain was inhibited.[113] Activation of calpain by itself is insufficient to induce microvesiculation because in Scott syndrome, calpain activation is normal even though PS externalization and microvesiculation are highly compromised.[114]

Proteolysis of cytoskeletal elements is also important for microparticle release associated with apoptosis. Effector caspases can cleave proteins such as filamin A, gelsolin, and talin in a manner similar to proteolysis by calpains.[105] This proteolysis precedes microparticle formation. However, the role of caspases in agonist-induced microparticle formation is controversial.[37,39,112,115]

Platelet apoptosis also yields microparticles and can be induced by the Bcl-2 inhibitor ABT737. Bcl-2 inhibition results in caspase-mediated proteolysis of filamin A, gelsolin, and talin and coincides with PS exposure and microparticle relsease.[39] Unlike the situations with calpains in agonist-induced microparticle formation, caspases are required for PS exposure and microparticle release in platelets treated with ABT737.

Caspases also play a role in microparticle release in T-lymphocyte cell lines undergoing apoptosis. In these cells, caspase-3 cleaves ROCK1, leading to phosphorylation of the myosin light chain, membrane contraction, and microparticle release.[116] A similar mechanism operates in microparticle release from endothelial cells during inflammation, which requires caspase-3 proteolysis of ROCKII.[44] Rho kinase has also been implicated in this pathway.[117]

Calcium Entry

Sustained elevations of intracellular Ca^{2+} are required for activation-mediated PS exposure and microparticle release.[110,111] Calcium activates both cytoskeleton-degrading enzymes such as calpains and scramblase activity.[90,106] Cytosolic calcium elevations originate from both intracellular and extracellular sources. The initial calcium wave comes from intracellular stores; when these are depleted, membrane channels are activated that allow calcium entry from external sources, a process called store-operated calcium entry (SOCE).[118,119] Activation of SOCE can induce PS externalization and microparticle release even in the absence of agonist stimulation, as evidenced by studies with the sarco/endoplasmic reticulum Ca^{2+}-ATPase ATPase inhibitor thapsigargin, which depletes intracellular calcium stores.[120]

SOCE is induced by the coordinated action of stromal-interacting molecule-1 (STIM1), which is present on membranes of the dense tubular system, and the Orai1 protein, a calcium channel present on the plasma membrane.[121] STIM1 senses low levels of dense tubular system calcium and induces the opening of Orai1, enabling the influx of calcium from outside the cell. The platelets of mice expressing a defective mutant Orai1 (Arg93Tyr) showed decreased SOCE upon agonist stimulation and decreased calcium transients.[122] However, their adhesion and aggregation on arterial collagen *in vivo* was normal, although the adherent platelets demonstrated decreased PS exposure.[122] In contrast, thrombin-mediated PS exposure was unaffected in the mutant platelets, suggesting that thrombin activates alternative calcium entry pathways.[123]

In addition to calcium, potassium and chloride have also been implicated in PS exposure and microparticle release. Elevated intracellular Ca^{2+} promotes the efflux of K^+ and Cl^-, leading to cell contraction, PS exposure, and membrane blebbing during apoptosis.[124] Blockade of the K^+ channel IKCa1 prevents these events. Ca^{2+} also activates Gardos potassium channels, another process implicated in PS exposure and microparticle release.[125] In addition, cellular sodium loading mediated through the Na/H exchanger has been proposed to be important for agonist-mediated PS exposure and microparticle generation.[126]

Role of Mitochondria in PS Exposure and Microparticle Release

Mitochondria are known to play a crucial role in apoptosis of nucleated cells and platelets.[38,127] Release of cytochrome c (Cyt c) from the mitochondria during apoptosis initiates the formation of an apoptosome and subsequent activation of executioner caspases.[128] The terminal phase of apoptosis is characterized by PS exposure, microparticle and apoptotic body formation, and cell shrinkage.[129,130]

Platelets contain much of the apoptotic machinery found in nucleated cells, including the Bcl-2 family of proteins and caspases.[131] Initiation of apoptosis-like changes by the Bcl-2 inhibitor ABT737 leads to Cyt c release from mitochondria and subsequent caspase-dependent microparticle formation and PS exposure.[132] It was initially assumed that the same pathway led to PS exposure and microparticle release in platelets undergoing apoptosis or activated by agonists because of the involvement of mitochondria in both processes.[36] This conjecture would indicate that agonist stimulation of platelets activated apoptotic pathways, but this has shown not to be the case in collagen/thrombin-stimulated platelets which externalize PS without undergoing apoptosis.[39,133]

Opening of the mitochondrial transition pore (MTP) induced by elevated Ca^{2+} is essential for collagen/thrombin-mediated PS exposure and microparticle formation.[115,134,135] However, inhibition of MTP opening does not completely block calcium ionophore–mediated PS exposure but does block microparticle shedding.[38] The MTP comprises many proteins including the adenine nucleotide transporter, cyclophilin D (CypD) and the voltage-dependent calcium channel (VDCC). The role of MTP was demonstrated both by pharmacologic blockade of the pore with cyclosporine, which inhibits the function of CypD,[136] and in mice deficient in CypD.[137]

The role of the apoptotic machinery in agonist-induced PS exposure and microparticle formation was also tested in mice that lack Bax/Bak, which is essential to form the mitochondrial outer membrane pore (MOMP).[39] These animals demonstrated normal PS exposure and microparticle formation in response to physiologic agonists.

Nevertheless, there is still debate regarding the exact contributions of MTP and MOMP in platelet PS exposure and microparticle formation mediated by activation or apoptosis. Some studies have shown that agonist activation of platelets can regulate Bcl-2 family proteins and activate caspases.[37,138] Yet other studies have shown that caspase inhibitors do not affect agonist-mediated procoagulant function.[37,138] The exact mechanism by which mitochondrial proteins participate in microparticle generation has not been fully delineated nor have the contributions of individual mitochondrial proteins and channels.

MICROPARTICLE COMPOSITION

Microparticles Originate from Rafts

Although they arise from cell plasma membranes, microparticles do not precisely reflect the composition of those membranes. This

tahir99-VRG & vip.persianss.ir

is because plasma membranes are not homogenous, but contain regions in which certain lipids or proteins are relatively enriched. Microparticles arise from areas of the membrane enriched in lipid termed rafts. Rafts represent regions of ordered lipid and protein floating within a sea of fluid, relatively disordered lipid.[139] Rafts comprise approximately 10% of the surface area of plasma membranes, the precise quantity depending on cell type, the state of cellular activation, and the cholesterol and sphingolipid content of the membrane.[140] Rafts are enriched in certain types of proteins: external membrane proteins attached to the membrane through glycosylphosphatidylinositol (GPI) anchors, cytosolic proteins posttranslationally modified through attachment of C16 (palmitate) and/or C14 (myristate) saturated fatty acids, and transmembrane proteins also largely modified by palmitate.[140] The precise relationship between microparticles and rafts is unknown, but it is clear that some proteins are overrepresented in microparticles (i.e., those that reside in detergent-resistant membranes in the parent cells) and some are underrepresented (i.e., those from the detergent-soluble portion of the plasma membrane).[141] Consistent with a raft origin of microparticles, treatment of parent cells with agents that deplete the membrane of cholesterol, a key raft-stabilizing lipid, decreases agonist-stimulated production of microparticles.[141] These findings have at least two important implications. First, they imply that microparticles are selectively enriched in signaling molecules, which they can transfer to other cells through membrane fusion. Second, the fact that microparticles arise from raft-rich regions implies that agents that lower membrane cholesterol, such as statins, may decrease production of microparticles under pathologic conditions. Consistent with this, statins have been shown to decrease the plasma concentration of platelet-derived microparticles in hyperlipidemic diabetic patients.[142]

In addition to differing considerably from the composition of the parent cells, the phospholipid and surface protein composition of microparticles differs between different parent cell types. Their composition also varies depending on the nature of the stimuli inducing them and on whether the cells produce them as a result of activation or apoptosis.

Membrane Lipids in Microparticles

Microparticle membranes isolated from healthy human subjects contain approximately 60% PC, 21% sphingomyelin, 9% PE, and 5% PS.[19,143] The lipid composition is reflective of the origins of microparticles from selected regions of the parent membrane. Platelet microparticles, for example, contain twice the PC and three- to sixfold more phosphatidylinositol than the platelet plasma membrane. In contrast, the contents of PS and PE were four- to fivefold and three- to fourfold less, respectively, in microparticles than in the platelet plasma membrane.[144]

Microparticles released from activated platelets are enriched in PS compared to those released from resting cells. The extent of microparticle PS exposure is determined by the nature of the agonist activating the platelets. For example, all of the microparticles released from calcium ionophore–activated platelets express PS on their surface. By contrast, only 50% of microparticles released from platelets activated with thrombin receptor activation peptide express PS.[145]

Similar differences in the phospholipid composition have been noted in microparticles released from endothelial cells. For example, IL-1-activated human umbilical vein endothelial cells (HUVECs) release microparticles enriched in PS and PE when compared to microparticles released from unactivated HUVECs. In addition, agonist-stimulated microvascular endothelial cells release more PS-containing microparticles than do those undergoing apoptosis.[47] Leukocyte-derived microparticles contain relatively more PE, sphingomyelin, and lysophospholipids when produced under inflammatory conditions.[27,146]

Microparticle Proteins

The protein profile of microparticles differs from that of the parent cell not only because they arise from selected regions of the plasma membrane but also because of the nature of the stimulus leading to their production. For example, platelets produce microparticles constitutively after stimulation or during apoptosis, but only microparticles produced as a consequence of activation express P-selectin (CD62P) and CD63.[32,33] These proteins are found in platelet α- and lysosomal granules, respectively, and only appear on the platelet surface when these granules fuse with the plasma membrane. Microparticles from activated platelets are also enriched in coagulation factor Va.[32] Similarly, microparticles from platelets activated with collagen express CD61, whereas those produced from complement-treated platelets do not.[33]

The situation is similar in other cells. For example, T-cell–derived microparticles express greater quantities of CD3ε and CD3ζ if produced in response to T-cell receptor activation rather than treatment with ionophore.[147] Likewise, microparticles from endothelial cells activated with TNF-α express more CD54 and CD62E and less PS than those released during apoptosis.[47]

Even a single stimulus can yield very heterogeneous populations of microparticles, a case in point being the vast heterogeneity in size and $\alpha_{IIb}\beta_3$ expression seen in microparticles from platelets exposed to sera of patients with heparin-induced thrombocytopenia.[148]

The protein composition of platelet microparticles has been examined by mass spectrometry–based proteomics. One study by Garcia et al.[149] identified 578 proteins in platelet microparticles. Many of these proteins were known to exist in platelets, but 380 had not been previously identified in platelets.

MICROPARTICLE QUANTIFICATION

To fully understand the role of microparticles in physiology and disease, it is imperative to be able to measure them accurately. Microparticle measurement is complicated by several factors, including the variety of cellular sources of microparticles found in blood, their heterogeneity in both size and composition even when derived from a single cell type, and the shortcomings inherent in virtually every technique used to measure them. These shortcomings, coupled with the inherent heterogeneity of microparticles from different cellular sources, render it almost impossible to compare different studies and call into question many of the conclusions derived from published studies.

Several methods are currently employed to measure microparticles and can be divided into optical and nonoptical methods. Optical methods include flow cytometry, nanoparticle tracking analysis, and fluorescence microscopy; nonoptical methods include scanning and TEM, atomic force microscopy (AFM), impedance-based flow cytometry, and functional and immunologic assays. None of these methods is considered standard for measuring and characterizing microparticles in

tahir99-VRG & vip.persianss.ir

biologic samples because each has unique advantages and liabilities. Flow cytometry has been the most common method used for detecting microparticles, but it has significant limitations. Perhaps the most prudent approach to microparticle measurement would be to use a combination of methods.

Light-Scattering Flow Cytometry

Flow cytometry is the most widely used method to detect and quantitate microparticles.[14] Most of the reported studies used this method to detect microparticles in biologic specimens because of the widespread availability of the equipment and several advantages inherent in its use. With this technique, microparticles can be analyzed singly and with high throughput, and a number of phenotypic parameters can be analyzed simultaneously.[24,65] The cytometer guides the microparticles in a focused fluid stream through a laser beam. The particle deflects light scattered forward and sideways, and the amount of light scattered in the two directions correlates with particle size and internal complexity, respectively. Conventional cytometers are unable to accurately resolve particles below a diameter of approximately 500 nm because this diameter is close to the wavelength of the light used to probe the sample (typically 488 nm).[12,145,150,151,152]

Efforts coordinated by the International Society on Thrombosis and Haemostasis (ISTH) have attempted to standardize microparticle analysis across laboratories by calibrating cytometers with polystyrene beads of uniform diameter (Megamix beads) across a range from 0.5 to 0.9 μm.[153,154] A bead of a particular diameter is meant to set the size of a microparticle with a similar forward scatter. However, because forward light scatter depends not only on particle diameter but also on its refractive index, a 0.5 μm bead displays the light-scatter characteristics of a microparticle of approximately 1 μm diameter.[16] This has led to significant underestimation of the number of microparticles in biologic samples. With this approach, conventional flow cytometry was able to detect close to 1,000 $CD41^+$ microparticles per 1 μL of plasma.[153,154] Other methods, such as AFM, detect close to 200,000 platelet microparticles per 1 μL.[12,155] Thus, enumeration of microparticles below 500 μm is currently not possible based on light-scattering characteristics alone. However, if microparticles can be labeled with a fluorescent marker of sufficient density, it is possible to identify those smaller than 500 μm. This advantage, however, is tempered by the fact that no universal marker of microparticle identity exists and because many phenotypic markers are present in insufficient quantity in smaller microparticles. Previously, microparticles were identified by their positivity for PS, but ample evidence now exists that not all microparticles express PS on their outer membranes and the percentage that do varies with the method used for PS detection.[23,47,145] Further, the extent of PS expression changes during sample preparation and storage.[11]

Perhaps, the biggest advantage of flow cytometry for microparticle measurement is the ability to identify the cellular source of the microparticles based on expression of unique protein markers detectable immunologically.[14] One caveat to this approach, however, is that a microparticle may express markers from more than one cell type because of fusion of microparticles from different sources, a possibility suggested by the fact that TF-bearing microparticles from monocytes are able to fuse with activated platelets in a process mediated by complementary counter-receptors on the two surfaces.[156]

Solid-Phase Capture Assays

Immunologic capture is not used as commonly in microparticle analysis as flow cytometry. The method is based on capture of microparticles with immobilized annexin V or cell-specific antibodies after appropriate centrifugation to remove cells.[24] Although this technique does not actually enumerate microparticles, it does give a very good indication of the number with certain characteristics. For example, although annexin V will only mark a subset of all microparticles, using it as the capture reagent could be a more accurate means of measuring the procoagulant potentials of plasma microparticles.[53,129]

This technique has several drawbacks. First, it depends on the ability of the immobilized reagent to recognize its target, the resistance of the interaction to washing, and the sensitivity of the detection.[15] Second, the technique is labor intensive and slow. Finally, antibody-based assays are subject to interference by soluble antigens.[157]

Functional Assays

These assays are primarily clot-based assays and may be the most clinically relevant if the intention is to assess the procoagulant activity of microparticles. Assays have been developed to detect both PS-expressing and TF-expressing microparticles.

PS-expressing microparticles can be evaluated with kits such as the Zymuphen MP activity assay.[129] This assay is similar to the solid-phase capture assay using immobilized annexin V except that coagulation factors V, X, and prothrombin are added to generate the prothrombinase complex and thrombin generated is detected using a chromogenic substrate. Another assay, called Proag PPL (Stago), assays the procoagulant activity of PS-expressing microparticles by the addition of phospholipid-free plasma to the test plasma and measurement of clotting time after the addition of factor Xa to the mixture.[158] A standard curve is used to extrapolate the quantity of phospholipid from the value obtained.

TF-bearing microparticles can be measured by capture using a TF antibody and then measuring the ability of the captured material to initiate coagulation by adding factors VIIa and X in the absence or presence of a TF antibody.[159] Another approach relies on isolation of the TF-bearing microparticles by ultracentrifugation and then testing their ability to initiate coagulation, as above.[160,161]

Atomic Force Microscopy

This infrequently used method was developed in 1986 by Binnig et al.[162] and is able to measure nanometer-sized particles, relying on the movement of a sharp-tipped cantilever over a biologic specimen affixed on a flat surface. Tip deflection and continuous scanning yield a three-dimensional representation of the surface, with a lateral resolution of 3 nm and a vertical resolution of 0.1 nm. Particles can be bound to the surface through antibodies, thus yielding information as to the quantity of particles of a certain phenotype.

Using this method, the quantity of platelet microparticles in normal plasma was estimated to be far greater than that estimated by conventional flow cytometry, approximately 200,000/μL.[12] The average diameter of the microparticles was 125 nm. However, AFM is unable to distinguish between microparticles and exosomes if

tahir99-VRG & vip.persianss.ir

the two share the membrane antigens used for capture, except by size since exosomes generally have diameters <100 nm.

AFM measurement of microparticles is limited by the complexity of the technique, the time required to run a single sample (i.e., hours), and the limited availability of the equipment.

Impedance-Based Flow Cytometry

This method relies on the Coulter principle that allows determination of the volume of a microparticle based on the change in impedance that occurs when a particle displaces electrolytes in a flow chamber. This technique is able to detect smaller particles than those detectable by conventional flow cytometry, with a lower limit of detection of 300 nm.[163] Given that AFM studies suggest that the majority of microparticles are below this size, impedance-based cytometry, while an improvement over conventional flow cytometry, may still be blind to the bulk of the microparticle population.

Most impedance-based flow cytometry only provides information about the size of particles. However, Zwicker et al.[164] were able to combine impedance with fluorescent labeling to quantify TF-bearing microparticles in a plasma sample.

Dynamic Light Scattering Spectroscopy

This method can detect particles ranging in size from 1 nm to 6 μm. Particle detection is based on the observation that their Brownian motion causes the intensity of scattered light to fluctuate.[165] The degree of fluctuation is inversely proportional to the size of the particle. This technique is useful for assessing particles of uniform size in a suspension but is not as useful when the particles vary substantially in size.[150]

Nanoparticle Tracking Analysis

This method also relies on the relationship between the size of a particle and its Brownian movement in a fluid medium. A laser beam is used to illuminate the particles and scattered light is detected with an optical microscope. Individual particles in the field of view are tracked by video to determine their velocity in the medium, and their size is calculated mathematically.[166] Recently, this technology was used to size and phenotypically characterize microparticles.[166,167]

Transmission Electron Microscopy

Because this technique uses electrons instead of photons to create an image, the shorter wavelength of electrons allows detection of smaller particles. The technique has a resolution of 1 nm, but is cumbersome because of the necessity to dehydrate and fix the samples. Further, these procedures can alter the size and morphology of the microparticles. TEM cannot be used to determine the microparticle concentration as it requires that the microparticles be concentrated by ultracentrifugation before analysis.

PREANALYTICAL CONSIDERATIONS IN THE ANALYSIS OF MICROPARTICLES IN BLOOD

Accurate quantification of microparticles is not only influenced by the technique used to measure them, but also by a number of important variables in how they are handled before that measurement. For the analysis of microparticles using flow cytometry, the ISTH workgroup has proposed a number of standardized methods for sample preparation, particle size calibration, and immunostaining, but did not specifically address the impact of preanalytical conditions on microparticle enumeration. Several of the conditions that can influence microparticle characterization are briefly discussed here.

Blood Collection

The use of smaller gauge needles increases the chance that blood cells will be damaged mechanically (or activated, in the case of platelets) due to the shear stress experienced in the needle lumen, thereby artifactually increasing the number of microparticles in the specimen to be analyzed.[51] This is particularly true when Vacutainer tubes are used to draw the blood because of the high velocity of the blood as it passes through the narrow tube. Ideally, needles of a larger gauge (19 gauge or larger) should be used, and the blood should be drawn without vacuum, preferably by gravity drainage. Artifactual elevations of microparticle counts due to endothelial damage can also be minimized by discarding the first 3 to 5 mL of blood drawn.[168,169]

Choice of Anticoagulant

It is important that the anticoagulant chosen not activate platelets. Commonly used anticoagulants include sodium citrate (3.2% or 3.8%), acid citrate dextrose (ACD), heparin, and ethylenediaminetetraacetic acid (EDTA). ACD significantly inhibits platelet function because of its low pH, minimizing platelet activation. In contrast, it was demonstrated that storage of platelet-rich plasma (PRP) obtained from sodium citrate–anticoagulated blood increased platelet activation and release of PS-expressing microparticles compared to PRP obtained from EDTA-anticoagulated blood.[170] It should be kept in mind that the binding of annexin V to PS requires a high concentration of calcium, and therefore blood collected into EDTA must be recalcified before evaluating the PS content of its microparticles.[23,171]

Another study demonstrated that the microparticle concentration of blood collected in heparin-containing tubes was much higher than that collected into sodium citrate anticoagulant.[172] Whether this represents an effect of the heparin on blood cells in the collection vessel or improved microparticle preservation in heparin is unknown.

Processing Time from Collection to Centrifugation

In general, as the interval between venipuncture and centrifugation increases, so does the concentration of PS-positive platelet microparticles in the blood due to activation of platelets in the tubes.[173] In one recent study, the concentration of microparticles almost doubled during the 2 hours between venipuncture and centrifugation.[174]

Centrifugation Speeds, Single versus Double Spins

As yet, a standardized protocol for blood centrifugation before microparticle analysis has not been established, with published studies using a wide variety of centrifugation speeds and times.[11]

tahir99-VRG & vip.persianss.ir

Protocols that include single centrifugation steps in general yield higher concentrations of PS-positive microparticles because they fail to remove all platelets from the suspension. The residual platelets continue to release microparticles when they are activated by agitation or centrifugation. A second centrifugation step was shown to decrease the quantity of residual platelets by approximately 65%.[24] High centrifugation speeds decreased the numbers of microparticles in plasma samples.[157,169]

Storage and Freezing of Samples

Platelet-poor plasma should ideally be prepared immediately following blood collection to avoid increasing the microparticle concentration in the sample.[173,174] If blood must be stored before centrifugation for logistical reasons, it should be kept at room temperature without agitation.[24] Storage of blood at cold temperatures can activate platelets and coagulation, increasing the production of microparticles.[11,175]

Although freezing and thawing of plasma samples is very common in medical investigations, standardized protocols have not been established for microparticle studies. One study on the effect of storage on microparticle number found that microparticle counts dropped dramatically in isolated microparticle samples even with only 4 hours of storage.[172] The decrease was not a result of protein proteolysis (marker removal). This finding contrasts to a study in which the number of platelet microparticles was found to be increased in frozen plasma samples prepared after a single centrifugation step.[176] In doubly centrifuged samples, the microparticle number was lower, probably reflective of more efficient platelet removal.[161]

Isolation of Microparticles

Although flow cytometry can be performed on plasma, methods such as TEM and AFM require concentrated microparticle preparations which are generally prepared by ultracentrifugation of plasma samples.[12] This step results in loss of microparticles and may prevent accurate enumeration of microparticles and comparison of their numbers between samples.[157,169]

MICROPARTICLES AND DISEASES

Microparticles have been implicated in the pathology of a number of pathologic states characterized by thrombosis, bleeding, inflammation, angiogenesis, or cancer. Because of the very large number of these studies, they are summarized in Table 36.2. Here, we focus on the procoagulant function of microparticles.

The procoagulant properties of microparticles relate primarily to the presence of PS and TF. Those containing both elements have higher procoagulant activity than those containing only one or the other.[66,177] PS on the external membrane leaflet of microparticles imparts on them the capacity to bind phospholipid-binding clotting factors, including those containing γ-carboxyglutamic acid (GLA) motifs (prothrombin and factors VII, IX, and X) and those with phospholipid-binding C domains (factors V and VIII).[29,32,178] In addition, PS-bearing microparticles are able to bind the GLA-containing anticoagulant proteins, protein C, and protein S.[21,179–181] This surface also allows formation of the enzyme complexes that catalyze activation of downstream serine protease zymogens in the amplification scheme of the coagulation cascade. One such complex is the tenase complex, composed of the activated forms of factors VIII and IX on a PS-rich surface in the presence of calcium. Tenase converts zymogen factor X to factor Xa, which itself participates in the prothrombinase complex that converts prothrombin to thrombin.

Before any of these reactions can take place in the blood, coagulation must be initiated by a complex of TF and factor VIIa, a small amount of which circulates in the blood as a result of autocatalytic activation of factor VII. The TF/VIIa complex activates the two zymogens, factors X and IX. The culmination of the coagulation cascade is the production of thrombin, which cleaves fibrinogen to fibrin, activates the transglutaminase factor XIII, and activates factors V, VIII, and XI to propagate its own generation. In addition, thrombin activates platelets, which can then aggregate, and endothelial cells, which can release large quantities of von Willebrand factor and display molecules on their surfaces that are adhesive for leukocytes.

Until relatively recently, TF was believed to be excluded from blood except under pathologic conditions.[182] In 1999, however, Giesen et al.[183] demonstrated the presence of low levels of TF in blood that were able to initiate coagulation. These investigators, and others,[184] found that most of the circulating TF was associated with microparticles,[185] although this group also described a circulating alternatively spliced isoform of TF that was incapable of activating coagulation pathways.[184]

During major blood vessel injury, coagulation is activated by TF in the vessel wall, of which the adventitia is a rich source.[186] In more circumscribed vessel wall lesions, the vessel wall TF may be quickly occluded by the platelet/fibrin thrombus, in which case the contribution of blood-borne TF may become more important. A similar situation exists in dealing with lesions that are more superficial and do not result in the exposure of TF. Such a mechanism of TF accumulation has been demonstrated in experimental models of arterial thrombosis.[156,187–189] Some investigators have argued that in healthy humans, the quantity of TF in the blood is insufficient to initiate coagulation[19,190,191]; the counter argument is that even if TF-bearing microparticles are present in low quantity, continual blood flow provides them in a virtually infinite and replenishing supply.

The association of TF-bearing microparticles with platelet-rich thrombi requires complementary membrane proteins on both the microparticles and platelet, which serve to dock the microparticles on the platelet surface. Activated platelets express P-selectin on their surfaces due to translocation of α-granule P-selectin to the plasma membrane. This protein serves to dock the microparticles through its counter-receptor P-selectin glycoprotein ligand-1.[192] Microparticle docking precedes fusion with the activated platelets, a process requiring expression of PS on both membranes and inhibited by annexin V.[193] Fusion of microparticles with activated platelets transfers to the platelets the contents of the microparticles, including TF, increasing the ability of the platelets to activate coagulation.

Elevated concentrations of microparticles, with potential procoagulant and proinflammatory roles, have been described in a large number of diseases associated with both arterial and venous thrombosis. Many of these studies are listed in Table 36.2. Among the diseases in which microparticles have been proposed as contributing to thrombosis, the most compelling evidence exists for cancer. Studies have demonstrated both increased microparticle-associated TF antigen[161,164,194] and TF activity[160,161,195–197] in cancers, even though the antigen and activity do not necessarily correlate. For example, increased

tahir99-VRG & vip.persianss.ir

concentrations of TF-bearing microparticles were found in patients with colorectal cancer, but there was no corresponding increase in the microparticle TF activity.[194] Elevated levels of TF-bearing microparticles in the blood of patients with cancers strongly correlate with occurrence of venous thromboembolism.[160,164,196,198,199] Some studies have also suggested a role for tumor-derived TF-bearing microparticles in venous thromboembolism in patients with ovarian and pancreatic cancers.[200,201] TF-bearing microparticles arising from the tumor have been demonstrated in a patient with florid Trousseau syndrome.[185]

CONCLUSIONS

There is substantial evidence that cell-derived microparticles circulating in blood play important roles in biologic phenomena and medical conditions, being both purveyors of information between cells and tissues and agents of disease. Much work has been done to unravel these roles, but much also remains to be done, particularly in the development of high-throughput, sensitive, and widely available means of measuring microparticles and in determining the appropriate parameters to measure.

CHAPTER 37

Overview of Vascular Biology

WILLIAM C. AIRD

OVERVIEW OF VASCULAR BIOLOGY

The coagulation system has evolved to prevent excessive blood loss at sites of vascular injury. As much as the fluid phase of clotting is readily amenable to detailed molecular and biochemical dissection, thrombus formation is typically localized at the blood vessel wall. Indeed, the vascular wall plays a central role in orchestrating the hemostatic response. Thus, a full appreciation of the mechanisms of coagulation requires a sound understanding of vascular biology. In recognition of the central role of the blood vessel wall in hemostasis and owing to significant advances in this area over the past 6 years, we have expanded the section on Vascular Biology in this sixth edition of Hemostasis and Thrombosis. By way of an overview, we wish to emphasize several themes that are relevant to this section.

ANGIOGENESIS: MULTIPLE LINKS WITH HEMOSTASIS

The formation of new blood vessels is essential during embryonic development (ontogeny). Angiogenesis continues to play an important role in the early postnatal period in the lung, heart, brain, and retina[1] and resumes and/or continues into adulthood with the reproductive cycle, wound healing, and post-ischemic tissue repair. Qualitative and quantitative abnormalities in angiogenesis underlie many disease states. It has long been recognized that hemostasis must be highly coordinated with angiogenesis to prevent excessive blood loss or thrombosis prior to the stabilization of newly formed vessels. Fibrin provides a provisional matrix scaffold along which endothelial cells can migrate. Also, fibrin serves as a sustained release reservoir for endothelial growth factors and fibrinolytic enzymes. Platelets release vascular endothelial growth factor (VEGF), and VEGF signaling, in turn, alters the expression of procoagulant and anticoagulant proteins in endothelial cells.

Clotting factors not only cleave downstream substrates in the clotting cascade but they also cleave and activate receptors on the surfaces of cells, including endothelial cells (see Chapter 44). The importance of these cellular effects is evidenced by studies of knockout mice. For example, deletion of tissue factor, but not fibrinogen, is embryonic lethal and is associated with abnormal vascular development.[2,3] Mice that are null for the thrombin receptor, protease-activated receptor 1 (PAR-1) may survive, but they too develop abnormal vasculature.[4] The latter phenotype is rescued by expression of endothelial PAR-1.[5] These and other findings suggest that thrombin-PAR-1 signaling in the endothelium is important for vascular development, independent of its effect on clotting.

In addition to their role as signaling molecules, proteins of the coagulation system have been found to harbor cryptic antiangiogenic fragments. For example, Judah Folkman's group first reported that angiostatin corresponds to the first four kringle domains of plasminogen.[6]

Since the last edition of Hemostasis and Thrombosis, the field of angiogenesis has witnessed significant advances. For example, as outlined in Chapter 38, we now have novel insights into the mesodermal origin of endothelial cells from different sites in the vasculature, not just arteries and veins but also capillaries and the endocardium. There is new information about the interplay between tip and stalk cells and mechanisms of lumen formation. Finally, there is an evolving awareness of the importance of lymphatics and their endothelial lining as dynamic components of the cardiovascular system.

THE BLOOD VESSEL WALL: A STRUCTURAL AND FUNCTIONAL ENTITY

The anatomy and histology of the vascular wall have been accurately described for over two centuries (FIGURE 37.1). As originally portrayed, the vasculature comprises a system of blood vessels aligned in series, beginning with arteries, followed by arterioles, capillaries, venules, and veins. There are some interesting exceptions to this canonical arrangement. For example, the hepatic artery and portal vein both empty into the capillaries of the liver (hepatic sinusoids). The glomerular capillaries drain into arterioles, not venules. In general, arteries have thicker walls than veins and carry oxygenated blood. However, that is not always the case. For example, the oxygen content of the pulmonary artery is less than that of the pulmonary vein. The same is true for the umbilical artery compared with umbilical vein.

Light microscopy and special stains reveal site-specific differences not only in wall thickness between different segments of the vasculature but also in the size and composition of different layers in the wall, including the intima, media, and adventitia. Electron microscopic studies have demonstrated remarkable ultrastructural heterogeneity at the level of the endothelium. Histochemical analyses have provided important information about the molecular composition of the blood vessel wall. Endothelial cells and smooth muscle cells express distinct patterns of genes, the nature of which varies between different regions of the vasculature. The subendothelial surface is rich not only in collagen but also in heparan, von Willebrand factor, and tissue factor. Indeed, presence of tissue factor on the abluminal side of the endothelium (on smooth muscle cells and fibroblasts) has given rise to the concept of a "hemostatic envelope" surrounding the vasculature.

tahir99-VRG & vip.persianss.ir

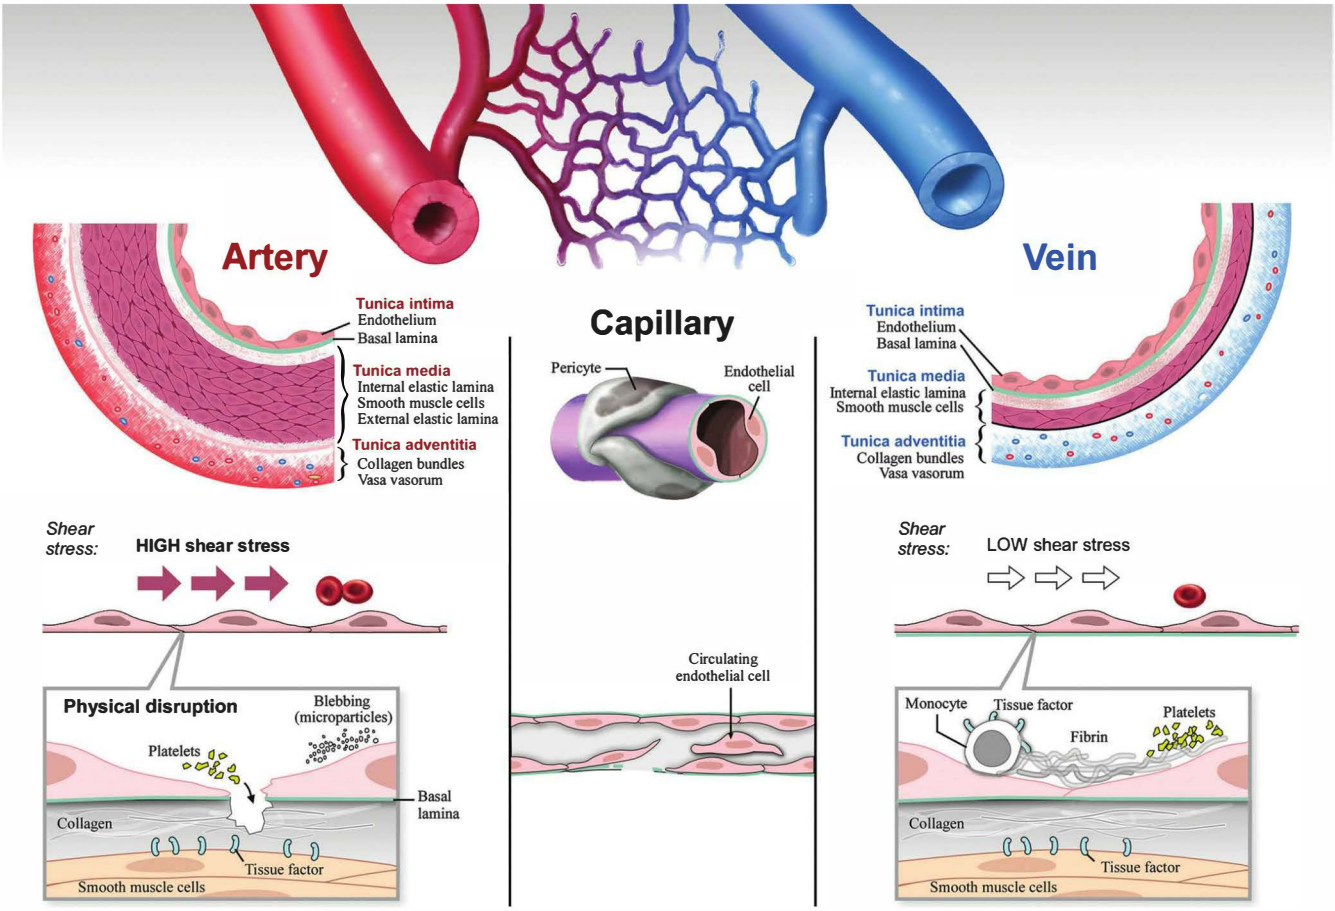

FIGURE 37.1 The blood vessel wall. Arteries and veins are surrounded by three distinct layers: the tunica intima, the tunica media, and the tunica adventitia. The tunica intima comprises endothelial cells and an underlying basement membrane or basal lamina, the media consists of an internal elastic lamina and one or more layers of smooth muscle cells, and the adventitia is composed of collagen bundles and vasa vasorum (with the interesting exception of intracranial arteries). Capillaries consist of a layer of endothelial cells (which may be continuous, fenestrated, or discontinuous), an underlying basal lamina (which may be incomplete, e.g., the case of liver sinusoids), and a variable number of pericytes (the degree of pericyte coverage varies between different vascular beds). All endothelial cells are derived from mesoderm, whereas other cellular components of the vascular wall may originate from mesoderm or neural crest. The vascular wall (especially the adventitia and the pericyte compartment) is a reservoir for different types of stem and progenitor cells. Flow patterns vary both between different blood vessel types (e.g., high flow in arteries and low flow in veins) and between different segments of the same blood vessel (e.g., at branch points in arteries and in valve pockets in veins). The pathophysiology of thrombosis differs between arteries and veins. In arteries, physical disruption of the endothelial lining leads to exposure of blood to underlying tissue factor (extravascular procoagulant activity). In veins, low shear stress and hypoxia lead to endothelial dysfunction and trapping of platelets and leukocytes, with secondary activation of the clotting cascade (intravascular procoagulant activity). Circulating endothelial cells and endothelial-derived microparticles are markers of endothelial cell dysfunction.

Like other components of the vessel wall, tissue factor levels vary between segments of the vasculature.[7] For example, expression is particularly high in the heart (tissue factor is expressed by cardiomyocytes), which may help explain why patients with hemophilia do not bleed into their hearts, despite the extreme forces associated with the cardiac cycle. Although tissue factor is readily expressed in cultured endothelial cells, there is little evidence that it is normally expressed in the intact endothelium.[7] Aberrant expression of tissue factor in the endothelium has been reported in certain diseases states, including atherosclerosis, tumors, and sickle cell disease, where it likely contributes to the underlying pathophysiology. Tissue factor is also expressed by circulating monoyctes. The relative role of vessel wall and hematopoietic tissue factor in mediating clot formation has been the subject of considerable debate and investigation.[8,9]

As discussed in Chapter 38, arteries and veins have different developmental origins. It is now widely accepted that all endothelial cells are derived from mesodermal progenitors. However, other components of the blood vessel wall may arise

tahir99-VRG & vip.persianss.ir

from other germ layers, namely, the neural crest. The importance of understanding the embryonic origins of the blood vessel wall lies in the fact that different origins may result in site-specific epigenetically programmed genes, including those that are involved in mediating hemostasis and thrombosis. The extent to which these differences are "locked in" will influence the modulability of the hemostatic balance from one location to the next. On a more general level, differences between arteries and veins have important implications for mechanisms of thrombosis. For example, it is widely believed that a breach in the vessel wall (and platelet activation) is a more common initiator of thrombosis on the arterial side of the circulation, whereas endothelial dysfunction and stasis of flow (and intravascular procoagulant activity) are more important in venous thrombosis.[10]

Whereas larger vessels (arteries, arterioles, veins, and venules) are invested with smooth muscle cells, capillaries are essentially three-dimensional tubes of endothelium surrounded to a variable extent by contractile cells termed pericytes. These cells are highly enigmatic. They express characteristic markers. However, none is specific to the pericyte lineage. Recent studies suggest that pericytes have properties of stem cells in both embryonic and adult tissues.[11] Stem and progenitor cells have also been identified in the adventitial layer of arteries. Interestingly, there is new evidence for the existence of hemogenic endothelium, which has the capacity to transdifferentiate into hematopoietic cells.[12]

Some but not all veins contain valves. These guide the direction of blood flow and prevent reflux. They are most numerous in veins of the lower extremity where the return of blood operates against gravity.[10] Venous thrombosis in the lower limbs typically occurs in the valve pockets, where endothelial cells are exposed to reduced flow velocities and shear stress during the valve cycle, where blood is relatively hypoxic, and where leukocytes and platelets tend to become trapped.

The walls of large arteries and veins contain a network of microvessels, termed vasa vasorum (see Chapter 41).[13] These tiny blood vessels provide oxygen and nutrients to the cells of the media and adventitia. There is increasing evidence for a role of the vasa vasorum in disease. For example, in atherosclerosis the vasa vasorum also extends into the intima and nourishes developing atherosclerotic plaques, and plaque growth is decreased through the inhibition of vasa vasorum angiogenesis and disruption of blood supply to the developing lesions.[13,14]

THE ENDOTHELIUM: ORCHESTRATOR OF LOCAL HEMOSTATIC BALANCE

The endothelium forms the inner cell lining of blood and lymphatic vessels. The endothelium was first recognized by Galen, who observed it grossly as a membrane on the inside surface of large arteries. In 1839, Theodor Schwann first noted the presence of cells lining capillaries using light microscopy of unstained samples.[15] In 1860, the use of silver nitrate staining provided definitive evidence for the existence of cells lining blood vessels. One year later, Wilhelm His named the endothelium, in order to distinguish it from epithelial surfaces that are directly or indirectly exposed to the outside world. The endothelium was once thought to serve as a physical barrier between flowing blood and underlying tissues. However, as discussed in Chapter 42, it is now appreciated that the endothelium participates in many physiologic functions. The endothelium plays several roles in hemostasis (see Chapter 43). First, it provides cell membrane surface and phospholipid for assembly of reactions. Second, it expresses and/or releases procoagulant and anticoagulant molecules. Third, it interacts with platelets and white blood cells, which in turn contribute to the hemostatic response. Fourth, it controls blood flow through the release of vasodilatory and vasoconstricting molecules. Endothelial cells display marked phenotypic heterogeneity. Thus, their contribution to hemostasis varies from one vascular bed to another. Site-specific impairment of endothelial function helps to explain the focal nature of many vasculopathic diseases, including thrombosis.

ENDOTHELIAL MICROPARTICLES: BLURRING THE LINE BETWEEN VESSEL WALL AND FLUID PHASES OF COAGULATION

There is now evidence that endothelial progenitor cells (EPCs), endothelial cells, and endothelial-derived microparticles circulate in the blood. There has been significant debate about how to define, enumerate, and phenotype these various elements (see Chapter 48). For example, in most studies, EPCs actually represent hematopoietic and not endothelial progenitors. True EPCs (also termed blood outgrowth endothelial cells or late outgrowth endothelial cells) are indeed present in blood but at extremely low numbers. Endothelial cells may detach from the vessel wall and circulate. These are termed circulating endothelial cells (CECs). They normally circulate in very low numbers (<10/mL). However, in certain disease states, such as sickle cell disease, their numbers may be increased. Endothelial plasma membrane blebbing leads to the formation of small (100 nm to 1 μm in diameter) anucleate microparticles. Endothelial microparticles (EMPs) can carry endothelial proteins such as vascular adhesion molecule 1, intercellular adhesion molecule 1, E-selectin, VEGF receptor 2, endoglin, and tissue factor. Thus, EMPs may contribute to the circulating pool of tissue factor. The protein composition of the EMP depends on the stimulus triggering their release. EMPs externalize phosphatidylserine and thus provide a surface for the assembly of activated coagulation factors. However, their procoagulant activity may be counter balanced to some extent by the expression of natural anticoagulants, such as thrombomodulin and endothelial protein C receptor. Interestingly, EMPs can result in the horizontal transfer of material from EMPs to other cells, including monocytes, platelets, and other endothelial cells. In this way, they are considered to be bioactive vectors that contribute in an endocrine manner both to physiology and pathophysiology. Their potential role as a diagnostic marker for vascular disease is discussed in Chapter 48. Importantly, the discovery of EMPs blurs the distinction between vessel wall and the fluid phase of coagulation.

VIRCHOW TRIAD: A USEFUL EXPLANATORY FRAMEWORK 150 YEARS LATER

Virchow triad represents a time-honored explanatory framework for understanding the mechanisms of thrombosis. A recent assessment of his work shows that Virchow proposed the triad (phenomena due to "irritation of the vessel," "blood coagulation," and "interruption of the bloodstream") in 1856 to describe conditions required for clot *propagation*.[16] At the

tahir99-VRG & vip.persianss.ir

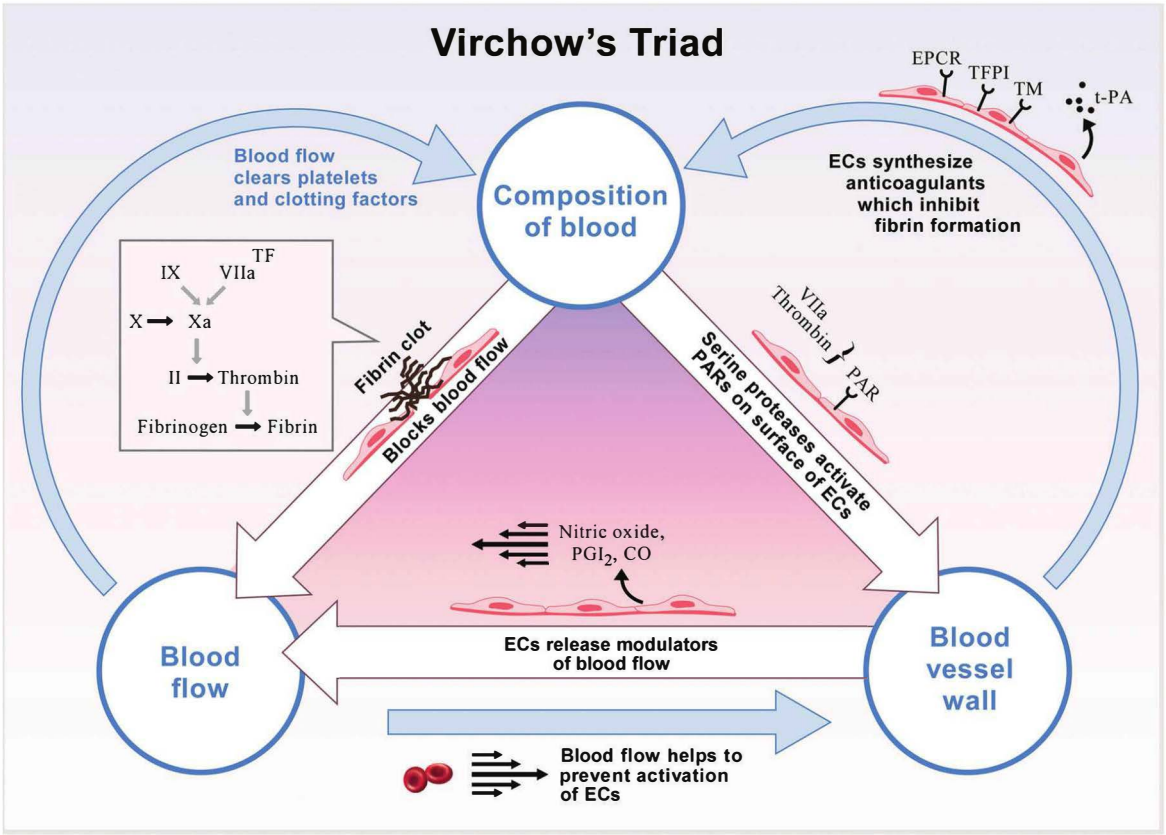

FIGURE 37.2 Virchow triad. Shown are the interconnections between the three components of the triad. ECs, endothelial cells; PGI2, prostacyclin; NO, nitric oxide; PAR, protease-activated receptor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; EPCR, endothelial protein C receptor.

time, there was no consensus as to the whether blood vessels had walls, let alone a cellular lining. Indeed, Virchow was unlikely to have been aware of the existence of endothelial cells when referring to the "vessel." Regardless of Virchow's original intentions, the triad has been adopted and refined over the past 150 years. Today, the triad may be classified as (a) the composition of blood, including circulating cells and plasma proteins; (b) the structural and functional integrity of the vessel wall; and (c) blood flow. The triad may be applied not only to the veins but also to the rest of the vasculature, including arteries and microvessels. It is now recognized that more than one abnormality in the triad is often required to provoke thromboembolism. Indeed, the three components of the triad are integrally linked (FIGURE 37.2). From the standpoint of the vessel wall, the following connections are worthy of consideration:

Vessel Wall–Flow Interactions

The endothelium contributes to and is in turn affected by blood flow. Endothelial cells are exposed to shear stress (a tangential force) and strain (a perpendicular force). These biomechanical forces alter signaling in endothelial cells and thus are important determinants of endothelial phenotypes (see Chapter 39). The architecture of the vasculature plays an important role in determining local flow regimes. For example, flow patterns differ between different regions of arteries (e.g., straight segments, branch points, curvatures, stenotic lesions) and veins (e.g., valve pockets). These different flow patterns translate into different susceptibilities to thrombosis. There are many reasons for this. For one, site-specific difference in shear stress can differentially influence the supply and clearance of clotting factors and cells at the blood vessel surface. Shear stress itself can activate platelets. Moreover, because shear stress is sensed and transduced by the endothelium, spatial differences in flow regimes contribute to phenotypic heterogeneity of the endothelium.

In addition to being affected by blood flow, endothelial cells contribute to vasomotor tone through the release of vasodilatory and vasoconstricting molecules, including nitric oxide (NO), carbon monoxide, endothelin-1, and epoxyeicosatrienoic acids. The discovery in the 1980s that NO is not simply a free radical but rather is a biologic signaling molecule in the cardiovascular system was recognized with the Nobel Prize in Physiology and Medicine in 1998. Since that time, there have been remarkable advances in the field (see Chapter 40). For example, there is new information on formation of NO adducts, the relative role of isoforms on homeostasis, and novel posttranslational modifications. There is compelling evidence that red blood cells carry an NO derivative. The precise nature of the interactions between NO and hemoglobin and their biologic significance have been hotly debated.[17,18] However, it is tempting to speculate that blood-transported NO functions in an endocrine manner to mediate distal vasodilation.

tahir99-VRG & vip.persianss.ir

Vessel Wall–Blood Components

As producers of procoagulant and anticoagulant molecules, endothelial cells contribute to the local balance of hemostatic factors. When activated, they provide a cell surface for the assembly of clotting factor complexes. Endothelial cells also release microparticles, which can promote clotting at distal sites. Several serine proteases, in turn, are capable of binding and activating PARs on the surface of endothelial cells, resulting in a proinflammatory and procoagulant state. In addition to the bidirectional communication between the endothelium and the various clotting factors, endothelial cells also engage in cross talk with circulating cells. The interaction between endothelial cells and platelets is an important theme throughout this volume. Chapters 46 and 47 detail the interactions between endothelium and circulating leukocytes, which also have important roles in prothrombotic states.

EVOLUTION

If we take a step back and ask why coagulation evolved in the first place, our answer focuses squarely on the vasculature. Clotting evolved in an ancestral vertebrate to prevent excessive blood loss and to maintain blood in its fluid state within blood vessels. Indeed, it is no coincidence that the clotting cascade arose during the same narrow window of time that saw the emergence of a highly pressurized closed circulation and that the clotting cascade acquired increasing complexity as blood pressures increased from fish to tetrapods. Thus, from an evolutionary perspective, it is the vasculature that drove the selection of coagulation.

In summary, it is not practical to approach blood coagulation without considering the role of the blood vessel wall. The field of vascular biology continues to make significant strides, and many recent advances have provided novel insights into mechanisms of hemostasis and thrombosis. This new and revised sixth edition section on Vascular Biology endeavors to capture many of the established and more recently recognized connections between the vascular and coagulation systems.

CHAPTER

38

Development of the Vasculature, Angiogenesis, and Lymphangiogenesis

AERNOUT LUTTUN AND PETER CARMELIET

As species have become larger and more complex during evolution, nature has provided them with two tubular transport and communication systems, the blood vascular and the lymphatic system. While the former is responsible for oxygen and nutrient delivery to nearly all tissues, the latter mostly runs alongside the blood vascular system and serves to recirculate excess interstitial fluid (ISF) to take up lipids from the gastrointestinal tract and to regulate immune responses. The blood vascular system forms a closed loop with three main segments: the arteries carrying oxygen-rich blood from the heart, the capillaries that exchange oxygen with the tissues, and the veins that bring the deoxygenated blood back to the heart. In contrast, the lymphatic system is a blind-ended circuit beginning with the initial lymphatics (capillaries; specialized in fluid uptake) that connect to collector vessels (which pump the lymph fluid forward) that end up in larger ducts. These ducts (the thoracic duct and the right lymphatic duct) connect the lymphatic system with the venous arm of the blood vascular system. Given their ubiquitous presence in nearly all organs of the body, both vascular systems are frequent targets of disease. For instance, excessive blood vessel growth promotes cancer growth, while a shortage of blood vessels leads to ischemia and ultimately tissue death. Impaired lymph clearance results in lymphedema, characterized by disfiguring tissue swelling, while increased lymphatic growth can result in metastatic spreading of tumors. Hence, in order to remedy these diseases, a thorough understanding of the development of both vascular systems is paramount.

Both systems are lined on the inside ("endo" in Greek) by endothelial cells (ECs). While this monolayer of cells was long thought to be merely a passive barrier between tissues and blood or lymph, now we have come to understand that ECs are dynamic sensors that continuously adapt their behavior to their environment. This versatile behavior results in remarkable morphologic, functional, and molecular differences, a phenomenon known as "endothelial heterogeneity."[1,2,3] We distinguish different levels of heterogeneity. During vascular growth, the EC can adopt at least three distinct functional behaviors, that is, the tip, stalk, or phalanx cell. In addition, "macrovascular heterogeneity" refers to the differences between ECs from arteries, veins, and lymphatic vessels, while "microvascular heterogeneity" relates to the differences at capillary level in distinct organs. The existence of EC heterogeneity has vast consequences for disease development and hence should be taken into account when designing new therapies based on stimulating or inhibiting vessel growth. While proper blood/lymphatic vessel formation also involves non-EC types (e.g., smooth muscle cells or SMCs and hematopoietic cells), in this overview we describe the development of both vascular systems mainly from an endothelial perspective.

THE BLOOD VASCULAR SYSTEM

On the Origin of Blood Vascular Endothelium

Endothelia in the developing vascular system have a common origin, the mesoderm. The mesoderm is one of the three embryonic germ layers that segregate during gastrulation, starting around embryonic day (E) 6.25 in the mouse embryo (reviewed in Refs.[4,5]). At this time, cells from the epiblast converge toward the posterior proximal pole of the embryo to form the primitive streak (PS), which subsequently extends in the anterior direction to the distal tip of the embryo (reviewed in Ref.[6]). Mesoderm is formed when epiblast cells entering the streak undergo epithelial-to-mesenchymal transition (EMT). Distinct mesodermal zones become patterned according to the time and site of passage through the PS (FIGURE 38.1; reviewed in Refs.[4,7]): the earliest, most posterior cells become extraembryonic mesoderm (the progenitor of yolk sac blood islands), the intermediate somewhat later invading cells become lateral plate (giving rise to the intraembryonic axial vessels), paraxial (giving rise to the somites), and cardiac mesoderm and the epiblast cells that enter through the anterior tip of the streak become axial mesoderm (comprising the notochord, the prechordal plate, and the node). Interestingly, each of these mesoderm layers has the intrinsic capacity to form ECs, with the exception of the axial mesoderm.[8]

Mesoderm induction, EMT, and mesoderm patterning involve a complex interplay and gradient of signals (including bone morphogenetic proteins [BMPs], Wnt, fibroblast growth factors [FGFs], nodal, and Hox proteins).[4–6,9,10] As epiblast cells have to move extensively during PS formation and mesoderm patterning, they do so by following certain physical (e.g., a basal lamina underneath the moving cells) and chemical guidance cues. In the avian embryo, this involves attractive and repulsive signals (e.g., SDF-1/CXCR4, cAMP, FGFs/FGFR; Refs.[4,6]). While moving, epiblast cells extend lamellipodia/filopodia in the direction of migration.[6] The idea that this process may resemble the movement of angiogenic sprouts or neural growth cones, which involves certain classes of guidance molecules (see below), is intriguing. For instance, the EphB4 receptor (expressed together with its ligand ephrinB2 in embryoid bodies) was recently shown to be involved in modulation of mesoderm induction, which may imply a role in migration/patterning as well.[11] Regarding the location of the emergence of ECs, two main regions can be distinguished, corresponding to two temporal waves of vascular development, extraembryonic

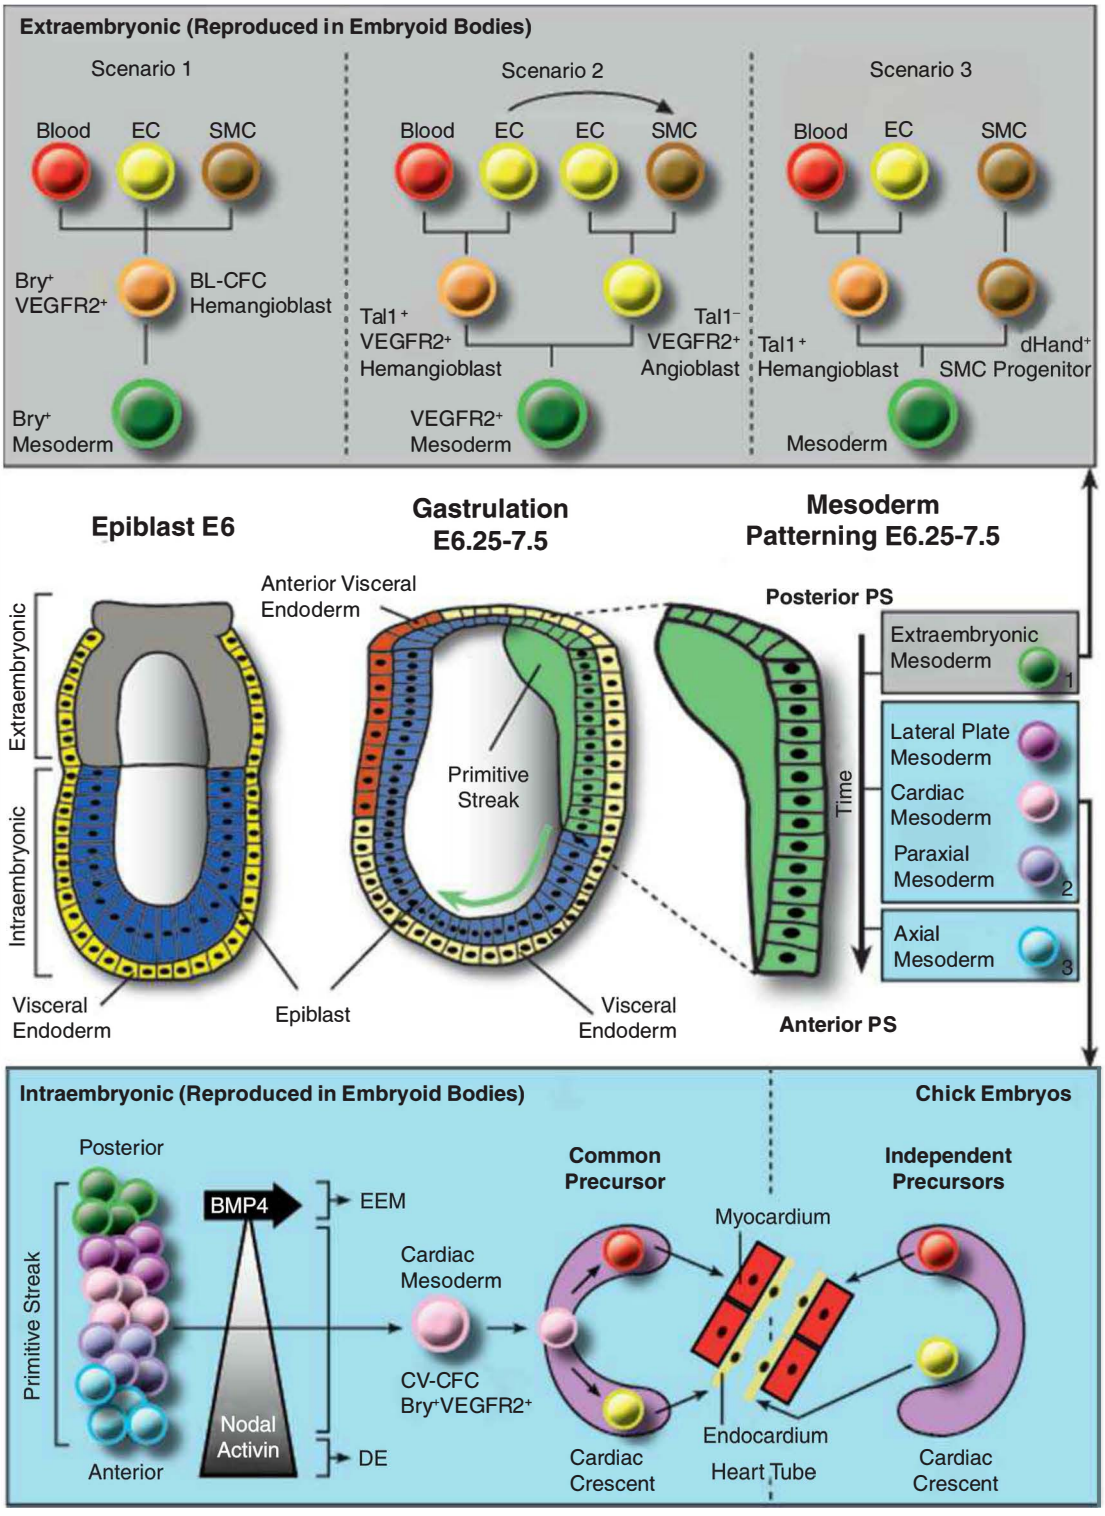

FIGURE 38.1 On the origin of blood vascular ECs. All embryonic tissues derive from the epiblast (*blue* in **left middle panel**). During gastrulation (**central middle panel**), a subset of epiblast cells converges toward the posterior proximal pole to generate the primitive streak (PS; *green structure* in **right** and **central middle panel**) that expands toward the anterior pole *(green arrow)*. Depending on timing (indicated by a time axis and numbering in boxes on the right) and location (across the anterior–posterior PS axis) of passage through the PS, epiblast cells give rise to distinct mesodermal derivatives. Extraembryonic hematopoiesis and vasculogenesis can be reproduced in a culture system based on ESCs, that is, embryoid bodies. At least three scenarios (*gray box* at the **top**) have been described for the cellular hierarchy that gives rise to the first hematopoietic and vascular precursors. In scenario 1, hematopoietic cells, endothelial cells (ECs), and smooth muscle cells (SMCs) arise from a common precursor, "the hemangioblast" (its corresponding ESC-derived culture equivalent is called "blast colony-forming

and intraembryonic, the former starting with the migration of EC precursors into the yolk sac (around E6.5 to 7.0 in the mouse[12]) and the latter starting slightly later around E7.3 with the appearance of EC precursors in the cranial region.[13]

Emergence of Extraembryonic EC Precursors

The extraembryonic mesoderm in birds and mammals is organized in two layers separated by the coelom, the somatopleural mesoderm (adjacent to ectoderm), and the splanchnopleural mesoderm (aligned with endoderm). EC emergence in the splanchnopleural mesoderm of the yolk sac occurs simultaneously with the appearance of primitive erythrocytes. This has fueled the idea of the existence of a common precursor, "the hemangioblast," a term that was already coined in 1932 by Murray.[14] *In vitro* evidence for the hemangioblast was given by the discovery of a bipotential precursor, called the "blast colony-forming cell" (BL-CFC) during mouse and human embryonic stem cell (ESC) differentiation, a system that faithfully recapitulates the early stages of vasculogenesis and (primitive) hematopoiesis (reviewed in Refs.[15,16]). *In vivo* evidence for the hemangioblast was shown in reporter mice expressing GFP under the *brachyury* (Bry) promoter[12] and in zebrafish.[17] Interestingly, the hemangioblast concept is evolutionary conserved since a similar vascular/hematopoietic precursor has been described in *Drosophila melanogaster*.[18] Around E6.5 to 7.0 in the mouse, the Bry-GFP$^+$ precursors, coexpressing vascular endothelial growth factor receptor-2 (VEGFR2), emerge in the posterior region of the PS and move into the yolk sac. There, they form polarized aggregates in which the outer cells give rise to flat ECs and the inner cells become primitive erythrocytes. Several of these structures subsequently fuse to form a rudimentary capillary network.[7,19]

Not all yolk sac blood vessels arise from hemangioblasts. Initial static observations of stained mouse embryos suggesting that some unipotential "angioblasts" are present in the yolk sac[13] were later confirmed by kinetic analysis of mouse embryonic/stromal cell cocultures (a system equivalent to the early gastrulating embryo), where two waves of EC precursors were found, one consisting of angioblasts and a second composed of hemangioblasts.[20] The relative importance of angioblast versus hemangioblast contribution to ECs is still a matter of debate since clonal analysis revealed that only a minor portion of ECs derives from hemangioblasts.[21] In addition to ECs and blood cells, the yolk sac mesoderm also harbors SMCs. Several scenarios exist concerning their origin (FIGURE 38.1). One theory claims that a common Bry$^+$VEGFR2$^+$ precursor (the hemangioblast) exists for the three lineages (blood, EC, and SMC).[12,15,22] According to another study, a VEGFR2$^+$ mesodermal precursor first segregates into a VEGFR2$^+$Tal1$^+$ hemangioblast (which can give rise to hematopoietic stem cells or HSCs and ECs) and a VEGFR2$^+$Tal1$^-$ angioblast (which can give rise to ECs and SMCs). A similar VEGFR2$^+$ progenitor with EC and SMC potential was described earlier by Yamashita et al.[23] This second model also considers the possibility that SMCs can arise by transdifferentiation from ECs, which would mean the hemangioblast can also be a common source for the three lineages.[24] This transdifferentiation may however be a culture-restricted phenomenon that does not occur *in vivo*.[25] A third possibility was recently proposed in the avian embryo, where the extraembryonic mesoderm would give rise to a Tal1$^+$ bipotential endothelial/hematopoietic precursor (the hemangioblast) and a separate dHand$^+$ SMC precursor, the segregation of which would be positively regulated by Notch signaling in cooperation with Wnt signaling.[26] A stimulatory effect of Notch on SMC differentiation at the expense of hematopoietic/endothelial fate was also shown during mouse ESC differentiation.[27] Finally, the transient nature of the hemangioblast has made it difficult to prove its existence during development; however there is now also evidence to suggest that such a bipotential progenitor may also persist during adulthood.[28,29]

Emergence of Intraembryonic EC Precursors

The first intraembryonic VEGFR2$^+$ EC precursors emerge in the cranial region of the mouse embryo around E7.3 where they contribute to the endocardium, the EC monolayer lining the primitive heart tube. A little thereafter (at E7.8), the VEGFR2$^+$ primordia of the bilateral dorsal aorta (DA) arise, followed by the lateral vascular networks (between E8 and E8.5) (see below). It has been suggested that the vast majority of ECs within the embryo arises from angioblasts with limited contribution of hemangioblasts.[30] In zebrafish, hemangioblast-derived ECs all clustered in a specific posterior region of the axial vessels[17] but were later also found more anteriorly.[31,32] Hemangioblast contribution to ECs has also been suggested in other regions, for example, the heart (see below). In agreement with hemangioblast activity around the axial vessels in zebrafish, in the mammalian embryo, the floor of the DA in the aorta-gonad-mesonephros region was shown to contain HSCs in intimate contact with the endothelial wall.

Two hypotheses exist concerning the relationship of the ECs and HSCs at this location.[16,33,34] According to one view, HSCs

← **FIGURE 38.1** *(Continued)* cell" or BL-CFC). According to scenario 2, SMCs and blood cells derive from separate precursors; however, hemangioblast-derived ECs may transdifferentiate to form SMCs (indicated by the *curved arrow*). In scenario 3, SMCs arise from a dHand$^+$ unipotent precursor. In the lower blue box, one example is shown of how the embryoid body system has been used to further reveal cell hierarchies during the formation of intraembryonic mesoderm derivatives. Passage through the PS can be mimicked by exposing the cultures to different levels of activin/nodal and BMP-4 expression. Intermediate activin/nodal concentrations result in the formation of a common cardiogenic mesoderm precursor, the cardiovascular colony-forming unit or "CV-CFC," giving rise in the cardiac crescent to (endocardial) ECs, cardiomyocytes (together forming the primitive heart tube), and SMCs (not shown). Studies in chick embryos have suggested an alternative scenario where endocardial and myocardial lineages derive from independent precursors in/outside the cardiac crescent. Bry, brachyury; VEGFR2, vascular endothelial growth factor receptor-2. (Adapted from Kattman SJ, Adler ED, Keller GM. Specification of multipotential cardiovascular progenitor cells during embryonic stem cell differentiation and embryonic development. *Trends Cardiovasc Med* 2007;17(7):240–246; Harris IS, Black BL. Development of the endocardium. *Pediatr Cardiol* 2010;31(3):391–399.)

may arise independent of the ECs from a mesodermal precursor in a region underneath the aortic endothelium, called "the subaortic patches" (only seen in mammals, not in lower vertebrates), and then subsequently move across the DA floor into the lumen. However, recent studies have favored another scenario that HSCs arise within the DA lumen as descendants of cells with endothelial characteristics, called "the hemogenic endothelium." Recent *in vivo* tracing experiments as well as ESC cultures have strongly supported such a process.[35–38] Interestingly, in birds, the aorta has been shown to be a chimeric structure, with ECs of the floor originating from the splanchnopleural mesoderm (also called the lateral plate mesoderm or LPM) and the roof deriving from the paraxial/somitic mesoderm (see below). In a later stage, the floor ECs are replaced by ECs coming from the somites, and this transition coincides with cessation of hematopoietic activity.[16,25,33] Since the paraxial mesoderm and LPM derive from distinct regions and at distinct time points during mesodermal patterning in the PS (see above), it is possible that the different hematopoietic capacities are already determined at that level.

While the ESC system was originally thought to represent the early, mostly extraembryonic stages of vasculogenesis/(primitive) hematopoiesis, recent advances have made it possible to adapt the system to also study several aspects of intraembryonic mesodermal fate mapping.[15,16,22] Based on the expression of an anterior PS marker, Foxa2, anterior (Bry^+Foxa2^{high}; induced by activin/nodal and giving rise to cardiogenic mesoderm) and posterior ($Bry^+Foxa2^{low/-}$; induced by Wnt signaling and giving rise to extraembryonic mesoderm) PS could be segregated.[39] Another group also demonstrated that different mesoderm types can be segregated in ESC cultures using specific tracers and culture conditions and that the common or single potential to make ECs and blood was different among these types.[40] Using their murine and human ESC differentiation system, Keller's group showed that in addition to the $Bry^+VEGFR2^+$ or BL-CFC population that is the *in vitro* equivalent of the hemangioblasts colonizing the yolk sac and originating from the posterior PS, a second $Bry^+VEGFR2^+(Islet1^+)$ population, the "cardiovascular colony-forming cell" (CV-CFC; FIGURE 38.1), can be obtained that is representative of the cardiogenic mesoderm precursor that originates from the anterior PS and gives rise to (endocardial) ECs, cardiomyocytes, and SMCs *in vitro*.[22] Others have confirmed that in embryoid bodies, these three lineages can arise from a common $VEGFR2^+(Islet1^+)$ precursor.[41] While these ESC-based studies have thus suggested a common origin for endocardial and myocardial lineages, another model of endocardial specification based on lineage tracing by cell labeling in chick and zebrafish embryos suggests that the endocardial lineage develops from an independent precursor in the cardiac crescent—the structure that gives rise to the primitive heart tube consisting of an endocard and myocard layer (both conceptual models have been reviewed in Ref.[42]; FIGURE 38.1). A recent study using fluorescent mapping/time-lapse imaging and quail tissue/mouse EC implantation in chick embryos supports the view that endocardium at least in part derives from endothelial-restricted precursors devoid of myocardial differentiation potential and which may reside outside the cardiac crescent (FIGURE 38.1).[43]

Vasculogenesis

Once EC precursors have emerged from their mesodermal origin, they need to acquire a more differentiated EC signature and be assembled and shaped into a primitive and disperse tubular network to lay down the basic architecture of the embryonic vasculature. This process is collectively called "vasculogenesis." Much of this happens before the first heartbeat, while further reshaping occurs after the onset of blood flow. The molecules that orchestrate this complex process are only partially known. Nevertheless, VEGF-A most likely is the conductor of this orchestra since it is expressed in spatial and temporal association with most—if not all—events during vascular formation. Indeed, lack of a single *VEGF* allele disrupts embryonic vascular patterning.[44,45] Complementary to this, the VEGFR2 receptor is the earliest marker to define the endothelial lineage, and cells subsequently express additional markers such as junctional molecules (VE-cadherin and CD31), CD34, and later Tie2.[13] This temporal sequence of expression is more or less recapitulated during EC differentiation of mouse ESCs.[46] In the mouse, the first $VEGFR2^+$ EC precursors are spotted at E7.3 in the cranial region corresponding to the endocardial primordia, while precursors that will give rise to the bilateral DA are first detectable around E7.6 flanking the notochord.[13] The region around the notochord remains avascular at this stage due to notochord-derived negative signals, that is, BMP antagonists chordin and noggin.[47] Subsequently, these DA EC precursors gradually merge into a tubular structure in a bidirectional fashion along the craniocaudal axis. Additionally, between E8 and E8.5, primary vascular networks arise laterally from this axis, called the "lateral vascular networks," that connect to the extraembryonic vasculature.[13] The first axial vein (the cardinal vein) emerges slightly later than the DA. In the following paragraphs, we give an overview of the different steps in vasculogenesis during development, thereby using specific examples and highlighting some recently identified novel concepts.

Although the extraembryonic tissues also go through a vasculogenic phase slightly earlier than within the embryo,[7] here we describe the different steps of the process using the sculpture of the first intraembryonic main axial vessels, the DA, and the posterior cardinal vein (PCV), as an example (FIGURE 38.2). Axial vessel formation has been studied in various species, including quail embryos, chick embryos, (transgenic) mouse fetuses, zebrafish embryos, and *Xenopus* tadpoles. There are some important differences between these species. In birds and mammals, the DA is initially paired and needs to merge into a single tube. In amphibians and fish, DA patterning is in part driven by the hypochord, a temporal tubular structure that does not exist in birds and mammals and lies just ventral from the notochord.[48] As such, there are slight variations in the mechanisms by which the axial vessels are formed (FIGURE 38.2). A first critical step in DA and PCV formation is migration of the EC precursors to the correct location, that is, the midline of the embryo ventral from the notochord. The process involves a combination of soluble factors, cell–cell interactions and cell–extracellular matrix interactions.[49] In zebrafish and *Xenopus*, axial vessel EC precursors originate and migrate mainly—if not exclusively—from the LPM.[50,51] The underlying endoderm and the overlying midline structures (notochord/hypochord) seem to direct this migration. In *Xenopus*, expression of the diffusible $VEGF_{122}$ isoform in the hypochord attracts precursors to the midline.[50] In contrast, in zebrafish, while somite-derived VEGF-A secretion (induced by Shh in the notochord) is important for arterial specification of these angioblasts (reviewed in Ref.[52]), VEGF-A does not seem to be absolutely required for their migration from

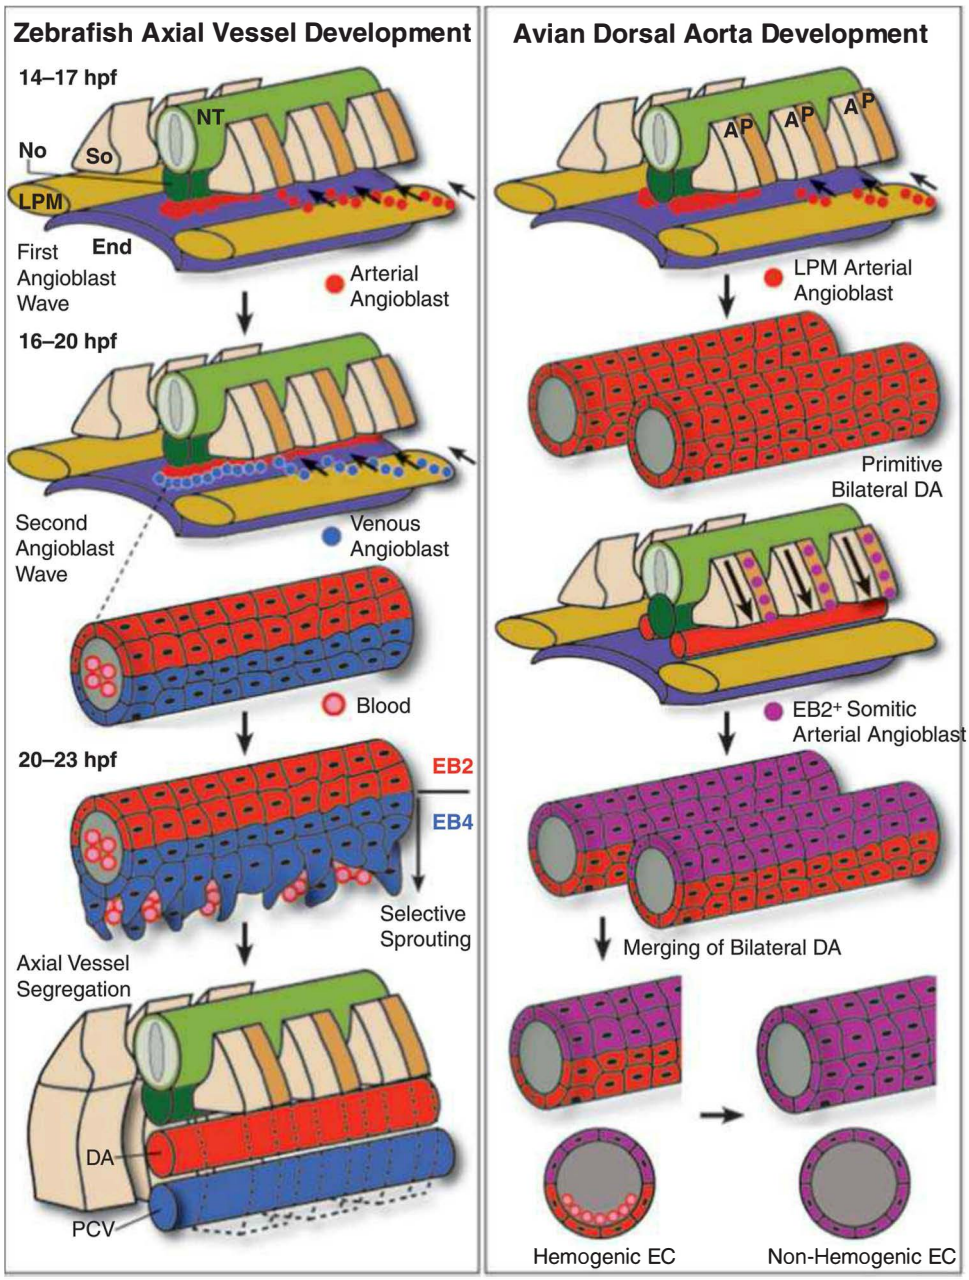

FIGURE 38.2 Vasculogenesis: the making of the main axial vessels. **Left:** *Axial vessel formation in zebrafish.* During early somitogenesis (14 to 17 hours postfertilization or hpf; somites indicated by "So"), the first wave of angioblasts (*red circles*) moves over the endoderm (End) from the lateral plate mesoderm (LPM) to the midline, just underneath the notochord (No). At some point during/after this journey, these angioblasts start to express ephrinB2a or "EB2" (under the influence of an arterial EC-inductive Shh-VEGF-Notch cascade) and give rise to a primitive vascular cord. Later (16 to 20 hpf), a second wave of LPM-derived angioblasts (*blue circles*, not expressing EB2) moves to the midline to join the cord. Subsequently (20 to 23 hpf), this common, mixed vascular cord gives rise to two axial vessels by selective sprouting, regulated by differential expression of EB2 and EphB4 ("EB4") where EB4-expressing cells sprout ventrally to form the PCV, while the EB2-expressing cells stay put and form the dorsal aorta (DA). Red blood cells (with *pink* nucleus) invading the nascent PCV are associated with lumen expansion of the PCV. **Right:** *Avian dorsal aorta development.* In contrast to zebrafish, the DA is initially paired in avian embryos. The primitive paired DA forms by lateral movement and merging of LPM-derived angioblasts (*red circles*). Later, the roof of the DA is replaced with angioblasts (*purple circles*) coming from the posterior ("P") part of the somites. These angioblasts express EB2 already at the onset of their journey. The paired chimeric DA then merges to form a single axial vessel. Around that time in the LMP-derived ventral part of the DA, "hemogenic" ECs give rise to hematopoietic cells (with *pink* nucleus), an activity that is terminated when the ventral part of the aorta is replaced by somite-derived ECs. NT, neural tube. (Adapted from Coultas L, Chawengsaksophak K, Rossant J. Endothelial cells and VEGF in vascular development. *Nature* 2005;438(7070):937–945.)

the LPM to the midline.[51] In addition, contact with endoderm causes the EC precursors to migrate as individual cells in zebrafish.[51] Additional signals may assist in angioblast navigation to the midline (reviewed in Ref.[49]): semaphorins (e.g., semaphorin 3a1, a repulsive signal expressed in the somites[53]), CXCR4/SDF-1, and sucrose nonfermenting-related kinase (Snrk)-1.[54] We recently identified the PDZ domain-containing scaffold protein synectin as a regulator of angioblast migration. Its absence in zebrafish resulted in angioblast stalling at the LPM or in between the LPM and the midline.[55] In zebrafish, there are two waves of migrating angioblasts, one starting around 14 hours postfertilization (hpf), another around 16 hpf. While the first wave will give rise to the DA, the second wave will contribute to the PCV (see below). In avian—and most likely mouse but not zebrafish—embryos, in addition to the laterally migrating angioblasts, there is a second source of angioblasts, migrating ventrally from the posterior half of the somites to contribute to the DA in response to a yet unidentified signal[56] (FIGURE 38.2). While the LPM angioblasts contribute to the floor of the primitive DA, this somitic angioblast population first invests the roof of the primitive DA and then spreads over the entire aorta to form the definitive DA. This coincides with the conversion of ECs in the floor of the aorta from hemogenic to nonhemogenic endothelium (see above)[56] (FIGURE 38.2).

The next step following migration is the establishment of a tube/cord-like structure. In *Xenopus*, avian, and mouse embryos, endoderm-derived hedgehog signals (Shh in chicks; an unidentified hedgehog signal in mice) provide necessary cues for tube formation.[57,58] Unlike its indirect effect (through stimulation of VEGF-A production) during arteriovenous specification and postnatal angiogenesis,[59] Shh most likely directly interacts with EC precursors during tubulogenesis.[58] Interestingly, however, regional differences seem to exist along the anterior–posterior axis of the DA of zebrafish. While in the posterior part of the DA, tube formation can occur in the absence of endoderm,[51] a recent study showed that the formation of the bilateral DA (the anterior portion of the DA) is critically dependent on the endoderm-derived cxcl12b (a zebrafish orthologue for SDF-1).[60] Analogous to what is known from epithelial tube formation,[61] the establishment of vascular tubes involves at least three coordinated activities,[62,63] that is, the increased cellular contact (mediated by junctional molecules, e.g., vascular tubulogenesis is severely affected in VE-cadherin knockout mice[64]), the establishment of apical–basal polarity (involving translocation of junctions to the lateral side, exocytosis to the apical surface of negatively charged antiadhesive proteins, such as CD34-sialomucins that form a cell–cell repulsive glycocalix, and rearrangement of the cytoskeleton), and interaction with the surrounding matrix (e.g., fibronectin[51,65]) through integrins (e.g., β_1 integrins[65,66]). In the zebrafish, angioblasts from the first migration wave initially aggregate without the expression of adhesion molecules, then a fibronectin matrix is deposited between the cells, and zona occludens-1 (ZO-1) only marks cell–cell junctions 2 hours later at 17 hpf.[51] Lumenization starts at 18 hpf according to a "hollow out" mode to form the future DA. Recently, it was shown in mice that lumenization of the DA is driven by VEGF-A that activates Rho-dependent kinases leading to cytoskeletal changes that open up a patent extracellular lumen between two apposing ECs.[67] This extracellular mode of tube formation thus requires junctional rearrangement between ECs as opposed to another model based on fusion of intracellular vesicles within single ECs described for lumen formation during intersomitic vessel (ISV) formation in the zebrafish.[68] The latter intracellular model has recently been complemented by another study showing that the lumens in the ISV of zebrafish are formed by rearrangement of ECs around an intercellular lumen.[69] The mechanisms of vascular lumen formation thus seem context dependent.

The first signs of arteriovenous differentiation appear in the zebrafish around 17 hpf, upon expression of the arterial marker *ephrinb2a* in the cell aggregate that will form the DA.[51] At this time, some cells in the ventral part of the cluster as well as those that constitute the second migratory wave do not express *ephrinb2a* and are therefore likely venous angioblasts. This is before the onset of circulation, meaning that this cell fate decision is independent of flow and hence genetically predetermined. When exactly arteriovenous fate decisions are made is not entirely clear. Similarly, in mice, polarized expression of ephrinB2 in the arterial cells and EphB4 in venous cells becomes apparent before the onset of blood circulation.[70,71] While ephrinB2 expression studies suggest that LPM angioblasts only acquire arterial specific markers after migration, some molecules, such as synectin, seem to specifically affect arterial angioblast behavior during (or perhaps before) migration.[55] Interestingly, the somitic angioblasts identified in birds and mice acquire ephrinB2 expression before/during their migration to the DA.[56] By 24 hpf, both axial vessels (ephrinB2a$^+$ DA and flt4$^+$ PCV) are formed in the zebrafish trunk.[51]

The molecular cascades responsible for the induction of arteriovenous fate have been mostly determined in zebrafish and mouse embryos (including a Shh-VEGF-Notch cascade, TGFβ, Sox, Fox, adrenomedullin, Spreds, phosphatidylinositol-3, and COUP-TFII or chicken ovalbumin upstream promoter-transcription factor II). This process has been elaborately described in many comprehensive reviews.[72–75] Due to space restrictions, here we only highlight the recent discovery that the Notch and Wnt/β-catenin pathways synergize to induce an arterial fate in vascular progenitors *in vitro* and *in vivo*.[76,77]

In mice, the size and segregation of the axial vessels seems to be critically determined by Notch and ephrinB2/EphB4 signaling, the former regulating the balance of arterial versus venous ECs and the latter "sorting" arterial and venous ECs into their respective vessels.[78] A recent time-lapse analysis of main axial vessel formation in zebrafish confirmed such a sorting process whereby arterial and venous angioblasts first reside in a common vessel primordium at the midline. Subsequently, ephrinB2a/EphB4 reciprocal signaling regulates the selective ventral sprouting of venous ECs (which then form the PCV) and the restricted dorsal sprouting of arterial ECs (which then generate the ISVs)[79] (FIGURE 38.2). Thus, according to this model, the PCV is not formed by vasculogenesis but rather by sprouting angiogenesis. Whether this is a characteristic of the zebrafish model or also applicable to other species remains to be determined.

Angiogenesis

Angiogenesis, or the generation of new endothelial-lined vessels from preexisting ones, expands and remodels the rudimentary vascular primordium resulting from vasculogenesis during development and most likely also is a ("the") main mechanism by which new vessels arise after birth. Angiogenic mechanisms have been mostly unraveled by studying a few stereotyped forms of developmental angiogenesis, that is, the formation of the ISVs

in the zebrafish and the formation of the retinal vasculature in the mouse, the latter occurring after birth. Many of the events during development are recapitulated in adult angiogenesis. Furthermore, different modes of vascular expansion/remodeling can be distinguished: sprouting angiogenesis (or the formation of vascular branches mostly triggered by hypoxia or other stimuli), intussusception (or transluminal pillar formation; reviewed in Ref.[80]), and circumferential growth (which for instance occurs during collateral enlargement driven by shear forces, also known as "adaptive arteriogenesis."[81]) Here, we review the process of angiogenic sprouting since our understanding of this process has significantly enhanced in the last decade.

Angiogenic sprouting is a dynamic and highly coordinated process during which ECs must perform distinct tasks and adopt specific functional identities[81,82,83,84,85] (FIGURE 38.3): tip cell selection/sprout initiation, tip cell navigation/sprout guidance, stalk cell proliferation/sprout extension, tip–tip cell anastomosis/sprout fusion, pericyte recruitment/vessel stabilization, and "phalanx" cell conversion/return to quiescence. In addition, during angiogenic remodeling, initial arteriovenous fate decisions can be "reconsidered." Again, VEGF-A takes a center stage position in this coordinated effort, with the help of another signaling pathway, the Notch pathway, which modulates VEGF signaling.[86,87]

Tip Cell Selection/Sprout Initiation

Expansion of the developing vasculature is largely driven by the need for oxygen in growing organs. Hypoxia, or the lack of oxygen, can trigger the local production of VEGF-A, which results in the creation of a VEGF-A gradient. The extracellular distribution of VEGF-A is additionally shaped by the existence of different splice isoforms with distinct matrix binding or diffusible properties, the bivalent $VEGF_{165}$ isoform being the most crucial for correct angiogenic sprouting.[88] In the retina, VEGF-A is secreted by astrocytes that move a little bit ahead of the expanding blood vascular network and are therefore indispensable for normal vascular expansion in the retina.[89] Upon contact with higher VEGF-A concentrations, certain individual ECs expressing VEGFR2 nearest by the source of VEGF-A in the avascular area, called "tip cells," flip their apical–basal polarity, send out long VEGFR2-expressing protrusions or "filopodia," and break out of the frontline.

At the same time, VEGF signaling upregulates the Notch ligand delta-like 4 (Dll4). Dll4 subsequently activates Notch signaling in the neighboring cell, which results in downregulation of VEGFR2 and upregulation of soluble VEGFR1, a decoy receptor. As such, this neighboring cell becomes less sensitive to VEGF-A presented at the vascular front and becomes unable to upregulate Dll4. This lateral inhibition and self-reinforcing negative feedback loop thus induces a "stalk cell" phenotype in cells immediately adjacent to the tip cell and makes sure that tip cells retain their leading position. Detailed time-lapse analysis has however shown that tip/stalk cell identity is very dynamic and transient and that cells in a given sprout constantly compete, by differential expression of VEGFR1 and VEGFR2, for the tip position which involves repeated tip-stalk cell identity switches.[90]

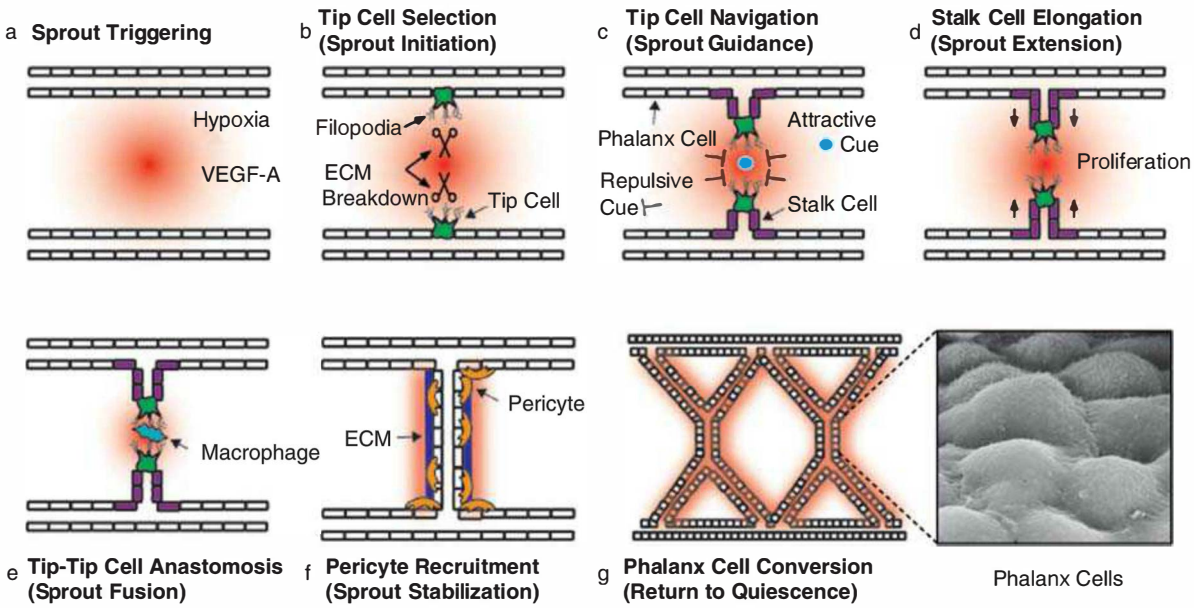

FIGURE 38.3 Angiogenesis: the different steps of the angiogenic ladder. Following a hypoxic trigger, a VEGF-A gradient arises (*red*; **panel a**). Next, cells encountering high VEGF-A concentrations change their polarity, break out from the vessel by breaking down the surrounding matrix, and develop filopodia to sense their immediate environment (**panel b**). These cells, "tip cells," are guided on their way to another tip cell by attractive and repulsive cues (**panel c**). Cells following the tip cell ("stalk cells") proliferate to elongate the sprout (**panel d**). Macrophages make both sprouting ends meet by fine-tuning tip cell guidance (**panel e**). After blood flow is restored, the new sprout is stabilized by deposition of extracellular matrix (ECM) and coverage with pericytes (**panel f**). The new vessel delivers oxygen to the tissue in need, thereby resolving hypoxia. As a result, the ECs revert to a quiescent phenotype, called "phalanx cells," as they arrange themselves in a tight formation resembling the ancient Greek soldiers (**panel g**). (Adapted from Carmeliet P, De Smet F, Loges S, et al. Branching morphogenesis and antiangiogenesis candidates: tip cells lead the way. *Nat Rev Clin Oncol* 2009;6(6):315–326.)

In contrast to tip cells, stalk cells form fewer filopodia, but instead trail behind the leading tip cell to elongate the sprout (see below). Interestingly, these two distinct functional behaviors are reflected in a different expression profile: tip cells express high levels of VEGFR2, VEGFR3, Nrp1, UNC5b, Dll4, CXCR4, Ang2, ESM-1, SLP-76, and PDGF-BB, while stalk cells express more Jagged-1 (a Notch ligand), VEGFR1, and Robo4.[87,91] Jagged-1 expression in stalk cells was recently shown to antagonize Dll4, thereby preventing Notch activation (and thus stalk cell induction) in neighboring cells. When modified by fringe glycosyl transferases, Notch1 is indeed activated more by Dll4 than by Jagged-1. Given that some Dll4 protein is detectable in stalk cells, Jagged-1 also helps to maintain differential Notch activity by antagonizing Dll4 that signals back to tip cells.[92] In addition to Notch signaling, VEGF-A/VEGFR2 signaling in tip cells is further modulated by other mechanisms (reviewed in Ref.[84]) including cooperation with other VEGF receptors and a newly identified transcriptional repressor complex composed of translocation ets leukemia gene (Tel) and carboxy-terminal–binding protein (CtBP). Proximity ligation assays revealed that VEGFR2 can heterodimerize with VEGFR3 in tip cell filopodia upon VEGF-A or -C binding.[93] The VEGFR2 coreceptor Nrp1, on the other hand, was shown to be involved in lateral filopodia extension, which is critical for tip cell turning and fusion (see below).[94] Alternatively, Nrp1 alone may induce vessel branching by direct signaling in ECs through synectin.[55] While VEGF coreceptors spatially modulate VEGF branching activity, the Tel–CtBP complex was shown to temporally restrict VEGF-A–stimulated Dll4 expression in sprouting ECs.[95] Furthermore, this complex also regulated the expression of antagonistic sprouting cues (e.g., VE-cadherin and Sprouty4). In addition to their sensing behavior through filopodia, tip cells also need machinery to invade the surrounding basement membrane to be able to break out and advance. Matrix metalloproteinases (MMPs), such as MT1-MMP, may be one of the molecular tools to dissolve the matrix (FIGURE 38.3), at least during postnatal angiogenesis where the "mother vessels" from which the new sprouts are formed are embedded in a thicker layer of basement membrane.[84]

Tip Cell Navigation/Sprout Guidance

The tip cell filopodia function as sensors that constantly probe their environment. In this respect, tip cells resemble the growth cone of navigating axons.[96] Therefore, certain guidance signals used by axons seem to have been co-opted by endothelial tip cells on their way to meet another tip cell[82,97] (FIGURE 38.3). Tip cell movement needs to be correctly monitored by attractive and repulsive guidance posts. There are at least four ligand/receptor classes of guidance molecules with a documented role in vascular navigation: Slits/roundabout4, netrins/Unc5B, Semaphorin 3E/Plexin-D1, and ephrinB2/EphB4. Due to space restrictions, we only briefly illustrate some examples as prototypic examples. One roundabout (Robo) family member (Robo4) is expressed in growing vessels. Robo4 deficiency in mice leads to hypervascularization during oxygen-induced retinopathy, and its high expression in stalk cells may prevent these cells from being activated by VEGF-A.[98] Mechanistically, Robo4 counteracts the leakage-promoting activity of VEGF-A by impairing VEGFR2-mediated activation of the kinase Src.[98] The nature of the Robo4 ligand is debated, since Robo4 lacks Slit-binding domains, and Robo4 also binds to Unc5B, another guidance receptor, suggesting that Robo4/Unc5B maintains vessel integrity via Unc5B activation.[99]

Unc5B is highly expressed in tip cells, and binding of netrin-1 to Unc5B causes filopodia collapse in the retina while Unc5B knockdown in zebrafish induces ectopic ISV sprouting.[100] Repulsion by netrin-1–Unc5B interaction requires the cytoplasmic domain of the receptor.[101] However, netrin-1–deficient mice do not have a vascular phenotype, suggesting that netrin-1 signaling might involve other yet unidentified receptors or that other molecules may take over its role in mice.[97] Alternatively, Unc5B could act as a dependence receptor that, in the absence of ligand, causes EC death.[102]

While secreted semaphorins usually bind to neuropilin receptors (functioning as a coreceptor for Plexins) and often inhibit vessel sprouting, Semaphorin 3E directly binds Plexin-D1 also causing vessel repulsion. Absence of either binding partner results in excessive branching in the trunk vessels of the mouse.[103] Within the developing mouse retina, neuron-derived Semaphorin 3E binding to Plexin-D1 activates RhoJ in ECs, thereby restricting and orienting VEGF-induced filopodia projection.[104] In addition, this Semaphorin 3E/Plexin-D1 interaction fine-tunes the balance between tip and stalk cells by coordinating VEGF's activity in a negative feedback.[105] Similarly, the zebrafish mutant *out of bounds* maps to a mutation in the *plexin-D1* gene which results in excessive and aberrant ISV branching into the somites; however, unlike in mice, the action of plexin-D1 in zebrafish is antagonized by Semaphorin 3E/plexin b2 signaling.[106]

Eph receptors and their ephrin ligands regulate cell contact-dependent signaling through bidirectional signaling in cells expressing the receptor (forward signaling) or ligand (reverse signaling), in most cases generating repulsive signals.[82,97] Notably, ephrinB2 was shown to regulate VEGFR2 endocytosis upon VEGF-A ligation during sprouting angiogenesis[107,108] (reviewed in Ref.[109]). EphrinB2/EphB4 have also been shown to be involved in directional sprouting of ECs during the formation of the PCV in zebrafish (see above).[79]

Stalk Cell Proliferation/Sprout Extension

While tip cells lead the way, stalk cells follow the tip cell and are responsible for sprout elongation and lumen formation. Unlike tip cells that seldom proliferate, stalk cells do proliferate as a means to make the sprout longer (FIGURE 38.3). As mentioned, stalk cells acquire their phenotype by activation of Notch signaling. Since Notch signaling is generally known to inhibit EC proliferation,[87] there must be another mechanism at play that overrules this inhibition. One of the downstream targets of Notch signaling in stalk cells is Nrarp which functions as a negative regulator of Notch through degradation of the Notch intracellular domain (NICD),[110] thereby creating a permissive environment for proliferation. At the same time, Nrarp also activates Wnt signaling in stalk cells which stabilizes the stalk by inducing firm intercellular junctions.[110] Instead of just passively trailing behind the tip cell, stalk cells may also actively push the sprout forward by secreting certain matrix components, for example Egfl7.[111] As a result of Notch signaling, stalk cells have lower expression of VEGFR2 while they preferentially express VEGFR1.[90] Notch activation also lowers endothelial expression of placental growth factor (PlGF), a VEGFR1-specific ligand.[112] Gamma-secretase (which generates NICD by cleaving Notch) was shown to cleave VEGFR1, leading to release of its soluble form which can scavenge VEGF-A in the vicinity of the stalk cells, further dampening its effect.[113] At the same time, the intracellular VEGFR1 fragment

may block VEGFR2 signaling. Collectively, these effects reduce and spatially restrict the overall response of ECs to VEGF-A and may fine-tune stalk cell morphogenesis. A recent paper revealed an additional fine-tuning mechanism of stalk cell behavior, whereby the response of an EC to Notch activation is negatively modulated through deacetylation—and hence destabilization—of NICD by SIRT1, an NAD^+-dependent deacetylase.[114]

Another task of cells in the stalk is the formation of a lumen, so blood flow can be initiated in the new sprout. Lumen formation in angiogenic sprouts may occur either before or after connection of the sprout to another tip cell[83]; it remains unknown how this occurs precisely. Possibly, lumen formation in anastomosing vessels mechanistically resembles that of vessels formed by coalescing angioblasts during vasculogenesis (see above).[62]

Tip–Tip Cell Anastomosis/Sprout Fusion

To make new connections, tip cells move toward each other. As they make contact, they need to convert their behavior of a migratory, navigating cell into a stalling connective cell. Recently, VE-cadherin, a junctional molecule, was shown to be expressed in filopodial protrusions of advancing tip cells, suggesting that interactions between cadherins of contacting tip cells may stabilize the connection.[115] Formation of these junctions may then induce the phenotypic change from an actively navigating tip cell to a more quiescent cell. Failure to make such a stabilized contact, for example by repulsive forces between approaching tip cells, may on the other hand lead to sprout retraction, leaving behind an empty matrix sleeve. ECs may get assistance from helper "bridge" cells to acquire the precision needed to find another tip cell, as recently demonstrated in zebrafish where proangiogenic macrophages serve as guiding posts for tip cells and promote tip cell fusion[116] (FIGURE 38.3). Recently, it was shown that VEGFR3 signaling in tip cells triggered by VEGF-C derived from macrophages positioned around sprout fusion sites results in fusion stabilization and phenotypic conversion of the fused tip cells to a stalk-like cell by reinforcing Notch signaling.[117]

Pericyte Recruitment/Vessel Stabilization

Maturation and stabilization of the nascent tube requires the deposition of extracellular matrix as well as the recruitment of pericytes (FIGURE 38.3). Pericytes, expressing PDGFRβ, are attracted to the endothelial tubes by PDGF-BB signals derived from the ECs. These EC–pericyte interactions additionally involve angiopoietin/Tie receptor signaling, S1P/sphingosine-1 phosphate receptor (S1PR) signaling, and Notch signaling (for comprehensive reviews[118,119]). Mural cell-secreted angiopoietin-1 activates its Tie2 receptor on ECs, thereby promoting pericyte adhesion to and junctional tightening between ECs. However, a recent study revealed that angiopoietin-1 seems less important for pericyte recruitment than originally thought and rather determines vessel diameter and number during vascular development.[120] S1P1/S1PR coupling strengthens EC/pericyte contacts by relocating *N*-cadherin to the abluminal side of ECs.[121] *NOTCH3* mutations in CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) patients lead to vascular SMC degeneration and results in arteriopathy, which was recently phenocopied in mice.[122]

Stabilization further prevents the newly formed sprout from pruning. While all previous steps of angiogenic sprouting can be studied in zebrafish, it has not been clear whether the zebrafish vasculature during early development becomes coated with a pericyte or SMC layer.[123] A recent paper demonstrated that only the proximal part of the DA is invested with a limited number of periendothelial ("mural") cells during zebrafish development.[124]

Phalanx Cell Conversion/Return to Quiescence

The flow of oxygenated blood in the lumen will further cause the hypoxia signal that initiated the sprout to subside, leading to a decrease in VEGF-A levels. This restores the balance between pro- and antiangiogenic factors and leads to quiescence. Quiescent ECs have yet another behavior than tip or stalk cells, since they do not (or to a much lesser extent) migrate nor proliferate in response to VEGF-A.[125] Indeed, VEGF-A mostly elicits a survival response in quiescent ECs, since the absence of VEGF-A in ECs causes widespread EC dysfunction and disintegration.[126] These cells have tight connections and are aligned in a smooth monolayer, resembling the "phalanx formation" of ancient Greek soldiers, hence their name "phalanx cells" (FIGURE 38.3). Recently, some of the molecules that determine this cell behavior were identified. Quiescent ECs in a normal vessel can be compared with sensors that constantly probe their environment for oxygen, thereby estimating the need for vascular expansion. Prolyl-hydroxylase domain-2 (PHD2) belongs to the family of oxygen sensors that regulate the stability of hypoxia-inducible factor (HIF), a major stimulator of VEGF-A production. When oxygen supply is normal, PHDs use oxygen to hydroxylate specific proline residues in HIFs, thereby targeting them for proteasomal degradation.[127] During hypoxia, the oxygen-dependent activity of PHDs is attenuated allowing HIFs to mount an adaptive response. In a recent study, it was shown that lowering the activity of the PHD2 sensor (by heterozygosity) in tumor ECs causes the normally hyperactivated tumor endothelium to become quiescent and adopt the phalanx phenotype, a process called "vessel normalization"[125] (reviewed in Refs.[85,128,129]). $PHD2^{+/-}$ tumor ECs had elevated levels of VE-cadherin and soluble VEGFR1, the latter which acts as a VEGF-A trap. Increased VE-cadherin expression is known to shift the EC response to VEGF-A from migration/proliferation to survival/quiescence.[130] This resulted in a better perfusion and oxygenation of the tumors which hence became less invasive and less metastatic.[125] Thus, by lowering the activity of an oxygen sensor, ECs can readjust their shape and behavior to improve oxygen delivery when needed. In addition to oxygen sensors, additional molecular pathways have been shown to regulate quiescence and survival, for example BMP-9/Alk1, thrombospondin, FGFs, HoxC9,[131] miR-132,[132] angiopoietin-2/FOXO1,[133] and angiopoietin-1/Tie2. Mural cell-derived angiopoietin-1 induces Tie2 clustering at EC–EC junctions in *trans* to promote EC survival and quiescence.[84,134,135]

Arteriovenous (Re)specification

Even though arterial/venous cell fates are acquired early in development during the vasculogenic phase independent of blood flow, these fate decisions are not completely irreversible and are sometimes reshaped during the angiogenic remodeling phase (coinciding with the onset of blood flow). The plasticity of ECs was demonstrated in the chick yolk sac where experimentally induced flow changes could transform arteries into veins and *vice versa*.[136] Also during development of the zebrafish trunk vasculature, such fate switches occur.[137] For the generation of the ISVs, primary bilateral sprouts emerge around 20 hpf from the DA which give rise to the primary ISVs. Despite

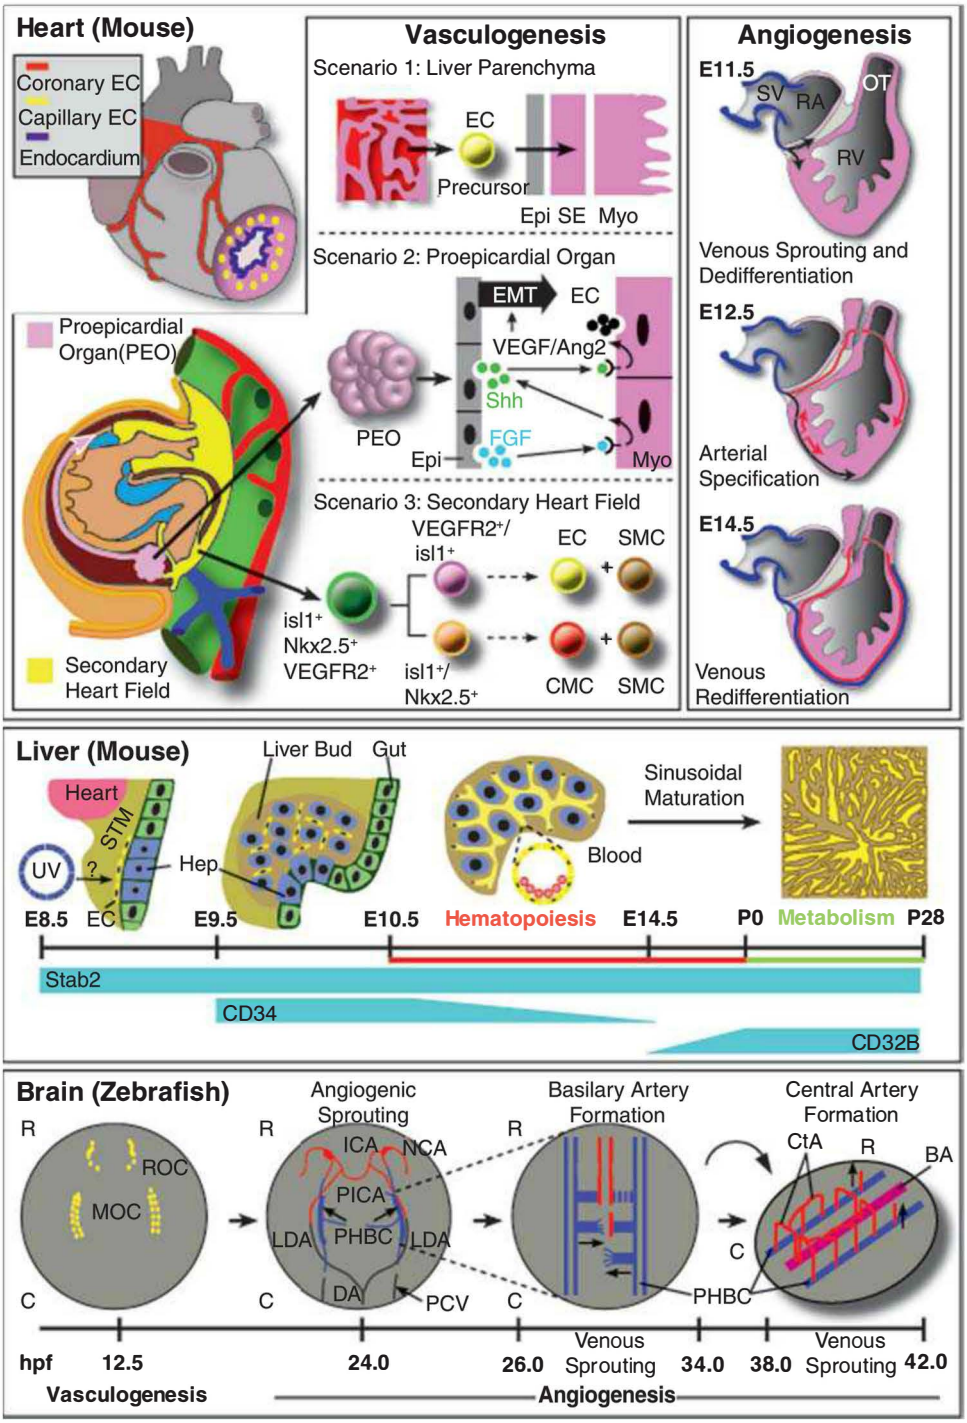

FIGURE 38.4 Generation of organ-specific vascular beds. **Upper panel:** *mouse heart*. There are three endothelial beds in the heart (the coronary, capillary, and endocardial bed; upper left pictogram). At least four different scenarios were proposed to explain the origin of the coronary vascular bed(s), three claiming a vasculogenic initial step (*left box*), challenged by a recently published fourth theory proposing an angiogenic mechanism (*right box*). The first vasculogenic theory claims that endothelial cell (EC) precursors move from the liver parenchyma to the subepicardium (SE). Alternatively, the PEO (*pink* structure in lower left pictogram), a grape-like protrusion of the sinus venosus (SV), is the common precursor of ECs, fibroblasts, SMCs (and part of the cardiomyocytes). This PEO first gives rise to the outer heart layer, the epicardium (Epi), by moving across the myocardium (*pink arrow*). Through an FGF-Shh-VEGF/angiopoietin-2 molecular cascade, the ECs arise from the epicardium by EMT. The third scenario proposes a common cardiomyocyte (CMC), EC, and SMC islet(isl)1^+Nkx2.5^+VEGFR2^+ precursor originating from the secondary heart field (*yellow* structure in lower left pictogram). According to the angiogenic scenario, the coronary vasculature derives by angiogenic sprouting from the SV, during which venous ECs (in *blue*) first dedifferentiate (in *black*), then transdifferentiate to arterial ECs (to give rise to the arterial

their aortic origin, the sprouting vessels, including their tip cells, express flt4, which is a venous marker in zebrafish. Only later, the expression of flt4 becomes restricted to the PCV.[138–140] Around 35 hpf, a secondary round of sprouting occurs, this time emanating from the PCV. About half of the secondary sprouts make connections with a primary ISV (originating from the DA) which converts them to venous ISVs, while the other half becomes part of the lymphatic system.[137,141,142] Therefore, the arteriovenous identity of trunk vessel ISVs is not fixed until after secondary sprout connection.

It is likely that flow dynamics determine the final differentiation to venous or arterial phenotypes.[137] For instance, in the developing mouse retina, Unc5B seems to be expressed in tip cells at the forefront of both arterial and venous sprouts, while Unc5B expression is otherwise mostly restricted to arterial vessels.[100] This may suggest that tip cells may lose their arteriovenous identity during sprouting, but may regain arteriovenous polarity once incorporated in an established vessel. Also adult ECs retain some arteriovenous plasticity since ECs of vein grafts, implanted into an arterial segment, acquire arterial characteristics (reviewed in Ref.[72]). Thus, refinement by hemodynamics (or other environmental signals) adds another layer of regulation on top of a genetically predetermined decision program.

Establishment of Organ-Specific Vascular Beds

Different organs fulfill distinct tasks that require a customized vascular supply. This is not only reflected in the existence of highly specialized angioarchitectures but even more so in the unique properties of the microvasculature within every organ. Indeed, the microvessels or capillaries are the exchange vessels that are in immediate contact with the cells that perform each organ's specific functions. This intimate relationship gives rise to remarkable functional, morphologic, and molecular differences among ECs from different organs.[1] While these differences have been recognized for decades, there is yet much to learn about how they were created and when exactly they appeared. Many of these differences already appear early in development. As an example, we discuss the heart, the liver, and the brain, since these organs are frequent targets of life-threatening vascular diseases. Studying the mechanisms underlying the ontogeny of specific capillary beds may give important clues for the design of life-saving "tailor-made vascular bed-specific" therapies.[143]

The Heart

Of all tissues, the heart is a frequently studied organ when it comes to how its vasculature is established during development. However, most studies have focused on the coronary arteries—a hot spot for atherosclerosis—while the cardiac microvasculature has received much less attention. Within the heart, there are at least three major types of blood vascular endothelium[1] (FIGURE 38.4): the endocardium (which lines the entire interior surface of the heart muscle, including the valves), the coronary macrovascular endothelium (consisting of arterial and venous ECs), and the myocardial capillaries that connect the coronary arteries to the veins. The endocardium is the first EC type appearing around E8 in the mouse,[13] when the heart is only a tube consisting of a few layers of cardiomyocytes lined on the inside by an EC monolayer that subsequently becomes trabeculated to allow maximal oxygen diffusion to the heart muscle.[144] The heart valves develop by endothelial-to-mesenchymal transformation from the endocardium.[1,145]

While the origin of the endocardium is debated (see above), there is also discussion concerning the origin of the ECs covering the coronary arteries, veins, and capillaries. Until recently,

FIGURE 38.4 *(Continued)* coronary tree in *red*), and subsequently redifferentiate to venous ECs (to form the venous coronary tree in *blue*). **Middle panel:** *mouse liver*. The first VEGFR2$^+$ EC (precursor)s (in *yellow*) appear in the septum transversum mesenchyme (STM) near the liver primordium (*blue* hepatoblasts or "Hep") around embryonic day (E)8.5. Another theory hypothesizes venous transdifferentiation from the umbilical vein (UV) as origin for liver EC (precursor)s. At E9.5, triggered by the EC (precursor)s, hepatoblasts invade the STM to form the liver bud, intermixed with EC (precursor)s that do not yet form lumenized structures. From E10.5 on, lumenized structures appear and the liver starts its activity as hematopoietic organ. During late development and several weeks after birth, the liver microvasculature gradually acquires its typical sinusoidal organization (*right* pictogram) which coincides with conversion to a metabolic function. During maturation, LSECs acquire expression of early (Stabilin2 or Stab2; CD34) and late markers (Stab2 and CD32B). **Lower panel:** *zebrafish brain*. The formation of the brain vasculature involves a vasculogenic phase, followed by an angiogenic and maturation phase (the latter not shown). Around 12.5 hours postfertilization (hpf), two angioblast centers arise, one in the rostral (R) part (the rostral organizing center or ROC) and one more caudally (C) in the midbrain (the midbrain organizing center or MOC). These angioblasts merge to form a primitive plexus that expands by angiogenic sprouting, giving rise to the first venous (the primordial hindbrain channels or PHBC) and arterial vessels (the nasal ciliary artery or NCA; the primitive internal carotid artery or PICA; the internal carotid artery or ICA). The extracranial arteries, the LDA or lateral dorsal aorta and dorsal aorta or DA, and extracranial veins (the posterior cardinal vein or PCV) that connect to the trunk vasculature are indicated in *black*. Starting at 26 hpf, the basilary artery (BA) arises by sprouting (*black arrows*) from the venous PHBC. Subsequently, the sprouts disconnect from the vein (indicated by *dashed blue lines*) and the disconnected ECs merge to form a lumenized BA. Similarly, the central arteries (CtA) arise by sprouting (*black arrows*) from the PHBC somewhat later in development. (Adapted from Proulx K, Lu A, Sumanas S. Cranial vasculature in zebrafish forms by angioblast cluster-derived angiogenesis. *Dev Biol* 2010;348(1):34–46; Lie-Venema H, van den Akker NM, Bax NA, et al. there were three (not necessarily mutually exclusive) hypotheses (FIGURE 38.4). One claims that the ECs lining the coronary vasculature are derived from angioblasts of the liver region, while a second theory argues that the ECs, together with the SMCs and fibroblasts and perhaps some cardiomyocytes,[146] have a common origin, that is, the proepicardial organ (PEO)—a transient grape-shaped protrusion that attaches to the looped heart tube around E9.5 in the mouse and subsequently spreads over its entire outer surface to form the epicardial layer by E11.[145,147–150] According to the "PEO theory," endothelial precursors are generated within the subepicardial layer by EMT (FIGURE 38.4). The inductive signals responsible for EC precursor generation are the result of cross-communication between the epicardium and the myocardium where an FGF-Shh-VEGF/Ang2 pathway has been described.[151] A third source of coronary ECs could be a population of Islet1$^+$VEGFR2$^+$Nkx2.5$^+$ multipotent progenitor cells residing within the secondary heart field, giving rise to the proximal part of the coronary endothelium and vascular smooth muscle (along with part of the cardiomyocytes).[152] According to each of these theories, the coronary vasculature initially arises by vasculogenesis, that is, the formation of a primitive network of vessels by EC precursor fusion. Some studies have suggested the presence of hemangioblasts and blood islands during cardiac development.[151,153,154,155,156] The rudimentary network then is remodeled into a hierarchical tree of arteries, veins, and capillaries. Very recently, these vasculogenesis theories have been challenged by a mouse study in which clonal analysis revealed that the majority of the endothelium of coronary vessels (including arteries, veins, and capillaries) originates from the sinus venosus by angiogenic sprouting[155] (FIGURE 38.4). This new theory also challenges the classical view that arteries and veins derive from distinct EC precursors and again underscores the plasticity of arteriovenous fate.

Due to the different hypotheses on the origin of coronary ECs, it is not really known when the capillaries in the heart acquire their specific characteristics. While these characteristics have been mainly defined by comparing the capillary ECs with the endocardial ECs,[1,157] few—if any—studies have compared the heart capillaries with those in other organs. The late connection of the coronary tree to the aorta implies that capillary formation occurs largely independent of blood flow and that there is a time window during which capillary ECs are only exposed to contractile forces coming from the contracting myocardium.[156] Therefore, these forces may codetermine the unique characteristics of capillary heart ECs. In addition, the very close apposition of these ECs to cardiomyocytes allows for intense reciprocal communication through secretion of (growth) factors, some of which may be specific for the cardiac vascular bed.[151,158] Transplantation and EC/cardiomyocyte coculture studies have revealed the importance of such signals by showing that von Willebrand factor expression in ECs was specifically upregulated by cardiomyocytes but not by hepatocytes.[159] Cardiomyocyte-specific deletion of VEGF-A resulted in an underdeveloped microvasculature but did not affect coronary artery structure revealing the specific sensitivity of the capillary endothelium to VEGF-A.[160] Specific loss of the heparin-binding isoforms of VEGF-A ($VEGF_{188}$ and $VEGF_{165}$) however did not affect microvascular development but disrupted arteriovenous differentiation, suggesting that different VEGF-A isoforms may target different steps in heart vascular development.[161] On the other hand, several recent studies revealed that VEGF-B, which is highly expressed in the heart, may affect the growth of large coronary vessels, while its effects on vessels outside the heart may be more limited.[154,162–164] Another cardiac-specific growth factor is brain-derived neurotrophic factor, since its general absence caused specific defects in myocardial arteries and capillaries. Accordingly, its receptor trkB is selectively expressed by neonatal and adult heart vessels.[165]

The Liver

The vascular architecture of the liver is particular since the liver capillaries, also called the sinusoids, are fed by two afferent vessels: the hepatic artery for delivery of oxygen (comprising 20% of normal hepatic flow) and the portal vein for providing nutrients from the intestine (constituting 80% of the normal hepatic flow). The sinusoids on their turn empty into the hepatic venules, the hepatic vein, the inferior vena cava, and ultimately the right atrium of the heart. The ECs in the hepatic sinusoids (called liver sinusoidal ECs or LSECs) have acquired unique anatomical/molecular features that allow them to function as selective "sieves" (by the presence of large nondiaphragmed cytoplasmic holes, called "fenestrae," and the absence of a basal lamina), scavengers for soluble waste molecules (by the expression of scavenger receptors), and inducers of immune tolerance (by the expression of MHC class I, II and costimulatory molecules).[1] The development or regeneration of the liver parenchyma is intimately related to its investiture with blood vessels—in part because ECs from these vessels produce specific inductive "angiocrine" signals[166]—and the same scenario is true for other gut tissues[167,168] (FIGURE 38.4). At approximately E8 in the mouse, the liver primordium (the liver "bud") arises from the ventral foregut endoderm. As early as E8.5, VEGFR2$^+$ angioblasts (the origin of which is not known) are found between the nascent hepatic epithelium and the septum transversum mesenchyme.[167,169] The essential role of these cells for liver development is shown by the complete failure of hepatoblast budding in VEGFR2$^{-/-}$ mice.[170] At E9.5, these cells begin to merge into vascular structures and hematopoietic cells appear in their lumens, indicating the onset of liver hematopoiesis.[167] These VEGFR2$^+$ cells start to express Stabilin-2 (Stab2), a scavenger receptor specifically expressed in sinusoidal ECs (including LSECs, bone marrow (BM), and spleen ECs), before they are organized in a lumen.[169] Another hyaluronan receptor, LYVE-1, becomes expressed 1 day later, and both remain expressed until adulthood. CD34 was expressed in fetal LSECs (from E9.5 to E14.5) but was downregulated later on. In contrast, the expression of CD32b, a receptor for the Fc fragment of immunoglobulins, started later in development (around E15.5).[169] This stepwise phenotypic transition mirrors the functional conversion of the liver as a hematopoietic organ during development to a metabolic organ after birth and also runs in parallel with morphologic changes of the sinusoids.[171,172]

After birth, the sinusoids further adopt regional changes resulting in "zonation" across the portal tract (see below).[173] LSECs share various molecular and structural features with lymphatic ECs. The latter emerge by transdifferentiation and budding from veins (see below). Intriguingly, since Stab2 expression was both observed in ECs of the vitelline vein as well as in VEGFR2$^+$ cells that give rise to LSECs during liver development, the hypothesis that LSECs may also arise by transdifferentiation from venous ECs is certainly worth pursuing[169,172] (FIGURE 38.4).

While zebrafish have been mainly used to study axial vessel formation since their introduction in the vascular community,

a new trend has emerged in which this animal model is also becoming applicable to study organ development (and its dependency on contemporary vascular development).[174,175] Liver vasculogenesis starts around 50 to 55 hpf in the zebrafish.[175,176] Unlike in mice, liver development was initially independent of the vasculature[177]; however the presence of sinusoids (starting at 68 hpf), and later on (at 72 hpf), blood flow in these sinusoids, was essential for further liver growth.[176]

The signals that control the acquisition of an LSEC-specific gene signature, function, and morphology remain largely unknown. Likely, the zebrafish model along with studies in mice will boost the discovery of these factors. By sequestering VEGF-A specifically in the mouse liver, upon overexpression of signaling-incompetent VEGFR2 in hepatocytes, this angiogenic growth factor was shown to be essential for maintaining fenestrae in LSECs throughout development.[178] Angiopoietin-like 3 (ANGPTL3), an integrin-binding member of the angiopoietin family that is specifically expressed in the liver during development and in adults, was shown to induce blood vessel formation in a rat corneal assay, but a role in LSEC behavior has not been documented.[179] In a recent differential transcriptome analysis, Wnt2 was found to be highly enriched and Frizzled4 was identified as a novel Wnt2 receptor in LSECs. VEGFR2 was a target of Wnt2 signaling, suggesting that autocrine Wnt2 and VEGF signaling cooperate to determine LSEC behavior.[180] In addition to this autocrine effect, LSEC-derived Wnt2 (triggered by VEGF-A signaling) also induced an "angiocrine" effect on hepatocytes by promoting their proliferation during liver regeneration after partial hepatectomy in adult mice.[166] Importantly, LSECs and hepatocytes were shown to have different characteristics depending on their location in the liver lobules. This so-called zonation reflects the performance of different metabolic tasks in different areas of the lobules and is in part determined by Wnt/β-catenin signaling.[181]

The Brain

In order to maintain a stable environment for neurons, the central nervous system has developed specialized epithelial and endothelial barriers for regulation of ionic balance and nutrient transport and for blocking transit of potentially toxic molecules.[182] The endothelial barrier that protects the brain is called "the blood–brain barrier" (BBB). This barrier is established by tight junctions that seal the intercellular clefts and hence restrict paracellular diffusion of water-soluble molecules. ZO-1, junctional adhesion molecule, occludins, and claudins are the most important building blocks of tight junctions.[183] Caveolae, present in small numbers at the luminal surface, regulate transcellular transport.[182] In addition, brain capillary ECs express transporter molecules (e.g., P-glycoprotein or multidrug resistance 1) that function as efflux pumps for excitotoxic compounds or to deliver vital molecules to the neurons (e.g., glucose transporter [GLUT] 1). In addition to brain capillary ECs, the BBB has two additional cellular components that share their basement membrane with the ECs, astrocytes (which make contact with the ECs through their end feet), and pericytes.[182] Although astrocytes and ECs have been thought to be more important in barrier formation, the crucial role of pericytes in BBB integrity has recently been highlighted by the observation that pericyte loss in brain vessels may progressively disrupt the BBB and result in neurodegeneration.[184]

The establishment of the brain vasculature can be divided into three phases: a vasculogenic phase, an angiogenic phase, and the maturation phase during which the specific BBB characteristics arise. The central nervous system originates from the surface ectoderm. Shortly thereafter, angioblasts originating from the somites and the LPM migrate to the cranial region where they merge into a primitive tubular network called "the perineural vascular plexus" that envelopes the neural tube.[185] The brain tissue becomes vascularized by angiogenic sprouts from the perineural plexus. While the early fetal brain vasculature is quite permeable (frequently showing fenestrations), the barrier gradually tightens during late development, although this may happen at a different rate in different species.[186] The acquisition of BBB characteristics is in large part not predetermined, but is induced by the environment, as evidenced by transplantation studies of nonbrain vessels into a brain environment.[187] In humans, acquisition of BBB features, such as the expression of P-glycoprotein, occurs quite early in development, and this rapid change has been suggested to constitute a "second line of defense" for the fetus in addition to the placental barrier.[188]

As for the liver, the zebrafish has been recently introduced as a model system to study brain vasculogenesis/angiogenesis and barrier formation.[31,189] Similarly as for mammals, brain vessels in zebrafish develop by a combination of vasculogenesis and angiogenesis. First, two bilateral angioblast clusters emerge at 12.5 hpf, one rostrally giving rise to the rostral portion of the brain vasculature and one more caudally being the common source of the posterior brain vessels and the endocardium.[31] Angiogenic sprouting from these clusters begins around 16 hpf. In a recent study, the formation of the basilar artery around 36 hpf was shown to arise by a novel mechanism, that is, by sprouting from the primordial hindbrain channels (PHBCs), a bilateral venous structure which itself arises by vasculogenesis from the caudal angioblast cluster[190] (FIGURE 38.4). Moreover, the central arteries subsequently were generated by a second wave of sprouting from this primitive venous vessel, another illustration that arteriovenous fate decisions are versatile (see above). Interestingly, the emerging sprouts subsequently disconnected from the PHBC whereby the resulting isolated ECs merged *in situ* into the basilary artery. Thus, the basilary artery forms by a combination of angiogenesis and vasculogenesis. These processes were guided by cxcr4a (expressed on PHBC ECs) and cxcl12b (expressed in the neural hindbrain keel immediately adjacent to the basilary artery).

An accompanying study revealed that the same chemokine signals in coordination with hemodynamics regulates proper arteriovenous connectivity in the hindbrain.[191] By using a transgenic zebrafish expressing an endogenous tracer to monitor BBB integrity, Xie et al.[189] found that the BBB starts to develop at 72 hpf, preceded by the expression of claudin5a in the central brain arteries at 48 hpf. Claudin5 was also identified in mice as being determinant for BBB permeability since its absence results in a loss of barrier function specifically against small molecules.[192] Neurothelin, an extracellular MMP inducer, is upregulated during BBB maturation while plasmalemma vesicle associated protein (Plvap, also known as Meca-32) expression inversely correlates with BBB differentiation.[193–196]

The molecular mechanisms that instruct BBB maturation are only beginning to be unraveled. Since VEGF-A is known to induce/maintain fenestrations in ECs[178] and induce vascular

permeability (hence its original name "vascular permeability factor"[197]), it may have a less significant role during BBB maturation. It does however play a role during the vasculogenic phase of brain vessel development by functioning as an attractant signal for angioblasts to migrate in the cranial direction and position themselves around the neural tube.[185,198] In support of the rather negative role of VEGF-A during BBB establishment, the Src-suppressed C kinase substrate (SSeCKS or gravin) is induced by hypoxia in astrocytes and reduces VEGF-A expression while upregulating angiopoietin-1 (a vascular maturation factor[199]). This event may mark the transition of the angiogenic phase to the BBB maturation phase in brain vascular development.[200] Recently, Wnt signaling was shown to be involved in BBB formation by upregulating claudin3. Wnt signaling was active as early as E9.5, when the immature perineural vascular plexus is completed, was maintained throughout development, but then subsided in the adult stage, suggesting that Wnt signaling is a requisite for BBB ontogeny but less important for long-term BBB maintenance.[196] Wnt3a, but not Wnt5a, induced claudin3 expression, suggesting a differential effect of Wnt ligands. In addition to Wnt3a, Wnt7a and 9a also seem specifically important for BBB development, since their absence in mice leads to a selective defect in the vasculature of the central nervous system.[201,202] Given the effect of Wnt2 on LSECs (see above), one may hypothesize that Wnt ligands may have tissue-specific functions.[203] One of the powerful advantages of the zebrafish system is the opportunity to perform forward genetic screens by chemical induction of genome-wide random mutations. Such screens have identified mutations that compromise vascular integrity, some specifically in the brain (e.g., *bubblehead* and *redhead* corresponding to *βPix* and *Pak2a* [Ref.[123] and references therein]). Recently, the orphan receptor GPR124 was shown to be highly expressed on brain ECs and to cell-autonomously regulate expression of Glut1 and induction of other BBB properties.[204,205]

THE LYMPH VASCULAR SYSTEM

On the Origin of Lymph Vascular Endothelium

Like the blood vascular system, the lymphatic system is present in most organs, except for the central nervous system, BM, the uterine mucosa, cartilage, the epidermis, hair, nails, and cornea. New lymphatic vessels form in certain physiologic situations after birth (e.g., wound healing and pregnancy[206]) and under pathologic circumstances (e.g., cancer, inflammation). In addition to the lymphatic vessels, the lymphatic system in higher organisms also comprises lymphoid organs (which include the lymph nodes, tonsils, Peyer's patches, the spleen, and the thymus).[207] Like blood vessels, lymphatic vessels are of mesodermal origin. Since the beginning of the last century, there has been a debate concerning the precise nature of this mesodermal origin.[208,209] While the original descriptive studies based on ink injections and analysis of serial histologic sections did not decisively determine the way the lymphatic vessels arise, more sophisticated technology based on interspecies chimerism, the use of specific lymphatic endothelial cell (LEC) markers, transgenic mice, and genetic lineage tracing has presented more conclusive evidence for two different scenarios.

According to the first theory, LECs arise by transdifferentiation from venous ECs and then, after moving away from the vein, arrange themselves into the first lymphatic structures, the lymph sacs ("the centrifugal theory" proposed by Florence Sabin in 1909; Ref.[210]). Another scenario states that LECs arise as descendants from separate scattered mesenchymal precursors ("lymphangioblasts") which move toward the venous system and make contact with it later on ("the centripetal theory" proposed by Huntington and McClure in 1910; Ref.[211]). While both theories are not mutually exclusive, the relative importance of both mechanisms may however be different between species. Indeed, the contribution of lymphangioblasts to the lymphatic system in higher organisms (such as the mouse) may be much less important than in birds or frogs.[207,208,212,213] The existence of lymphangioblasts has been most elaborately shown in avian embryos, with several embryonic tissues harboring these cells, including the cardiac mesenchyme, the dermatomes, and the somites.[214–217] Interestingly, it was recently shown that the initial development of lymph nodes does not require the presence of lymph sacs; hence the origin of these lymphoid organs remains elusive.[218]

While nothing is known concerning the precise origin of and the molecular mechanisms underlying the differentiation of lymphangioblasts from their mesodermal precursors, recent studies have yielded insight into the molecular cascade that gives rise to the first LECs by transdifferentiation from venous ECs.[213,219,220] The earliest marker, LYVE-1, expressed by a subset of venous ECs in the anterior cardinal vein is already apparent around E8.5 in the mouse. Yet, the functional significance of this is unclear since mice lacking LYVE-1, alone or in conjunction with its homolog CD44, do not have a lymphatic defect.[221] Subsequently, these cells start to express Sox18, which supposedly makes them "competent" to respond to a lymphatic inductive signal. Sox18 can directly induce the expression of another transcription factor, Prox1, around E9.75, by binding to its promoter[222] (FIGURE 38.5). The signal that is responsible for the asymmetric expression of LYVE-1 and Sox18 remains to be determined. A number of recent studies in mice and small animal models have shown that COUP-TFII also induces and temporarily maintains Prox1 expression in LECs and therefore is absolutely required for lymphatic development.[223–225] COUP-TFII, by forming heterodimers with Prox1, can then codetermine the LEC-specific gene signature.[226,227] The ubiquitous expression of COUP-TFII in the entire cardinal vein makes it unlikely that this factor is involved in asymmetric LYVE-1/Sox18 expression. Recently, synectin was shown to regulate Sox18-driven lymphatic reprogramming *in vitro*, suggesting that it may have a role in the commitment phase, in addition to its involvement in lymphangiogenic sprouting later on (see below).[228] Finally, microRNAs (miR-181 and miR-31) may be involved in the regulation of Prox1 protein expression.[229,230]

Lymphangiogenesis

While the onset of Prox1 expression defines the commitment of the first LECs during development, many additional steps and accompanying molecular mediators are required to establish the first rudimentary lymphatic vascular network, which initially consists of a number of lymph sacs spread across the anterior–posterior axis[207,213,220,231,232] (FIGURE 38.5). Subsequently, lymphatic vessels arise from these structures and are further remodeled into a hierarchical network of initial lymphatics (capillaries), collectors, and larger ducts (the thoracic duct and the right lymphatic duct) that connect to the blood vascular

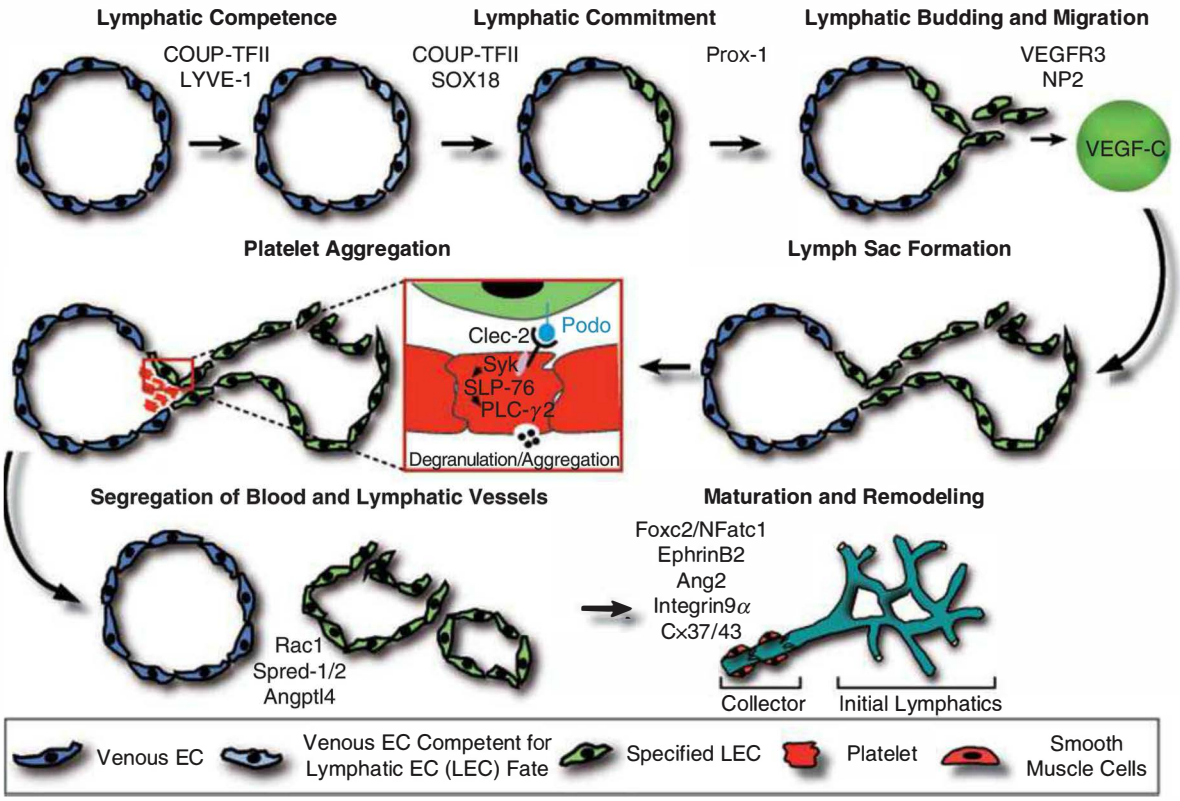

FIGURE 38.5 Lymphangiogenesis: stepwise toward a lymphatic tree. The most common route through which LECs arise in mammals is by transdifferentiation from venous ECs. First, a subset of ECs in the anterior cardinal vein become competent to respond to a lymphatic inductive signal. LYVE-1, as the earliest detectable LEC marker, was thought to be the "competence" factor; however, since mice deficient for LYVE-1 do not feature a lymphatic defect, other factors, perhaps Sox18 in cooperation with COUP-TFII, are involved in this step. Subsequently, Sox18 together with COUP-TFII induces the expression of Prox1 by which the cells become committed to an LEC fate. In response to lymphangiogenic signals (mainly VEGF-C), Prox1$^+$VEGFR3$^+$ LECs bud off from the vein and migrate outward. Thereafter, cells merge into primitive lymphatic structures, called "lymph sacs." To separate these newly formed lymphatic structures from the vein, platelets localized at the interface communicate through their Clec-2 receptor with podoplanin-expressing LECs. As a consequence, a molecular cascade is triggered resulting in platelet degranulation and aggregation. The platelet clot physically separates the two vessels, after which they segregate. In addition, other molecules have been shown to regulate lymphatic venous segregation, such as Rac1, Spreds, and Angptl4. Finally, the rudimentary lymphatic network is remodeled into a hierarchical system composed of bare initial lymphatics and SMC-coated collector vessels, the latter which have valves to prevent backflow of lymph. (Adapted from Tammela T, Alitalo K. Lymphangiogenesis: molecular mechanisms and future promise. *Cell* 2010;140(4):460–476; Schulte-Merker S, Sabine A, Petrova TV. Lymphatic vascular morphogenesis in development, physiology, and disease. *J Cell Biol* 2011;193(4):607–618.)

system at the level of the subclavian vein. A first step following LEC commitment is the acquisition of additional LEC markers, for example, VEGFR3 and neuropilin-2, and budding of Prox1$^+$ LECs from their venous mother vessel. This process, as well as the sprouting of LECs during the formation of lymph vessels from the lymph sacs, may be similar to angiogenic sprouting and likely requires destruction of the basement membrane, removal of SMC coating, and the induction of a tip cell phenotype. Such lymphangiogenic tip cells were already described at the beginning of the previous century.[208] A recent study has shown that, in analogy to angiogenic sprouting, lymphangiogenic sprouting (and hence the tip cell vs. stalk cell phenotype) is regulated by Notch signaling, since Notch induced a stalk cell phenotype in LECs.[233]

It is not clear whether the merging of two approaching lymphangiogenic tip cells is guided by macrophages (as is the case in angiogenic sprouting), since increased accumulation of macrophages seems to rather induce aberrant fusion of lymphatic and venous vessels.[234] Instead, macrophages may have a role in determining lymphatic vessel size by limiting LEC proliferation.[235] The "centrifugal" movement away from the vein occurs in response to VEGF-C. However, given the ubiquitous expression of this lymphangiogenic growth factor in the surrounding mesenchyme, additional guidance cues are likely required to guide the LECs to their precise locations.

Intriguingly, in zebrafish, the first functional lymphatic trunk vessels, that is, the thoracic duct and the dorsal longitudinal lymph vessel, are formed when the PCV-derived parachordal

lymphangioblasts move ventrally and dorsally, respectively. These lymphangioblasts arise by secondary sprouting from the PCV, a process that was specifically affected in the absence of synectin.[228] The ventral or dorsal lymphangioblast movement seems to require signals from the arterial vessels, since the lymphangioblasts systematically follow the arterial ISVs to reach their final destination.[142] As for sprouting, this guidance also required Notch signaling.[236] In addition, environmental signals, such as Ccbe1, a secreted collagen and calcium-binding EGF-domain-1 protein, were also necessary for correct lymphatic sprouting.[141] "Classical" guidance signals for blood vessels and nerves may also be used by LECs for path finding and sprouting. Recent studies in mice have revealed a role for ephrinB2 in LEC sprouting by regulating VEGFR3 internalization and signaling.[108] Furthermore, Robo1 is expressed by LECs and was found to mediate LEC migration and tube formation upon Slit2 stimulation.[237] Finally, netrin4 stimulated LEC proliferation, migration, adhesion, and tube formation, through a yet unidentified receptor.[238]

A next crucial step is the separation of the nascent lymphatic structures from the vein (FIGURE 38.5). While the involvement of hematopoietic cells was already demonstrated 8 years ago, it was only last year that the identity of the responsible hematopoietic cells was revealed.[239,240] LECs, which by now have acquired podoplanin expression, interact with the corresponding Clec-2 receptor on platelets located at the border of the budding lymphatic vessel. This interaction results in the activation of a signaling cascade involving Syk, Slp-76, and Plcγ-2 leading to platelet aggregation. The aggregate seals off the vein from the lymphatic vessel causing them to separate. Meis-1 that controls thrombopoiesis also is required for venolymphatic separation.[241] In certain organs, appropriate blood vascular-lymphatic segregation requires specific signals, such as fasting-induced adipose factor (fiaf or Angptl4); however, the underlying signaling mechanism remains to be determined.[242]

Further maturation of the lymphatic network involves the specification of the proximal blind-ending initial lymphatic vessels (capillaries) from the distal collector vessels (FIGURE 38.5). While the former lack a continuous basement membrane, pericyte/SMC coating, and intraluminal valves, collector vessels have all these three features. In addition, the junctional organization between LECs of these two different segments of the lymphatic vasculature is distinct: initial lymphatic vessel LECs feature button-like junctions optimal for fluid absorption, while the collector vessel LECs are joined by zipper-like junctions that support better their transport function.[243,244] The functional and morphologic differences between LECs in collectors versus capillaries are reflected by a differential expression profile (with collector LECs expressing more VEGFR2, ephrinB2 and capillary LECs expressing more LYVE-1, VEGFR3, neuropilin-2, Cox1/2, eNOS, and iNOS).[209,245] The molecular mechanisms underlying this functional, molecular, and morphologic heterogeneity have only recently been revealed (reviewed in Refs.[213,220,240]). Here, we only highlight a number of them showing that many are common to blood vascular development.

In Foxc2$^{-/-}$ mice, collecting lymphatics lack valves and the capillaries wrongfully acquire an SMC coat and basement membrane.[246] Upon VEGF-C stimulation, the nuclear factor of activated T-cell c1 transcription factor synergizes with Foxc2 for regulating lymphatic maturation.[247] The PDZ domain of ephrinB2 is also crucial for lymphatic maturation since deletion of this domain aborts valve formation and induces collector hyperplasia.[248] Angiopoietin-2 is important for SMC recruitment[249] while in the absence or upon lower expression of Tie1, an angiopoietin-2 receptor, there is an abnormal remodeling/patterning of the lymph sacs and a breach in lymphatic vessel integrity due to LEC apoptosis.[250,251] Furthermore, lymphatic remodeling defects have also been observed in Akt1$^{-/-}$ mice and in PI3 kinase signaling–deficient mice, perhaps because these pathways are acting downstream of angiopoietin-2 receptor Tie2 signaling.[252–254] Lymphatic valve formation is also regulated by integrin9α and its ligand fibronectin containing the EIIIA domain.[255] In the absence of integrin9α, the valve leaflets cannot be elongated, leading to the formation of ring-like constrictions that do not prevent lymph backflow. Finally, connexin-37 and -43 are potential targets of Foxc2 and are highly expressed on valvular LECs, and their single or combined absence leads to lymphatic valve disruption in lymphatic collectors.[256]

Establishment of Organ-Specific Lymphvascular Beds

While remarkable differences concerning the blood microvasculature in different organs have been elaborately documented, and in contrast to the rapidly emerging notion that there is clearly morphologic, functional, and molecular differences among ECs in collector versus initial vessels, few studies have considered the possibility that the same heterogeneity may also exist among lymphatic microvessels in different organs.[257–259] Vascular bed–restricted lymphatic phenotypes occurring in knockout mice lends further support for such heterogeneity.[260] Even less is known about how these lymphatic vessel networks develop in order to adopt their final organ-specific architecture. Since the lymphatic system needs to balance the amount of ISF that leaks out from the blood vessels, the absence of lymphatic vessels within certain vascularized tissues, such as the brain and the BM, is unexpected. Like we did for the blood vasculature, here we discuss the heart, liver, and brain as examples to document interorgan differences in the lymphatic system.

The Heart

In the adult heart, there are three major lymphatic plexi, a subendocardial, a myocardial, and a subepicardial plexus.[261] The two main lymphatic collectors run closely alongside the subepicardial branches of the coronary arteries.[262] A recent study in the mouse reveals that the first LYVE-1$^+$ cells appear around E11 scattered in the subepicardium and the trabecular myocardium with a positive gradient from the base to the apex of the heart.[263] In addition, LYVE-1 expression was also found at the venous pole of the heart in the proximal part of several early systemic veins (e.g., the left and right cranial caval vein and the pulmonary vein). From E14.5 on, these scattered cells started to merge into lumenizing tubules extending in the apical direction, and the first collecting lymphatic vessel could be observed running cranially on the surface of the coronary sinus. In many cases, scattered LECs had an "arborized" appearance reminiscent of nerve outgrowths and vessel sprouts coming of the primitive tubular plexus were frequently observed. Around birth, the heart contained two main drainage areas, one collecting lymph from the left, another from the right ventricle, and two major collectors were apparent. Interestingly, some endocardial cells also stained for LYVE-1. Partial SMC coverage was seen around E17.5 in LYVE-1$^+$ vessels in the aortopulmonary sulcus and, in

accordance with the human heart,[264] maturation and expansion of the lymphatic vasculature continued at least until 4 weeks after birth at which time scattered LYVE-1$^+$ cells were no longer present.[263] While the static LYVE-1$^+$ stainings do not deliver direct mechanistic evidence, they suggest that the heart lymphatic system arises by a combination of venous transdifferentiation and "lymphvasculogenesis," that is, the merging of lymphatic precursors scattered within and originating from the heart mesenchyme. Another study confirmed the presence of scattered LYVE1$^+$CD45$^+$ lymphangioblasts in the avian embryonic heart supporting the "lymphvasculogenesis" theory.[214] While according to one scenario, blood vascular EC precursors originate from the PEO (see above), this temporary structure does not deliver lymphangioblasts to the heart.[214] Given the significant overlap between LSECs and LECs, and in analogy to the presumed liver origin of the heart coronary ECs,[145] it has been hypothesized that lymphatic vessels of the heart may have a hepatic origin.[263] In the avian heart, ECs on the inner side of the semilunar heart valves express Prox1.[214] Since ECs from the endocardium give rise to valvular ECs (see above), it is tempting to speculate that the LYVE-1$^+$ cells observed in mouse endocardium are precursors of valvular ECs. Finally, while the lymphatic and blood vascular systems in general stay separate, except for a connection at the level of the thoracic duct and right lymphatic duct to the venous system, some lymphovenous anastomoses have been reported in human, porcine, and avian hearts.[214,265]

The Liver

For the liver, studies on the lymphatic network have been merely descriptive, and not much is known about when and how the lymph vessels arise in this organ.[266] Nevertheless, the liver produces a large amount of lymph, estimated to constitute as much as 25% to 50% of the total lymph that is drained by the thoracic duct.[267] Like in the heart, there are three major lymphatic plexi, a portal, a sublobular (absent in the rat[268]), and a superficial (or capsular) plexus, the portal plexus being the most significant lymph drain. Lymph is primarily produced in the sinusoids, from where it enters the space of Disse underneath the sinusoidal endothelium and flows through the channels traversing the limiting plate either independently of blood vessels or alongside the inlet venules to end up in the interstitial space of the portal tract.[266] As mentioned earlier, the ECs lining the blood vascular and the lymphatic microvessels in the liver, LSECs, and LECs, respectively, are very similar in their molecular characteristics.[169] As for the developmental origin of the latter, it has been suggested by quail/mouse chimera experiments that liver tissue has its own intrinsic capacity to give rise to VEGFR3$^+$ lymphatic vessels, suggesting a "lymphvasculogenic" scenario.[269]

The Brain

Since the brain (as well as the rest of the central nervous system) does not feature conventional lymphatic vessels, drainage of extracellular fluid requires alternative mechanisms. Interestingly, despite the absence of lymphatic vessels, VEGF-C, the main lymphangiogenic signal, is amply produced in the brain where it serves as a trophic factor for VEGFR3-expressing neural progenitors during development.[270,271] Unlike in other organs, two sources of extracellular fluid exist in the brain: the cerebrospinal fluid (CSF; produced by the choroidal plexus and serving as a liquid shield to protect the brain from traumatic damage) and the ISF (produced by brain capillaries). For drainage of CSF, two routes have been described: the arachnoid villi and granulations (projections of the arachnoid mater into the cranial venous system) or the extracranial lymphatic vessels (those in the vicinity of the olfactory bulb in the nasal submucosa, those in the dura mater, or those around cranial nerves); however, the relative importance of each of these routes is species dependent and has been debated.[272,273,274] Drainage of ISF follows a perivascular route which is largely separate from the routes described above for CSF drainage.[274] Tracer studies in animals have revealed this route that runs along the basement membrane of capillaries and along the basement membranes and between the SMCs of arteries to the extracranial cervical lymph nodes. Efficient drainage is dependent on an active propulsive force, most likely, the contraction of the arteries. Most intriguingly, such a route has also been revealed in the human brain by looking at the clearance of the "natural tracer" amyloid-β (Aβ) peptides (derived from the amyloid precursor protein) that accumulate in the brain tissue of Alzheimer disease patients. This may suggest that the acquired arterial stiffness in older individuals (which may reduce active ISF drainage) is responsible for the accumulation of Aβ peptides in Alzheimer patients.[274] Interestingly, impaired perivascular drainage of protein may not be limited to the brain and may occur at other sites leading to protein elimination failure arteriopathy. For instance, periarterial protein accumulation has been observed in patients with CADASIL in the skin and kidney in addition to the brain.[275]

CONCLUSIONS AND FUTURE PERSPECTIVES

The existence of the blood vascular and lymphatic systems has been recognized since ancient times; however, the first studies were mainly descriptive, thereby providing little information about cellular and molecular mechanisms that underlie their ontogeny and final appearance. Understanding these mechanisms is however an important mission since this may teach us how to design new rationalized therapies for the growing list of diseases that find their origin in defects in the blood or lymph vascular systems.[213,220,231,276] With the advent of increasingly more sophisticated technology, substantial progress is being made in identifying key molecules and mechanisms that can be therapeutically exploited. The first drugs to treat vascular-related diseases have already reached the clinic in the form of strategies to combat cancer by inhibiting blood (and lymphatic) vessel growth. Perhaps not surprisingly, these drugs are targeted against VEGF-A, a molecule that has an orchestrating role in almost every step during the formation of blood vessels. Nevertheless, another recurrent theme related to the availability of more advanced technologies is that they have often forced us to revisit and reconsider certain concepts that became dogmatic over the years. For instance, since Judah Folkman launched the concept in the 1970s that cancer cells need blood vessels for their growth, antitumor strategies have been focusing on how to reduce vessel growth in cancer. Now, it has become clear that it may be also relevant to "normalize" the tumor blood vasculature, that is, to change the phenotype of tumor blood vessels from a hyperactive to a quiescent one, thereby limiting tumor invasiveness/metastasis and making them more accessible for chemotherapeutic drug delivery.[129,277] Another important example is the realization that ECs are not all the same in every vascular bed and that more specific "tailored" therapies may be required. In addition, this EC heterogeneity can be exploited for vascular bed–specific drug delivery.[278]

At the same time, technologic refinement also has surfaced new concepts that likely will gain more attention in the near and distant future. Here we only highlight one example. A cross-control link between angiogenesis and metabolism has been recently demonstrated.[279,280,281] Similar to the previously described neurovascular link,[96] these two areas of research seem more closely related than previously anticipated. When there is sufficient oxygen, most cells use this for generating energy, as its reduction provides the largest free energy release per electron transfer. When there is shortage of oxygen, cells switch from aerobic to anaerobic metabolism (known as "the Pasteur effect"), which is a less efficient means of generating energy. The link with angiogenesis (which improves oxygen supply) ensures that oxygen consumption by oxidative metabolism remains in close balance with vascular oxygen supply. Certain metabolic regulators, such as PGC-1α, function by mounting an angiogenic response to improve oxygen reserves.[282] Other metabolic sensors, like PHD1, do not induce an angiogenic response but instead make cells tolerant against hypoxia by reprogramming oxygen consumption.[283] In ischemic (oxygen-deprived) limbs, the absence of PHD1 results in reduced oxygen consumption in muscle fibers, which protects them from oxidative stress. This may open perspectives for the use of PHD inhibitors in ischemic diseases.

In conclusion, here we summarized our current knowledge about the mechanisms behind blood/lymphatic vessel development which are quickly being unveiled thanks to sophisticated technology allowing research at incremental resolution. Obviously, this has been realized by many researchers and we apologize to those whose work we have not discussed here, but was nevertheless of central importance. By using technology as an "engine of progress," we will soon arrive at the next generation of (lymph)angiogenic therapies that will help millions of patients suffering from vascular disease.

CHAPTER

39 Rheology and Vessel Wall Stress

LARRY V. MCINTIRE, JUAN M. JIMÉNEZ, SUZANNE G. ESKIN, AND PETER F. DAVIES

The classical conditions considered favorable for thrombosis and attributed to the triad of observations assembled by Virchow[1] in 1856 remain central to the modern interpretation of thrombotic mechanisms. They are (a) alterations in normal blood flow, particularly low flow or its cessation; (b) vessel wall injury, particularly of the protective anticoagulant endothelium; and (c) blood hypercoagulability. To promote most forms of pathological coagulation, blood-borne elements are delivered to a relatively fixed interface of the vessel wall surface. This places rheology (study of the flow of materials) and its principal components—molecular transport, shear stresses, and strain deformation of cells—as important physical properties in the regulation of coagulation. In this chapter, we first define and outline in context the fluid mechanical aspects of rheology and the experimental *in vitro* models that address mechanisms of interactions between blood and surfaces and vascular cells. We then consider how different natural vascular geometries *in vivo* promote spatial variations of rheology that can influence the phenotype of the endothelium with implications for its anticoagulation properties. Finally, we consider how similar rheologic principles apply at the microscale to flow around intracoronary stents to promote a local environment conducive to stent-related thrombosis.

Blood flow–induced shear stresses and pulsatile-induced vessel wall strain can considerably modulate blood kinetics and vascular cell function. Local mechanical forces can directly alter the metabolism and gene expression of vascular cells.[2,3,4] While the kinetics of thrombus formation depends on local flow conditions, flow-responsive cell receptors and ligands support cell–cell and cell–blood protein adhesion under arterial, venous, and pathologic shear conditions. Additionally, mass transport of cells and proteins to and from reactive surfaces, such as a damaged vessel wall, varies in different flow regimes. Understanding hemodynamics requires the application of the fundamentals of classical fluid mechanics and rheology coupled with deformable vessel mechanics. Theoretical models of the vascular system have been developed by applying the governing principles of fluid flow and mass transport. On the basis of these relatively simple models, dynamic experimental systems have been designed that simulate vascular shear conditions. These systems are valuable tools for investigating the molecular mechanisms supporting vascular processes important to thrombosis under flow, as seen *in vivo*.

BLOOD FLUID DYNAMICS

Principles of Rheology

Physical blood flow characteristics have long been considered to be as important to vascular function as are the blood vessel itself and the circulating components. A simple, but relevant, model of the vascular system may be developed by considering the steady, pressure-driven laminar flow of an incompressible newtonian fluid through a long cylindrical tube with a constant cross-sectional area.[5–8] These conditions yield an axisymmetric flow field that can be described by the radial position (r), the mean fluid velocity (v), and the vessel radius (R):

$$v_z = 2(v)\left[1-\left(\frac{r}{R}\right)^2\right] \tag{39.1}$$

As suggested by Equation 39.1, the axial velocity, v_z, reaches a maximum at the center of the tube where r is equal to zero (see FIGURE 39.1). Moving away from this center position, velocity decreases as the wall of the tube is approached. The fluid is assumed not to slip along the wall; that is, the fluid velocity at the wall is assumed to be zero.[6] The presence of maximum velocity at the center and zero at the wall yields a velocity gradient called *Shear*, which refers to the relative motion of the different fluid planes in the velocity profile. The shear rate (γ) is a measure of the velocity gradient and indicates the rate at which fluid layers are sliding past one another.

$$\gamma = \frac{dv_z}{dr} = -\frac{4(v)r}{R^2} \tag{39.2}$$

The units of the shear rate are inverse time, commonly reported as inverse seconds. Although the fluid velocity is greatest at the center of the tube, the velocity gradient, and therefore the shear rate, is zero there. Conversely, at the wall of the tube, the velocity gradient and therefore the shear rate reach a maximum (FIGURE 39.1), but the actual velocity is zero. Important to the rheology of the vascular system is the shear rate at the wall of the tube ($r = R$), which corresponds to the shear rate at the vessel surface (γ_w):

$$\gamma_w = -4v/R \tag{39.3}$$

The mean fluid velocity, (v_z), may be expressed in terms of physical quantities as in Equation 39.4:

$$(v) = \frac{Q}{\pi R^2} \tag{39.4}$$

where Q is the volumetric flow rate. Substituting Equation 39.4 into the wall shear rate equation (Equation 39.3) leads to a more practical expression of γ_w:

$$\gamma_w = -\frac{4Q}{\pi R^3} \tag{39.5}$$

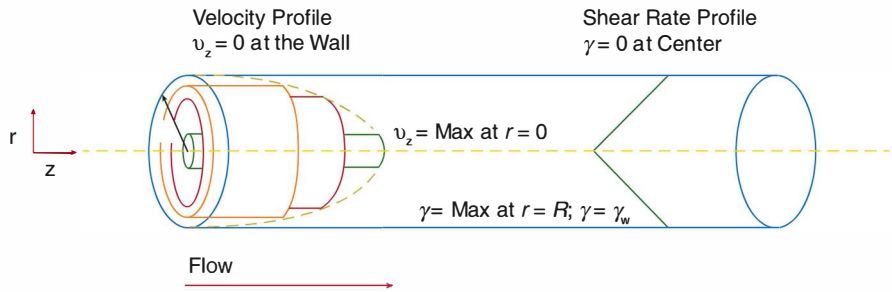

FIGURE 39.1 Velocity (v_z) and shear rate (γ) profiles produced by steady, laminar flow of an incompressible, newtonian fluid through a long cylindrical tube with a constant cross-sectional area. Shear refers to the relative motion of the different fluid planes in the velocity profile. The shear rate indicates how fast the fluid layers are sliding past one another. The fluid velocity is greatest at the center of the tube while the shear rate is zero. Conversely, at the wall of the tube, the shear rate (γ_w) reaches a maximum and the fluid velocity is zero. r, radial position; R, vessel radius. (Modified from Alevriadou BR, McIntire LV. Rheology. In: Loscalzo J, Schafer AI, eds. *Thrombosis and hemorrhage*. Boston, MA: Blackwell, 1994:369–381; Goldsmith HL, Turitto VT. Rheological aspects of thrombosis and haemostasis: basic principles and applications. ICTH9 Report—Subcommittee on Rheology of the International Committee on Thrombosis and Haemostasis. *Thromb Haemost* 1986;55:415–435.)

As predicted from the range of vessel sizes and volumetric blood flow rates, the wall shear rates corresponding to the different regions of the vascular system can vary greatly (see Table 39.1).

In addition to shear rate, the fluid *shear stress* is commonly used to describe rheologic conditions in the vascular system. Shear stress is a measure of the force per unit area exerted by the flowing blood as different fluid layers slide past one another. Shear stress is typically expressed in dynes per square centimeter (dyn per cm^2) or Pascals (1 Pa = 10 dyn per cm^2). For newtonian fluids, shear stress (τ_z) is directly proportional to both the viscosity of the fluid (μ) and the shear rate[7]:

$$\tau_z = -\mu \frac{dv_z}{dr} = \mu\left(\frac{4(v)r}{R^2}\right) \tag{39.6}$$

At the vessel wall, $r = R$, and Equation 39.6 becomes the equation for the wall shear stress (τ_w):

$$\tau_w = \mu\gamma_w = \mu\left(\frac{4Q}{\pi R^3}\right) \tag{39.7}$$

Table 39.1

Shear rates in the vascular system

Vessel	Shear Rate (Per Second)
Large arteries	300–800
Veins	20–200
Arterioles	500–1,600
Stenotic vessels, stents	800–10,000

(Modified from Alevriadou BR, McIntire LV. Rheology. In: Loscalzo J, Schafer AI, eds. *Thrombosis and hemorrhage*. Boston, MA: Blackwell, 1994:369–381.)

Fluids resist shear, and so pressure gradients along the tube length are necessary to produce the work required to overcome the frictional resistance to flow. In fully developed laminar flow, a balance exists between the force generated by the pressure gradient (acting across the luminal surface) and the force of shear resistance generated by viscous drag (acting on the vessel wall)[5]:

$$\frac{\Delta P}{\Delta z}\pi R^2 = 2\pi R\tau(R) \tag{39.8}$$

where ΔP is the pressure difference across a given tube length in the axial direction, Δz. Substituting for $\tau(R)$, which equals τ_w in Equation 39.7, yields the Hagen-Poiseuille equation that relates the pressure drop along a vessel to the volumetric flow rate[7]:

$$\frac{\Delta P}{\Delta z} = \frac{8\mu Q}{\pi R^4} \tag{39.9}$$

This model of the vascular system describes flow regimes where viscous forces rather than inertial forces dominate, a type of flow known as *Poiseuille flow*.[5–7] The Reynolds number (N_{Re}) is a dimensionless parameter that describes the relative importance of the inertial and viscous forces present under flow[6]:

$$N_{Re} = \frac{\text{inertial force}}{\text{viscous force}} = \frac{\rho(v)^2}{\left(\mu\frac{(v)}{2R}\right)} = \frac{2R(v)\rho}{\mu} \tag{39.10}$$

where ρ is the fluid density. When the viscous forces are dominant relative to the inertial forces, specifically when N_{Re} is less than approximately 2,100, the fluid flow is laminar and Equations 39.1 through 39.9 are valid descriptions of the velocity and shear profiles.[5,7] This is nearly always the case in the straight portions of blood vessels, with the possible exception of the largest vessels with high blood flow rates, such as the ascending aorta, and in severely stenotic atherosclerotic vessels.

When N_{Re} is >2,100, the steady, Poiseuille flow becomes unstable and is replaced by complex, turbulent flow regimes.[5–7] Under these conditions, the inertial forces required to accelerate and decelerate the fluid along its flow path dominate. The pulsatile motion of blood flow contributes to the inertial forces present, and a specific modified Reynolds number has been developed to determine when inertial forces resulting from the pulsations in the cardiac cycle must be considered. This dimensionless parameter is called the *Womersley alpha parameter*[5]:

$$\alpha = R\left(\frac{\omega\rho}{\mu}\right)^{1/2} \qquad (39.11)$$

where ω is the frequency of the oscillation in radians per second. Pulsation effects predominantly impact the flow fields in major arteries that have large diameters and are located proximal to the heart where oscillations have not been significantly dampened by vascular compliance.[5]

Adding to the complexity of flow in the vascular system is the elasticity of the blood vessels. As indicated by Equations 39.5 and 39.9, the shear profiles and the pressure gradients required to produce flow are highly sensitive to changes in the vessel radius. Although most vessels do not substantially dilate under the oscillatory conditions of normal blood flow, very large vessels (e.g., the aortic and the pulmonary arteries) experience radial changes during the different phases of the cardiac cycle.[5] Additionally, the velocity and shear profiles in a broad distribution of vessels are affected by events such as vasoconstriction and vessel stenosis that also lead to changes in vessel radius.

Applicability to Blood Vessels

The model of the blood vessel as a long cylindrical tube is applicable to much of the vascular system, and in the straight portions of vessels, turbulence due to a Reynolds number higher than 2,100 is rarely observed. Even in the presence of physiologic shear rates, however, complex vessel geometries may change the flow from simple Poiseuille to a more complex form while remaining laminar. This complexity can induce flow separation from the vessel wall, stagnant regions, transient flow reversal, and eddy formation.[7,8] In the vascular system, recirculating flow conditions increase the residence time between the vessel wall and circulating cells and proteins, leading to a potential increase in the local deposition of the components necessary for plaque and thrombi formation. FIGURE 39.2 outlines some common sites of vascular flow complexity, which include bifurcations, T-junctions, highly curved vessels (e.g., aortic arch), regions near valves, and vessels with abruptly changing diameters such as a stenosis.[5,9–12] These sites correspond with areas of increased thrombi and plaque formation.[13,14,15–19]

Nonnewtonian Characteristics

In addition to geometric and flow-rate influences, blood flow regimes vary because the viscosity of blood depends on the shear rate applied; that is, blood is not strictly a newtonian fluid.[20] At very low-shear rates, blood does not flow in response to the subthreshold levels of shear stress applied.[20–22] This property of having a yield stress is characteristic of elastic materials rather than newtonian fluids. After the yield stress is applied, blood flows and, as the shear rate is increased further, the effective viscosity of blood decreases (see FIGURE 39.3).[20,23,24,25] In contrast to whole blood, *plasma* is a newtonian fluid.[21] Therefore, the nonnewtonian properties of blood can be attributed to the presence of cells and cell crowding. All cells in the bloodstream experience shear from the flowing blood. If the cells were simply hard spheres, the shear would cause simple rotation and

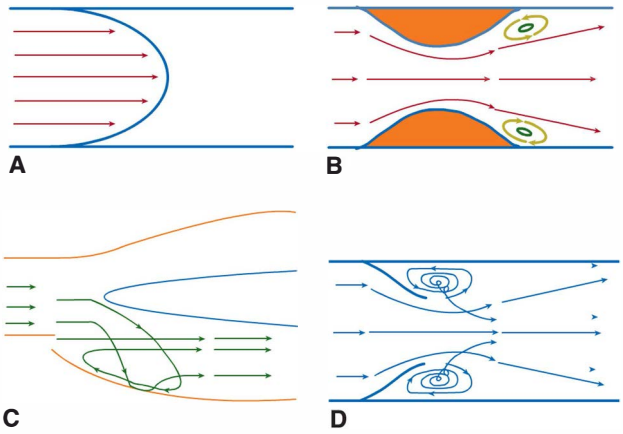

FIGURE 39.2 Streamlines in normal Poiseuille flow **(A)** and flow at sites of complex laminar flows, including vessels with abruptly changing diameters **(B)**, bifurcations **(C)**, and regions near valves **(D)**. (Modified from Karino T, Goldsmith HL, Motomiya M, et al. Flow patterns in vessels of simple and complex geometries. *Ann N Y Acad Sci* 1987;516:422–441.)

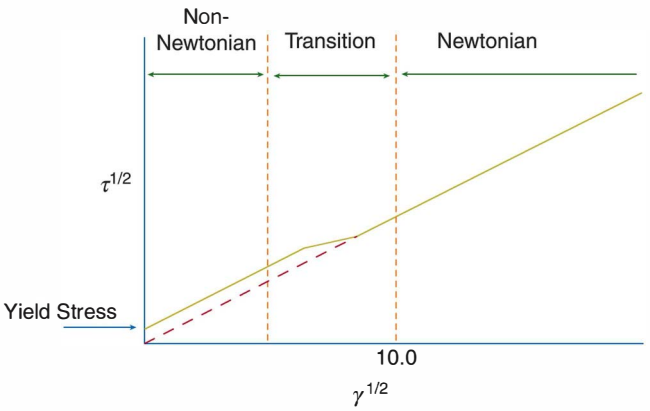

FIGURE 39.3 The nonnewtonian nature of blood. At very low shear rates (γ), blood will not flow in response to the subthreshold levels of shear stress (τ) applied. After the yield stress is reached, blood will flow, and as the shear rate is increased further, the viscosity of blood will decrease, as indicated by the decrease in slope with increasing shear rate. For newtonian fluids, the shear stress is directly proportional to the shear rate over the entire range of shear rates and no yield stress is present. Blood behaves as a newtonian fluid at shear rates >100 to 200/s. (Modified from Merrill EW. Rheology of blood. *Physiol Rev* 1969;49:863–888.)

translation.[26,27] Owing to the viscoelastic nature of cells, however, shear can twist, stretch, or compress the cells causing deformations.[26,28] Red blood cells, constituting 99% of the blood cellular volume, contribute significantly to the nonnewtonian nature of blood. At low shear rates (<50/s), fibrinogen mediates red cell aggregation into chains called *rouleaux*.[5,20,29] As the shear rate is increased, the rouleaux breaks down and the effective blood viscosity decreases.[25,30,31] At shear rates >20/s, red cells deform and align in the direction of flow.[32,33] Deformations on single cells in dilute suspensions lead to cell migration toward the center of the flow stream[32,33] due to the Magnus effect. However, in concentrated suspensions, crowding restricts the rotation and translational movements of the red cells and increases the number of red blood cell collisions. These crowding effects drive the cells toward the wall and offset the migration of deformable particles to the vessel center.[32] In vessels with diameters larger than 100 μm, the flow of a suspension with a physiologic concentration of red cells will result in a cell-free layer of approximately 4 μm at the wall.[5,32] Red cell crowding and collisions also complicate the flow paths of circulating white blood cells, platelets, and large plasma proteins.[32,33] Additionally, under physiologic red cell concentrations, the velocity profile is no longer parabolic as in Poiseuille flow, but becomes blunted at the leading edge.[5,32] Despite all these limitations, blood can normally be considered a homogeneous, newtonian fluid for shear rates >100 to 200/s.[5,20] At these shear rates, the viscosity of blood remains relatively constant and is determined primarily by the hematocrit, temperature, and the concentration of fibrinogen and other proteins.[20]

Blood Cell Rolling and Adhesion

The shear forces due to flowing blood also influence the interactions between the vascular wall and adherent cells. The shear force and torque that a cell experiences when it is tethered to a surface depend on the cell size, the fluid viscosity, and the shear rate.[34–36] At higher shear forces, stronger cell–surface bonds are required to support firm cell adhesion. If the energy from shear in the bloodstream is high enough to deform the cell membrane and overcome the adhesive bond strength, cells will not adhere firmly to the wall.[36] Under these conditions, rapid cell–surface bond formation may support transient adhesion, or rolling, on the vascular surface (see FIGURE 39.4A). Cells that constitute the vascular wall itself, such as endothelial cells and smooth muscle cells, also experience tangential shear stress when exposed to flowing blood. Additionally, these cells may experience circumferential stress resulting from deformations caused by expansion and contraction of the blood vessel as well as compressive stress resulting from hydrodynamic pressure (FIGURE 39.4B).[3,4]

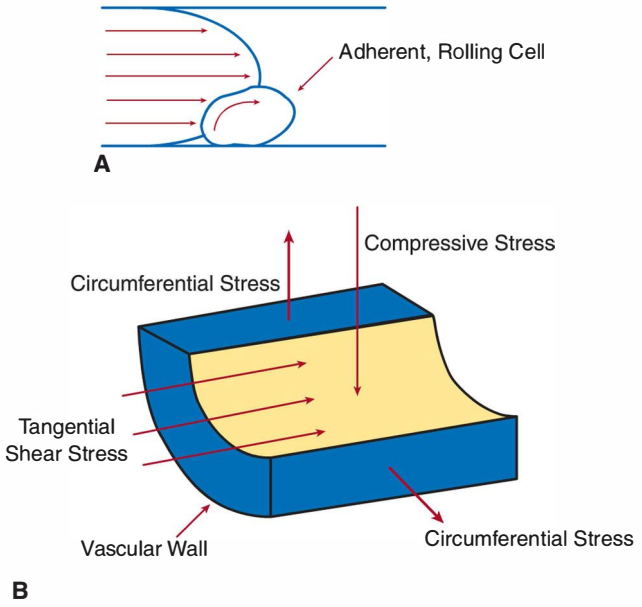

FIGURE 39.4 **A**: Shear forces acting on an adherent, rolling cell in a flow stream. **B**: Stresses acting on cells that constitute the vascular wall, such as endothelial cells and smooth muscle cells. Tangential shear stress results from the flow of blood over the vascular wall. Circumferential stress results from deformations caused by the expansion and contraction of the blood vessel, whereas compressive stress results from hydrodynamic pressure. (Modified from Papadaki M, Eskin SG. Effects of fluid shear stress on gene regulation of vascular cells. *Biotechnol Prog* 1997;13:209–221.)

BLOOD TRANSPORT PROCESSES

Diffusion and Convection

The primary function of blood is to transport materials to and from the organs, thereby sustaining life. Although vital, this transport may also augment pathological states such as thrombosis and atherosclerosis. The transport of materials occurs by two processes: diffusion and convection. *Diffusion* is the movement of material relative to the average fluid motion, irrespective of whether the fluid is flowing or stationary. Diffusion is random and results from Brownian motion of the particles. *Convection* is the movement of materials with the fluid and results from flow. Diffusion of materials is a very slow process in liquids, whereas convection can be very rapid. If flow is present, convection forces will dominate the mass transfer in blood, and diffusion effects will be negligible in the directions of flow. The *Peclet number* (N_{Pe}) is a dimensionless parameter that describes the relative importance of convection and diffusion in a given fluid stream[7,37]:

$$N_{Pe} = \frac{\text{convection effects}}{\text{diffusion effects}} = \frac{(v)2R}{D} \qquad (39.12)$$

where D is the molecular diffusion coefficient. Large Peclet numbers correspond to fluid flow where convection dominates, whereas for small Peclet numbers, diffusion is the dominant method of mass transport.

Considering again the model of the vascular system using Poiseuille flow of a newtonian fluid through a cylindrical tube of constant cross-sectional area, convection moves fluid along streamlines parallel to the wall and, therefore, the effects of diffusion are negligible in the axial direction. In the radial direction, convection does not occur and mass transfer is due solely to diffusion. The rate of mass transfer is proportional to the product of the molecular diffusivity and the local concentration gradient. Under these conditions, radial diffusion is required to transport material to the wall, and the steady state mass balance

at any point in the tube for a single species reduces to (neglecting homogeneous reactions):

$$v_z \frac{\partial C}{\partial z} = \frac{1\partial}{r\partial r}\left(rD\frac{\partial C}{\partial r}\right) \tag{39.13}$$

where C is the concentration of the species in the bulk fluid and D is the effective diffusion coefficient.[8,38] When turbulence, which generates an effective radial convection that directly pushes cells and soluble proteins to the wall (*cf* FIGURE 39.2), is present, Equation 39.13 does not apply. Turbulence and complex laminar flows in the vascular system most commonly result from complex vessel geometries or high flow rates, although blood pulsations and vessel elasticity may also contribute to the development of secondary flows. Independent of its origin, any radial transport present greatly enhances the transfer of material from the bloodstream to the wall of the vessel.

Cell and Protein Transport

Mass transfer processes are also significantly affected by the presence of red blood cells, even in steady, laminar flow regimes where blood can be considered newtonian. Because red cells deform in response to shear, the cells align in the direction of flow and migrate to the center of the flow stream. This effect is less pronounced in blood with a normal hematocrit flowing at high shear rates, but even under these physiologic conditions, a thin red cell–free layer exists at the wall. Radial mixing of circulating platelets, white blood cells, and large protein components occurs as these components are pushed to the vessel surface by red cell crowding in the vessel center. Increasing hematocrit increases the frequency of platelet, white cell, and protein collisions with the vessel wall.[5] Relative to Brownian motion alone, movements by red cells can increase the diffusivity of platelets by two to three orders of magnitude.[39] The diffusion of platelets in response to red cells has been quantified and is a function of the shear rate[37–39]:

$$D = b\gamma^n \tag{39.14}$$

where b is a proportionality constant and n is a power law constant.

On a reactive surface, such as a damaged vessel wall, both fluid dynamics and reaction kinetics influence mass transport. To solve the mass transfer equations, the mass and the momentum boundary layers must first be evaluated.[5,7] These boundary layers indicate the distance from the wall at which the concentration profile (mass boundary layer) or the velocity profile (momentum boundary layer) reaches maximum values. When the Peclet numbers are large, indicating convection forces are dominant, the height of the mass boundary layer is much smaller than the height of the momentum boundary layer. Under these conditions, it can be assumed that within the mass boundary layer the diffusion coefficient is essentially the diffusion coefficient at the wall and the velocity profile is a linear function of the distance from the wall. Applying these two assumptions, Equation 39.13, developed for steady state, laminar, Poiseuille flow through a cylindrical tube with constant cross-sectional area, can be solved using the following boundary conditions[5,7]:

$$C = C_\infty \text{ at } r \le \delta \tag{39.15}$$

$$-D\frac{\partial C}{\partial r} = kC \text{ at } r = R \tag{39.16}$$

where δ is the thickness of the boundary layer, C_∞ is the concentration of the homogeneous reactant outside the boundary layer, and k is the reaction rate constant. The boundary conditions also assume the reaction is first order and the surface does not become saturated or exhibit decreasing reactivity. Evaluation and substitution of these boundary conditions leads to the general solution for the steady state flux (j) of platelets at any point on the surface[4,37]:

$$j = \left[-D\frac{\partial C}{\partial r}\right]_{r=R} = \frac{C_\infty}{\underbrace{\frac{1}{k}}_{\text{reaction control}} + \frac{1.48}{\left(\frac{D^2\gamma_w}{2z}\right)^{1/3}}} = \frac{C_\infty}{\frac{1}{k} + \frac{1.48}{\left(\frac{D^2}{2z}\left(\frac{4(v)}{R}\right)\right)^{1/3}}} \tag{39.17}$$

As shown in Equation 39.17, the flux of platelets at any point on the vessel surface is determined by the wall shear rate of the fluid (γ_w), the axial position (z), the reactant concentration in the homogeneous phase outside the boundary layer (C_∞), the reaction rate constant (k), and the effective diffusion coefficient (D).

Platelet Transport

To investigate the thrombotic process, it is useful to determine the parameters controlling platelet transport to the surface under three different vascular conditions. The first condition occurs when platelets flow across an intact monolayer of endothelial cells. In this case, the surface is nonthrombogenic and $k \ll D$. Therefore, the flux of platelets at the vessel wall is limited by the reaction kinetics and no longer depends on the axial position or the shear rate:

$$j_z = kC_\infty \tag{39.18}$$

The second condition occurs when platelets flow across a mildly reactive surface, $k \simeq D$, and Equation 39.17 cannot be simplified. In this circumstance, in order to determine the flux of platelets at the wall, the equations of motion must be solved first. For simple cases, such as steady Poiseuille flow, these solutions can be found analytically. However, when more complex flow regimes are present, the equations of mass transfer must be determined simultaneously with the equations of motion, and an analytical solution is difficult.[6,8]

The third condition occurs when platelets flow across a very reactive surface (e.g., exposed subendothelium), $D \ll k$, and the flux is limited by the diffusion of platelets to the surface[7,38]:

$$j_z = 0.67C_\infty\left(\frac{D^2\gamma_w}{2z}\right)^{1/3} = 0.67C_\infty\left(\frac{D^2}{2z}\left(\frac{4(v)}{R}\right)\right)^{1/3} \tag{39.19}$$

In this case, flux depends on the shear rate, the axial position, and the effective diffusion coefficient. As shown in Equation 39.14, the effective diffusion coefficient of platelets in flowing blood is a function of the shear rate. This indicates that for a given increase in shear rate, platelet flux at the vessel wall will increase by more than $\gamma_w^{1/3}$. The inverse relation between the axial position and the platelet flux is compounded by the depletion of platelets in the mass boundary layer as a result of upstream thrombi growth.[40] In addition to platelets, circulating proteins and other soluble compounds that support platelet adhesion and growth of thrombi may become depleted in the mass boundary layer. Platelets partially offset the decrease in the delivery of soluble blood components by secreting activating factors and other necessary compounds that then accumulate downstream of the growing thrombi.[41] Despite the presence of these secreted components, the rate of thrombus growth on the thrombogenic components of the subendothelial matrix is decreased in the axial direction.[40]

MODELS OF THROMBOSIS UNDER FLOW

Thrombosis in the vascular system may occur in the bulk fluid phase leading to circulating platelet aggregates or on the vessel wall leading to mural thrombus growth. To identify the molecular mechanisms supporting each type of thrombosis, the dynamic nature of the vascular system must be incorporated into experimental models. This requires the application of engineering principles to develop systems that are physiologically relevant to a number of conditions present in the vascular system.

Aggregometry

The platelet aggregometer was one of the first experimental systems developed to study thrombosis occurring in the bulk fluid phase.[42] In this system, aggregation in platelet-rich plasma can be monitored over time by measuring light scattering or particle counts. The observed platelet aggregation depends on the addition of chemical agonists to the platelet-rich plasma that induce platelet binding to fibrinogen or von Willebrand factor (vWF).[43–46] Agonists include substances present in the blood, such as adenosine diphosphate (ADP),[42] but nonphysiologic modulators, such as the antibiotic ristocetin[47] or the snake venom botrocetin,[44] also induce aggregation and have been used extensively to study thrombosis. Agitation is required for aggregation to occur, and, therefore, the system can be described as shear dependent. However, the shear produced by the aggregometer is low and cannot be quantified with certainty owing to the variable flow patterns produced in response to agitation.

Viscometry

In contrast to the aggregometer, rotational viscometers can produce constant and uniform shear stress on all cells and proteins in liquid suspensions, independent of the individual particle location.[6] The shear profiles in viscometer systems are well characterized and can be varied widely to match a number of physiologic and pathologic vascular conditions. Shear stresses high enough to directly induce platelet aggregation can be developed in viscometer systems, so that the addition of chemical agonists is not necessary.[48–52] In concentric, or Couette, viscometers, the sample to be investigated is placed between a stationary bob and a rotating outer cylindrical shell (see FIGURE 39.5A). In cone-and-plate viscometers, the sample of interest is placed between a rotating cone and a stationary platen (FIGURE 39.5B). To study arterial thrombosis, the rotating cone and stationary platen are separated by approximately 25 μm, and the cone angle ranges from 0.3 to 1.0 degree. Over the range of shear stresses used to investigate arterial thrombosis, blood viscosity is constant and

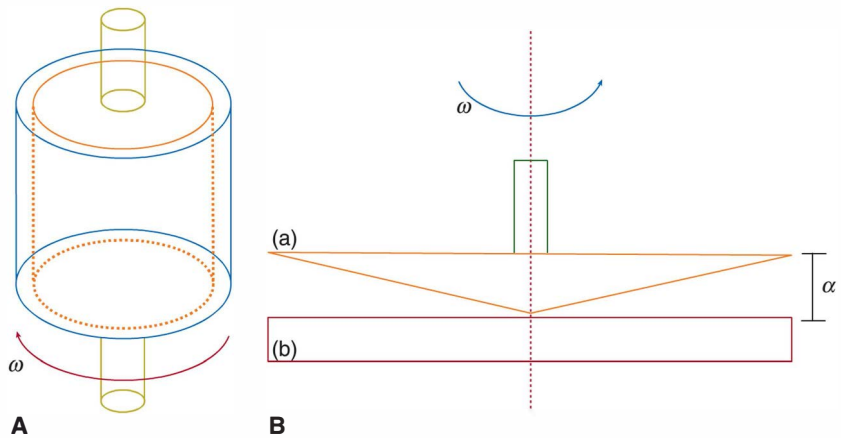

FIGURE 39.5 Schematic of a concentric, or Couette, viscometer **(A)** and cone-and-plate viscometer **(B)**. These rotational viscometers can produce a constant and uniform shear stress on cells and proteins in liquid suspensions, independent of the individual particle location. In a Couette viscometer, samples are placed between a stationary bob and a rotating outer cylindrical shell. In a cone-and-plate viscometer, samples are placed between a rotating cone (*a*) and a stationary plate (*b*). The cone angle (α) typically ranges from 0.3 to 1.0 degree. The shear stress that particles experience in a cone-and-plate viscometer depends on the cone angle, the rotation rate (ω), and the fluid viscosity (Equation 39.20). (Modified from Alevriadou BR, McIntire LV. Rheology. In: Loscalzo J, Schafer AI, eds. *Thrombosis and hemorrhage*. Boston, MA: Blackwell, 1994:369–381; Wang LN, Keller KH. Augmented transport of extracellular solutes in concentrated erythrocyte suspensions in Couette flow. *J Colloid Interface Sci* 1985;103:210–225.)

the shear stress is varied by changing the shear rate. The shear rate in a cone-and-plate viscometer depends on the cone angle (α) and the rotation rate of the cone (ω):

$$\tau = \mu\gamma = \frac{\mu\omega}{\alpha} \qquad (39.20)$$

The extent of shear-induced platelet aggregation can be determined by directly comparing the number of single platelets in samples before and after exposure to shear.[52,53,54] Additionally, the size of the platelet aggregates formed in response to shear can be quantified.[55,56]

Platelet aggregation in the bulk fluid phase can be investigated in viscometer systems using whole blood, platelet-rich plasma, or washed platelet suspensions. The presence of other cellular and protein components will affect platelet function and, therefore, whole blood is particularly useful for studying samples from patients receiving therapeutics,[57] recovering from a thrombotic event,[58] or both. However, the use of washed platelets is extremely valuable to isolate and investigate distinct molecular mechanisms supporting the thrombotic process. For example, by using washed platelet suspensions in physiologic concentrations, it has been shown that shear stress induces the binding of vWF to the platelet glycoprotein (GP) Ib and GP IIb/IIIa receptors.[59] More recently, using dilute suspensions of washed platelets, it has been determined that vWF binding to platelet GP Ib precedes binding to platelet GP IIb/IIIa.[60] The cone-and-plate viscometer system can also be used to study cell–surface interactions by immobilizing cells or proteins on the stationary plate. This method has been used to study the responses of smooth muscle cells and endothelial cells to shear including quantifying the released compounds and changes in gene expression.[61–66,67,152]

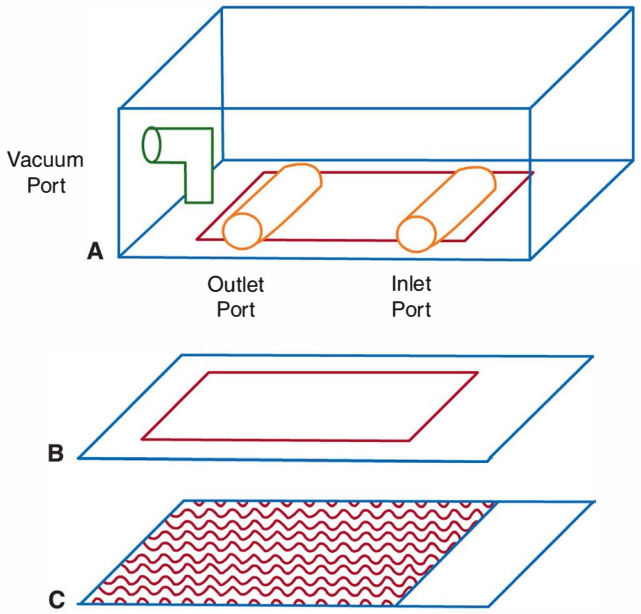

FIGURE 39.6 Schematic of a parallel plate flow chamber. The chamber consists of a polycarbonate slab **(A)**, a silicon gasket **(B)**, and a glass coverslip **(C)** held together by vacuum. The thickness of the silicon gasket determines the height of the gap between the coverslip and the polycarbonate slab. A syringe pump connected to the outlet port draws fluid across this gap through the chamber. The wall shear stress depends on the height of the gap, the width of the chamber, the fluid viscosity, and the flow rate through the chamber (Equation 39.21).

Flow Chambers

Cell–surface interactions have also been investigated through the use of flow chambers. In these systems, whole blood or a cell suspension is perfused through the chamber across a surface of immobilized cells or proteins. Parallel plate,[68–71] annular,[72–76] and tubular[65,77–80] flow chamber geometries have been developed. The parallel plate flow chamber, consisting of a polycarbonate slab, a silicon gasket, and a glass coverslip, can be used to illustrate the fundamental principles of these systems (see FIGURE 39.6). The glass coverslip forms the bottom side of the parallel plate flow chamber, and cells or proteins may be immobilized on this surface. The thickness of the silicon gasket determines the height of the gap between the coverslip and the polycarbonate slab. Fluid is pumped across this gap through the chamber. The wall shear stress in the system depends on the height of the gap (G), the width of the chamber (W), the fluid viscosity (μ), and the volumetric flow rate through the chamber (Q)[6,80]:

$$\tau_\omega = \frac{6Q\mu}{G^2W} \qquad (39.21)$$

In the range of shear stresses applied to investigate arterial thrombosis, plane Poiseuille flow is developed and the velocity and shear profiles are similar to those shown in FIGURE 39.1. The use of washed platelets or platelet-rich plasma in flow chambers is limited because the absence of red blood cells considerably changes the mass transfer of platelets to the surface. Therefore, to study platelet-mediated events in arterial thrombosis, whole blood is generally perfused through the chambers across glass coverslips coated with thrombogenic components of the subendothelial matrix, such as collagen or vWF. Significant insight into the molecular mechanisms supporting mural thrombosis, including the roles of fibrinogen and vWF and the platelet receptors GP Ib and GP IIb/IIIa, has been gained through the use of whole blood in flow chambers.[74–76,81–86] Distinct pathways in the thrombotic process are commonly investigated by the addition of blocking antibodies or by the use of patient blood that is deficient in an individual component. Specific interactions may also be studied by using mammalian cells transfected with only the receptor or ligand of interest.[87–89] The transfected cells may be in the fluid suspension, immobilized on the surface, or both. In addition to basic mechanism studies, flow chambers have been used to evaluate the effects of potential or current therapeutic compounds on mural thrombosis from patient samples under arterial shear conditions.[90,91]

Both arterial and venous shear conditions can be produced using flow chambers of the same geometry, with the only modification required being a change in the volumetric flow rate (Equation 39.21). A wide range of laminar shear conditions have been used to study the interactions of platelets and leukocytes with immobilized proteins, endothelial cells, or transfected

mammalian cells. Turbulent or complex laminar flow regimes, such as those in regions of stenoses or valves, may be produced by changing the geometry of the chamber or tube to resemble the complex geometry of interest. Under these conditions, the equations of Poiseuille flow (Equations 39.1 through 39.10, 39.21) no longer apply.

Measurement of Platelet Deposition by Imaging

Endpoint measurements of platelet deposition after perfusion of whole blood through a flow chamber may be measured either by fixing and staining the mural thrombi formed[81,92–95] or by using radiolabeled platelets reconstituted in blood.[15,92,94,96,97] Using these methods, the total number of platelets deposited may be evaluated by observing thrombi morphology with light microscopy or by radioactive measurements and imaging. Although these methods provide a snapshot of thrombi growth at a specific point, direct visualization of platelet deposition over time may be determined by combining epifluorescent microscopy and digital image processing.[68,71,86,98–100] In this method, platelets are fluorescently labeled before perfusion through the flow chamber. Platelets can be labeled by adding the fluorescent dye mepacrine[101] or fluorescent platelet monoclonal antibodies[102] directly to whole blood. During experiments, the flow chamber is mounted on an inverted-stage microscope equipped with an epifluorescent illumination attachment and a CCD camera connected to computers for image acquisition and processing. Whole blood is pumped through the chamber, and quantitative values for the number of platelets deposited and the total surface coverage over time are measured to calculate the real-time growth of thrombi.[68,98] The imaging can be extended to evaluate the surface interactions with larger cells such as leukocytes and transfected mammalian cells. These larger cells are phase bright, and fluorescent illumination is not necessary. Leukocytes and transfected mammalian cells in suspensions can be clearly distinguished by phase-contrast microscopy even if the suspensions are perfused over a cell monolayer immobilized on the surface. The mean velocity of rolling platelets or larger cells may be calculated by overlapping sequential digital images obtained and determining the distance the cells rolled during the period of the image acquisition.[103]

FLOW EFFECTS ON COAGULATION

The coagulation cascade is a complex series of linked enzymatic reactions that support the formation of mural thrombi by producing thrombin and fibrin at sites of vascular injury.[104,105] The reactions are catalyzed by complexes composed of circulating proteases and surface-associated protein cofactors. The key regulating enzyme complexes and a number of the reaction products form on phospholipid surfaces.[104,105,106] This surface requirement localizes reactions to certain elements in the subendothelial matrix, as well as membranes of endothelial cells (intact or damaged) and peripheral blood components such as platelets.[106,107] The formation of enzyme complexes depends on the delivery of the required circulating protease to the vessel wall where the protein cofactor is immobilized. Under noncomplex flow conditions, the protease may only reach the wall by radial diffusion. Increasing velocity, and therefore increasing shear, enhances the mass transfer of the protease to the surface.[79,106,108] Thrombin production measured in a phospholipid/cofactor-coated capillary tube clearly demonstrates the effects of mass transfer on the formation of surface-bound enzyme complexes in the coagulation cascade.[108] The production of thrombin is accelerated by the phospholipid-bound enzyme complex, prothrombinase, formed by circulating factor Xa associating with surface-bound factor Va. In the capillary tube system, the steady-state production level of thrombin can be limited by a low concentration of factor Va bound to the phospholipid surface. When factor Va is limiting, increasing the concentration of circulating factor Xa or increasing the shear does not change the final, steady-state thrombin production values. However, under these conditions, the time to reach the steady-state production values is reduced by increasing the concentration of circulating factor Xa or by increasing the shear rate. These results indicate that shear increases the formation of the prothrombinase complex by increasing the delivery of factor Xa to the surface. When the concentration of the circulating component rather than the surface component is limiting, increasing shear will lead to an increase in steady-state production values. In addition to increasing the supply of circulating components to the vessel surface, increasing shear will increase the removal of species produced at the wall but not bound to the vessel. This may explain the decrease in fibrin deposition on exposed subendothelium observed in response to increasing shear.[109] Alternatively, the decrease in fibrin deposition may be attributed to shear-induced secretion of tissue-type plasminogen activator (tPA) by endothelial cells upstream of the wound.[110]

MOLECULAR MECHANISMS OF CELL–SURFACE AND CELL–CELL ADHESION UNDER FLOW

Endothelial cells lining the blood vessels constitute a nonthrombogenic surface over which platelets flow during normal homeostasis. When the endothelium is compromised after angioplasty, atherosclerotic plaque rupture, or other vascular injury, mural thrombi form on the thrombogenic components of the exposed subendothelial matrix. Platelets are transported to the injury site by convection. If platelet transport were the only determinant of thrombi growth, increasing shear would always increase the deposition of platelets. The growth of thrombi on some surface components isolated from the subendothelium is decreased by increasing shear, however, suggesting that the bonds between platelets and these components either are not strong enough to withstand the increasing drag force on the platelet or do not have a fast enough on rate to fully form during the decreased contact time between the cell and the surface. Increasing shear also decreases the local concentration of activating factors produced at the vascular wall, potentially decreasing the total number of platelets deposited. A final explanation for observed inverse relation between shear and growth of thrombi on these surfaces is that shear may change the affinity of platelet–surface interactions by directly affecting the structure of the ligand or the platelet receptor. Dynamic experimental models have been used successfully to determine the molecular mechanisms supporting thrombus formation under the different shear conditions present in the vascular system.

Under arterial shear conditions, vWF is the principal mediator of both initial platelet adhesion to exposed subendothelium and subsequent platelet aggregation on the vessel wall, although fibrinogen and other proteins may also participate.[74–76,81,86,93,111–114]

vWF is well suited to support platelet adhesion because a single platelet may form multiple bonds to the repeating subunits within the vWF molecule.[115] Multiple bonds increase the strength of interaction, potentially allowing the platelet to remain attached to the vessel surface in the presence of high shear forces. Soluble vWF, released into the blood from the α-granules of platelets and from the Weibel-Palade bodies of endothelial cells, is rapidly insolubilized on exposed subendothelial matrix.[116] Endothelial cells may also secrete vWF directly into the subendothelium.[116] Unusually large forms of vWF, not found in plasma but present in platelets and endothelial cells, are most effective in promoting thrombus formation.[52] Further research is necessary to fully determine the primary components supporting the binding of soluble vWF to exposed subendothelial matrix, but it has been shown that collagen type I plays a role in the process.[117]

The platelet GP Ib/IX/V complex binds immobilized vWF under high shear conditions, mediating the initial step of platelet adhesion to the subendothelium of a damaged vessel.[86,93,111] This result has been demonstrated in flow chambers using patient blood deficient in GP Ib/IX/V (Bernard-Soulier syndrome)[93,111] and normal blood with added monoclonal GP Ib/IX/V antibodies.[86] Aggregation to the initial and subsequent layers of platelets on a damaged arterial wall is mediated by soluble vWF and possibly other proteins such as fibrinogen binding to GP IIb/IIIa complexes on adjacent platelets. This has been demonstrated in flow chambers using patient blood deficient in GP IIb/IIIa (Glanzmann thrombasthenia)[93,111] and normal blood with added monoclonal GP IIb/IIIa antibodies.[86,90,91] Adhesion of platelets to the subendothelial matrix under high shear conditions may also involve platelet GP IIb/IIIa.[93,118]

In contrast to thrombosis occurring in high shear conditions, mural thrombus formation under low shear conditions is supported mainly by fibrinogen–platelet rather than by vWF–platelet interactions.[119,120] Collagen VI[121] and fibrillin[122] have also been shown to support mural thrombosis under low shear conditions only. Adhesion on these surfaces is supported by the platelet GP IIb/IIIa complex, although other platelet receptors may play a role.[123] As with high shear conditions, the platelet GP IIb/IIIa complex is required for subsequent platelet aggregation.

Circulating platelet aggregates form in the presence of elevated shear conditions, such as are found in stenotic vessels, as a direct result of shear-induced platelet activation.[48–52] This high shear–induced platelet aggregation depends on vWF binding to GP Ib and GP IIb/IIIa receptors.[52,53,86,124] It has been established that calcium influx, platelet activation, and platelet GP Ib–vWF binding precede GP IIb/IIIa–vWF binding.[59,60,125,126] Platelet–vWF binding is minimal in the absence of shear. Currently it is unknown whether a change in vWF itself or a change in the platelet complexes enhances vWF–platelet binding under high shear conditions, although evidence suggests the change occurs on the platelet receptors.[52] Under low shear conditions (<12 dyn/cm^2), platelet–vWF binding becomes less important and platelet–fibrinogen binding predominately supports the observed shear-induced platelet aggregation.[127]

Leukocytes, which have been observed to accumulate in atherosclerotic plaques[128,129] and thrombotic clots[130,131] *in vivo*, may amplify the thrombotic process through the release of secretory products that activate platelets, promote vasoconstriction, aggravate endothelial damage, and increase local generation of thrombin and fibrin.[132–135] Additionally, the physical presence of leukocytes on mural thrombi may augment the coagulation cascade by providing an assembly site for the prothrombinase complex.[136,137] Monocytes may contribute further to the coagulation cascade because these cells express tissue factor (TF) after certain types of stimulation.[138] The effect of shear on leukocyte adhesion to the vascular surface has been characterized using parallel plate flow chambers.[103,139–147] Leukocyte rolling on stimulated, intact endothelium is mediated primarily by selectins, and rolling is optimal at wall shear stresses of 1 to 2 dyn per cm^2.[103,142] Under these conditions, firm adhesion (no rolling) of leukocytes to the stimulated endothelial cells requires the formation of integrin bonds.[141,142] At higher shear stresses, the number of rolling leukocytes decreases rapidly and at 10 dyn per cm^2 it is nearly zero.[103,142] In contrast, P-selectin expressed on activated platelet monolayers supports leukocyte rolling at higher levels of shear characteristic of the arterial system.[146] Circulating leukocyte–platelet aggregates may also contribute to the vascular response to injury and have been observed to increase in number after percutaneous transluminal coronary angioplasty[134] or cardiopulmonary bypass.[148,149] Shear enhances the formation of these circulating aggregates by activating platelets to express P-selectin.

It is of interest that unactivated platelets appear to be able to bind to activated endothelium, perhaps through an interaction of GP Ib and endothelial cell P-selectin.[88] In addition, GP Ib can utilize the I-domain of the leukocyte Mac-1 integrin as a ligand, providing a mechanism for platelet accumulation at the site of activated leukocyte adhesion (see[150] and FIGURE 39.7).

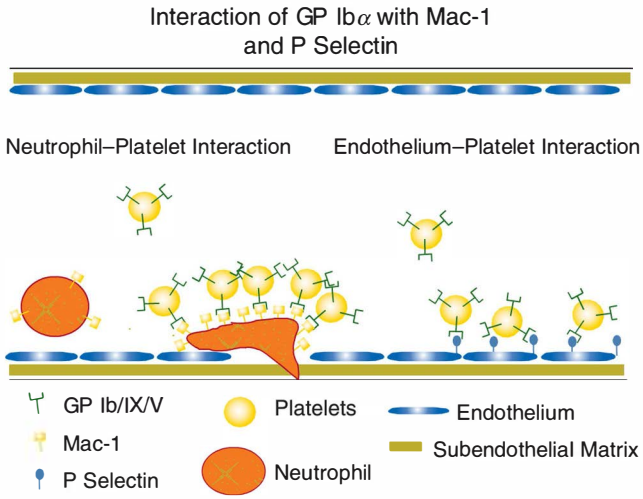

FIGURE 39.7 Additional ligands for platelet receptor GP Ib. Unactivated platelets can interact with activated endothelial cells through GP Ib/P-selectin interactions or with activated leukocytes at sites of inflammation via GP Ib/Mac-1 binding through the I-domain of the α chain (CD 11b) of Mac-1. This provides another possible direct strong connection between thrombosis and inflammation.

RHEOLOGIC MECHANOTRANSDUCTION MECHANISMS INFLUENCING VASCULAR WALL FUNCTION

The role of endothelial cells in the vascular system extends beyond providing a simple cover for the thrombogenic components of the subendothelial matrix. Instead, endothelial cells,

responding to both chemical and mechanical stimuli, express and secrete a wide variety of molecules that regulate thrombosis, fibrinolysis, coagulation reactions, vasoconstriction, leukocyte adhesion, and recruitment.[151] The mechanical stimuli acting on endothelial cells include tangential, circumferential, and compressive stresses (FIGURE 39.4B).[6,7] Circumferential stress is generated primarily by cyclic strain in compliant arterial vessels. Mechanotransduction in response to these stresses on and within endothelial cells are considered to respond both by activating signal transducers and by deforming the cytoskeletal structure to transmit forces to other locations throughout the cell.[152,153,154] Since intracellular mechano*transmission* is very fast[155,156] and focuses the strain to adhesion sites, junctional complexes and the nucleus, mechanotransduction can occur simultaneously at multiple cellular locations, and it is probable that they are interconnected and integrated within the cell, a decentralization model.[152] Mechanical stimuli, propagated through several cascade systems distributed at multiple subcellular sites, ultimately leads to altered gene and protein expression resulting in sustained functional responses (see FIGURE 39.8). There are many possible mechanisms for the initiation of mechanotransduction (conversion of deformation to a biochemical response), including force-induced conformational changes in membrane proteins, physical effects upon the lateral mobility of membrane molecules, direct force effects on ion channels, separation of assembled cell–cell oligomeric proteins at junctions, deformation of caveolar structures, and physical inhibition of integrin dynamics and clustering especially at the basal sites of cell adhesion to extracellular matrices.[152,154] Physical deformation may also displace local cofactors engaged in homeostatic regulation, including soluble and bound forms. Experimentally, parallel plate flow chambers, cone-and-plate viscometers, and other dynamic models have been used to determine the molecular mechanisms that translate mechanical stresses into cellular

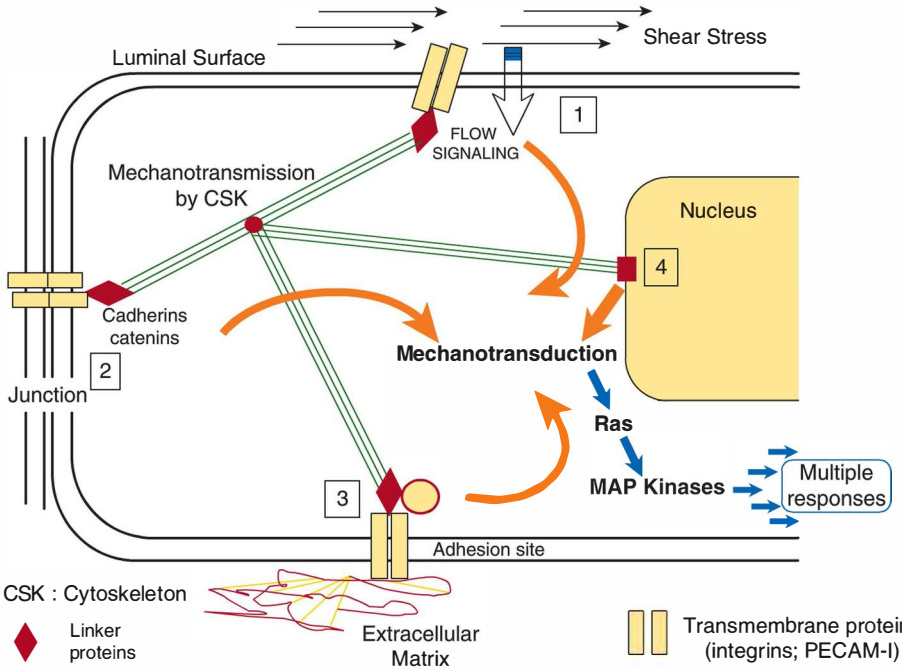

FIGURE 39.8 Decentralized model of endothelial mechanotransduction by shear stress. The cytoskeleton plays a central role in mechanotransmission of tension changes throughout the cell. Examples of direct signaling at the luminal surface (*1*), junctional signaling (*2*), and adhesion site signaling (*3*) are shown. Nuclear deformation also likely results in mechanosignaling (*4*). The locations are based on direct or indirect experimental evidence, are not mutually exclusive, and are likely interconnected.

At *1*, deformation of the luminal cell surface, possibly via the glycocalyx. Examples include localized activation of K^+, Na^+, and Cl^- ion channels, phospholipase activity leading to calcium signaling, G-protein activation, and caveolar signaling. At *2*, transmission of forces to the intercellular junction protein complexes via the cortical and/or filamentous cytoskeleton. Vascular Endothelial Growth Factor Receptor 2 (EGFR2) located at the luminal surface (site 1) or near the junction (site 2) may associate with VE-cadherin, b-catenin, and phosphatidylinositol 3-kinase to phosphorylate Akt and the primary transmembrane protein at this location, PECAM-1. At *3*, cytoskeletal force is transmitted to adhesion sites. Transmembrane integrins bound to extracellular matrix serve as a focus for deformation that results in autophosphorylation of focal adhesion kinase (FAK). FAK binds the SH2 domain of c-Src, a kinase family that phosphorylates paxillin and p130 Cas leading to integrin-dependent activation of MAPKs via Ras G-proteins. A second integrin-mediated pathway is via RhoA activation that profoundly influences actin assembly. At *4*, nuclear deformation/displacement may result in mechanotransduction possibly via lamins in the nuclear membrane. Other possible direct effects are on macromolecular conformation relevant to gene regulation. (Reprinted From Davies PF, Helmke BP. Endothelial mechanotransduction. FIGURE 39.9 The cytoskeleton is instantaneously deformed by flow. **A**: Stable transfection of living confluent endothelial cells with green fluorescence protein (vimentin) permits the dynamics of intermediate filaments of the cytoskeleton to be measured. **B**: Intermediate filaments deform (red-to-green shift) within 1 second after imposition of flow over the monolayer. **C**: Calculation (*left image*) of the strain concentrations (yellow/red) in the basal plane of a confluent endothelial cell following exposure to flow. The distribution of the cytoskeleton in the same plane is also shown (*right image*). (Reprinted from Helmke BP, Rosen AB, Davies PF. Mapping mechanical strain of an endogenous cytoskeletal network in living endothelial cells. *Biophys J* 2003;84:2691–2699, with permission from Elsevier.)

responses. Both venous and arterial levels of shear stress and strain have been investigated, and there is now appropriate consideration of the complex flow waveforms encountered *in vivo* when designing *in vitro* experiments.[157]

The Central Role of the Cytoskeleton in Force Transmission

Flow deformation of a connected system under tension—adherent endothelial cells in a confluent monolayer—results in instantaneous transmission of the forces throughout the connected elements. The transmission conduit is principally the cytoskeletal fibers distributed throughout the cell body and the submembranous spectrin-like cortical cytoskeleton around the cell. Both systems provide rigidity, shape, and structure to the cell and are under tension. Demonstrations of flow-initiated intermediate filament displacement,[158] actin filament deformation,[159] and directed motion of mitochondria attached to microtubules[160] support the view that apical forces are transmitted to "remote" sites via cytoskeletal displacements. Interference with cytoskeletal structure inhibits flow responses as defined for various experimental systems.[161] Thus, as proposed in the decentralization model, the actual mechanotransduction event may occur not only at the site of fluid shear interaction with the cell but also at considerable subcellular distances (microns) from the apical surface. Furthermore, the deformation effects may extend to adjacent cells, communicated through cell junctional structures[158] as shown by live cell imaging of green fluorescent protein (GFP)-cytoskeletal dynamics under flow and calculation of strain concentrations at a limited number of subcellular sites[156] (FIGURE 39.9). Such studies also draw attention to the dynamic motion of the cytoskeleton consistent with continuous remodeling of adhesion sites[162] and junctions.[156]

Responses at the Cell Surface

Ion channels, G-protein–linked receptors, tyrosine kinase receptors, and integrins have been identified as mechanoreceptors, although it has not yet been determined if all of these receptors initiate the primary response, or whether some act downstream of additional mechanoreceptors. Mechanoresponsive ion channels include a nonselective stretch-responsive ion channel that depolarizes the cell on activation.[163] Additionally, at least three shear-responsive ion channels have been identified. Two of the shear-responsive ion channels, an HCO_3^-/Cl^- exchanger and an Na^+/H^+ exchanger, acidify the intracellular cytosol within minutes of endothelial cell exposure to shear.[164] The third shear-responsive ion channel, a potassium channel, becomes activated within 10 seconds of exposing endothelial cells to shear.[165,166] Activation of this potassium channel leads to hyperpolarization of the cell in contrast to the cell depolarization observed in response to cyclic strain. There is some evidence that this potassium channel is linked to a G-protein that elevates intracellular guanosine 3′,5′-cyclic monophosphate levels in response to shear.[167]

Functional expression studies suggest that Kir2.2 and Kir2.1 are primary determinants of endogenous K^+ conductance in HAECs under resting conditions and that Kir2.2 provides the dominant conductance by these channels.[168] They are also sensitive to the concentration of plasma membrane cholesterol, higher levels of which inhibit their function.[169] The presence of other mechanoresponsive G-protein–linked receptors is suggested by the shear-induced elevation of the levels of other signal transducers, such as inositol 1,4,5-trisphosphate (IP_3)[170,171] and cyclic adenosine 3′,5′-monophosphate (cAMP),[172] which are generated by the activation of G-proteins. Cyclic strain also elevates the level of the G-protein activation–dependent signal transducers, IP_3, and diacylglycerol.[173,174] Direct shear-induced G-protein activation has been observed within 1 second of endothelial cell exposure to shear.[175] This fast activation process requires no mechanoreceptor and may be due to shear effects on membrane fluidity.[176] The presence of tyrosine kinase mechanoreceptors is suggested by the shear-induced elevation of multiple protein kinases. The major protein kinases activated by shear stress are extracellular signal-regulated kinase (ERK) 1/2, c-Jun NH_2-terminal kinase, and p38 mitogen-activated protein kinase (MAPK)/ERK. Protein kinase C is also responsive to both cyclic strain[177] and shear stress.[178] Integrins, transmembrane GPs that link the cytoskeleton and extracellular adhesion proteins, may also serve as mechanoreceptors[179] and transmit decentralized signals to the cell through the cytoskeleton as outlined below. Shear has been shown to enhance the integrin-mediated activation of the MAPK and ERK 1/2[179,181] and also enhances the integrin-mediated phosphorylation of the focal adhesion kinase (FAK), which may alter the cytoskeleton and lead to rearrangements of focal adhesion sites, eventually producing changes in the cell shape.[179,180,181] Cytoskeletal changes also regulate the gene expression of a number of proteins, including the urokinase-type plasminogen activator, which modulates the generation of plasmin and, therefore, affects blood clot dissolution.[182]

Transcription Factors

Changes in cellular pH, production of G-protein activation-dependent signal transducers, and stimulation of protein kinases may impact cellular responses by regulating transcription factors that activate or inhibit gene expression by binding to promoter regions within DNA. Two transcription factor families have been shown to be shear responsive: nuclear factor activator protein-1 (AP-1) and *Rel*-related nuclear factor κB (NFκB).[183] AP-1 can bind cAMP response element and tumor-promoting agent response element promoter regions of DNA. In response to shear, AP-1–binding activity increases fourfold in the first 20 minutes, then falls back to basal levels.[183] The shear-induced response of AP-1 is biphasic; however, and after 2 hours of shear exposure, the binding activity of AP-1 is increased substantially relative to both the basal level and the initial burst of activity. AP-1 has binding sites on the promoters of many proteins important to thrombosis and vascular wall function, including tPA, plasminogen activator inhibitor 1 (PAI-1), endothelin-1 (ET-1), monocyte chemotactic protein-1 (MCP-1), collagenase, intercellular adhesion molecule-1 (ICAM-1), transforming growth factor-β_1 (TGF-β_1), platelet-derived growth factor (PDGF)-A, and PDGF-B.[64,184,185] However, only MCP-1 has been shown to depend on shear-induced AP-1/DNA binding.[185] Binding of NFκB to DNA increases within 30 minutes of cell exposure to shear and reaches maximum levels of activity in 1 hour. Binding sites of NFκB have been identified on vascular cell adhesion molecule-1 (VCAM-1), E-selectin, interleukin (IL)-1, IL-6, IL-8, *c*-myc, and TF.[186] NFκB has also been shown to interact with a shear stress–responsive element (SSRE) in the promoter region in PDGF-B.[187] This SSRE is distinct from other DNA-binding sites of NFκB and is required for shear-induced elevation of PDGF-B messenger RNA levels in endothelial cells. Promoter regions with identical sequence homology to this SSRE are present on tPA, ICAM-1, and TGF-β_1, all of which are increased in response to shear.[61,187]

Of particular importance to thrombus formation is the increase in tPA messenger RNA level in response to arterial levels of shear.[110] Endothelial secretion of tPA increases by a factor of three after 4 to 6 hours of exposure to arterial, but not venous, levels of shear. In contrast, neither arterial nor venous shear levels increase the secretion of the prothrombotic compound, PAI-1. Further illustrating the selective response of endothelial cells to mechanical stimuli are the mechanisms that may support shear-induced vasodilation. Only minutes of arterial shear exposure are required to increase the production of prostacyclin (PGI_2), a potent platelet aggregation inhibitor and vasodilator.[66,188,189] Within 4 hours, the production of the vasoconstrictor and smooth muscle mitogen, ET-1, decreases.[190] Shear-induced vasodilation may also depend on nitric oxide (NO) production that increases with increasing shear.[64,191,192,193,194] The synthesis of several other biomolecules is regulated by shear, including prostaglandin $F_2\alpha$[195] and fibronectin.[196] The response of endothelial cells to cyclic strain differs from their response to shear. Physiologic levels of cyclic strain increase the secretion of PAI-1, whereas the secretion of tPA is unchanged.[197,198] Cyclic strain has also been shown to increase the secretion of both ET-1 and PGI_2 from endothelial cells.[197–199]

Integrin-Associated Mechanisms

Transmembrane integrins are well represented in regions of subcellular concentration of strain in endothelial cells subjected to flow change, and there is a burgeoning literature associated with this mechanism. Shyy and Chien[200] investigated the role of adhesion site integrins in mechanotransduction. They combined the results of endothelial flow studies with the data obtained from platelet activation and growth factor signaling (both being integrin mediated). In their proposed mechanism, flow activates integrins, increasing their avidity for the extracellular matrix (ECM). Integrin activation by many different stimuli is influenced by extracellular or intracellular factors, particularly small GTPases. If activation is blocked with RGD peptides or by monoclonal antibodies against integrin b subunits, typical downstream responses to flow/shear stress are inhibited, for example, MAPK phosphorylation and NFκB activation. One mechanism of involvement of integrins in flow mechanotransduction is proposed to be through the assembly of signaling complexes on the cytosolic side of the membrane where integrin-dependent autophosphorylation of FAK leads to its association with the SH2 domain of c-Src that in turn phosphorylates paxillin and p130 Cas.[201] These act as a scaffold to assemble C3G, a guanine nucleotide exchange factor for Ras G-protein family member Rap1, and adapter protein Crk that leads to the activation of MAPKs. There is spatial evidence (using GFP as a reporter) for the recruitment of activated FAK to new focal adhesion sites when endothelial cells (ECs) are subjected to shear stress, suggesting that the scaffold assembly is likely to be highly compartmentalized to portions of the plasma membrane.

A similar spatial relationship may occur in a second mechanism of integrin activation by shear stress in which the protein Shc is activated and binds Src family tyrosine kinases through SH2 binding.[202] Fyn is one such kinase which, together with its associated caveolar protein Cav-1, binds to Shc, phosphorylates it, and recruits an adaptor protein growth factor receptor–binding protein 2. This leads to activation of the Ras-MAPK pathway prominent in endothelial flow responses.

RhoA is also activated by shear stress through mechanisms that require integrin–ECM binding. Given the association of Rho with regulation of the cytoskeleton through Rho-associated kinase ROCK, and LIM kinase via cofilin,[203] it is likely that the flow-responsive adhesion site complexes involving integrins are intimately related to the binding of cytoskeletal elements at adhesion sites and cell junctions. Integrins are not restricted to the abluminal surface; flow activation via integrins may occur without the engagement of the ECM. Furthermore, it has also been proposed that nonintegrin mechanisms of activation of the Ras pathway occur by direct G-protein activation in the plasma membrane as a direct result of deformation of membrane lipids without cytoskeletal or integrin involvement.[204]

Transduction through Junctional Mechanosensors

Fujiwara et al.[205] first demonstrated the phosphorylation of the endothelial junction adhesion protein platelet EC adhesion molecule-1 (PECAM-1), its binding to SH2 tyrosine phosphatase, and the subsequent accumulation of signaling molecules at the junction in response to shear stress; they proposed PECAM-1 to be a mechanosensor. Shay-Salit et al.[206] demonstrated flow activation of vascular endothelial growth factor receptor 2 (VEGFR2) and its assembly with phosphorylated vascular EC cadherin (VE-cadherin), b-catenin, and PI3-K, leading to the phosphorylation of Akt-1. Building on these findings, Tzima et al.[202] reported that a mechanosensory complex involving junctional proteins regulates a subset of mechanotransduction pathways through integrins. In transfection studies of non-ECs, they showed that PECAM-1, VE-cadherin, and VEGFR2 are sufficient to transduce shear stress in the presence of an intact cytoskeleton and its associated proteins. Conversely, their selective inhibition or deletion in ECs inhibited important flow-related transduction; flow-induced activation of VEGFR2 did not occur in PECAM-1$^{-/-}$ and VE-cadherin$^{-/-}$ ECs nor did pathways that are dependent upon integrin activation. *In vivo* evidence in support of the mechanism was provided by local regions of endothelial activation (NFκB nuclear translocation) that correlated with disturbed hemodynamic sites in wildtype mice but were not activated in PECAM-1$^{-/-}$ mice.

The cell must either filter or integrate the spatially and temporally variable signaling events of mechanotransduction.[152] These mechanisms are not likely to be exclusive to endothelial cells.

Smooth Muscle

Vascular smooth muscle cells also produce and secrete biomolecules in response to mechanical stimuli. Like endothelial cells, vascular smooth muscle cells are continually exposed to circumferential and compressive stresses. Direct smooth muscle cell exposure to tangential shear stress results from deep vessel injuries produced by angioplasty or atherosclerotic plaque rupture. Even in the presence of an intact endothelium, transmural pressure gradients lead to interstitial fluid flow that continuously produces a shear stress on smooth muscle cells under normal physiologic conditions.[207] It has been found that either with[208,209] or without[210,211] an intact endothelium, increasing tangential shear stress reduces the proliferation of smooth muscle cells. Increasing shear also increases smooth muscle cell secretion of tPA, NO, prostaglandin E_2, PGI_2, PDGF, and basic fibroblast growth factor.[210–213] The shear-induced release of mitogens may partially inhibit the observed shear induced decrease in smooth muscle cell growth. Under dynamic conditions, however, it is more likely that mitogens released in high shear regions will accumulate in low shear regions downstream and potentiate the higher smooth muscle cell proliferation rates observed in regions of low shear. In addition to the secreted products discussed previously, in response to either shear or cyclic strain, smooth muscle cells release a factor, potentially carbon monoxide, which inhibits the ADP-induced aggregation of platelets.[64] Activated smooth muscle cells may also express VCAM-1 and ICAM-1 that support leukocyte–smooth muscle cell binding.[214–217] After angioplasty or atherosclerotic plaque rupture, expression of these surface molecules may recruit leukocytes to sites of vascular injury.[218] The shear-induced mechanisms that lead to smooth muscle cell expression and secretion of biomolecules remain largely undetermined, but cellular pH may play a role. It has been shown that shear induces alkalinization of smooth muscle cells mediated by an Na^+/H^+ exchanger.[219]

HEMOSTASIS-RELEVANT RHEOLOGIC EFFECTS UPON ENDOTHELIAL PHENOTYPE *IN VIVO*

The endothelium modulates coagulation and is normally antithrombotic through its heparin-like surface properties and its synthesis and release of both NO to inhibit platelet adhesion and of prostacyclin which inhibits platelet aggregation. Its surface ectonucleotidase enzymes also rapidly deplete ADP released by activated platelets in the early stages of aggregation, thereby reducing the recruitment and degranulation of other platelets. The disruption of endothelium is associated with many acute thrombotic events in arteries. Exposed subcellular matrix, particularly collagen, interacts with platelet GpVI, vWF (factor VIII; vWF), and Gp1b-V-IX complex, leading to platelet adhesion and activation. Platelet activation also occurs through ADP binding to P2Y receptors, leading to aggregation. Rheology contributes to platelet activation via two significant mechanisms. First, platelets passing through high shear regions in blood flow (and high gradients of shear) may be exposed to levels that physically promote activation,[220] and second, activated platelets captured within a vortex of flow separation have relatively long residence times that favor sustained interactions with vascular wall matrix and procoagulant bulk phase molecules also trapped there.[220,221]

Platelet Activation in Branches, Stenoses, and Devices

As platelets pass through complex shear fields associated with normal vessel geometries such as branching and curves, or traverse pathological stenoses,[220] or flow around intravascular

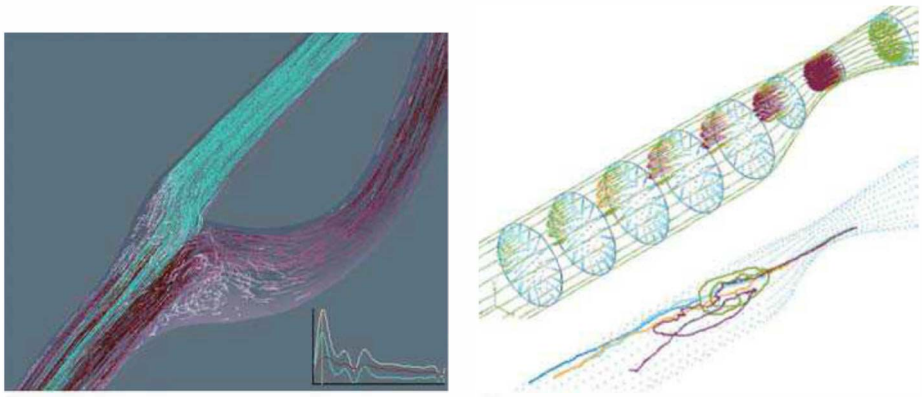

FIGURE 39.10 **A**: Flow characteristics in the normal male human carotid artery at the bifurcation into internal and external branches near peak systole showing spatial characteristics of the flow. Note the transition from unidirectional laminar flow (and shear stress) in the carotid artery sinus, a site of high susceptibility for atherosclerosis, where complex disturbed flow develops with oscillating flow reversal and the formation of transient vortices. Flow varies in velocity but is laminar and unidirectional elsewhere. This frame captures an instantaneous event at peak systole during unsteady arterial blood flow. As diastole develops, the flow velocities (indicated by bar length) fall sharply in the flow separation region as predicted from the steady flow model of panel A. Mean common carotid artery diameter in males is approximately 6.3 mm. Frame from a combined medical imaging and CFD sequence of human blood flow by Professor David A. Steinman of the Department of Mechanical and Industrial Engineering, University of Toronto (Image gallery URL: http://www.mie.utoronto.ca/labs/bsl/). (Kindly provided by Dr. Steinman as a high resolution image.) **B**: Velocity vectors and platelet trajectories through an 84% eccentric model stenosis. (From Einav S, Bluestein D. Dynamics of blood flow and platelet transport in pathological vessels. *Ann N Y Acad Sci* 2004;1015:351–366.)

devices,[222,223] they frequently experience shear rates that exceed their activation threshold and predispose them to aggregation. Such regions typically contain vortices created by flow separation, which capture a fraction of activated platelets into a zone of low flow velocity with oscillatory characteristics and within which they are retained for a longer period than in fast-flowing arterial bulk flow. Soluble procoagulant factors released from the vessel wall (e.g., free radicals and other reactive oxygen species, ROS) and from platelets themselves (e.g., ADP) are also retained within the recirculation zone. When this occurs adjacent to a stenosis or an intravascular device deployed during angioplasty where endothelium is lost, conditions are highly favorable for thrombosis. A potent mixture of slow-moving activated platelets, the absence of a functional antiplatelet endothelium, and localized prothrombotic chemical gradients tip the equilibria toward coagulation. Thus local shear rates and fluid dynamics patterns together with increased plasma procoagulation factors and diminished anticoagulation factors promote the activated state of platelets, leading to higher probabilities of thrombosis. The generation and characteristics of flow separation in such geometries are predictable by computational fluid dynamics (CFD).[220] *In vitro* experimental models of micro- and macrospatial relationships of particles, platelets, and other blood cells and proteins encompassing periods of extensive flow separation throughout the cardiac cycle have validated CFD predictions. FIGURE 39.10A demonstrates the complex flow separation in the sinus of the human internal carotid artery and FIGURE 39.10B illustrates the trajectory of platelet particles downstream of a simulated eccentric coronary region with >80% stenosis; a similar process on a microscale in the peristrut region of a commercial coronary stent is shown and discussed in the next major section. Measurements of thrombus formation itself are spatially consistent with predicted and measured platelet activation in a number of *in vitro* systems.[220,224] Flow separations close to significant stenoses shed smaller vortices of greater dynamic complexity from the primary separation region.[225] These regions will further trap procoagulant platelets, cells, and proteins. At the microscale around stent struts, it is less likely that vortex shedding occurs, but strong evidence for retention of the primary vortex region throughout the entire cardiac cycle is predicted by CFD with only minor oscillations of the separation boundaries. The contribution of such regions to late stent thrombosis (LST) is discussed in more detail below.

Natural Endothelial Heterogeneity Influenced by Arterial Geometry

The endothelium is highly sensitive to the local geometry of arteries via variability in hemodynamic force distribution and cell surface transport characteristics.[152] Throughout the majority of the arterial circulation, the flow is pulsatile but always moving forward. However, regions of flow separation such as arterial branches, bifurcations, and curvatures experience low average shear stress, steep temporal and spatial shear stress gradients, and oscillatory flow.[221] Since temporal multidirectional forces act on the cells in disturbed flow regions, the endothelium, unlike elsewhere in the arterial circulation, lacks preferential cell alignment and the cells frequently adopt a polygonal morphology; transition of cell shape from aligned to polygonal at the boundary of flow separation is clearly shown in FIGURE 39.11. Atherosusceptibility and disturbed flow are closely correlated *in vivo*. There is significant differential endothelial gene

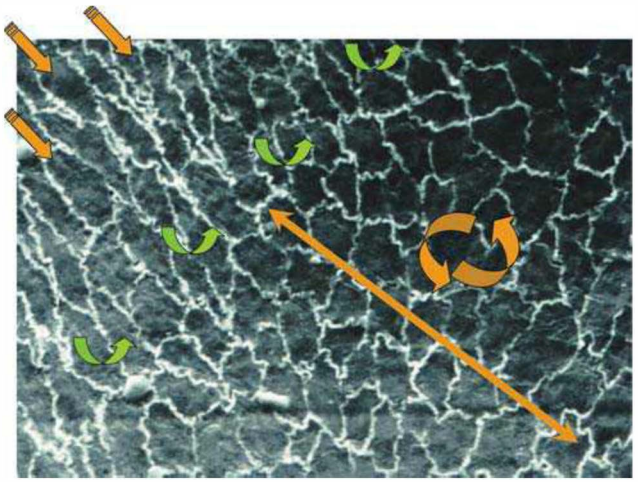

FIGURE 39.11 Transition of endothelial cell morphology in a region of flow disturbance near an intercostal branch from the aorta. When undisturbed flow (*top left*) separates to disturbed flow (boundary at *curved arrows*) cell shape changes from aligned to polygonal (no preferred orientation) in the region to the right of the separation line.

expression between susceptible and protected (undisturbed flow) regions.[226,227] Thus, a site-specific important rheological influence upon susceptibility to, or protection from, pathological change mediated by the endothelium is proposed.[228,229]

Flow–phenotype relationships were initially addressed by gene expression studies using cultured endothelium.[230–232] Candidate genes were identified *in vitro* and were subsequently demonstrated to have *in vivo* relevance.[233–236] However, high-throughput methodologies applied to cells isolated from small regions of the endothelium *in situ*[226] can directly address endothelial phenotype heterogeneity *in vivo*.

Endothelial phenotypes in atherosusceptible sites can be considered to reflect the kinetic status of multiple interacting cellular pathways in cells that are adapted to locally complex flow characteristics. Since the interpretation of gene expression networks *in vivo* is informative for optimal design of *in vitro* experiments that address the underlying mechanisms, a combined *in vivo/in vitro* approach greatly expands the relevance of *in vitro* investigations alone.

Function to Dysfunction

The subtle and complex pathways that determine functional phenotype *in vivo* are reflected in multiple levels of regulation of gene and protein expression. There is a range of endothelial phenotypes in the arterial circulation—and significant variability within the same artery—each arising from the complex interplay of cellular pathways that regulate function and are subjected to different physical environments including local rheology differences. Unbiased genomic analyses have shown that atherosusceptible and atheroprotective regions express significant differences of endothelial phenotypes before any pathology develops.[226,237–242,243,244] The transition from normal phenotype to overt dysfunction at these sites is not defined; it is generally assumed to be a threshold event but may represent subtle and gradual chronic changes of function—subtle adjustments in multiple subcellular equilibria. Within this heterogeneity lie differences in the endothelial expression of molecules that regulate or participate in thrombogenicity and that are associated with the rheology because of their location.

Passerini et al.[226] identified the coexistence of differential pro-and anti-inflammatory gene expression in endothelium at disturbed flow sites in normal swine. This was accompanied by differential expression of coagulation molecules. vWF and factor XIII, both procoagulant, were significantly elevated in regions of flow disturbance. Expression of plasminogen activator and its substrate plasminogen, molecules that promote the degradation of formed clots (fibrinolysis) by plasmin cleavage of fibrin, were also elevated while expression of PAI-1 was decreased. Thus, endothelial phenotype in disturbed flow appears to be sensitized toward platelet proaggregation offset by enhanced degradation of formed/forming clots. *In vitro* experiments that applied disturbed atheroprone disturbed flow waveforms to cultured human umbilical vein endothelial cells demonstrated decreased expression of thrombomodulin (TM).[245] TM forms a complex with thrombin that is responsible for the conversion of protein C to activated protein C. This cleaves factors VA and VIIIA (activated cofactors of the coagulation mechanism) and thereby reduces the amount of thrombin generated. The lower expression in disturbed flow therefore suggests a procoagulation balance consistent with the *in vivo* phenotype.

ER Stress, UPR, and Reactive Oxygen Species

A consistent finding in endothelial genomics analyses of disturbed flow locations *in vivo* is enhanced endoplasmic reticulum stress (ER stress).[243,244] ER stress is an adaptive protective mechanism that arises because of excessive protein biosynthesis or interference with normal protein folding mechanisms in the ER lumen in response to multiple kinds of cellular stress. Excessive newly synthesized and/or misfolded polypeptides in the ER lumen exceed its protein-folding capacity. It results in the activation of the unfolded protein response (UPR), a ubiquitous adaptive cell response that assists cell survival in an adverse environment by activating a set of intracellular signaling pathways.[246] The UPR signals a coordinated transcriptional upregulation of ER chaperones and folding enzymes to promote the correct assembly of unfolded polypeptides and prevent incompletely folded proteins from aggregating. The products of the activated UPR transducers converge as transcriptional regulators in the nucleus to upregulate ER chaperones and UPR transducer synthesis and to ubiquitinate unfolded proteins for degradation through the proteosome; both processes relieve ER stress accumulation of unfolded proteins and restore homeostasis. Failure to restore ER protein equilibrium to a normal range leads to apoptosis through transcriptional induction of the transcription factor C/ERB homologous protein, inflammation through activation of NFκB, and generation of ROS through excessive protein oxidation in the ER.

In a multisite study in 45 normal adult swine, endothelium in atherosusceptible regions of the aortic arch, proximal brachiocephalic artery, aortorenal branch region, and abdominal aorta was analyzed relative to protected sites of the common carotid artery, descending thoracic aorta, and the distal renal artery. All atherosusceptible regions are associated with complex disturbed blood flow. From this multisite study, the most

abundant common feature of the endothelium of all disturbed flow regions was the upregulation of genes associated with ER processing of proteins, ER stress, and the UPR.[243,244]

ER stress/UPR are protective mechanisms in response to a variety of stresses that include free radicals, physical perturbation, osmotic, radiation, metabolic stress, and inflammation. Their elevations in regions of flow separation reflect a low-level chronic stress associated with these locations. This may arise by adverse localized chemical concentrations resulting from suboptimal transport at the endothelial surface or from physical force differences resulting from oscillatory flow in regions of disturbed flow. *In vitro* analyses of ER stress/UPR in cultured endothelium under different flow conditions are consistent with a hemodynamic contribution to ER stress *in vivo*.[247,248] ER stress is a signature of multiple sites in the swine arterial circulation where proinflammatory NFκB pathway molecules are activated,[226,249] and where regulatory transcription factors[236,250] and microRNAs[249] are differentially expressed. ER stress pathways are both stimulated by ROS and can generate ROS. Direct visualization of ROS by the dihydroethidium in swine has shown a markedly increased ROS load in the inner curvature of the aortic arch (flow separation) when compared with the descending thoracic aorta[244] (FIGURE 39.12A). In swine coronary arteries, ROS is distributed throughout the right coronary, circumflex, and left anterior descending coronary arteries (FIGURE 39.12B), demonstrating a heavier overall ROS load in the coronary circulation than noncoronary arteries that may be linked to enhanced coronary sensitivity to cardiovascular disease.[244] The mechanisms of ROS load and Redox signaling for thrombosis/hemostasis may be via effects upon integrin signaling, particularly platelet integrins.[251] Ligation of integrins in endothelial cells and platelets induces activation of the Ras/MAPK, NFκB, and phosphatidylinositol 3-kinase and Rho-GTPases pathways. Following vessel wall injury and associated with activation and recruitment of platelets, there is a production of ROS concomitant with the stimulation of the blood coagulation.[252] Moreover, ROS are capable of inducing

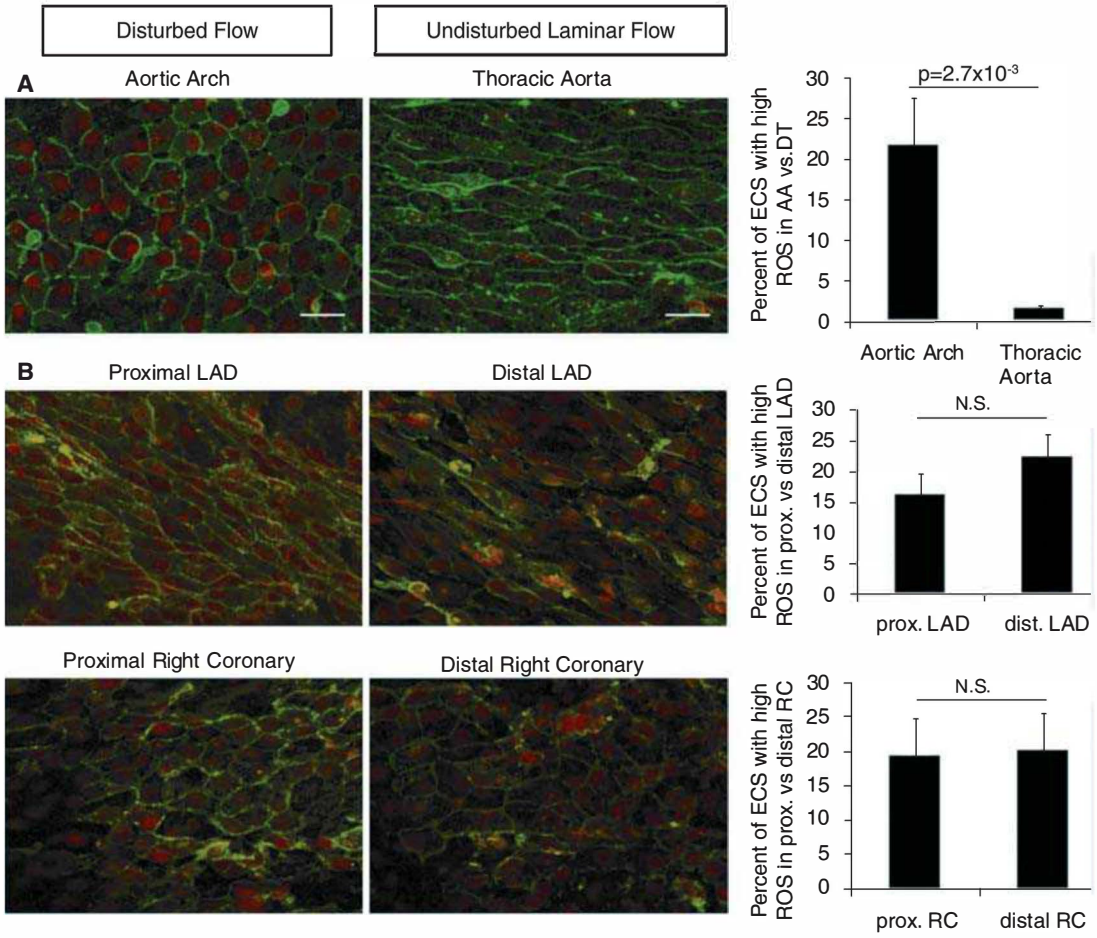

FIGURE 39.12 Endothelial ROS detection in freshly harvested normal swine. **A**: aorta. **B**: coronary arteries incubated with dihydroethidium (oxidized product red) and isolectin B_4 (endothelial identity; green) and imaged *en face* using confocal microscopy under identical conditions. Percentages of endothelial cells with high ROS were determined by counting the red nuclei. This percentage was used to calculate a ratio for each pair of atherosusceptible and atheroprotected samples. Data represent mean ± SEM. *P*-values were calculated by one-sample, one-sided, paired Wilcoxon test. Scale bar 25 μm. $^{**}P < 0.01$, NS, not significant. (From Civelek M, Manduchi E, Riley R, et al. Coronary artery endothelial transcriptome *in vivo*: identification of endoplasmic reticulum stress and enhanced ROS by gene connectivity network analysis. *Circ Cardiovasc Genet*. 2011;4:243–252.)

conformational changes in integrins to change their binding affinity and function. ROS is therefore a likely participant in the interplay of differentially expressed pathways in endothelial cells from regions where flow separation is a prominent characteristic influencing the force and transport environment in a proinflammatory, prothrombotic direction.

MICROSCALE RHEOLOGY AND STENT-ASSOCIATED THROMBOSIS

Rheological factors play an important role in the potential for thrombus generation around intravascular devices. Although anticoagulant surface materials are readily available, arterial devices promote flow separations that contribute to platelet activation, aggregation, and thrombus formation. Coronary artery stents are an important example at the microscale.

Stent Rheology May Influence Late Stent Thrombosis (LST)

The standard of care for coronary artery occlusion commonly includes the deployment of drug-eluting stents (DESs) into the lumen of the affected vessel. The stents provide immediate relief by widening the lumen, and the eluted drugs are effective in inhibiting restenosis. However, episodes of LST that are frequently fatal occur in 1% to 2% of patients up to 4 years after stent insertion. Typically, DES struts remain at, or close to, the vessel/blood interface and therefore represent an obstacle to the flow field for extended periods. Reendothelialization of DESs is typically slow and often incomplete, contributing further to a procoagulant environment.[253] Although <150 microns in height, DES struts provide a physical perturbation in the flow field that yields local pockets of disturbed flow,[222,223] which are associated with low endothelial cell migration rates. Simon et al.[254] demonstrated that endothelialization of the strut surface was inversely proportional to the thickness of the strut, and areas devoid of cells were largest on the downstream side, which is the side with the largest flow separation zone. The ISAR-STERE0 and ISAR-STERE0 2 clinical trials reported a proportional relationship between strut thickness and angiographic restenosis.[255,256] CFD demonstrated that as the stent strut thickness increases, the flow recirculation zones in the vicinity of the struts also increase in magnitude.[222] Lack of endothelialization, endothelial dysfunction, and hypersensitivity to the stent coating have been implied as possible factors in LST. However, an additional feature of current commercial DESs (FIGURE 39.13A) is significant peristrut flow separation.[223] As the stent strut thickness decreases, there is a nonlinear decrease in the proximal and distal flow recirculation zones around the struts[223] as shown in FIGURE 39.13B(I–III). The rate of endothelialization is proportional to the local flow rate (and shear stress), with slower moving flow in a recirculation zone yielding lower shear stress levels and retarding endothelialization.[257,258]

Flow Separation Creates Shear Values Sufficient for Platelet Activation

Within the flow separation zones of current rectangular commercial stent struts, the low flow velocities yield low wall shear stresses. However, they generate peaks of shear at the rectangular corners that approach 10,000/s at the upstream edge and >3,000/s at the downstream edge of the strut as shown computationally in FIGURE 39.14A. These levels exceed the shear required to activate platelets.[220,222]

A Procoagulation Reaction Zone in Regions of Flow Separation

In the undamaged coronary artery, a noncoagulation state is maintained where the secreted and surface-presented anticoagulant molecules of the endothelium help maintain hemostatic balance (FIGURE 39.15B(I)). These molecules include ADP, TF, vWF, PGI_2, NO, tissue factor pathway inhibitor, tPA, and TM. FIGURE 39.15B(II) shows how the deployment of current commercial (nonstreamlined) stents promotes flow separation and consequent recirculation zones in the proximal and distal regions of the strut. Thrombosis is promoted by disturbed flow, lack of endothelial cells, and increased residence time in a "microreaction chamber" created by flow separation.

Streamlined Geometry Mitigates Coagulation

A modest streamlining of stent struts has therefore been proposed to mitigate flow separation.[222,223] Streamlining the stent contours significantly reduces flow separation as shown experimentally by particle streamlines (FIGURE 39.15A) and by numerical analysis (FIGURE 39.13(IV–VI)). Furthermore, sharp peaks of high shear are attenuated by a streamlined geometry of a 100 μm height circular arc (FIGURE 39.14B). Fully streamlined stents would minimize or eliminate flow disturbances in the vicinity of the struts to restore flow conditions that allow the natural washout of the vessel wall. Short residence times of platelets and rapid dilution of procoagulation factors and intermediates (FIGURE 39.15III) should promote healing (FIGURE 39.15IV). The goal of modifying the stent strut cross-sectional geometry is to decrease the morbidity and mortality associated with LST via rheological mechanisms.

Transport in the Flow Separation Regions

A consequence of flow separation around nonstreamlined stent strut geometries is an impact on surface enzyme reactions. A number of critical enzymatic reactions in the coagulation cascade, such as the generation of active factor X (Xa) by both extrinsic and intrinsic tenase complexes and the generation of thrombin by prothrombinase, are heterogeneous reactions that require a lipid surface for proper enzyme–cofactor assembly and proteolytic activity. Unlike platelets, which due to their size are minimally affected by Brownian diffusion, soluble proteins readily diffuse into the recirculation zones created by nonstreamlined stent struts, whereas platelets have to follow pathlines to be transported to a recirculation zone. The effects that recirculation zones have on the generation of high local concentrations of reactive enzymes, specifically thrombin, surrounding stent struts could be crucial to understanding LST events.

Numerical Prediction of Strut Geometry on Heterogeneous Surface-Catalyzed Reactions

A diffusion-convection-reaction numerical model for a stented vessel flow field was developed to investigate the role of stent strut cross-sectional geometry in the increase of the local

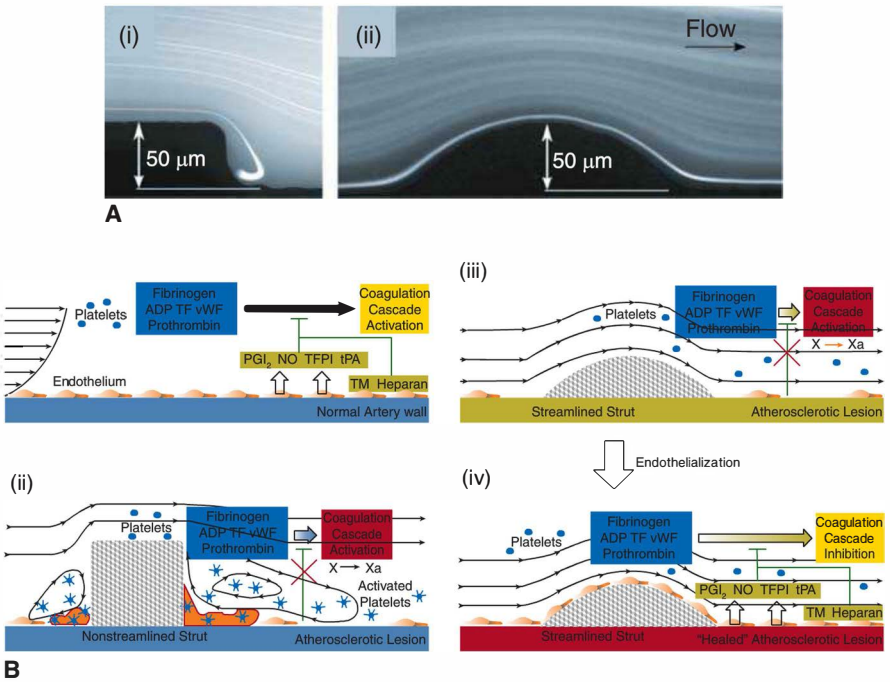

FIGURE 39.15 Flow separation adjacent to commercial stent geometry. **A**: Flow visualization around a (*i*) rectangular and (*ii*) streamlined stent strut. **B**: Blood contains multiple procoagulant proteins as well as natural anticoagulants that together with the endothelium normally maintain a noncoagulant state. (*i*) In the normal artery wall the secreted and surface anticoagulant molecules of the endothelium help maintain hemostatic balance. ADP, adenosine diphosphate; TF, tissue factor; vWF, von Willebrand factor; PGI2, prostacyclin; NO, nitric oxide; TFPI, tissue factor pathway inhibitor; tPA, tissue plasminogen activator; TM, thrombomodulin. (*ii*) The deployment of current commercial rectangular or circular nonstreamlined stents promotes flow separation in the proximal and distal regions of the strut. Procoagulant conditions are greatly increased around the stent strut by the following: (*1*) accelerated flow over the strut edges yields shear rate magnitudes that can activate platelets some of which will enter the distal flow separation zone, (*2*) recirculation zones retain activated platelets and procoagulant factors that can reach critical concentrations for activation of the coagulation cascade, (*3*) the removal of endothelium during angioplasty and stenting eliminates anticoagulant mechanisms and exposes the highly thrombogenic extracellular matrix surface. Furthermore, (*4*) low flow velocity (shear stress) inhibits endothelialization of the vessel and strut surface. (*iii*) A streamlined stent strut inhibits fluid flow separation and high shear rate peaks that can activate platelets. Furthermore, a streamlined geometry will be less likely to generate recirculation zones, thereby decreasing the residence time of procoagulant molecules and the probability of thrombogenesis despite the absence of endothelium. Undisturbed flow proximal and distal to the streamlined strut favors endothelialization of the vessel and strut surface. (*iv*) An endothelialized vessel and strut surface provide an anticoagulant environment that helps maintain hemostatic balance and protect against stent-related thrombosis. (Adapted from Jiménez JM, Davies, PF. Hemodynamically driven stent strut design. *Ann Biomed Eng* 2009;37:1483–1494.)

concentration of a soluble product from a reactive surface. At a lumen diameter of 3 microns, Re of 100, and strut height 50 microns, the maximum concentration regions coincide with the proximal and distal recirculation zones for a rectangular stent, but after streamlining (circular arc; peak 50 microns) only a very small concentration zone was predicted to remain on the proximal side of the strut (Jimenez; manuscript in preparation). The combination of a high concentration zone of reactive enzymes in the flow separation zone generated by a nonstreamlined strut in a blood vessel denuded of endothelial cells provides an optimal environment for thrombogenesis when combined with the transport of platelets from the mainstream to the recirculation zone by flow pathlines (*cf.* FIGURE 39.15).

Experimental support for the numerical predictions has been obtained in a *macro*fluidics *in vitro* coagulation model operated at coronary artery flow velocities using polymer casts of rectangular and streamlined stent struts. In this model, thrombin was first deposited in peristrut regions of the stent after which a fibrinogen solution was perfused into the model coronary system. The transport of soluble fibrinogen to the regions where thrombin was deposited was dictated by the local flow field generated by the different stent strut geometries. In the case of the rectangular (nonstreamlined) stent struts, the flow patterns carried fibrinogen and entrapped it in the long residence time recirculation zone, enabling the fibrinogen/thrombin interaction and yielding local formation and deposition of fibrin. Greater fibrin accumulation was measured in the vicinity of rectangular strut flow separation regions than when streamlined geometries were tested.[259]

SUMMARY

The process of thrombosis depends on complex interactions between fluid dynamics, convective mass transfer, reaction kinetics, and cell adhesion. Dynamic experimental models that mimic the local environment *in vivo* have been used successfully to determine the molecular mechanisms supporting thrombus formation under different shear conditions present in the vascular system. Under arterial shear conditions, it has been shown that mural thrombosis requires the binding of vWF to platelet GP Ib and GP IIb/IIIa receptors. Inhibiting these interactions during the onset of thrombosis not only decreases the formation of thrombi but also helps to prevent long-term restenosis of the vessel.[200,201,202] The use of these dynamic models has been extended to investigate how shear modulates endothelial and smooth muscle cell metabolism, smooth muscle cell proliferation, the coagulation cascade, the inflammatory process, and tumor cell metastasis. *In vivo* site-specific analyses of endothelial phenotypes have identified the steady-state expressions of many endothelial pathway molecules and prioritized their importance for *in vitro* studies. All of these studies lead to the conclusion that the local rheologic environment can have a profound effect on the molecular mechanisms of thrombosis. With the advent and accessibility of massive parallel (next-generation) sequencing facilities, substantial progress is to be expected in understanding the complexity of thrombotic mechanisms in an appropriate *in vivo* site-specific context in blood vessels that should accelerate the development of novel, more potent therapeutic agents perhaps tailored to the individual patient.

Nitric Oxide: The Vascular Biology of Nitric Oxide and Nitric Oxide Synthases

BRADLEY A. MARON AND THOMAS MICHEL

Nitric oxide (NO) is a ubiquitous, biologically versatile, and structurally unique molecule that is central to a diverse range of cell signaling processes that influence vascular function. The chemical properties of NO are ideally suited for participation in the inter- and intracellular reactions that modulate blood vessel relaxation.[1,2] NO is distinctive among other endothelium-derived relaxing factors in several ways. NO is a small (30 Da) lipophilic gaseous molecule. These properties allow NO to easily traverse vascular endothelial and smooth muscle cell membranes and participate in intercellular signaling.[3,4,5] Moreover, NO is a labile free radical that may react with a diverse range of molecules including thiols, heavy metals, and other biologically active free radicals such as superoxide anion. The relatively short half-life (5 to 10 seconds)[6] of NO ensures a rapid and localized signaling effect,[4,7] permitting NO to exert a tightly regulated, juxtacrine effect on the function of neighboring cells while also modulating intracellular signaling pathways. Importantly, the endothelial isoform of nitric oxide synthase (eNOS), which synthesizes NO, plays an important role in maintaining vascular homeostasis by virtue of the heterogeneous array of extracellular signals that modulate NO levels through influencing the *eNOS* gene, transcript, and protein. Posttranslational modifications to eNOS regulate its enzyme activity, subcellular targeting, and, importantly, the role of eNOS in vascular homeostasis; alterations in eNOS are implicated in the pathogenesis of several vascular disease states.

NITRIC OXIDE BIOCHEMISTRY

Targets of NO

NO produced by eNOS in vascular endothelial cells rapidly diffuses into adjacent vascular smooth muscle cells (VSMCs) and into the blood vessel lumen. The chemistry of NO allows for numerous reactions, including those with (a) proteins that contain metallic centers and/or sulfhydryl groups; (b) low molecular weight thiol compounds; (c) hemoproteins; or (d) other radicals.

Soluble Guanylyl Cyclase

In VSMCs and circulating platelets, the heterodimeric (α_1/β_1 or α_1/β_2) enzyme soluble guanylyl cyclase (sGC) is a critical NO target. NO-sGC signaling is essential for normal vascular reactivity and for suppression of abnormal platelet aggregation. NO binding to the heme prosthetic group of sGC disrupts a nitrogen–iron interaction, thereby freeing an axial histidine residue on the catalytically active β_1 subunit of sGC. Nanomolar concentrations of NO may induce a 100-fold increase in the sGC-dependent conversion of cytosolic GTP to cGMP, which in VSMCs activates cyclic GMP-dependent protein kinase (also known as protein kinase G [PKG]) to promote vascular relaxation (discussed below). Diminished eNOS abundance and decreased enzyme activity can lead to reduced NO synthesis, leading to the attenuated activation of sGC and causing increased vascular tone and blood vessel injury. These alterations in eNOS bioactivity are implicated in the pathophysiology of important vascular diseases including stroke and myocardial infarction.[8,9] Moreover, the potent vasodilatory effects of NO may be limited significantly owing to pathologic posttranslational modifications of sGC or other downstream signaling intermediaries. For example, oxidation of the heme moiety or key cysteinyl thiol(s) located near the NO-sensing pocket of sGC converts sGC to an NO-insensitive state and attenuates NO-dependent vasodilation.[8,10] This model illustrates a key distinction in NO biology: NO *bioavailability*, which suggests the presence of NO levels that are sufficient to induce a biologic response, is not synonymous with NO *bioactivity*. The latter implies an appropriate interaction between NO and NO targets that results in a downstream functional effect on cellular physiology.

Formation of NO Adducts: Nitrosothiols

The relatively short half-life of NO has generated speculation regarding potential storage forms of NO that may serve to sustain adequate basal levels of NO and permit actions of NO to occur at targets distant from its sites of synthesis.[11] The redox reactivity of nitrogen oxides with sulfhydryl groups is well characterized, and various nitrosothiols, including proteins covalently modified by a NO adduct, may represent a molecular "depot" for storage of NO *in vivo*.[12] Both protein and nonprotein nitrosothiols have been found in cells and biologic fluids *in vivo*. Compared with a free plasma NO concentration of approximately 3 nM, the concentration of plasma nitrosothiol is approximately 1 μM, of which 85% is nitrosoalbumin.[13–15] *S*-nitrosothiols are endogenously formed in both the cardiovascular and pulmonary systems,[13,14] and micromolar concentrations of *S*-nitrosoglutathione have been isolated from the lung.

Nitrosothiols share a qualitatively similar pharmacodynamic profile with NO, such as stimulating sGC,[11] inducing vascular relaxation and hypotension, and exerting antithrombogenic effects via inhibition of platelet aggregation.[16] The molecular mechanism(s) by which endogenous nitrosothiols induce biologic effects remains speculative: nitrosothiols may undergo spontaneous nonenzymatic decomposition to release NO, induce transnitrosylation of other proteins, or directly exert nitrergic effects.[17]

Hemoglobin is proposed to be a nitrosoprotein with potential biologic relevance. While it is clearly established that hemoglobin has the ability to bind NO at its heme moieties, hemoglobin

may also undergo nitrosylation at Cys93 in the β globin protein to form a protein nitrosothiol. Although there is evidence to suggest that nitrosohemoglobin may release NO, the utility of exploiting NO binding by hemoglobin as a pharmacotherapeutic system for NO delivery to distal points in the vascular system remains under investigation.[18] However, other mechanisms that utilize *S*-nitrosothiols for NO delivery have been tested *in vivo*. Through *S*-nitrosothiol linking, numerous NO molecules may be covalently bound to polyethylene glycol-conjugated bovine serum albumin, a macromolecule that is resistant to intermolecular disulfide bond formation. It has been demonstrated that intravenous injection of this compound in mice is associated with an increase in whole blood levels of the stable NO metabolite, nitrite, and a reduction in mean arterial blood pressure.[19] The translation of this technology into an effective therapy remains the focus of ongoing investigations.[20,21]

In addition to functioning as a storage reservoir of NO, NO-protein adducts may serve as an important posttranslational modification of biologically active proteins.[22] For example, a novel molecular mechanism by which *S*-nitrosylation influences vascular tone has recently been reported. Zhou et al. demonstrated that activation of angiotensinogen, a key vasoactive octapeptide that regulates blood pressure in mammals, is dependent, in part, on oxidation-induced disulfide bond formation between Cys18 and Cys138. Under reduced conditions in which this disulfide bond is broken, however, *S*-nitrosylation at these critical cysteines may occur. In turn, this induces a stereometric change to angiotensinogen that prevents Cys18-Cys138 disulfide bond formation, and thereby attenuates the angiotensinogen-mediated hypertensive response *in vivo*.[23]

Nitrosylation pathways may also regulate proteins associated with hemostasis. For example, *S*-nitrosoglutathione may interact with fibrinogen and impair fibrin cross-linking, without chemically reacting with fibrinogen but possibly by inducing a conformational change in fibrinogen.[24] Nitrosylation of factor XIII may be an antihemostatic mechanism that could attenuate fibrin cross-linking and render a nascent clot more susceptible to fibrinolysis.[25] While nitrosylation of tissue-type plasminogen activator (S-NO-t-PA) has no effect on its interaction with fibrin or the catalytic activation of plasmin, S-NO-t-PA may act as a nitrosothiol carrier of NO to inhibit platelets and cause vasodilatation at sites of thrombus where the local endothelium may be dysfunctional and producing insufficient quantities of NO.[26]

NO Adducts and Reactive Oxygen Species

Formation of NO adducts may be affected by the cellular redox potential, and in turn may influence the nature of redox-active species (e.g., reactive oxygen species) present in the vascular wall and influence NO bioavailability. The most prominent example of this phenomenon is the formation of peroxynitrite through the reaction of NO and superoxide. Although this process may be a mechanism for detoxifying superoxide, it also leads to decreased levels of bioavailable NO through several mechanisms. First, generation of peroxynitrite results in depletion of the NO substrate. Second, peroxynitrite may react with nitrite to form peroxynitrate, thereby decreasing levels of nitrite, which is a key substrate for NOS-independent NO synthesis.[10] Finally, peroxynitrite itself is a chemically reactive species that may adversely modify cellular proteins involved in NO-dependent cell signaling pathways.

SOURCES OF NITRIC OXIDE

Nitric Oxide Synthases

NO is synthesized endogenously in mammalian tissues by a family of three nitric oxide synthase (NOS) isoforms, each the product of a distinct gene. The mammalian NOSs are homodimeric enzymes containing an *N*-terminal heme-binding domain and a *C*-terminal reductase domain, separated by a calmodulin-binding domain. The *C*-terminal domains of the three proteins in the mammalian NOS enzyme family are structurally similar to cytochrome P450 reductases.[27–29] The *N*-terminal domain of NOS, also known as the oxygenase domain, contains binding sites for heme (protoporphyrin IX), tetrahydrobiopterin, and the substrate L-arginine.[28] The *C*-terminal flavoprotein oxidoreductase domain binds flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and NADPH.[30] As these two functions are often the products of separate polypeptides, the combination of the oxygenase and reductase functions of NOS suggests that the prototypical NOS protein evolved by gene fusion, with a binding site for the Ca^{2+}-binding protein calmodulin separating the *N*- and *C*-terminal domains.

eNOS Catalysis

Under basal conditions, electron transfer between NOS domains is suppressed; however, it appears that calmodulin promotes the flow of electrons from the reductase to the oxygenase domains.[31] The fact that NOS binds five redox-active cofactors—more than any other enzyme known—suggests an intricate catalytic mechanism. NOS catalyzes the five-electron oxidation of the guanidine nitrogen of L-arginine, although reactions of NADPH and flavoproteins typically involve an even number of electrons. NOS catalysis proceeds in two distinct monooxygenation steps, each involving electron transfer to molecular oxygen: in the first step, one mole of NADPH transfers, via FAD and FMN,[32] two moles of electrons to a heme-bound oxygen, which reacts with L-arginine to form one mole each of omega-*N*-hydroxy-L-arginine and water.[33] In the second step, one half mole of NADPH transfers electrons to a second heme-bound oxygen, which reacts with omega-*N*-hydroxy-L-arginine to release one mole each of NO and L-citrulline.

NOS Isoforms

Of the three distinct NOS isoforms that have been identified, two are constitutively expressed in their archetypal cells of origin: eNOS in vascular endothelial cells and neuronal NOS (nNOS) in neurons. As the name implies, inducible NOS (iNOS) is an inducible isoform found in a broad range of immunoactivated cells (see Table 40.1). Such terminology is somewhat misleading, however, because NOSs are expressed in a diverse range of tissues other than endothelium, neurons, and immunoactivated cells. Furthermore, the designation of constitutive and iNOS expression patterns are not strictly maintained, as nNOS and *eNOS* genes can undergo tissue-specific transcriptional regulation. Moreover, while eNOS is constitutively expressed, it may be induced by extracellular mediators. The overall catalytic scheme of the three mammalian NOS isoforms is conserved, and the members of this gene family share similar gene structure and exhibit 50% to 60% mammalian amino acid sequence homology,[34–36] as well as nearly identical locations of cofactor binding sites. There is considerable heterogeneity among the isoforms at the *N*-termini. For example, nNOS contains an additional sequence of approximately 290 amino acids not found in either eNOS or iNOS. Moreover, the *N*-terminus of eNOS is distinguished from nNOS and iNOS by

Table 40.1

Cellular and tissue localization of NOS expression

eNOS (NOS 3)	iNOS (NOS 2)	nNOS (NOS 1)
• Vascular endothelial cells, including arteries and veins	Immunoactivated cells, including: • Macrophages • Neutrophils • Vascular smooth muscle • Cardiomyocytes • Small vessel endothelial cells	• "Nitrergic" nerves innervating large vessels in diverse vascular beds
• Blood platelets		• Central nervous system
• Cardiomyocytes		• Skeletal muscle
• Brain (hippocampus)		• Gastrointestinal system
• Mast cells		• Cardiomyocytes

the presence of consensus sites for acylation, which are thought to determine eNOS subcellular localization.[37]

All three NOS isoforms catalyze the same chemical reaction and have similar redox cofactor requirements. A major difference lies in the isoforms' differential affinity for calmodulin: although all three NOS isoforms are dependent on calmodulin binding for activity, there are important differences in the calcium dependence for calmodulin binding. Whereas eNOS and nNOS require elevated intracellular calcium levels in order to bind calmodulin and thereby become activated, the affinity of iNOS for calmodulin is sufficiently high that iNOS fully binds calmodulin at the ambient intracellular calcium concentrations present in resting cells, and typically iNOS is persistently activated once the protein is synthesized.[38]

VASCULAR FUNCTIONS OF NOS-DERIVED NITRIC OXIDE

NOS, NO, and the Blood Vessel Wall

NO is an essential endogenous vasodilator, platelet inhibitor, and natural antithrombotic agent. Numerous experiments in both animal models and humans indicate that the physiologic role of eNOS is to produce NO in response to diverse extracellular stimuli and thereby maintain both a baseline level of systemic vasodilatation and establish vasomotor tone. In addition to its anticoagulant activity, endothelium-derived NO also attenuates endothelial proliferation and leukocyte adhesion. In turn, endothelial dysfunction that occurs as a consequence of decreased eNOS-derived NO may be a central mechanism involved in the pathobiology of vascular diseases characterized by vasoconstriction, hypertension, and a prothrombotic state.

The functional consequences of abnormal eNOS activity have been extensively studied. Both knockout and overexpression experiments suggest a role of eNOS and NO in maintaining basal vascular homeostasis. eNOS^{null} mice are hypertensive, demonstrate increased leukocyte-endothelial adherence, and diminished bleeding time.[39–41] These eNOS^{null} mice also develop pulmonary hypertension, hypoxia, and right ventricular hypertrophy.[42] Conversely, transgenic mice that overexpress eNOS show increased basal levels of NO and cGMP, associated with decreased blood pressure.[43]

Compensatory Bioactivity of NOS Isoforms

Animals genetically engineered to express various combinations of NOS isoforms (including the absence of all three isoforms), provide insight into the compensatory bioactivity of these enzymes *in vivo*. For example, pyramidal tissue-initiated long-term potentiation (i.e., sustained signal transmission) of hippocampal neurons is abolished in doubly mutant n/eNOS^{null} mice, but preserved in mice singly mutant for nNOS or eNOS.[44] Although eNOS protein expression levels are elevated in pyramidal tissue relative to central nervous tissue overall, the ratio of eNOS: nNOS protein expression in pyramidal tissue is quite low.[45] Thus, the observation that eNOS-derived NO levels are sufficient to sustain long-term potentiation suggests that functional efficiency of NOS varies between enzyme isoform and/or with respect to tissue type.

Studies performed in mice lacking all three isoforms (e/i/n NOS^{null} "triple knockout" mice) provide insight into the importance of NOS-independent mechanisms of NO synthesis *in vivo*. This "triple knockout" model also provides an informative model for understanding compensatory actions in the absence of NOS isoforms. Although the e/i/n NOS^{null} mice develop normally, they demonstrate significantly decreased rates of survival compared to wild type counterparts.[46] Interestingly, basal levels of NO are detectable in vascular tissue harvested from the triple-null animals, which probably reflects the conversion of dietary or bacteria-derived nitrite to NO.[47] In fact, there is accumulating evidence to suggest that nitrite (NO_2^-) and nitrate (NO_3^-), present in plasma of mammals via metabolism of endogenous NO, or, in the case of NO_3^-, from dietary intake of foods rich in inorganic nitrate, are biologically important through their recycling to NO.[48] A typical Western diet, for example, is rich in NO_3^-, which is readily absorbed in the gastrointestinal tract. Although mainly excreted in urine, the balance (as much as 40%) of circulating NO_3^- is ultimately excreted into the saliva.[49] There, NO_3^- may be converted to NO_2^- by endogenous oral flora in a reaction that requires nitrate reductase. In the circulation, NO_2^- may be reduced by deoxyhemoglobin and/or deoxymyoglobin to form bioavailable NO.[50] Cycling of NO, NO_2^-, and NO_3^- may be facilitated in the presence of xanthine oxidoreductase, hypoxia, or, even by NOS.[48]

In addition to the implications of NOS-independent NO synthesis on vascular function that are gathered from NOS knockout rodent models, it has been demonstrated previously that

dietary NO_3^- loading or the administration of inorganic NO_2^- via nebulizer or intravenous access influences vascular tone to decrease blood pressure. This has been demonstrated in the peripheral, pulmonary, and cerebrovascular circulations.[51–54,48]

As expected, the triple null mice exhibit many of the features associated with the absence of single NOS isoforms. For example, they have equivalent rates of hypertension and bradycardia as compared to eNOS-deficient mice. However, the loss of more than one isoform results in pathophysiologic changes not observed in singly NOS^{null} mice. For example, the number of disrupted *NOS* genes appears to positively correlate with the development of hypotonic polyuria, polydipsia, and renal responsiveness to vasopressin (i.e., nephrogenic diabetes insipidus).[46] The development of nephrogenic diabetes insipidus in triply NOS^{null} mice may be linked with decreased NO-dependent cGMP formation and membrane insertion of aquaporin-2 in renal collecting ducts, two biomolecular processes that regulate urine tonicity.[46]

Despite the inhibitory effects of eNOS-derived NO on pathobiologic processes linked to the development of coronary artery disease, such as promoting vasodilation and inhibiting platelet aggregation and leukocyte adhesion, eNOS-deficient mice do not spontaneously develop arteriosclerosis. In contrast to $eNOS^{null}$ mice, nNOS-deficient mice demonstrate elevated rates of metabolic syndrome, vascular lesion formation, and spontaneous myocardial infarction while iNOS deficiency is linked to atherogenesis.[47] These findings suggest that nNOS and/or iNOS may play a vascular-protective, compensatory role under conditions in which eNOS levels are diminished.

eNOS Uncoupling

Synthesis of NO by eNOS is dependent upon the transfer of electrons from NADPH to FAD and then to FMN in a reaction that occurs in the reductase domain of the eNOS dimer complex. Tetrahydrobiopterin (BH_4) is an eNOS cofactor required for electron donation from FMN to heme on the oxygenase monomer of eNOS that catalyzes the conversion of L-arginine + O_2 → L-citrulline + NO.[55] However, under conditions in which levels of BH_4, L-arginine, or NADPH are depleted, the eNOS dimer "uncouples" and oxygen is converted to superoxide in preference to NO (FIGURE 40.1).

Decreased levels of bioavailable NO that occur as a consequence of eNOS uncoupling is a critical downstream effect of increased vascular oxidant stress, and is linked to the pathobiology of vascular dysfunction in hypertension, diabetes mellitus, hypercholesterolemia, and atherosclerosis.[56] For example, eNOS uncoupling is postulated to be a mechanistic link between hyperaldosteronism and systemic hypertension. In peripheral blood vessels, elevated levels of aldosterone are associated with a vasculopathy characterized by activation of NADPH oxidase(s) that generates vascular endothelial superoxide formation. In turn, superoxide may oxidize BH_4 to BH_3 that results in eNOS uncoupling, decreased eNOS-dependent NO synthesis, and impaired endothelium-dependent vascular relaxation.[57]

In mice treated with streptozotocin to induce diabetes via pancreatic β-cell destruction, mouse aortas demonstrate increased total eNOS expression levels that are associated with diminished BH_4 and low levels of eNOS dimer formation.[58] Vascular dysfunction despite eNOS protein overexpression has been observed under a variety of experimental models of increased vascular oxidant stress. This paradox appears to reflect the effects of accelerated BH_4 consumption by increased eNOS activity,

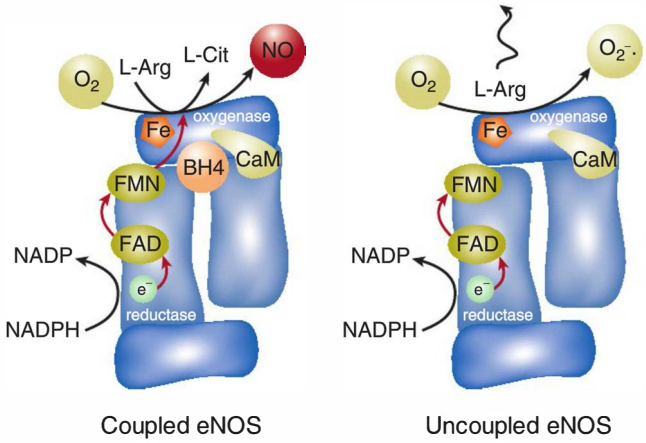

FIGURE 40.1 eNOS catalysis under normal conditions and in the uncoupled state. The synthesis of NO and L-citrulline (L-Cit) from molecular oxygen (O_2) L-arginine (L-Arg) by eNOS requires five cofactors that permit the flow of electrons from the reductase domain to the oxygenase domain. NADPH donates an electron to the FAD-FMN complex. FAD/FMN facilitates the transfer of an electron to the iron of heme on the oxygenase domain, while calmodulin is believed to promote the flow of electrons from the reductase to the oxygenase domains. This, and the donation of an electron and proton from tetrahydrobiopterin (BH_4) to O_2/L-Arg are necessary for the synthesis of NO/L-Cit. In turn, if levels of the eNOS cofactors BH_4 or NADPH, or the substrate L-Arg are insufficient, eNOS may become "uncoupled." Under these conditions, O_2 is converted to the reactive oxygen species superoxide ($\cdot O_2^-$) in preference to NO. CaM, calmodulin; Fe, iron; e^-, electron. (From Schulz E, Jansen T, Wenzel P, et al. Nitric oxide, tetrahydrobiopterin, oxidative stress, and endothelial dysfunction in hypertension. *Antioxid Redox Signal* 2008;10:1115–1126.)

which overall contributes to further superoxide formation by uncoupled eNOS, diminished levels of bioavailable NO, and worsening endothelium-dependent vascular relaxation.[56,59]

Other important mechanisms in addition to BH_4 depletion are implicated in the uncoupling of eNOS. For example, the endogenous NOS inhibitor asymmetric dimethylarginine (ADMA) is linked to eNOS-derived superoxide formation in pulmonary artery endothelial cells,[60] possibly by competitively inhibiting the binding of L-arginine. Circulating ADMA levels positively correlate with cardiovascular mortality.[61] Interestingly, the ADMA-degrading enzyme dimethylarginine dimethylaminohydrolase (DDAH) is redox sensitive: under conditions of increased vascular oxidant stress, inhibition of ADMA by DDAH is decreased resulting in elevated plasma ADMA levels.[61,62,63]

Genetic Etiologies of eNOS Dysfunction

A number of human studies have reported increased prevalence of specific eNOS polymorphisms in hypertensive cohorts.[64] For example, one major eNOS polymorphism is Glu298Asp, which has been associated with decreased NOS activity in the renal artery,[65] reduced basal production of NO,[66] coronary vasospasm,[67] essential hypertension,[68,69] hypertension in pregnancy,[70,71] high-altitude pulmonary edema,[72] as well as elevated risk of atherosclerosis[73] and possible myocardial infarction.[74,75]

However, the mechanism by which this genetic polymorphism alters eNOS function remains to be determined.

NO and Vascular Smooth Muscle Relaxation

NO produced in the endothelium stimulates sGC in VSMCs to produce cGMP. Increase in cGMP functions as a potent second messenger to promote vascular smooth muscle relaxation by activating cGMP-dependent PKG-myosin light chain phosphatase (MLCP) signaling, as well as by regulating intracellular calcium levels (FIGURE 40.2). The latter response may be mediated by the effects of cGMP on voltage-gated calcium channels, sodium/calcium exchangers, calcium-ATPase, phospholamban (PH), the IP3 receptor, and G proteins.[76] Alternatively, cGMP may independently regulate monovalent cation channels to affect intracellular calcium levels.

NO may also influence vasomotor tone through cGMP-independent pathways, including the activation of calcium-dependent potassium channels, which serve to hyperpolarize vascular smooth muscle.[77] NO can also rapidly and reversibly inhibit cytochrome c oxidase (complex IV). Additional evidence suggests that prolonged exposure to NO may persistently inhibit other heme or iron-sulfur cluster enzymes of the respiratory chain including aconitase, NADH-ubiquinone oxidoreductase (complex I), and succinate-ubiquinone oxidoreductase (complex II).[78] The rapid, reversible inhibition of cytochrome c oxidase is believed to provide a mechanism whereby NO may limit cell respiration and available cellular ATP, thereby attenuating smooth muscle contraction and causing passive vasodilatation.[78,79] Longer-term inhibition of other enzymes in the respiratory chain may lead to the suppression of key metabolic pathways and to pathologic changes in VSMCs.[78]

NO and Vascular Smooth Muscle Proliferation

NO inhibits the migration and proliferation of VSMCs.[80] Pharmacologic NO donors exhibit antiproliferative effects *in vitro*,[81] possibly by attenuating activity through activation of the cGMP-dependent protein tyrosine phosphatase, or "PTP-PEST."[82] Elevated levels of cGMP also activates cAMP-dependent protein kinases, which may account, in part, for the antiproliferative effect of NO (see below for additional details on NO and cAMP-dependent protein kinase).[83]

Antiproliferative characteristics of NO-donating drugs may also have an antiatherogenic effect in healthy endothelium vis-à-vis preventing neointimal formation in vascular smooth muscle.

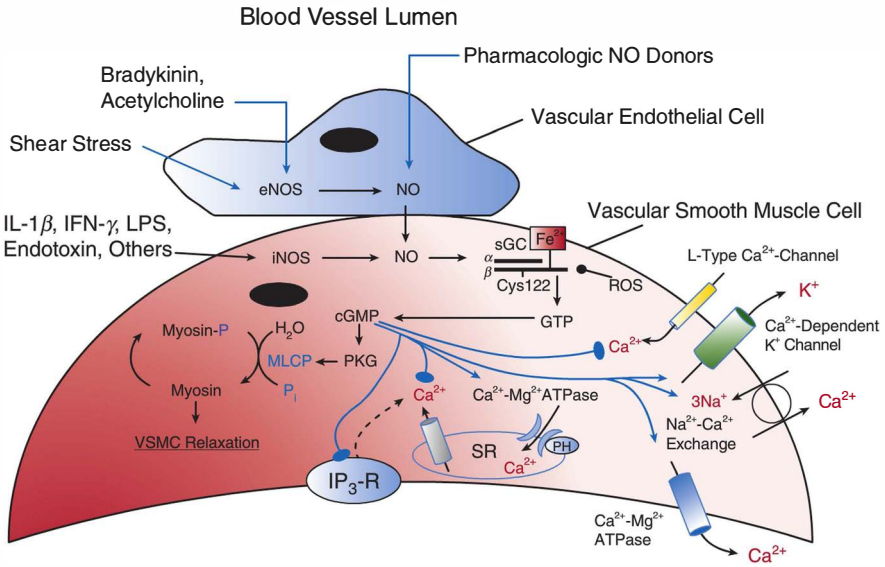

FIGURE 40.2 NO-induced cGMP formation modulates VSMC relaxation. In vascular endothelial cells, shear stress and/or agonist-mediated activation of a broad range of cell surface receptors increases eNOS activity and results in NO synthesis. NO derived from eNOS and/or pharmacologic donors may traverse the vascular endothelial cell membrane into the vascular smooth muscle cell (VSMC) layer. Alternately, induction of iNOS by various cytokines and/or endotoxin increases levels of bioavailable NO in VSMCs. The interaction of NO with soluble guanylyl cyclase (sGC) results in the conversion of cytosolic GTP to cGMP. Importantly, oxidative modification of sGC at the heme site or at key cysteinyl thiols (e.g., Cys122) on the catalytically active β_1-subunit may impair NO-sensing by sGC and decrease conversion of GTP to cGMP. Protein kinase G (PKG)-dependent activation of myosin light chain phosphatase (MLCP) by cGMP induces VSMC relaxation. Additionally, cGMP modulates VSMC relaxation by decreasing intracellular levels of Ca^{2+}. This occurs via cGMP-induced inhibition of Ca^{2+} mobilization through L-type Ca^{2+} channels or the inositol triphosphate-3 receptor (IP_3-R) located on either the plasma membrane or in the sarcoplasmic reticulum (SR). In turn, cGMP also decreases intracellular Ca^{2+} levels by stimulating Ca^{2+}-dependent K^+ exchange, Na^{2+}-Ca^{2+} exchange, Ca^{2+}-Mg^{2+} ATPase(s), and phospholamban (PH) in the SR. *Arrows* and *circular* heads indicate agonist and inhibitory effects, respectively. eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; ROS, reactive oxygen species; LPS, lipopolysaccharide. (Adapted from Lucas KA, Pitari GM, Kazerounian S, et al. Guanylyl cyclases and signaling by cyclic GMP. *Pharmacol Rev* 2000;52(3):375–414. Ref. 238.)

However, endogenous NO signaling pathways are also linked to migration[84] and proliferation[85] of VSMCs, as well as vascular endothelial growth factor (VEGF)-NO signaling–associated angiogenesis. Despite this and other similar observations, the preponderance of data currently available suggests that the attributable contribution of NO to the development of atherosclerosis is small, and is offset significantly by the proven beneficial effects of NO on maintaining normal endothelial function.

NO and Vascular Apoptosis

NO is a key mediator of apoptosis in various cell types including vascular endothelial and VSMCs.[86] The effect of NO on apoptosis is concentration-dependent: low levels of NO are protective against apoptosis, whereas elevated levels of NO promote apoptosis and are cytotoxic.[87] This provides a framework for interpreting the variable effects of each NOS isoform on the cell cycle. For example, iNOS induction in VSMCs or macrophages, which is associated with apoptosis, tends to generate significantly higher levels of NO compared with eNOS. In turn, eNOS exerts a predominantly antiapoptotic effect in vascular endothelial cells.

The mechanisms whereby NO inhibits apoptosis in the endothelium appear to be independent of cGMP and may involve the increased expression of heat shock proteins,[88] inhibition of apoptotic kinase cascades, as well as inhibition of a family of proapoptotic cysteine proteases (termed caspases), probably via cysteine sulfhydryl nitrosylation and/or tyrosine nitrosation.[89,90] Shear stress over the endothelial layer, which is an important determinant of basal NO synthesis by eNOS, may be an important antiapoptotic factor that serves to protect the endothelium against apoptosis in the initial stages of atherogenesis.[91]

The ability of iNOS-derived NO to exert proapoptotic and antiproliferative effects on vascular smooth muscle may contribute to the putative role of iNOS in vascular wall remodeling.[92] NO-induced apoptosis of VSMCs may also be important in atherogenesis and plaque instability.[93,94] The proapoptotic functions of iNOS-derived NO also appear to be cGMP-independent, and may relate to NO-induced oxidative damage of cytosine residues, which results in DNA fragmentation.[95] Other mechanisms that have been proposed include: increased formation of peroxynitrite; activation of caspases; activation of poly(ADP ribose) polymerase; and increased mitochondrial permeability. Some evidence indicates an upregulation of p53 and/or p73 protein in apoptotic cells, and experiments demonstrate vascular smooth muscle from $p53^{null}$ mice are specifically more susceptible to NO-induced apoptosis as compared to wild type.[96,97]

Endothelial expression of iNOS may also induce apoptosis in endothelium in diabetic vasculopathy, where circulating glycosylated albumin derivatives have been reported to upregulate iNOS activity in small vessels.[98] Additionally, expression of iNOS has been suggested as a mechanism of neuronal apoptosis that contributes to cardiovascular autonomic depression in septic shock.[99]

eNOS and Leukocyte–Endothelial Interactions

eNOS-derived NO exerts broad anti-inflammatory and antithrombogenic effects that arise in large part by the inhibition by NO of leukocyte–endothelial interactions. NO downregulates expression of P-selectin on endothelial cells.[100] NO-mediated inhibition of P-selectin expression prevents the entire process of leukocyte recruitment. NO may also limit the expression of leukocyte adhesion molecules such as L-selectin or CD11/CD18.[101] Since superoxide in the endothelium and leukocytes can promote oxidant-dependent adhesion, the inhibitory effects of NO on cell adhesion may be mediated in part by detoxification of superoxide.[102] Inhibition of eNOS enzyme activity may result in the enhanced adherence of leukocytes to the vascular endothelium.[102] Since monocyte adhesion may be one of the initial events in atherogenesis, eNOS may function as an antiatherogenic agent in part by inhibiting recruitment of leukocytes to endothelium. eNOS enzyme inhibition by arginine analogs also leads to increases in vascular permeability, extravasation of plasma proteins, and microvascular edema, involving both cGMP-dependent[103] and cGMP-independent pathways of vascular permeability.[104] These increased vascular permeability responses may be mediated in part by the increased adherence of leukocytes to endothelium in the absence of NO.[105]

eNOS and Blood Platelets

The same eNOS isoform originally described in vascular endothelium is also expressed in blood platelets, but the vascular endothelium is more significant quantitatively as a source of NO.[106,107] Endothelial cell–derived NO is important to the regulation of platelet function, and is a key determinant of the balance between physiologically appropriate hemostasis and pathologic thrombosis. Nevertheless, platelet-derived NO from endogenous platelet eNOS may also play an important role in inhibiting platelet adhesion,[39,80,108] aggregation,[80] and activation. NO may affect platelets through several interrelated signaling pathways that variously involve cGMP, calcium, eicosanoids, and phosphoinositides as key effectors of the NO response.

Platelet adhesion to the endothelium depends on a number of adhesion molecules expressed on both cells, including intercellular adhesion molecule (ICAM)-1 and α/β 3 integrin on the endothelium, and β_1 integrin, P-selectin, glycoprotein Ib, and glycoprotein IIb/IIIa on platelets.[109] NO released by nitrovasodilator drugs inhibits expression of P-selectin on platelets.[110] In addition to antagonizing platelet–endothelial interactions, the downregulation of P-selectin also inhibits platelet–leukocyte interactions. A PKG-modulated pathway also disrupts activation of GP IIb/IIIa, one of the more critical mechanisms of platelet adhesion to the endothelium. In this pathway, cGMP-activated PKG phosphorylates both phospholipase C and vasodilator-simulated phosphoprotein,[111] which results in a decline in intraplatelet calcium. cGMP can also lower intraplatelet calcium by inhibiting release of intracellular calcium stores and shuttling more calcium out of the cell while limiting extracellular calcium reabsorption.[108] Low calcium hinders protein kinase C signaling, hindering the activation of GP IIb/IIIa.[110] The GP IIb/IIIa receptor is also necessary for aggregation of platelets in nascent thrombi by cross-linking platelets and fibrin. The potent platelet aggregating effects of thrombin are inhibited by NO[112] from eNOS, which may also be activated by insulin.[113] In platelets, insulin stimulates the Akt-mediated phosphorylation of eNOS Ser1177 via phosphoinositide-3-kinase (PI3K) and AMP-activated protein kinase (AMPK) pathways.[113] In addition to insulin's direct effects on eNOS in endothelial cells, insulin may also induce vasodilatation by activating platelet eNOS and

PKG,[114] resulting in release of vesicles containing the vasoactive substances ATP, adenosine, and serotonin, which may in turn activate eNOS.[115] The lipid mediator sphingosine-1-phosphate (S1P) is involved in a signaling between platelets and the endothelium: activated platelets secrete S1P, which stimulates activation of eNOS, thus releasing NO into the vascular lumen, which serves to attenuate platelet activity.

NO inhibits a number of arachidonic acid pathways that normally function to activate platelets. NO inhibits platelet release of ADP[16] as well 12-lipoxygenase, thus preventing formation of leukotrienes and hydroxyeicosatetraenoic acids. NO attenuates the activity of phospholipase A2, the rate-determining enzyme in the arachidonate pathway by which platelets ultimately produce thromboxane. PKG in platelets also impairs thromboxane-mediated signaling by directly phosphorylating the G-protein–coupled TXA_2 receptors, further inhibiting thromboxane-mediated platelet activation via the downstream phospholipase C cascade.[116] These mechanisms of thromboxane antagonism coordinately attenuate a potent stimulus of platelet activation and recruitment.

NO also positively affects the *in vivo* synthesis of prostacyclin, the physiologic antagonist of thromboxane.[117] Synergy in the antiplatelet effects of prostacyclin and NO may result from cGMP-mediated inhibition of cAMP-specific phosphodiesterase III, which elevates intraplatelet cAMP and attenuates platelet activation. NO-mediated inhibition of platelet function may also occur via cGMP-independent mechanisms, as suggested for the NO-dependent suppression of thromboxane synthesis.[118,119]

Platelets derived from $eNOS^{null}$ mice show several abnormalities in agonist-induced platelet aggregation,[39] confirming the role of platelet eNOS–derived NO in normal hemostasis. The loss of NO-cGMP signaling in these $eNOS^{null}$ mice shifts the balance of platelet function toward platelet adhesion and aggregation. In mice with normal eNOS but with eNOS-deficient platelets, bleeding time is decreased owing to increased platelet-endothelial adhesion.[39] In humans, NO-mediated inhibition of platelet function results in decreased bleeding time[120] and it has been suggested that nitrovasodilator-mediated inhibition of platelet aggregation may affect the progression of coronary thrombosis in patients with unstable angina pectoris.[121]

NO is antithrombotic through mechanisms that are independent of its inhibitory effects on platelet aggregation and NO-dependent activation of ICAMs. For example, increased eNOS-derived NO synthesis is a well-established countermeasure to the prothrombotic effects of shear stress on vascular endothelial structure and function.[122] NO synthesized under these conditions is protective against the development of prothrombotic molecular and phenotypic changes in the blood vessel wall such as lipid oxidation, smooth muscle cell proliferation, and apoptosis.[123] Protecting the integrity of the endothelial cell layer is associated with a decrease in the thrombogenicity of the blood vessel lumen. In turn, eNOS deficiency is linked to increased thrombosis following endothelial injury induced by mechanical force or by activation of the procoagulant protein von Willebrand factor.[124] Other factors that suppress eNOS activity, such as the endogenous NOS inhibitor known as ADMA, are found in thromboembolic diseases.[125] For example, elevated ADMA levels are present in chronic thromboembolic pulmonary hypertension, which is a disease characterized by pathologic changes to the normal pulmonary vascular architecture and *in situ* thrombosis.[125]

Regulation of eNOS in Endothelial Cells

eNOS is expressed in endothelial cells, and to a lesser extent in platelets,[106] mast cells, and neutrophils.[126] The tissue-restricted expression of eNOS has lead to analyses of the eNOS promoter. The promoter for the *eNOS* gene lacks a prototypical TATA promoter, and instead contains promoter sites for the binding of SP1 and GATA transcription factors, two mechanisms that are utilized by other constitutively expressed genes.[127,128] Despite constitutive expression, the precise levels of eNOS protein are further controlled by specific transcriptional stimuli and by posttranscriptional modulation of eNOS mRNA stability.[129]

Several extracellular factors influence eNOS mRNA levels. For example, shear stress is a key determinant of basal eNOS transcription. This effect may be mediated, in part, by nine consensus shear stress–response elements in the eNOS promoter.[76] The transcription factor KLF2 is specifically upregulated by shear stress in the endothelium,[130] and KLF2 itself serves as an important regulator of basal eNOS transcription in response to laminar shear stress.[131] Shear stress also induces eNOS transcription via a c-Src/NF-κB dependent pathway.[132,133] Hypoxia has been shown to induce *eNOS* gene transcription. This effect is mediated by a hypoxia-responsive element 5.3 kb upstream of the transcription start site.[134] However, the role of hypoxia in regulating eNOS is not entirely clear, as some evidence suggests that hypoxia may actually inhibit eNOS expression via the Rho kinase pathway.[135] Cytokines, including tumor necrosis factor (TNF)-α, downregulate eNOS transcription in part by inhibition of SP1.[136] High levels of oxidized low density lipoprotein (LDL) have been shown to impair eNOS mRNA stability.[137] Statins, which may exert an indirect effect on eNOS mRNA via LDL-lowering properties, furthermore have an independent effect in increasing eNOS mRNA,[137,138] which may be mediated by limiting the cytokine-mediated downregulation of eNOS transcription,[139] or by statin-mediated inhibition of RhoA GTPase.[140] Many other mediators exert effects at the level of eNOS transcription, including thrombin and Rho kinase, both of which attenuate the half-life of eNOS mRNA.[141,142]

In endothelial cells, the eNOS enzyme is subject to an intricate scheme of modifications and controls that result in a dynamic pattern of stimulation and inhibition in response to a number of physiologic stimuli. Five themes have emerged from a wide variety of experiments that elucidate some of the biochemical systems controlling eNOS in vascular endothelial cells: (a) eNOS is targeted to plasmalemmal caveolae, (b) in the caveolae, eNOS is tonically inhibited by its interaction with the scaffolding-regulatory protein caveolin, (c) certain extracellular signals, including shear stress and specific agonists, establish a basal level of eNOS activity for NO signaling in the endothelium, (d) a diverse family of eNOS agonists—generally involving calcium- or phosphorylation-mediated pathways—dynamically regulates eNOS activity by promoting a rapidly reversible activation of eNOS followed by the return of eNOS activity to basal levels, and (e) part of this inhibitory mechanism and return to baseline may involve subcellular translocation of eNOS from caveolae in a reversible agonist-mediated process.

eNOS and Caveolae

Most eNOS in a resting endothelial cell is targeted to specialized plasmalemmal domains called caveolae. Caveolae are small invaginations of the plasma membrane that are relatively

enriched with cholesterol and sphingolipids, and are further distinguished by the presence of the transmembrane scaffolding protein caveolin-1. The unique biochemical composition of caveolae generates an "ordered liquid phase" that may facilitate various protein–protein and protein–lipid interactions.[143] Caveolae are now recognized as important domains for the sequestration of diverse receptors and signaling molecules, including G-protein–coupled receptors and growth factor receptors and their downstream activators, as well as calcium regulatory proteins, and sphingolipids. The targeting of eNOS to caveolae is dependent on dual acylations of the protein by myristoylation and palmitoylation. Myristoylation of eNOS is irreversible and cotranslational, and occurs on the amino group of glycine-2 after removal of the *N*-terminal methionine; this modification is absolutely essential to caveolar targeting.[144] Palmitoylation of eNOS is posttranslational and occurs at two cysteine residues, Cys15 and Cys26, near the *N*-terminus. The thiopalmitoyl bond is relatively labile, and palmitoylation is reversible in the presence of the enzyme acyl protein thioesterase-1 (APT-1).[145]

When anchored in caveolae, eNOS is tightly associated with caveolin-1 via protein–protein interaction; eNOS can be coimmunoprecipitated with anticaveolin-1 antibodies. The association with caveolin maintains eNOS in an inactive state in resting endothelial cells. Dynamic regulation of eNOS activity is achieved through various calcium- and phosphorylation/dephosphorylation-mediated pathways that appear to operate in tandem with cycles of enzyme acylation/deacylation. Regulation of intracellular calcium levels appears to provide the most rapid increase in eNOS activity through the binding of calcium/calmodulin to the enzyme. eNOS agonists, including acetylcholine (acting *via* M2 muscarinic receptors), bradykinin, and estradiol,[146] are known to initiate receptor-specific intracellular signaling pathways in endothelial cells. For example, bradykinin and acetylcholine activate a Gq pathway that increases phospholipase C activity, leading to inositol triphosphate generation and the release of calcium from intracellular stores.[76] These agonist-induced transient increases in intracellular calcium lead to the activation of the ubiquitous calcium regulatory protein calmodulin. Binding by eNOS of the calcium–calmodulin complex disrupts the caveolin-eNOS inhibitory protein–protein interaction, and increases the catalytic activity of eNOS, apparently by facilitating the transfer of electrons from the NADPH/FAD/FMN cofactors in the reductase domain to the oxygenase domain in eNOS. Displacement of caveolin from eNOS occurs in concert with the binding of calcium–calmodulin to the enzyme.[147] In turn, calcium–calmodulin binding to eNOS facilitates the depalmitoylation of eNOS catalyzed by the enzyme APT-1.[145] In the cytosol, eNOS activity is downregulated further, possibly via reversible phosphorylation at Ser 116.[148] Recent evidence indicates that calmodulin itself is under control of kinase CK2; phosphorylated calmodulin is less efficiently bound, and thus the response of eNOS to intracellular calcium is abbreviated and eNOS activity is attenuated. Since calmodulin levels in the cell are low relative to total capacity of calmodulin binding proteins, this CK2 phosphorylation mechanism may serve to selectively displace calmodulin from eNOS without decreasing total cellular calmodulin levels or disturbing other signaling pathways.[149]

Caveolin-1 may have important roles in the pathobiology of cardiovascular diseases as a consequence of the inhibitory effect of caveolin-1 on eNOS activity (see a detailed review of caveolae and caveolins by Patel et al.[150]). Blood vessels isolated from caveolin-1–deficient (Cav-$1^{-/-}$) mice show an exaggerated response to agonists that promote eNOS activation, yet systemic blood pressure in these animals is not substantively changed. Indeed, there are mixed results regarding the functional effects of caveolin-1 inhibition on key hemodynamic indices. For example, Wunderlich et al.[151] demonstrated that in Cav-$1^{-/-}$ mice, increased levels of eNOS activity, but not BH_4 are observed, resulting in eNOS uncoupling and an increase in pulmonary artery pressure compared to wild type mice. Others have observed no significant change in central aortic blood pressure in Cav-$1^{-/-}$ mice despite biochemical evidence to suggest increased levels of NO.[152] Understanding further the complexities of caveolin-1–eNOS signaling *in vivo* to develop this as a therapeutic target is a goal of ongoing translational investigations.[153]

eNOS Phosphorylation

In addition to these mechanisms involving acylation and calcium, the complete picture of eNOS regulation includes extensive pathways of phosphorylation and dephosphorylation at multiple sites on the enzyme (FIGURE 40.3). Phosphorylation at Ser1179 in bovine eNOS (Ser1177 in human eNOS) leads to enzyme activation, whereas phosphorylation at Thr 497 and Ser 116 leads to attenuation of eNOS activity. Recent studies suggest that Ser 635 is a stimulatory phosphorylation site, possibly responsive to shear stress,[154] while phosphorylation of Ser 617 may sensitize eNOS to calmodulin binding.[155] Src-dependent phosphorylation at Tyr81 in the oxygenase domain of eNOS appears to be one mechanism by which stimulation of endothelial cells by bradykinin, ATP, and acetylcholine, among others, promotes NO generation.[156,157] Indeed, compared to wild type eNOS, site-directed mutagenesis in which phenylalanine, which is resistant to phosphorylation, is substituted for Tyr81 (Y81F) is unresponsive to stimulation with bradykinin or VEGF. Proposed but as yet unconfirmed mechanism(s) by which eNOS phosphorylation at Tyr81 increases eNOS-derived NO production include changes to eNOS activity levels, alterations in Ca^{2+}-sensing by eNOS, and direct effects on eNOS stability.[156,157]

In contrast to Tyr81, phosphorylation at Tyr657 results in a complete loss of eNOS-dependent NO, citrulline, and superoxide production.[158] The inhibitory effect of Tyr657 phosphorylation on eNOS activation may be linked to the location of this tyrosine residue, which lies within the FMN domain on the reductase eNOS monomer. It has been hypothesized that limitations to FMN mobility imposed by phosphorylation restricts FMN-mediated delivery of electrons to the heme moiety of the oxygenase monomer, which is necessary to facilitate the conversion oxygen/L-arginine to NO/L-citrulline.[159] Phosphorylation at Tyr657 is proline-rich tyrosine kinase 2 (PYK2) dependent; in mice aortas, angiotensin II infusion, which is associated with increased vascular hydrogen peroxide formation and subsequent activation of PYK2, attenuates NO synthesis and endothelium-dependent vascular relaxation.[160]

Phosphorylation of eNOS Ser1179 is mediated directly by kinase Akt, also known as protein kinase B,[156] and numerous other protein kinases have been implicated in phosphorylation of this site. Akt is itself activated by phosphorylation pathways downstream of PI3K. Although Akt is predominantly found in the cytosol, membrane targeting of both eNOS and Akt is

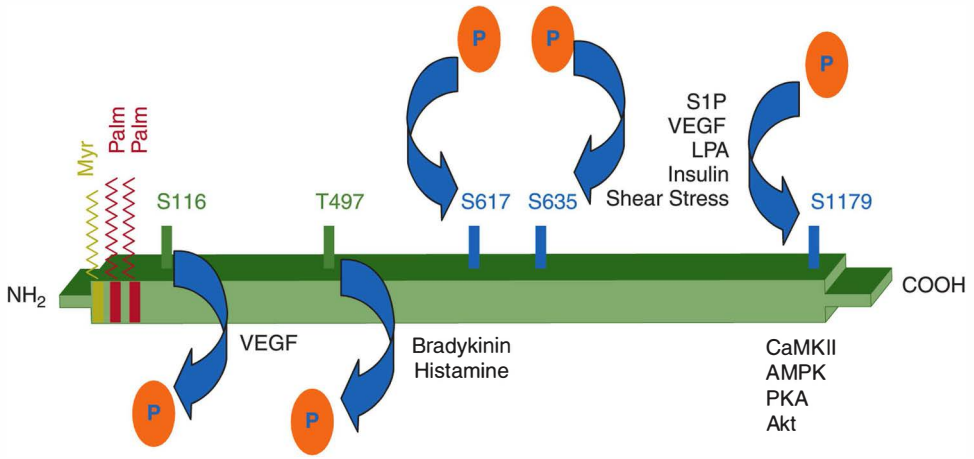

FIGURE 40.3 Regulation of eNOS activity. eNOS activity is regulated by agonist-mediated phosphorylation and dephosphorylation at a number of eNOS serine and threonine sites (amino acid sequence numbers refer to bovine eNOS). Phosphorylation at Ser1179 and Ser 635 are believed to stimulate eNOS activity, while phosphorylation at Ser 617 may promote calmodulin binding and thus increase eNOS activity. Many eNOS agonists, including shear stress, VEGF, S1P, estrogen, and leptin, lead to phosphorylation at Ser1179. Phosphorylation at Ser 116 or Thr 497 attenuates eNOS catalytic activity. VEGF induced dephosphorylation at Ser 116 increases eNOS activity; similarly, protein phosphatase 2A may dephosphorylate Thr 497 and Ser1179.

necessary for eNOS to undergo phosphorylation at Ser1179.[144] Upon activation, Akt is known to translocate to the membrane, as its upstream activators are membrane associated. Several molecules superimpose another level of control on eNOS by interacting with kinase Akt in the vascular endothelium. Thrombin, acting via the Rho/Rho kinase pathway, inhibits Akt-mediated phosphorylation and activation of eNOS.[141] The heat shock protein hsp90 appears to bind to eNOS and/or kinase Akt to promote eNOS activation.[161] Adipocyte-released hormones appear to cause vasodilatation: leptin may activate endothelial Akt in a tyrosine kinase–dependent mechanism,[162] while adiponectin, an insulin mimetic, activates insulin receptor tyrosine kinases leading to eNOS activation via a PI3K/AMPK pathway.[163]

Part of the overall endothelial response to shear stress is mediated by phosphorylation of eNOS at Ser1179. Shear stress is likely a key determinant of the tonic stimulation of NO production and the maintenance of basal vascular tone.[164] Shear stress is transduced via a mechanochemical coupling that increases both calcium and potassium currents and leads to activation of the PI3K/Akt kinase and PKA pathways.

VEGF is a potent stimulus of eNOS activity via kinase Akt–mediated phosphorylation at eNOS Ser1179.[148] Activation of the VEGF receptor KDR results in PI3K α and PI3K β activation, and leads to increased activity of Akt. In addition to its effects at Ser1179, VEGF induces dephosphorylation at eNOS Ser116 in a pathway that involves the activation of the phosphatase calcineurin.[148] Since phosphorylation of eNOS at Ser116 appears to inhibit enzyme activity, the involvement of calcineurin in eNOS dephosphorylation may provide a clue to the hypertensive effects of the calcineurin inhibitor cyclosporine.

Other agonists activate eNOS by a PI3K/Akt-dependent mechanism, including estrogen,[165,166] and a class of platelet-derived lipid mediators that includes S1P and lysophosphatidic acid (LPA).[167] In addition to S1P release from activated platelets and endothelial cells, S1P release is induced by platelet-derived growth factor and released by platelets into the extracellular space, where it activates endothelial cells through its interaction with G-protein–coupled S1P receptors (formerly known as EDG, or endothelial differentiation gene receptors). Moreover, S1P has many functions in endothelial cells including angiogenesis, vasorelaxation, and proliferation. S1P induces translocation of S1P receptors to caveolae.[168] This translocation may facilitate coupling of the S1P receptor to downstream effectors that lead to eNOS Ser1179 phosphorylation *via* a PI3K β/Akt pathway.[169]

LPA is released by platelets activated by agonists, including thrombin. Although LPA exerts actions similar to S1P, including phosphorylation of kinase Akt and eNOS, LPA acts independently of S1P receptors,[170] and appears to bind the related family of LPA receptors.[171] S1P and LPA signaling provides a paradigmatic example of cross-talk between platelets and endothelial cells in the regulation of eNOS.

VEGF is a critical regulator of eNOS in that it directly exerts effects via PI3K/Akt but also sensitizes the endothelium to the effects of lipid mediators.[172] VEGF induces S1P receptor mRNA and receptor levels, and thereby augments eNOS activity and endothelial responses to S1P. S1P and VEGF may synergize and coordinately promote angiogenesis by stimulating NO-dependent endothelial cell migration.

PI3K/Akt pathways are but one of a number of phosphorylation cascades that modulate the activity of eNOS. VEGF, S1P, and bradykinin all stimulate various mediators in the MAP kinase pathway, especially ERK1 and ERK2.[148,173–175] The pleiotropic effects of various agonists evince a possible developing paradigm of complex temporal regulation of eNOS. A wide variety of protein kinases have been implicated in phosphorylation of eNOS. In addition to the role clearly established for kinase Akt, other reports have implicated PKA, PKC, PKG, MAP kinases, and the AMPK in eNOS phosphorylation. The relative roles of different kinase pathways represent an active area of investigation, and it is safe to say the pattern of eNOS regulation by

protein kinases and phosphoprotein phosphatases is complex. The phosphorylation of eNOS at different sites has profound effects on stimulating and inhibiting eNOS activity, and it is clear that various phosphatases, as well as kinases, contribute to these processes. Part of the eNOS-activating effect of bradykinin may derive from calcineurin-mediated dephosphorylation of Thr 497.[176] In addition to the phosphatase calcineurin, protein phosphatase 2A appears to be a key regulator with an overall inhibitor effect on eNOS activity that dephosphorylates eNOS on Thr 497 and Ser1179.[177] Reciprocal control of phosphorylation at Thr 497 may contribute to the balance of production of NO and superoxide, respectively, by eNOS.[149]

eNOS (De)acetylation

There is growing evidence to support a role for (de)acetylation in modulating eNOS bioactivity. For example, Mattagajasingh et al.[178] demonstrated that by deacytylating lysine 496 and 506 in the calmodulin-binding domain of eNOS, silent mating type information regulation 2 homolog (SIRT1), a lysine deacetylase histone deacetylase-3 (HDAC3), increases levels of the stable NO byproducts nitrite and nitrate (NOx) and promotes endothelium-dependent vasodilation. Laminar flow, which is associated with shear stress and eNOS activation, increases SIRT1-mediated deacetylation activity in cultured endothelial cells. In contrast, oscillatory flow, in which flow is disturbed and without uniform direction, has no effect on SIRT1 activity.[179] Overall, these findings are consistent with observations made by others that aortic endothelial cell exposure to the SIRT1 stimulator resveratrol increases eNOS activity.[180] Furthermore, calorie restriction–induced eNOS deacetylation may provide one potential mechanism to explain the beneficial effects of calorie restriction as an established strategy to improve blood pressure and vascular reactivity in both obese and nonobese mammals.[181,182]

Similar to the divergent site-dependent effects of serine phosphorylation on eNOS activation, it has been demonstrated that acetylation of lysine 607 (Lys609 in mammals), which is located in the autoinhibitory domain of calmodulin (i.e., activation of this domain interferes with eNOS binding to calmodulin to decrease eNOS activity), is a critical protein posttranslational modification that increases eNOS-dependent NO synthesis.[183] Jung et al. investigated the possibility that Lys609 acetylation is one mechanism by which aspirin increases vascular NO levels to induce a decrease in systemic blood pressure. Indeed, their findings suggest that by inducing Lys609 acetylation, low-dose aspirin promotes eNOS–calmodulin binding to increase eNOS-dependent (but cyclooxygenase-independent) NO generation *in vitro* and in mice aortas *in vivo*. Conversely, these authors demonstrate by inducing deacetylation of Lys609, SIRT1 inhibits aspirin-mediated eNOS activation by preventing lysine acetylation.

AMP-Activated Protein Kinase

AMPK is a heterodimeric enzyme that is stimulated by an increase in cellular levels of AMP:ATP and is also a target of several protein kinases.[184] Within many cell types, the role of AMPK may be most closely related to the effects of this kinase on cellular energetics. Studies of AMPK in vascular endothelial cells have focused on signaling pathways that regulate cellular metabolism and vasodilatory function. Chen et al.[185] demonstrated that AMPK coimmunoprecipitates with eNOS in rat cardiac myocytes and promotes phosphorylation of eNOS at Ser1177 in the presence of Ca^{2+}-calmodulin to increase eNOS activity. Moreover, under conditions of myocardial ischemia, which are associated with decreased levels of bioavailable ATP, a twofold increase in AMPK levels was associated with a significant increase in P-eNOS (Ser1177) protein expression levels and Ca^{2+}-calmodulin–dependent eNOS activity.

In aortic endothelial cells, it has been discovered that factors conventionally associated with eNOS activation—shear stress, statins, and adiponectin—induce phosphorylation of AMPK at Thr172, which, in turn, is linked to phosphorylation of eNOS at Ser633 and increased levels of eNOS-derived NO.[186] Increases in statin-induced eNOS phosphorylation at Ser633 are not maintained in aortas harvested from AMPK α_2 null mice *in vivo*.[179] Moreover, it appears that Ser633 may compete with Ser1177 for phosphorylation by AMPK. Overall, these findings suggest that AMPK functions in an important role to regulate NO bioavailability in vascular endothelial cells.

The framework of AMPK-eNOS signaling has been expanded recently. For example, VEGF-stimulated AMPK results in eNOS phosphorylation at Ser1177, and provides one potential mechanism to account for the observation that inhibition of VEGF-induced activation of PI3K does not fully attenuate eNOS activation.[187] Furthermore, it has recently been reported that AMPK is a regulatory target of eNOS. In cultured aortic endothelial cells, molecular or pharmacologic inhibition of eNOS is associated with increased intracellular levels of H_2O_2, which, in turn, is a potent agonist for Ca^{2+}/calmodulin-dependent protein kinases II β (CaMKII β)-dependent phosphorylation and activation of AMPK.[188] As stated above, AMPK is an established agonist for eNOS activation. Thus, collectively these findings raise the possibility that oxidant stress-mediated AMPK activation, either from eNOS-dependent (i.e., NOS uncoupling) or eNOS-independent reactive oxygen species generating sources (i.e., NADPH oxidase, mitochondrial sources, others), is a key counter regulatory mechanism to maintain cellular levels of NO under conditions in which eNOS may be dysfunctional or present at low levels.

INDUCIBLE NOS-DERIVED NITRIC OXIDE AND VASCULAR PHYSIOLOGY

iNOS has been isolated from macrophages, endothelial cells, hepatocytes, neutrophils, airway epithelium, fibroblasts, bone, microglia, retina, and mast cells; its prototypical function is as a component of the innate immune response to pathogens and turnover cells.[189,190] iNOS is generally absent in quiescent cells, but iNOS mRNA levels rise rapidly within hours following exposure to proinflammatory stimuli, including bacterial lipopolysaccharide (LPS), lipoteichoic acid, and some exotoxins like TSST-1; heat stress and hypoxia may induce similar transcriptional responses. Bacteria-generated proinflammatory cytokines including IFNγ, TNF-α, TNF-β, interleukin (IL) 1, IL 12, and platelet activating factor[191] promote iNOS transcription via NF-κB–dependent signaling pathways.[192,193] Induction of iNOS leads to persistent NO production, as the tight binding of calmodulin to iNOS at low levels of intracellular calcium leads to "constitutive activation" of this inducible enzyme once it is synthesized in response to proinflammatory stimuli. The relatively high concentrations of iNOS-derived NO destroy cellular structures and inhibit iron-containing enzymes. Intricate

molecular cross-talk between the cyclooxygenase and NOS pathways interconnects NO with inflammation. Specifically, iNOS-derived NO may stimulate cyclooxygenase-2 directly or via cGMP that is generated by NO-sGC signaling. Activation of cycloloxygenase-2 results in the subsequent production of prostaglandin E_2/I_2, each of which, in turn, may induce iNOS.[194]

iNOS and Infection

Widespread induction of iNOS in macrophages, VSMCs, hepatocytes, and cardiomyocytes is a central feature in the pathophysiology of endotoxemia, sepsis, and circulatory shock. Supraphysiologic induction of iNOS in macrophages and VSMCs significantly raises NO production in the vasculature, such that blood levels of NO and its metabolites can reach micromolar levels.[195] iNOS-dependent increases in NO has been proposed as the major impetus for systemic hypotension that is observed clinically in patients with septic shock. In fact, the role of iNOS in modulating abnormal hemodynamics in sepsis is undoubtedly more complex. For example, endotoxemia-associated iNOS induction is associated with disrupted vascular endothelial metabolic signaling pathways, skeletal muscle insulin resistance, and abnormal hypothalamic arginine vasopressin synthesis, all of which may contribute to hypotension in sepsis.[196,197] In addition to the influence of iNOS on vascular function in shock, iNOS induction in the heart is a negative inotrope, and thus by decreasing cardiac output exacerbates hypotension directly.[198] Therefore, through this pathway, iNOS is a likely stimulator of worsening local metabolic derangement (e.g., lactic acidosis) in vascular and skeletal tissue that contributes to end-organ injury via hypoperfusion-induced mitochondrial dysfunction.

iNOS and Vascular Diseases

In addition to its roles in inflammation and infection, iNOS has important roles in vascular biology, and iNOS-derived NO has been associated with several vascular disease states. In iNOS-deficient mice, cholesterol levels and the incidence of atherosclerotic plaques were found to be significantly increased.[199] Several studies have reported that iNOS is induced in vascular smooth muscle within human atherosclerotic lesions, and the expression of iNOS in macrophages colocalizes with peroxidized lipids and necrotic cores in advanced atheromas.[200,201] Activation of iNOS by the inflammation-regulating nuclear receptor of peroxisome proliferator-activated receptor gamma results in VSMC proliferation and neointimal formation in carotid arteries following vascular injury.[202]

The precise roles of iNOS in atherogenesis are still being defined, and it is not yet clear whether iNOS reflects a pathologic or protective response, or both. For example, iNOS-derived NO may possibly function as an antioxidant in atherosclerotic plaques.[203] Additionally, by combating certain pathogens, iNOS may prevent the initiation or exacerbation of the inflammatory and immunologic reactions of atherosclerotic responses in the vascular wall.[204] Statins have been demonstrated to upregulate iNOS mRNA levels in vascular smooth muscle and may contribute to the atheroprotective effect of this class of therapeutics.[205] In turn, iNOS expression has been correlated with decreased extracellular collagen content and atherosclerotic plaque instability. Moreover, aortas from rats fed a high fructose diet to induce the metabolic syndrome are characterized by elevated levels of ADMA, an endogenous eNOS inhibitor, but also have increased protein expression levels of iNOS and nitrotyrosine (i.e., consistent with peroxynitrite formation).[206] These findings reflect the unresolved role of iNOS in atherosclerotic disease: increased iNOS expression could be a compensatory measure to offset ADMA-induced degradation of eNOS, or, conversely may be induced by elevated oxidant stress levels to function as a promoter of vascular injury.[206,207]

iNOS may also play a role in the pathogenesis of hypertensive states, including preeclampsia and some forms of pulmonary hypertension. In preeclampsia, vascular reactivity of peripheral blood vessels is impaired as early as the first trimester when assessed by flow-mediated dilation, and is associated with increased serum levels of iNOS and NO metabolite formation, but also increased placental levels of protein tyrosine nitrosation.[208] In a rabbit ischemia–reperfusion lung injury model, iNOS inhibition was associated with decreased pulmonary vasoconstriction and platelet–arteriolar wall interactions.[209] Following pulmonary embolism, pathophysiologic levels of iNOS-derived NO and subsequent increases in vascular reactive oxygen species formation are implicated in the development of lung injury and abnormal pulmonary vascular reactivity.[210] Although iNOS inhibition appears to reduce the levels of pulmonary vascular oxidant stress in animal models of pulmonary embolism, this therapeutic strategy has not been proven effective for mitigating pulmonary embolism-induced pulmonary hypertension *in vivo*. Thus, the potential of iNOS inhibition as a treatment target to modify systemic or pulmonary hypertension remains unresolved and is a topic of ongoing investigation.[211]

NEURONAL NITRIC OXIDE AND VASOREGULATION

nNOS is found in relatively high concentrations in specific regions of the mammalian central nervous system.[212] However, nNOS is also expressed in myocardium, skeletal muscle and in parasympathetic nervous systems of the gastrointestinal tract, bladder, ureter, prostate, and in neurons that innervate the walls of corpus cavernosa large blood vessels.[213] nNOS transcription is complexly regulated in pathways involving the p38 MAPK[214] and OCT2[215] transcription factors, while differential splicing of nNOS results in at least three tissue-specific variants.[216,217]

Neurogenic Vasodilatation Mediated by NO

Experiments demonstrating a vasodilatory response mediated by nonadrenergic, noncholinergic nerves that was not mediated by other well known neurotransmitters, was independent of denuded endothelium, and yet was susceptible to NOS inhibitors led to the hypothesis that nitrergic (also termed nitroxidergic) nerves modulate local NO release to mediate vasodilation.[218] This phenomenon of nitrergic innervation has been revealed in the cerebral, mesenteric, temporal, and ophthalmic arteries and arterioles of dogs, cows, and monkeys, as well as the human uterine artery.[219] Some evidence from experiments in humans suggests that NO functions in vasoneuronal coupling of cerebral blood flow to neuronal activity, which may be relevant to maintenance of cerebral blood flow and the pathophysiology of migraine.[220] Nitrergic nerves, like noradrenergic nerves, directly innervate vascular smooth muscle. nNOS is localized

to postsynaptic terminals of perivascular nerves, and there is immunohistochemical evidence for nNOS in the adventitia and outer media of nitrergic innervated vessel.[219] Dual innervation of VSMCs by noradrenergic and nitrergic nerves provides a mechanism for reciprocal neurogenic control of vasoconstriction and vasodilatation.[218]

nNOS is expressed in cardiomyocytes and localized in the sarcoplasmic reticulum (SR).[221] Owing to the close association between nNOS and ryanodine receptor Ca^{2+} release channel (RyR2) and SERCA2, both key intermediaries necessary for myocyte r(d)epolarization, it has been hypothesized that nNOS is important for maintaining normal ventricular function. In fact, $nNOS^{null}$ mice demonstrate pathologic left ventricular remodeling[222] and an increased predilection to L-type Ca^{2+} channel–dependent ventricular arrhythmias and death following myocardial infarction. NO donor therapy, in turn, attenuated this effect by maintaining intracellular calcium levels. nNOS-derived NO may accomplish this by inducing *S*-nitrosylation of the L-type Ca^{2+} or SERCA2, and/or inhibition of L-type Ca^{2+} channel-mediated intramyocyte Ca^{2+} overloading, mechanisms linked to the prevention of electromechanical disassociation.[223,224–228]

EFFECT OF PHARMACOLOGIC SOURCES OF NITRIC OXIDE ON VASCULAR SIGNALING

Exogenous Sources: Nitrovasodilator Drugs and NO-Donating Molecules

Nitrovasodilator drugs encompass a chemically heterogeneous group of molecules that have the ability to generate NO *in vivo*. As such, NO has been termed the "endogenous nitrovasodilator" and nitrovasodilator drugs have been dubbed "endothelial cell replacement therapy."[229] However, it is important to note that exogenous and endogenous sources of NO can differ importantly in their kinetics and reactivity. Of the various organic nitrovasodilators in clinical use, the NO donating group is either a nitrate group, as in nitroglycerin, isosorbide dinitrate, and isosorbide mononitrate, or a nitrite group as in amyl nitrite. The pathways whereby organic nitrovasodilators release NO are incompletely understood, but several mechanisms for the enzymatic transformation to NO have been proposed.[230] Sodium nitroprusside is an organometallic compound that directly releases its NO ligand apparently in a nonenzymatic process. The nitrovasodilators also differ importantly in their bioavailability, route of administration, doses, elimination half-life, and side effects, but share common characteristics in their releasing NO as their principal bioactive product.[231]

The ability of nitrovasodilators to deliver NO and thereby dilate venous and coronary vessels is exploited in the treatment of hypertension, angina, and heart failure. Prolonged nitrate therapy generally leads to tolerance, characterized by a decreased sensitivity of vascular cells to the nitrovasodilator. Numerous theories have been advanced to account for the observation of tolerance, including vascular tolerance via feedback inhibition, sulfhydryl depletion, increased endothelial production of free radicals including superoxide, neurohumoral reflexes, and alteration in local vascular production of vasoactive compounds.[231] The sulfhydryl hypothesis posits that tolerance is related to depletion of reactive sulfhydryl groups necessary for the enzymatic release of NO from nitrovasodilators.[231] Tolerance could be related to inhibition of NO-cGMP signaling in response to elevated vascular NO levels.[43] At least with respect to nitroglycerin, tolerance has been linked to downregulation of mitochondrial aldehyde dehydrogenase an enzyme reported to be involved in the metabolism of nitroglycerin to release NO.[232]

Importantly, nitroglycerin also induces production of reactive oxygen species, which, in part, blunt the response to vasodilatory agonists while sensitizing the vascular response to endogenous vasoconstricting agents.[232] Overactivation of eNOS by pharmacologic NO donors that ultimately results in BH_4 depletion and eNOS uncoupling has also been suggested as a mechanism to account for nitrate tolerance.[233]

Other Pharmacotherapies that Increase NO Bioavailability

Inhibitors of angiotensin converting enzyme (ACE) exert vasodilatory effects not only by limiting generation of angiotensin II, but also by blocking the breakdown of the key eNOS agonist bradykinin. By inhibiting the catabolism of bradykinin by ACE, ACE inhibitors result in increased endothelial formation of NO in a bradykinin-dependent manner.[234] Likewise, by attenuating the adverse effects of aldosterone on vascular NADPH oxidase-dependent reactive oxygen species formation, mineralocorticoid receptor antagonism is associated with increased vascular levels of bioavailable NO and improved vascular reactivity assessed by flow-mediated vasodilation in humans with hyperaldosteronism.[57,235] HMG-CoA reductase inhibitors are associated with eNOS phosphorylation and increased expression of SIRT1 (see above) in vascular endothelial cells *in vitro*.[236] In preclinical trials, atorvastatin is associated with increased microvascular eNOS mRNA levels, decreased protein nitration (i.e., suggestive of decreased vascular oxidant stress), and improved endothelium-dependent vascular reactivity in normocholesterolemic smokers, suggesting that statin therapy may lead to beneficial effects on vascular function via lipid-independent mechanisms.[237]

CONCLUSION

The distinctive chemical properties and crucial biologic functions of NO place this molecule in a central role for maintaining vascular homeostasis in humans. NO synthesized in the endothelium by eNOS targets sGC in VSMCs and platelets to modulate blood vessel dilation and prevent thrombosis. Additionally, NO also targets leukocytes to prevent cell adhesion in the blood vessel lumen and exerts a favorable effect on endothelial cell senescence. eNOS, the primary NO generating enzyme in the endothelium, itself is regulated by a complex, interlinked network of agonists, calcium transients, and posttranslational modifications including (de)phosphorylation and (de)acetylation. Recently, the discovery of molecular cross-talk between eNOS and key proteins involved in regulating cell metabolism has illuminated novel mechanisms linking bioenergetics with NO biology.

Genetically engineered double- and triple-NOS knockout animal models have further elucidated the roles of iNOS and nNOS as important intermediaries that modulate vascular

function. iNOS appears to be a particularly important player in the hemodynamic responses to sepsis and preeclampsia. Likewise, nNOS assists in vasoneuronal coupling and the regulation of cerebral blood flow, as well as modulating the tone peripheral vessels via nitrergic neurons.

Advancing our understanding of nitrate tolerance and the biochemistry of nitrosothiols in order to develop more sustained, efficient pharmacologic systems of NO delivery are key areas of current investigation. In this way, it is hoped that heightened understanding of NOS molecular regulation and NO chemistry may identify novel treatment targets for patients with vascular disease.

CHAPTER

41 Blood Vessel Wall in Health and Disease

KEITH R. BRUNT, SONYA HUI, JAGDISH BUTANY, AND MANSOOR HUSAIN

Large arteries and veins are comprised of concentric layers of smooth muscle cells (SMCs) and connective tissue, and a protective inner lining of endothelial cells (ECs). The latter normally functions as a pacifying inner lining that prevents thrombosis and secretes factors that regulate underlying SMC function and phenotype to modulate both vessel diameter and vessel wall structure. When cardiovascular risk factors harm or "activate" the endothelium and impair its normal function, pathogenic processes such as inflammation, thrombosis, SMC proliferation, and abnormal vessel contractility can be initiated. Sustained endothelial dysfunction of this nature is ultimately believed to underlie the earliest stages of atherosclerosis. Similarly, vascular dysfunction can be *the* incipient event of most acquired cardiovascular diseases. This chapter orients the reader to key anatomical and physiologic aspects of the vasculature, from the major conduit vessels to specific clinically relevant vascular beds, with a focus on their cellular composition and function.

BASIC VASCULAR ANATOMY AND HISTOLOGY

All vessels conform to certain common anatomical features. With the exception of capillary beds, the blood vessel wall is organized into three layers, or tunica: the intima, media, and adventitia (FIGURE 41.1).

The *intima* extends from the endothelium to the inner elastic lamina, which is a highly organized tensile matrix. The endothelium and its basement membrane is a dynamically regulated single-cell-thick semipermeable layer interposed between the blood and the rest of the vessel wall or, in the case of capillaries between the blood and tissue parenchyma. The endothelium is the principal site of production for many hemostatic and vasoactive substances such as nitric oxide and prostacyclin (see Chapter 42). Immediately abluminal to the endothelium is a thin layer containing fibroblasts and a fenestrated sheet of elastic fibers, termed the *elastic lamina interna*. This elastic layer membrane is surrounded on both sides by covalently bound loose connective tissue that provides scaffolding for endothelial adherens and integrins, which are proteins that anchor cells to the intimal matrix or to other cells in the intima. In larger vessels, the intima may also contain SMCs. While rarely found in the intima of healthy blood vessels, leukocytes from the blood such as lymphocytes, dendritic cells, or monocyte–macrophages can enter the blood vessel wall at sites of vascular injury or inflammation and contribute to pathologies such as atherosclerosis (see Chapter 89).

In larger blood vessels, the *media* is the thickest layer of the vessel wall and is comprised of several circumferential, spirally aligned SMC layers, each of which can be sandwiched between additional elastic laminae. The general function of the media is to maintain vascular tone (i.e., the state of contraction exerted by SMCs in response to stretch and/or neuroendocrine stimulation). The media of veins is thinner than that of arteries and contains more connective tissue, although major veins such as the inferior vena cava also possess thick medial walls with some longitudinally oriented SMC layers as well. The extracellular composition (e.g., collagen, elastin, and proteoglycan content) of the media varies depending on vessel size, compliance, and muscularity. The medial wall is innervated, and in large arteries with high metabolic requirements, the media is also supplied by small blood vessels known as *vasa vasorum* (see "Vasa Vasorum" below). In large- and medium-sized arteries, the border between the media and adventitia is marked by an external elastic lamina. This border can be difficult to discern as the external elastic lamina disappears in small arteries and is absent in arterioles.

The *adventitia* begins where the media ends and is composed of a complex mixture of mesenchymal and myeloid cells with loose extracellular matrix. In large arteries, the adventitia can be nearly as thick as the media, containing abundant collagen and even elastin fibers. The adventitia contains abundant fibroblasts, as well as SMCs, adipocytes, and leukocytes. It also houses the majority of the *vasa vasorum* (see "Vasa Vasorum" below). The general function of the adventitia is to provide metabolic and structural support for large vessels.

AORTA AND CONDUIT VESSELS

Anatomy of the Aorta

Adult vascular anatomy begins at the aortic root, as blood exits the left ventricle through the aortic valve. The aorta has four noteworthy anatomical segments: (a) ascending aorta (length ~5 cm in humans), (b) aortic arch (~4 cm), (c) descending aorta (1, 2, and 3 are collectively referred to as the *thoracic aorta*), and (d) abdominal aorta. The ascending aorta, just past the cusps of the aortic valve, is also the location of three sinuses: the left, right, and posterior sinuses. The left and right sinuses are the origins of the left and right coronary arteries, respectively. The three sinuses provide eddies that aid in the closure of the proximal cusps of the aortic valve during diastole. The superior curve of the aortic arch contains branches that form the brachiocephalic (becoming the left carotid and subclavian), right carotid, and left subclavian arteries before descending approximately 20 cm left of the midline. Below the diaphragm, the abdominal aorta extends another approximately 15 cm before it terminally branches into two common iliac arteries. As the aorta descends from thorax to abdomen, its diameter narrows from approximately 3.5 to 2.5 cm, as it gives rise to several intervertebral

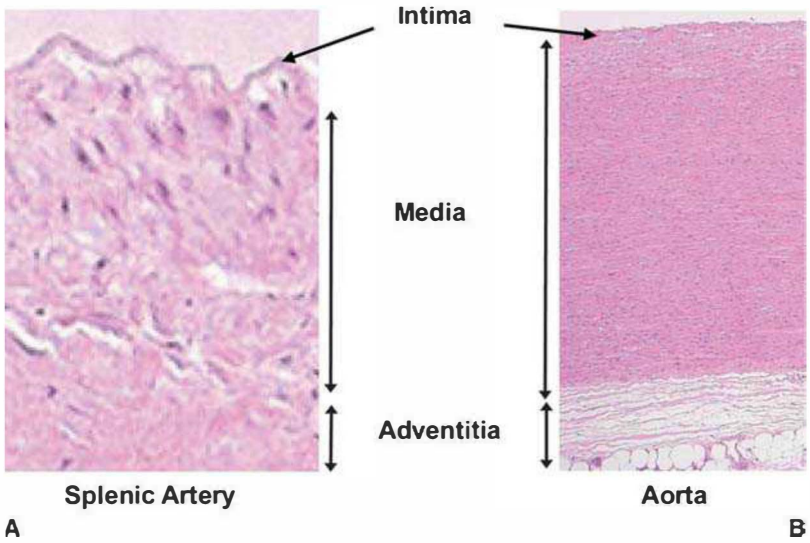

FIGURE 41.1 Tunica of the vessel wall. Cross sections showing the tunica intima, media, and adventitia of a human splenic artery (10×) and human aorta (2.5×), both stained with hematoxylin and eosin (H&E).

arteries in the thorax, and major conduit arteries in the abdomen, namely the celiac, mesenteric, and renal arteries as well as smaller gonadal, lumbar and sacral branches.

Histology of the Aorta

The histology of the aorta is consistent with its function as a major conduit vessel. Its composition is predominately elastic > fibrous > muscular. This differs from resistance arteries, which are muscular > elastic > fibrous. The walls of the aorta and other large arteries contain large numbers of elastic fibers arranged in circumferential lamellar units.[1,2] Each unit consists of two tightly packed elastic lamellae with cells and extracellular matrix contained within. A cross section of the thoracic aorta can reveal as many as 35 to 56 U, whereas the abdominal aorta typically has approximately 28 U.[2,3]

Physiology of the Aorta

To fulfill its functions as the central conductance vessel of the body, the aorta must have the elasticity and strength to stretch during systole, and to recoil during diastole, to correspondingly receive and transmit the entire left ventricular ejection volume and pulse pressure through to the smaller conduit arteries. The pressure pulse of blood created by systolic contraction of the ventricle is cushioned by the compliance of a highly elastic aorta. As the aortic valve closes during diastole, the potential energy stored in the aortic wall is converted into kinetic energy, propelling blood forward into the peripheral arteries with a smooth declination in flow velocity prior to the next systolic contraction.

Pathology of the Aorta

While the aortic endothelium is exposed to both high flow rate and shear stress, the curved geometry of the aorta also results in turbulent blood flow. In the lesser curvature of the aorta, turbulent flow can reduce shear stress, which predisposes the development of atherosclerosis.[4–6,7] Additionally, during ventricular contraction the aorta bears both the circumferential wall tension (from transmural wall pressure) and tensile stress (transmural wall pressure divided by wall thickness), which is exerted perpendicular to the flow of blood. These forces also contribute to aortic remodeling and aneurysm formation that can accompany aortic inflammation and atherosclerosis. Any deficiency in the aortic wall that decreases elasticity will impair compliance and conduit function and can contribute to adverse effects such as aortic dilatation, aortic wall thickening, or even rupture. By contrast, aortic coarctation is a rare congenital anomaly that is associated with aortic constriction, typically at or near the *ligamentum arteriosus*, the adult remnant of the fetal ductus arteriosus (whose function was to allow oxygenated fetal blood from the placenta to bypass the nonfunctioning pulmonary circulation and enter the descending aorta of the fetus from the main pulmonary artery). Aortic compliance can also diminish with age. In this degenerative process, elastic fibers are lost, SMC apoptosis is observed, and extracellular matrix is altered, changing the architecture of the aortic wall. This pathology typically includes intimal thickening and calcification. Although less severe than the mechanical narrowing of aortic coarctation, age-associated aortic degeneration also creates an increased afterload on the heart, causing pressure overload hypertrophy with hypertension. Over time, age-related pathologic alterations to the composition of the aorta may include vessel wall breakdown and aortic ectasia, or dilatation of the aortic wall. Ectasia results in widening, elongation, and uncoiling of the aortic arch, which can so alter the geometry of the aortic root as to limit competency of the aortic valve leaflets and contribute to aortic regurgitation. Accordingly, both diminished or exaggerated aortic wall compliance may eventually affect cardiac function.

As mentioned previously, the aorta is susceptible to turbulent blood flow, endothelial dysfunction, and atherosclerosis (FIGURE 41.2).[8,9] Atherosclerosis of the aorta can in turn lead to aortic aneurysm formation (FIGURE 41.3). Aneurysm, often secondary to atherosclerosis and rarely related to infection, can be: (a) dissecting (FIGURE 41.4), typically caused by cellular necrosis in the aortic media with subsequent tearing of a dissection plane between the lamellar units; (b) saccular, appearing as a bulging "sac" to one side; or (c) fusiform, a circumferential dilatation, in

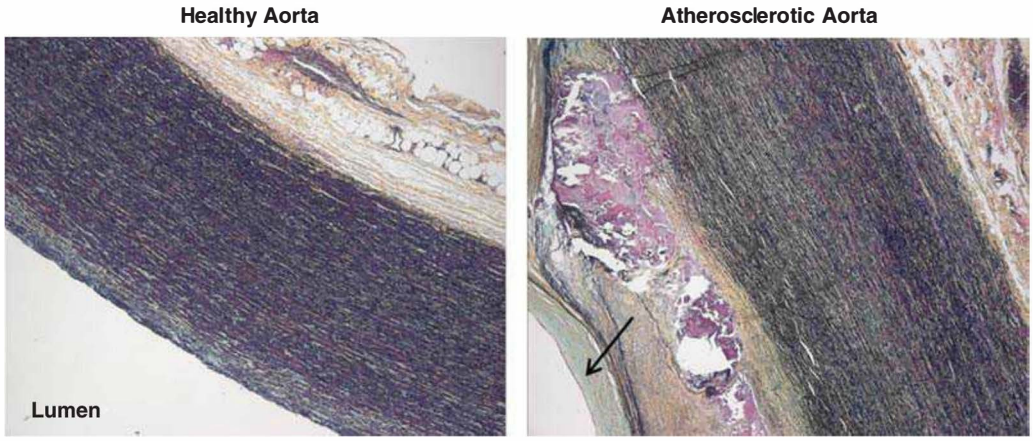

FIGURE 41.2 Human aortic atherosclerosis. Human aortic cross sections (all images 2.5×) stained with Movat pentachrome are shown from a healthy, 61-year-old male **(left panel)** and a 71-year-old female with an advanced atherosclerotic lesion **(right panel)**. Notable features of the complex atheroma include varying/irregular thickness of the plaque, calcification (*purple with Movat pentachrome*), lipid accumulation (*clear spaces*), and neointima formation, indicated by the *arrow*.

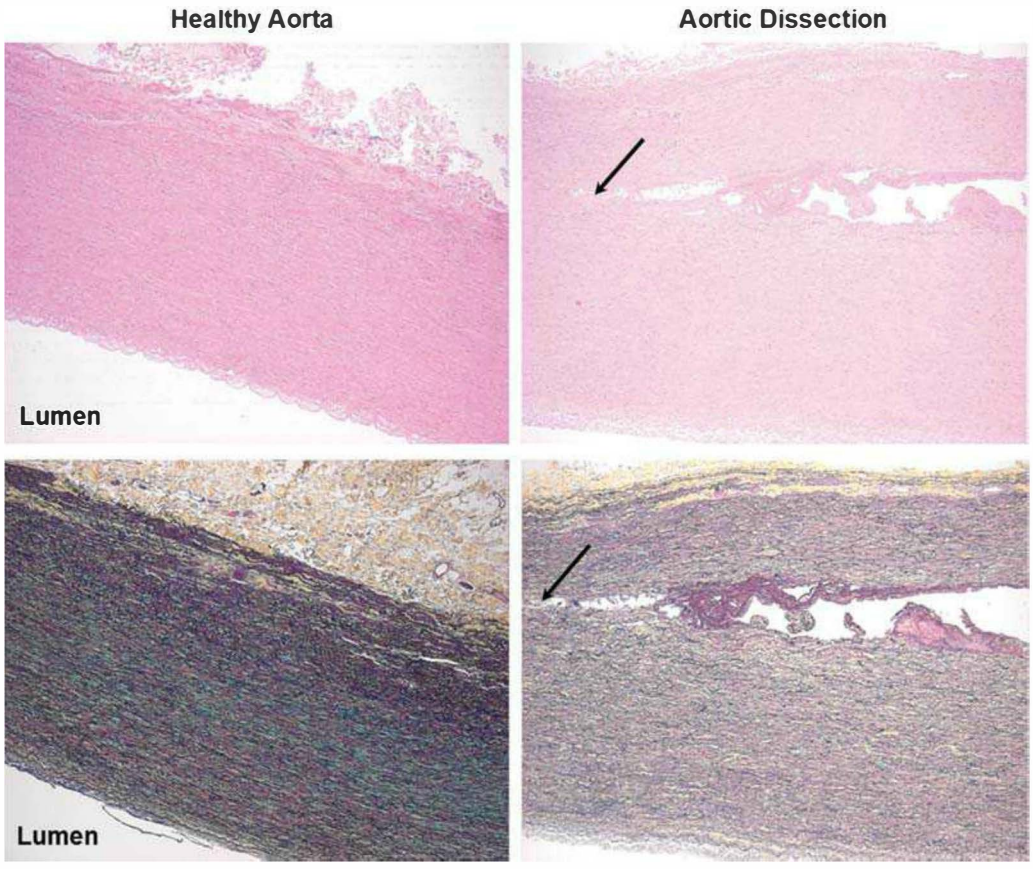

FIGURE 41.3 Histologic images of acute aortic dissection. Human aortic cross sections stained with H&E **(top panels)** and Movat pentachrome staining **(bottom panels)** are shown (**left panel**, 2.5×) and with an aortic dissection (**right panel**, 5×). The site of medial tearing is indicated by the *arrows*. The plane of cleavage usually occurs through the layer of the media in which the vasa vasorum change from radial to circumferential branching.

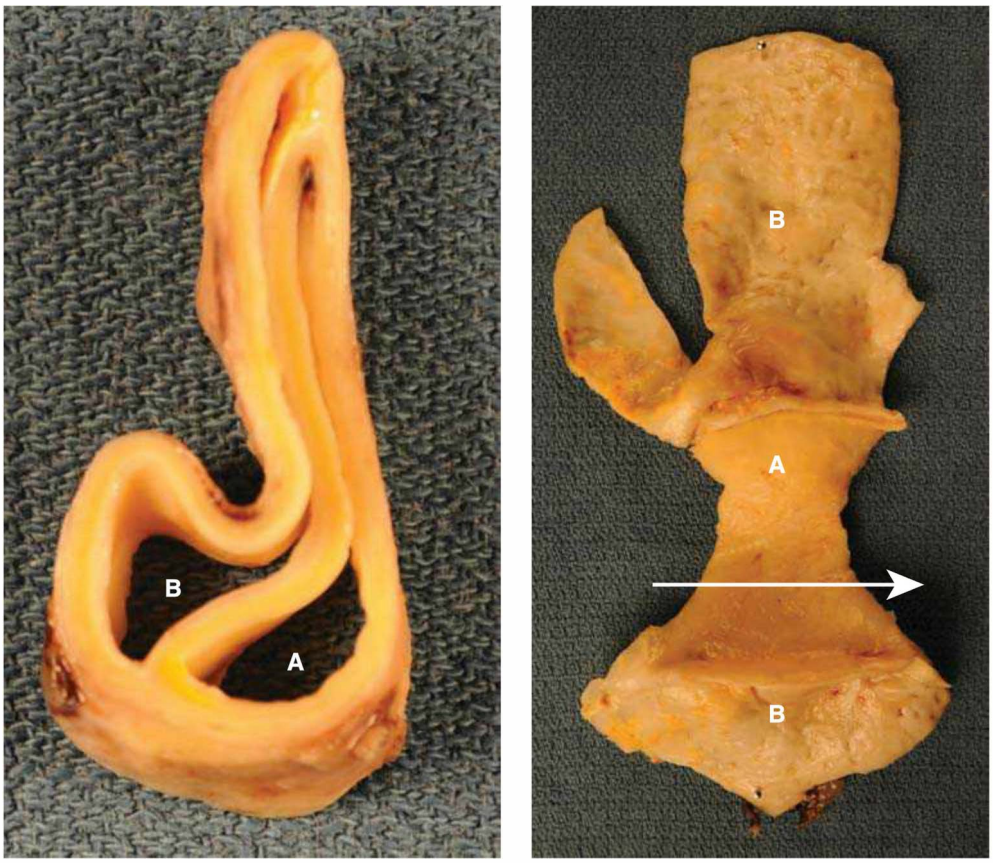

FIGURE 41.4 Gross anatomical images of chronic aortic dissection. Both the true lumen (*A*) and the reendothelialized false lumen (*B*) are shown.

the thoracic or abdominal aorta (see Chapter 72). Hypertension is a major contributing factor to aortic aneurysm.[10] Certain vasculitides also predispose to aortic aneurysm including Takayasu arteritis, giant cell arteritis (FIGURE 41.5), and ankylosing spondylitis (see Chapter 100). Trauma, in particular midspeed motor vehicle accidents, can also result in aortic damage, particularly those in which passengers are exposed to sudden decelerations or concussive force trauma, including seat belt injury. Finally, genetic defects of specific extracellular matrix proteins, such as in Marfan disease, are uncommon but important causes of potentially catastrophic aortic pathology.

VASA VASORUM

Anatomy of the Vasa Vasorum

While the inner third of the largest conduit vessels, such as the aorta, and inferior vena cava, is avascular, the outer two-thirds[11] is vascularized by a branched microvascular bed called the *vasa vasorum* (latin "vessel of a vessel"; FIGURE 41.6). The "vasa" can emerge from the lumen, branch up, out and through the adventitial layer (arborize), and weave into smaller vasa throughout the adventitia (and to a lesser degree, the media). However, the

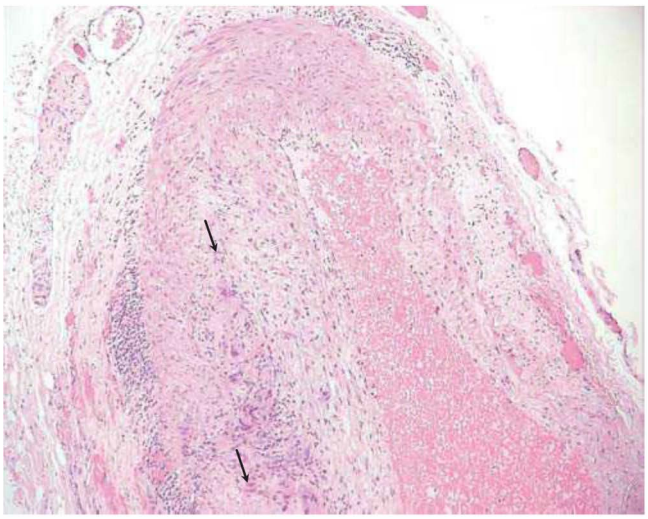

FIGURE 41.5 Giant cell arteritis in the temporal artery. Cross section of a human temporal artery with giant cell arteritis is shown (10×). Multinucleated cell fusions ("giant cells") caused by autoimmune reactions and chronic inflammation are indicated by the *arrows*.

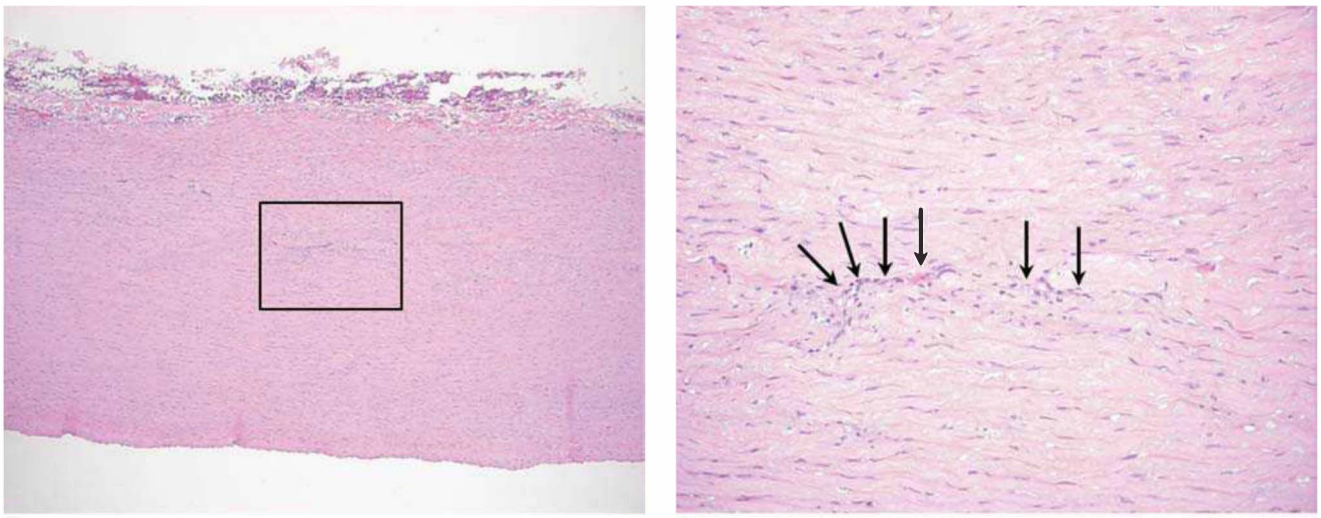

FIGURE 41.6 Vasa vasorum of different vessels. Vasa vasorum are indicated by *arrows* in cross sections of the aorta stained with H&E at **(A)** 5× and **(B)** 10× magnification. In the aorta, vasa vasorum are seen in the media.

vasa can also be a component of more distal arterialization from smaller arteries such as the brachiocephalic artery to ascending aorta, coronary to pulmonary artery, or mesenteric artery to abdominal aorta/inferior vena cava.[12,13] The evidence for both arborized and "nonself" arterialization of vasa arose initially from plastic cast dissections and electron microscopy (EM).[14] However, more recent evidence is based on microanatomical computed tomography and microparticles that assessed both vasa anatomy and blood flow. Large arteries also contain lymph vessels, which can only be distinguished from the vasa through immunocharacterization. Most blood vessels with a cross-sectional thickness of more than 30 to 50 cells possess some form of mural vascularization, invariably more identifiable in adventitia than media. Generally, vasa are limited to the adventitia of vessels with media less than approximately 300 to 500 nm thickness or arteries with <28 lamellae.[15] Diffusion distance is thus a key determinant of vasa. In the adventitia, vasa form capillaries, while in media, they may also form short-distance connections or unique arteriovenous shunts that empty into an adjacent vein.[16] Importantly, vasa are end arteries, or arteries that supply the only perfusion to an anatomical site. As such, reduced flow or occlusion of vasa can result in hypoxia or ischemia of cells within the blood vessel wall.[17]

Physiology of the Vasa Vasorum

Vasa are required to meet the metabolic needs of thicker blood vessels. As such, vasa are governed by the same metabolic cues that regulate angiogenesis in other beds,[17] with vessel wall hypoxia representing a trigger for new vasa formation, increased vasa density,[18,19] and even increases in blood flow.[13] Consistent with this, large energy-consuming arteries are more vascularized in the media than compliant vessels of similar size such as veins.[13] Commensurate with lower vasa density, blood flow through the vasa of veins tends to be lower than in the vasa of arteries.[3,20] However, the more muscular the vein, the greater its metabolic demand and the greater its vasa density and blood flow.[13,21] Compression forces in larger arteries also influence flow, with perfusion through the vasa of carotid arteries occurring mostly after pulse velocity flow.[22] Finally, these vessels are also innervated and also respond to neuroendocrine factors that regulate tone.

Pathology of the Vasa Vasorum

While vasa vasorum appear to play a role in vascular disease, the extent to which their dysfunction is causal or correlative remains unknown. Restricted or occluded flow through the vasa can result in hypoxia or necrosis of the vessel wall.[23] Experiments in dogs have demonstrated that removal or occlusion of vasa caused medial necrosis, reduced vessel compliance,[23] and neointimal formation akin to restenosis.[24] Obstructions of the vasa can also occur as a result of thrombosis, hypertension, or interventions, such as bypass graft surgery or angioplasty, in which vasa may be cut or compressed. Since vasa possess arterial tone, regulated by autocrine and neuroendocrine responses, they are susceptible to constriction from pressor molecules (e.g., angiotensin II or endothelin I) that are typically elevated in hypertension.[16,25] Also, similar to the coronary circulation, vasa blood flow is reduced by compression forces from elevated systemic blood pressure during systolic contraction.[26] Chronic hypertension is associated with impaired vasodilator capacity[27] and can reduce vasa flow, which may partially underlie aortic remodeling in models of chronic hypertension.

Atherosclerotic lesions, particularly in humans, display significant vasa remodeling, with increasingly disorganized microvessel density in proportion to the extent of the lesion. This has broadly led to the hypothesis that vasa play a pathogenic role in atherosclerosis.[28,29] Specifically, thrombotic occlusion of vasa may create acute necrotic events that trigger monocyte invasion and further lipid infiltration.[30,31] Of considerable interest, the vasa of atherosclerotic lesions are anatomically distinct from normal vasa; their architecture resembles that of tumor vessels with increased tortuosity and instability.[32] As such, the

term *vasa plaquorum* has been proposed for vasa supplying atherosclerotic lesions. Vascular lesions in vasa-perfused vessels are not only a source of potent thrombotic and inflammatory stimuli, they also increase arterial wall thickness, and thus reduce oxygen tension in the plaque. Indeed, vasa plaquorum angiogenesis may be initiated by mitogenic stimulation and/or hypoxic demand. However, upon encountering the hostile microenvironment of the plaque itself, vasa plaquorum fail to develop normally; they can be leaky, with fragile endothelium lacking the pericytes (see below) necessary for development of proper tone.[33] Therefore, vasa plaquorum can be a source of intraplaque accumulation of albumin, fibrinogen, hemorrhage, and inflammatory cells. Counteracting these negatives, the vasa plaquorum may also support nutrient flow to the lesion, thereby preventing necrosis.[29] Depending on lesion composition, the vasa may also provide the circulatory basis for plaque regression and vessel remodeling.[34] As such, the role of vasa plaquorum is far from definite.

CORONARY ARTERIES

Anatomy of the Coronary Arteries

The coronary arteries emerge from the left and right aortic sinuses to provide the entire blood supply of the myocardium. The left main coronary artery branches to form the circumflex (Cx) and left anterior descending artery (LAD). The LAD traverses the left ventricle in the anterior interventricular groove, giving off septal perforators and typically two distal diagonal branches as it makes its way toward the apex. The Cx, which lies in the atrial-ventricular (AV) groove, also gives off two descending marginal branches. The right coronary artery (RCA) traverses the descending circumferential aspect of the right ventricle (RV). It branches toward the apex of the RV as the marginal artery, before continuing on to form a dedicated arterialization of the AV node, with the remaining vessel forming the posterior descending artery (PDA) that runs along the posterior interventricular groove toward the left ventricular apex. In approximately 15% of humans, the PDA is formed by a continuation of the Cx rather than the RCA, in which case the coronary circulation is termed "left dominant" (as opposed to the more common "right dominant"). All of the above epicardial arteries give off smaller penetrating branches that perfuse the myocardium from epicardium to endocardium.

The coronary circulation has many small connecting arterial processes termed *collaterals* and *anastomoses* that allow blood to flow between the main epicardial vessels, providing alternative routes of blood flow. The prevalence of collaterals and anastomoses in the coronary circulation undoubtedly reflects the importance of the heart as a vital organ, and the critical importance of redundant perfusion routes, particularly in the event of a coronary vessel occlusion. Having said this, the papillary muscles that tether the AV valves are often vulnerable to ischemic damage and dysfunction with the occlusion of specific coronary territories. The anterior papillary muscle of the left ventricle is perfused by the LAD, whereas the posterior papillary muscle is perfused by the PDA.[35] The atria are vascularized by branches of the AV and sinoatrial (SA) nodal arteries; the SA nodal artery arising most commonly from the RCA.[36–38]

The large coronary veins run in parallel with the coronary arteries (FIGURE 41.7) and connect with venules at right angles to collect deoxygenated blood. The veins ultimately coalesce and form the coronary sinus which traverses through the left AV groove posteriorly to empty into the right atrium. The Thebesian valve at the coronary sinus orifice prevents retrograde flow. Also within the coronary microvasculature, there exists a unique venous system known as *Thebesian veins* that drain blood directly into the cardiac chambers.[39]

Physiology of the Coronary Arteries

The coronary circulation is responsive to both physical (myogenic)[40] and neurohormonal regulation.[41,42,43] Coronary blood flow is a product of aortic pressure, coronary artery resistance, and extravascular compression. The heart produces large intraventricular pressures that compress penetrating myocardial coronary arteries, arresting and potentially reversing arterial flow during systole. By comparison, venous flow is greater during systole.

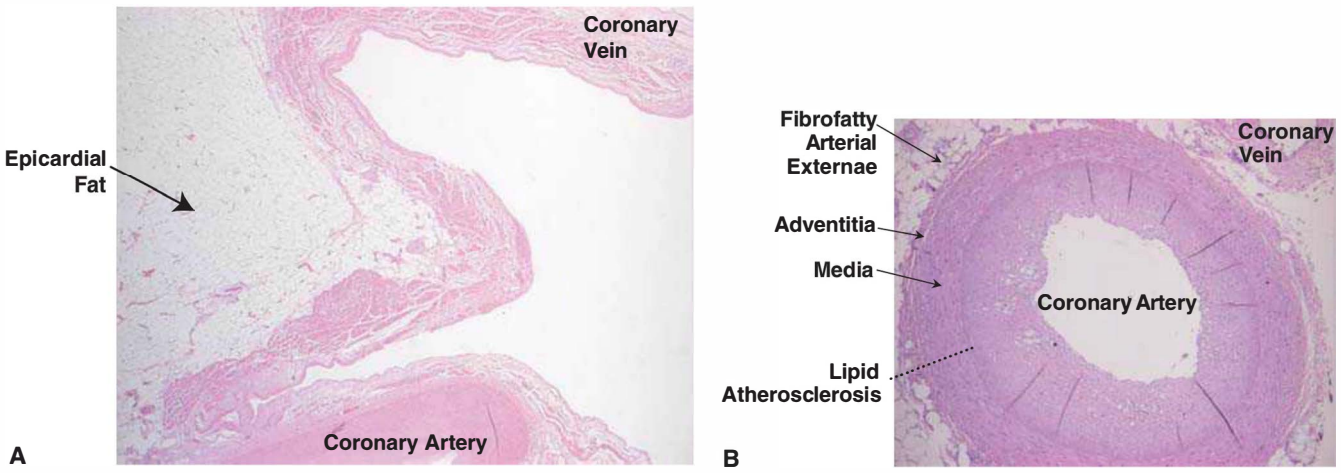

FIGURE 41.7 Coronary arteries from different surfaces of the heart. Images of human coronary arteries stained with H&E are shown from the epicardial (**top panel**, 2.5×) and endocardial (**bottom panel**, 5×) surfaces of the heart.

Heart rate is also a factor in determining coronary flow. At normal resting human heart rates, one-third of the cardiac cycle is systole while two-thirds is diastole, during which coronary flow and myocardial perfusion occurs. However, at elevated heart rates, the diastolic time interval shortens significantly with reduced opportunity for myocardial perfusion. Despite this, the release of metabolites in proportion to increased oxygen consumption can cause profound local coronary vasodilation and dramatically increase diastolic flow. Indeed, as long as the coronary flow reserve has not been compromised (see below), myocardial perfusion can be increased as much as fivefold in response to ventricular myocardial oxygen demand and 15-fold in the atria.[41]

Pathology of the Coronary Arteries

The coronary arteries are critical to cardiac performance. Coronary artery diseases such as atherosclerosis, thrombosis, and/or embolization result in myocardial infarction (MI), which can, in turn, lead to electrical complications such as arrhythmias or sudden death, and/or mechanical complications such as valvular regurgitation, congestive heart failure, or cardiogenic shock.

Coronary artery atherosclerosis is the leading cause of coronary flow impairment.[44] The development of coronary lesions and intraluminal narrowing of the arteries can present clinically as angina pain caused by myocardial ischemia, or infarction following complete vessel occlusion (FIGURE 41.7). The latter is typically an abrupt event caused by plaque rupture and acute occlusive thrombosis.

The location of a coronary occlusion is a major determinant of post-MI survival. More proximal artery occlusions cause larger infarcts and are thus more significant than distal artery occlusions that produce smaller amounts of myocardial damage. Similarly, the duration of coronary occlusion is a major determinant of clinical outcomes. A major revolution in acute coronary care has been the development of rapid pharmacological, interventional, and combined strategies for prompt restoration of coronary patency.

As a consequence of anatomical structure and corresponding increases in turbulent blood flow, the main epicardial coronary artery branch points have a higher propensity for atherosclerosis and plaque rupture.[45–49] While occlusions of arteries supplying the RV and papillary muscles are less common, even small infarcts in these areas can produce disproportionately large clinical effects. For example, both RV and papillary muscle infarcts can result in cardiogenic shock and dramatically diminished survival.

SMALL RESISTANCE ARTERIES

Anatomy and Histology of Small Resistance Arteries

Ranging from 30 to 300 μm diameters, small resistance arteries and arterioles are the end branches of the arterial circulation, lying immediately upstream of tissue capillary beds. Although smaller in diameter, the walls of resistance arteries are proportionately more muscular and less elastic than those of larger conduit vessels. As such, resistance arteries can be distinguished by the presence of several SMC layers in their media, comprising the bulk of their thick, muscular walls.

Physiology of Small Resistance Arteries

In contrast to the elastic, compliant walls of conduit arteries, resistance arteries have muscular walls better suited to their constrictor function. Unlike the large arteries from which they arise, the primary function of resistance arteries is to dynamically regulate tissue perfusion in response to the metabolic needs and physiologic functions of the organs they supply. For example, skeletal muscle resistance arteries dilate in response to the local ischemia caused by increased muscle work. By contrast, resistance arteries within the kidney and lung function to divert blood flow on the basis of glomerular filtration–tubular reabsorption needs and ventilation–perfusion matching, respectively. Overall vasomotor tone of resistance arteries (i.e., total peripheral resistance) is also an important determinant of systemic blood pressure, with blood volume and cardiac output representing the other key factors.[50]

In addition to responding to neurohormonal factors affecting vasoconstriction (e.g., angiotensin and catecholamines) and vasodilation (e.g., nitric oxide and kinins), resistance arteries also possess an inherent autoregulatory ability to respond to sustained increases in transmural pressure with vasoconstriction, a property known as the *myogenic response* (or Bayliss effect). This reversible response serves to establish baseline vascular tone and is believed to maintain consistent blood flow and capillary integrity in the face of varying systemic blood pressures.[51] The myogenic response is believed to be an intrinsic property of resistance artery SMCs, as dissected and cannulated resistance arteries demonstrate myogenic responsiveness *ex vivo*, *in situ*, and in the absence of circulating neurohormonal factors. Of particular interest, specific parameters of the myogenic response have been shown to vary as a function of age, gender, and blood pressure.[52]

Pathology of Small Resistance Arteries

Resistance arteries are susceptible to "arteriosclerosis," or thickening of the arterial wall resulting in decreased elasticity and luminal diameter. Arteriosclerosis has been associated with hypertension, but whether this association is cause or consequence remains uncertain. Indeed, despite high prevalence and decades of investigation, the etiology of hypertension remains a mystery. In approximately 90% of cases, hypertension is "essential," with no single underlying mechanism, and polygenic predisposition.[53–56] Having said this, hypertension can contribute to luminal narrowing (FIGURE 41.8) and predispose vessels to atherosclerosis and dissection.

In addition to age- and gender-related variations in the myogenic response mentioned above, several common clinical conditions have been associated with alterations in the myogenic responsiveness of resistance arteries. These include diabetes,[57] hypertension,[58,59] and heart failure.[60,61] Although the precise molecular mechanisms are not well characterized, studies have implicated the sphingosine-1-phosphate signaling pathway as a major regulator of resistance artery myogenic responsiveness.[62–64] Importantly, in specific animal models, disturbances in myogenic tone have been implicated in the pathophysiology of hypertension and heart failure.[61,65] If these findings translate to the clinic, they may represent novel therapeutic targets for these conditions.

The small resistance arteries can also be affected by a plethora of vasculitides, such as polyarteritis nodosa, microscopic

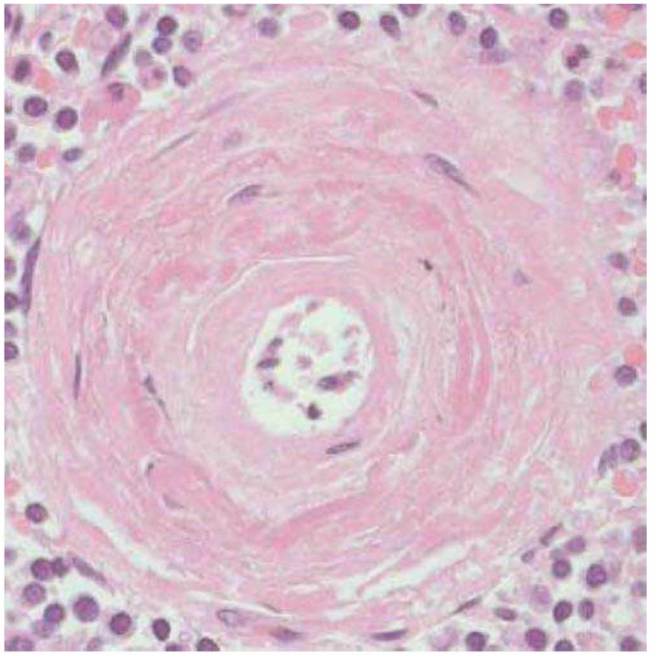

FIGURE 41.8 Smooth muscle hypertrophy in chronic hypertension. Cross section of a human resistance artery stained with H&E from the spleen from a 64-year-old male with chronic hypertension (40×). Hypertrophy is indicated by the few nuclei in the thickened muscle wall.

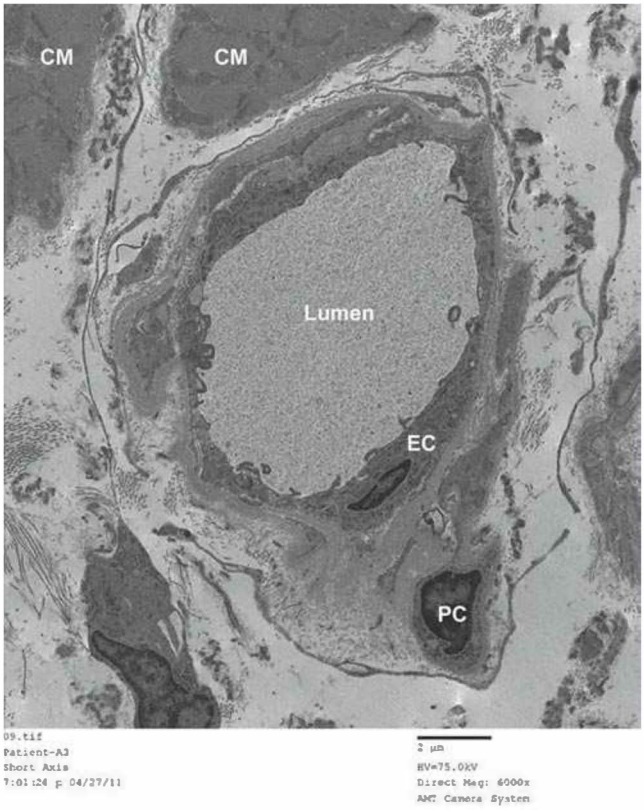

FIGURE 41.9 Cellular structure of the capillary wall. EM image of a pericyte (PC)/endothelial cell (EC) in the capillary wall from human atrial appendage tissue.

polyangiitis, and thromboangiitis obliterans (Chapter 100). Abnormal resistance artery contraction can also result in conditions such as Raynaud phenomenon, in which intensive resistance artery vasospasm leads to cyanosis of peripheral digits. Another example is cerebral vasospasm, in which cerebral resistance arteries profoundly constrict in response to cerebral hemorrhage. The mechanisms underlying these abnormal responses are not fully defined.

CAPILLARIES

Capillary Anatomy and Histology

Capillaries are composed of spirally aligned, circumferential monolayers of ECs that branch off from arterioles into tissue. At the arteriole–capillary junction lie precapillary sphincters, consisting of one or more ring-like SMCs, that can regulate the amount of blood entering the capillary bed.[66] A capillary is made up of at least one circumferential EC, with its two polar ends joined by an adherens junction. As such, the capillary wall can be as thin as 0.1 μm. Capillary beds are typically 3 to 9 μm in diameter, allowing for the serial transit of elastic, biconcave-shaped erythrocytes (diameter ~7 μm, thickness ~2 μm).

The capillary bed is a crisscross of anastomoses that span an average distance of 0.5 to 1 mm between arteriole and venule. The number of capillaries present in a particular tissue is proportional to its metabolic demand or unique function. For instance, heart muscle can have up to 40 times the capillary density per unit area than skin.

A single basal lamina surrounds the capillary, while pericytes, often identifiable by their proximity and larger nuclei as compared to ECs, provide structural, paracrine, and juxtacrine support to the endothelium (FIGURE 41.9). As discussed in detail below, the pericyte is a contractile cell unique to the microcirculation, with a shared EC/SMC profile.[67–69] Pericytes can be thought of as a proxy for vascular SMCs. However, pericytes do not form a continuous, single-celled tunic around capillaries as SMCs do in arterioles, as there are substantial capillary segments completely lacking pericytes. The pericyte is believed to be from the same developmental lineage(s) as vascular SMCs. That being said, it is now well established that vascular SMCs of the various segments of the circulation can have diverse developmental origins.[70,71] Whether pericytes demonstrate similar site-specific origins is unknown. Moreover, it has been shown that endothelial-to-mesenchymal differentiation into pericytes can also occur.[72,73] The transition from capillary to venule can be identified by two factors: the increase in relative diameter and the increase in pericyte number, as pericytes are also present in portions of the postcapillary venule wall.

Capillary Physiology

Capillaries can be thought of as the business end of the microcirculation. They are the principal site of gas, fluid, and metabolite exchange between blood and tissue. Capillary density, flow rate, surface area, and permeability are key factors influencing gas and nutrient exchange. As such, these factors are collectively greater in highly active tissues.[41] Molecular exchange is facilitated by the relative volume-to-surface area ratio in the

capillaries. Accordingly, the capillaries possess the highest cross-sectional area of the vascular system. Exchange occurs principally through simple diffusion (Brownian), as well as advection (Gaussian), and transcytosis.[74,75] Advection describes the process of nonrandom particle exchange, typical of size/charge selective channels or membrane transporters, such as the water transporters aquaporins.[76] Transcytosis is a process common to endothelial barriers that promotes transcellular transport of macromolecules through the intracellular space.[76]

Capillary structure varies between tissues and organs. The endothelium may form a thin continuous layer, as occurs in the lung, benefiting the principal goal of gas exchange. Alternatively, the endothelium may be permeated by small holes, or fenestrae. Fenestrated endothelium is characteristic of vascular beds involved in a high degree of secretion or filtration, including the kidney glomerulus. A third phenotype, the so-called discontinuous endothelium, contains intracellular gaps and is associated with an incomplete basal lamina. Discontinuous endothelium is observed in the sinusoids of the liver, spleen, and bone marrow. The interendothelial cleft functions as a molecular sieve and is the principle pathway for fluid and electrolyte exchange. Compared with other capillary beds, brain ECs have particularly tight junctions, which serve to limit diffusion of substances (particularly hydrophilic macromolecules) between blood and underlying neural tissue, and is supported by both astrocytes and pericytes as part of the blood–brain barrier.[77]

While energy-dependent exchange is important (e.g., transcytosis or ATP-dependent exchangers), the majority of exchange of fluids and small molecules in the capillary bed occurs by passive transport. Passive transport is driven by osmotic, hydrostatic (fluid pressure), and oncotic (proteinaceous and organic constituents) pressures (together comprising the Starling forces), which significantly affect the permeability of the capillary. Starting from the arteriole, relative hydrostatic pressure is higher in the capillary than the osmotic pressure, allowing net fluid transport to the tissue. In the greater capillary bed, pressures and fluid exchanges equalize, allowing the simple exchange of metabolites and gas by diffusion across relative concentration (e.g., glucose, urea) or partial pressure gradients (e.g., oxygen and carbon dioxide). When blood enters the capillary–venule bed, hydrostatic pressure is low in comparison to osmotic pressure, allowing interstitial fluid and metabolites to be drawn up by venous blood. Blood flow in the venous circulation is regulated by different constituents, such as the skeletal muscle, respiratory pumps, resting venous tone, and venous valves (see section on *Physiology of the Veins*). This simplification of microvasculature exchange is important to note as three-dimensional geometry, porosity, matrix composition, and molecular constituents in the abluminal and adluminal sides of the EC membrane can vary substantially in specialized structures such as the blood–brain barrier, kidney glomerulus, liver sinusoids, placenta, muscle, and skin.[76,77,78,79]

In addition to their principal function in metabolic exchange, capillaries can also influence systemic vascular tone through pericyte-dependent regulation of capillary constriction.[68,80] However, our current knowledge of pericyte biology is limited, especially with regard to the intimate structural and functional relationship between pericytes and capillary endothelium. Pericytes are of mesenchymal origin and are more similar to SMCs than ECs. However, they possess molecular markers of both cell types (e.g., vascular cell-adhesion molecule-1, intercellular adhesion molecule-1, inward rectifier potassium channels K_{ir}, platelet-derived growth factor receptor-beta), in addition to their own distinct markers, such as combinations of chondroitin sulfate proteoglycan 4 (NG2), regulator of G-protein signaling 5, vimentin, and/or alpha-smooth muscle actin.[69] In addition to maintaining microvascular tone, pericytes confer endothelial cytoprotection, basement membrane maturation, barrier function, and capillary stability.[81–83] This occurs through direct physical contact with ECs or shared matrix contact via integrin, Notch, and ephrin molecules.[84–87] Pericytes may also contribute to capillary angiogenesis and angiostasis through the secretion of growth factors and proteases,[88,89] as well as inflammation-associated alterations of vascular permeability.[90,91] Moreover, pericytes have also been shown to be involved in ischemia and stress responses. As part of the initial response to acute trauma, pericytes in damaged tissue can respond instantly by constricting capillary blood flow, which is beneficial for hemostasis. However, with ischemic injury, prolonged pericyte constriction can lead to further tissue ischemia.[92,93] For example, middle cerebral artery ischemic reperfusion injury can lead to microvascular constriction such that red blood cells are trapped against the capillary walls, essentially reducing blood flow to zero (so-called *no-reflow phenomenon*).[94]

Capillary Pathology

Physiologic properties of the microvasculature can be altered dramatically with negative impacts on healing, inflammation, and hypoxia. The most common microvascular complications impacting heavily on our society are related to age, diabetes, and inflammation. For instance, age-dependent macular degeneration (AMD) can present as a severe form of microvessel angiogenesis of the choriocapillaris behind the retina. This aberrant growth of capillaries is of unknown etiology but has been correlated with genetic defects, cholesterol levels, and inflammation.[95,96] AMD is the principal cause of blindness in persons over 60 years of age. Diabetic retinopathy is a consequence of glycation stress that primarily affects pericytes, causing apoptosis and breakdown of the capillary barrier function in the retina.[97] This can result in subsequent macular edema and blurred vision. Over time, increased extravascular pressure creates local hypoxia, which stimulates unstable angiogenesis (lacking pericytes).[98–100] The weak microvasculature structure can leak, causing retinal disruption or neovascular glaucoma. Inflammation or autoimmune disruption of microvascular integrity can produce acute and/or life-threatening conditions. For example, Goodpasture syndrome is a form of vasculitis involving autoimmune targeting of the basement membrane, which leads to lung and kidney failure, as these organs have the highest capillary surface area–dependent functions.

VEINS

Anatomy of the Veins

Veins are principally capacitance vessels. Those on the body surface are referred to as superficial veins, as distinct from deep veins that lie in deep-tissue planes and run parallel to arteries of comparable size. Although the venous wall is trilayered, the layers are not as distinguishable as they are in arteries. The venous wall contains a greater accumulation of loose connective tissue, collagen, and elastin fibrils between muscle layers, but less high-tensile

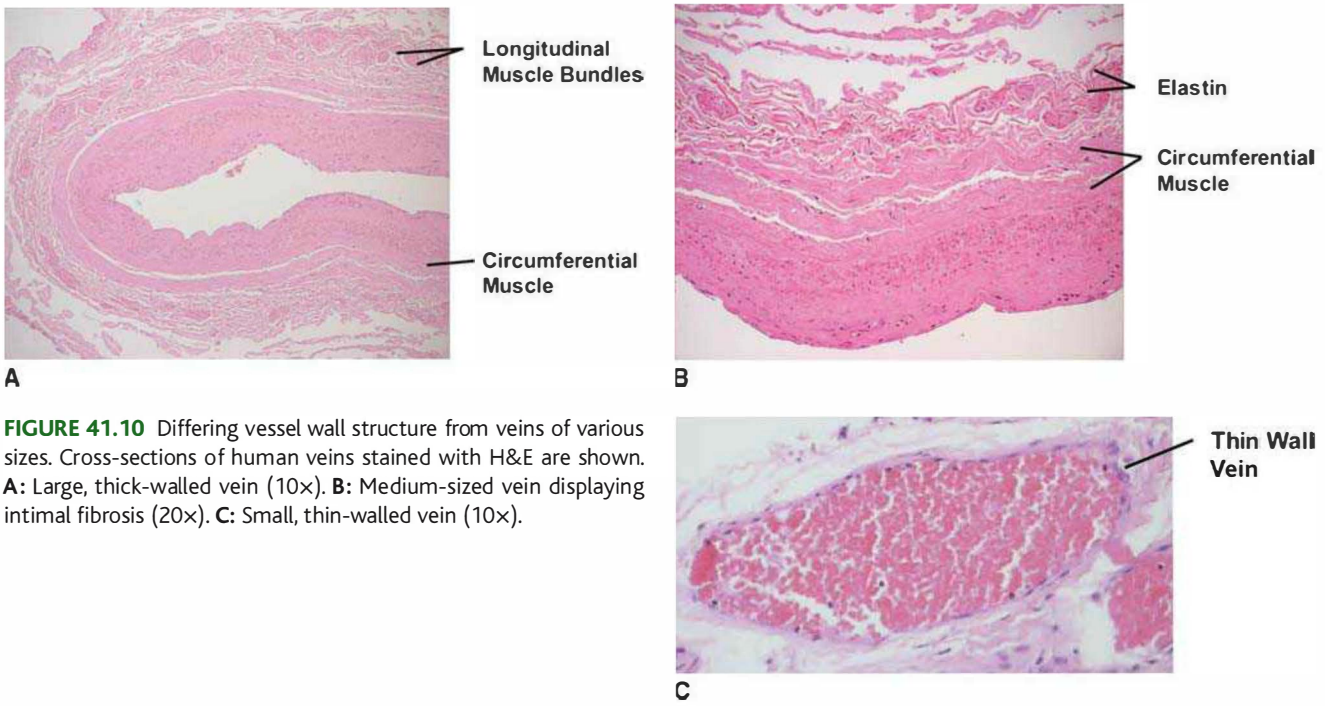

FIGURE 41.10 Differing vessel wall structure from veins of various sizes. Cross-sections of human veins stained with H&E are shown. **A:** Large, thick-walled vein (10×). **B:** Medium-sized vein displaying intimal fibrosis (20×). **C:** Small, thin-walled vein (10×).

elastic laminae, and a decreased smooth muscle-to-fibrocyte ratio (FIGURE 41.10). The head-to-tail circular SMC alignment of arteries is also not as apparent in veins; instead venous SMCs are bundled together around dense extracellular matrix. Larger veins, including the vena cava and saphenous vein, also display some longitudinal alignment of myocyte bundles.

The most important feature of venous anatomy is the presence of intimal folds that act as one-way venous valves. They are typically composed of two flexible, sail-like (bivariate) projections that originate perpendicularly from the inner wall, protrude in parallel with the lumen, and point in the direction of blood flow. Venous valves are covered on both sides by endothelium, accompanied by a base of matrix fibers connected to the venous wall. Larger vein valves may also have fibroblasts, myofibroblasts, or SMCs (near the origin) that function to produce matrix and maintain strength. The latter functions may be impaired with age or a variety of conditions, particularly those associated with elevated venous pressures (right-sided heart failure), venous compression (obesity, pregnancy), or thrombosis.

There is anatomic variability in human deep-vein valves. The femoral veins may have one to six valves, whereas the popliteal only 0 to 4.[101] Though Canadian pathologist Nicholas Popoff first wrote in 1934 that Even very small peripheral digital veins show the presence of valves,[102] there remains a common misconception that valves are absent from smaller veins.[103] In fact, distinct microscopic venous valves are present in veins as small as 20 μm, where they are believed to provide similar function as valves in larger vein or collecting lymphatics. Of interest, large and small veins valves are not universally distributed, but rather occur in areas where pressure, irregular flow, or gravitational backflow is more likely.[103] Venous valve structure is similarly inconsistent. Fenestrated, univariate, or trivariate valves in the coronary veins[104] are a consequence of pressures developed by the heart, whereas no valves, and indeed little or no musculature, exist in the cerebral veins.[105]

Physiology of the Veins

Veins are far more compliant than conduit and resistance arteries. Vein structure is uniquely adapted to low pressure and provides a high capacity for distension. This is a factor that allows veins to serve as the predominant fluid compartment of the circulation. As such, veins act as a reservoir for blood; at any given time, more than 65% of the body's total blood can be found in the venous circulation.[106,107] However, in response to increased cardiac demand, veins are able to contract and actively increase venous blood return, particularly under neuroregulatory control. Moreover, situations requiring increased cardiac output, such as strenuous physical activity, can also increase venous return through mechanical compression of veins. For instance, skeletal muscle contraction "squeezes" the venous circulation (skeletal muscle pump). In combination with venous valves, this action pushes blood toward the heart (see below). Heavy breathing, also a product of exertion, promotes venous return through the respiratory pump. The lowering of intrathoracic pressure reduces the left atria pressure, allowing for greater venous return. Posture and gravity are also factors in venous return. Indeed, cardiac output is regulated by volume and pressure adjustments in the venous circulation by both passive and active physical and neuroendocrine cues.

With regard to venous valves, any reversal of blood flow closes the valves, preventing retrograde blood flow. In this way, venous pressure moves blood toward the heart, even against gravity.

Pathology of the Veins

The venous pathology that most significantly affects quality of life is *deep-vein thrombosis* and subsequent pulmonary

embolism. Predisposing factors include prolonged immobilization, postoperative state, pregnancy, local infection, heart failure, and neoplasia. Prolonged standing can raise hydrostatic pressure over oncotic pressure, gradually increasing interstitial volume in the lower extremities. If this persists for a prolonged period of time, such as in obesity or pregnancy, it can be accompanied by elastin breakdown, and incompetency of the venous valves and ultimately the veins themselves. Arteriovenous fistulas can also contribute to increases in venous pressure in some cases. Vein dilatation by high intraluminal pressure and blood stasis can result in complete venous valve failure, producing *varicose veins*. This condition usually appears on the lower extremities as abnormally dilated and tortuous vein architecture. In addition to trophic skin changes, varicose veins coincide with persistent edema, dermatitis, and can lead to ulceration.

CONCLUSION

As outlined in this chapter, the cellular and matrix components of the blood vessel wall come together to deliver the specialized forms and functions of every compartment of the human circulatory system, from conduit arteries to capillaries and capacitance veins. Together, this highly evolved system enables cardiovascular competence, including the homeostasis of every other organ. From traditional hemodynamics, perfusion physiology, and advanced imaging techniques including EM and *in vivo* imaging, we will continue to gain insights into the pathophysiology of the human vasculature. Future investigations on the molecular mechanisms of the myogenic response, the pathobiology of the vasa plaquorum, and the role of microscopic venous valves may yield particularly new insights into vascular biology.

CHAPTER

42 Endothelial Cell Function

WILLIAM C. AIRD

The endothelium is an expansive organ, reaching all recesses of the human body. At one time, it was believed that endothelial cells (ECs) were relatively inert, acting as a physical barrier between blood and underlying tissue. It is now well established that ECs are highly metabolically active, and play a critical role in many physiologic processes, including the control of vasomotor tone, the trafficking of leukocytes between blood and underlying tissue, the maintenance of blood fluidity, permeability, angiogenesis, and both innate and adaptive immunity. EC phenotypes display remarkable heterogeneity in structure and function, in space and time, and in health and disease (reviewed in[1–3]). The goals of this chapter are to review the scope and nature of endothelial phenotypes and to apply these principles to an understanding of the endothelium in hemostasis and thrombosis.

ENDOTHELIAL CELL PHENOTYPES

Defining the Endothelium

An interesting question is how do we define the endothelium? Anatomically, the endothelium is the cell layer that lines the inner wall of blood and lymphatic vessels. However, there are examples of vascular mimicry in which other cell types (e.g., trophoblasts) form the inner lining of blood vessels. ECs tend to be extremely flat or thin. In that way, the diffusional path length for gases and solutes across the capillary wall is minimized. However, there are exceptions, including the plump, cuboidal ECs of high endothelial venules (HEV) (reviewed in Ref.[4]). Weibel-Palade bodies, which contain von Willebrand factor (vWF) and P-selectin, are specific to the endothelium, but there is no evidence that these storage granules are present in all ECs. Other ultrastructural features that are characteristic of ECs, such as caveolae, are also observed in other cell types. During development, endothelium arises from mesoderm *via* the differentiation of hemangioblasts and/or angioblasts. However, other cell lineages may transdifferentiate into ECs, and ECs into other lineages. From a molecular perspective, few, if any, genes are both specifically and uniformly expressed in the endothelium. For example vWF is also expressed in megakaryocytes and its expression in the endothelium is patchy. CD31 (also termed platelet–endothelial cell adhesion molecule 1) is also expressed in monocyte/macrophages, and vascular endothelial (VE)-cadherin in trophoblasts and fetal stem cells. Functionally, the endothelium displays a remarkable division of labor, whereby cells from different segments of the vasculature carry out unique activities. Finally, when endothelial-specific promoters are targeted to the mouse genome, they invariably fail to direct expression throughout the endothelium. Rather, they promote expression in specific subsets of ECs (reviewed in[5]). In summary, each of the above definitions—anatomical, structural, functional, and molecular—falls short of fully capturing the endothelium. The "elusiveness" of the endothelium undoubtedly reflects its marked heterogeneity in structure and function. Indeed, far from being a giant monopoly of identical cells, the endothelium is a consortium of smaller enterprises, each uniquely adapted to the needs of the local tissue. In the final analysis, a full understanding of this cell type in health and disease requires a consideration of both the spatial and temporal dynamics of the system.

Scope of Heterogeneity

EC heterogeneity has been described at the level of cell morphology, function, gene expression, and antigen composition. EC phenotypes vary between different organs, between different segments of the vascular loop within the same organ, and between neighboring ECs of the same organ and blood vessel type. *In vivo* proteomic approaches have revealed a striking array of vascular bed-specific phenotypes (reviewed in[6,7]). For example, antibody and subfractionation strategies have been employed to generate monoclonal antibodies that specifically target the caveolae in one vascular bed or another.[8] Others have used phage display peptide libraries to select for peptides that home to specific vascular beds *in vivo*.[9,10] These latter studies have uncovered a vascular address system that allows for site-specific targeting of biologically active compounds, for example, to the endothelial lining of tumor blood vessels.[11]

Structural Heterogeneity

ECs that line straight segments of arteries, but not those lining veins, are oriented along the longitudinal axis of blood flow. Previous studies have demonstrated that flow-dependent alignment of ECs represents reversible endothelial structural remodeling in response to hemodynamic shear stress.[12,13] The transfer of material across the endothelium, a process termed *transcytosis*, is mediated by caveolae and vesiculo–vacuolar organelles (VVOs). Caveolae are 70-nm membrane-bound, flask-shaped vesicles that open to the luminal or abluminal side of the cell. The density of caveolae in capillary endothelium (up to 10,000 per cell) greatly exceeds that in the arteries, arterioles, veins, or venules (reviewed in Refs.[2,14]). An exception is the blood–brain barrier, where the number of caveolae is greatly reduced.[15] VVOs comprise focal collections of membrane-bound vesicles and vacuoles. They are most prominent in venular endothelium.[16] In contrast, clathrin-coated pits, which are involved in endocytosis, are particularly prominent in liver sinusoidal endothelium.

The endothelium of arteries and veins forms a continuous uninterrupted layer of cells, held together by zipper-like tight junctions. The endothelium of capillaries may be continuous, fenestrated, or discontinuous, according to the needs of the underlying tissue. For example, fenestrated endothelium is characteristic of organs involved in filtration or secretion, including exocrine and endocrine glands, gastric and intestinal mucosa, choroid plexus, glomeruli, and a subpopulation of renal tubules. Discontinuous endothelium is similar to fenestrated endothelium, with the exception that the fenestrations are larger in diameter (they may manifest as gaps in the cell) and they lack a diaphragm. Moreover, the underlying basement membrane is poorly formed. Discontinuous endothelium is found in certain sinusoidal vascular beds, including the liver.

Functional Heterogeneity

The endothelium has many functions. In almost every case, the activity is carried out by distinct subsets of ECs within the vascular tree. Below, we discuss three examples of functional heterogeneity: permeability, leukocyte trafficking, and angiogenesis. We review vascular bed-specific hemostasis and thrombosis separately in a subsequent section.

Permeability

Basal and inducible permeability is differentially regulated across the vascular tree. Constitutive flow of material between blood and underlying tissue takes place primarily at the level of capillaries. Transport of fluids and small solutes occurs in between cells (the so-called *paracellular route*), whereas macromolecules are transferred through the cell (the *transcellular route*) *via* caveolae, VVOs, and transendothelial channels. Basal permeability is lower in nonfenestrated vascular beds that are enriched in tight junctions and possess fewer caveolae (e.g., the blood–brain barrier). As evidence for the role of tight junctions in mediating barrier function, mice that null for the tight junction molecule, claudin-5, have a selective barrier defect in the brain.[17] Inducible permeability refers to changes in barrier function that occur in acute or chronic inflammation. These changes take place primarily in postcapillary venules. The extent to which regulated leakiness is mediated by paracellular or transcellular pathways is debated. The predilection for postcapillary venules as a site for inducible permeability may be explained by the relative abundance of VVOs, the relatively low number of tight junctions, and/or high expression levels of agonist-responsive receptors (reviewed in Ref.[2]). Severe inflammation may result in increased permeability in sites other than postcapillary venules, including large veins, arterioles, and capillaries.

Leukocyte Trafficking

The endothelium plays a key role in regulating the trafficking of leukocytes between blood and underlying tissue (hence the metaphor of the endothelium as gatekeeper). Leukocyte trafficking involves a multistep cascade that begins with rolling, followed by firm adhesion and transmigration (reviewed in Ref.[2,18,19,20]). As with transfer of fluids and solutes, transmigration may occur between ECs (the paracellular pathway) or through ECs (the transcellular pathway). Each step in the cascade is mediated by the upregulation of cell adhesion molecules on the surface of the endothelium as well as the expression of chemokines. Binding of endothelial E-selectin and P-selectin to leukocyte carbohydrate-based ligands promotes rolling of leukocytes on the endothelium, whereas binding of endothelial cell adhesion molecules, including vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 to leukocyte integrins mediates firm adhesion. The mechanisms of transmigration are poorly understood, but involve CD31 and junctional adhesion molecule-1. Similar to inducible permeability, transfer of white blood cells occurs primarily in postcapillary venules. One mechanism underlying this site-specificity is the preferential expression of E-selectin, P-selectin, VCAM-1, and ICAM-1 in the endothelium of postcapillary venules. Under certain conditions, leukocyte trafficking may occur in other segments of the vascular tree, including large veins, arterioles, and capillaries. For example, previous studies suggest that leukocyte sequestration and transmigration in the pulmonary circulation occurs primarily in alveolar capillaries by a rolling- and E-/P-selectin–independent mechanism that involves trapping of poorly deformed activated leukocytes on activated endothelium.[21,22] Similarly, in liver inflammation, the majority of leukocyte adhesion occurs in the sinusoidal endothelium.[23] Another form of leukocyte trafficking is the transmigration of lymphocytes across the specialized postcapillary venules, termed HEV, which are located in secondary lymphoid organs (reviewed in Ref.[24]). Trafficking at these sites occurs constitutively, and is mediated by interactions between lymphocyte L-selectin and its ligand (peripheral node addressin) on HEV ECs. In summary, the "universal cascade" for leukocyte trafficking is, in fact, mediated by spatially and temporally diverse mechanisms.

Angiogenesis

Recent studies have emphasized the existence of structural and functional heterogeneity of ECs during angiogenesis. For example, endothelial sprouts comprise leading-edge tip cells followed by morphologically and functionally distinct stalk cells. The tip cells are enriched in filopodia and in response to guidance cues, they promote the extension of new sprouts and fusion with adjacent sprouting capillaries to form new vascular connections (reviewed in Ref.[25]). This process involves the coordinated activity of Notch and Wnt signaling.

Molecular Heterogeneity

Spatial and temporal differences in the structure and function of ECs ultimately reflect differences in mRNA and protein expression. Endothelial genes may be classified according to whether they are constitutively or inducibly expressed, whether they are specific or not to ECs, and whether they are expressed throughout the endothelium or in subsets of ECs (reviewed in[5]). There are remarkably few endothelial-specific genes that are constitutively expressed throughout the vascular tree. VE-cadherin and Robo4 are two such genes. There are many more examples of endothelial-restricted genes whose constitutive and/or inducible expression is limited to subsets of ECs. For example, several endothelial markers are expressed specifically on the venous versus arterial side of the circulation (reviewed in Ref.[26]). ECs from different arteries, and even from different sites of the same artery, express overlapping but distinct molecular profiles. An example of an inducible, endothelial-restricted gene is E-selectin, which is expressed in activated, but not "resting"

endothelium. In activated endothelium, E-selectin expression is largely confined to postcapillary venules.

Mechanisms of Endothelial Heterogeneity

EC heterogeneity is mediated by one of two proximate mechanisms.[27] First, some site- and time-dependent differences in endothelial properties are governed by differences in the extracellular milieu. Because blood vessels are distributed throughout the body, their endothelial lining is exposed to an enormous variety of tissue microenvironments. In so far as ECs are capable of sensing and responding to their environment, the wide range of signal inputs from one organ to the next is sufficient to generate phenotypic heterogeneity across the vascular tree. When ECs are removed from their native tissue and grown in tissue culture, they become uncoupled from critical extracellular cues and undergo phenotypic drift. For this reason, studies of cultured ECs are fraught with limitations. Second, certain site-specific properties are epigenetically "fixed" and impervious to changes in the extracellular environment. Such properties are mitotically stable, and are thus retained under *in vitro* culture conditions. The relative roles of epigenetic and nonepigenetic forces in mediating phenotypic heterogeneity are not fully understood. A previous DNA microarray study of multiple human EC types grown in culture revealed site-specific signatures even in multiply passaged cells, providing genome-wide evidence for the importance of epigenetics in mediating differential gene expression.[28] A study of ECs from human tonsils revealed that approximately 50% of the vascular bed-specific genes were "washed out" when cultured *in vitro*, implicating a role for *both* the tissue environment and epigenetics in mediating differential gene expression.[29] This conclusion was supported by a DNA microarray study in which the transcriptome of ECs was compared between porcine coronary and iliac arteries. The data revealed that most, but not all, differences observed *in vivo* were lost in multiply passaged cells.[30]

In addition to proximate mechanisms, every biologic trait requires an evolutionary explanation. Proximate explanations (how?) employ traditional approaches of cell biology and molecular biology to determine the anatomy, physiology, and ontogeny (developmental history) of a trait at the level of a single organism. By contrast, evolutionary explanations (why?) draw on the fossil record and comparative morphology and DNA sequences to uncover the phylogeny (evolutionary history) of a trait as well as the fitness advantage that the trait provides at the level of a population or species. Comparative studies have revealed that the endothelium is present in all vertebrate species, but absent in invertebrates. Thus, the endothelium evolved in a common ancestor of the vertebrates following the divergence of the urochordates and cephalochordates some 500-600 million years ago over a period of only 50-100 million years. This same short period witnessed the evolution of a closed circulation, the clotting cascade (see Chapter 2), and acquired immunity.

An interesting question is whether EC heterogeneity, as a trait, appeared early on during evolution of the endothelium or whether it appeared later during vertebrate evolution. One way to address this question is to study hagfish, the oldest extant vertebrate. Any feature that is shared by hagfish and humans may be inferred to have evolved in the ancestral vertebrate. Unlike other vertebrates, hagfish are completely devoid of bone and cartilage. However, similar to the jawed vertebrates, hagfish have a closed circulation lined by endothelium. Importantly, our studies revealed that hagfish endothelium is remarkably heterogeneous at the level of ultrastructure, lectin binding, and function.[31,32] We may conclude from these observations that phenotypic heterogeneity evolved as an early feature of the endothelium. In other words, endothelial heterogeneity is not simply a descriptor of many distinct properties of the endothelium, but rather is itself a core property of the endothelium.

Evolutionary approaches also seek to explain the fitness advantage that a trait confers at a population level. This is a difficult question to definitively answer, but there are two important considerations. One is that the endothelium in traversing the body must provide a broad menu of functions that are adapted to the diverse needs of the underlying tissues. Site-specific differences in function will, in turn, be reflected by structural and molecular heterogeneity. Second, ECs must adapt to different environments simply to survive. For example, ECs in the vasa recta of the inner medulla of the kidney are exposed to profoundly low levels of oxygen, in addition to a hyperosmolar hyperkalemic environment. Although the precise properties of these cells are unknown, it is certain that they are uniquely adapted to this "harsh" environment in ways that render them phenotypically distinct from other types of ECs.

ENDOTHELIAL CELL ACTIVATION AND DYSFUNCTION

The two most common terms used to describe the endothelium in disease are *activation* and *dysfunction*. The term *endothelial cell activation* was introduced in the 1980s when it was observed that numerous inflammatory mediators, including endotoxin, tumor necrosis factor, and interleukin (IL)-1, induced the expression of new antigens (so-called activation antigens) on the surface of cultured ECs, and was correlated with the expression of proadhesive, antigen-presenting, and procoagulant activities (reviewed in[33]). Today, the term *activation* is used more broadly to describe the response of ECs to an inflammatory stimulus *in vitro* or *in vivo* (some investigators in the angiogenesis field employ the term to describe proliferating ECs). The activation phenotype varies according to the nature of the activation agonist, the net signal input, and the vascular bed of origin. Typically, it consists of some combination of a proadhesive and procoagulant surface, increased permeability, and the release of inflammatory mediators. *Activation* should not be confused with *activity*. The normal endothelium is highly active, constantly sensing and responding to cues in its extracellular environment. EC activation describes a phenotype. It does not refer to the cost of that phenotype to the host. In other words, EC activation may be adaptive or nonadaptive.

In contrast, EC dysfunction is by definition maladaptive. The term *dysfunction* was initially applied to the phenotype of the endothelium overlying atherosclerotic lesions in animal models of hyperlipidemia. Today, the term is almost always used to describe abnormalities in endothelium-dependent vasomotor tone in atheromatous conduit arteries. However, because the endothelium is widely distributed, and because it is involved in so many different functions (over and above the control of blood vessel diameter), the term *dysfunction* should be used more broadly to describe situations in which the endothelial

phenotype—whether or not it meets some predetermined definition of activation—represents a net liability to the host.

Assigning liability scores is of course a subjective exercise. An evolutionary biologist might argue that EC dysfunction is most relevant in its effect on an individual's reproductive capacity. A physician would surely expand the meaning of dysfunction to include a far broader spectrum of morbidity. An investigator interested in applying evolutionary principles to an understanding of endothelium in health and disease would point out that the endothelium evolved to a state of maximal fitness in the early ancestral environment, and is not adapted to withstand the rigors of high fat diet, epidemics associated with high density populations, sedentary lifestyle, or old age.

DIAGNOSIS AND THERAPY

The endothelium has remarkable, yet largely untapped diagnostic potential. At the bedside, the endothelium is difficult to assay. It is hidden from view and cannot be inspected, palpated, percussed, or auscultated. Moreover, the endothelium is poorly circumscribed and therefore is not amenable to conventional radiologic imaging. The most commonly used assays for the endothelium are flow studies, which measure endothelium-dependent vasodilation (reviewed in Ref.[34]). Abnormalities in endothelium-dependent flow have been correlated with atherosclerosis and risk for acute coronary syndrome. However, these studies are highly operator dependent, and they measure only a single function of the endothelium. An important goal in vascular biomedicine is to develop novel methods for diagnosing endothelial dysfunction. Such a diagnostic platform may ultimately include some combination of soluble mediators, cell-based assays, and molecular imaging. Dysfunctional ECs release a number of soluble mediators into the blood, including endothelin-1, vWF, tissue-type plasminogen activator (t-PA), soluble thrombomodulin, soluble VCAM-1, soluble ICAM-1, and soluble E-selectin. Cell-based assays include quantification and/or phenotyping of circulating ECs, endothelium-derived microparticles, and late outgrowth endothelial progenitor cells. Finally, molecular imaging holds promise. As an example, phage display has been used to identify a novel VCAM-1–specific cell-internalizing peptide that allows sensitive magnetic resonance imaging of atherosclerotic lesions in mice.[35] It appears likely that clinical events occur minutes, hours, days, or even weeks after initiation of processes that are occurring at the endothelial level. Developing test strategies to identify these processes before their phenotypic expression has great potential.

The endothelium is a highly attractive therapeutic target. It is rapidly and preferentially exposed to systemically delivered agents. Given the capacity of ECs to sense and respond to the local environment, it is hard to imagine that there exists any treatment for any disease that does not affect EC phenotypes in one way or another. From a therapeutic standpoint, the combination of phenotypic heterogeneity and modulability offers both opportunities and challenges. On one hand, the identification and characterization of vascular bed-specific "zip codes" should provide a foundation for site-specific targeting. On the other hand, drugs that lack such specificity are likely to exert mixed effects on the vasculature—with protective effects in some vascular beds and neutral or deleterious consequences in others. This idea is supported by the many knockout models that demonstrate vascular bed–specific phenotypes (reviewed in Ref.[36]). In so far as treatment against one or another target creates a functional knock out of that target, the effects on the vasculature will be similarly heterogeneous. For example, a treatment aimed toward neutralizing P-selectin might reduce leukocyte trafficking in the gastrointestinal tract, but not the liver. A drug that is designed to promote refenestration in liver disease might also induce de novo fenestrations (hence permeability) in vascular beds such as blood–brain barrier, with potentially disastrous consequences.

ENDOTHELIUM IN HEMOSTASIS

An Integrated Model of Hemostasis

Vascular thrombotic disorders are the leading causes of mortality in the Western world. It is noteworthy that most, if not all of these disorders, although consisting of a systemic balance in hemostasis, are associated with local thrombotic phenotypes.[36,37,38] These clinical observations are supported by genetic mouse models, in which the deletion of one or another natural anticoagulant mechanism results in vascular bed-specific fibrin deposition and thrombosis. An important question that arises from these clinical and animal studies is how a systemic imbalance in hemostasis is ultimately manifested by local rather than diffuse vasculopathic lesions. The answer lies, at least in part, in the endothelium.

The endothelium plays a critical role in mediating hemostasis. ECs synthesize many procoagulant and anticoagulant molecules. On the anticoagulant side, they express tissue factor pathway inhibitor (TFPI), heparan, thrombomodulin, endothelial protein C receptor (EPCR), and t-PA. On the procoagulant side, ECs synthesize plasminogen activator inhibitor-1, vWF, protease-activated receptors, and (at least in cell culture) tissue factor (TF). Each of these mediators is differentially expressed across the vascular tree. For example, TFPI is expressed predominantly in capillary endothelium, EPCR in large veins and arteries, endothelial nitric oxide (NO) synthase on the arterial side of the circulation, vWF in veins, t-PA in pulmonary and cerebral arteries, and thrombomodulin in blood vessel types of every caliber in all organs except the brain.[39–41] TF is not detectable in normal endothelium, whereas in a baboon model of sepsis, the gene is upregulated in a subset of ECs in the marginal zone of splenic follicles, and in regions of disturbed flow.[42,43] In response to systemic inflammation, the expression of these various procoagulants and anticoagulants changes in ways that differ between vascular beds. Thus, the picture that emerges is one of heterogeneity layered upon heterogeneity, such that ECs from different sites of the vascular tree employ site-specific "formulas" of hemostatic proteins to maintain blood in its fluid state and to promote limited clot formation when there is a breech in the integrity of the vascular wall (FIGURE 42.1).

The site specificity of endothelial hemostatic function provides a foundation for understanding how systemic imbalances in coagulation are channeled into local thrombotic phenotypes. The liver synthesizes and releases into the circulation a relatively constant amount of precursor serine proteases (zymogens) of the clotting cascade, the structural molecule fibrinogen and certain natural anticoagulant molecules including antithrombin III (ATIII), protein C, and protein S. The bone marrow produces and releases into the circulation a relatively fixed number of monocytes and platelets, cells that are capable of expressing TF and/or promoting clotting reactions. This net output of liver-derived

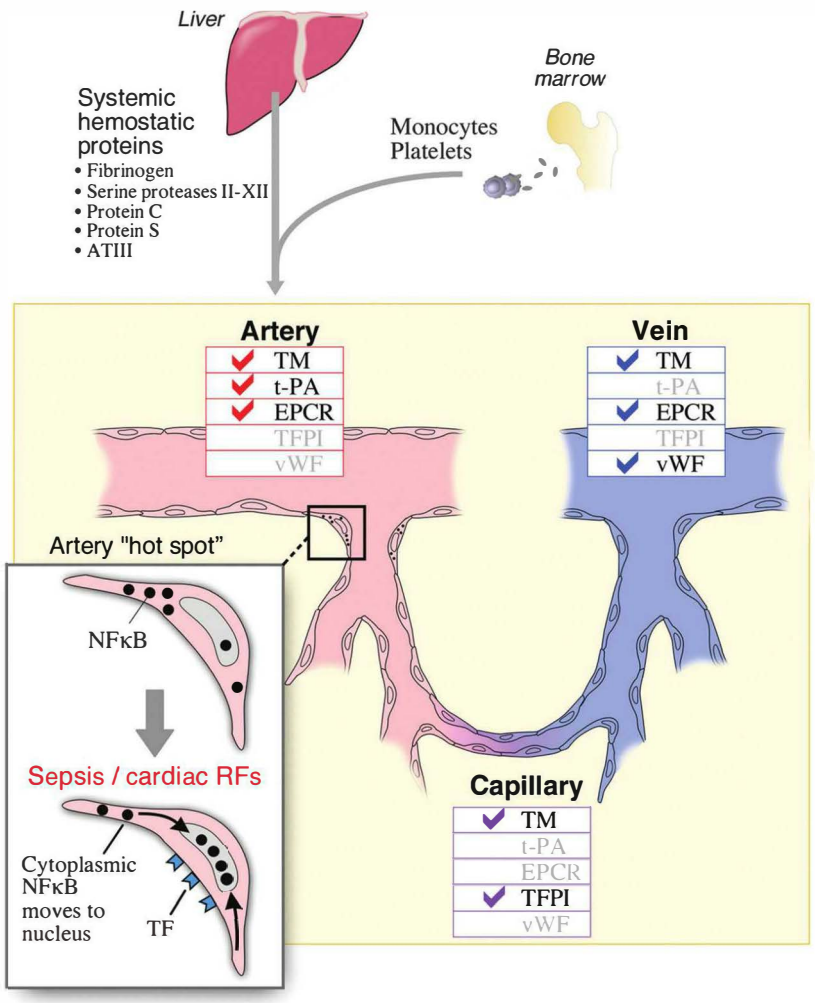

FIGURE 42.1 Endothelium and hemostasis. The liver synthesizes a relatively constant supply of clotting factors (serine proteases II through XII) and fibrinogen. In addition, hepatocytes synthesize several natural anticoagulants including protein C, protein S, and ATIII. The bone marrow produces and releases a relatively constant number of monocytes and platelets. Monocytes are capable of expressing TF, whereas activated platelets provide a cell surface for assembly of clotting reactions. ECs also express procoagulants and anticoagulants. However, the repertoire of EC-derived hemostatic factors varies between vascular beds (shown are reported differences between arteries, veins, and capillaries, though differences also exist between different types of arteries, veins, and capillaries). The systemic mix of liver-derived soluble mediators and bone marrow-derived blood cells is integrated into the unique hemostatic balance of each vascular bed. It follows that changes in the systemic balance (as occurs, e.g., in patients with congenital deficiency of protein C, protein S, or ATIII, or with factor V Leiden) will have different local effects, giving rise to site-specific thrombotic phenotypes. Recent evidence suggests that ECs in regions of disturbed flow in arteries are primed for activation (they have increased levels of nuclear factor-kappaB [NF-κB] in their cytoplasm) and that systemic imbalances (e.g., associated with sepsis or cardiac risk factors) may result in the translocation of NF-κB to the nucleus and increased expression of procoagulants such as TF and adhesion molecules. TM, thrombomodulin; t-PA, tissue-type plasminogen activator; EPCR, endothelial protein C receptor; TFPI, tissue factor pathway inhibitor; vWF, von Willebrand factor (Adapted from Aird WC. Phenotypic heterogeneity of the endothelium. I. Structure, function, and mechanisms. *Circ Res* 2007;100:158–173, with permission).

proteins and bone marrow-derived cells is systemically distributed and integrated into the unique hemostatic balance of each and every vascular bed. Thus, when an alteration occurs in the output of proteins (e.g., protein C or protein S deficiencies, or production of factor V Leiden) or cells (e.g., increased number of activated monocytes in sepsis), the changes affect the hemostatic balance in ways that differ between sites of the vascular tree.

Adding another layer of complexity to the model is the fact that the endothelium may become activated. Moreover, the activation phenotype may vary in different vascular beds. For example, sepsis is associated with widespread, though organ-specific, changes in the extracellular milieu, with subsequent local changes in EC adhesion, permeability, and hemostatic balance.

The value of the above scheme is that it recognizes the involvement of four functionally linked organ systems in mediating coagulation: namely, the liver, bone marrow, cardiovascular system, and endothelium. In this way, we are reminded of the importance of the hepatocyte in synthesizing serine proteases, the two cofactors, fibrinogen, and the natural anticoagulants, ATIII, protein C, and protein S; the critical role of TF-expressing monocytes in initiating coagulation; the participation of the platelet in localizing and perpetuating the coagulation response; and the importance of the EC as a manufacturer of hemostatic factors and regulator of the hemostatic balance.

It is not difficult to reconcile this model with that of Virchow's triad. Two observations have not changed over the past 150 years. First, stasis of blood flow (e.g., secondary to obesity, tumor, congestive heart failure, pregnancy, or immobility) when introduced into the system, may lead to the accumulation of activated clotting factors, reduction in protective hemodynamic forces, and downstream hypoxia—all of which may tip the balance to the procoagulant side. Second, frank disruption or denudation of the endothelium (e.g., as occurs in trauma, surgery, or catheter placement) may result in the exposure of blood to subendothelial adventitial TF and secondary thrombosis. However, two new observations warrant emphasis. First, when referring to blood constituents, we now recognize the importance not only of soluble clotting factors, but also of the cells—not just the platelet, but also the monocyte. Second, we now understand that an intact endothelium may contribute to hemostatic imbalance. In other words, both the structural and functional integrity of the vascular wall are important determinants of thrombotic risk.

The Endothelium and Vascular Bed-Specific Thrombosis

Venous Thrombosis

In the lower extremities, most venous thrombi occur in the pockets of valves (FIGURE 42.2). Three design features render valve pockets particularly vulnerable to thrombus formation. First, ECs lining the valve pocket are exposed to reduced flow velocities and shear stress during the valve cycle.[44] Secondly, the blood in the cusps of the valve is relatively hypoxic.[45] Finally, there is a tendency for leukocytes and platelets to become trapped in the valve pocket.

Venous flow is normally pulsatile. During standing, the venous valves open and close approximately 20 times per minute (reviewed in Ref.[36]). Flow through the valve creates vortices inside the valve pocket, which flush out the blood. Immobilization results in reduced venous blood flow in the lower extremities, with maximal stasis occurring in the valve pockets.

According to Virchow's triad, deep venous thrombosis may occur when there is a reduction in flow velocity or pulsatility (immobilization), when there is a shift in the circulating hemostatic balance (factor [F] V Leiden, G20210A prothrombin mutation, congenital deficiency of ATIII, protein C, or protein S), and/or when there is a loss of vascular wall integrity. Frank structural injury to the valve endothelium is rare, even with surgery.[46] Far more commonly, the intact endothelium becomes activated and dysfunctional, through exposure to stasis, hypoxia, and/or inflammatory mediators. Activated ECs may express increased levels of E-selectin and P-selectin. The selectins in turn bind to their ligands on circulating leukocytes and microparticles, resulting in increased leukocyte–endothelial interactions and TF-mediated initiation of the clotting cascade. There is evidence that TF-mediated activation of clotting precedes platelet activation in venous thrombosis (reviewed in[47]). The source of TF is debated. It is likely derived from circulating hematopoietic cells or microparticles. There is no evidence that TF is expressed in the ECs in the valve pocket. However, it has been proposed that TF may be transferred from microparticles to ECs (reviewed in Ref.[47]).

Thrombosis of intra-abdominal veins occurs with particularly high frequency in patients with myeloproliferative disorders (e.g., essential thrombocythemia and polycythemia vera) and paroxysmal nocturnal hemoglobinuria.[48] Intra-abdominal veins have very few valves compared with veins of the lower extremities. Thus, we must look for other mechanisms to explain thrombosis in this region of the vasculature. ECs lining the intestinal veins are exposed to a very different microenvironment compared with other blood vessels. For example, they experience boluses of absorbed nutrients following meals. Moreover, they are constantly exposed to oral antigens and pathogen-related products. Previous studies have demonstrated that hepatic sinusoidal ECs are immune tolerant and fail to mount an abnormal response to innocuous antigens and endotoxin (reviewed in[3]). It is not known whether the endothelium of mesenteric and portal veins is also immune tolerant. If not, then perhaps these cells are chronically activated and/or express site-specific genes that render them preferentially vulnerable to changes in the circulating blood of patients with myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria. Such changes may include a combination of increased blood viscosity, activated platelets and/or leukocytes, increased microparticles, free hemoglobin, and activated complement. In the case of paroxysmal nocturnal hemoglobinuria, it is interesting to speculate that ECs (perhaps in intra-abdominal veins) are clonally abnormal. As TFPI is a glycosyl phosphatidylinositol-linked protein,[49] ECs derived from the affected clone might be deficient in this anticoagulant.

The vasculature of the adrenal gland is unique in that a large number of arteries feed into a relatively small number of venules *via* medullary sinusoids. As a result of this architecture—which has been referred to as a "vascular dam"–thrombosis of the adrenal vein commonly presents as hemorrhage (reviewed in[36]). The musculature of the adrenal vein is not concentric, but rather is composed of thick longitudinal bundles. It has been suggested that the eccentric arrangement of the muscle in the adrenal vein creates pockets of turbulence and stasis, thus predisposing to thrombus formation. Also, the adrenal vein drains high concentrations of catecholamines, which might be predicted to induce vasoconstriction and activate platelets.

Arterial Thrombosis

Most arterial thrombosis occurs at the sites of atherosclerosis. Branch points and greater curvatures of arteries are normally exposed to disturbed flow. Previous studies have shown that ECs lining these regions of disturbed flow are primed for activation (reviewed in Ref.[50]). This is a classic example of an evolutionary tradeoff. In this case, the fitness advantage a closed circulation must outweigh the disadvantages of regional flow disturbances. In the modern day environment, systemic risk factors for atherosclerosis, including hypertension, hyperglycemia, smoke-related toxins, and hyperlipidemia, may serve to push the primed ECs into a dysfunctional state. Consistent

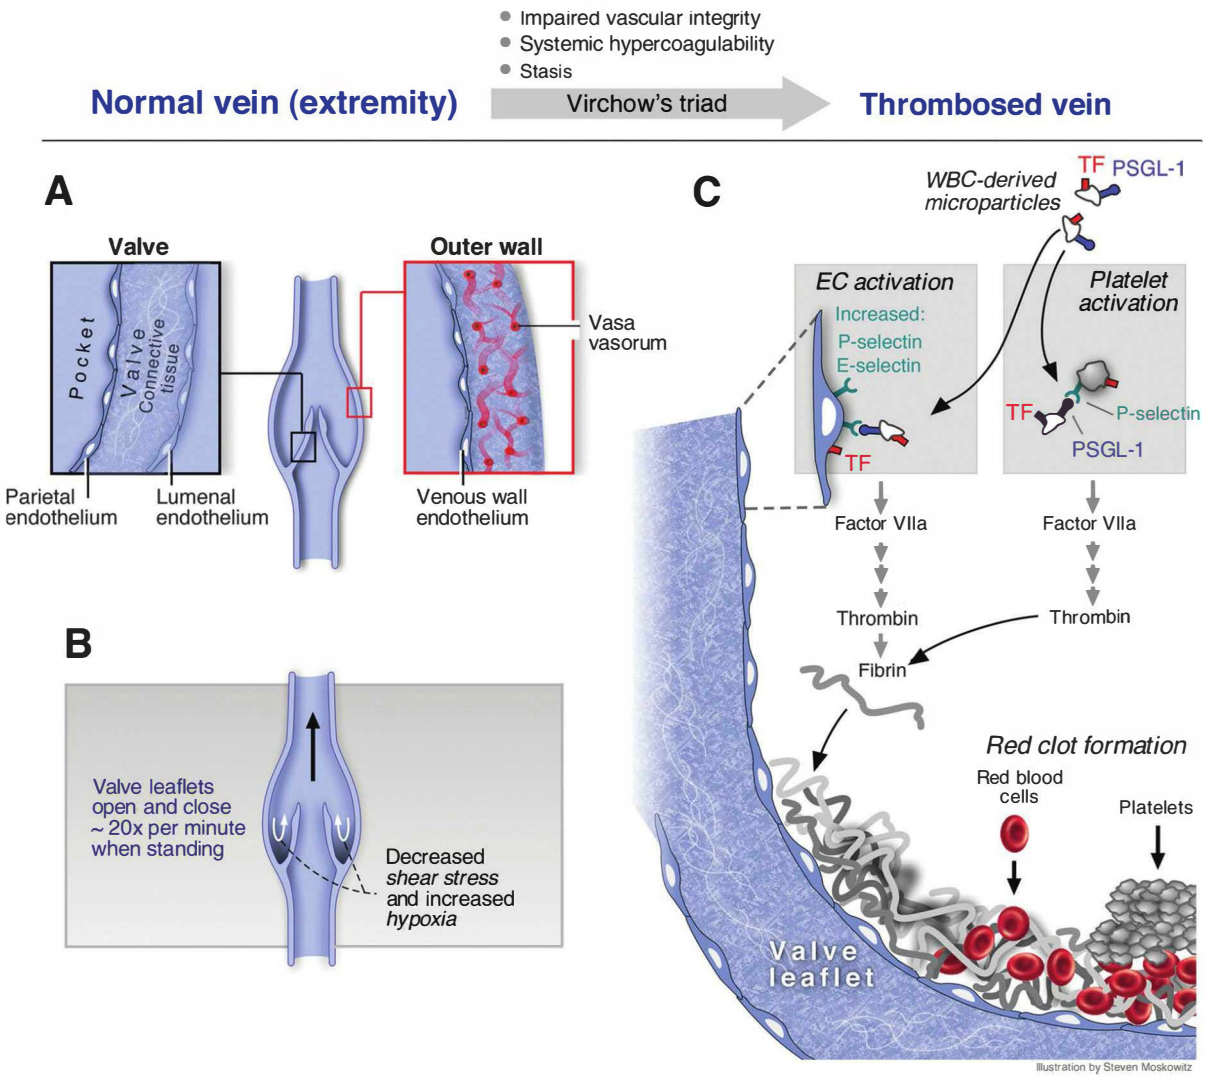

FIGURE 42.2 Venous thrombosis in the lower limbs. **A:** Under normal conditions, the veins of the lower limbs contain a high number of valves, the vast majority of which are bicuspid. The valves consist of a connective tissue core covered on both surfaces (parietal and lumenal) by endothelium. The endothelial linings of the valve leaflets are phenotypically distinct from ECs lining the vein wall (e.g., their density is higher, they are not oriented in the direction of blood flow, and by extension of studies in heart valves and by virtue of their exposure to unique flow patterns, they may demonstrate microheterogeneity in gene expression). In contrast to the vein wall, the valve leaflets do not contain vasa vasorum (and are thus reliant on venous blood oxygen). **B:** The valve cycle is associated with vortical flow behind the valve cusps, which reduces stasis inside the valve pocket. Valve pocket blood is hypoxic relative to blood in the mainstream. **C:** A combination of stasis (e.g., caused by immobilization, congestive heart failure, obesity), systemic hypercoagulability (e.g., associated with congenital deficiency of anticoagulants, factor V Leiden; use of oral contraceptive pills (OCP); pregnancy; or activated platelets), and/or loss of vascular integrity (particularly an activated, as distinct from frankly denuded, endothelium), may lead to TF-mediated initiation of clotting cascade. The thrombus begins as a microscopic nidus of fibrin-red cell collections near the apex of the valve pocket. Alternating layers of fibrin and platelet clumps are characteristic of the propagating thrombus. TF- and P-selectin glycoprotein ligand-1-(PSGL)-positive circulating microparticles bind to P selectin on platelets, or P-selectin or E-selectin on ECs, leading to transfer of TF to the cell and activation of the clotting cascade. (Adapted from Aird WC. Vascular bed-specific thrombosis. J Thromb Haemost 2007;5 Suppl 1:283-291, with permission.)

with this view, ECs overlying atheromatous plaques demonstrate abnormal ultrastructure,[51] increased expression of adhesion molecules,[52] TF and TFPI,[53,54] and reduced expression of thrombomodulin and EPCR.[55] Once the disease process is set in motion, atheromas may compromise the lumen and ultimately lead to occlusive thrombosis.

Arterial thrombi may occur in the absence of atherosclerosis. For example, patients with different types of vasculitis may develop arterial thrombi in characteristic and distinct sites of the arterial tree (reviewed in Ref.[36]). The molecular basis for the site-specific patterns of the vasculitides is likely to involve immune-mediated targeting of spatially restricted antigens or neoantigens

present in the vascular wall, including the macroendothelium and/or endothelium of the vasa vasorum. Essential thrombocythemia is a rare cause of coronary artery occlusion.[56] Essential thrombocythemia-associated arterial thrombus may occur in the absence of atherosclerosis, and is likely to be mediated, in large part, by abnormalities in platelet function. In heparin-induced thrombocytopenia (HIT), the ratio of venous to arterial thrombosis is normally 4:1. However, patients with risk factors for atherosclerosis (i.e., those undergoing open heart surgery), have a higher risk for arterial thrombi,[57,58] suggesting a permissive role for atherosclerosis in HIT-associated arterial occlusive lesions. In contrast to the distribution of atherosclerosis-related complications (coronary > cerebral > lower extremity arteries), HIT-associated arterial thrombi occur most commonly in the aorta and iliofemoral arteries, followed by cerebral and coronary arteries. These differences argue for distinct pathophysiologies underlying atherosclerosis- and HIT-mediated arterial thrombosis.

In general terms, there are some important differences between mechanisms of thrombus formation in veins and arteries. Compared with valve pockets in veins, the loss of vascular integrity (e.g., *via* plaque rupture or fissure) is more common at sites of arterial thrombi. Second, while TF is thought to play a primary role in mediating venous thrombosis, interactions between platelets (particularly GP1b), vWF (or other GP1b ligands) and extracellular matrix (particularly collagen) may be the most important determinant of arterial clots.[59,60,61,62] Finally, the development of arterial thrombosis is not generally increased in patients with thrombophilic mutations, such as FV Leiden or the prothrombin gene G20210A mutation.

Microvascular Thrombosis

Microvessels comprise the vast majority of the surface area of the circulation. Microvascular thrombosis is typically manifest as acute or chronic organ dysfunction. The chronic type is exemplified by such disorders as sickle cell disease and small vessel vasculitis. Acute small vessel occlusion is seen in disseminated intravascular coagulation, catastrophic antiphospholipid syndrome, Trousseau's syndrome, HELLP (hemolysis, elevated liver enzymes, and low platelets), microangiopathic hemolytic anemias (thrombotic thrombocytopenic purpura [TTP] and hemolytic uremic syndrome [HUS]), coumarin-induced skin necrosis, erythromelalgia, and HIT. Although the precise pathophysiology of clot formation is unclear in most of these disorders, the endothelium is likely to play a critical role in mediating their site specificity. For example, in classical TTP and sporadic HUS, platelet-rich thrombi are observed in the microvascular beds of every organ examined with the exception of the liver and lung.[63] Previous studies have demonstrated that plasma from patients with TTP or HUS induces apoptosis of microvascular ECs cultured from many organs, but not the lung.[64] Another major theme in the pathogenesis of TTP is a deficiency in ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin motif-13), which mediates proteolytic processing of newly released proadhesive ultralarge vWF multimers from ECs. Mice that are null for ADAMTS13 are not at risk for spontaneous development of TTP phenotype.[65] Indeed, it has been proposed that the pathophysiology of classical TTP and sporadic HUS requires two hits: altered vWF activity (e.g., as might occur with ADAMTS13 deficiency) and site-specific activation and/or apoptosis of microvascular ECs.[66,67]

Patients with polycythemia vera or essential thrombocythemia may present with erythromelalgia (i.e., painful red or blue toes, soles of feet or fingers) (reviewed in Refs.[68,69]). Pathology reveals fibromuscular hyperplasia, narrowing of the lumen, swollen ECs, and platelet-rich thrombi in arterioles. Although untreated erythromelalgia may progress to gangrene, the syndrome is exquisitely sensitive to aspirin therapy. In contrast, warfarin-induced skin necrosis is associated with paresthesias, skin discomfort, and/or discoloration in the regions of the buttocks, breasts, and thighs. Pathology reveals fibrin deposition in the postcapillary venules, and treatment includes the institution of potent and rapidly acting anticoagulants (e.g., heparin). The distribution of lesions in coumarin-induced skin necrosis suggests that the dermal microvascular endothelium is uniquely sensitive to changes in circulating levels of functional protein C. In patients with HIT, warfarin-induced skin necrosis is more commonly observed in the limbs. HIT has also been reported to cause skin necrosis in the absence of coumarin, with thrombosis of venules and capillaries, but sparing of arterioles. The distinct microvascular phenotypes associated with erythromelalgia, coumarin-induced skin necrosis, and HIT underscore the existence of heterogeneity within a single microvascular bed.

SUMMARY

The endothelium is a widely distributed organ system that plays an important role both in physiology and disease. The endothelium has many functions, over and above its well-recognized role in mediating vascular tone. One of these critical activities is maintenance of blood fluidity and repair of injured blood vessels. The endothelium is remarkably heterogeneous in structure and function. Indeed, ECs regulate hemostatic balance by site-specific formulas of anticoagulants and procoagulants. These different equations are sufficient to explain why systemic imbalances in coagulation factors invariably lead to local thrombotic phenotypes. The propensity to develop clots in specific vascular beds is further accentuated by local endothelial dysfunction. An important goal for the future is to identify diagnostic markers that reflect phenotypic changes at the level of individual vascular beds, and to develop therapies that target selected sites of the vasculature.

CHAPTER

43 Role of the Endothelium in Hemostasis

MICHAEL J. KRISINGER AND EDWARD M. CONWAY

Hemostasis and coagulation, which refer to the arrest of bleeding and the formation of a fibrin clot, respectively, are generally used interchangeably to describe the processes by which blood is maintained in a fluid state in the circulatory system. Normal function of the endothelium, the single cell layer lying at the interface of circulating blood and the underlying tissue, is required for optimal organ function and for maintaining and regulating blood flow to meet the body's dynamically changing demands over a range of pathophysiologic conditions. Rather than playing a passive role in the transport of blood, the endothelium has, in the past half century, become recognized as a central and active player in homeostasis. In response to damaging stimuli, such as trauma or infections, the vascular endothelium, in conjunction with other components of the hemostatic system, serves to rapidly and effectively limit tissue destruction to a local site and to promote healing.

The hemostatic system is continuously in an "on" position, dynamically exhibiting antithrombotic and prothrombotic properties that are delicately balanced to meet local and systemic needs (FIGURE 43.1). Under normal physiologic conditions, natural antithrombotic forces override the prothrombotic ones, limiting platelet adhesion and activation and excess fibrin clot formation, while vasomotor tone is optimized, overall maintaining critical blood flow to ensure organ function. Not unexpectedly, the switches that control hemostatic system activity are tightly regulated. Genetic, environmental, and epigenetic factors that disrupt the exquisite and dynamic balance between prothrombotic and antithrombotic forces are clinically manifest by either bleeding or thrombosis. The major prothrombotic forces are mediated by platelets, monocytes, the clotting cascade, and the vascular endothelium, while the predominant antithrombotic mechanisms center around the endothelium. In this chapter, we explore the major properties of the endothelium in regulating the hemostatic system.

TISSUE FACTOR AND INITIATION OF COAGULATION ON THE ENDOTHELIAL CELL SURFACE

The coagulation system is characterized by the sequential activation of a series of serine proteases, culminating in the generation of thrombin, with subsequent conversion of fibrinogen into an insoluble fibrin clot. The molecular events surrounding initiation of coagulation have been extensively examined and revised since the original description in 1964 of the cascade/waterfall hypothesis of hemostatic system activation.[1] Following vascular injury, tissue factor (TF) is exposed to the circulation and binds to coagulation factor VIIa.[2] When not associated with TF, the factor VIIa that constitutively circulates at low levels has poor enzymatic properties. When complexed with TF, factor VIIa acquires potent catalytic properties and triggers coagulation by converting the zymogens factor IX and factor X to enzymes factor IXa and factor Xa, respectively. The initial factor Xa formed when bound to membrane is sufficient to generate trace (pM) amounts of thrombin from prothrombin. This initial thrombin serves as the primary activator of the zymogen factor XI, the procofactors V and VIII, and importantly platelets, which together provide important amplification feedback. Surface exposure of anionic phospholipids (e.g., phosphatidylserine) is essential in promoting assembly and efficient catalytic activity of the two subsequent membrane-bound enzyme complexes, namely "intrinsic factor Xase" and "prothrombinase." The factor IXa generated from the TF-factor VIIa combines with its cofactor factor VIIIa on the activated platelet membrane to form the "intrinsic factor Xase," which becomes the major activator of factor X. Similarly, the factor Xa formed combines with factor Va on the activated platelet membrane to form "prothrombinase," which converts prothrombin to thrombin.

In what is viewed as the central event in coagulation, the serine protease thrombin finally cleaves fibrinogen to generate fibrin, which is cross-linked by factor XIIIa. The scheme supports the notion that the TF-factor VIIa pathway of blood clotting is the major physiologic mechanism for triggering coagulation and that exposure of TF to the circulation is the critical event that induces the vasculature to acquire a procoagulant phenotype.[3]

TF is a 263–amino acid integral membrane protein, structurally comprised of three domains.[4] The extracellular domain constitutes over 80% of the amino acid sequence of the molecule and provides binding sites for factor VIIa, such that the protease activity of TF-complexed factor VIIa toward its substrates, factors X and IX is dramatically increased. The transmembrane domain of TF is important for optimizing its cofactor function with factor VIIa.[5] The cytoplasmic tail mediates intracellular signals in processes that impact on a range of cellular activities, including cell proliferation, angiogenesis, and inflammation.[6–8]

Expression of TF varies in different organs, with particularly high levels in the heart, lung, brain, testis, uterus, and placenta, and lower amounts in the joints and skeletal muscle.[9] It is found throughout the vasculature, synthesized by adventitial fibroblasts, smooth muscle cells, pericytes, and several hematopoietic and nonhematopoietic cells.[10,11] When stimulated by proinflammatory cytokines, monocytes and macrophages prominently express TF.[10,12] Tumor cells also synthesize TF, which impacts on metastasis formation.[13] In some pathologic conditions, small amounts of TF that are in or on platelets and/or a component of platelet-derived microparticles may also contribute to the overall pool of TF, although the relevance of these sources is not yet clear.[14,15]

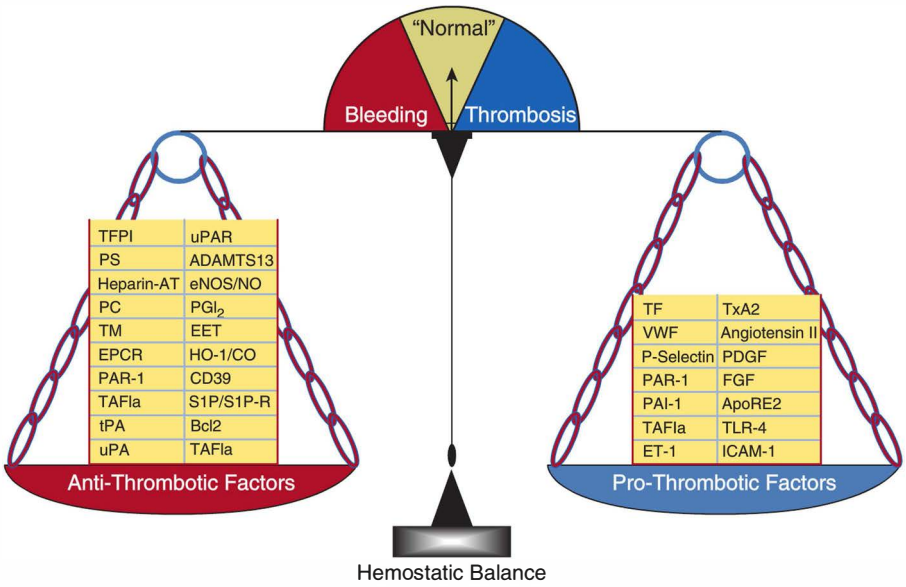

FIGURE 43.1 Balance between endothelial prothrombotic and antithrombotic factors. Relative imbalances in expression of prothrombotic and antithrombotic factors will determine the response to pathophysiologic stresses that may be exhibited by bleeding or thrombosis.

In spite of some conflicting data, most studies concur with the earliest reports that TF is not normally expressed by endothelial cells *in vivo*.[16,17] Indeed, in the absence of injury, functionally active TF is excluded from the intravascular space. However, during disease, vascular endothelial cells may express TF. For example, TF may be prominently expressed by endothelial cells of the pulmonary veins of hypoxic mice with sickle cell anemia,[18] of tumor vessels,[19] and overlying atheromatous lesions.[20] Some investigators have suggested that TF is normally expressed by circulating monocytes but in a functionally inactive "encrypted" form, able to undergo "decryption" during inflammation.[21] Thus, given its prominent perivascular distribution, TF has been represented as a hemostatic "envelope" for the vasculature, readily available to initiate coagulation upon exposure to blood when vascular integrity is compromised by chemical or mechanical injury.[16] Indeed, recent studies suggest that preformed TF-factor VIIa complexes may reside around blood vessels in the absence of injury, allowing even more rapid coagulation activation upon injury.[22]

Numerous extracellular stimuli that are implicated in disorders associated with thrombosis may trigger coagulation *in vivo* by inducing TF expression by most cells exposed to the circulation, including for example endothelial cells, monocytes, platelets, and subendothelial cells (after vessel injury). Among these agonists are proinflammatory mediators, including lipopolysaccharide, tumor necrosis factor (TNF)-α, interleukin (IL)-1β, thrombin, vascular endothelial growth factor (VEGF), infectious agents (e.g., herpes simplex virus, rickettsia, and measles), oxygen free radicals, and low shear stress. This list is not comprehensive, but underlines the fact that the vascular endothelium is constantly exposed to agents that are likely to induce varying degrees of damage with exposure of TF, with constant generation of small amounts of thrombin. Indeed, it has been well established that in normal individuals, there is a persistent low level of activation of coagulation.[23,24] For the TF-factor VIIa triggering reaction to proceed to full-fledged coagulation, the amount of TF exposed and thus the amount of thrombin generated must exceed a threshold to overcome the activity of endogenous natural anticoagulant pathways that otherwise serve to limit thrombin bursts and prevent physiologically excessive thrombotic responses. There are in fact, four dominant natural vasculoprotective mechanisms that regulate thrombin generation and fibrin clot formation. These are tissue factor pathway inhibitor (TFPI), the heparin–antithrombin (AT) pathway, the protein C (PC) anticoagulant pathway, and the fibrinolytic system.

TISSUE FACTOR PATHWAY INHIBITOR

TFPI-1, commonly referred to as TFPI, is the principle inhibitor of the TF pathway, binding to and neutralizing TF-factor VIIa in a factor Xa–dependent manner (reviewed in[25,26]). TFPI is primarily associated (~85%) with microvascular endothelial cells where it is constitutively expressed. Lesser amounts are also found on the surface of monocytes, smooth muscle cells, platelets, mesangial cells, fibroblasts, cardiomyocytes, and plasma.[27,28]

TFPI is a 276–amino acid, 43 kDa, multivalent Kunitz-type serine protease inhibitor[29] that comprises an acidic *N*-terminal region, three Kunitz-type domains, and a basic *C*-terminus. Interaction of TFPI with the endothelial cell surface is achieved via two mechanisms. The *C*-terminal stretch of basic residues of TFPI binds to cell surface glycosaminoglycans.[27] This is therefore heparin releasable and accounts for a two- to four-fold increase in plasma levels after heparin infusion.[30] Most of the cell surface–associated TFPI, which cannot be released by heparin, is bound through a glycosylphosphatidylinositol (GPI) anchor.[31] However, TFPI does not contain a consensus sequence for attachment of a GPI anchor, and thus it is believed that there exists a hitherto unidentified coreceptor that binds to the third Kunitz domain of TFPI.

Alternative pre-mRNA splicing yields at least three isoforms of TFPI in the mouse (α, β, γ) and human ($\alpha\beta\delta$). Only the full-length form (TFPIα or TFPI) contains the third Kunitz domain and the basic *C*-terminal region. The other isoforms contain

two Kunitz domains and the *C*-terminal region. In humans, TFPI is the only one that has been identified at the protein level in tissues.[25] During embryonic development in mice, TFPI and TFPIβ are both widely expressed and at about equal levels. However, adult mouse tissues produce mostly TFPIβ. In contrast to TFPI, TFPIβ has a *C*-terminal GPI anchor attachment sequence, allowing it to directly associate with the cell surface.[31] The role of TFPIγ is unknown. Although it is believed that inhibition of TF-factor VIIa and factor Xa require the third Kunitz and the basic *C*-terminus of TFPI, several *in vitro* studies suggest that TFPIβ may have anticoagulant activity on the cell surface.[32] *In vivo* studies are required to fully assess the relative anticoagulant activity of TFPIβ. Functional data for TFPIδ are lacking. It contains two Kunitz domains and a 12–amino acid *C*-terminus, the latter having no similarity to the other isoforms.

To effectively regulate TF-factor VIIa–induced initiation of coagulation, TFPI must be appropriately localized at the cell surface where vascular injury exposes TF to the circulation. At that site, TFPI is well positioned to prevent small amounts of TF-factor VIIa, formed in response to a minor injury, from unnecessarily generating a large thrombin burst. Indeed, TFPI provides the first natural barrier threshold, without which coagulation would otherwise proceed and amplify in an unregulated fashion (FIGURE 43.2). TFPI utilizes the two *N*-terminal (first and second) Kunitz-type serine protease domains to inhibit the active sites of both factor Xa and TF-factor VIIa. As TF-factor VIIa activates factor X, the second Kunitz domain of TFPI binds to the active site of the newly generated factor Xa that is still associated with the TF-factor VIIa complex, rendering the factor Xa inactive. The flanking Kunitz domains and the basic *C*-terminal region of TFPI enhance their interaction with factor Xa. Protein S (PS), a vitamin K–dependent protein and cofactor in the PC-thrombomodulin (TM) anticoagulant system (see below), also acts as a cofactor for TFPI by interacting with its third Kunitz domain and its *C*-terminus, accelerating inhibition of factor Xa.[33,34] Binding of factor Xa causes TFPI to undergo a conformational change, thereby facilitating subsequent interaction of the TFPI-factor Xa complex via the first Kunitz domain of TFPI, in a Ca^{2+}-dependent manner, with the active site of factor VIIa when bound to TF.[35] The resultant quaternary complex TF/factor VIIa/factor Xa/TFPI lacks both TF-initiated blood coagulation activity as well as protease-activated receptor (PAR)-1/2-mediated cellular signaling activity involved in inflammation. Although the interactions of TFPI with factor Xa and TF-factor VIIa are usually depicted as a two-step process, these effectively occur simultaneously. Indeed, once factor Xa is released from TF-factor VIIa and complexed with factor Va, it cannot any longer be inhibited by TFPI.[36] Thus, the window during which TFPI must function is critically narrow.

As noted above, TFPI has several cellular sources. While endothelial TFPI predominates, it is synthesized by megakaryocytes, and stored in α-granules of platelets, whereupon it may be translocated to the platelet surface upon activation.[37] TFPI is also found in the plasma, the origin of which is primarily endothelial. It circulates in a complex with low-density lipoproteins (LDLs), and comprises various degraded forms, probably generated by proteolysis by a range of enzymes, including thrombin, plasmin, and matrix metalloproteinases.[26] The gamma-carboxyglutamic acid (Gla) domain of PS and the *C*-terminal region of TFPI effectively bind negatively charged phospholipid surfaces and thus localize this negative regulatory system to sites where TF may be exposed for initiation of coagulation, including injured or denuded endothelial cells and activated platelets.[33,34] Nonetheless, delineation of the role of different pools of TFPI and their physiologic site(s) of action require further study.

Not surprisingly, inactivation of the *TFPI* gene in mice results in embryonic lethality[38] due to a consumptive coagulopathy. Heterozygous *TFPI* deficiency in combination with factor V_{Leiden} in mice increases thrombotic susceptibility.[39] The finding that TFPI administration had efficacy in animal models of sepsis prompted phase III clinical trials. Unfortunately, although TFPI dampened activation of coagulation in patients with sepsis, there was no survival benefit.[40] Indeed, the link in humans between TFPI deficiency and thrombotic disease has not been clearly established. There are suggestions that inadequate release of TFPI into the circulation might increase the risk of thrombosis, and only isolated TFPI polymorphisms have been weakly associated with thrombosis.[41] This lack of a clear association is intriguing, as it implies that there may be additional natural anticoagulant mechanisms that compensate for deficiencies in TFPI. It may also mean that moderate deficiencies of TFPI may be incompatible with life.

Similar to TFPI (TFPI-1) in structural architecture, TFPI-2 also has three Kunitz-type domains, but does not inhibit factor Xa and has minimal inhibitory activity for TF-factor VIIa.[42,43] Rather, TFPI-2 expressed by endothelial cells, inhibits trypsin, plasmin, kallikrein, factor XIa, and some matrix metalloproteinases, interacts with complement-binding proteins, and

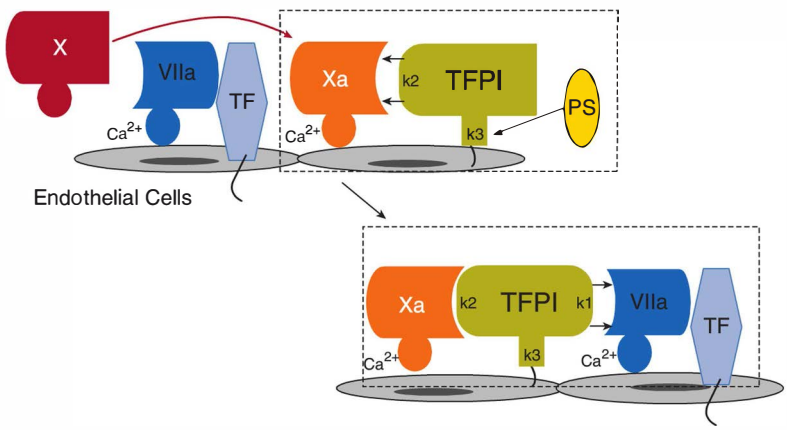

FIGURE 43.2 TFPI-mediated neutralization of factors VIIa and Xa. Localized to the site of injury on the endothelial cell surface, tissue factor pathway inhibitor (TFPI) binds first to factor Xa via its second Kunitz domain (k2), enhanced by protein S (PS) which interacts with the *C*-terminus and the third Kunitz domain (k3) of TFPI. TFPI then undergoes a conformational change, facilitating Ca^{2+}-dependent binding via the first Kunitz domain (k1) and neutralization of factor VIIa which is complexed with tissue factor (TF).

suppresses growth factor–induced proliferation of endothelial cells.[44] Although TFPI-2 may play a role in the coagulation cascade and as a vasculoprotective molecule, it is more likely important in inflammation, atherosclerosis, and tumor cell invasion.[45]

ANTITHROMBIN AND ENDOTHELIAL HEPARIN SULFATE

AT is a circulating serine protease inhibitor (serpin) that neutralizes thrombin, factor Xa and factor IXa,[46] and to a lesser extent the procoagulant factors XIa, XIIa, and TF-factor VIIa. It also exhibits some activity against plasmin, kallikrein, urokinase-type plasminogen activator (uPA), and tissue-type plasminogen activator (tPA). AT is synthesized primarily in the liver and has a molecular weight of approximately 58 kDa. In the circulation, AT exists in a "repressed" conformation that has minimal protease inhibitory activity. In the presence of heparin or heparin sulfate, the neutralizing capacity of AT is accelerated over 500-fold for factor Xa, more than 2,000-fold for thrombin, and approximately one millionfold for factor IXa. Indeed, this is the rationale for using heparin as an anticoagulant drug. Endogenous heparin, however, does not freely circulate in the blood. Rather, endothelial cells express heparin sulfate–containing proteoglycans, including, for example, syndecan-1, -2, -4, glypican-1, betaglycan, CD44, and fibroblast growth factor (FGF) receptor-2, allowing direct interactions with AT,[47,48] as well as with TFPI, thrombin, heparin cofactor II, and tPA. The pattern of sulfation on the repeating disaccharide backbone helps define the binding specificity of each heparin sulfate structure. Although somewhat controversial,[49,50] it is generally believed that the anticoagulant properties of AT are localized to the surface of the endothelium, thereby contributing to the nonthrombogenic properties of the vessel wall. Vascular-bed–specific heterogeneity in the expression of the different heparin sulfate–containing proteoglycans helps to explain the diversity in the anticoagulant properties within different vascular beds.[51,52] In the setting of injury, luminal and subluminal sources of heparin may also activate AT, thereby restricting clot extension.

Heparin-induced activation of AT to a form that rapidly inhibits procoagulant serine proteases occurs via at least two mechanisms (FIGURE 43.3). Through ionic and nonionic interactions, a sequence-specific, negatively charged pentasaccharide within heparin binds to AT with high affinity, thereby inducing allosteric changes in AT that allow it to specifically react with and inhibit factors Xa and IXa. This pentasaccharide is insufficient but necessary to promote inhibition of thrombin by AT. The pentasaccharide must be part of a longer negatively charged polysaccharide of heparin (minimally a 16-mer), which provides a binding site for thrombin. With AT simultaneously bound to the pentasaccharide and a more remote polysaccharide chain, the thrombin molecule thus can be oriented via this heparin bridging mechanism for neutralization by AT. This bridging effect also enhances AT reactivity with factors Xa and IXa for more effective neutralization.[53,54,55] Protease inhibition rates by AT due to heparin sulfate bridging and allosteric changes in AT are estimated to be augmented approximately 2,000-fold and 300-fold, respectively.[56,57] Interestingly, heparin-activated AT is a poor neutralizer of the natural anticoagulant serine protease, activated PC (APC), highlighting the specificity of AT for procoagulant proteases.[58]

AT also plays a role in protecting organisms against inflammatory and infectious disorders, in part via effects on the vascular endothelium. At least in animal models, administration of AT protects against septic shock,[59] although this has not uniformly been observed in human studies.[60] *In vitro*, AT interferes with nuclear factor kappa B (NF-κB) nuclear translocation, thereby suppressing release of cytokines by endothelial cells and the expression of leukocyte adhesion molecules. AT also enhances prostacyclin (PGI_2) release from the vasculature[61] that was protective in a rat model of abdominal sepsis.[62]

The physiologic importance of the heparin-AT mechanism as a natural inhibitor of coagulation is unquestioned. Inherited heterozygous AT deficiency has a reported prevalence that ranges from 1:500 to 1:5,000 and is associated with a significantly increased risk of venous thromboembolic disease.[63,64] Indeed, by the age of 50 years, approximately 50% of patients with AT deficiency will have had at least one thrombotic episode, half of which will be unprovoked.[65] Congenital or inherited deficiencies of heparin have not been reported, suggesting that its absence is not compatible with survival.

THE PROTEIN C SYSTEM

The PC system represents a major physiologically relevant natural anticoagulant mechanism, the function of which depends on the integrity of endothelial cell integral membrane glycoproteins TM and endothelial protein C receptor (EPCR). This system also provides a critical link between coagulation and

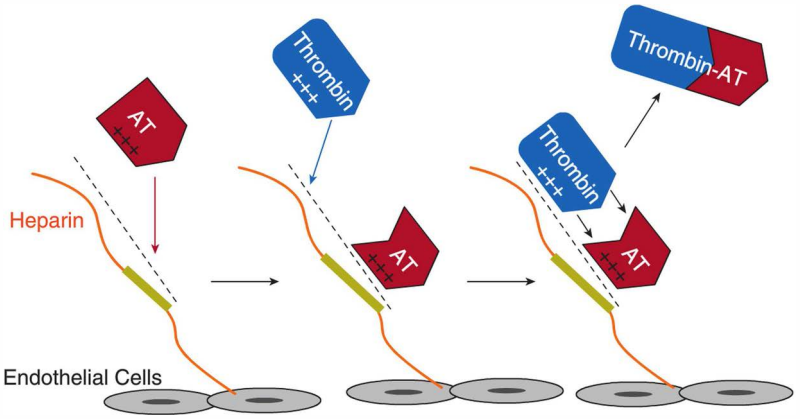

FIGURE 43.3 Heparin-AT neutralization of thrombin. Antithrombin (AT) binds, via nonionic and ionic interactions, to a specific negatively charged pentasaccharide (*green*) within heparin or heparan sulfate molecules on the endothelial cell surface and undergoes a conformational change, allowing it to efficiently react with and inactivate factors Xa and IXa (not shown). For AT neutralization of thrombin, a longer polysaccharide chain provides an additional binding site for thrombin (exosite II), bridging the interaction between thrombin and AT. Once formed, the thrombin–AT complex dissociates from the polysaccharide chain and is cleared from the circulation.

inflammation,[66] highlighting how these biologic processes are spatiotemporally integrated.

PC is a vitamin K–dependent protein, synthesized in the liver that circulates as a two-chain zymogen.[67] APC is a serine protease that is generated by thrombin-mediated cleavage of PC, an event that requires TM, and is indeed amplified over 1,000-fold by its presence[68] (FIGURE 43.4). As the name implies, TM has the remarkable ability to modulate thrombin by allosteric alteration of its active site, converting it from a procoagulant enzyme to an anticoagulant enzyme. This switch in substrate specificity prevents thrombin–TM from cleaving fibrinogen, activating factor V and factor VIII, and triggering platelet activation. PC activation by thrombin–TM is amplified a further 20-fold when PC is bound to EPCR.[69] Platelet factor 4 (PF4) may also accelerate PC activation by inducing allosteric changes in PC that increase its affinity for thrombin-TM.[70] Facilitated by its cofactor PS, APC has potent anticoagulant activities by proteolytically cleaving and inactivating factors VIIIa and Va, which thereby suppresses further production of factor Xa and thrombin[71,72] (FIGURE 43.5). The physiologic importance of this system is underlined by the fact that patients with deficiencies of PC or PS, or who have a mutation in factor V (factor V_{Leiden}) that renders it resistant to inactivation by APC, all have an increased risk of thromboembolic disease[73,74,75] APC also has profound anti-inflammatory properties, mediated by several mechanisms including, for example, suppressing exposure of TF and the release of TNF-α, IL-1β, IL-6, and IL-8, and preventing endothelial expression of leukocyte adhesion molecules.[76–78] Numerous *in vivo* studies have confirmed the important anti-inflammatory properties of APC.[6]

The thrombin–TM complex exhibits additional effects on hemostasis through the activation of the plasma procarboxypeptidase, thrombin-activatable fibrinolysis inhibitor (TAFI). Activation of TAFI by thrombin alone is inefficient but in the presence of TM, is enhanced over 1,000-fold[79] (FIGURE 43.6). The carboxypeptidase activity of activated TAFI (TAFIa), in turn, cleaves *C*-terminal lysine residues from fibrin cleavage products.[80] Fibrin cleavage products, produced by limited plasmin proteolysis of fibrin, accelerate the conversion of plasminogen to plasmin by tPA. Thus, removal of these *C*-terminal lysine residues impedes the degradation of insoluble fibrin, with less incorporation of plasminogen and tPA into the fibrin clot. Accordingly, TM serves an important antifibrinolytic function. TM may also be considered a profibrinolytic factor, since, via APC, it suppresses thrombin generation which

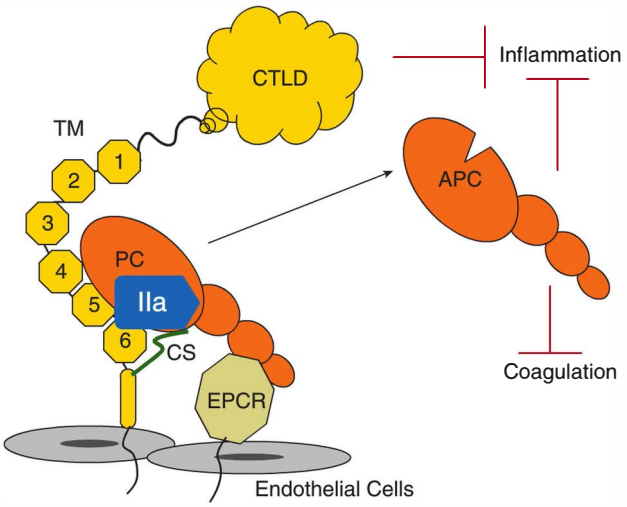

FIGURE 43.4 Activation of PC by thrombin–TM-EPCR. EGF-like 4–6 repeats of thrombomodulin (TM, *yellow*), the chondroitin sulfate (CS) of TM, and the endothelial protein C receptor (EPCR) provide cofactor function for thrombin (IIa)-mediated activation of protein C (PC). Activated protein C (APC) has anticoagulant and anti-inflammatory properties. The C-type lectin-like domain (CTLD) of TM also suppresses inflammation.

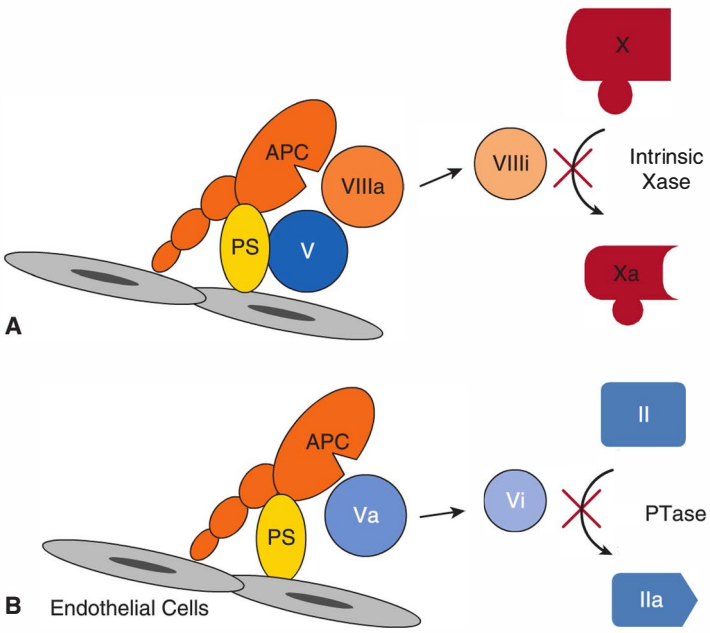

FIGURE 43.5 Anticoagulant properties of APC. When free of EPCR, APC localizes with cofactor protein S (PS) on the surface of endothelial cells or platelets and inactivates factor VIIIa, using factor V as a synergistic cofactor **(A)** or inactivates factor Va **(B)**. This yields, respectively, the inactive species factor VIIIi and factor Vi. Lack of the active cofactors (factors VIIIa and Va) abrogates conversion of factor X to factor Xa by the intrinsic factor Xase complex **(A)**, and prothrombin (II) to thrombin (IIa) by the prothrombinase (PTase) complex **(B)**, respectively.

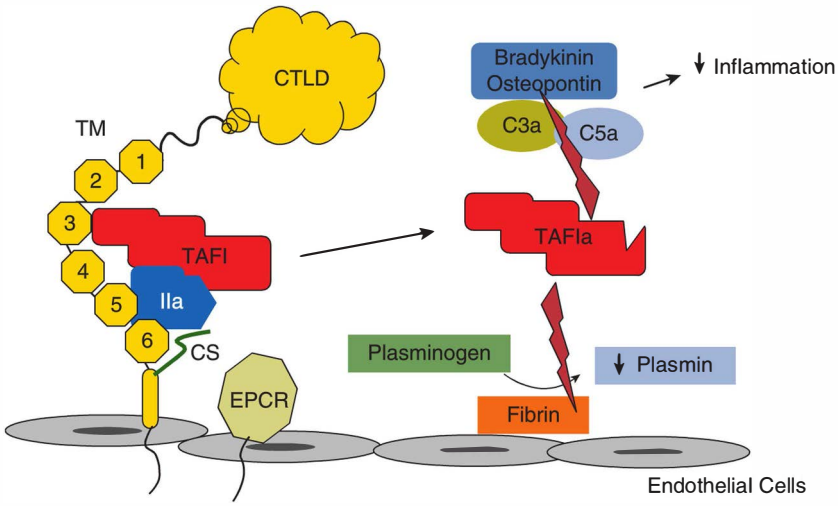

FIGURE 43.6 Activation of TAFI by thrombin–TM. EGF-like 3–6 repeats of TM provide cofactor function for thrombin-mediated generation of TAFIa, which cleaves basic *C*-terminal amino acid residues from several substrates including complement components C3a and C5a, bradykinin, and osteopontin, thereby reducing proinflammatory forces. TAFIa also cleaves fibrinogen, interfering with efficient generation of plasmin from plasminogen.

in turn, down-regulates further TAFIa production. Patients with impaired thrombin generation due to factor XI deficiency exhibit a bleeding tendency that is contributed to by excess fibrinolysis that may be attributed to reduced thrombin–TM-mediated activation of TAFI.[81] Extensive studies have been performed in mice lacking TAFI. However, the *in vivo* significance of TAFIa as a regulator of fibrinolysis remains controversial (reviewed in[82]), although elevated circulating levels of TAFIa in humans may confer a mild increased risk of thrombosis.[83] A role for TAFIa as a natural anti-inflammatory molecule has more recently become of greater interest with recognition of its ability to inactivate the anaphylatoxins C3a and C5a by des-argination.[84] Moreover, the proinflammatory mediators, bradykinin and osteopontin,[85] are also inactivated by TAFIa.

TM, encoded by an intronless gene, is a 557–amino acid, type 1 transmembrane glycoprotein (GP). It is expressed by endothelial cells in all vascular beds. The ectodomain of TM comprises a juxtamembranous serine/threonine-rich domain with potential sites for *O*-linked glycosylation which support the attachment of a chondroitin sulfate that enhances the activation of PC by thrombin–TM,[86] accelerates the neutralization of thrombin by heparin-AT, and facilitates binding of PF4 to PC to increase its activation. The next domain contains six epidermal growth factor (EGF)-like repeats. EGF-like repeats 3, 4, 5, and 6 (EGF3–6) are essential for thrombin-mediated activation of PC and TAFI.[87–90] Via its anion binding exosite I, thrombin binds to EGF5–6. EGF4–6 is required for activation of PC,[91] and EGF3–6 is required for TAFI activation.[92] An aspartic acid residue (Asp349) within EGF4 is required for Ca^{2+}-mediated binding of TM to the gamma-carboxyglutamic acid (Gla) containing domain of PC, and thus for activation of PC by thrombin. Oxidation of methionine 388, which resides between EGF4 and EGF5, abrogates thrombin's ability to activate PC, an event that likely occurs during inflammation when neutrophils are activated. At the *N*-terminus of the molecule, there is a globular *C*-type lectin-like domain.[93] This structure lacks anticoagulant function, but plays a major role in inflammation (FIGURE 43.4). Mice lacking the lectin-like domain of TM are more sensitive to endotoxin challenges and proinflammatory stimuli and exhibit increased tissue accumulation of neutrophils and monocytes, and excess activation of complement,[94] in part by preventing the proinflammatory cytokine high-mobility group box 1 from binding to the receptor for advanced glycosylation end products.[95]

As might be expected, endothelial TM expression is reduced in many prothrombotic conditions. This is achieved via transcriptional and posttranscriptional mechanisms. Thus, for example, shear stress,[96] oxidized LDL,[97] hyperhomocysteinemia,[98] proinflammatory cytokines,[99,100] sepsis,[101] and aging[102] are associated with suppressed TM levels and often enhanced TF exposure, an imbalance that promotes fibrin deposition. Conversely, TM is upregulated by VEGF and statins,[103,104] both of which may be vasculoprotective. Transgenic mice that carry a TM mutation that reduces its cofactor function in thrombin-mediated activation of PC exhibit increased fibrin deposition in the lungs.[105] Total inactivation of the TM gene is incompatible with life, and this is likely the same situation for humans, since no cases of homozygous deficiency have been reported. The clinical significance of TM mutations in venous and arterial thrombotic disease in humans otherwise remains controversial. Since the first report of familial thrombophilia associated with a TM gene mutation,[106] other mutations and polymorphisms in the coding region and the promoter region have been described, and several have been examined *in vitro* with mixed results.[107] In a large prospective analysis of men, the A455V and -1208-1209TTdelTT variants exhibited a small, but not statistically significant increased risk for coronary heart disease.[108,109] In some segments of the population, the Ala25Thr substitution is a risk factor for ischemic heart disease.[110] Mutations in the lectin-like domain and in the serine–threonine region have been associated with an increased risk of developing the thrombotic microangiopathy, atypical hemolytic uremic syndrome.[111] Overall, genome-wide association studies and advances in proteomics should provide more insights into the relevance of TM polymorphisms in human disease.

EPCR is also a transmembrane GP, constitutively expressed by endothelial cells, but more prominently in large vessels.[112,113] EPCR provides a platform for PC so that it may be more accessible for activation by thrombin–TM.[69,114] Lack of EPCR in mice

results in early embryonic lethality with thrombosis[115] while blocking its function postnatally with antibodies accelerates thrombus formation.[116] Its structural similarity to the major histocompatibility complex class 1/cluster of differentiation 1 family of proteins[117] and its expression by dendritic cells[118] suggests that it also likely regulates innate immunity.

EPCR is also a receptor for APC, with similar affinity as for PC. It has been generally accepted that APC interferes with coagulation only when dissociated from EPCR. This has recently been challenged by claims that when docked on EPCR, APC may actually more efficiently inactivate factor Va, particularly when the latter is associated with the endothelial cell surface (reviewed in[119]). Nonetheless, when complexed with EPCR, APC activates endothelial cell PAR-1, inducing many of its anti-inflammatory and vasculoprotective intracellular signals[119,120] (FIGURE 43.7). These include the release of sphingosine-1-phosphate (S1P), expression of the antiapoptotic Bcl-2,[121] augmented endothelial cell proliferation,[122–128] activation of Rac1, inhibition of RhoA and NF-κB signaling, prevention of expression of vascular adhesion molecules,[129,130] and enhanced endothelial barrier function.[131] With reduced expression of EPCR, which occurs in inflammation or injury, excess thrombin cleaves and activates PAR-1 which initiates a proinflammatory response[132] with increased vascular leakage. Although other pathways have recently been implicated,[133,134] EPCR may be considered a master regulator for APC–PAR-1 interactions.

EPCR is also a receptor for plasma coagulation factors VII and VIIa, binding with similar affinities as PC and APC.[135] As noted above, factor VIIa is the key initiating enzyme for the generation of factor Xa and downstream production of thrombin. The EPCR–factor VIIa complex is unable to activate PAR-1 or downstream coagulation factors IX or X, and inhibits the procoagulant activity of factor VIIa–TF.[136] EPCR binding to factor VIIa facilitates internalization of both molecules,[137] possibly providing a clearance mechanism for the procoagulant factor VIIa. These data further support the dual role of EPCR in suppressing inflammation and coagulation.

Both TM and EPCR circulate in the plasma in soluble forms. The literature for soluble TM remains controversial in that there are many fragments that are probably generated by proteolysis of endothelial TM, and the function(s) or the significance of these are not well defined. Soluble EPCR (sEPCR) is generated via alternative pre-mRNA splicing and by proteolytic shedding.[138] sEPCR circulates in normal human plasma, is increased in sepsis,[139] and in patients with the EPCR A3 haplotype. sEPCR binds to the proinflammatory proteinase-3[140–142] and to the integrin Mac-1 receptor on activated neutrophils.[143] The precise role of sEPCR is not known, but patients with the A3 haplotype are at increased risk of venous thromboembolic disease and coronary heart disease.[144–147]

FIBRINOLYSIS

The vascular endothelium is afforded protection from excess fibrin deposition by the action of the fibrinolytic system. The two major activators of fibrinolysis are tPA and uPA. tPA is released primarily by endothelial cells[148] and acts locally at the site of a fibrin clot by catalyzing conversion of plasminogen to plasmin, which in turn degrades fibrin. tPA release from Weibel-Palade bodies where it is stored, is enhanced by desmopressin (DDAVP), thrombin, bradykinin, and endothelin (ET).[149,150] The extent to which uPA contributes to the fibrinolytic response remains incompletely understood.[151] The strongest evidence is derived from genetic studies in mice in which uPA deficiency results in excess fibrin deposition.[152] However, uPA also facilitates cell migration and plays a critical role in tissue repair processes and angiogenesis.[153] uPA and its GPI-linked receptor, uPAR, are minimally expressed by resting endothelial cells, but increase upon stimulation with inflammatory cytokines.[154]

The endothelium also plays an active role in suppressing fibrinolysis. In response to procoagulant and inflammatory stresses,[155] plasminogen activator inhibitor-1 (PAI-1), the major physiologic inhibitor of tPA and uPA, is highly expressed by endothelial cells, thereby dampening the fibrinolytic response. There are two other PAIs, PAI-2 and PAI-3, but their roles in regulating fibrinolysis are less clear. Finally, and as noted previously, when bound to the endothelial cell integral membrane protein, TM, thrombin converts the procarboxypeptidase, TAFI, to its active form, which interferes with fibrinolysis.[80]

The fibrinolytic potential of endothelial cells of different vascular sites varies considerably.[156,157] For example, the absolute and relative amounts of tPA and PAI-1 released after thrombin

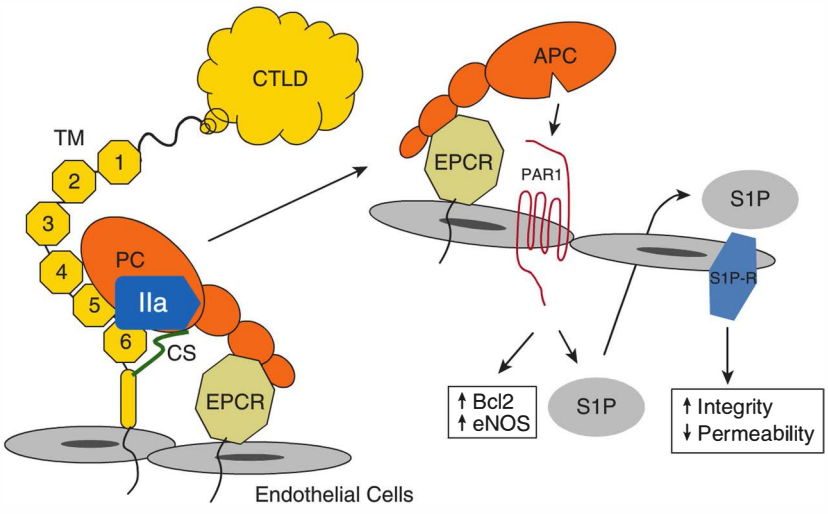

FIGURE 43.7 Vasculoprotective properties of APC. When complexed with EPCR, APC activates endothelial cell PAR-1, inducing anti-inflammatory and vasculoprotective intracellular signals that induce the release of sphingosine-1-phosphate (S1P), expression of Bcl-2, synthesis of endothelial nitric oxide synthase (eNOS), reduction of expression of leukocyte adhesion molecules, and enhancement of endothelial barrier function.

or cytokine stimulation are different with endothelial cells from the umbilical vein *versus* adult saphenous vein. tPA has been localized throughout the bronchial circulation, whereas its expression is much more limited in the pulmonary vasculature, only detected in 7 to 30 μm diameter vessels in the lungs of mice and nonhuman primates.[158] uPA is most prominent in the kidney as compared to many other tissues. And in healthy aortas, tPA is prominently expressed in the vasa vasorum, whereas PAI-1 is found in the aortic endothelium.[159] It is interesting to note that there is little evidence that defects in individual components of the fibrinolytic system (tPA, alpha2-antiplasmin, plasminogen, PAI-1) enhance the risk of venous or arterial thromboembolic disease.[160] This underscores the complexity of these pathways and the compensatory capacity of the endothelium.

PLATELET-ENDOTHELIAL CELL INTERACTIONS

The vascular endothelium has a remarkable capacity, under normal conditions, to prevent circulating platelets from inappropriate recruitment and activation that would otherwise result in vascular occlusion (reviewed in[161]). The intact endothelial monolayer provides a barrier function, separating platelets from subendothelial procoagulant agonists, such as collagen and von Willebrand factor (vWF). Endothelial cells also liberate vasodilatory and platelet-stabilizing factors, such as nitric oxide (NO), PGI_2, and CD39 (see below). In response to injury, the phenotype of the endothelium transforms such that it promotes recruitment, adhesion, activation, and focal aggregation of platelets to form a platelet-rich blood clot. This occurs primarily in the high-flow arterial circulation.[162] In the low-flow venous circulation, platelets play a lesser role, as activated coagulation factors can accumulate on damaged endothelial cell surfaces, allowing for local thrombin generation and fibrin deposition. It is on the venous side that the natural anticoagulant TFPI, heparin-AT and PC systems are most active.

Damaged or denuded endothelium uncovers a matrix to the circulation that is rich in collagen and vWF.[163,164] In response to arterial vascular injury, platelets bind directly to collagen types I and III via platelet GP VI and the integrin $\alpha_2\beta_1$, or indirectly via vWF that is complexed with the exposed collagen. vWF is a multimeric protein that is synthesized in endothelial cells and megakaryocytes and stored in platelet granules and in Weibel-Palade bodies in endothelial cells until released at a basal rate and in a regulated manner, induced by a range of chemical and mechanical agonists.[165,166] There is also a constitutively secreted pool of an uncleaved vWF precursor, the function of which remains unclear.[167] Multimeric vWF from the vessel wall or the circulation forms complexes both with collagen on the exposed vessel wall[168] and with P-selectin. Under high shear conditions, vWF that is immobilized to the endothelium via collagen, undergoes conformational changes,[169] revealing a binding site on its A1 domain that serves as a receptor for capturing fast-flowing platelets via GP Ibα-IX-V. This slows the transit of the rapidly moving platelets long enough to be activated by collagen, ADP (primarily from erythrocytes), and thrombin.[170] The platelets thus form an adherent layer on the damaged endothelium and provide a nidus upon which circulating platelets aggregate and "tether" to join the growing thrombus to establish a hemostatic plug.[171] Serious human disorders underscore the pivotal role of the endothelium in regulating the hemostatic function of platelets. For example, the key role of the endothelium in promoting platelet plug formation is evident from the most common hereditary bleeding disorder, von Willebrand disease, caused by qualitative or quantitative deficiencies in vWF.[172,173] In the rare syndrome, thrombotic thrombocytopenia purpura, the endothelium is believed to contribute to inappropriate thrombus formation by inadequate release of the metalloprotease, ADAMTS13.[174] The size and thus the platelet-aggregating and prothrombotic capacity of vWF multimers is normally held in check by proteolytic processing by ADAMTS13[174,175] that at least *in vitro*, may be released by endothelial cells.[176]

Understanding the role of the endothelium in platelet activation is also uncovering potential therapeutic targets. For example, CD39 is a vascular endothelial ectonucleotidase that hydrolyzes ADP to AMP, limiting platelet adhesion and activation by effectively neutralizing ADP that is released at the injury site by erythrocytes. Overexpression of CD39 in preclinical studies protects against ischemia reperfusion–induced vascular injury and organ damage.[177]

REGULATORS OF VASCULAR TONE

Vascular constriction is a normal physiologic hemostatic response to vascular injury, serving to help restrict blood flow, and orchestrated to occur in concert with formation of the platelet plug. The endothelium plays a pivotal role in regulating vasomotor tone primarily by releasing soluble mediators that cause vascular smooth muscle cells to relax or contract, thereby inducing vessel dilation or constriction, respectively. Many of the key mediators also exert direct or indirect effects on the hemostatic system.

Nitric Oxide

NO is generated by the enzymatic conversion of L-arginine to L-citrulline and is the most potent endothelial cell–derived vasodilator.[178,179] In endothelial cells, endothelial NO synthase (eNOS) is responsible for NO production, and is activated by bradykinin, ADP, shear stress, and proinflammatory cytokines. Endothelial-derived NO has several additional properties, some of which have direct effects on hemostasis.[180] NO interferes with the secretion of vWF, at least in part via S-nitrosylation of key signaling proteins that are required to drive membrane fusion and secretion of prestored vWF from Weibel-Palade bodies.[181] Release of NO from endothelial cells also reduces leukocyte–endothelial cell interactions and inhibits platelet adhesion and aggregation.[182] $eNOS^{-/-}$ mice exhibit increased leukocyte and platelet accumulation in models of inflammation.[183] Antiphospholipid antibodies that are associated with the antiphospholipid syndrome induce thrombosis partly by binding to apolipoprotein E receptor 2 on endothelial cells, inducing intracellular signals that attenuate the function of eNOS and that enhance TF expression.[184,185] Reduced endothelial NO release is also caused by activation of toll-like receptor 4 in response to injury or infection, with concomitant elevated expression of TNF-α, IL-6, and NF-κB, and has thus been linked to thrombosis and with cardiac microvascular endothelial dysfunction after ischemia reperfusion.[186,187]

Eicosanoids

Eicosanoids comprise several compounds that, in response to a range of stimuli, are synthesized from arachidonic acid, whereupon they are released into the extracellular space to act in autocrine and paracrine manners, inducing effects on vascular tone, reactivity, and endothelial cell integrity. The best-characterized and physiologically important products are PGI_2 and epoxy eicosatetraenoic acids (EETs).

PGI_2 is constitutively expressed by quiescent endothelial cells, but is rapidly upregulated by several agents, including thrombin, bradykinin, histamine, and cytokines (e.g., IL-1β, TNF-α).[188] Although the pattern and extent of expression is stimulus dependent, production of PGI_2 declines rapidly after stimulation, exerting potent but short-lived biologic effects. By binding to the so-called I-type prostaglandin receptor, PGI_2 mediates cAMP-dependent signaling pathways that suppress platelet aggregation and leukocyte reactivity, induce vasorelaxation, and antagonize the action of the potent vasoconstrictor and platelet aggregator, thromboxane A_2.[189] PGI_2 may also protect endothelial cells from hydrogen peroxide-induced apoptosis and TF expression via PPARδ pathways.[190,191] Several PGI_2 analogs are being evaluated clinically to treat pulmonary hypertension and intermittent claudication due to peripheral arterial disease.[192]

EETs are a diverse group of compounds that are synthesized by endothelial cells from many, but not all arteries, in response to agonists such as bradykinin or shear stress.[193,194] Their modes of action are complex, but most EETs act as endothelium-derived hyperpolarizing factors that induce arterial relaxation in the presence of NOS and cyclooxygenase inhibitors. In a concentration-dependent and vascular bed–specific manner, EETs suppress endothelial cell expression of proadhesive molecules such as vascular cell adhesion molecule-1, induce release of tPA, interfere with platelet adhesion to damaged endothelial cells, and protect against endothelial cell apoptosis.[195–197] Reversal of endothelial dysfunction via strategies that enhance delivery or expression of EETs represent a potentially viable approach to prevent or treat a range of thrombotic disorders.

Carbon Monoxide

Analogous to the NO/NOS system,[198] heme oxygenase-derived carbon monoxide (CO) plays an important role in hemostasis and vascular endothelial function, promoting vasodilation, suppressing pro-apoptotic and proinflammatory pathways, and interfering with platelet aggregation.[198] CO is endogenously produced in blood from the degradation of heme by the action of inducible and basal microsomal heme oxygenases (HO-1 and HO-2, respectively). Both forms, and possibly a third (HO-3), are found in most, if not all tissues, including endothelial cells and vascular smooth muscle cells, and are important in vasoregulation. In response to injury or stress, endothelial HO-1 is markedly up-regulated,[199] thereby increasing production of CO. Disruption of HO-1 activity in mice increases sensitivity to ischemia–reperfusion injury.[200] Conversely, HO-1 overexpression provides protection against myocardial, renal, and brain ischemia–reperfusion injury.[201,202] The most convincing evidence of an important role of HO-1 in modulating endothelial hemostatic system activity and vascular integrity comes from a child with HO-1 deficiency who developed a thrombotic microangiopathic hemolytic anemia with diffuse vascular endothelial damage and elevated circulating levels of soluble TM and vWF.[203] Taken together, there is strong rationale for considering HO-1 and/or CO as a primary or adjunct therapeutic target for hemostatic disorders associated with vascular endothelial damage.[204]

Endothelin

Countering its vasodilatory properties, the endothelium also produces and secretes several soluble factors that promote vasoconstriction and facilitate platelet activation, adhesion, and thrombus formation during disease. Prominent among these is ET. There are at least three isoforms of ET (ET-1, ET-2, and ET-3), all of which are pleiotropic 21–amino acid peptides that have potent vasoactive properties and that are involved in several pathologic processes (reviewed in[205]). ET-1 is the most abundant form in the vascular system. It is secreted by several cells, particularly in the cardiovascular, endocrine, and reproductive systems. Its inactive precursor, big ET-1, is highly expressed by endothelial cells,[206,207] yielding the mature active form through proteolytic cleavage by membrane-associated endothelin-converting enzymes (ECE-1 and ECE-2) and chymase (reviewed in[208]).[209] ET-1 is released from endothelial cells via 2 pathways; constitutively at low levels from vesicles,[210] and in a regulated manner from Weibel-Palade bodies in response to stimuli[211] such as thrombin, IL-1, oxidized LDL, epinephrine, and hypoxia.[212] Over 75% of ET-1 release is abluminal, while the minority is into the blood, consistent with it having paracrine and autocrine modes of action.

Although ET-1 is recognized as one of the most potent vasoconstrictors, its activities are tightly regulated and partly dependent on the relative expression and distribution of its two G-protein coupled receptors, ETA and ETB, which have largely opposing properties. ETA is highly expressed on vascular smooth muscle cells surrounding arteries, particularly in the lung and kidney, where stimulation by ET-1 triggers vasoconstriction and apoptosis.[213] ETA is also expressed on the surface of endothelial cells in several organs, including the brain, where it regulates blood brain barrier function.[214] On the other hand, ETB is prominently expressed on endothelial cells in veins and in the renal and pulmonary vascular endothelial cells, but is almost undetectable in normal aortic and coronary vessel endothelial cells.[213] Activation of ETB by ET-1 limits the vasoconstrictor response mediated via ETA by promoting the endothelial cell release of vasodilators such as NO and PGI_2, and by removing ET-1 from the circulation, probably by endocytosis.[208,215,216]

There is little evidence that ET-1 has direct effects on hemostasis. However, several lines of evidence indicate that with endothelial dysfunction associated with injury, inflammation, or aging, ET-1 facilitates progression to a thrombotic phenotype by enhancing TF expression,[217] platelet adhesion and activation, and leukocyte–endothelial cell interactions.[218] Several preclinical and clinical studies, using either ETA-selective or dual ETA/ETB pharmacologic blockade have demonstrated efficacy in preserving organ function, at least in part by improving vascular tone, endothelial integrity, and function.[205]

Other endothelial cell–derived molecules that cause vasoconstriction and play a role in the hemostatic response to injury include, for example, angiotensin II,[219] platelet-derived growth factor,[220] and FGF-1 and FGF-2.[221]

Complement

Protection from injury requires simultaneous and coordinated activation of coagulation to restrict bleeding and innate immunity to limit pathogen invasion. Several lines of evidence indicate that these two systems are linked via the endothelium, and the data are leading to new therapeutic strategies. The complement system, a major component of innate immunity, comprises over 30 soluble and membrane-bound proteins.[222] Three complement activation pathways converge to transform plasma factor C3 into C3b, with generation of the C3 and C5 convertases, release of the anaphylatoxins C3a and C5a, and formation of the C5b-9 membrane attack complex which promotes lysis of the pathogen. P-selectin that is translocated to the surface of thrombin-activated endothelial cells and platelets, acts as a receptor for C3b[223] which in turn, facilitates a localized and coordinated thrombotic and innate immune response at the site of injury. Endothelial cells also express receptors for the anaphylatoxins C3a and C5a, the latter of which triggers the release of vWF multimers from Weibel-Palade bodies, thereby promoting the deposition of platelet-rich fibrin clots. Indeed, inhibitors of C5 and the receptor for C5a have shown therapeutic efficacy in some clinical and preclinical trials for the thrombotic microangiopathy, atypical hemolytic uremic syndrome,[224] and for cerebral ischemia–reperfusion injury.[225] C5b-9 complexes are also deposited *in vivo* on endothelial cells. Although they are usually removed by vesiculation from the quiescent, undamaged endothelial cell membrane before lysis occurs, C5b-9 can at least transiently facilitate an influx of calcium into the cell, stimulating heterotrimeric G-proteins which upregulate TF and more vWF secretion.[226] C5b-9 containing vesicles that are shed from the endothelial cell surface provide docking sites for factors Va and Xa which support prothrombinase assembly.[227,228] The *in vivo* significance of the C5b-9 complex in endothelial hemostatic system activity remains incompletely understood, although it likely plays a role in thrombotic syndromes involving complement fixing antiendothelial antibodies.[229]

ENDOTHELIAL CELL DIVERSITY AND ITS IMPACT ON HEMOSTASIS

Endothelial cells are plastic and heterogeneous, anatomically and functionally, with differences reflected during growth and development, in response to specific stresses, and based on their spatial distribution in different organs (e.g., lung, liver, brain, pancreas, eye) and the types and calibers and locations of vessels (e.g., vein, lymphatic, artery, arteriole, capillary).[230,231] This heterogeneity is reflected in hemostasis most notably by site-specific and age-dependent differences in bleeding and thrombosis.[232] For example, patients with hemophilia tend to bleed into their joints, whereas those with primary platelet function defects suffer primarily from mucosal bleeds. Hemolytic uremic syndrome mainly affects the kidneys. Patients with heterozygous deficiency of PC, PS, or AT develop lower limb clots, yet homozygous PC deficiency and warfarin-induced skin necrosis cause diffuse microvascular thrombosis. Atherothrombotic disease has an early predilection for coronary, carotid, and femoral arteries. Finally, aging is a major determinant of both venous thromboembolic disease and of atherothrombotic disease. Investigators are only just starting to study the mechanisms by which endothelial heterogeneity impacts on hemostasis. However, viewing the endothelium in this context is critical for understanding the pathogenesis of disorders associated with excess bleeding and/or thrombosis, and for the strategic design of more effective diagnostics and therapeutics.

Coagulation-Independent Signaling of the Extrinsic Coagulation Pathway

WOLFRAM RUF

Tissue and vascular injury requires a rapid hemostatic response that is critically dependent on the tissue factor (TF)-initiated extrinsic coagulation pathway. TF triggers coagulation by forming a catalytic cofactor–enzyme complex with coagulation factor VIIa (VIIa), converting factor X to Xa, and thereby initiating the common downstream coagulation pathway, activating platelets, and converting fibrinogen to fibrin. TF is required for embryonic development in the mouse,[1–3] and no deficiencies of TF have been reported in humans. The central role of TF–VIIa complex formation for postnatal hemostasis is underscored by the highly similar phenotypes of genetically engineered mice in which TF or VII expression levels are severely reduced. These mice develop cardiac microbleeds, progressive fibrosis, and heart failure.[4] Expression of TF in a variety of cell types in mouse and man[5,6] supports a role in providing a "hemostatic envelope" around organs and at boundaries to the environment, but TF also has broader functions beyond providing hemostasis and maintaining vascular integrity.

Expression of TF by leukocytes and blood-derived monocytes initiates coagulation that is pivotal for intravascular sequestration of microorganisms in host defense[7] and for fibrin formation supporting cell-mediated immune responses in extravascular locations.[8,9] Conversely, excessive activation of the TF procoagulant pathways drives disseminated coagulation and lethality in sepsis.[10] However, TF is also a direct regulator of myeloid cell-dependent inflammation.[11,12] Thus, the concept is emerging that TF-initiated coagulation and direct cell signaling cooperate to protect from infection and regulate innate immune cell function.

TF expression by nonhematopoietic cells also has nonhemostatic functions. TF is synthesized by smooth muscle cells where it can initiate acute intravascular thrombosis following vessel wall injury.[13] In addition, TF is upregulated by growth factor stimulation and promotes smooth muscle cell migration and intima hyperplasia.[14,15,16–18] TF expressed by smooth muscle cells or endothelial cells has been implicated in angiogenic processes by coagulation-independent pathways.[19,20,21,22,23] TF is expressed by epithelial cells in the gastrointestinal tract and plays a pivotal role in coagulation activation and inflammatory cell recruitment in experimental colitis.[24] TF is distinctly expressed in the basal layers of epithelial barriers in the skin, and reduced wound healing in VII-deficient mice indicates roles for the TF–VIIa complex in stimulating epithelial migration and wound closure.[25]

The association of TF with cell adhesion integrin receptors,[26,27] cytoskeletal structures and cell–cell contacts,[28–30] and a promigratory G protein–coupled receptor, the protease-activated receptor (PAR)2 provides molecular connections by which TF can support regenerative tissue repair as well as cancer progression. This chapter reviews the basic mechanisms of TF-initiated cell signaling and our current understanding as to how these noncoagulant roles of the TF pathway support physiologic and pathologic processes.

MOLECULAR CELL BIOLOGY OF TF

TF is evolutionary related to the cytokine receptor family, and the TF extracellular domain shares the cytokine receptor architecture of two fibronectin type III domains aligned in an elongated manner with an angled and rigid intramodule interface.[31–34] However, the TF cytoplasmic domain lacks the typical cytokine receptor tyrosine kinase recognition motifs. Instead, a Ser/Thr-Pro phosphorylation site that is the target for unidentified Pro-directed kinases is highly conserved in all mammalian species.[35] Phosphorylation of the canonical Ser258 in the human TF cytoplasmic domain requires prior protein kinase C–dependent phosphorylation of a more amino-terminal Ser–Xxx–Lys motif[35–37] and is regulated by palmitoylation of a conserved membrane proximal Cys residue[36,38] (FIGURE 44.1). The phosphorylated TF cytoplasmic domain has a more compact structure, and phosphorylation might thus prevent or promote the binding of intracellular adaptor proteins supporting TF trafficking.[39]

The TF extracellular domain mediates ligand interactions with each of the structural domains of VIIa. The docking of the protease domain leads to allosteric activation of catalytic activity of the zymogen-like protease VIIa,[40] whereas interactions of the VIIa light chain with the carboxyl-terminal module of TF confer high-affinity binding and stable TF–VIIa complex formation necessary for efficient activation of macromolecular substrates X and IX. The details of these procoagulant interactions of TF have been elucidated at the molecular level.[41–44] On cell surfaces, a substantial portion of TF is not involved in the initiation of coagulation, although these pools of TF bind VIIa and activate its catalytic activity. Procoagulant TF, as found on activated monocytes, has high affinity for VIIa (K_D < 1 nM), but noncoagulant cell surface pools of TF are only saturated at higher concentrations of VIIa.[45–47] Chemical cross-linking and the binding of substrate-dependent inhibitors[48] or antibody reactivity[49] indicate that the noncoagulant pools of TF have a distinct tertiary or quaternary structure. Heterogeneity of cell-surface TF is also evident from functional dose–response curves, demonstrating that higher concentrations (5 to 20 nM) of VIIa are required to saturate pools of TF involved in direct TF–VIIa signaling.[49,50,51]

Multiple factors contribute to the functional and structural heterogeneity of cell-surface–expressed TF. Negatively charged surfaces containing phosphatidylserine increase the measured

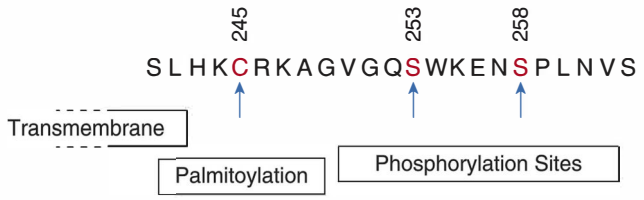

FIGURE 44.1 Features of the human TF cytoplasmic domain.

affinity of VIIa for TF in purified systems.[52,53] The cellular lipid environments surrounding TF could alter TF structure[54] or increase VIIa affinity through contacts of the VIIa Gla domain. TF is found in phospholipid-rich as well as glycosphingolipid-rich raft microdomains and caveolae of the cell membrane. The dynamic trafficking of TF between subcellular locations is a critical determinant for TF procoagulant activity.[55–58] TF cell-surface expression is regulated by basolateral sorting in endothelial and epithelial cells,[59] and basolateral sorting and formation of cell–cell contacts influences cell-surface procoagulant activity and changes TF glycosylation.[49,60]

Human TF has three extracellular *N*-linked glycosylation sites that to a variable degree determine the overall carbohydrate content of the molecule.[61–63] Whereas secretion of recombinant soluble TF extracellular domain is markedly reduced by mutation of the most amino-terminal *N*-linked glycosylation site,[61] overexpression of full-length TF in commonly used cell lines did not reveal reduced procoagulant activity following mutation of any of the TF glycosylation sites.[63,64] However, biochemical comparison of highly purified TF from natural and recombinant sources demonstrated that recombinant TF has less complex, high mannose carbohydrates, while natural TF recovered from a particular thromboplastin reagent contains only hybrid, highly fucosylated, and sialylated sugars.[65] Natural TF has higher specific procoagulant activity, indicating that these complex carbohydrates significantly modulate TF activity. Recent experiments in mice show that TF glycosylation either marks or is required for cell-surface expression of TF in epithelial cells *in vivo*. A rapid change in TF glycosylation in intestinal epithelial cells occurs following colonization of the small intestine with microbiota, and the resulting cell-surface expression of TF triggers coagulation, procoagulant PAR1 signaling, and adaptive angiogenesis.[66]

The carbohydrate composition of proteins is determined by intracellular trafficking and recycling routes. Ligand binding of VIIa to TF induces internalization and degradation, but a significant portion of procoagulant TF recycles back to the cell surface with its ligand VIIa associated.[67] TF–VIIa endocytosis and the subsequent mobilization of additional pools of TF from the Golgi are regulated by the activation of PAR2.[68,69] In addition, the TF–VIIa–Xa ternary coagulation initiation complex is inhibited on cells by TF pathway inhibitor (TFPI). TFPI is anchored to the cell surface by a glycosylphosphatidyl-inositol (GPI) lipid attachment, either by direct protein modification of the splice variant TFPIβ or potentially by binding to an unidentified GPI-anchored receptor in the case of TFPIα.[56,70–72] TFPIβ is mainly responsible for regulating TF procoagulant function and represents the major GPI-anchored form in endothelial cells in culture.[73,74] TFPI is coexpressed in most tissues with an androgen-induced, raft localized protein that regulates TFPI expression and inhibitory activity.[75] GPI-anchored TFPI directs the TF ternary complex to caveolae and initiates a slow recycling pathway that eventually restores in part both TF coagulant activity and TFPI inhibitory control on the cell surface.[56,76] Thus, binding of VIIa or formation of the ternary coagulation initiation complex are not static cell-surface events, but promote cellular trafficking and internalization of TF.

TF function in thrombosis and cell signaling is under the control of thiol–disulfide exchange pathways.[49,77] *In vitro* and *in vivo* evidence supports roles for protein disulfide isomerase (PDI)–mediated thiol exchange in regulating TF procoagulant activity, microparticle release, and thrombosis.[49,78–81] The TF extracellular domain has a surface exposed Cys186–Cys209 disulfide bond with a redox potential indicative of a functional, allosteric disulfide that can undergo reversible reduction and oxidation.[77,82] Mutational breaking of this disulfide impairs procoagulant activity,[83] but an intact disulfide is not required for direct TF–VIIa cell-signaling activity that is supported by a TF mutant with a single, unpaired Cys186 with a dose–response curve indistinguishable from wild TF.[49] Precise mechanisms of breaking the allosteric disulfide on cells remain to be elucidated, and it is still debated whether thiol modifications of TF itself is the predominant regulator of cellular procoagulant function.[84,85] Evidence that cell-surface PDI is associated with TF on cells expressing a TF–PAR2 signaling complex indicates that disulfide exchange is a cellular pathway that can switch certain cellular pools of TF to a selective signaling receptor.[49]

TF-SIGNALING COMPLEXES AND CORECEPTORS CONTRIBUTING TO PROTEOLYTIC PAR ACTIVATION

Groundbreaking studies by Hans Prydz and colleagues demonstrated that the upstream coagulation proteases VIIa and Xa elicit cell-signaling events that are dependent on their proteolytic activities, but independent of thrombin-mediated activation of PARs.[86,87] VIIa in addition to TF-expressing cells activates several signaling cascades and transcriptional responses, as documented subsequently in various experimental systems.[88–93] TF–VIIa signaling prevents apoptosis and anoikis (cell death following loss of adhesion).[94,95] Several of these TF–VIIa signaling events, including the activation of mitogen-activated protein kinase (MAPK) pathways and the upregulation of kinase cascades promoting protein synthesis, were found to be independent of the TF cytoplasmic domain in overexpression systems.[91,96]

The intracellular signaling elicited by VIIa was reminiscent of thrombin signaling through the G protein–coupled receptor PAR1, but a candidate PAR receptor that is cleaved by TF–VIIa remained elusive.[97] Reconstitution experiments clearly demonstrated that TF–VIIa signals through the thrombin-insensitive PAR2.[98,99] Experiments with blocking antibodies or knockdown approaches confirmed the critical role of PAR2 as a signaling receptor for TF–VIIa in normal and transformed cells.[51,100,101] Similarly, PAR2 emerged as the receptor that mediates signaling of Xa,[102–104] but Xa also cleaves PAR1 directly and independent of thrombin generation.[105] The structure–function analysis of PAR2 cleavage by TF–VIIa identified hotspots for binding of PAR2 in the VIIa catalytic cleft and enabled the design of PAR2 variants that are selectively activated by TF–VIIa, but not Xa.[106] Thus, PAR2 is a common signaling receptor for upstream coagulation proteases of the TF pathway, but distinct coreceptors

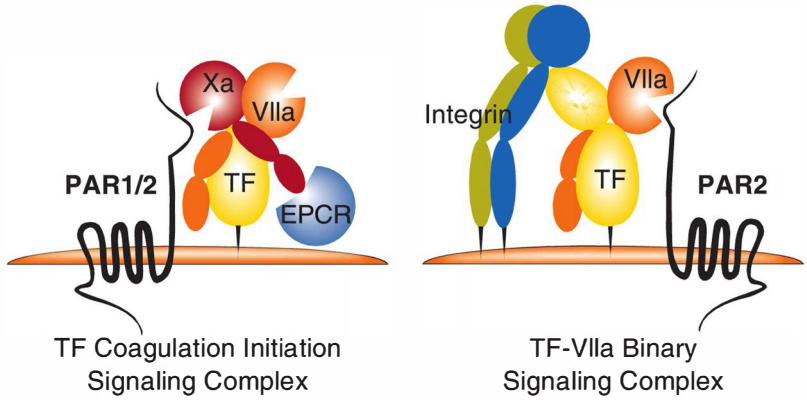

FIGURE 44.2 Schematic overview of the proteolytic TF-signaling complexes and associated coreceptors.

further diversify the signaling responses induced by proteolytic activation *via* TF–VIIa or Xa (FIGURE 44.2).

The combined addition of VIIa and X to TF-expressing cells is a potent stimulus for PAR2 signaling that occurs concomitantly with coagulation activation.[98,99] Although high concentrations of VIIa elicit cell signaling independently of Xa generation, it is the nascent product Xa in the high-affinity TF–VIIa coagulation initiation complex that primarily cleaves and activates PAR1 or PAR2.[49,99] Cell-surface–anchored TFPI not only regulates the procoagulant function but also signaling of the ternary TF–VIIa–Xa complex *via* PARs.[107] Thus, initiation of coagulation is mechanistically coupled with cell-signaling events and controlled by the physiologic inhibitor of the TF pathway. This principle similarly operates in the anticoagulant pathway in which the thrombomodulin–thrombin complex generates activated protein C (APC).[108] Initiation of the anticoagulant pathway is supported by Gla domain–mediated binding of PC to the endothelial cell protein C receptor (EPCR),[109] which subsequently supports APC-mediated cytoprotective PAR1 signaling.[110,111]

A broader role for EPCR is emerging, because EPCR binds not only APC but also VIIa with similar affinity,[112,113] and EPCR has been implicated in Xa-mediated PAR1 activation in overexpression systems.[114] The low affinity of X/Xa for EPCR relative to VIIa and APC[115] suggested a preferred interaction of TF–VIIa with EPCR. However, mutations of the VIIa Gla domain that severely reduce EPCR binding were without effect on PAR cleavage by either the binary or the TF–VIIa–Xa ternary complex.[116] In contrast, signaling of the ternary TF–VIIa–Xa complex was strictly dependent on EPCR, in both human and mouse cells,[116,117] indicating that EPCR is involved in functional interactions with Xa, rather than VIIa. These initial data indicate that EPCR is a cosignaling receptor for both procoagulant and anticoagulant protease complexes, a concept that requires further exploration *in vivo*.

An entirely different class of receptors participates in signaling of the binary TF–VIIa complex. On epithelial cell surfaces, VIIa at concentrations required to elicit cell signaling promotes the association of TF with integrin heterodimers, foremost integrins $\alpha_3\beta_1$ and $\alpha_6\beta_1$ involved in basal membrane anchoring and epithelial cell migration.[27] An anti-TF antibody was identified that has no appreciable anticoagulant activity and no effect on VIIa binding to TF on cells. This antibody prevents VIIa-induced association of TF with integrins and potently inhibits TF–VIIa binary complex–induced chemokine production, but not signaling of the TF–VIIa–Xa ternary complex.[27,49] Thus, distinct surface pools of TF are involved in the noncoagulant and coagulation-associated cell-signaling events of the TF pathway. Whereas TFPI controls signaling of the ternary TF–VIIa–Xa complex, it is currently unknown whether signaling of the binary TF–VIIa complex is similarly regulated by protease inhibitors that can neutralize the TF–VIIa complex, including GPI-anchored TFPI,[118] antithrombin,[119,120] or plasminogen activator inhibitor 1.[121]

TF–VIIa promotes transcriptional responses in epithelial cells. In noncancerous cells, the TF–VIIa signaling-induced transcriptional program indicates roles in wound healing and tissue repair.[88,93] Extracellular matrix–regulated TF–VIIa signaling in tumor cells elicits an even broader array of antiapoptotic proteins, angiogenic regulators, chemokines, and growth factors for myeloid cells.[122] These mediators are predicted to change the cellular composition and vascular organization of the tumor microenvironment.

TF SIGNALING IN THE REGULATION OF CELL MIGRATION

Coagulation-independent functions of TF in cell adhesion and migration were uncovered by the demonstration that immobilized ligands for TF, including VIIa and TF antibodies, promote spreading of TF-positive cells.[28] Similarly, cells expressing the TF–VIIa binary complex bind matrix- and potentially cell-associated TFPI to engage in proadhesive interactions.[123] Chimeric receptors with an unrelated extracellular domain demonstrated a critical role for the TF cytoplasmic domain in the induction of actin polymerization and colocalization of the actin-binding protein filamin A at sites of TF-induced cell adhesion points.[28] TF ligation induces cell migration through activation of the small GTPase Rac and the p38 MAP kinase pathway.[124] Smooth muscle cell migration toward inactive VIIa is markedly reduced in mice lacking the TF cytoplasmic domain ($TF^{\Delta CT}$ mice).[125] Consistently, intima hyperplasia after injury is impaired in $TF^{\Delta CT}$ mice[125] or mice deficient in smooth muscle cell TF.[15]

Although these functions of the TF cytoplasmic domain were uncovered in experiments that utilized inactive extracellular ligands for TF, proteolytic signaling of TF-bound VIIa promotes promigratory PAR2 signaling[101] and the phosphorylation of the TF cytoplasmic domain.[126] PAR2 recruits the intracellular adaptor protein β-arrestin.[127] β-arrestins are best known for their role in receptor internalization and desensitization, but the recruitment of β-arrestin to PAR2 targets and activates the MAP

kinase extracellular signal–regulated kinase to pseudopodia of migrating cells[128] and promotes breast cancer migration through the cofilin pathway that is crucial for cytoskeleton reorganization.[129–131] TF is closely associated with the cell adhesion machinery, because the TF extracellular domain is a ligand for several integrin heterodimers of the β_1 integrin family as well as the integrin $\alpha_v\beta_3$.[26] In noncancerous cells, VIIa promotes TF coprecipitation with these integrin heterodimers under cell lysis conditions that preserve lipid-raft structure.[27] TF expression results in a marked, TF cytoplasmic domain–dependent reduction of integrin $\alpha_3\beta_1$-dependent migration of melanoma cells on the extracellular matrix protein laminin 5. However, addition of VIIa reverses this inhibitory effect by inducing TF cytoplasmic domain phosphorylation.[26] Thus, the TF cytoplasmic domain regulates the function of integrins that interact with the extracellular domain of TF.

In mesenchyme-derived smooth muscle cells and fibroblasts, TF–VIIa–PAR2 signaling synergizes with platelet-derived growth factor (PDGF) BB-induced migration by Src kinase-dependent crossphosphorylation of the PDGF receptor.[20,132] This promigratory response also requires the TF cytoplasmic domain for efficient cell migration.[133] In cancer cells, TF–VIIa–PAR2 signaling–stimulated production of the promigratory chemokine interleukin-8 (IL-8) plays additional essential roles in promoting cell migration and invasion.[51] Thus, VIIa is crucial for outside-in signaling that regulates TF cytoplasmic domain function and promigratory effects of PAR2 signaling.

TF-DEPENDENT SIGNALING PATHWAYS IN ANGIOGENESIS

Much of our understanding of the functional contribution of TF-signaling pathways to physiologic and pathologic processes is derived from results in genetic mouse models. Deletion of the TF gene revealed an important role for TF in developmental angiogenesis.[1] In the absence of TF, pericyte recruitment and maturation of the yolk sac vasculature is reduced in a phenotype that is very similar to the loss of PAR1 signaling in endothelial cells.[134,135] TF on both smooth muscle and endothelial cells contributes to the formation of vascular structures in an *in vitro* coculture assay.[19] TF expression in endothelial cells upregulates the chemokine CCL2, a gene induced by endothelial PAR1 signaling.[111] While pericyte recruitment to sprouting vessel *in vivo* is critically dependent on PDGF-BB signaling,[136] CCL2 may enhance smooth muscle cell recruitment to newly formed endothelial tubular structures.[19] However, cell type–specific deletion of TF from either endothelial or smooth muscle cells is compatible with normal embryonic development, indicating that residual TF expression due to incomplete gene deletion or functional redundancy of vessel wall cell-derived TF is sufficient to generate proteases to locally trigger PAR1 signaling.[13,137] Consistently, TF-deficient mice that are reconstituted with a human TF transgene to approximately 1% of normal activity also develop normally with no apparent embryonic vascular abnormalities.[138]

The concept that TF is not a *bona fide* initiator of angiogenesis but rather a modulator of angiogenic processes is further supported by studies of postnatal angiogenesis. Deletion of the cytoplasmic domain of TF is dispensable for embryonic angiogenesis,[139] but altered postnatal angiogenesis is found in $TF^{\Delta CT}$ mice. Colonization of the gut with microbiota induces broad adaptive changes, including angiogenesis in the small intestine that improves nutrient uptake. Vascular remodeling in the small intestine following microbial colonization is prevented by anti-TF treatment and requires the TF cytoplasmic tail downstream of PAR1 signaling in epithelial cells.[66] In this context, TF-PAR1 signaling increases the expression of the proangiogenic angiopoietin 1 (Ang1) and stimulates a paracrine signal to expand and remodel the intestinal villi vasculature.

In contrast, the postnatal development of the retina superficial vascular plexus occurs faster in $TF^{\Delta CT}$ relative to wildtype mice.[21] Increased vascular sprouting was also seen from $TF^{\Delta CT}$ relative to wildtype aortic rings *in vitro*. This phenotype is dependent on PAR2 and requires VIIa and PDGF-BB, suggesting that the TF cytoplasmic domain in vessel wall cells counteracts *de novo* sprouting angiogenesis. Further studies confirmed *in vivo* that the proangiogenic phenotype of $TF^{\Delta CT}$ mice is dependent on PAR2 and growth factor signaling.[140] The oxygen-induced retinopathy model mimics the hypoxia-driven angiogenesis observed in premature infants. In this model, $TF^{\Delta CT}$ mice revascularized areas of central vasoobliteration significantly faster than wildtype controls. The enhanced angiogenesis was abolished by genetic deletion of PAR2, but not of PAR1, as well as the tyrosine kinase inhibitor Gleevec, which blocks PDGF-BB receptor signaling, or a specific inhibitor of the TF-VIIa complex, NAPc2.[140] NAPc2 has also direct effects on host angiogenesis in tumor models, and these effects are not recapitulated by coagulation blockade with direct inhibitors of Xa.[141] These data implicate vessel wall TF signaling in the regulation of hypoxia-driven angiogenic processes *in vivo*.

TF localization to endothelial cells is observed in pathologic angiogenesis in tumors and endometriosis.[22,142] TF is not necessarily synthesized by the endothelium, because recent data point to important roles of alternatively spliced TF (asTF) in the regulation of angiogenesis. The TF mRNA can be spliced in two distinct gene products, full-length TF with a transmembrane anchor and cytoplasmic domain, or asTF that lacks exon 5 encoding an extracellular region involved in substrate X binding. Instead asTF has a unique carboxyl-terminus translated from an alternative reading frame of exon 6 with a concomitant deletion of the transmembrane domain.[143] A genetic mouse model expressing normal levels of human full-length TF, but no asTF, has no spontaneous bleeding or developmental abnormalities, excluding that asTF is a significant contributor to developmental angiogenesis.[144] In contrast, overexpression of asTF by tumor cells promotes angiogenesis[145] and purified asTF induces endothelial cell sprouting *in vitro* and *in vivo* independent of ligand VIIa binding.[146] Proangiogenic effects of asTF are mediated by ligation of endothelial cell-expressed integrins $\alpha_6\beta_1$ and $\alpha_v\beta_3$. Both asTF and the unspliced TF extracellular domain share a binding site tentatively localized by antibody inhibition studies to an amino-terminal region in proximity to the VIIa-binding site.[146,147]

Integrin-dependent endothelial activation by asTF also upregulates leukocyte adhesion molecules and enhances monocyte–endothelial interactions.[148] This pathway is likely distinct from TF-dependent transmigration and reverse migration of monocytes that is blocked by an antibody localized to an epitope that is not contained in the asTF sequence.[149] The endothelium has the capacity to take up TF^+ microparticles released from stromal,[150] immune,[151] or tumor cells.[152] Full-length TF transfer can induce changes in endothelial function through integrin ligation[153]

or promote PAR2-dependent signaling in hypoxic endothelial cells.[152] These paracrine transsignaling pathways of asTF or TF^+ microparticles may occur locally as part of the TF-dependent regulation of angiogenesis or wound healing.[23,154] Our understanding of these mechanisms is currently incomplete, and the roles of alternative ligands for TF, including plasminogen and its proteolytic fragment angiostatin, have not been studied *in vivo*.[155–157]

TF SIGNALING IN CANCER PROGRESSION

TF is expressed by multiple cell types in the tumor microenvironment, but tumor cell–expressed TF is a key marker for poor outcome and tumor progression.[158] TF expression in cancer cells is caused by tumor-specific oncogenic events,[159–161] and tumor cell TF expression significantly enhances tumor growth through TF cytoplasmic domain–dependent regulation of angiogenesis.[162,163] Oncogenic transformation or hypoxia also cause ectopic synthesis of VIIa[164,165] and upregulate PAR2,[164,166] endowing tumor cells with an autonomous upstream coagulation signaling pathway that can operate prior to tumor angiogenesis-induced vessel leaks and extravasation of coagulation factor from the blood. A comprehensive gene profiling study in breast cancer cells[122] compared gene induction of TF–VIIa–PAR2 with the direct activation of the thrombin receptor PAR1. This approach identified highly selective cancer cell responses to TF–VIIa–PAR2 signaling, including induction of proangiogenic chemokines and growth factors (IL-8, CXCL1, and vascular endothelial growth factor C) and immune regulators such as granulocyte macrophage colony stimulating factor (CSF2) and macrophage colony stimulating factor (CSF1).

The identification of an antibody that selectively blocks human TF–VIIa–PAR2 signaling enabled unique approaches to specifically address the roles of TF signaling in tumor growth and angiogenesis. Aggressive clinical breast cancer is characterized by an upregulation of TF and PAR2.[166] Tumor growth of a TF–PAR2 signaling–competent breast cancer cell line was inhibited by signaling blockade selectively on tumor cells, whereas an anticoagulant anti-TF antibody was without significant effects.[27] TF–VIIa signaling blockade reduced angiogenesis, supporting *in vitro* studies that tumor cell TF–VIIa–PAR2 signaling is proangiogenic. Treatment with this antibody also induced similar tumor growth inhibition in glioblastoma[167] and melanoma,[27] although some of these tumors are also sensitive to coagulation blockade.[168] Thus, tumor cell–expressed TF initiates significant proangiogenic signaling though PAR2 activation, even in the context of triggering the coagulation cascade in the tumor microenvironment.

Genetic approaches further demonstrated tumor-promoting roles of TF–PAR2 signaling. The mammary tumor virus promoter-driven expression of the polyoma middle T antigen (PyMT) results in spontaneous development of breast cancer in mice that mimics important aspects of human breast cancer progression. PAR1 deficiency had no effect on the incidence, growth, and metastasis to the lungs of breast cancer in the PyMT model.[169] In contrast, $PAR2^{-/-}$ mice displayed a significant delay in the transition from adenomas to invasive carcinoma. PyMT $PAR2^{-/-}$ early tumors were less vascularized, showed lower levels of the chemokine CXCL1, and had less abundant macrophages relative to wildtype tumors. Reconstitution of PAR2 in PyMT $PAR2^{-/-}$ cells directly showed that tumor cell, rather than host PAR2 signaling, supports breast cancer development.[170] Consistent with the clinical observation that PAR2 expression and TF cytoplasmic domain phosphorylation is closely correlated with cancer recurrence and that TF cytoplasmic domain phosphorylation is reduced in PyMT-$PAR2^{-/-}$ tumors,[166] $TF^{\Delta CT}$ mice showed delayed spontaneous breast cancer development similar to $PAR2^{-/-}$ mice in this oncogene-driven model.[170] In a different model of cancer development, the $Apc^{Min/+}$ mouse, which models colon cancer development in familial adenomatous polyposis, inhibiting TF–VIIa signaling and coagulation with the inhibitor NAPc2, also significantly reduced the number of intestinal tumor nodules that spontaneously develop.[171] Thus, TF-dependent upstream coagulation signaling is an important pathogenetic event in tumor progression.

TF–PAR2 SIGNALING IN INFLAMMATION AND METABOLIC DISORDERS

TF in monocytes and macrophages is induced by toll-like receptor agonists (lipopolysaccharide [LPS]), oxidized lipoproteins, and the inflammatory cytokine interferon γ and suppressed by anti-inflammatory cytokines, including IL-4 and IL-10 that promote alternative macrophage activation.[172,173] While roles of TF in promoting disseminated intravascular coagulation in the most extreme form of acute inflammation, that is sepsis, are well appreciated, TF signaling more broadly and directly regulates the function of mononuclear phagocytes. VIIa induces proinflammatory cytokines in endotoxin-stimulated monocytes *in vitro*,[174] which may explain the reduced inflammatory responses of endotoxin-challenged mice with very low levels of VII.[175] VIIa induces reactive oxygen species production in monocytic cells, and this effect is dependent on the TF cytoplasmic domain.[176] Mice that lack the TF cytoplasmic domain, but retain the cytosolic palmitoylation site ($TF^{\Delta CT}$ mice), are protected from inflammation and lethality in endotoxemia models,[177,178] and the TF cytoplasmic domain regulates MAPK activation in LPS-stimulated macrophages.[178]

TF not only plays a role in acute, but also in chronic inflammation. Cutaneous delayed-type hypersensitivity requires macrophage TF^8 and is significantly attenuated in $TF^{\Delta CT}$ mice.[179] In animal models of arthritis, blocking TF with active site–inhibited VIIa decreases synovial thickness as well as cartilage damage,[180] and both PAR1 and PAR2 contribute to arthritis severity.[181,182] Arthritis severity is similarly reduced in $TF^{\Delta CT}$ mice, and reduced macrophage inflammation is observed in these experiments.[183] $TF^{\Delta CT}$ mice and PAR2-deficient mice are similarly protected from antiphospholipid antibody–induced pregnancy complications.[12] Thus, TF and PAR2, in many cases dependent on functional crosstalks with the TF cytoplasmic domain, play important roles in the regulation of inflammation.

Chronic macrophage inflammation in the visceral adipose tissue is important for the development of type 2 diabetes and the metabolic syndrome associated with obesity in mouse models.[184] TF expression is increased in the adipose tissue in genetic models of obesity relative to nonobese mice,[185] and circulating TF is detectable at increased levels in the blood of patients with signs of low-grade inflammation and insulin resistance.[186] TF is also upregulated in models of diet-induced obesity and specifically expressed on macrophages in the inflammation-prone visceral adipose tissue of mice. Adipose tissue macrophages of $TF^{\Delta CT}$ and PAR2 knockout mice express reduced levels of inflammatory cytokines.[11] In addition, acutely blocking macrophage TF signaling rapidly attenuates inflammation and reduces

insulin resistance in obese mice. Similarly, reduced levels of TF in hematopoietic cells have beneficial effects on hepatic inflammation and steatosis in mice fed a proatherogenic diet.[187,188] Surprisingly, $TF^{\Delta CT}$ or PAR2 mice also developed less obesity.[11] VIIa association with adipocyte-expressed TF directly influences insulin signaling and suppresses adiponectin, a systemic regulator of insulin resistance and energy expenditure.[11] These data provide initial evidence that TF is not only a prothrombotic mediator in the complications of obesity and metabolic disorders, but rather a significant contributor to the development of these diseases.

THERAPEUTIC PERSPECTIVES

These studies document noncoagulant roles of upstream coagulation proteases and TF in regenerative processes, angiogenesis, cancer, inflammation, and metabolic diseases. In several of these physiologic and pathologic contexts, TF initiates coagulant responses that provide the platform and support the full biologic complexity of multicellular interactions, for example in inflammatory lesions or the tumor microenvironment. Nevertheless, prototypic antibody reagents that selectively block direct TF signaling are effective in scenarios where coagulation inhibitors also have partial efficacy.[11,27,167,168,189,190] Thus, TF signaling makes significant and independent contributions to pathologic processes. The elucidated basic mechanisms of TF signaling identify distinct targets to interrupt these pathways, including the interaction of TF with integrins, catalytic activities of the TF-associated proteases VIIa or Xa, and the activation of PAR2 as the central receptor for proteolytic signaling by upstream coagulation proteases. Considering the broad biologic functions of PAR2, PAR2 antagonists may not specifically target TF-signaling pathway. Our current basic understanding of TF signaling further predicts that direct inhibitors of Xa will not provide the same antisignaling effects as inhibitors that block the activity of VIIa. Crucial next steps are to evaluate the expanding clinical experience with direct inhibitors for Xa and thrombin in the context of these basic research findings and to explore the clinical profiles of direct VIIa inhibitors for their efficacy to attenuate disorders with potential direct TF-signaling contributions.

CHAPTER

45 Heparin and Vascular Proteoglycans

DOUGLAS M. TOLLEFSEN AND LIJUAN ZHANG

Heparin is a sulfated glycosaminoglycan isolated from mammalian tissues that are rich in mast cells. When administered intravenously, heparin binds to the plasma protein antithrombin (previously known as antithrombin III), causing it to rapidly inhibit proteases of the intrinsic and common coagulation pathways. This interaction produces a potent anticoagulant effect. Endogenous heparin-like molecules appear to be involved in the inhibition of coagulation within normal blood vessels and may have a variety of other biologic functions. Although heparin is an effective agent for the treatment of venous thromboembolic disease, unstable angina, and acute myocardial infarction, it occasionally produces life-threatening bleeding or triggers an immune reaction, causing thrombocytopenia associated with venous and arterial thrombosis.

HISTORICAL OVERVIEW

The term *heparin* was used by Howell[1] in 1923 to describe an aqueous extract of canine liver that inhibited coagulation of blood *in vitro*. These extracts later were shown to consist of mixtures of sulfated polysaccharides containing uronic acid and glucosamine.[2] The suggestion that heparin might be used to treat thromboembolism was initially greeted with skepticism because of the fear that patients given heparin would bleed to death. According to Jaques,[3] this fear was allayed by a dramatic demonstration conducted by Charles Best at the University of Toronto in 1937:

> Best asked me [Jaques] to anesthetize a dog, prepare it for laparotomy, and inject heparin intravenously. When the most illustrious surgeons in the world arrived, Best explained what I had done (a blood sample which I had taken was incoagulable). Best then picked up a scalpel and handed it to Dr. Balfour with the request that he make a midline incision. The surgeons, properly dressed in their morning suits, jumped back, whereupon Best made the incision and I applied haemostats to two tiny bleeding points and showed a clean dry incision. Within months of this demonstration, surgeons all over the world took up heparin enthusiastically.

Canadian and Swedish investigators reported success in the use of heparin to treat recurrent thrombosis and pulmonary embolism in 1939.[2,4] The indications for heparin were soon expanded to include vascular surgical procedures, extracorporeal circulation, and prophylaxis of thromboembolism.

Despite the ensuing widespread clinical use of heparin, its mechanism of action remained obscure for several decades. As early as 1895, "thrombin" had been observed to lose activity gradually when added to defibrinated plasma or serum[5]; this inhibitory potential became known as the progressive antithrombin activity. In 1939, Brinkhous et al.[6] showed that heparin was effective as an anticoagulant only in the presence of a nondialyzable plasma component that they termed *heparin cofactor*. These early observations were linked in 1968, when Abildgaard[7] reported that a single protein (i.e., antithrombin) isolated from human plasma possessed both progressive antithrombin and heparin cofactor activity. Rosenberg and Damus[8] purified larger quantities of antithrombin, enabling a more detailed physicochemical characterization of the protein. Subsequently, a second protein with heparin cofactor activity was purified from plasma by Tollefsen et al.[9] and termed *heparin cofactor II* (HCII).

In the sections that follow, we discuss the structure, biosynthesis, and isolation of heparin and heparan sulfate (HS); the synthesis of anticoagulantly active heparan sulfate proteoglycans (HSPGs) by endothelial cells; the physiologic role of the heparin–antithrombin system; some of the nonanticoagulant actions of heparin; the synthesis of anticoagulant heparin analogs; and the interaction of HCII with glycosaminoglycans. A discussion of the structures and mechanisms of action of antithrombin and HCII is presented in Chapter 18.

STRUCTURE AND BIOSYNTHESIS OF HEPARIN AND HEPARAN SULFATE

Heparin is a highly sulfated polymer built on a backbone of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues[10,11] that is widely distributed in the animal kingdom, being found in both vertebrates and invertebrates.[12] In mammals, heparin is initially synthesized in mast cells as a heparin proteoglycan in which multiple heparin chains, each containing 100 to 150 disaccharide units, are covalently linked to a core protein called *serglycin*.[13,14] Once generated, the heparin proteoglycan is degraded by three different types of lysosomal enzymes: (i) proteases that cleave the polypeptide chain; (ii) endoglycosidases that cut the heparin chain between glucuronic acid and glucosamine residues; and (iii) exoglycosidases that remove monosaccharide units from the nonreducing ends of heparin oligosaccharides.[15] The degraded products are then stored in the secretory granules of mast cells, which are widely distributed in a variety of organs, including the liver, heart, lungs, kidneys, and intestine.

Mammalian cells also synthesize HSPGs that consist of core proteins with covalently attached HS chains of 50 to 150 disaccharide units.[16] Both heparin and HS chains exhibit structural diversity, which arises from various patterns of *N*-sulfation, *N*-acetylation, and *O*-sulfation of the disaccharide units. The distinction between heparin proteoglycan and HSPGs is based on (i) the structure of the core protein; (ii)

the location of the glycoconjugate within the cell; and (iii) the relative amounts of *N*-acetylglucosamine and glucuronic acid present in the carbohydrate chains. In particular, the heparin core protein is small and relatively simple in structure with extended runs of Ser–Gly attachment sites,[13,14,17] whereas HS core proteins are large and more diverse in structure[18] with short runs of Ser–Gly or closely spaced Ser–Gly attachment sites[19]; heparin proteoglycan is found within mast cell granules, whereas HSPGs are located on cell surfaces or in the surrounding matrix[20]; and heparin contains larger amounts of *N*-sulfate, *O*-sulfate, and iduronic acid, whereas HS is less extensively modified.

Biosynthesis of a heparin or HS proteoglycan occurs in the Golgi apparatus and is initiated by attachment of a linkage region tetrasaccharide containing one xylose, two galactose, and one glucuronic acid to the serine hydroxyl group of a Ser–Gly (or Ala) dipeptide in the core protein.[10,11] The formation of heparin/HS chains depends on nearby acidic or hydrophobic residues or close spacing of Ser–Gly sites.[19–21] In humans, the heparin core protein serglycin contains an extended run of eight Ser–Gly repeats, in which virtually all of the Ser residues become modified with the linkage region tetrasaccharide. The tetrasaccharide is synthesized by the sequential action of four glycosyltransferases (xylosyltransferase, galactosyltransferase I, galactosyltransferase II, and glucuronyltransferase I) that use uridine diphosphate (UDP) sugars as their substrates. The structures of serglycin and its linkage region are depicted in FIGURE 45.1.

Immediately after formation of the linkage region tetrasaccharide, α-*N*-acetylglucosaminyltransferase I adds an *N*-acetylglucosamine residue and thereby commits the nascent chain to the heparin/HS biosynthetic pathway (see FIGURE 45.2).[11] Linkage region tetrasaccharides on other core proteins can be modified at this stage by β-*N*-acetylgalactosaminyltransferase I, resulting in biosynthesis of chondroitin sulfate or dermatan sulfate chains.[20] The heparin/HS chain is assembled by the alternate incorporation of glucuronic acid and *N*-acetylglucosamine from the corresponding UDP sugars. This is accomplished through the action of copolymerases that are members of the *EXT* gene family having β-glucosaminyltransferase II and α-*N*-acetylglucosaminyltransferase II activities. Thereafter, this simple copolymer is modified by a concerted process that leads to different modifications in various regions of the glycosaminoglycan chain.

First, glucosamine residues are partially *N*-deacetylated, and the exposed amino groups serve as acceptors of sulfate groups in a transfer reaction with 3'-phosphoadenosine-5'-phosphosulfate (PAPS). These two reactions are carried out by a bifunctional enzyme, *N*-acetylglucosamine *N*-deacetylase/*N*-sulfotransferase (NDST), which is composed of a single polypeptide chain. Four isoforms of human NDST (NDST-1, -2, -3, and -4) have been identified, differing in their expression in various tissues and in their relative *N*-deacetylase and *N*-sulfotransferase activities.[22] Mice that lack NDST-2 do not synthesize mast cell heparin but produce HS,[23,24] whereas mice that lack NDST-1 produce undersulfated HS and die at birth of lung failure.[25,26] At this stage of biosynthesis, the nascent heparin or HS polymer contains stretches of *N*-sulfoglucosamine interspersed with unmodified *N*-acetylglucosamine residues.

Next, glucuronic acid residues are variably epimerized to iduronic acid by glucuronyl C5-epimerase. Then the iduronic acid residues and, to a lesser extent, glucuronic acid residues are partially *O*-sulfated at the C2-position. Finally, the glucosamine moieties are *O*-sulfated to a variable extent at the C6- and the C3-positions. Epimerization and *O*-sulfation occur only in regions of the polymer that contain

Ser, serine; Gly, glycine; Xyl, xylose; Gal, galactose; GlcA, glucuronic acid; GlcNAc, *N*-acetyl-glucosamine.

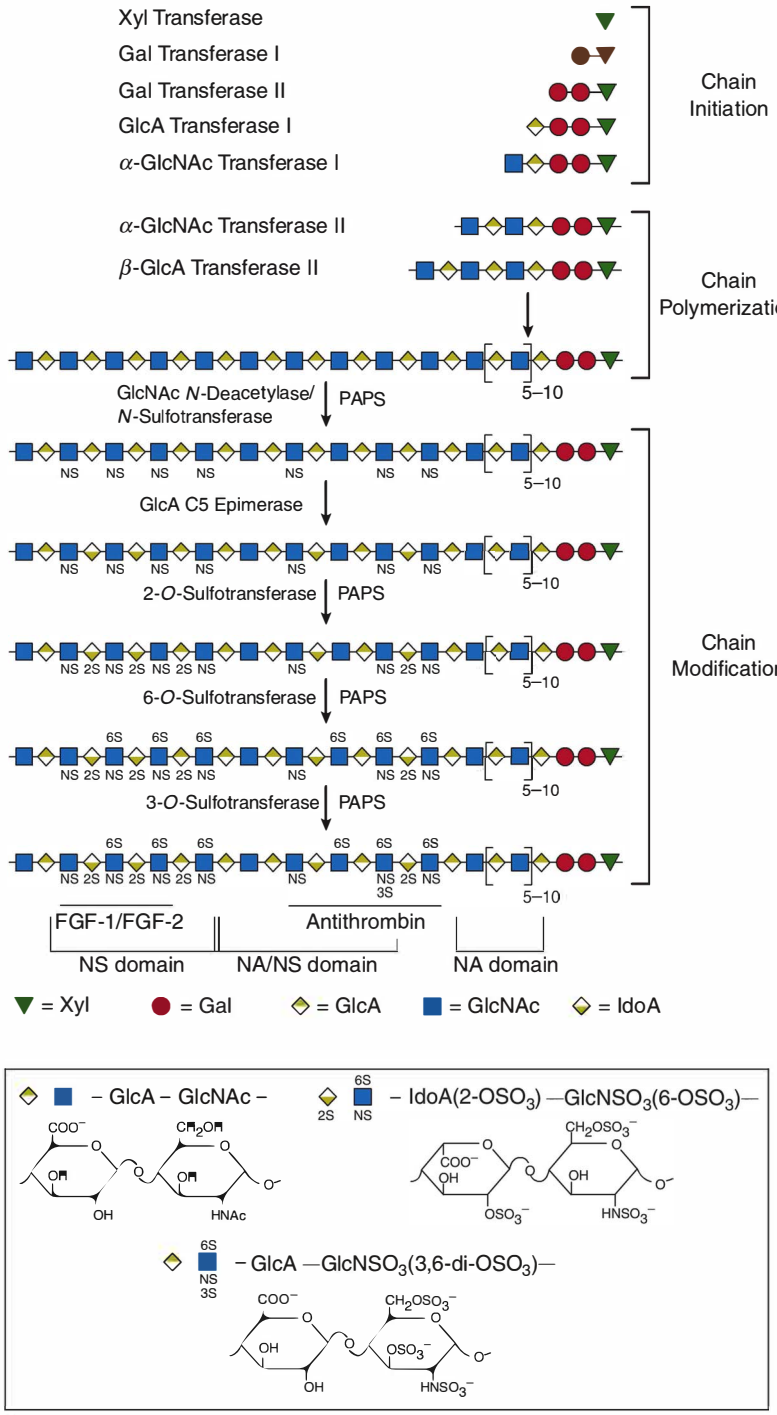

FIGURE 45.2 Heparin/HS biosynthesis. The symbols are defined by the structures shown below the scheme. Representative tracts of contiguous *N*-acetylated disaccharide units (NA domains), contiguous *N*-sulfated sequences of variable length (NS domains), and alternating *N*-acetylated and *N*-sulfated units (NA/NS domains) in HS are indicated. Heparin is predominantly composed of a single, extended NS domain. Regions that have been implicated in binding of fibroblast growth factors FGF-1/ FGF-2 and antithrombin are shown. IdoA, iduronic acid; PAPS, 3′-phosphoadenosine-5′-phosphosulfate. Other abbreviations are defined in the legend to FIGURE 45.1. (Reprinted from Esko JD, Lindahl U. Molecular diversity of heparan sulfate. *J Clin Invest* 2001;108:169–173, with permission.)

N-sulfoglucosamine, but these modifications are incomplete. As a result, a wide variety of oligosaccharide structures can be formed, each having the ability to interact with a different protein (e.g., antithrombin) or class of proteins (e.g., fibroblast growth factors [FGFs] or viral capsid proteins).[10] One HS 2-*O*-sulfotransferase, three HS 6-*O*-sulfotransferases, and six HS 3-*O*-sulfotransferases have been identified in humans.[22] Multiple isoforms make possible tissue-specific and developmentally regulated expression of the corresponding enzyme activities. Because the enzymatic properties of the isoforms may differ in subtle ways, their selective expression may be responsible for unique oligosaccharide sequences found in heparin/HS in different tissues and different animals. For example, 3-*O*-sulfotransferase-1 (3-OST-1) is primarily responsible for sulfation of the C3-position of glucosamine in the sequence GlcA-GlcNS, which gives rise to the high-affinity antithrombin-binding site (discussed in the subsequent text).

ANTITHROMBIN-BINDING SEQUENCES IN HEPARIN

A segment of a heparin chain containing an antithrombin-binding site is depicted in FIGURE 45.3. It is important to emphasize that this sequence is only one of many possible arrangements of uronic acid and glucosamine moieties found elsewhere in the polymer. As progress was being made in defining various aspects of the biosynthesis, linear sequence, and three-dimensional configuration of heparin and HS, it was tacitly assumed that heparin may exhibit numerous alternative structures equally capable of interacting with antithrombin.[27] This assumption was shown to be incorrect in 1976, when several groups demonstrated that only approximately 30% of commercial heparin is able to bind to antithrombin but that the bound fraction is responsible for virtually all of the anticoagulant activity.[28–30]

These findings led to investigations designed to determine the structural differences between active/high-affinity (AT+) and inactive/low-affinity (AT−) heparin species.[27] Rosenberg et al.[31] showed that oligosaccharides produced from high-affinity heparin were enriched in a tetrasaccharide sequence that contained glucuronic acid and *N*-acetylglucosamine. Leder[32] isolated an enzyme that removes sulfate from the 3-*O* position of glucosamine, and Lindahl et al.[33] showed that this substituent is critical for high-affinity binding of heparin to antithrombin. These observations were confirmed and extended by Choay et al.[34,35] who synthesized a series of pentasaccharides that are able to catalyze the factor Xa–antithrombin reaction. The contributions of individual substituents within the antithrombin-binding pentasaccharide have been evaluated by comparing the avidity of synthetic oligosaccharides for antithrombin.[36] On the basis of these data, the relative importance of individual residues is shown in FIGURE 45.4. The presence of an *N*-sulfate in place of the *N*-acetyl group on the first glucosamine residue increases the affinity for antithrombin approximately twofold. Similarly, the 2-*O*-sulfate and 6-*O*-sulfate groups on the fourth and fifth residues of the pentasaccharide increase the affinity but are not

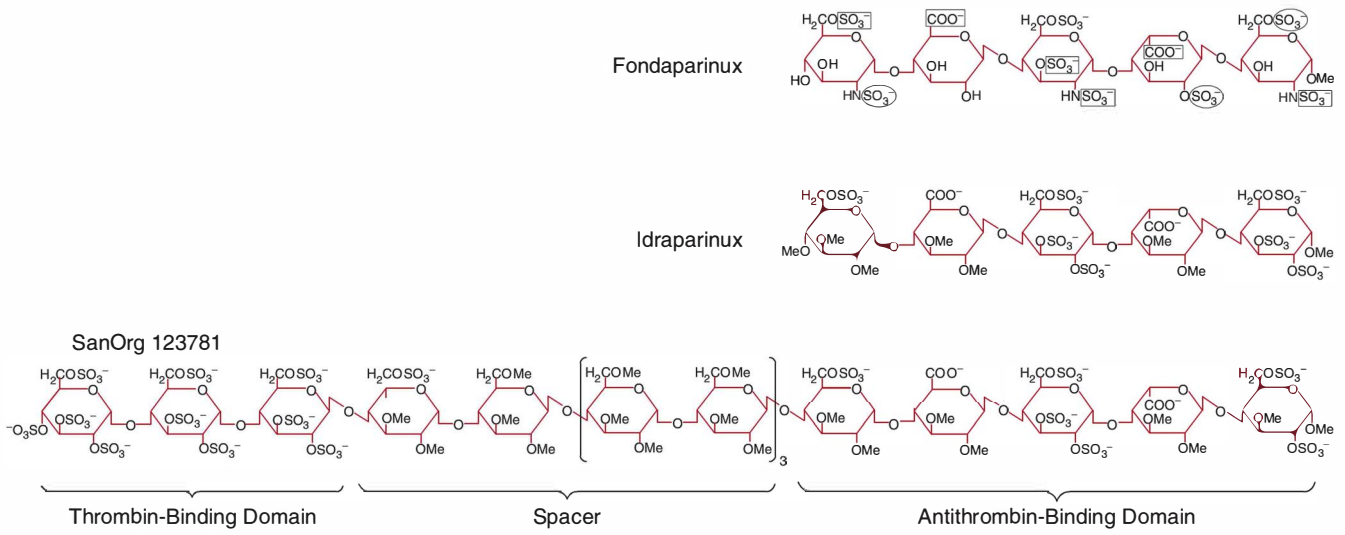

FIGURE 45.4 Synthetic heparin–like oligosaccharides. Sulfate and carboxylate groups required for high-affinity binding to antithrombin are indicated by *boxes* in the structure of fondaparinux. Sulfate groups that are not essential but that contribute to high-affinity binding are *circled*.

absolutely required for high-affinity binding. Therefore, some variability in the structure of heparin at these sites is compatible with antithrombin binding and anticoagulant activity. In contrast, certain structures are critical for antithrombin binding, including the presence and orientation of carboxylate groups on the two uronic acid residues, the 6-*O*-sulfate on the first glucosamine, the 3-*O*-sulfate and *N*-sulfate on the middle glucosamine, and the *N*-sulfate on the last glucosamine of the pentasaccharide.

Although synthetic heparin pentasaccharides that bind to antithrombin with high affinity accelerate the factor Xa–antithrombin interaction, they do not significantly increase the rate of neutralization of thrombin or other hemostatic enzymes. Isolation of oligosaccharides derived from partial chemical depolymerization of heparin revealed that molecules at least 16 monosaccharide units in length are required to accelerate both the thrombin–antithrombin and factor Xa–antithrombin interactions.[37] For inhibition of factor Xa to occur, it is sufficient to form a binary complex between heparin and antithrombin that leads to a conformational change in the reactive site loop of the inhibitor. To facilitate thrombin inhibition, however, longer heparin chains must bind simultaneously to thrombin and antithrombin to form a ternary thrombin–heparin–antithrombin complex. These differences in mechanism of inhibition explain why smaller heparin molecules can inhibit factor Xa while failing to inhibit thrombin. The inhibitory mechanism of antithrombin is discussed in more detail in Chapter 18.

SYNTHESIS OF ANTICOAGULANTLY ACTIVE HEPARAN SULFATE PROTEOGLYCANS BY ENDOTHELIAL CELLS

Mast cells were once thought to be the only site of synthesis of anticoagulantly active heparin. These cells are located beneath the endothelium and sequester heparin within their secretory granules,[38] where it forms crystalline arrays with cationic molecules such as histamine and neutral proteases. Ordinarily, heparin is not released from mast cells into the circulation; one exception may be patients with systemic mastocytosis, in whom small amounts of heparin can appear in the bloodstream and slightly prolong the activated partial thromboplastin time.[39] Therefore, mast cell heparin is unlikely to affect hemostasis under normal circumstances. These considerations led to the suggestion that endothelial cells might synthesize HSPGs endowed with the critical oligosaccharide structure required to bind and activate antithrombin.[40] In parallel investigations of the structure of anticoagulantly active mast cell heparin, HSPGs synthesized by endothelial cells were shown to contain a small subpopulation (~1%) of HS that binds antithrombin with high affinity (HS^{AT+}) and accelerates inhibition of thrombin and factor Xa by antithrombin *in vitro*.[41] These studies suggested that HS^{AT+} might be a major physiologic modulator of hemostasis.

Early investigations revealed that HS is present in the aorta and other vessels and exhibits trace amounts of anticoagulant activity.[42,43] It proved difficult, however, to rule out the possibility that mast cells were the source of this material. Direct evidence that endothelial cells are able to generate anticoagulantly active HSPGs was eventually obtained by Marcum and Rosenberg,[44] who studied cloned microvascular endothelial cells isolated from the rat epididymal fat pad. They showed that polysaccharides extracted from these cells possessed antithrombin accelerating activity that could be completely eliminated by treatment with purified *Flavobacterium* heparinase. Virtually all of the heparin-like material could be harvested by a brief exposure of the endothelial cells to dilute trypsin, which suggested that these components are located on the cell surface. Furthermore, metabolic labeling of the polysaccharides with [^{35}S]sulfate, followed by affinity fractionation with antithrombin and structural analysis, revealed the presence of oligosaccharide structures typically found in anticoagulantly active commercial heparin. Similar studies conducted with cloned bovine aortic endothelial cells gave virtually identical results and indicated that the level of anticoagulantly active HS species present would correspond to approximately 50,000 antithrombin-binding sites per endothelial cell.[45] This estimate of surface-bound anticoagulantly active polysaccharide was in excellent agreement with the data generated by characterization of the interactions of antithrombin with bovine aortic tissue sections.

Two major endothelial cell core proteins that are endowed with anticoagulantly active HS chains have been characterized. Kojima et al.[46] isolated intact HSPGs from rat microvascular endothelial cells using a combination of ion-exchange chromatography, affinity fractionation with antithrombin, and gel filtration in denaturing solvents. The anticoagulantly active HSPGs bound to antithrombin ($HSPG^{AT+}$) constituted approximately 5% of the total HSPGs and were endowed almost entirely with anticoagulantly active HS chains, whereas the anticoagulantly inactive HSPGs that did not interact with antithrombin ($HSPG^{AT-}$) represented approximately 95% of the total HSPGs. The two types of HS chains had the same molecular mass of approximately 25 to 30 kDa, and the anticoagulantly active HS chains possessed a single antithrombin-binding region. The core proteins of $HSPG^{AT+}$ and $HSPG^{AT-}$ were isolated after treatment with *Flavobacterium* heparitinase and purification by ion-exchange chromatography. Peptide mapping studies suggested that $HSPG^{AT+}$ and $HSPG^{AT-}$ contained the same two major core proteins with molecular masses of 50 and 30 kDa.

The primary sequences of internal peptides derived from the HSPG core proteins were used to clone two cDNAs from a rat microvascular endothelial cell library.[47] The first cDNA constituted a previously unidentified species, termed syndecan-4 (ryudocan), whereas the second cDNA represented the rat ortholog of syndecan-1. The latter molecule was a known proteoglycan that was originally thought to be limited in its distribution to epithelial cells. The two cDNAs encode integral membrane proteins of 202 amino acids (syndecan-4) and 313 amino acids (syndecan-1), which have extraordinarily homologous transmembrane and intracellular domains but very distinct extracellular regions. Syndecan-4 has three potential glycosaminoglycan attachment sites in its extracellular domain, whereas syndecan-1 has five. Both molecules are expressed at high levels (0.1% to 0.5% of total mRNA) in primary endothelial cells, primary smooth muscle cells, and primary fibroblasts. The possibility that slightly different core proteins direct the synthesis of $HSPG^{AT+}$ and $HSPG^{AT-}$ was excluded by stably expressing an epitope-tagged syndecan-4 in cells that synthesize anticoagulantly active and anticoagulantly inactive HS chains; after isolation of the proteoglycan with a specific antibody against the epitope, both HS^{AT+} and HS^{AT-} were found to be present.[48] This finding suggested that the presence of HS biosynthetic enzymes rather than expression of specific core proteins determines the fine structure of the HS chains. Further studies

suggested that in addition to syndecan-1 and syndecan-4, glypican-1[49] and perlecan[50] synthesized by endothelial cells also bear anticoagulantly active HS chains.

The HS biosynthetic pathway generates limiting amounts of $HSPG^{AT+}$ with regions of defined structure that contain the antithrombin-binding site; this pathway also produces the more abundant $HSPG^{AT-}$ with regions of varying structure that carry out other biologic functions. Analyses of cell mutants, created by overexpression of the syndecan-4 core protein or by chemical mutagenesis, revealed that anticoagulant HS generation requires a component present in limiting amounts.[51,52] To identify this component, a cell-free system was developed by Shworak et al.[53] in which wild-type microsomes were incubated with radiolabeled HSPG precursor extracted from mutant cells blocked during $HSPG^{AT+}$ generation; coincubation of these two extracts resulted in the production of large amounts of $HSPG^{AT+}$. Furthermore, in many different cell types, the concentration of this "microsomal conversion activity" correlated with the cell's ability to generate $HSPG^{AT+}$. Treatment of microsomal and cell surface HSPGs from wild-type cells with excess microsomal conversion activity transformed up to 35% of total HSPGs into $HSPG^{AT+}$. This extent of conversion was much greater than the normal levels of cell surface $HSPG^{AT+}$, which average approximately 1% to 5% of total HSPGs.[53] These investigations provided evidence that a microsomal component limits transformation of small amounts of a HSPG precursor population into $HSPG^{AT+}$.

The assay described in the preceding text was then used to isolate the limiting component, which proved to be the long-sought glucosaminyl 3-OST-1.[54,55] This enzyme usually is present in trace amounts as compared to other HS biosynthetic enzymes. When 3-OST-1 is no longer limiting, the cell's capacity to generate HS^{AT+} is determined by the abundance of HS^{AT+} precursors.[56] *In vitro* 3-*O*-sulfation with purified 3-OST-1 was used to tag the regions of the HS^{AT+} precursors destined to become antithrombin-binding sites and allow the HS^{AT+} precursors to be captured. The tagged regions were then structurally examined.[57] It was shown that six 3-*O*-sulfation sites existed per HS^{AT+} precursor chain. At least five out of the six 3-*O*-sulfate-tagged oligosaccharides in HS^{AT+} precursors bound antithrombin, whereas none of 3-*O*-sulfate-tagged oligosaccharides from HS^{AT-} precursors bound antithrombin. When treated with low pH nitrous acid or heparitinase, 3-*O*-sulfate-tagged HS^{AT+} and HS^{AT-} precursors exhibited clearly different structural features: They had different uronic acid epimerization and *O*-sulfation patterns around the 3-*O*-sulfate acceptor sites. 3-*O*-sulfate-tagged HS^{AT+} hexasaccharides were antithrombin affinity purified, sequenced by chemical and enzymatic degradation, and shown to have structures compatible with the antithrombin-binding sequence illustrated in FIGURE 45.3. The differences in structure surrounding potential 3-*O*-sulfate acceptor sites in HS^{AT+} and HS^{AT-} precursors suggested that these precursors might be generated by different concerted assembly mechanisms in the same cell.[57]

ANATOMIC LOCATION OF ANTICOAGULANTLY ACTIVE HEPARAN SULFATE PROTEOGLYCANS

The anatomic location of $HSPG^{AT+}$ was investigated by de Agostini et al.,[58] who perfused normal rat aorta for short periods of time with ^{125}I-antithrombin and observed that the labeled protein was bound to the aortic subendothelium (see FIGURE 45.5). Quantitation of the data revealed that only approximately 1% of the bound ^{125}I-antithrombin was associated with the luminal surface of the endothelium and that only small amounts were associated with smooth muscle cells or connective tissue deeper in the vessel wall. The labeled antithrombin was also noted to bind to regions around capillaries, especially in the subendothelium associated with the basal lamina/basement membrane. Perfusion of the aorta with ^{125}I-antithrombin–labeled

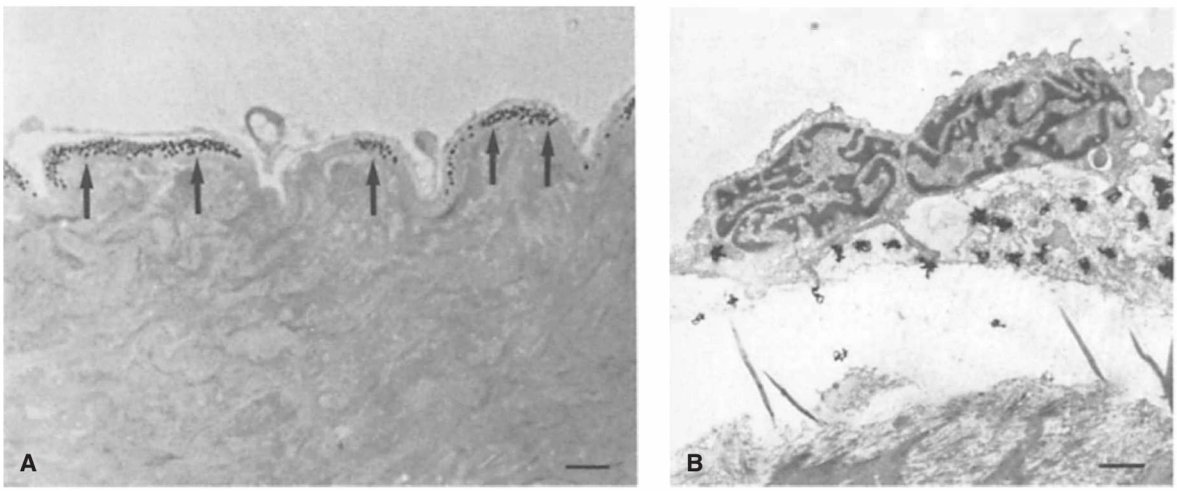

FIGURE 45.5 Autoradiography of normal rat aortas perfused with ^{125}I-antithrombin. **A:** Light microscopic autoradiograph. Intense labeling is present in the basement membrane beneath the endothelial cells (*arrows*). Bar, 10 μm. **B:** Electron microscopic autoradiograph. Labeling is again evident beneath the endothelium. Bar, 1.0 μm. (Reprinted from de Agostini AI, Watkins SC, Slayter HS, et al. Localization of anticoagulantly active heparan sulfate proteoglycans in vascular endothelium: antithrombin binding on cultured endothelial cells and perfused rat aorta. *J Cell Biol* 1990;111:1293–1304, with permission.)

bovine serum albumin produced no detectable binding, which indicated that the binding of ^{125}I-antithrombin within the aorta was not due to nonspecific interactions or trapping of the labeled protein. To demonstrate that the ^{125}I-antithrombin specifically interacted with HS chains, the vasculature was perfused with *Flavobacterium* heparinase before perfusion with labeled antithrombin. This treatment effectively prevented any binding of ^{125}I-antithrombin to all regions, including the subendothelium, while leaving the endothelial layer intact.

These data were consistent with the known synthesis of HSPG^{AT+} by endothelial cells and suggested that the proteoglycans are released from these cells and accumulate predominantly in the basement membrane. This observation suggested two possible ways in which coagulation system activity could be regulated by blood vessel wall HSPG^{AT+}. On the one hand, the small amounts of luminal HSPG^{AT+} could be in a critical position to bind and activate antithrombin and thereby regulate hemostatic activity at the blood–vessel wall interface. The much larger quantities of abluminal HSPG^{AT+} could serve as a potential reservoir that could be brought into play with extensive damage to the overlying endothelium. On the other hand, plasma antithrombin may have relatively free access to the much greater amounts of HSPG^{AT+} that accumulate on the abluminal surface of the endothelial cells, as suggested by studies that document the permeability of the endothelial cell layer.[59] Indeed, the presence of ^{125}I-antithrombin bound to subendothelium after *ex vivo* perfusion suggests that this region is readily accessible to antithrombin. The accessibility of subendothelial HSPG^{AT+} would also explain kinetic tracer data, which suggest that 10% to 20% of antithrombin partitions to an extravascular compartment.[60] These observations imply that coagulation proteases might be inhibited by antithrombin bound to HSPG^{AT+} in the subendothelium.

Marcum et al.[61] obtained evidence that intact blood vessels possess HSPGs that stimulate the activity of plasma antithrombin. In their experiments, rat hindlimb preparations were perfused with purified thrombin at a constant level, and purified antithrombin was infused at several different concentrations. The amount of thrombin–antithrombin complex formed within the vasculature was estimated by a specific radioimmunoassay for the interaction product. The rate of complex formation was enhanced 19-fold in the animal with respect to the uncatalyzed rate *in vitro*. The antithrombin-stimulating activity detected in the hindlimb vasculature appeared to be due to an HSPG, because the rate of thrombin–antithrombin complex formation was reduced to the uncatalyzed rate by preinfusion of the vasculature with *Flavobacterium* heparinase. Furthermore, when the hindlimb preparation was perfused with antithrombin chemically modified at Trp49 to decrease its affinity for HS, complex formation also occurred at the uncatalyzed rate. Finally, when purified human platelet factor 4 (PF4) was added to the perfusion stream along with antithrombin, thrombin inhibition occurred at the uncatalyzed rate. These data suggested that PF4, after being released from activated platelets, may play a role in thrombogenesis by neutralizing anticoagulantly active vascular HSPGs. Similar results were obtained with mice genetically deficient in mast cells, strongly suggesting that mast cell heparin plays little or no role in this phenomenon.[62]

In summary, it appeared likely that a small fraction of plasma antithrombin is normally bound to HSPG^{AT+} associated with endothelial cells of the blood vessel wall. It was unclear whether the functionally important HSPGs are primarily the small amounts present on the luminal surface of the endothelium, or the much larger quantities located in the subendothelial region, or both. In either case, the endothelial HSPGs could interact with antithrombin to produce an antithrombotic effect at blood–surface interfaces where coagulation proteases are commonly generated. Therefore, antithrombin would be in a position to protect surfaces lined by normal endothelium against thrombus formation. Furthermore, the catalytic nature of anticoagulantly active HS species would ensure the continual regeneration of the nonthrombogenic properties of the endothelial cell layer.

THE PHENOTYPE OF 3-*O*-SULFOTRANSFERASE-1–DEFICIENT MICE

As discussed in the preceding section, a critical limiting factor in the biosynthesis of HS^{AT+} is the presence of 3-OST-1, which creates the high-affinity antithrombin-binding motif by modification of selected regions within the HS polymer.[54,55] 3-OST-5 can also generate HS^{AT+}, although much less efficiently than 3-OST-1.[63] Therefore, 3-OST-1 is likely to be the major enzyme responsible for generation of HS^{AT+} *in vivo*. Mice lacking the gene that encodes 3-OST-1 (*Hs3st1*) were generated by HajMohammadi et al.[64] to evaluate the biologic role of HS^{AT+}. The absence of 3-OST-1 enzyme caused large reductions (75% to 98%) in HS^{AT+} levels in most tissues as determined by the ability of HS purified from these tissues to accelerate inhibition of factor Xa by antithrombin. Unexpectedly, removal of most HS^{AT+} did not alter the basal rate of fibrin generation in 3-OST-1–deficient mice, nor did it lead to enhanced fibrin deposition in the lungs under hypoxemic conditions known to produce a strong procoagulant stimulus. To evaluate the possibility that HS^{AT+} plays a role only after endothelial injury, which might allow direct contact of the blood with the subendothelial matrix, mice were investigated in a carotid arterial injury model in which application of ferric chloride to the adventitia rapidly induces endothelial denudation leading to thrombosis. However, *Hs3st1*$^{-/-}$ and *Hs3st1*$^{+/+}$ mice had similar thrombotic occlusion times and equivalent postinjury levels of thrombin–antithrombin complexes, despite the virtual absence of HS^{AT+} in the uninjured carotid artery of the *Hs3st1*$^{-/-}$ mice as determined by ^{125}I-antithrombin binding.

Because 3-OST-1–deficient mice lack an obvious procoagulant phenotype, hemostatic balance does not appear to be tightly correlated with HS^{AT+} levels. Whereas *Hs3st1*$^{-/-}$ mice appeared normal on a mixed C57BL/6 × 129S4/SvJae genetic background, intrauterine growth retardation and early postnatal lethality were observed in *Hs3st1*$^{-/-}$ mice backcrossed into the C57BL/6 background. Although the cause of neonatal mortality in these mice is unclear, histologic examination did not reveal evidence of focal thrombosis as seen in antithrombin-deficient embryos,[65] which further suggests a lack of association between 3-OST-1 and antithrombin activity. The unexplained phenotype of *Hs3st1*$^{-/-}$ mice raises the possibility that HS^{AT+} participates in a novel biologic function(s). Indeed, recent analyses of *Drosophila* deficient in the orthologous enzyme, 3-*O*-sulfotransferase-B, suggest a critical role in Notch signaling pathways.[66] Novel functions might even occur outside of the vascular system, because 3-OST-1–derived HS^{AT+} is produced in several nonendothelial cell types, including

fibroblastic cell lines,[67] ovarian granulosa cells,[68] embryonal carcinoma cells,[57] alveolar type II cells,[69] and glomerular epithelial cells.[70]The lack of a prothrombotic phenotype in 3-OST-1 knockout mice challenges the concept that HS^{AT+} plays a major role in hemostasis. However, unprovoked thrombosis occurs in humans or mice homozygous for antithrombin mutations that reduce the inhibitor's affinity for HS.[71,72] These findings suggest that HS binding is required for proper antithrombin function *in vivo*. How, then, could one explain the 3-OST-1 knockout data?

First, the residual 2% to 20% anticoagulant HS activity in the 3-OST-1–deficient mice likely reflects 3-*O*-sulfation by 3-*O*-sulfotransferase isoforms other than 3-OST-1. As indicated in the preceding text, 3-OST-5 might play an important role if hemostatic balance requires only low levels of HS^{AT+}.[63] Because the plasma antithrombin concentration (2 to 5 μM) greatly exceeds the dissociation constant of antithrombin for HS^{AT+} (~15 nM), small amounts of HS^{AT+} might always be saturated with antithrombin and thereby exert a basal anticoagulant tone. Assessment of this possibility will require deletion of the gene for 3-OST-5 and perhaps other isoforms that may be responsible for the synthesis of the HS^{AT+} present in *Hs3st*$^{-/-}$ mice.

Second, HS^{AT+} may not be responsible for the anticoagulant properties of HS *in vivo*. Scully et al.[73] reported that HS that failed to bind to a column of immobilized antithrombin (generally defined as HS^{AT-}) accelerated the factor Xa–antithrombin reaction by 1,100-fold, although much higher concentrations were required in comparison with high-affinity HS (HS^{AT+}). They proposed that the nonthrombogenic property of blood vessels is due to acceleration of the factor Xa–antithrombin interaction by the greater mass of vascular HS^{AT-} rather than by the much smaller proportion of HS^{AT+} molecules. If this hypothesis is true, one would predict that defective HS synthesis would lead to a procoagulant phenotype. To complicate matters, HS interacts with a great variety of proteins other than antithrombin, and multiple functions have been attributed to HS throughout embryonic development, including interactions with the FGF, Wnt, transforming growth factors-β (TGF-β), and hedgehog (Hh) signaling pathways.[74] Targeted disruption of *EXT1*, one of the genes responsible for HS chain polymerization, resulted in the loss of HS, disruption of gastrulation, and embryonic lethality before embryonic day 8.5.[75] Conditional knockouts of *EXT1* or other HS biosynthetic genes in vascular tissue at later stages of development could be more informative with regard to the hemostatic properties of HS but have not yet been achieved. Knockout of the syndecan-4 gene (*Synd4*) suggests that HS might be involved in anticoagulation of the placenta.[76] Syndecan-4, a transmembrane protein bearing both HS^{AT+} and HS^{AT-} chains, was detected in the fetal vessels of the placenta by *in situ* hybridization and immunohistochemical staining. During late gestation, degeneration of fetal vessels in the placental labyrinth was more extensive in *Synd4*$^{-/-}$ embryos than in wild-type controls and was associated with deposition of fibrin(ogen). These findings suggest that the absence of syndecan-4 produces a deficit in placental anticoagulation.

Third, chondroitin sulfate or dermatan sulfate in the vessel wall might compensate for the reduction in anticoagulant HS activity in the 3-OST-1 knockout mouse. For example, the chondroitin sulfate moiety on thrombomodulin enhances the reactivity of thrombomodulin-bound thrombin with antithrombin,[77,78] and dermatan sulfate may promote inhibition of thrombin by HCII in the carotid arterial injury model, as discussed in the subsequent text.[79]

Fourth, HS^{AT+} synthesized by 3-OST-1 might serve an anticoagulant role in a distinct subset of tissues or under pathologic conditions not yet examined.[64] For example, $HSPG^{AT+}$ is synthesized by ovarian granulosa cells and secreted into the developing follicle in response to gonadotrophins.[80] In this location, $HSPG^{AT+}$ is thought to interact with antithrombin and other serpins (i.e., protease nexin-1 and plasminogen activator inhibitor-1) to prevent fibrin formation in the follicular fluid surrounding the oocyte.[81,82] During ovulation, the HSPGs are released from the follicle and may have anticoagulant activity in the oviduct or uterus.

Fifth, unmasking of an overt procoagulant effect might require a second genetic defect in addition to 3-OST-1 deficiency. For example, the combination of factor V_{Leiden} and protein Z deficiency produces a much greater procoagulant phenotype than does either of the two deficiencies alone.[83]

PREPARATION OF HEPARIN FOR CLINICAL USE

Pharmaceutical-grade heparin is usually isolated from mammalian tissues such as the lung or intestinal mucosa. Preparation of the polysaccharide involves homogenization of tissues; treatment of the resultant material with proteolytic enzymes, such as papain, or extraction at elevated pH and temperature; differential precipitation of complex sugars with quaternary ammonium salts such as cetylpyridinium chloride; and chromatography of the substances on anion exchange resins such as QAE-Sephadex.[84] The purified products behave as single glycosaminoglycan chains with molecular weights varying from approximately 3,000 to 35,000, with a mean of approximately 12,000. If oxidizing agents have been avoided during the purification procedure, approximately 15% to 30% of the polysaccharide chains remain covalently linked to fragments of the core protein. The remainder have free uronic acid or glucosamine-reducing groups. This suggests that the polysaccharide species are generated by cleavage of the larger individual polysaccharide chains of the heparin proteoglycan at three to five separate sites. In most commercial preparations of heparin, oxidizing agents are used late in the isolation procedure to "bleach" the polysaccharide. This treatment appears to be responsible for the absence of protein linkage regions within these preparations. Low molecular weight heparins are prepared by controlled depolymerization of standard heparin.[84]

In 2007 and 2008, certain lots of standard heparin from a single manufacturer were associated with an excess of anaphylactoid reactions and death of at least 149 patients after intravenous administration. Oversulfated chondroitin sulfate[85] and other oversulfated glycosaminoglycans,[86] which mimick the anticoagulant activity of heparin, were identified as contaminants in the affected heparin lots. Further work demonstrated that the oversulfated contaminants activate the contact system,[87] leading to generation of vasoactive mediators such as bradykinin and complement components C3a and C5a, and that they induce cell signaling events through a variety of growth factor receptors.[88] Oversulfated glycosaminoglycans have also been implicated in the pathogenesis of heparin-induced

thrombocytopenia (HIT)[89] and may explain the increased incidence of HIT observed in patients exposed to contaminated heparin.[90]

SYNTHETIC HEPARIN–LIKE ANTICOAGULANT DRUGS

In the early 1980s, the total chemical synthesis of a pentasaccharide related to the antithrombin-binding domain in heparin was achieved in more than 60 individual steps by chemists at Sanofi and Organon.[36] Extensive structure-activity studies using a variety of other synthetic oligosaccharides, as well as nuclear magnetic resonance (NMR) and x-ray crystallography, were subsequently performed.[91] On the basis of these studies, a concerted drug development effort was undertaken to develop the synthetic pentasaccharide fondaparinux, which has proven to be safe and effective in human trials and is now used for prevention and treatment of venous thromboembolism[92] (FIGURE 45.4). Fondaparinux mediates factor Xa inhibition by antithrombin but does not cause thrombin inhibition because of its short polymer length. In fact, fondaparinux has a stronger affinity for antithrombin and a higher anti-Xa activity in comparison with the most common antithrombin-binding pentasaccharide structure in porcine heparin. These differences have been attributed to the first glucosamine residue in fondaparinux being *N*-sulfated, whereas that of porcine heparin is *N*-acetylated. Fondaparinux does not interact significantly with platelets or with plasma proteins other than antithrombin and therefore has predictable pharmacokinetic behavior. Because it does not interact with PF4, fondaparinux is unlikely to trigger HIT.[93] A derivative (idraparinux; FIGURE 45.4) with a much longer half-life than fondaparinux (120 vs. 16 hours) has also been evaluated in clinical trials, but, lacking an antidote, it was deemed to present an unacceptable risk of bleeding. An idraparinux–biotin conjugate (idrabiotaparinux), which can be cleared rapidly from the circulation by intravenous injection of avidin, is undergoing clinical evaluation.[94,95]

A synthetic polymer that could mimic heparin's full anticoagulant activity (i.e., inhibition of both thrombin and factor Xa) would need to have both an antithrombin-binding domain and a thrombin-binding domain. Thrombin binds nonspecifically to highly sulfated heparin oligosaccharides and to other anionic polymers. Therefore, heparin analogs have been synthesized to contain a highly sulfated oligosaccharide linked to the nonreducing end of an antithrombin-binding pentasaccharide through a neutral spacer region.[96] In these compounds, *N*-sulfate groups were replaced by *O*-sulfates, and hydroxyl groups were alkylated, thereby greatly simplifying the synthetic process. The resulting compounds, one of which is depicted in FIGURE 45.4, catalyzed inhibition of thrombin by antithrombin and were 5- to 10-fold more potent than standard heparin in *in vivo* models. This is probably because these compounds interact much less avidly with basic plasma proteins including PF4, thereby leaving more molecules available for binding to thrombin and antithrombin. More importantly, these compounds seem to have little effect on platelets; they do not activate platelets in the presence of plasma from patients with HIT and do not affect the bleeding time of rats while still inhibiting thrombosis. Recently, more complicated constructs that include a fondaparinux analog, a benzamidine-based direct thrombin inhibitor, and biotin have been synthesized.[97] Enzymatic and chemoenzymatic methods have also been employed to synthesize heparin-like anticoagulants. Rosenberg's group has synthesized a series of potent anticoagulant heparin analogs by using a capsular bacterial polysaccharide (heparosan) obtained from *Escherichia coli* K5 and different mammalian-expressed HS sulfotransferases and epimerase with yields in the microgram range.[98–100] This approach is currently limited by the high cost of the enzymes and the low yield compared to commercial heparin production.

Lindahl et al.[101] have been able to generate gram amounts of "neoheparin" with antifactor Xa and antithrombin activities similar to those of heparin using chemoenzymatic modifications of heparosan. However, it is unknown whether the significant amounts of nonnaturally occurring 3-*O*-sulfated GlcA and IdoA residues in the neoheparin molecule might create undesirable side effects *in vivo*.

NONANTICOAGULANT ACTIONS OF HEPARIN AND HEPARAN SULFATE

Heparin and HS have a wide variety of biologic actions that are independent of its anticoagulant effects. As one of the most acidic biopolymers found in nature, heparin interacts with hundreds of proteins such as growth factors, cytokines, chemokines, extracellular matrix components, protease inhibitors, proteases, and lipases.[102] HS has been implicated in the control of many processes in multicellular organisms, including cell division, adhesion, spreading, migration, chemoattraction, inflammation, axon guidance, matrix assembly, lipoprotein uptake, extracellular proteolysis, tumor metastasis, angiogenesis, body size, body weight, and uptake of bacteria and viruses.[10,18,74,103–107,108,109,110] In this section, we briefly consider a few examples of the nonanticoagulant effects of heparin and HS.

Effects on Platelets

Heparin administration commonly produces an immediate, mild reduction in the platelet count, which is thought to result from enhanced platelet aggregation.[111] This phenomenon, termed *nonimmune heparin-associated thrombocytopenia*, probably results from direct interactions between heparin and platelets.[112] Heparin binds in a saturable and specific manner to approximately 2,500 sites on the platelet surface.[113,114] The affinity of heparin for platelets increases with the size and charge density of the polymer. Dissociation constants of 1.3 and 0.3 μM have been determined for heparin molecules having molecular weights of approximately 3,000 and 15,000, respectively.[115] Although it has been reported that the $\alpha_{IIb}\beta_3$ integrin (fibrinogen receptor) interacts with heparin,[116] the binding sites for heparin on platelets have not been identified with certainty.

When added to citrate-anticoagulated platelet-rich plasma, heparin alone weakly stimulates platelet aggregation and potentiates platelet activation induced by adenosine 5'-diphosphate or other agonists.[117–121] These effects are probably not artifacts of decreased ionized calcium produced by the citrate anticoagulant, because heparin also enhances platelet aggregation induced by collagen in hirudin-anticoagulated whole blood.[122] Low molecular weight heparin is less able to stimulate platelet aggregation than is unfractionated heparin,[112,117,119–121,123–125] consistent with the relative binding affinities of these polymers.[115] Furthermore, heparin species with low affinity for antithrombin or fibronectin are more active, presumably because these proteins

competitively inhibit binding of heparin to platelets.[112,124] The mechanism by which heparin enhances platelet function is unknown, in part, because inconsistent effects of heparin on aggregation of washed platelets have been observed.[112,123,124,126,127] Nevertheless, it is clear that the mechanism is distinct from that of HIT, which is triggered by antibodies that bind to neoepitopes on PF4–heparin complexes and activate platelets by interaction with their Fc receptors.[128]

Heparin may also interfere with platelet function and thereby contribute to the hemorrhagic side effects of the drug. In the presence of antithrombin, heparin blocks activation of platelets induced by thrombin.[123,129] Heparin also inhibits binding of von Willebrand factor to platelets, reducing adhesion of platelets to the subendothelium of an injured vessel.[130,131] These effects may cause prolongation of the bleeding time in patients receiving heparin.[132,133]

Inhibition of Selectins

The selectins (L-, P-, and E-selectin) are integral membrane proteins involved in cell adhesion interactions, including lymphocyte homing, inflammation, and tumor metastasis.[134] L-selectin is expressed constitutively on leukocytes, whereas P-selectin is rapidly translocated from secretory granules to the cell surface upon activation of platelets or endothelial cells. E-selectin expression is induced more slowly in endothelial cells by proinflammatory agonists. Selectins bind to carbohydrate structures related to the sialyl–Lewis^x tetrasaccharide; these structures are components of glycoproteins found on the surface of leukocytes, activated endothelium, and mucinous adenocarcinoma cells. Heparin and HS also interact with L-selectin and P-selectin (but not E-selectin) and inhibit binding of these proteins to sialyl-Lewis^x at concentrations less than those typically used for anticoagulation.[135] In mouse models, heparin produces a potent anti-inflammatory effect, which appears to be caused by blockade of L- and P-selectins; modified heparins that lack anticoagulant activity are also effective in these models.[136]

Experimental studies suggest that heparin inhibits tumor cell proliferation, migration across the endothelial barrier, invasion of tissues, and angiogenesis.[137,138,139] Furthermore, clinical studies have documented a survival benefit for certain patients with cancer receiving heparin.[140] Although the mechanisms responsible for these effects are unknown, selectin-mediated cellular interactions have been implicated in the hematogenous phase of tumor metastasis. For example, adhesion of activated platelets expressing P-selectin to mucin-bearing tumor cells is blocked by heparin.[141] In a mouse model in which human colon adenocarcinoma cells were injected intravenously, tumor cell–platelet aggregates accumulated rapidly in the pulmonary vasculature, and tumor foci were detectable in the lungs 6 weeks later. A single dose of heparin administered 30 minutes before injection of the tumor cells markedly decreased the number of metastatic foci at 6 weeks.[141] Subsequent studies showed that nonanticoagulant heparin derivatives blocked metastasis by interference with selectins or inhibition of heparanase, a tumor endoglycosidase that degrades HS in the extracellular matrix.[142]

Selectin–mucin interactions also may trigger migratory thrombophlebitis (Trousseau syndrome) in patients with mucinous adenocarcinomas.[143] In wild-type mice, injection of mucins extracted from human colon carcinoma cells led to formation of platelet-rich microthrombi in the lungs. Thrombus formation was inhibited by heparin but not by hirudin and therefore appeared to be independent of thrombin generation. Furthermore, thrombus formation was largely absent in mice deficient in either P-selectin or L-selectin. Although the mucins did not activate platelets suspended in buffer or plasma, platelet activation occurred when mucins were added to whole blood. Platelet activation by mucins *in vitro* was inhibited by heparin and did not occur in blood from L-selectin–deficient mice. These observations are consistent with a model in which soluble carcinoma mucins first bind to L-selectin on leukocytes, stimulating release of an unidentified platelet agonist. The activated platelets then bind to mucins via P-selectin and become cross-linked to form aggregates or bind to P-selectin glycoprotein ligand-1 on neutrophils or monocytes to signal production of thromboxane A_2 or tissue factor. Heparin could block some or all of these selectin interactions. This mechanism may explain the clinical observation that heparin is generally more effective than vitamin K antagonists for treatment of Trousseau syndrome.

Complement, Antiphospholipid Antibodies, and Fetal Loss

Heparin is used to prevent fetal loss in patients with the antiphospholipid syndrome.[144] Injection of pregnant mice with human IgG containing antiphospholipid antibodies caused fetal resorption at a rate of more than 40%; in comparison, approximately 10% of fetuses were absorbed in mice given normal human IgG. Experiments with gene-targeted mice showed that activation of both the classical and alternative complement pathways is necessary to produce fetal loss in this model.[145] Fetal loss was prevented by treatment with unfractionated or low molecular weight heparin but not by fondaparinux or hirudin.[146] *In vivo* and *in vitro* experiments showed that heparin inhibited activation of complement factor C3, as well as deposition of C3b on the surface of placental trophoblasts. Therefore, the ability of heparin to inhibit complement may explain its beneficial effect in pregnant patients with antiphospholipid antibodies[147]; heparin may also inhibit the inflammatory response that normally follows complement activation by blockade of P- and L-selectins, as described in the preceding section.

Microbial Adherence and Invasion

A wide variety of bacteria, parasites, and viruses adhere to HSPGs on cultured cells *in vitro* and are displaced from the cell surface by soluble heparin.[107] In some cases, binding of the microbe to an HSPG is thought to mediate internalization or tissue tropism. Although some of these interactions may be nonspecific, specific adhesion molecules that bind to heparin have been identified on the surfaces of pathogens such as *Plasmodium falciparum, Trypanosoma cruzi, Bordetella pertussis*, human immunodeficiency virus, and herpes simplex virus (HSV).[148] One of the best-studied examples is HSV-1. This virus contains two envelope glycoproteins, gB and gC, that are responsible for reversible adhesion of the virus to HSPGs on target cells. A third viral glycoprotein, gD, then interacts with one of several other cellular proteins to mediate fusion of the viral envelope with the cell membrane, resulting in entry of the viral nucleocapsid into the cytoplasm. Although the first proteins found to interact with gD did not have attached glycosaminoglycan chains, HSPGs with

HS chains modified by a specific 3-*O*-sulfotransferase (3-OST-3) also bind to gD.[109] Therefore, HSPGs may be sufficient for adhesion and entry of HSV-1 into susceptible cells.

Growth Factor Signaling

HSPGs serve as coreceptors for a variety of soluble ligands, including FGFs, vascular endothelial growth factors, glial cell line–derived neurotrophic factor, hepatocyte growth factor, TGF-β, CC and CXC chemokines, and various cytokines.[149,150] An example that has been well studied is the interaction of FGF2 with the receptor tyrosine kinase FGFR1. Efficient signal transduction by FGFR1 does not occur in cells that are unable to synthesize HS or cells treated with enzymes that degrade HS,[151,152] but addition of soluble heparin to these cells restores the signaling pathway. Heparin or an HS chain of syndecan or glypican on the cell surface appears to facilitate the formation of a complex containing two FGF monomers and two FGF receptors, which leads to receptor dimerization and signaling. Although crystallographic studies have identified potential heparin-binding sites in both FGF and its receptor, the precise orientation of heparin in the signaling complex is unknown. Heparin oligosaccharides with a minimum of 12 sugar residues are required for FGF signaling. Binding to FGF requires *N*-sulfation of glucosamine and iduronic acid 2-*O*-sulfate, whereas binding to the receptor also requires 6-*O*-sulfation of glucosamine (FIGURE 45.2).[153]

Anti-Inflammatory Activity of Antithrombin

High concentrations of antithrombin (10 to 20 μM) inhibit nuclear factor-κB (NF-κB) activation in cultured monocytes and endothelial cells, thereby interfering with expression of various proinflammatory and procoagulant genes (e.g., interleukin-6, tumor necrosis factor-α, and tissue factor) that are regulated by NF-κB.[154] The anti-inflammatory effect appears to depend on interaction with cell surface HSPGs, because the effect is abolished by chemical modification of antithrombin's heparin-binding site, by the presence of free heparin, or by enzymatic removal of HS from the cell.[155] Intravenous infusion of antithrombin has been reported to ameliorate experimental models of sepsis, disseminated intravascular coagulation, and ischemia/reperfusion injury.[156] Although a large phase III trial of intravenous antithrombin in patients with severe sepsis failed to demonstrate a reduction in mortality at 28 days,[157] subgroup analysis showed a possible survival benefit in those patients who did not concomitantly receive heparin.[158]

Functions of Heparan Sulfate in Development

Direct evidence implicating proteoglycans in development was obtained initially from studies with *Drosophila*, in which mutations at the *dally* (*division abnormally delayed*) locus cause morphologic abnormalities in the wings, eyes, antennae, and other tissues.[74,108] The *dally* gene and its homolog *dlp* (*dally-like protein*) encode HSPG core proteins homologous to vertebrate glypicans, which are attached to the plasma membrane by glycosyl phosphatidylinositol linkers. Subsequent studies revealed that *dally* or *dlp* mutations affect signaling pathways that involve known HS-binding growth factors, including decapentaplegic (Dpp), Hh, and wingless (Wg).[159] Mutations that affect development in *Drosophila* have also been discovered in genes involved in glycosaminoglycan biosynthesis. These genes include *sugarless*, which encodes a UDP-glucose dehydrogenase homolog required for synthesis of UDP-glucuronic acid; *sulfateless*, which encodes an *N*-deacetylase/*N*-sulfotransferase homolog; and *tout-velu*, which encodes an HS-specific copolymerase homologous to EXT1. Mutations in these genes appear to affect pathways involving the growth factors Dpp, Hh, Wg, and FGF. Enzymes that determine specific sulfation patterns in HS are also important in development. For example, down-regulation of *Drosophila* 3-*O*-sulfotransferase-B by RNA interference causes neural abnormalities due to defects in Notch signaling pathways.[66] The mechanisms by which HSPGs affect these growth factors are not entirely clear. HSPGs may serve as coreceptors that facilitate activation of signaling receptors on the cell surface as in the case of FGF, they may control diffusion of growth factors from their sites of production and thereby assist in formation of morphogenic gradients in tissues, or they may be involved in stabilization or clearance of the growth factors or their receptors.

Mutations that affect vertebrate HSPGs also cause developmental abnormalities.[108] For example, Simpson-Golabi-Behmel syndrome is a human disorder caused by mutations in glypican-3. This syndrome is characterized by overgrowth of many somatic tissues, including heart, kidneys, and bone, as well as increased susceptibility to Wilms tumors and neuroblastoma. A murine knockout of glypican-3 produced a similar phenotype. Other examples include mutations in the HS copolymerase genes *EXT1* and *EXT2*, which cause familial exostoses (cartilaginous tumors of the growth plates of bones), and targeted mutations in the murine HS 2-*O*-sulfotransferase gene, which lead to renal agenesis as well as eye and skeletal defects. Many other examples exist in which specific biosynthetic modifications of HS chains appear to be important for particular aspects of development.[160]

Lipoprotein Metabolism

HSPGs bind to lipoprotein lipase and anchor this enzyme to the luminal surface of endothelial cells, where it hydrolyzes triglycerides in circulating lipoprotein particles.[18] The lipoprotein particles also interact with endothelial HSPGs through their apolipoprotein B or E components. Interestingly, lipoprotein lipase is synthesized by myocytes and adipocytes, and transport of the enzyme from the basal to the luminal side of the endothelial cell appears to require HSPGs on the basal surface of the cell.[161] Intravenous administration of unfractionated or low molecular weight heparin displaces lipoprotein lipase from the endothelium into the circulation, from which the enzyme is cleared by hepatic receptors.[162] By this mechanism, repeated exposure to heparin may contribute to the elevated serum triglyceride levels observed in patients undergoing hemodialysis and play a role in the development of atherosclerosis.

HSPGs are expressed by endothelial cells that line the hepatic sinusoids and the underlying hepatocytes and are present in the perisinusoidal space (space of Disse).[163] Genetic data indicate that the HSPG syndecan-1 acts as an independent receptor for the clearance of triglyceride-rich lipoproteins in the liver.[164] Moreover, HS chains of syndecan-1 bind to plasma triglyceride-rich lipoproteins. Triglyceride-rich lipoprotein uptake depends less on overall charge of the HS chains than on uronic acid 2-*O*-sulfation[165] and glucosamine *N*-sulfation,[166] with glucosamine 6-*O*-sulfation making little contribution.[163] These data suggest that some familial human dyslipidemias may

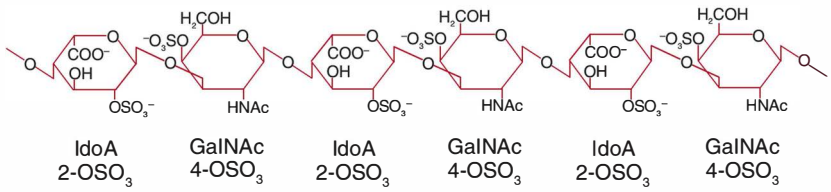

FIGURE 45.6 Structure of a dermatan sulfate hexasaccharide with high affinity for HCII. IdoA, iduronic acid; GalNAc, *N*-acetylgalactosamine.

be explained by polymorphisms in genes encoding syndecan-1 and enzymes involved in HS biosynthesis.

ACTIVATION OF HEPARIN COFACTOR II BY DERMATAN SULFATE

The rate of inhibition of thrombin by HCII increases more than 1,000-fold in the presence of heparin, HS, or dermatan sulfate.[167] The HCII–thrombin reaction is also stimulated by a variety of other sulfated polyanions, several of which have been studied as potential antithrombotic agents. They include naturally occurring compounds such as chondroitin sulfate E[168] and fucoidan[169] as well as semisynthetic polyanions such as dextran sulfate,[170] pentosan polysulfate,[171,172] and sulfated bis-lactobionic acid amide.[173]

HCII is unique in its ability to be stimulated by dermatan sulfate and binds to a minor subpopulation of dermatan sulfate oligosaccharides.[174] The high-affinity binding site for HCII in porcine skin dermatan sulfate is a tandem repeat of three iduronic acid 2-*O*-sulfate → *N*-acetylgalactosamine 4-*O*-sulfate disaccharide subunits (see FIGURE 45.6). The HCII-binding site in dermatan sulfate from tissues other than porcine skin may also include iduronic acid → *N*-acetylgalactosamine 4,6-*O*-disulfate subunits.[175–177] Unlike antithrombin, HCII binds nonspecifically to heparin oligosaccharides at least four monosaccharide units in length.[178]

Hexasaccharide sequences with high affinity for HCII are present at low abundance in dermatan sulfates of mammalian origin.[174] Dermatan sulfates with the same backbone structure but with different patterns of sulfation are present in ascidians (marine invertebrates commonly known as sea squirts). Ascidian dermatan sulfates have a high content of iduronic acid 2-*O*-sulfate residues, but they differ in the pattern of sulfation of the *N*-acetylgalactosamine units. For example, the *N*-acetylgalactosamine residues of *Halocynthia pyriformis* are predominantly 4-*O*-sulfated,[179] whereas those of *Ascidia nigra* are quantitatively 6-*O*-sulfated.[180] Dermatan sulfates stimulate thrombin inhibition by HCII with the following relative potencies: *H. pyriformis* > mammalian >> *A. nigra*.[179,180] These results indicate that the ability of dermatan sulfate to activate HCII is not simply a function of the overall charge density of the polymer, because the total sulfate contents of the ascidian dermatan sulfates are similar; instead, activity appears to require the presence of *N*-acetylgalactosamine 4-*O*-sulfate residues.

Mice with targeted deletion of the gene for HCII have been produced independently in two laboratories.[79,181] He et al.[79] found that HCII$^{-/-}$ mice develop normally and have no evidence of spontaneous thrombosis despite the complete absence of HCII antigen and dermatan sulfate–dependent thrombin inhibitory activity in their plasma. Subsequently, Aihara et al.[181] reported that homozygosity for the HCII–null allele is embryonically lethal and suggested that the more severe phenotype of their knockout could be due to minor differences in genetic background. Both groups found that a decreased level of circulating HCII promotes the accumulation of smooth muscle cells in the arterial intima after mechanical injury, and Vicente et al.[182] reported that intravenous administration of dermatan sulfate (but not heparin) during the first 48 hours after injury markedly inhibits neointima formation in HCII$^{+/+}$ mice but not in HCII$^{-/-}$ mice. Both groups also noted that HCII deficiency promotes atherosclerosis in apolipoprotein E (apoE)–null mice fed a cholesterol-rich diet.[181,182] These observations are consistent with experimental work implicating thrombin in the pathogenesis of neointima formation and atherosclerosis.[183] Furthermore, human studies have demonstrated an inverse correlation between plasma HCII levels and in-stent restenosis[184,185] or atherosclerosis,[186–188] although in one study baseline HCII levels did not predict the subsequent occurrence of symptomatic coronary artery disease.[189] HCII deficiency also increases the severity of angiotensin II–induced cardiomyopathy (concentric remodeling and cardiac fibrosis) in mice.[190]

He et al.[79] discovered that thrombi form more rapidly in the carotid arteries of HCII$^{-/-}$ mice in comparison to wild-type mice following photochemically induced endothelial injury. Subsequent experiments suggested that the antithrombotic effect depends upon interaction of HCII with dermatan sulfate in the vessel wall.[191] Thus, intravenous injection of either wild-type recombinant HCII or a variant with low affinity for HS (K173H) corrected the abnormally short thrombosis time of HCII-deficient mice, while a variant with low affinity for dermatan sulfate (R189H) did not. Immunohistochemical studies demonstrated that dermatan sulfate is present predominantly in the adventitia of the mouse carotid artery, whereas HS is found mainly in the intima and media. When HCII was incubated with frozen sections of the mouse carotid artery, it bound to the adventitia, and binding was abolished by pretreatment of the section with chondroitin B-lyase, which specifically cleaves glycosidic linkages in dermatan sulfate. HCII was undetectable in the wall of the uninjured carotid artery, but it became concentrated in the adventitia following endothelial injury. These results support the hypothesis that HCII interacts with dermatan sulfate in the vessel wall after disruption of the endothelium and that this interaction regulates thrombus formation *in vivo*.

CHAPTER

46 Endothelial Cell–Blood Cell Interactions

KLAUS LEY

Interactions between monocytes, platelets, and endothelial cells are intimately involved with and are of key importance for the regulation of hemostasis, thrombosis, inflammation, and atherosclerosis. Although other cells such as neutrophils and T lymphocytes participate, the monocyte–platelet–endothelial cell axis has emerged as a predominant factor in vascular disease and thrombosis. This chapter introduces the molecular basis of the adhesive interactions among the three cell types, explores the crosstalk between hemostasis, thrombosis, and inflammation, and discusses the pathophysiologic significance of these cell–cell interactions with an emphasis on vascular disease.

CELLULAR AND MOLECULAR BASIS

Monocytes

Monocytes are myeloid cells produced in the bone marrow. Although originally thought to be a homogeneous population, it has become clear that in human and mouse blood at least two subpopulations of monocytes exist.[1,2] One type is characterized by a more inflammatory phenotype while the other type can migrate along the vascular endothelium.[3] Dendritic cells are the most important antigen-presenting cells of the immune system. Both dendritic cells and monocytes are derived from macrophage-dendritic cell progenitors in the bone marrow.[4,5] In mice, a committed blood precursor for dendritic cells (pre-DC) has been described, which is distinct from monocytes.[6] Both "inflammatory" and "resident-type" monocytes express adhesion molecules, chemokine receptor, and cytokine receptor molecules that support interaction with platelets and endothelial cells (Table 46.1). It is unclear whether the human blood monocyte subsets correspond to the mouse subsets.[7,8]

Most adhesion molecules are integral transmembrane cell surface molecules that can bind to the same (homotypic), or other cell surface molecules (heterotypic), or molecules in the extracellular matrix. Most adhesion molecules provide mechanical strength to the interaction between cells by mechanically linking the extracellular environment to the intracellular cytoskeleton through reversible interactions. Many if not all cell adhesion molecules also transduce signals into the cells upon engagement by extracellular ligands.

Monocyte Adhesion Molecules

Integrins

Integrins are transmembrane $\alpha\beta$ heterodimers that bind many extracellular matrix proteins and certain immunoglobulin-like adhesion molecules to other cells.[9,10] Most integrins require conformational activation to support binding. The mechanisms of integrin activation have been studied in detail for $\alpha_V\beta_3$,[11] an integrin also expressed on monocytes, and lymphocyte function-associated antigen 1(LFA-1),[12] an integrin highly expressed on monocytes and other leukocytes. Activation of $\alpha_x\beta_2$[13] and $\alpha_4\beta_1$ integrins[14] has also been studied. Both are expressed on blood monocytes at low and high levels, respectively. Integrin activation is probably initiated by the binding of the intracellular cytoskeletal adaptor molecules talin and kindlin-3 to the integrin β chains,[15,16] which causes extension of the extracellular domain that exposes the ligand-binding site and greatly increases the on-rate of ligand binding (FIGURE 46.1A). This process is called inside-out signaling, because the change in the extracellular domain of the integrin is brought about by intracellular processes. The mechanism of activation-induced conformational change is thought to apply fairly generally to many, if not all integrins.[10] However, the regulation of affinity by reducing the dissociation of the ligand from the integrin is much less clear. Although conformational changes in the ligand-binding domain have been reported,[17] it is not clear whether these changes are directly linked to integrin extension or could be regulated separately.[14]

Integrins may first undergo some initial conformational change (probably extension) through inside-out signaling, followed by ligand binding, which then causes outside-in signaling that leads to full activation and strong binding[10,18,19] (FIGURE 46.1B). However, not all experimental data are consistent with this model.[20] In addition, integrins can also rearrange in the plasma membrane to cluster and form patches, which results in enhanced binding (FIGURE 46.1C). This rearrangement and clustering probably happens after ligand binding, results in increased binding of multivalent ligands, and is called avidity change. It does not result in increased affinity for the monovalent ligand.[21] Under *in vivo* conditions, cell activation probably results in a combination of integrin affinity and avidity increase. Although this can be tested by looking at monovalent versus polyvalent ligand binding, the role of avidity and affinity regulation remains controversial.[10,18,21]

Of the 24 known integrins, mature blood monocytes express only a few. The most abundant monocyte integrin is $\alpha_4\beta_1$ integrin or very late antigen-4 (VLA-4) (CD49d/CD29). It is composed of a 150 kDa α_4 chain that can undergo proteolytic cleavage and a noncovalently associated 130 kDa β_1 chain. $\alpha_4\beta_1$ integrin is preferentially expressed on cell surface projections that are often called microvilli, but resemble ridges rather than true villous processes.[22] This position is believed to facilitate the interaction of $\alpha_4\beta_1$ integrin with its ligands under conditions of flow. The most important ligands for $\alpha_4\beta_1$ integrin include

Table 46.1

Cell surface molecules on monocytes relevant to cell–cell interaction

	"Inflammatory" Monocytes		"Resident" Monocytes			
Molecule	**Mouse**	**Human**	**Mouse**	**Human**	**Main Function**	**Secondary Function**
CD11a/CD18 ($\alpha_L\beta_2$, LFA-1)	+	+	+	+	Inducible adhesion to ICAM-1, 2	Reduces rolling velocity (neutrophils)
CD11b/CD18 ($\alpha_M\beta_2$, Mac-1)	+	+	+	+	Inducible adhesion to C3bi, ICAM-1, 2, fibrinogen	Phagocytosis
CD11c ($\alpha x\beta 2$)	–	+	–	+	Inducible binding to VCAM-1	Complement binding
CD14	–	+	–	low	LPS coreceptor	
CD16 (FcγRIII)	+	–	+	+	Fc receptor for IgG	
CD64 (FcγRI)		+		–		
CX3CR1	low	+	high	high	Binds CX3CL1, activates monocytes	May mediate adhesion
CCR1	n.d.	+	n.d.	–	Binds chemokines CCL3, 5, 7, 14, 15, 16, 23; causes activation	Chemokine binding causes arrest of rolling cells
CCR2	+	+	–	–	Binds chemokines CCL2, 7, 12, 13, causes activation, chemotaxis	Soluble CCL2 can cause monocyte arrest
CCR4	n.d.	+	n.d.	–	Binds chemokines CCL17, 22	
CCR5		–		+		
CCR7	n.d.	+	n.d.	–	Binds chemokines CCL19, 21	Promotes mature DC migration to lymphatic organs
CXCR1 (IL-8 receptor)	–	low	–	–	Binds chemokines, mainly CXCL8	
CXCR2	n.d.	+	n.d.	–	Binds chemokines CXCL1, 2, 3, 5, 6, 7, 8	Chemokine binding causes arrest
CXCR3	n.d.	–	n.d.	–	Binds chemokines CXCL9, 10, 11	Promotes type 1 inflammation
CXCR4	n.d.	low	n.d.	+	Binds CXCL12, induces arrest	Release from bone marrow
Ly-6C (Gr-1)	+	–	–	–	No known function	
CD49b ($\alpha_2\beta_1$, VLA2)	+	n.d.	–	n.d.	Inducible binding to collagen	
CD49d ($\alpha_4\beta_1$, VLA4)	+	n.d.	+	n.d.	Inducible binding to VCAM-1, fibronectin	Monocyte arrest on atherosclerotic lesions
CD62L (L-selectin)	+	n.d.	–	n.d.	Binds PSGL-1, secondary tethering	Binds PNAd, monocyte rolling in lymph nodes
CD162 (PSGL-1)	+	+	+	+	Binds P-selectin on platelets, endothelial cells, microparticles	Binds L-selectin for secondary tethering, binds E-selectin
Myeloperoxidase		high		Low		
MHC-II		low		High		
Tissue factor	Inducible, but unknown in which subsets				Initiator of coagulation	Signaling into monocyte
PECAM-1 (CD31)	Most or all				Transendothelial migration	Monocyte activation

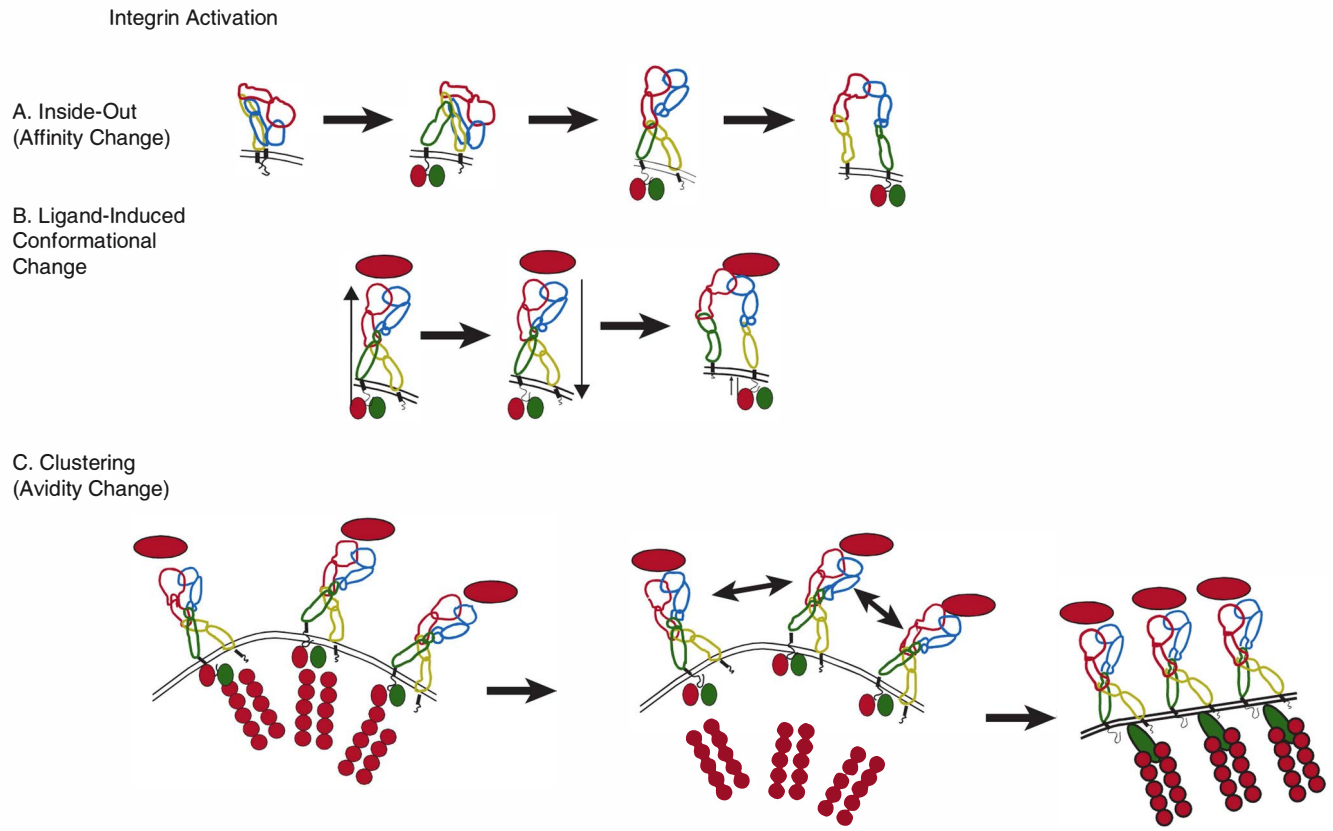

FIGURE 46.1 Regulation of integrin ligand binding activity. **A**: Integrin affinity regulation by conformational changes in the α and β chains (*red-yellow and blue-green, respectively*), resulting in increased availability and accessibility of ligand binding sites (third diagram) and, through an additional activation step, increased affinity for monovalent ligands (last diagram). During conformational activation, talin and kindlin-3 (*green and red ellipses*) bind to the integrin β cytoplasmic tail, causing the integrin "legs" to move apart. **B**: Ligand-induced activation and outside-in signaling. After activation as in (A, inside-out signaling, *arrow up*), ligand (*red ellipse*) binding to integrin induces outside-in signaling (*arrow down*) and bond maturation. **C**: Integrin avidity regulation by lateral mobility/clustering. Transient release of integrins from cytoskeletal anchorage (actin filaments, represented as *strings of circles*) allows integrin rearrangement and clustering in the plane of the cell membrane, resulting in increased avidity for multivalent ligands. It is not known whether the release occurs at the level of talin-actin binding. Integrins bind actin through talin, and various other linker proteins (not shown).

the vascular cell adhesion molecule 1 (VCAM-1) on endothelial and other cells (Table 46.2) and the heparin-binding region of alternatively spliced fibronectin expressed in the extracellular matrix and on the luminal surface of inflamed endothelial cells.[23] Like other integrins, $\alpha_4\beta_1$ integrin can probably undergo conformational activation.[14,24,25] This process of affinity regulation can be triggered by monocyte activation, for example, through chemokines. Gene-targeted mice lacking either α_4[26] or β_1[27] are not viable. Blocking $\alpha_4\beta_1$ with a monoclonal antibody or a peptide based on the fibronectin sequence ILDV reduces atherosclerosis in mice,[28] suggesting that $\alpha_4\beta_1$ is important in monocyte recruitment to atherosclerotic lesions.

The integrin $\alpha_M\beta_2$ (CD11b/CD18) is also known as Macrophage-1 or Mac-1. Mac-1 antibodies were some of the earliest monocyte-macrophage specific antibodies described. Although Mac-1 is also expressed on neutrophils, most of its function seems to be related to monocyte-macrophages. First, Mac-1 participates in monocyte adhesion to various substrates including endothelial cells. Second, Mac-1 is an important receptor for the complement and is also known as complement receptor 3 (CR3). Mac-1 binds complement C3bi and is critically involved in phagocytosis of complement-coated bacteria and particles. Mac-1 engagement promotes a proinflammatory response, including a respiratory burst with vigorous oxygen radical production, actin polymerization, induction of nitric oxide synthase, and shape change. Interestingly, under flow conditions such as those achieved in flow chambers *in vitro*, or isolated perfused vessels *ex vivo*, Mac-1 does not appear to contribute to monocyte adhesion to endothelial cells.[29] Mac-1 has been shown to lower the rolling velocity of neutrophils,[30] but the role of Mac-1 in monocyte rolling has not been studied. Mice lacking Mac-1, prepared by targeting the gene for α_M, are viable, fertile, and healthy under vivarium conditions.[31] There is no evidence that these mice are protected from atherosclerosis, but their response to vascular injury is blunted.[32] Like all β_2 integrins, Mac-1 has an I-domain with homology to the von Willebrand factor (vWF) A-domain inserted in its α subunit, which contains the ligand-binding site. Mac-1 binds many other ligands

Table 46.2

Ligands for monocyte and platelet integrins

Integrin	Ligands	Function
$\alpha_4\beta_1$	VCAM-1	Adhesion to endothelial cells
	Fibronectin	Adhesion to extracellular matrix
Mac-1	Complement C3bi	Phagocytosis of opsonized particles
$\alpha_M\beta_2$	Coagulation factor Xa	Assembly of prothrombinase complex
	Fibrinogen	Bridging between monocytes and platelets
	Intercellular adhesion molecule-1 (ICAM-1)	Adhesion to endothelial and other cells
	Intercellular adhesion molecule-2 (ICAM-2)	Adhesion to endothelial cells and platelets
	Denatured collagen	Migration, phagocytosis?
	Denatured albumin	Migration, phagocytosis?
	Leishmania GP63	Uptake of leishmania
	Bortedella FHA	Uptake of Bortedella
	Fibronectin	Adhesion to extracellular matrix
CD11c/CD18	Complement C3bi	Phagocytosis of opsonized particles
$\alpha_x\beta_2$	VCAM-1, ICAM-1	Monocyte adhesion
	Fibrinogen	Bridging between monocytes and platelets
LFA-1	Intercellular adhesion molecule-1 (ICAM-1)	Adhesion to endothelial and other cells
$\alpha_L\beta_2$	Intercellular adhesion molecule-2 (ICAM-2)	Adhesion to endothelial cells and platelets
$\alpha_V\beta_3$	Vitronectin	Bone remodeling?
	Entactin	Unknown
	L1	Unknown
$\alpha_{IIb}\beta_3$	Fibrinogen	Binds immobilized Fg without activation
	Fibronectin	Induced by GPIb binding to vWF
	vWF	Promotes CD40L shedding
	Vitronectin	
	CD40L	
$\alpha_2\beta_1$	Collagens	On platelets, requires activation by GPVI

including fibrinogen and coagulation factor X (Table 46.2). Mac-1 is thought to be involved in assembling prothrombinase on the monocyte surface and may be able to support platelet binding to monocyte through a fibrinogen bridge between $\alpha_{IIb}\beta_3$ on platelets and Mac-1 on monocytes.[33] Although Mac-1 deficient mice have no obvious defect in hemostasis, Mac-1 could participate in monocyte activation and the delivery of tissue factor to sites of thrombosis.[34] Human, but not mouse monocytes also express a closely related integrin, $\alpha_x\beta_2$, which is also a complement receptor, alternatively known as CR4. Abundant α_x expression is found on dendritic cells. Like Mac-1, $\alpha_x\beta_2$ binds the intercellular adhesion molecule 1 (ICAM-1), C3bi, and denatured proteins,[35] but in addition VCAM-1 also.[36]

The LFA-1, or $\alpha_L\beta_2$ integrin (CD11a/CD18) is expressed on all leukocytes including monocytes. While LFA-1 is responsible for lymphocyte arrest, the sudden stopping of rolling cells upon activation[37] and participation in neutrophil arrest under flow, little is known about its function in monocytes. LFA-1 binds to cell surface immunoglobulins including InterCellular Adhesion Molecules ICAM-1 and-2, and has no known extracellular matrix ligands. Mice lacking LFA-1 were prepared by targeting the gene for αL[38] and are viable, healthy, and fertile under vivarium conditions. There are no reports of these mice having altered thrombosis, hemostasis, or atherosclerosis. Like the other β_2 integrins, LFA-1 has an I-domain and undergoes extensive conformational changes of the extracellular domain upon activation.[12]

The integrin $\alpha_V\beta_3$ is expressed on blood monocytes at a low copy number. Its expression increases upon differentiation to osteoclast-like cells. This integrin was initially called leukocyte response integrin[39] because it participates in inducing the respiratory burst associated with NADPH oxidase activation and oxygen free radical production in neutrophils. Ligands for $\alpha_v\beta_3$ integrin include vitronectin, entactin, and possibly the immunoglobulin-like adhesion molecule L1. Gene-targeted mice lacking α_V are not viable, whereas mice lacking β_3 have a defect in both $\alpha_V\beta_3$ on monocytes, neutrophils, and proliferating endothelial cells, and $\alpha_{IIb}\beta_3$ on platelets, which share the common β_3 subunit. The phenotype of these mice is dominated by the platelet defect (Glanzmann thrombasthenia-like), and these mice also have osteosclerosis, suggesting defective osteoclast function.[40] $\alpha_V\beta_5$ integrin is also a vitronectin receptor. Monocytes express $\alpha_2\beta_1$ integrin, a collagen receptor, at the mRNA and protein levels. $\alpha_5\beta_1$, a fibronectin receptor, $\alpha_{10}\beta_1$, a collagen receptor, and $\alpha_E\beta_7$, a receptor for E-cadherin, are found at the message level, but functional data have not been published.

Immunoglobulins

Blood monocytes express many immunoglobulin-like molecules. Of importance for this chapter is ICAM-1, because it supports homotypic aggregation of monocytes via LFA-1 and Mac-1 and because it can bind fibrinogen.[41] Mice with hypomorphic mutations in the ICAM-1 gene or lacking ICAM-1 entirely have no overt defect in hemostasis or thrombosis, but are somewhat protected from atherosclerosis in the C57BL/6 and apolipoprotein E knockout models.[42] However, these mice also lack ICAM-1 on endothelial cells, smooth muscle cells, lymphocytes, and many other cells. ICAM-2 and ICAM-3 are found in monocytes at the message level, but have no known function in monocytes.

Platelet endothelial cell adhesion molecule 1(PECAM-1) (CD31) is a homotypic adhesion molecule expressed on blood monocytes and has an important role in transendothelial migration and in monocyte activation.[43,44] Monocyte PECAM-1 interacts with PECAM-1 on endothelial cells during transmigration. PECAM-1-deficient C57BL/6 mice have no apparent defect in leukocyte and monocyte transmigration, demonstrating that PECAM-1-independent pathways of transmigration exist.[45]

Other immunoglobulin-like molecules expressed on monocytes include major histocompatibility complex (MHC) class II, which is important in antigen presentation, but is not fully induced until monocytes differentiate to macrophages. CD83 is also expressed and has costimulatory functions in macrophages, but no known function in blood monocytes.

Selectins and their Ligands

L-selectin (CD62L) is expressed on "inflammatory" blood monocytes and most other leukocytes. Its most important function is in lymphocyte homing to secondary lymphatic organs,[46] but it is also involved in inflammation.[47] Like the other selectins, L-selectin can mediate leukocyte rolling, a passive motion of leukocytes down a vessel wall driven by the blood flow and the forces exerted on the loosely attached cell. During rolling, molecular bonds form at the leading edge and continually break at the trailing edge of the cell, allowing the leukocyte to stay in contact with the endothelium without actually stopping[48] (FIGURE 46.2). Rolling is thought to serve to "scan for" inflammatory stimuli, and rolling cells can stop (arrest) in response to appropriate stimuli.[18,49] On neutrophils, L-selectin is expressed on the tips of microvilli[50] and can be rapidly shed upon cell activation by a protease-dependent mechanism involving tumor necrosis factor-α-converting enzyme (TACE) (ADAM-17).[51] Although L-selectin has been shown to support monocyte rolling on L-selectin ligands in flow chambers, it is not known whether L-selectin–mediated monocyte rolling on endothelial cells serves a physiologic function. Endothelial ligands for L-selectin known as peripheral node addressins are expressed in endothelial cells of lymphoid organs, but L-selectin ligands on endothelial cells outside lymphoid organs have not been identified. It is tempting to speculate that monocyte L-selectin may enhance monocyte recruitment to atherosclerotic lesions by nucleating monocyte-monocyte interactions through binding

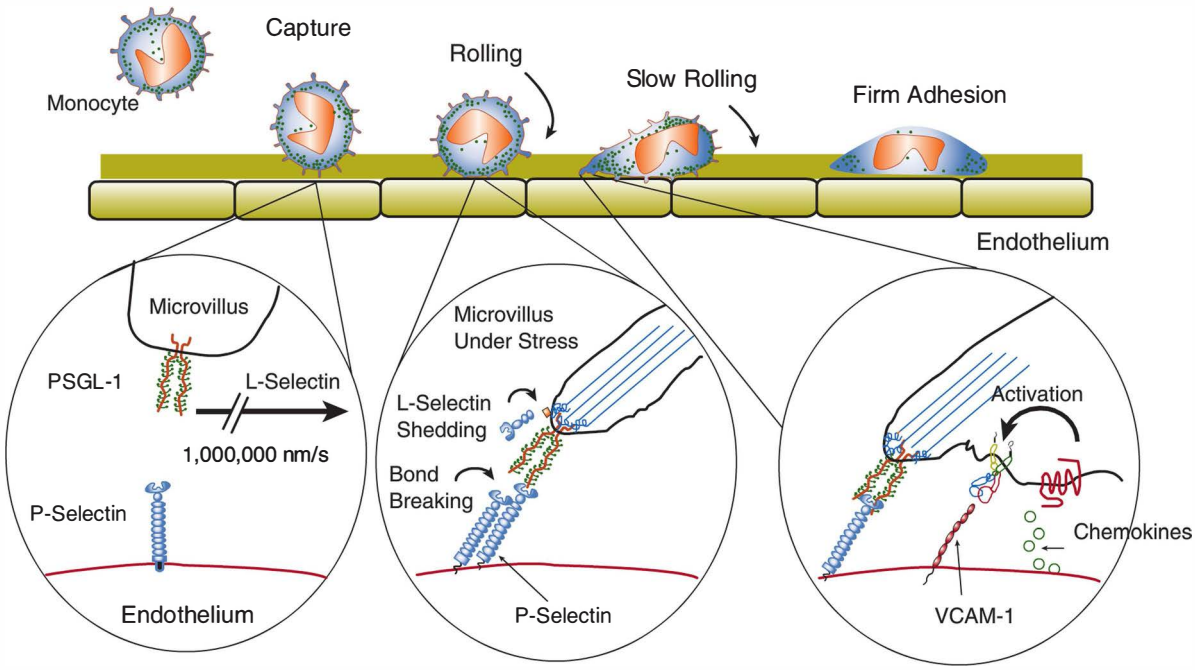

FIGURE 46.2 Sequence of monocyte capture, rolling, slow rolling, and adhesion on endothelial cells. Flow from left to right, endothelial surface layer shown in *green*. Primary capture or tethering is initiated by monocyte PSGL-1 binding to endothelial P-selectin (*left insert*). Note high velocity of monocyte (1 mm/s). The *middle insert* shows a P-selectin/PSGL-1 bond at the trailing edge of a rolling monocyte. Applied stress induces faster bond breakage and may also activate cleavage of L-selectin. The *right insert* shows VLA-4/VCAM-1–dependent bond required for slow rolling. Monocyte activation via surface-immobilized chemokine binding to chemokine receptor resulting in integrin affinity upregulation and firm binding to endothelial ligands such as VCAM-1 (shown here).

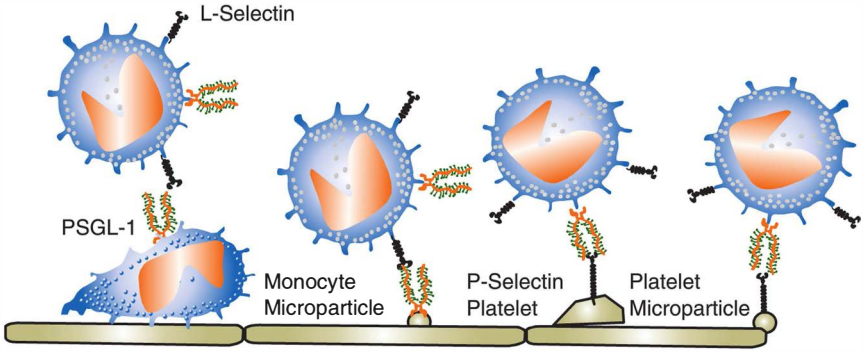

FIGURE 46.3 Secondary capture or secondary tethering. Monocytes can be captured by binding to other, already adherent monocytes or other leukocytes **(left)** or to monocyte-derived microparticles **(middle)**. Both require L-selectin on the circulating and PSGL-1 on the adherent monocyte or microparticle. Monocytes can also adhere to platelets or platelet-derived microparticles **(right)**, which requires monocyte PSGL-1 and platelet P-selectin.

to P-selectin glycoprotein ligand-1 (PSGL-1, CD162, see below) in a process called secondary capture[52] (FIGURE 46.3). Secondary capture is initiated when a vessel wall-adherent monocyte or monocyte-derived microparticle exposes PSGL-1 to other monocytes that pass by in the free stream. These cells can transiently bind to the adherent monocyte through L-selectin and then attach to the endothelium downstream from the nucleation site. While this process is certainly plausible and has been observed to occur in mouse aortas,[53] no direct evidence has been provided to support its importance in atherosclerosis, thrombosis, or hemostasis.

The most important selectin ligand on monocytes is PSGL-1, (CD162). PSGL-1 is somewhat of a misnomer, because PSGL-1 also binds L- and E-selectins with similar affinity as P-selectin.[54] All monocytes, like most leukocytes, express PSGL-1 protein on the cell surface, but not all cell surface-expressed PSGL-1 can bind selectins. PSGL-1 binding to selectins is regulated by a series of glycosyltransferases and sulfotransferases required to make it a functional selectin ligand (Table 46.3). Blood monocytes express fucosyltransferase VII, core2 *N*-acetylglucosaminyltransferase-I, and at least one sialyltransferase. Therefore, PSGL-1 on monocytes is constitutively active and can bind all three selectins. PSGL-1 is a covalent homodimer and, like VLA-4 and L-selectin, is expressed on microvilli.[55]

Recently, PSGL-1 has been shown to be of key importance for the delivery of tissue factor to sites of thrombosis.[56,57] PSGL-1-expressing microparticles, presumably derived from monocytes, deliver tissue factor to sites of thrombosis in a PSGL-1 and P-selectin-dependent process. Apparently, the generation of these microparticles can be induced by soluble P-selectin[58] in a process that requires PSGL-1 expression. Taken together, PSGL-1 is one of the most important molecules connecting inflammation with hemostasis and thrombosis. PSGL-1 deficient mice show reduced inflammatory responses in many models and have a remarkable defect in tissue factor recruitment to sites of vascular injury and thrombosis.[56,57] The importance of PSGL-1 is underlined by epidemiologic evidence that humans expressing PSGL-1 alleles that encode shorter isoforms (fewer tandem repeats) are relatively protected from cardiovascular disease.[59] The shorter versions of PSGL-1 support less monocyte-platelet adhesion.

Recently, P-selectin was also found to be expressed on peritoneal macrophages[60] and in foam cells found in the neointima

Table 46.3

Glycosyl- and sulfotransferases relevant to selectin binding

Enzyme	Abbreviation	Involved in Ligands for:	Expression
Fucosyl transferase-VII	FucT-VII	L, E, P	myeloid, act. T cells, HEV
Fucosyl transferase-IV	FucT-IV	L, E, P[a]	myeloid, some HEV
core2 $\beta_{1,6}$ glucosaminyl transferase	C2GlcNAcT-I	L, P	myeloid, act. T cells B cells
sialyl 3-galactosyltransferase	ST3Gal	L, E, P	ubiquitous
$\beta_{1,4}$ galactosyl transferase	$\beta_{1,4}$GalT-I	P[b]	ubiquitous
tyrosine protein sulfotransferases	1, 2 TPST-1, 2	L, P	ubiquitous
HEC-glucosaminyl sulfotransferase	HEC-GlcNAc6ST	L	HEV, chronically inflamed ECs

[a]Only in myeloid cells, not T cells.
[b]Not yet tested for E, L; probably involved for L.
From Ley K, Kansas GS. Selectins in T-cell recruitment to non-lymphoid tissues and sites of inflammation. *Nat Rev Immunol* 2004;4:325–335.

formed after vascular injury in atherosclerotic mice.[61] There is no evidence for P-selectin expression on blood monocytes.

Integrin-Associated Molecules

The urokinase plasminogen activator receptor (UPAR) is expressed on blood monocytes and sharply upregulated by activation. UPAR associates with $\alpha_1\beta_2$, $\alpha_M\beta_2$, and various other integrins. UPAR coexpression increases the affinity of integrins and can change ligand specificity.[62] Tetraspanins have also been reported to associate with integrins and change their activation status.[63] A third integrin-associated molecule is CD47, which is associated with leukocyte activation and transendothelial migration.[64] These integrin-associated cell surface glycoproteins can change integrin affinity for ligand, ligand specificity, and serve signaling functions.[65,66]

Monocyte Chemokines

Chemokines are small peptides that bind to G-protein-coupled receptors on monocytes, lymphocytes, neutrophils, platelets, and many other cells.[67] Most chemokines are classified according to the location of two conserved pairs of cysteins that either do (CXC), or do not (CC) have an intervening amino acid. Chemokines are named for their ability to induce a chemotactic response, that is, initiate migration of a receptor-bearing cell from areas of lower to areas of higher concentration of chemokines. However, chemokines have many other important functions. Some, but not all can induce rapid integrin activation by inducing conformational changes and/or clustering of integrins (see above). When chemokines act on rolling leukocytes, such integrin activation often results in arrest, converting the rolling motion to firm adhesion.[49,68] Inflammatory chemokines such as interleukin-8 (CXCL8) also induce degranulation of secondary and tertiary granules in neutrophils and monocytes, and induce a respiratory burst resulting in production of oxygen-derived free radicals. Stromal cell-derived factor-1α (SDF-1α, CXCL12) has homeostatic functions in the bone marrow where it supports progenitor cells and hematopoiesis. Other chemokines participate in the organogenesis of lymphatic organs.

In the context of this chapter, we will discuss chemokines elaborated by monocytes, platelets, and endothelial cells. These chemokines can have autocrine, paracrine, and remote effects. Monocytes express low levels of CCL2, 3, 4, 20 and CXCL8, which are heavily and immediately upregulated upon activation. CCL7 and 8 as well as CXCL9 and 10 show only modest upregulation. By contrast, CCL5 is downregulated in activated monocytes. CCL22 (macrophage-derived chemokine [MDC]) is an inflammatory chemokine that shows low expression on monocytes, but is induced by macrophage differentiation. CCL2 (monocyte chemotactic protein-1[MCP-1]), CCL3 (macrophage inflammatory protein 1 alpha (MIP-1α)), CCL4 (MIP-1β), CCL7 (MCP-3), CCL8 (MCP-3) and CXCL8 (interleukin-8) are considered proinflammatory chemokines, because they can activate neutrophils and monocytes. Injection of these chemokines into experimental animals results in a rapid and significant accumulation of monocytes and/or neutrophils. CCL20 (liver activation regulated chemokine [LARC]), MIP-3α) is considered a constitutive chemokine that was first described to be expressed in the intestine and skin. Its function in monocytes is not known. CXCL9 (Mig) and CXCL10 (IP-10) are considered classical T-helper1 chemokines that are proinflammatory and can attract effector T lymphocytes by binding to their CXCR3 receptor. Although CCL5 is considered an inflammatory chemokine, it is constitutively expressed in many organs including the lung and in some blood cells, predominantly platelets.[69] Overall, it is clear that monocytes produce proinflammatory chemokines that can sustain and increase inflammation, attract more monocytes, neutrophils, and inflammatory T cells. In the context of this chapter it is interesting to note that monocytes can synthesize several chemokines including CCL3, CLL5, and CCL22 that can help activate platelets and promote platelet aggregation in the presence of suboptimal concentrations of agonist. Platelets express the corresponding chemokine receptors CCR1, 3, and 4 (Table 46.4).

Monocyte Chemokine Receptors

Chemokine receptors are G-protein-coupled receptors that transduce signals via phospholipase C (PLC) and phosphatidylinositol-3-kinase (PI3K). CCR2 is the main receptor for CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), and CCL13 (MCP-4). MCP-1 was the first monocyte-specific chemoattractant to be discovered. Atherosclerosis-prone mice lacking CCL2[70] or CCR2[71] are about 50% protected from atherosclerosis in all models tested. CCR2 is not only important in monocyte recruitment to sites of inflammation, but also crucial for their release from the bone marrow,[72] and CCR2-deficient mice have reduced circulating monocyte numbers. Monocyte exit from the bone marrow compartment is mainly controlled by the CCR2 ligand CCL7 (MCP-3).[73] Beyond CCR2, monocytes express many other chemokine receptors, including CCR1, 5, CXCR1, 2, and 4, and CX3CR1. CXCR1 and 2 are of special interest, because they elicit no chemotactic response in monocytes, but can very effectively activate monocyte integrins to promote arrest.[29] In fact, CXCR2 on monocytes is the first example of a "pure" arrest chemokine receptor, because it only induces arrest of rolling monocytes but no other responses like chemotaxis. CCR1 is upregulated in activated monocytes and stays expressed in macrophages, which suggests possible autocrine effects of CCR1 chemokines such as MIP-1α and RANTES, which are also produced by monocytes. CCR1 is the receptor responsible for RANTES-induced monocyte arrest.[74] CCR5 is also expressed on monocytes, another receptor for the chemokines RANTES, MIP-1α and MIP-1β. RANTES has been shown to induce platelet–monocyte and monocyte–endothelial interactions.[69,75] CCR7 is not highly expressed in monocytes, but induced upon macrophage differentiation. CCR7 binds and responds to the secondary lymphoid tissue-expressed chemokines CCL19 and CCL21, attracting macrophages (and dendritic cells) to lymph nodes and Peyer patches. CXCR4 is very highly expressed on resting monocytes and downreguated upon activation. It stays low in macrophages. CXCR4 is believed to be involved in retaining monocytes in the bone marrow, but is also a very effective arrest chemokine[76] (Table 46.1). The fractalkine receptor CX3CR1 is highly expressed on "resident-type" blood monocytes and is involved in controlling monocyte development and survival.[77]

Endothelial Cells

Endothelial cells line all blood and lymph vessels. Endothelial cells are specialized by organ and even by vessel size (large artery, arteriole), or position in the circulatory system

Table 46.4

Cell surface molecules on platelets relevant to cell-cell interaction

Molecule	Main Function	Secondary Function
GPIbα	Binds vWF, mediates adhesion under high shear	Binds P-selectin
GPIIb/IIIa	Promotes platelet aggregation by binding fibrinogen	Binds monocyte Mac-1
GPVI	Main platelet receptor for collagen	
CD16	Obligatory co-receptor for GPVI	Binds Fc
P-selectin	Binds PSGL-1 on monocytes, microparticles, neutrophils	Anchors vWF
vWF	Binds GPIbα on other platelets, binds P-selectin	
ICAM-2	Binds LFA-1 on monocytes, neutrophils, lymphocytes	
CCR1	Receptor for MIP1α, RANTES	Augment responses to low-dose ADP
CCR3	Receptor for RANTES, eotaxin	
CCR4	Receptor for MDC	
CXCR4	Receptor for SDF-1α	
CD40L	Binds CD40 on monocytes and endothelial cells	GPIIb/IIIa on platelets
FcγRIIa	Binds Fc portion of IgG	Activates platelets

(arteriole, capillary, venule). The endothelial cell properties and molecules mentioned below apply to endothelial cells in a general sense. Most data are derived from experimental systems using cultured human umbilical vein endothelial cells.

Endothelial Cell Adhesion Molecules

Endothelial cells express a host of constitutive and inducible adhesion molecules, some chemokines, and some chemokine receptors (Table 46.5).

P-Selectin

In the context of this chapter, P-selectin is probably the most important endothelial adhesion molecule. As a member of the selectin class of adhesion molecules, it mediates leukocyte rolling (see FIGURE 46.2). P-selectin is prepackaged in Weibel-Palade bodies of endothelial cells, where it is intimately associated with vWF.[57] From Weibel-Palade bodies, P-selectin can be transported to the luminal surface by exocytosis induced by mild inflammatory stimuli. Endothelial P-selectin, once surface-expressed, can

Table 46.5

Cell surface molecules on endothelial cells relevant to cell-cell interaction

Molecule	Main Function	Secondary Function
P-selectin	Leukocyte/monocyte rolling, binds PSGL-1	Platelet rolling
E-selectin	Leukocyte/monocyte slow rolling, binds PSGL-1 and unknown ligand	leukocyte activation
PNAd	Lymphocyte rolling in HEV, binds L-selectin	
ICAM-1	Leukocyte/monocyte adhesion, binds LFA-1, Mac-1	binding Fg
ICAM-2	Leukocyte/monocyte adhesion, binds LFA-1	
VCAM-1	Monocyte adhesion, binds $\alpha_4\beta_1$	slow rolling
Fibronectin	monocyte adhesion, binds $\alpha_5\beta_1$, $\alpha_V\beta_3$ and $\alpha_4\beta_1$	
vWF	interaction with GPIb-V-IX on platelets	
GPIbα	interaction with vWF	binds Fg, Fn
CCL5 (RANTES)	monocyte arrest through CCR1	chemotaxis
CXCL1 (GRO-α)	monocyte arrest through CXCR2	chemotaxis
PSGL-1	Leukocyte rolling in intestinal microvessels	

also support platelet interactions with the endothelium.[78] Once platelets are activated, it is platelet and not endothelial P-selectin that is responsible for platelet–endothelial interactions.[69,75] Mice lacking P-selectin are about 50% protected from atherosclerosis[79] and show almost no neointima formation in response to vascular injury.[80] Experiments in bone marrow chimeric mice show that in both spontaneous atherosclerosis[81] and injury-accelerated neointima formation,[82] it is mainly the platelet and not the endothelial P-selectin that is responsible for inflammatory cell recruitment and neointimal growth. In addition to cell surface expression, both endothelial and platelet P-selectin can also be released into the plasma by alternative splicing and by a poorly understood shedding mechanism.[83]

Most of the knowledge about endothelial P-selectin function was derived from mouse experiments. However, the regulation of endothelial P-selectin expression is different in mice and primates, where P-selectin shows less sustained expression during inflammation.[84] It is possible that the function of human P-selectin is not quite as important as that of mouse P-selectin. There is some evidence that E-selectin is important for atherosclerosis in humans,[85] but less so in mice.[42] Human monocytes roll on human endothelial cells through P-selectin under shear. Human PSGL-1, like its mouse counterpart, can transmit proinflammatory and prothrombotic signals into monocytes.[86,87]

E-Selectin

Activated endothelial cells express E-selectin, which binds PSGL-1[88,89] and other unidentified ligands.[90] E-selectin ligand-1[91] and CD44 have been proposed as relevant E-selectin ligands on neutrophils.[92] Functionally, E-selectin ligands are heavily dependent on glycosylation by fucosyl transferase-VII and at least one sialyltransferase,[93] but unlike PSGL-1 binding to P-selectin, they do not require modification by core2GlcNAcT-I,[94] or sulfyltransferases. Like the other selectins, E-selectin supports leukocyte and monocyte rolling on inflamed endothelial cells *in vitro* and *in vivo*. E-selectin–dependent rolling is typically slower than P- or L-selectin–dependent rolling, suggesting that cells rolling through E-selectin can more closely scan the endothelial surface for activating signals. Neutrophils rolling on E-selectin induce the extended, but not high affinity conformation of LFA-1,[20,95] which is required for slow rolling. Endothelial E-selectin does not support platelet interactions, but very efficiently binds neutrophils and monocytes. E-selectin is required for an additional activating signal[96] that can arrest rolling neutrophils[97] and possibly monocytes. This signal is independent of Gαi-coupled receptors such as chemokine receptors.[20] E-selectin–deficient mice have no spontaneous defect in inflammation, platelet aggregation, or thrombus formation, suggesting that E-selectin function in mice overlaps with other rolling and activation molecules. Indeed, mice lacking both P- and E-selectin have a severe defect in neutrophil recruitment to sites of inflammation and show spontaneous pathology and altered hematopoiesis.[98,99] In humans, a "hyper-adhesive" polymorphism in the E-selectin gene correlates with an increased incidence of myocardial infarctions,[85] suggesting that E-selectin may be involved in atherosclerosis in primates.

ICAM-1

Endothelial cells constitutively express ICAM-1 (see above). Endothelial ICAM-1 expression is increased by inflammatory cytokines such as IL-1-β or tumor necrosis factor-alpha (TNF-α) and further enhanced in the presence of interferon-gamma (IFN-γ). Endothelial ICAM-1 is thought to be the major ligand supporting the binding of the β_2 integrins LFA-1 and Mac-1, but other ligands exist.[30] One of these other ligands is ICAM-2, a molecule with two extracellular immunoglobulin domains that is constitutively expressed on the endothelial surface and platelets, and is not upregulated by inflammatory mediators.

VCAM-1

Most endothelial cells express VCAM-1 upon cytokine stimulation. VCAM-1 is an immunoglobulin-like cell adhesion molecule with six to seven immunoglobulin domains. VCAM-1 is the most important endothelial ligand for VLA-4 ($\alpha_4\beta_1$ integrin), and intimately involved with monocyte recruitment to sites of inflammation and atherosclerosis. VCAM-1 expression is localized in areas at risk for atherosclerosis and precedes lesion formation.[100] Mice deficient in VCAM-1 are not viable because of developmental defects, but endothelial cell-specific knockouts and mice expressing a low level of a mutated VCAM-1 that lacks one of the VLA-4 binding sites have been prepared. These VCAM-1 hypomorphic mice are dramatically protected from atherosclerosis is all models tested.[101,102]

PECAM-1

Endothelial cells constitutively express CD31 (PECAM-1) and CD99, both of which have been implicated in monocyte transmigration.[103] C57BL/6 mice lacking CD31 have no transmigration defect, but on other genetic backgrounds, the migration defect is evident. Other endothelial-expressed adhesion molecules include junctional adhesion molecule (JAM)-1, 2, and 3.[104] They may function in monocyte and leukocyte transmigration.

Other Adhesion Molecules

Some specialized endothelial cells express adhesion molecules in an organ-specific manner. This includes mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expressed by high endothelial venules of the mesenteric lymph node and Peyer patches,[105] E-selectin expressed in resting skin endothelial cells,[106] and peripheral node addressin (PNAd) expressed in high endothelial venules of peripheral lymph nodes.[107] These region- and organ-specific adhesion molecules will not be discussed further, because they have not been reported to be involved in platelet–monocyte–endothelial interactions.

The endothelial adhesion molecules mediating interactions with platelets are not well defined. Endothelial-expressed P-selectin can support platelet rolling,[108] but interaction of activated platelets with endothelial cells is dependent on platelet P-selectin.[75] The endothelial adhesion receptors responsible for binding P-selectin are unknown. Activated endothelial cells secrete vWF as a very large multimer (ultralarge vWF), which can form long adhesive strings that can capture platelets by binding to platelet GPIbα.[109] The fluid drag force on the attached platelets stretches out vWF multimers, exposing a cleavage site that allows a plasma protease, a disintegrin and metalloproteinase with thrombospondin motif (ADAMTS-13), to cleave the multimers into shorter oligomers of vWF that are released into the plasma.[110] This seems to be an important source of plasma vWF.

Endothelial Cell Chemokines and Chemokine Receptors

Endothelial cells can express a number of proinflammatory chemokines, most notably of the IL-8 family.[111] The endothelial isoform of IL-8 is slightly different from the monocyte-expressed isoform,[112] but there are no known functional differences. IL-8 is immobilized on the endothelial cell surface, where it is in a strategic position to activate and arrest monocytes and neutrophils that may be rolling by. Although endothelial cells synthesize little MCP-1 or RANTES, RANTES can be delivered by rolling platelets and be immobilized on the endothelial surface.[69,75] Immobilized RANTES triggers monocyte arrest, whereas MCP-1 immobilization is less efficient and triggers monocyte arrest in some,[113] but not all vascular beds.[75] The ability of endothelial cells to produce other chemokines has not been tested systematically. Endothelial cells express the decoy chemokine receptor, the Duffy antigen receptor for chemokines (DARC), which promotes transport of inflammatory chemokines across the endothelial barrier and thus helps transmigration.[114] Endothelial cells may also express CCR2, the main receptor for MCP-1.[115] Lung endothelial cells express CXCR2, which regulates permeability and leukocyte migration.[116] The role of endothelial CCR2 and CXCR2 for interactions with platelets and monocytes has not been studied.

Platelets

Platelets are nonnucleated disks (2 × 0.5 μm) derived from megakaryocytes. They are abundant in blood (about 300,000/μL) and primarily responsible for hemostasis.

Platelet Adhesion Molecules

P-Selectin

Platelets express large amounts of P-selectin, which is stored in α secretory granules (Table 46.4). Upon activation, platelet P-selectin is translocated to the cell surface by exocytosis. In fact, platelet surface P-selectin is a hallmark of platelet activation. P-selectin-expressing platelets are found in patients with stable and unstable angina pectoris, myocardial infarction, and other cardiovascular diseases.[117] P-selectin is also found on the surface of a subset of blood platelets in apolipoprotein E–deficient mice,[75] a standard model of atherosclerosis. Platelet P-selectin is not only a marker of, but also an active participant in vascular disease. Injecting activated platelets into apolipoprotein E–deficient mice exacerbates the size of atherosclerotic lesions.[75] Similarly, preventing platelets from interacting with the vascular endothelium reduces atherosclerotic lesion size.[118] L- and E-selectin are not expressed in platelets.

Platelet Integrins

Platelets express several integrin adhesion molecules. The most abundant, best known, and possibly most important of them is integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa). Even in the resting state, GPIIb/ IIIa can bind immobilized fibrinogen and fibrin. This integrin rapidly acquires ligand-binding activity upon platelet activation.[119] $\alpha_{IIb}\beta_3$ is well documented to change its conformation and express neoepitopes related to the ligand-binding site.[19,120] Platelets from patients or mice that do no express GPIIb/IIIa (Glanzmann thrombasthenia) show defects in platelet aggregation and clot retraction.[40,121] vWF, vitronectin, and fibronectin bind GPIIb/IIIa through Arg-Gly-Asp (RGD) sequences, fibrinogen binds through Ala-Gly-Asp-Val (AGDV), and soluble CD40 ligand (sCD40L) uses a Lys-Gly-Asp (KGD) sequence. In the context of this chapter, GPIIb/IIIa binding of fibrinogen is of particular interest, because it may provide a means to promote platelet–monocyte interactions through Mac-1, which can also bind fibrinogen.[122] Blocking GPIIb/IIIa by antibodies or small molecules is a successful clinical treatment for coronary artery disease.[123] In addition to inhibiting platelet adhesion and aggregation, the various GPIIb/IIIa antagonists also reduce formation of the proinflammatory sCD40L from platelets. Interestingly, deficiency in GPIIb/IIIa does not confer protection from atherosclerosis.[124]

Other platelet integrins include $\alpha_5\beta_1$, which binds fibronectin and the collagen receptor $\alpha_2\beta_1$ (GPIa-IIa). Knockout mice have been prepared for both of these integrins, but show no detectable platelet defect. Humans lacking $\alpha_2\beta_1$ have a mild bleeding tendency and decreased platelet adhesion to the subendothelium.[125] $\alpha_2\beta_1$ appears to be activated by inside-out signaling secondary to GPVI binding (see below).

Collagen Receptors

The main platelet collagen receptor is GPVI, a 339 amino acid immunoglobulin-like molecule with similarity to the natural killer receptors.[126] GPVI ligation causes platelet activation and thus initiates hemostasis. It associates through its transmembrane domain with the Fc Receptor gamma (FcRγ) chain, which has an immunoreceptor tyrosine-based activation motif (ITAM) domain[127] for signaling. There is some evidence that GPVI resides preferentially in so-called lipid rafts, domains of the platelet membrane that are rich in sphingolipids and cholesterol.[128] Lipid rafts can merge and possibly give rise to platelet-derived microparticles (see below). A congenital defect in GPVI causes a mild bleeding tendency.[129] There is no evidence that GPVI is involved in platelet interactions with other cells.

GPIb, the main platelet receptor for vWF, is associated with GPV and IX in a GPIbα/Ibβ/V/IX complex,[130] also known as CD42bα/CD42bβ/CD42d/CD42a. All four glycoproteins belong to the leucine-rich repeat family. GPIb/V/IX mediates platelet adhesion to vWF under high shear. GPIbα also has binding sites for P-selectin, Mac-1, thrombin, and coagulation factors XI and XIIa. Deficiency of GPIb-V-IX in humans causes Bernard-Soulier syndrome, a relatively severe bleeding disorder. GPIb-V-IX binding to vWF triggers intracellular signals that lead to activation of GPIIb/IIIa. Injecting *Apoe*$^{-/-}$ mice with an antibody to GPIbα reduces the size of atherosclerotic lesions,[118] suggesting that platelet GPIbα interaction with endothelial vWF may have proinflammatory consequences.

Fc Receptors

Platelets express one Fc-gamma receptor, FcγRIIa. Upon cross-linking by intact immunoglobulin G (IgG), FcγRIIa relocates to lipid rafts and activates platelets through src-family kinases and adapter proteins. Fc γRIIa associates with GPIb.[128]

von Willebrand Factor

Platelet α-granules contain vWF, which is rapidly secreted upon activation and forms long strings that may be anchored to platelets by P-selectin. Platelet vWF is very large and very thrombogenic. Deficiency in vWF protects from atherosclerosis in mice.[131]

Platelet Chemokines and G-Protein Coupled Receptors

Platelet Chemokines

Platelets constitutively and abundantly express the chemokines CXCL4 (platelet factor 4, PF4) and RANTES (CCL5). Both are important in mediating monocyte–platelet–endothelial cell interactions. RANTES is deposited by transiently interacting platelets on inflamed endothelium *in vitro*,[69] and on atherosclerotic endothelium and monocytes *in vivo*,[75] where it promotes monocyte arrest and activation, most likely through CCR1.[74] PF4 is of importance in macrophage differentiation.[132] PF4 forms heterodimers with CCL5 (RANTES), and these heterodimers are very efficient at promoting monocyte adhesion.[133] On endothelial cells, PF4 binds to and activates a splice variant of CXCR3.[134]

Platelet Chemokine Receptors

Platelets express the chemokine receptors CCR1, 3, 4, and CXCR4 (Table 46.4). These receptors bind proinflammatory cytokines and SDF-1α, respectively. Chemokine receptor ligation can augment platelet responses to low doses of agonists.[135] These chemokine receptors are modifiers rather than initiators of responses, but are nevertheless important in the cross-talk between inflammation, platelet aggregation, hemostasis, and thrombosis (see below).

Other G-Protein Coupled Receptors

The most important activating G-protein–coupled receptors on platelets belong to the protease-activated receptor (PAR) and adenosine diphosphate (ADP)-receptor (P2Y) families. Of the four known PARs, platelets express PAR-1 and 4 in humans, and PAR-3 and 4 in mice. These receptors are responsible for thrombin-induced platelet activation, a prominent event initiating platelet aggregation. The PAR receptors bear a tethered ligand that becomes available to bind to and activate the receptor after cleavage of the receptor *N*-terminus by a specific protease such as thrombin.[136] Details of PAR receptors on platelets are covered in Chapter 33. Platelets also express G-protein–coupled receptors for ADP, most prominently, P2Y1 coupled to Gαq, and P2Y12 coupled to Gαi. P2Y12 is the molecular target of platelet aggregation inhibitors of the clopidogrel-type. In the context of atherothrombosis and vascular disease, ADP may be released from red and other blood cells, triggering platelet aggregation. *Per se*, ADP is not a very strong stimulus for platelet activation, but may synergize with other stimuli such as low-dose thrombin, or chemokines. Blocking P2Y12 also reduces formation of CD40L. Other platelet GPCRs include receptors for epinephrine and thromboxane A2, a cyclooxygenase product that amplifies platelet aggregation. Some GPCRs, including PAR-1, are preferentially found in lipid rafts.[128]

Platelet Cytokines

The most important cytokine produced by platelets is the TNF-like CD40 ligand (CD40L), which has both prothrombotic and proinflammatory effects.[119] CD40L is a type II transmembrane protein that binds CD40 on antigen-presenting cells and GPIIb/IIIa on platelets. GPIIb/IIIa binding promotes cleavage ("shedding") of CD40L by an unknown metalloproteinase in response to activation by collagen or thrombin. sCD40L also has proinflammatory and prothrombotic effects. Almost all CD40L in blood is on platelets, although some lymphocytes also express CD40L. Mice lacking CD40L have a thrombosis defect and are protected from atherosclerosis. sCD40L accumulates in stored platelet concentrates, and elevated levels of serum sCD40L are associated with thrombotic diseases, acute coronary syndrome, rheumatoid arthritis, lupus, and other inflammatory diseases. Platelets also contain the platelet-derived growth factor (PDGF), a cytokine-like growth factor for smooth muscle and other cells, and transforming growth factor-β (TGF-β), which is important in wound healing, fibrosis, and lymphocyte differentiation.

Small Molecules Secreted by Platelets

Thromboxane A2 (TXA2) and serotonin are powerful vasoconstrictors released by activated platelets. Both bind to receptors on smooth muscle and endothelial cells. TXA2 binding to thromboxane receptor (TP) is an important amplifier of platelet aggregation. TXA2 is a cyclooxygenase-1 product, an enzyme that is inhibited by aspirin.

Microparticles

Blood contains a host of microparticles with diameters between 50 nm and 1 μm that can support platelet–monocyte–endothelial interactions.[137] Most (about 90%) microparticles in normal human plasma are derived from platelets,[138] but others come from monocytes, endothelial cells, smooth muscle cells, and other cells. Platelet-derived microparticles are very prothrombotic by providing a phosphatodylserine-rich surface on which coagulation factors can assemble.[139] Monocyte-derived microparticles are a major source of tissue factor that initiate intravascular coagulation during thrombus formation.[137] The adhesion molecules used by microparticles to interact with endothelial cells, monocytes, and platelets are most likely derived from the cells from which the microparticles were generated. Indeed, the delivery of tissue factor to platelet aggregates has been shown to require PSGL-1 on monocyte-derived microparticles, and P-selectin on activated platelets.[56,57] Intravascular thrombosis can also be initiated by coagulation factor XII.[140]

Plasma and Extracellular Matrix Proteins Relevant to Cell–Cell Interactions

Although platelet–monocyte–endothelial cell interaction is often studied in tissue culture media, these adhesive interactions occur naturally in blood, which is itself a rich source of other adhesive proteins. Plasma fibrinogen can bind to many cell adhesion receptors, including Mac-1, $\alpha_V\beta_3$ integrin, and ICAM-1 on monocytes, activated GPIIb/IIIa on platelets, and ICAM-1 on endothelial cells. Fibrinogen has multiple binding sites per molecule that can bridge between platelets, endothelial cells, and monocytes. Fibrinogen-deficient mice have a surprisingly mild bleeding defect[141] and demonstrate that fibrinogen is not strictly necessary for hemostasis.

Plasma contains vWF, most of which exists as dimers and oligomers. vWF is required for platelet adhesion under high shear stress. vWF deficient mice,[142] and humans have a significant bleeding disorder (von Willebrand disease). By binding to platelet GPIb-V-IX, vWF promotes platelet–endothelial interactions. Plasma also contains fibronectin, an adhesive protein that can bind to integrins $\alpha_5\beta_1$ and $\alpha_V\beta_3$ on endothelial cells and

supports endothelial cell interaction with monocytes (through binding of $\alpha_4\beta_1$) and platelets (through binding to $\alpha_{IIb}\beta_3$). Mice lacking fibronectin are not viable.[143] Upon coagulation, fibrin is formed from fibrinogen, forming a tight meshwork that can entrap all classes of blood cells including poorly adhesive red blood cells. Fibrin shares some of its adhesive properties with fibrinogen. Immobilized fibrin can bind GPIIb/IIIa even in its nonactivated state.

When in the course of vascular injury the subendothelial matrix is exposed, various collagens, laminin, fibronectin, vWF, and other adhesive molecules become exposed. Collagen and vWF are very important for platelet binding. These interactions are treated in Chapters 28–30.

CELL–CELL INTERACTIONS

Shear Rate and Shear Stress

To understand the mutual interactions among platelets, monocytes, and endothelial cells, their attachment must be studied under shear flow conditions, because such conditions exist in almost all situations where these interactions occur in the flowing blood. Shear flow in the circulatory system is usually a pressure-driven flow through a series of distensible tubes. Owing to the physical principle of the no-slip condition at the fluid/solid interface, the fluid particles very near the vessel wall (and near each blood cell) do not move relative to that surface. In tube flow, there is a gradient of flow velocities such that the highest velocity is reached in the center of the vessel. The rate of change of flow velocity between adjacent fluid layers is called the shear rate, and has units of meters per second (velocity) divided by meters (distance between layers), or s^{-1}. The change in velocity between adjacent layers of fluid is associated with a drag force (Newtons) that is calculated per unit surface area (square meters), which is defined as the shear stress (in N/m^2 or Pascals). The cgs unit, dyn/cm^2, is also used for shear stress, and 10 dyn/cm^2 is equal to 1 Pa. The ratio between shear stress and shear rate is the viscosity, which is measured in Pas. An older unit, centipoise, is often used, where 1 centipoise is equal to 0.001 Pas. In blood, the viscosity is not constant across the cross section of a blood vessel, but changes as a function of radial position and hematocrit.[144] The shear stress and shear rate along the vessel wall, the wall shear rate, and wall shear stress, are most relevant for cell interactions with the vessel wall. When only one shear stress or shear rate is reported without a qualifier, this usually refers to the wall shear stress or wall shear rate.

Endothelial Surface Layer

Under normal conditions, the luminal aspect of most endothelial cells is covered by a thick layer of extracellular matrix material called the glycocalyx. The thickness and composition of this layer probably varies between vascular beds, vessel sizes, and physiologic conditions, but most reports place its thickness between 0.3 and 0.6 μm.[145] This layer contains proteoglycans, glycosaminoglycans, and hyaluronic acid. The mechanical properties of this layer are such that there is almost no fluid flow through this layer along the vessel surface.[146] This means that the wall shear stress and wall shear rate on the surface of the endothelium of healthy blood vessels is nearly equal to zero.[147] All known endothelial adhesion molecules are buried deep within this layer and hardly accessible to adhesion molecules on monocytes, platelets, and other cells in the flowing blood. However, as monocytes and other white blood cells pass through and exit from small capillaries, they can compress the endothelial surface layer sufficiently to initiate adhesive interactions and start rolling.[148] In large vessels such as the aorta, carotid artery, or coronary arteries, where cells do not exit from capillaries, it is probably necessary that the endothelial surface layer is degraded before productive leukocyte–endothelial cell interactions can occur.[149] It is not known whether cultured endothelial cells maintain a surface layer of similar size and composition as that found *in vivo*, although there is indirect evidence that they express some hydrodynamically relevant layer on their luminal surface. The glycocalyx layer is thinner in areas of disturbed flow, endothelial dysfunction, or under inflammatory conditions.[150]

Cell–Cell Interactions Under Shear

To study cell–cell interactions under shear, several *in vitro* and *in vivo* methods have been developed. A defined shear stress and shear rate can be applied to cells in suspension using a plate-and-cone apparatus, which produces a uniform shear throughout the fluid.[151] A modification of this apparatus is the rheoscope, constructed of two counter-rotating transparent cones, which allows the direct visualization of cell–cell interactions at a defined shear rate and shear stress.[152] A very popular device is the parallel plate flow chamber,[153] which combines excellent visibility due to its optical properties with versatile use of adhesion molecules, cultured endothelial cells, and other substrates. Leukocyte–endothelial and platelet–endothelial interactions have also been studied using capillary tubes,[154] which mimic the radial symmetry of the flow profile in most blood vessels *in vivo*, but have limited visibility due to optical diffraction. In a traveling capillary apparatus, the microscope stage is moved at a speed equal and opposite to that of the cell suspension flow such that the interacting cells appear to remain stationary.[155] Other adhesion assays include the radial flow chamber[156] and the graded shear stress flow chamber.[157] Recently, autoperfused flow chambers have been developed that allow the study of leukocyte and platelet interactions with adhesion molecules in their natural blood environment.[158,159] This flow chamber was miniaturized so that studies in mouse blood became possible without returning the blood to the mouse.[160] Microfluidic devices allow control of the local site density of adhesion molecules.[161] In so-called static adhesion assays, adhesion occurs in the absence of shear stress, but nonadherent cells are washed off with an undefined shear stress. Such assays are not suitable for studying blood cell interactions with each other, or with endothelial cells. In some tissues and species, monocyte interaction can be studied by intravital microscopy. Relevant to this chapter, monocyte and platelet interactions have been studied in the mouse aorta,[162] carotid artery,[163] and femoral artery (Huo and Ley, unpublished) *in vivo*.

Monocyte–Endothelial Interactions

Monocytes may encounter the endothelium in two fundamentally different situations. In the microcirculation, the initiation of monocyte interactions with the endothelium has not been studied systematically, but the process is probably similar to that described

Table 46.6

Endothelial–monocyte interactions

Endothelial Cell	Monocyte	Remarks
P-selectin	PSGL-1	Rolling, monocyte activation?
VCAM-1	$\alpha_4\beta_1$	Slow rolling, adhesion
Fibronectin CS-1	$\alpha_4\beta_1$	Adhesion
ICAM-1	LFA-1, Mac-1	Adhesion strengthening?
ICAM-2	LFA-1	
E-selectin	Unknown ligand	Slow rolling?
CXCL1, 2, 3, 8	CXCR1, 2	Monocyte activation

for neutrophils.[164] In postcapillary venules, most leukocyte–endothelial interactions are initiated at the point where leukocytes enter the venules from capillaries. Since capillary diameters are smaller than leukocyte diameters in most organs, leukocytes must deform to pass, and in the process probably squeeze down the endothelial surface layer, which brings them in close contact with the endothelial adhesion molecules. Once engaged, these adhesion molecules (Table 46.6) support stable rolling, during which the endothelial surface layer is probably continuously flattened. The layer appears to recover after the leukocyte has passed. In large vessels such as arteries, this mechanism is not operative because the vessel is much wider than the monocyte. In these cases, most monocyte–endothelial interaction is initiated by secondary capture.[53]

Monocyte Capture

In large vessels such as arteries, it is likely that the endothelial surface layer is damaged or reduced in thickness during the initiation of atherosclerosis or other forms of vascular inflammation. Monocyte interaction is largely P-selectin/PSGL-1 dependent.[163] In these larger vessels, secondary capture is very important.[53] Secondary capture or secondary tethering describes the transient interaction between a free-flowing blood cell and an already adherent blood cell that can greatly facilitate the initiation of monocyte interactions with the endothelial wall. Although this process was originally described as an interaction between like cells,[154] monocyte capture onto the endothelial surface of inflamed arteries can also be initiated by platelets that transiently or stably interact with the vessel wall[75] (FIGURE 46.3). In this case, the interaction requires platelet P-selectin and monocyte PSGL-1. When a monocyte is captured through interaction with another monocyte, secondary capture probably requires PSGL-1 on the adherent monocyte and L-selectin on the incoming monocyte. Secondary capture does not allow predictions about whether or how rolling along the endothelium will ensue. There is evidence that interaction with platelets is more important for monocytes than for other leukocytes.[165]

Monocyte Rolling

In mouse models, monocyte rolling is almost entirely dependent on P-selectin expressed by the inflamed, or atherosclerotic endothelium and PSGL-1 on the monocytes. Monocyte rolling is slowed by transient $\alpha_4\beta_1$/VCAM-1 interactions.[166] In human atherosclerotic lesions, E-selectin expression has been described.[167] Monocytes express E-selectin ligands, which remain to be identified at the molecular level. With the exception of high endothelial venules in secondary lymphatic organs,[113] monocyte rolling in small microvessels has not been studied systematically.

Monocyte Arrest

Rolling *per se* is not sufficient to allow monocyte recruitment. Monocyte arrest is commonly triggered by specific arrest chemokines, chemokines that are deposited on the endothelial surface and can signal integrin activation by binding to G-protein–coupled receptors while the cell is rolling by. Identified arrest chemokines for monocytes include CXCL1, 2, and 3, all of which bind to CXCR2, and CCL5, which mediates arrest by binding to CCR1. In the human system, IL-8 (CXCL8), which binds to CXCR1 and CXCR2, can also act as an arrest chemokine.[168] CXCL1, 2, 3, and 8 are synthesized by inflamed endothelial cells, while CCL5 is deposited by platelets that transiently interact with the vessel wall.[69,75] Soluble CCL2 (MCP-1) can also trigger monocyte arrest, but the relevance for monocyte arrest of endothelial-bound CCR2 has not been demonstrated outside lymph node venules.[29,113] The arrest function of many chemokines for monocytes has not been investigated, but it is likely that other chemokines may be able to trigger arrest. Of note, the arrest and chemoattractant functions of chemokines do not necessarily correlate with each other.[169] Monocyte arrest does not require a change in intracellular free calcium ("calcium flux") or activation of MAP kinase.[169]

When a rolling monocyte is exposed to an arrest chemokine, its surface integrins are activated by inside-out signaling. In adhesion assays conducted in atherosclerotic vessels under shear flow conditions, monocyte arrest is triggered by $\alpha_4\beta_1$ integrin binding to VCAM-1,[29] but an arrest component through β_2 integrins has been described in a flow chamber system using cultured endothelial cells.[168] While it is clear that monocyte arrest is integrin dependent, the detailed molecular mechanisms can currently only be inferred from studies in other cells (see above). In addition to affinity regulation, integrins also cluster in the plane of the monocyte membrane, giving rise to patches of integrins with increased apparent affinity for multivalent ligands (avidity regulation, FIGURE 46.1). The lateral movement of integrins requires their temporary release from cytoskeletal constraints and subsequent reattachment to cytoskeletal elements, an event that is unlikely to occur within milliseconds. A third possibility is that monocyte integrins undergo some limited conformational change, followed by ligand binding and outside-in signaling that leads to rapid bond maturation.[18] The exact contribution of affinity and avidity regulation during monocyte arrest is controversial and awaits further experimentation.

Outside-In Signaling

Once α_4 and β_2 integrins are activated and engage their respective ligands, they transmit signals into the adherent monocyte in a process called outside-in signaling.[170] These signals probably help the adhesive contact to mature, initiate cell crawling on the endothelial surface, and initiate transmigration into the subendothelial space. In neutrophils,[164] but not monocytes,[169]

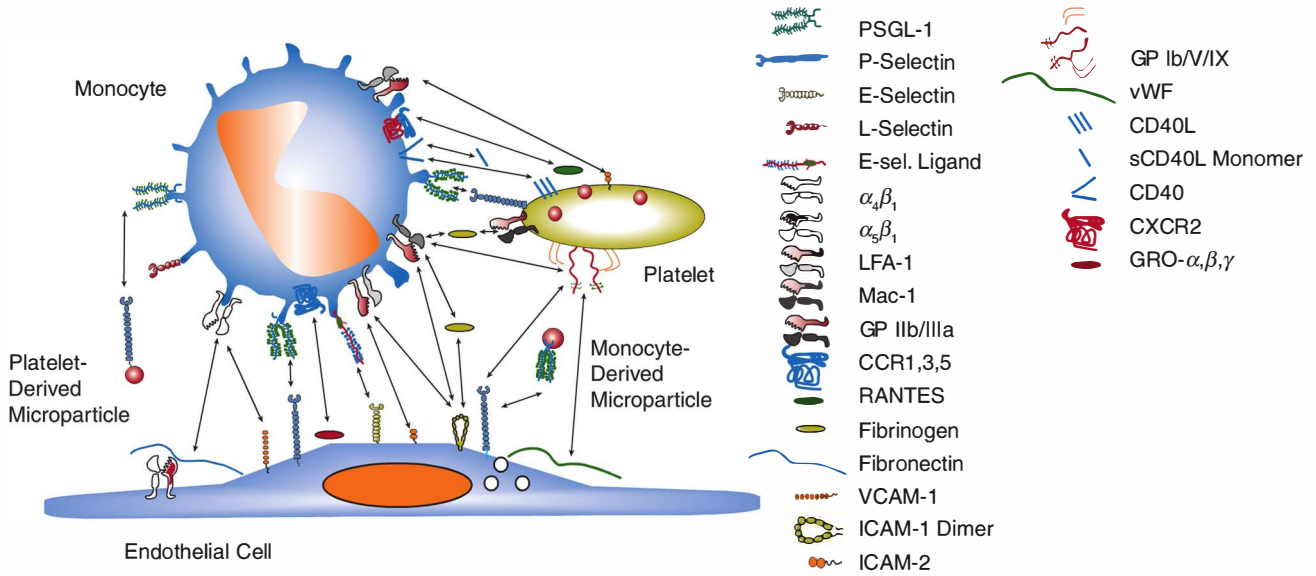

FIGURE 46.4 Monocyte–platelet–endothelial interactions. Each arrow shows a molecular interaction, legend for molecules indicated in figure. Monocyte- and platelet-derived microparticles are also shown. See text for details.

a gradual increase in intracellular free calcium has been shown during rolling, with a massive increase in intracellular free calcium upon arrest.

Cytoskeletal interactions of integrins are likely to be important not only for outside-in signaling, but also for lending mechanical strength to the bonds between the adherent cells and the vascular endothelium. Many of the relevant monocyte–endothelial cell interactions in the arterial circulation occur in the presence of very high shear forces. α_4 integrins attach to VCAM-1 and fibronectin. β_2 integrins attach to endothelial ICAM-1, ICAM-2, and other ligands. Although arrest of monocytes under moderate wall shear stress of 3 dyn/cm^2 was attributed to α_4 integrins and did not require β_2 integrins,[29] it is likely that β_2 integrins contribute to bond strengthening, migration, and transendothelial migration.

Platelet–Monocyte Interactions Under Shear

Platelet–monocyte interactions are most commonly studied in plate-and-cone devices, which produce a uniform shear rate and shear stress throughout the cell suspension.[171] It is clear that most if not all monocyte–platelet adhesion is mediated by P-selectin on the activated platelet surface and PSGL-1 on the monocyte. That this interaction occurs *in vivo* is demonstrated by the presence of P-selectin–dependent platelet–monocyte aggregates in patients with coronary heart disease.[172] The abundance of these aggregates correlates with the incidence of unstable angina, myocardial infarction, and stroke.[117] Platelet–monocyte aggregates are also found in the blood of apoE-deficient mice on a proatherogenic diet, but not in control mice.[75,173]

Monocyte interactions have also been studied in flow chambers coated with platelet monolayers. This model is most relevant to the adhesion of monocytes at sites of vascular injury, where a platelet monolayer forms almost immediately. Monocyte interaction with platelet monolayers is strictly P-selectin and PSGL-1 dependent and shares many similarities with monocyte–endothelial cell interactions, with the exception that P-selectin expression on monolayers of activated platelets is probably higher than on endothelial cells, and the rolling velocity is consequently lower. Monocytes can adhere to platelets via an interaction of monocyte Mac-1 with plasma fibrinogen and platelet GPIIb/IIIa.[174] Platelets express ICAM-2, a known ligand for LFA-1, which is expressed on monocytes (FIGURE 46.4). The relative importance of these other pathways *in vivo* is not known. P-selectin/PSGL-1 interactions seem to dominate platelet–monocyte interactions (Table 46.7).

Platelet–Endothelial Interactions Under Shear

Platelets can roll on and adhere to endothelial cells through at least two mechanisms. One requires P-selectin expression on inflamed endothelial cells and results in platelet rolling in microvessels.[108] In this interaction, endothelial P-selectin binds to a ligand on platelets, most likely GPIbα.[175] Another mechanism for platelet–endothelial cell interactions is found in large arteries and appears to be relevant for the process of atherosclerosis.[75] It requires P-selectin expression on platelets, which interact with an unknown ligand on endothelial cells (Table 46.7). A third candidate mechanism for platelet attachment to endothelial cells is dependent on platelet GPIbα interacting with vWF, which is stored in Weibel-Palade bodies of endothelial cells and can be released as an ultralarge vWF upon activation.[109]

Enhanced Monocyte Adhesion by Platelets and Microparticles

Given these extensive interactions, the monocyte–platelet–endothelial cell system can be viewed as a synergistic proinflammatory and prothrombotic triad. Platelets enhance monocyte

Table 46.7

Platelet interactions with endothelial cells (left) and monocytes (right)

Endothelial Cell	Platelet	Monocyte	Remarks
Fibronectin	GP IIb/IIIa	Mac-1	IIb/IIIa with Mac-1 through Fg
CD40	CD40L	CD40	Activates EC and monocytes
P-selectin	GP Ib V IX	Mac-1	Also binds vWF
		ICAM-1	Homotypic aggregation
	ICAM-2	LFA-1	Function not demonstrated
Unknown	P-selectin	PSGL-1	GPIbα on EC controversial
		L-selectin	Secondary capture
Proteoglycans	RANTES	CCR1, 3, 5	Activates monocytes
CXCR3b	PF4	unknown	Activates ECs and monocytes
VEGF-R	VEGF		Activates EC

Table 46.8

Proinflammatory and prothrombotic molecules on platelets, monocytes, and endothelial cells

Platelets
Prothrombotic
vWF, IIb/IIIa, fibrinogen
CD40L, sCD40L: induces MCP-1, IL-6, IL-8 in monocytes, E-selectin, VCAM-1, ICAM-1 in endothelial cells

binding to inflamed endothelium, which is critically important in atherosclerosis.[75,118] Conversely, monocytes rolling on endothelial cells can deliver platelets that are attached to them.[172] Since each of these cell types brings critical components of the hemostasis, coagulation, and inflammation system, it is easy to see how the mutual interaction of these cells greatly enhances both inflammation and thrombosis (Table 46.8). The intimate interaction between platelets, endothelial cells, and monocytes results in enhanced monocyte recruitment (FIGURE 46.5), and accelerated atherosclerosis.[75]

Tissue Factor and Monocyte-Derived Microparticles

Tissue factor initiates coagulation through the extrinsic pathway (see Chapter 11). Although tissue factor is expressed in many extravascular cells, its expression is highest on activated monocytes. Monocytes continuously shed microparticles ranging in size from 0.05 to 1 μm. Monocyte-derived microparticles lack metabolic functions, but are enriched in tissue factor and many other monocyte components.[56,137] Microparticles of both platelet[176] and monocyte origin are abundant in human and mouse plasma, and their number can increase during disease states.

Some[177] if not most of the "plasma" tissue factor is in fact contained in monocyte-derived microparticles.[56,137] This source of tissue factor is available for incorporation into platelet aggregates, where it initiates coagulation. Monocyte-derived microparticles express PSGL-1, and activated platelets express P-selectin. Since the P-selectin/PSGL-1 interaction is critical for microparticle recruitment to sites of thrombosis, P-selectin–deficient mice[178] and PSGL-1 deficient mice[179] both have a reduced propensity for intravascular thrombus formation with little evidence of an overt bleeding disorder. The formation of monocyte-derived particles can be induced by soluble P-selectin,[179] which has been proposed to be a useful mechanism for delivering procoagulant activity to hemophilia patients.

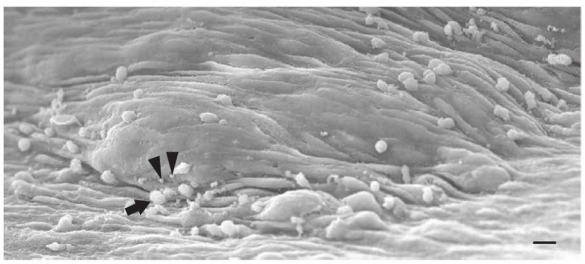

FIGURE 46.5 Monocyte and platelet adhesion in an atherosclerotic apoE-/- mouse carotid artery. Monocytes (*arrow*) and platelets (*arrowheads*) preferentially adhere in the shoulder region of this atherosclerotic plaque. Sample taken 30 minutes after IV infusion of activated mouse platelets. Scale bar indicates 10 μm. (Scanning electron micrograph prepared by Jan Redick and Yuqing Huo.)

CROSSTALK BETWEEN INFLAMMATION AND HEMOSTASIS

Monocyte Activation by Interaction with Platelets

Activated platelets can bind to monocytes and deposit chemokines such as CCL5, which cause an increase in $\alpha_4\beta_1$ integrin avidity (lateral clustering) and affinity (conformational change).[69,75] Platelet-induced deposition of PF4 can also induce monocyte differentiation into macrophages.[132,180] Disrupting heterodimer formation between CCL5 and PF4 reduces monocyte recruitment to atherosclerotic lesions.[133] Platelet CD40L, either surface-expressed or secreted, interacts with monocyte CD40, and causes monocyte activation.[119] Chemokine-induced L-selectin shedding on monocytes could potentially limit the inflammatory response. Chemokines can also induce a secretory response in monocytes, including release of specific, secretory, and tertiary granules. Monocyte degranulation releases a wide variety of proinflammatory mediators and enzymes.

Proinflammatory Effects of Coagulation Products

Not only does the inflammatory response enhance the coagulation response (discussed above), but the converse is also true. Many coagulation products are proinflammatory, including fibrin degradation products. Thrombin has strong proinflammatory effects, as has the binding of coagulation factor X to monocyte Mac-1.[181]

CHAPTER

47 Leukocyte Function and Contribution to Disease

EDITH VAN DE VIJVER AND TACO W. KUIJPERS

Inflammation is a tightly regulated process initiated after tissue injury or infection. The main function of inflammation is to eliminate the pathogenic insult and remove damaged tissue, with the aim of restoring tissue homeostasis. The concerted action of professional phagocytes—neutrophils, monocytes, and macrophages—is crucial to the effective elimination of intruders and cell debris.

Neutrophils are short-living cells that are recruited early in the inflammatory response. Upon binding of cytokines, which originate either from microorganisms or from surrounding cells, neutrophils transmigrate through the vascular wall toward the infected tissue. The opsonized pathogen is bound and phagocytosed by the neutrophil, whereupon it is killed by mediators such as toxic granular proteins or reactive oxygen species (ROS). These inflammatory mechanisms are potentially harmful to the host, with the risk of inducing sepsis. Therefore, neutrophil activation has to be tightly controlled by several negative regulation mechanisms.

Inflammation also shifts the hemostatic mechanisms in favor of thrombosis. Multiple mechanisms are at play, including upregulation of tissue factor leading to the initiation of clotting and amplification of the clotting process by augmenting exposure of cellular coagulant phospholipids. Moreover, a decrease in the activity of natural anticoagulant pathways takes place, which is particularly targeted toward downregulation of the activated protein C (APC) pathway through multiple mechanisms. The decreased function of the natural coagulation pathways appears to play a role in dampening inflammatory responses. The dual roles of the neutrophil in inflammatory responses and hemostasis are highlighted in this chapter.

DEVELOPMENT AND TURNOVER

About 60% of all nucleated cells in the bone marrow belong to the myeloid series. Neutrophils originate from myeloid progenitor cells, and they mature in the bone marrow in about 2 weeks. During maturation and until activation of neutrophils, it is important that the neutrophils are retained in the bone marrow. Interactions between chemokine receptor CXCR4 on neutrophils and its ligand CXCL12, which is constitutively expressed by bone marrow stromal cells, play a crucial role in this process. Disruption of this interaction by administering CXCR4 antagonist AMD3100 results in neutrophilia due to increased neutrophil release from the bone marrow.[1]

During myelopoiesis, which includes the development of granulocytic as well as monocytic lineages, the myeloid-specific growth factors, granulocyte colony-stimulating factor (G-CSF) and granulocyte-monocyte-CSF (GM-CSF), play an important role.[2] G-CSF and GM-CSF exert a dual effect: a boost in cell survival as well as the induction of myeloid development through an increase in the number of colony-forming units. The effect of G-CSF is transmitted to the myeloid cell through the G-CSF receptor. Mice deficient in either G-CSF or its receptor have a reduced neutrophil count (~20% of normal).[3,4]

Normally, <2% of all neutrophils in the body are circulating in the blood. When released from the bone marrow, neutrophils normally have a short life span (6 to 10 hours) in the bloodstream.[5] Thereafter, they move to the extravascular tissues and within hours undergo spontaneous apoptosis. Indeed, neutrophils are predisposed to cell death by apoptosis. This process prevents the cytotoxic contents in neutrophil granules from being released into the surrounding tissues, and it facilitates the elimination of dead neutrophils by tissue macrophages.

The exact molecular mechanisms underlying neutrophil apoptosis are unknown, although members of the Bcl-2 protein family and caspases have been shown to be involved.[6] At the level of mitochondria, these two groups of proteins are intimately connected: Bcl-2 homologues govern the activity of caspases by exerting their effect through regulation of mitochondrial function.[7] Proapoptotic Bcl-2 proteins, such as Bax, redistribute from the cytosol to the mitochondria to disturb the mitochondrial membrane integrity by forming channels, which facilitates the subsequent release of cytochrome *c* and the activation of Apaf-1 and downstream caspases. The family of caspase proteases executes cleavage of specific targets, which then leads to cell disassembly and death. Among these proteases, caspase-3 stands out for the large number of substrates that it destroys, including nuclear proteins, cytoplasmic structures, and cytoskeletal elements.

In the clinic, survival of both the immature myeloid progenitor cells and mature neutrophils can be extended by delaying apoptosis through the action of a wide variety of agents, including G-CSF and GM-CSF. During infections, the release of neutrophils into the circulation is accelerated, and these cells are also among the first to leave the blood vessels by extravasation and to migrate toward the site of infection.

EXTRAVASATION AND MIGRATION

During inflammation, circulating neutrophils migrate to the site of infection following a gradient of chemotaxins in a process called chemotaxis. Chemotaxins may be derived from either the infected tissue or local complement activation, or directly from the pathogens themselves, and diffuse within the tissue into the local vasculature. These gradients of chemotaxins recruit the neutrophils in interplay with factors expressed on the

luminal side of blood vessel endothelial cells locally.[8] Many of the chemotaxins involved in granulocyte movement are small proteins of about 60 to 100 amino acids, very homologous in structure. The major family of chemotaxins, known as the chemokine superfamily (see Chapter 46), consists of over 30 different chemotactic molecules, which are produced by host cells in response to inflammation, injury, hypoxia, or other forms of stress. Most chemokines can be classified into α (CXC) and β (CC) chemokines, distinguished by the presence or absence of a single amino acid between the first two of four conserved cysteines.[9] The γ (single C) and δ (CX_3C) classes of chemokines have only recently been coined, each with as yet one member. As exemplified by CXCL8—the first CXC member described—most CXC chemokines activate neutrophils, whereas the CC chemokines act toward various lymphocyte subsets, monocytes, eosinophils, or basophils. CXCL8 is also referred to as interleukin-8 (IL-8).

In addition to the chemokines, chemotactic peptides are released by infecting microorganisms, for example, formyl-methionyl-leucyl-phenylalanine, and the host complement system, for example, the split product of activated C5 (C5a). Cell membrane-derived lipid mediators, such as platelet activating factor, are also strong chemoattractants. For each of these agents, specific receptors on the neutrophil plasma membrane exist. These receptors, as well as those for the chemokines, belong to the seven-span superfamily of G-protein–coupled receptors (GPCRs), which are integral membrane proteins with seven transmembrane domains. Ligand specificity is created by differences in the extracellular domains. The intracellular domains interact with trimeric guanidine triphosphate (GTP)-binding proteins, enabling a link with signal transduction pathways leading to a wide range of functional responses, the complexity of which is still largely unclear.

Cells following the chemotaxin gradient toward the site of infection have to leave the bloodstream in a process called extravasation (FIGURE 47.1). Extravasation is a multistep process involving adhesion molecules in which chemotaxins function as activating agents or (pro-) inflammatory mediators. The first step of extravasation consists of initial contact between endothelial cells and neutrophils marginated by the fluid flow of the blood. L-Selectin (CD62L) on leukocytes plays a role herein, contacting several cell adhesion molecules on endothelial cells. Within the local environment of an inflammatory tissue reaction, the endothelium begins to express the adhesion molecules P-selectin (CD62P) and later on E-selectin (CD62E) (see Chapter 46).[10] The low-avidity interaction of these selectins with their ligands on the opposite cells forces the neutrophils to slow down and make a rolling movement along the vessel wall.

In contrast to the low-avidity binding of neutrophils to selectins, the final step of firm adhesion and subsequent migration depends on stable interaction between integrins on the neutrophil and their ligands on the endothelial cells. For this process, the integrins need to be "activated," that is, change their conformation into one with high binding avidity for their ligands, which is described in more detail in Chapter 46. Integrins consist of heterodimeric proteins of an α-chain covalently associated with a β-chain.[11] One particular β-chain may associate with one of various α-chains. As a consequence, several integrin receptor subfamilies exist. The β_2 integrin receptor subfamily is only expressed on leukocytes and comprises four different heterodimeric proteins, each of which contains a different α subunit: that is, $\alpha_L\beta_2$ (LFA-1; CD11a/CD18), $\alpha_M\beta_2$ (CR3; CD11b/CD18), $\alpha_X\beta_2$ (gp150,95; CD11c/CD18), and $\alpha_D\beta_2$ (CD11d/CD18). The β_2 integrins bind to adhesion molecules on endothelial cells (intercellular adhesion molecule [ICAM]-1 and ICAM-2) and to several complement factors. The main β_2 integrin on neutrophils is CR3.

In contrast to rolling and adhesion of neutrophils, the mechanisms that mediate migration through venular walls are less well understood. However, there is now good evidence that besides ICAM-I and -II junctional molecules such as PECAM-1 (CD31) and the junctional adhesion molecule (JAM) family (JAM-A, -B, and -C) play a major role.[12,13]

As mentioned above, slowly rolling neutrophils are able to recognize concentration differences in a gradient of chemotaxins and to direct their movement toward the source of these

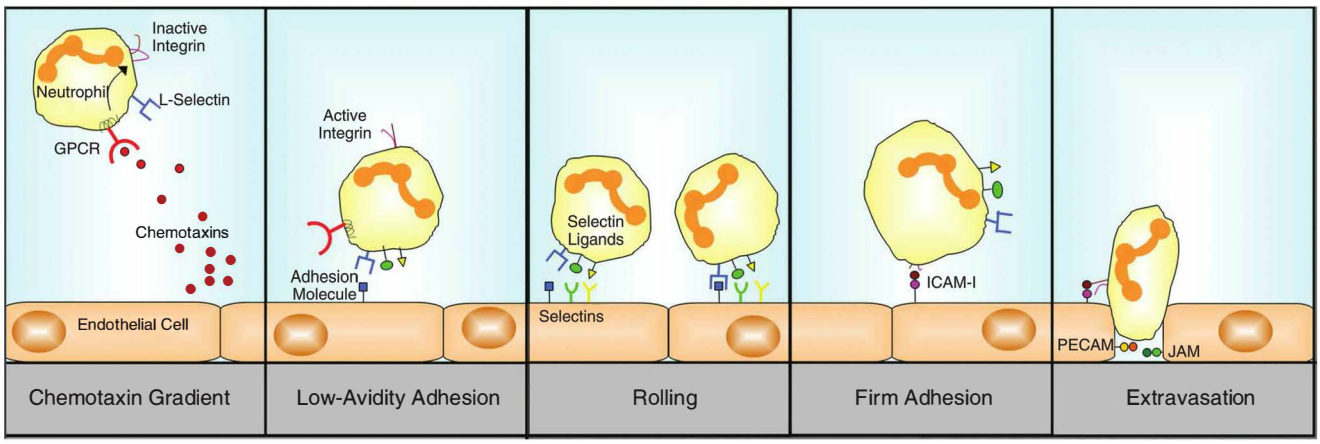

FIGURE 47.1 Extravasation of neutrophils. Neutrophils migrate in the direction of a gradient of chemotaxins, released at the site of infection. Upon initial contact with the endothelial cells through L-selectin, neutrophils slow down and interact with endothelial cell selectins while rolling along the vessel wall. Subsequently, integrins on the neutrophil are activated and bind to adhesion molecules on the endothelial cells, which results in stable adhesion. Binding to PECAM, JAMs, and other adhesion molecules guides neutrophils through the endothelial layer in the direction of the infection.

agents. Although the details of this process remain unknown, the gradient mostly likely causes a difference in the number of chemotaxin receptors on either side of the cell, thereby inducing the cytoskeletal rearrangements needed for movement. Since adhesion molecules such as the β_2 integrins are essential for the connections with the tissue cells or with the extracellular matrix proteins, these connections must be formed at the front of the moving neutrophils and broken at the rear end.[8,14] Moreover, for continued sensing of the chemotaxin gradient, the chemotaxin receptors on the neutrophil must be freed from their ligand for repeated usage. This occurs through internalization of the ligand–receptor complex, intracellular disruption of the connection, and transport of the free receptor to the front of the cell, followed by reappearance of the free receptor on the leukocyte surface. Within the infected tissue, the chemotaxin gradient persists, and leukocyte migration is maintained.

INTRACELLULAR SIGNALING

This complex process of cytoskeletal remodeling and cellular movement is controlled by several small GTPases of the Rho family and their guanine-nucleotide exchange factors (GEFs). In neutrophils, it has been shown that, in particular, Rac-2 is crucial in the signaling leading to cytoskeletal remodeling and cellular motility. Deficiency in Rac-2 or its upstream regulator PI3Kγ results in failure to chemotax and to degranulate upon GPCR activation. P-Rex1, a GEF for Rac, is believed to be regulated by G$\beta\gamma$ and PtdIns(3,4,5)P3 signaling and thereby links GPCRs and PI3Kγ activity to Rac-dependent neutrophil responses.[15]

Several other GEFs, for example, DOCK2 and the Vav proteins, are also important for cell movement. Upon GPCR stimulation, neutrophils deficient for DOCK2 show impaired chemotaxis due to loss of polarization of the cell.[16] Vav1/3 knock-out neutrophils, on the other hand, show defective β_2 integrin-induced responses, which are specifically required for stable adhesion.[17]

Recent studies have suggested that GTPase Rap1 is also involved in neutrophil adhesion. We were the first to describe a syndrome of combined leukocyte adhesion deficiency and platelet dysfunction despite normal integrin expression, designated as LAD-1/variant syndrome.[18,19] In a boy with a similar clinical syndrome, then named LAD-III, Rap1 activity was found to be absent.[20] Therefore, the Rap1 regulation by CalDAG-GEF1 was suspected to be defective in these clinical pictures.[21] However, recently we and others showed mutations in *FERMT3*, encoding a hematopoietic structural protein called kindlin-3, as the genetic cause for this syndrome. Kindlin-3 acts as a switch to activate the integrins similar to what was known for talin at the time.[22,23] Whether and how exactly these two proteins interact is still unclear.[24]

IL17-PRODUCING CELLS AS A DRIVING FORCE BEHIND NEUTROPHILIA

Neutrophil release from the bone marrow into the blood stream has been extensively studied, and depends to a great extent on cytokines.[25] An important group of cytokines in this respect is the IL family, which is mainly produced by activated lymphocytes and macrophages. ILs stimulate other immune cells to differentiate and proliferate, and can induce fever. The identification of ILs, as well as discoveries of their receptors, and their production have markedly changed the way in which we study immunologic processes. Through the study of the role of IL-23 in autoimmunity, an alternative T cell subset was discovered: the adaptive Th17 cell, whose expression is promoted by both chronic inflammation and tissue damage.[26] The Th17 cell was identified as a cell that induces an inflammatory response by producing IL-17, IL-21, and IL-22, and is thereby clearly distinct from the well known Th1 and Th2 subsets. Furthermore, Th17 cells have been associated with autoimmune diseases.[27]

Interestingly, the IL-17–mediated immune pathway is induced within 4 to 8 hours following epithelial cell injury or activation of pattern recognition receptors (PRRs), which is too short to allow the development of Th17 cells. *In vivo* models of infection have shown that several innate cell subsets, among which unconventional $\gamma\delta$ T cells, cooperate to promote this immediate IL-17–mediated response. Studies of extracellular pathogens that target the lungs showed that IL-23 was a main stimulator of innate IL-17 production.[28] Innate IL-17–producing cells activate epithelial cells to release granulopoietic factors such as G-CSF, thereby recruiting large numbers of neutrophils crucial for effective and rapid control of bacterial and fungal pathogens. Furthermore, IL-17 synergizes with other inflammatory cytokines, such as IL-1, IL-6, and tumor necrosis factor (TNF)-α.

It is notable that IL-17 often works cooperatively with IL-22, during homeostasis as well as during pathogenic insults. In the airways, IL-17 and IL-22 have been shown to work together to promote the secretion of human β-defensin-2, β-defensin-3, and calgranulin by bronchial epithelial cells, essential for killing of bacterial and fungal pathogens.[29] A defect in this pathway may explain the recurrent skin and lung infections in hyper-IgE syndrome caused by dominant-negative mutations in STAT3, a transcription factor required for Th17 cell development. Synergistic effects of IL-17 and IL-22 may also play a role in the gut mucosa, on the induction of antimicrobial proteins by gastrointestinal epithelial cells. Hereby these cells, known as Paneth cells, limit dissemination of commensal bacteria that penetrate a disrupted epithelial barrier. These innate and adaptive memory immune cells can be assumed to act in concert to produce a basal level of IL-17 and IL-22, which then maintain a constitutive level of antimicrobial proteins.[30] At the same time, phagocytes are generated and attracted to guarantee a first line of defense.

RECOGNITION OF MICROBIAL-DERIVED INFLAMMATORY SIGNALS

Neutrophils bind a wide variety of pathogens and commensal microorganisms, including gram-positive and Gram-negative bacteria, viruses, and fungi. Binding occurs by affinity of neutrophil receptor proteins for common patterns, the pathogen-associated molecular patterns (PAMPs), on the surface of the pathogen. The receptors for PAMPs are called PRRs, and are expressed on the surface of or intracellular in many effector cells of the innate immune system (such as macrophages, dendritic cells, neutrophils) as well as epithelial cells. Whereas immune cells respond vigorously to invading microorganisms, the epithelial linings have to discriminate more selectively to avoid a response to the commensal flora in the guts, the oropharynx, or on our skin. The most common family of PRRs are the Toll-like

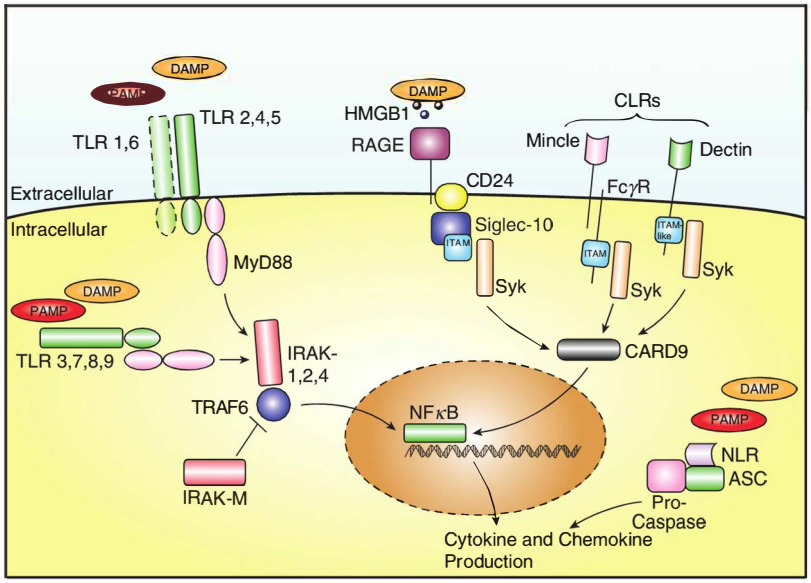

FIGURE 47.2 Pattern recognition receptors (PRRs). Several PRRs recognize pathogen-associated molecular patterns (PAMPs), for example, Toll-like receptors (TLR2/TLR1, TLR2/TLR6, TLR3,-4,-5,-7,-8,-9), C-type lectin receptors (CLRs; Dectin-1,-2, Mincle), and NLRs (NOD-like receptors; NOD1,2). DAMPs bind to carriers like HMGB1 and bind to RAGE as well as to certain TLRs. TLR3 and TLR7 are not expressed on neutrophils.

receptors (TLRs), which upon ligand binding recruit adaptor molecules to their intracellular signaling domain (FIGURE 47.2).[31] This interaction leads to the activation of several kinases that ultimately results in the activation of transcription factor NF-κB and immune-responsive genes and the release of cytokines, for example, TNFα. The TLRs recognize a wide variety of ligands, including lipopeptides by TLR2/TLR1 and TLR2/TLR6 and bacterial lipopolysaccharide (LPS) and flagellin by TLR4 and TLR5. Besides these extracellular pathogen fragments, microbial RNA and DNA are detected by TLR3, 7 and 8, and 9, respectively, all located inside the host cell.

Neutrophils express all TLRs, except TLR3 and TLR7.[32,33] However, in comparison with monocytes and macrophages, TLR2 and TLR4 are expressed at relatively low levels (in addition to the TLR2/TLR1 and TLR2/TLR6 dimers). This may explain partially why the concentration of LPS required to activate neutrophils is about 100- to 1,000-fold higher than that needed for monocytes.

Most TLR family members have a conserved intracellular signaling motif, the so-called TIR domain. This signaling motif, which is also found in the intracellular domain of the IL-1 receptor (IL-1R), is responsible for NF-κB activation/translocation after TLR or IL-1R ligand binding, and is an essential signaling pathway for IL-1β and TNFα secretion.[34] All TLRs signal through MyD88 and Mal, which interact with various IL-1 receptor-associated kinases (IRAKs). However, both TLR3 and TLR4 can also activate cells through a MyD88-independent pathway in which TRIF (TIR-domain-containing adapter-inducing interferon-beta) and TRAM (TRIF-related adaptor molecule) play a role. This can result in phosphorylation and activation of IRF3 or IRF7, which in turn activates a wide range of proinflammatory genes, such as interferon-β. These pathways are specifically active in monocytes and subtypes of dendritic cells. Although mRNA for both TRAM and TRIF is expressed in neutrophils, MyD88-independent signaling in neutrophils does not exist. LPS-responsiveness is strictly IRAK-4 dependent.[33]

Apart from the TLRs, another family of important surface-expressed PRRs is the transmembrane C-type lectin receptors (CLRs or CLECs).[35] The most studied CLR members to date are Dectin-1 (CLEC7a), detecting certain yeast species, and its close homologue Dectin-2 (CLEC4n), which recognizes several fungi. All CLRs are activating members of the myeloid-specific Ig superfamily.

The activating members of this family stimulate cells by virtue of cytoplasmic immunoreceptor tyrosine–based activation motifs (ITAMs) in their cytoplasmic tails or in the tails of associated molecules. Tyrosine phosphorylation of these molecules permits binding of phosphotyrosine kinases such as Syk and ZAP-70. Next, tyrosine phosphorylation of these kinases allows binding of tyrosinephosphatases such as SHP1 and 2, which results in activation of NF-κB and the subsequent secretion of cytokines and chemokines. Contrarily, the inhibitory members of the family contain an immunoreceptor tyrosine–based inhibitory motif (ITIM), which has the potency to decrease NF-κB activity.

A third CLR, CLEC4e (also known as Mincle), was also recently shown to recognize fungal pathogens, thereby inducing an intracellular signaling cascade that, besides phosphotyrosine kinases, involves adaptor protein CARD9.[36] This ultimately leads to the production of proinflammatory cytokines and chemokines, including TNFα, IL-6, CXCL1 (GROα), and CXCL2 (MIP-2), which stimulate the recruitment of neutrophils to infected tissues.[35]

In addition to extracellular pathogen recognition by TLRs and CLRs, intracellular recognition of microbial derivatives by host cells can also mount an appropriate immune response. PAMP recognition by these cytosolic NOD-like receptors (NLRs) results in assembly of protein complexes called inflammasomes.[37] Only some NLRs are present in neutrophils, and their role may be limited in this cell type. Macrophages and DCs are considered to be the main cell type in which the NLR proteins function as cytoplasmic or intracellular PRRs. The ubiquitously expressed NOD1 senses diaminopimelic acid–containing peptidoglycan present in Gram-negative bacteria, whereas epithelial and myeloid NOD2 sense the muramyl dipeptide present in most organisms. The cytosolic inflammasomes may contain different members of the NLR protein family, suggesting that

they have their own specificity, which in many instances has not yet been identified.[38]

DAMAGE-INDUCED INFLAMMATORY SIGNALS

In addition to recognizing PAMPs, the immune system has evolved to recognize endogenous danger signals or, by analogy, damage-associated molecular patterns (DAMPs), such as single-stranded DNA and extracellular ATP or nucleosomes, many of which are released by dying or necrotic cells (FIGURE 47.2). Recognition of DAMPs contributes to inflammation in a noninfectious sterile setting. One of the best known endogenous alarm signals is high-mobility group box 1 protein (HMGB1), which is a nuclear protein that modulates chromatin accessibility. When cells undergo necrosis, HMGB1 is released and plays an important role in initiating inflammation upon binding to several extracellular DAMPs, for example, DNA, RNA, or nucleosomes from the necrotic cell, as well as IL-1β and LPS.[39] These complexes between HMGB1 and DAMPs can interact with several receptors on macrophages, including HMGB1 receptor RAGE (receptor for advanced glycation end products) as well as TLR2, TLR4, TLR9, and IL-1R. This interaction induces macrophages to synthesize proinflammatory cytokines, such as TNFα and IL-6, as well as phagocyte-attracting chemokines, such as CXCL8 (IL-8), CCL3 (MIP-1α), and CCL4 (MIP-1β), thereby promoting the recruitment of neutrophils. Besides HMGB1, RAGE can also bind to several members of the calcium-binding S100 family of proteins and various RNA and DNA ligands. Not only HMGB1 but also the homologous HMGB2 and HMGB3 proteins have been reported to function as universal sentinels for nucleic acid–mediated activation of innate immune responses. The relative contribution of intracellular and extracellular HMGBs in this response remains to be determined.

Heat shock proteins (HSPs) and several cytokines, including IL-1α and IL-33, have also been shown to be involved in damage signaling. HSP exposed on dying cells serves as an immunostimulator, whereas cells dying under conditions of no HSP exposure are rapidly cleared without an immune response. It is unclear, however, whether HSPs function as DAMPs or that they are carriers of DAMPs, like HMGB1, and signal as a HSP–DAMP complex.[40] IL-33 is constitutively present in the nucleus of endothelial and epithelial cells, and is released upon damage together with HMGB1.[41] Unregulated IL-33 activity leads to activation of T-helper type 2 cells, mast cells, dendritic cells, eosinophils, and basophils, ultimately leading to increased expression of cytokines and chemokines that define the disease. Although widely studied in allergy and infectious models, the role of IL-33 in DAMP-associated inflammation has not yet been studied in great detail.[42]

NEGATIVE REGULATION MECHANISMS

Excessive inflammation can cause severe conditions like autoimmunity or (after infection) sepsis, a serious systemic disorder with a high mortality rate. Therefore, innate immune responses must be finely regulated, and underlying mechanisms are now being examined extensively. Several autoinflammatory mechanisms have been reported so far. In the case of PRR signaling, several negative regulators of TLR-mediated signaling pathways have been proposed.[43] First, overactivation of TLR pathways is prevented by IRAK-M. Whereas IRAK-1, -2, and -4 have stimulatory roles, IRAK-M prevents dissociation of activating IRAK-1 and IRAK-4 from MyD88 and subsequent formation of the activating IRAK-TRAF6 complexes. IRAK-M$^{-/-}$ cells exhibit increased cytokine production upon TLR/IL-1 stimulation, as well as increased inflammatory responses in mice to bacterial infection. Thus, IRAK-M negatively regulates TLR signaling and innate immune homeostasis by preventing, in particular, IRAK-4 signaling. Expression in myeloid cells of IRAK-M seems restricted to macrophages.[44] Several other cytoplasmic proteins are also implicated in these TLR-related counteractive processes.[45–47]

Other important regulators of the balance between pro- and anti-inflammatory signals are several members of the previously mentioned Ig superfamily. Certain subfamilies, for example, the KIRs (killer immunoglobulin-like receptors), ILTs (immunoglobulin-like transcripts), and SIRP (signal regulatory proteins), consist of ITAM- as well as ITIM-containing members in which the latter perform a counterregulatory role.[48] KIRs and at least two ILTs are known to recognize different members of the human leukocyte antigen (HLA) class I of proteins. SIRP1α, being a negative regulator, protects against inflammation upon binding hematopoietic self-antigen CD47 (integrin-associated protein).

Furthermore, to induce different outcomes of trauma and infection, the signaling pathways downstream of DAMPs and PAMPs are not identical.[39] It has recently been shown that the DAMPs, HMGB1 and HSPs, but not PAMPs, can interact with inhibitory molecule CD24, a glycosylphosphatidylinositol (GPI)-anchored membrane protein. CD24 binds sialic acid–binding immunoglobulin-like lectin-10 (Siglec-10), which contains an ITIM and is an inhibitory member of the previously mentioned Ig superfamily.[49] The CD24 and Siglec-10 receptor complex appears to provide a molecular brake for endogenous danger signals without compromising responses to infectious agents.

Another molecule that may distinguish between DAMP and PAMP pathways is thrombomodulin, a cell-surface glycoprotein expressed on vascular endothelial cells that has anti-inflammatory as well as anticoagulant functions. Thrombomodulin binds HMGB1 and promotes its cleavage, thereby blocking its interaction with RAGE and thus reducing its proinflammatory potential.[50]

Thrombomodulin is also able to downregulate the complement system. The role of complement in innate immunity is known for its association with the susceptibility of certain infections and the involvement in direct clearance of microorganisms and immune complexes.[51] To prevent unwanted complement activation and deposition on the host's own cells, complement activation is controlled by a number of regulatory complement proteins, among which is complement factor H (CFH).[52] Heterozygous mutations in the genes encoding CFH and thrombomodulin may both result in the clinical trials of nonimmune hemolytic anemia, thrombocytopenia, and renal impairment, known as atypical hemolytic-uremic syndrome (HUS).[53] It implicates that—apart from CFH and its cofactor CFI—also thrombomodulin is able to facilitate complement inactivation.

During tissue infiltration, negative regulation of neutrophils is performed through CD200 receptor (CD200R). CD200R is expressed by infiltrating neutrophils and monocytes, and engages its ligand CD200, which is a glycoprotein exposed by many opposing tissue cells. Hereupon, CD200R restrains tissue-damaging activity by associating with the

SH2-containing inositol phosphatase (SHIP), consistent with a role in downregulation of myeloid activity.[54]

IgG RECEPTORS BRIDGE INNATE AND ADAPTIVE IMMUNITY

Besides their importance for the primary innate immune response, neutrophils play an important role in adaptive immunity. Complement factors and IgG antibodies bind to microorganisms in a process called opsonization, whereupon these complexes can be bound by neutrophils. The proximity of the Fc regions of the IgG antibodies promotes direct binding of the opsonized microorganisms to the Fcγ receptors FcγRs (FcγRs) on the neutrophils. There are three main classes of FcγRs: FcγRI, FcγRII, and FcγRIII, which are all members of the Ig superfamily.[55] Each has its characteristic IgG-binding avidity, functional properties, and expression profile among hematopoietic cells.

The activating members of the FcγR family, that is, FcγRIa, FcγRIIa, FcγRIIIa, and FcγRIIIb, contain ITAMs or associate with ITAM-containing signaling molecules, whereas a single inhibitory Fcγ receptor, FcγRIIb, contains an ITIM. The balance between activating and inhibitory IgG receptors largely depends on the cell type and the expression level of the various receptor subtypes.

Further complexity arises from the fact that each FcγR is encoded by various genes, some of which can undergo alternative splicing. For instance, FcγRII is encoded by three genes (*FCGR2A*, *FCGR2B*, and *FCGR2C*). Recently, we have found evidence for the functional expression of FcγRIIc, encoded by *FCGR2C*,[56] which was previously assumed to be a pseudogene.[55] More genomic variation was demonstrated by the presence of copy number variation as well as a gene-dosage effect on the functional expression of FcγRIIc, FcγRIIIa, and FcγRIIIb.[57,58] We and others have indicated the presence of such variation in cohorts that suffer from systemic forms of autoimmunity, vasculitis or hematologic disease, indicating potential contribution to the susceptibility, and course of clinical disease in autoinflammation or infection.[58,59]

DEGRANULATION

After phagocytosis of a microorganism, or in its close proximity, intracellular granules in the neutrophils fuse with the plasma membrane or phagosomal membrane, thereby releasing the contents out on the pathogen. Granule constituents are traditionally considered as potent antimicrobial peptides and proteolytic enzymes. These proteins assist in the killing and digestion of microorganisms, but are also potentially harmful to the host if released inappropriately. The granules exocytose only after considerable cell activation, which is a fail-safe mechanism preventing unnecessary injury.

Neutrophils contain different subsets of granules: azurophil, specific and gelatinase granules, and secretory vesicles (FIGURE 47.3).[60] The azurophil granule proteins are synthesized at the promyelocytic stage only. Specific granule proteins are synthesized at the myelocyte stage, with an increasing amount of gelatinase being formed at the later metamyelocyte and early-band cell stage, after which granule formation stops. The so-called secretory vesicles are believed to be formed by endocytosis and fuse with the plasma membrane most readily, to some extent already during standard purification steps.[61]

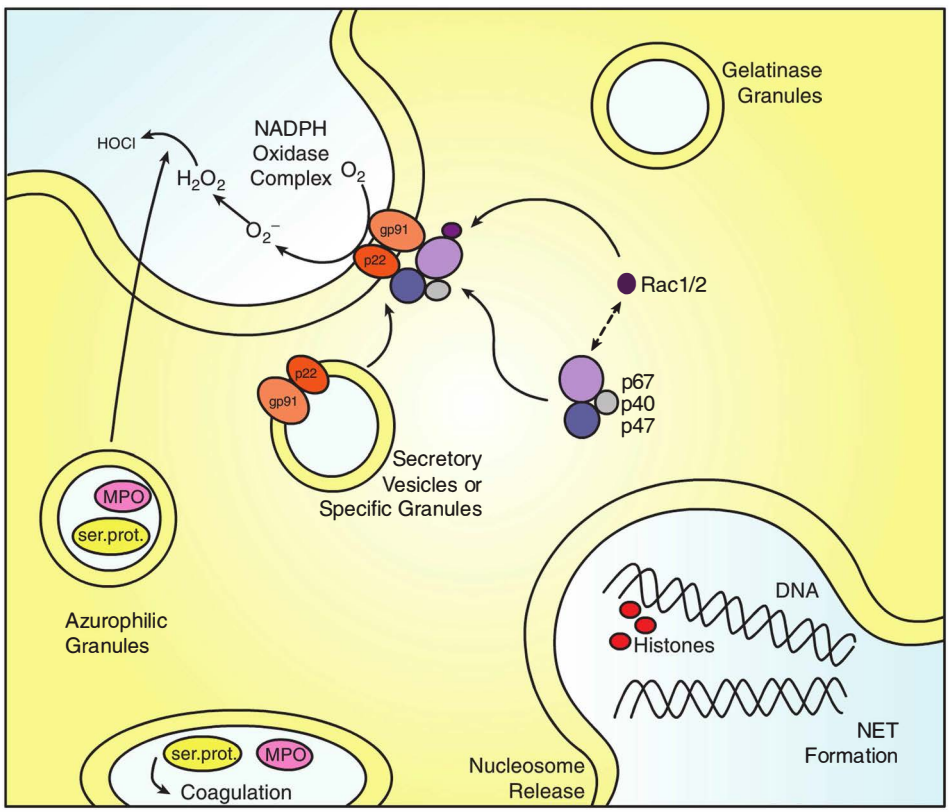

FIGURE 47.3 Neutrophil degranulation and nucleosomes' release. Neutrophils contain several granule subsets (i.e., azurophilic, gelatinase and specific granules, and secretory vesicles) as well as nucleosomes, which release cytotoxic compounds. Nearby or after phagocytosis of pathogens, cytoplasmic p67, p40, p47, and Rac1/2, together with gp91 and p22 from secretory vesicles or specific granules, form the NADPH oxidase complex, which generates ROS. Azurophilic granules release serine proteases such as elastase, which are cytotoxic as well as capable to induce a simultaneous coagulatory response. Release of nucleosome components results in pathogen trapping in NETs and damage signaling.

The specific granules support cell movement in the tissues, and the azurophilic granule proteins are for killing and degrading ingested material. Moreover, not all proteins released from the specific granules act proinflammatory. Also several protease inhibitors, such as secretory leukocyte protease inhibitor, α_1-antitrypsin, and cystatins, are released from the specific granules of neutrophils.[60] These soluble proteins may help to respond rapidly to the environment and at the same time minimizing tissue destruction by, for instance, secreting inhibitors of its own proteases.

Recent data have revealed that some granule proteins, previously believed to be specific to neutrophils, are also expressed in a variety of other cell types, for instance in epithelial cells of skin and mucosal barriers. The important difference is that epithelial cells make these antibacterial peptides and proteins only when an infection or inflammation is established, whereas neutrophils have these antibacterial proteins stored in granules ready for use without any delay when needed.

KILLING ACTIVITY

Simultaneous with degranulation, an oxidase enzyme complex (flavocytochrome b_{558} subunits p22-*phox* and gp91-*phox*) located in the membrane of secretory vesicles and specific granules is activated to generate ROS needed in the killing process (FIGURE 47.3). This NADPH oxidase complex is activated in the plasma membrane or the phagosome membrane by fusion of these vesicles and granules with the membrane and by translocation of a number of activity-regulating proteins from the cytoplasm (p40-*phox*, p47-*phox* and p67-*phox*).[62] The enzymatic subunit is gp91-*phox*. This protein consists of a membrane-spanning *N*-terminus, containing two heme moieties, and a hydrophilic, probably cytosolic, *C*-terminus, which contains one FAD group and one NADPH-binding domain. The other flavocytochrome b_{558} subunit, p22-*phox*, serves to stabilize gp91-*phox* in the membrane of specific granules and secretory vesicles and in the phagosomal membrane of activated cells.

The proteins p40-*phox*, p47-*phox*, and p67-*phox* form a complex in the cytosol of resting cells. This complex unfolds during cell activation, in concert with activation of small GTPase Rac2 (in neutrophils) or Rac1 (in macrophages).

Upon interaction of the cytosolic components with flavocytochrome b_{558}, the enzyme complex starts to generate superoxide (O_2^-). NADPH donates electrons, which are passed on within gp91-*phox* from the NADPH-binding site to FAD, then to the two heme groups, and finally to the edge of the protein that faces the phagosome or the extracellular space. At that site, the electrons are attached to molecular oxygen, thus generating superoxide. Superoxide spontaneously dismutates into hydrogen peroxide (H_2O_2), which may then react with chloride ions to form hypochlorous acid (HOCl), in a reaction catalyzed by myeloperoxidase. This enzyme is an abundant constituent of neutrophil azurophilic granules, and is released upon cell activation into the phagosome and into the extracellular space (FIGURE 47.3). HOCl is very toxic for a broad range of microorganisms, but is rather short-lived. However, it can react with primary and secondary amines, and thus gives rise to *N*-chloramines, some of which are very stable, microbicidal agents. Under normal, phagocytosing conditions, neutrophils convert more than 75% of their superoxide into HOCl and *N*-chloramines, and thus create a highly toxic environment within the phagosomes and in the cell surroundings.[63] Patients with a defect in the NADPH oxidase system suffer from a syndrome called chronic granulomatous disease, characterized by recurrent, serious infections with bacteria, yeasts, and fungi.[64]

Besides phagocytosis of pathogens and the secretion of cytotoxic compounds, there is a third way of defense against pathogens: the formation of neutrophil extracellular traps (NETs) (FIGURE 47.3).[65,66] When neutrophils are overwhelmed by pathogens, the necrotic cells release DNA and histones that form long net-like stretches, which, together with large amounts of granular antimicrobial enzymes, are capable to bind, disarm, and kill pathogens extracellularly. The granular cytotoxins are concentrated within the NETs, thereby minimizing damage to the host cells. In addition to their role in pathogen killing, the NETs may serve as a physical barrier that prevents further spreading of the pathogens.

The role and contribution of cell death in NET formation have been recently reviewed. The involvement *in vivo* of NETosis remains unclear to date. Moreover, *in vivo* discrimination between fibrin and NETs is not as easy as once thought.[67] NETosis or the passive leakage of DNA from dying cells may well contribute to the inflammatory process, as will be described below for nuclear proteins including HMGB1 but also for DNA-associated histones.

SYSTEMIC INFLAMMATION AND DAMAGE CONTROL

As mentioned above, overactivation of the inflammatory system can induce severe conditions like sepsis. In humans, sepsis is defined as suspected or proven infection plus a systemic inflammatory response syndrome (e.g., fever, tachycardia, tachypnea, and leukocytosis).[68] Severe sepsis is defined as sepsis with organ dysfunction (hypotension, hypoxemia, oliguria, metabolic acidosis, thrombocytopenia). Septic shock is defined as severe sepsis with hypotension, despite adequate fluid resuscitation. This situation of septic shock represents a combination of an inflammatory response and ischemia/reperfusion injury in which both PAMPs and DAMPs are taking their toll. Septic shock and multiorgan dysfunction are the most common causes of death in patients with sepsis. The incidence of severe sepsis is estimated to be between 70 and 150 cases per year per 100,000 population. The mortality rates associated with severe sepsis and septic shock are around 30% and 60%, respectively.

Several inhibitors of inflammatory pathways have been suggested as a potential cure for sepsis. However, antibodies toward cytokines, such as anti-LPS, anti-TNFα, and IL-1-antagonism, failed to inhibit septic shock in humans. Up to now, none of the TLRs have been targeted to bend inflammation or infectious disease in the human setting.

One of the major causes of severe damage and host mortality during sepsis might be the release of nuclear components of necrotic cells. As mentioned above, extracellular localization of nucleic protein HMGB1 induces inflammation, and this might be a positive feedback loop causing a switch from local inflammation to sepsis. In mice, injection of nucleus-derived HMGB1 is lethal.[69] These observations raise the possibility that nuclear contents in the circulation might indicate severe damage and contribute to mortality in the host. In concordance with these results, inhibition of HMGB1 has been shown to inhibit sepsis remarkably. In mice, antibodies against HMGB1 inhibit LPS lethality and reduce lung inflammation following airway LPS

exposure. The activity of HMGB1 under these conditions seems to depend on RAGE, since RAGE-deficient mice are also protected from endotoxemia-induced lethality. Although widely expressed, RAGE expression on the endothelium appears to be essential and sufficient to mediate lethality.[70]

Thus, antagonists of HMGB1 may be highly effective to avoid unwanted damage, even when administered at a later time point in the inflammatory response.[71] In humans, the late application of a blocking agent is the only realistic option that matters. However, the major problem until now is the lack of high-affinity monoclonal antibodies and the involvement of HMGB1 protein homologues in the DAMP-mediated responses.

HMBG1 is not the only nuclear protein involved in sepsis or septic shock. Release of nucleosomes during necrosis results in increased serum concentration of histones H3 and H4, which have a high cytotoxic potential.[72] Histones kill endothelial cells *in vitro* and mimic the symptoms of sepsis, including organ failure, when injected into mice. Antibodies against histone 4 (H4) protected mice in three different models of sepsis: injection of LPS, injection of TNFα, and a cecal ligation and puncture (CLP) model.

An alternative approach was reported recently; this concerned blockade of a survival and proliferation signaling molecule, sphingosine-1 phosphate kinase (SPHK1).[73] SPHK1 expression was found to be highly upregulated in neutrophils and macrophages stimulated with various bacteria or bacterial components, including LPS. SPHK1 blockade in two mouse models of sepsis—the first involving intraperitoneal injection of a lethal dose of LPS and the second involving CLP to trigger polymicrobial sepsis—showed 100% survival. A small inhibitor of SPHK1 was 100% effective if given 2 hours after CLP, with a much reduced efficacy (10%) if given 12 hours after CLP. However, combined treatment of the inhibitor and broad-spectrum antibiotics to treat patients with sepsis had synergistic effects, extending the time window for treatment and resulting in better outcomes than either drug alone, which is most welcome in medical practice.

To date, the most promising drug trial for critically ill septic shock patients consisted of the early administration of APC, although the efficacy is still relatively limited.[68,74] APC effectively degrades the toxic extracellular histones. It targets also protease-activated receptor-1 (PAR1) and endothelial cell protein C receptor, which are essential for protection in a mouse sepsis model.[72]

Despite its known role as a natural anticoagulant, APC appears to have important anti-inflammatory functions. Recombinant human soluble thrombomodulin has also been identified as anti-inflammatory and a successful drug toward sepsis in humans. Thrombomodulin is also most prominently known as an anticoagulant.[75] The high potency of these anticoagulants to treat sepsis implicates that the coincidence of inflammation and coagulation potentiate each other considerably in sepsis-induced host damage. However, for the same reason, the disadvantage of sepsis treatment with these proteins is an increased risk of bleeding.

SYNERGISM OF INFLAMMATION AND COAGULATION

Clinical data give multiple implications for the coincidence of inflammatory and coagulation problems. First, the majority of critically ill patients with a systemic inflammatory response have coagulation abnormalities. These abnormalities may vary from a mild thrombocytopenia to thrombosis and bleeding, known in its most severe form as disseminated intravascular coagulation (DIC). In a consecutive series of patients with severe sepsis, the mortality of patients with DIC was 43%, compared with 27% in those without DIC.[76] Furthermore, several studies have shown the importance of IL-6 in the initiation of coagulation activation and the role of TNFα and IL-1 in the regulation of physiologic anticoagulation.

All together, there is a clear simultaneous induction of inflammation and coagulation, suggesting that this synergism is beneficial for the inflammatory response. In line herewith, recent studies have confirmed that activation of coagulation by neutrophils results in "trapping" of bacteria in small blood vessels.[77] During coagulation, the production of blood clot components such as fibrin is increased, which allows formation of NET-like structures, thereby preventing tissue damage during killing of pathogens.

Inflammation can induce the procoagulatory response through several pathways. The most prominent pathway involves tissue factor. Tissue factor is a cell surface procoagulant glycoprotein, expressed by extravascular tissues and conspicuously absent from most cells that come in contact with blood, that is, endothelial cells, red blood cells, lymphocytes, neutrophils, and platelets. After injury, blood is exposed to tissue factor, which results in a procoagulant pathway involving factor VIIa, IX, X, and Xa and induces generation of thrombin from prothrombin. One key function of thrombin is to convert fibrinogen into fibrin, a major component of blood clots. During infection, the fibrin forms barriers that restrict microbial dissemination. In addition, thrombin itself is also involved in inflammation, as it is chemotactic to neutrophils and monocytes and stimulates the release of IL-1 and CXCL-8 (IL-8). Furthermore, thrombin-activated endothelial cells or platelets express P-selectin, thereby facilitating neutrophil rolling and adhesion to platelet-bound fibrinogen in the hemostatic plug.

Although the general view of hemostasis has been that tissue factor only becomes exposed after vessel wall injury, it can as well have its origin within the vessels. Resting monocytes have very little tissue factor activity, but several inflammatory mediators, such as LPS, IL-1, IL-6, and TNFα, for example, during sepsis, can induce tissue factor synthesis in monocytes (see Chapter 46).[76,78] Furthermore, leukocyte-derived tissue factor–bearing microvesicles may fuse with activated platelet membrane and have thereby emerged as a possible contributor to normal hemostasis and thrombosis.[79,80]

Tissue factor antigen is present in most cells, but it is functionally inactive. The physicochemical basis for activation of tissue factor is unknown. Phosphatidylserine has been proposed as a possible mediator, based on the fact that addition of phosphatidylserine to tissue factor–containing vesicles enhances its activity. Phosphatidylserine, like other anionic phospholipids, is normally sequestered on the inner leaflet of the membrane bilayer.

Besides the stimulatory linkage between inflammation and coagulation through tissue factor, several inhibitory pathways are also involved. The physiologic inhibitor of tissue factor is tissue factor pathway inhibitor (TFPI), which is synthesized by endothelial as well as by other cells. TFPI is degraded by serine proteases like elastase, which are released from neutrophil granules (FIGURE 47.3). The previously mentioned extracellular

histones bind TFPI and serve as a platform for its degradation by elastase. In mice, infusion of a mutant TFPI protein resistant to proteolysis by elastase results in decreased bacterial clearance, showing the crucial role of tissue factor and the subsequent generation of fibrin in host defense.[77]

Next to TFPI, other anticoagulants are the previously mentioned APC and thrombomodulin. Thrombomodulin binds to thrombin and inhibits its role in coagulation. This heterodimeric thrombomodulin/thrombin complex converts protein C into APC. As mentioned above, APC and thrombomodulin have been recently discovered as potent drugs in the treatment of septic shock.

In addition to synergism between inflammatory and coagulatory pathways, neutrophils and platelets undergo physical interactions. Activated platelets attract neutrophils and have increased P-selectin expression, thereby allowing formation of neutrophil–platelet clots.[81] Similarly, arthrosclerotic plaques can be the pathologic substrate for binding neutrophils in the pathogenesis of acute arterial thrombotic events. Furthermore, activated platelets induce nucleosome release, which results in TFPI degradation and a loop that increases coagulation even further. This pathway also stimulates the formation of NETs.

Thus, neutrophils and platelets interplay at several layers and the outcome should be controlled by a fine balance between pro- and anticoagulatory and inflammatory signaling. Overactivation of any of these pathways may result in an accumulated response and may trigger sepsis as well as (myocardial) infarction and stroke.

CONCLUSION

Neutrophils are a major leukocyte subset when it comes to degradation of pathogens. Several stimulatory pathways as well as negative regulatory mechanisms participate to tune this inflammatory response and to prevent damage to the host. However, severe systemic inflammation and septic shock cannot always be avoided. Interestingly, severe inflammation often occurs in parallel with coagulatory problems. In turn, inflammatory response may cause coagulation. The coincidence of these symptoms has led to the discovery of many synergistic pathways, including, for example, tissue factor, and the anticoagulatory proteins TFPI, thrombomodulin and APC, and several cytokines. These findings are now being implemented in the treatment of sepsis as well as coagulation problems, and major improvements in these therapies can therefore be expected in the near future.

CHAPTER

48

Laboratory Markers of Endothelial Cell Activation and Dysfunction

EDUARD SHANTSILA, GREGORY Y.H. LIP, AND ROBERT P. HEBBEL

The diverse functions of the vascular endothelium are of critical importance in maintaining physiologic homeostasis, yet they also are participants in a great variety of disease processes.[1,2] These functions include provision of the physical and biologic interface between blood and tissue, integration of disparate signals and coordination of responses, governance of hemostatic balances, regulation of vasomotor tone, management of vascular permeability, participation in immune and inflammatory processes, transduction of mechanosensitivity signals, and operation as an autocrine/paracrine/endocrine signaling network. Yet, the endothelium retains the flexibility to exhibit regional and local variations in these functions as required. Moreover, the endothelial cell lies at the interface of these multiple physiologic functions and thereby fundamentally links them. Illustrative examples of this include the frequent associations of coagulation activation and of vasoregulatory disturbance with inflammatory states.

ENDOTHELIAL CELL ACTIVATION AND DYSFUNCTION

Each of these component biologies exhibits quantitative and qualitative variation (albeit with substantial interdependence), so endothelial phenotype potentially can exist in a complex continuum of states. Nevertheless, the traditional description of the endothelium as being "quiescent," "activated," or "dysfunctional" is still conceptually useful in biomedicine. In actuality, however, the normal state of the endothelium is anything but quiescent; rather it contributes active homeostatic adjustments for maintenance of physiologically optimal states, an example being its vigilant husbandry of vasomotor tone. Its normal phenotype is anti-inflammatory, antithrombotic, and antiadhesive.[1,2]

The term "activated" endothelium generally refers to its state of response—often localized or regional—to a challenge as part of the host response to disease. Typically, such states are adaptive and organized to be of benefit to the host. Examples are the endothelial cell's participation in the normal inflammatory response, adjustment of hemostatic balance to staunch bleeding or favor fibrinolysis, and its assumption of an angiogenic phenotype as required for wound healing and placentation.[1,2] Some activation responses occur rapidly (e.g., shedding of surface adhesion and hemostasis molecules, retraction, decryption of tissue factor [TF], and release of P-selectin, von Willebrand factor [vWF], and monocyte chemoattractant protein-1), while others require gene transcription and protein synthesis (expression of E-selectin, intercellular adhesion molecule [ICAM]-1, vascular cell adhesion molecule [VCAM]-1, plasminogen activator inhibitor [PAI]-1, TF, and platelet activating factor).

In contrast, "endothelial dysfunction" is typically used to describe states in which the extant endothelial biology is harmful to the patient, typically by developing phenotypes with features that are the converse of the normal state. Examples include the counterproductive roles of a dysfunctional endothelium in atherosclerosis,[3] chronic renal failure,[4] reperfusion injury physiology,[5] sickle cell anemia,[6] gestational disorders,[7] diabetes,[8] and sepsis.[9] Notably, these all involve widespread, not just localized, endothelial dysfunction, which is pathologic and has escaped from normal, delicate, adaptive control. Not coincidentally, each of these disorders includes disturbance of hemostatic systems and elevated risk for untoward clinical events, particularly thrombosis,[10] because an endothelial dysfunctional state potentially perturbs all arms of Virchow triad.

The difficulty arises in attempting to distinguish between activation and dysfunction. From the perspective of the cardiovascular literature, a functional deficiency of endothelial nitric oxide synthase (eNOS) is the sine qua non of endothelial dysfunction, as documented by experimental and physiologic studies.[11] Indeed, the eNOS knockout mouse provides the paradigmatic experimental model of endothelial dysfunction and demonstrates that this leads to deficient endothelial-dependent vasodilation, hypertension, increased thrombosis, atherosclerosis, and stroke.[12] Accompanying defects include loss of the nitric oxide (NO) inhibitory effect upon platelet aggregation, leukocyte adhesion, smooth muscle cell proliferation, and expression of some surface molecules (e.g., VCAM-1 and TF). In human biomedicine, however, eNOS is not absent but rather becomes functionally inadequate and uncoupled so that it produces superoxide. This state is promoted by disparate conditions, for example, inflammation, oxidative stress, substrate/cofactor deficiencies, elevated levels of the competitive inhibitor asymmetric dimethylarginine (ADMA), oxidized lipids, aberrant wall shear stress, perturbation by microparticles (MP), and others.

However, this eNOS-based definition of endothelial dysfunction is perhaps too restrictive, as the majority of clinical information about it is derived from atherosclerosis and its risk factors and comorbidities, in which deficient NO bioavailability is paramount. Yet, there are various dysfunctional states where it perhaps need not be.[10] Endothelial dysfunction additionally involves various mixes of multiple activation-related imbalances leading to a proinflammatory and prothrombotic phenotype, permeability barrier dysfunction, and oxidative stress in addition to disturbed vasoregulation. While inflammation in general, with its attendant oxidant generation, is a major cause of eNOS dysfunction,[13] it remains possible that defective endothelial-dependent vasodilation may not be a universal feature of endothelial dysfunction. Indeed, from the hemostasis perspective, endothelial dysfunction is typically regarded to be

the provisional interpretation if the patient is put at increased risk for clinical harm.[10]

Regardless of the definition, these changes provide the basis for the available laboratory testing of endothelial status. Interpretation of these is complicated by the continuum of activation states, and the ability of biomarkers to distinguish between activation and dysfunction is by no means unambiguous. This chapter discusses the four types of available laboratory testing that have sufficient endothelial specificity so as to be useful. Physiologic testing provides the gold standard of evidence for endothelial dysfunction from the cardiovascular perspective. Blood biomarkers and their associations with disease have received the most attention. Circulating MP, although still emerging as a tool, perhaps offers the most potential promise for revealing pathobiologically useful information about the endothelium *in situ*. Circulating endothelial cells (CECs) are still in development as a potentially useful tool. Cells popularly referred to as "endothelial progenitor cells" (EPCs) cannot be recommended as a biomarker of endothelial dysfunction. Predictably, most clinical information on validity and utility of these biomarkers is derived from the atherosclerosis context. However, that is advantageous since there is a wealth of information regarding all aspects of atherosclerosis, in particular its state of clinically inapparent, subtle inflammatory involvement that is tightly associated with endothelial dysfunction.

PHYSIOLOGIC ASSESSMENT OF ENDOTHELIAL FUNCTION

Dynamic regulation of vascular tone by the endothelium is realized by its production of substances having either vasoconstrictive or vasodilatory properties, the balance of which (along with other inputs) governs vascular hemodynamics. The major endothelial-derived vasodilator is NO,[14,15] which additionally contributes to several other aspects of vascular health, as noted above. In aggregate, these exert antiatherogenic effects.[16] Because endothelial dysfunction typically involves impaired endothelial-dependent vasodilatation, its investigation can provide useful information even if clinical focus is not upon vasoregulation *per se*. Indeed, physiologic assessment is the only method that directly identifies endothelial dysfunction.

Invasive Assessment

Angiography—the Gold Standard

Direct angiographic measurement of the change of coronary artery diameter, blood flow, and vascular resistance in response to an intracoronary infusion of acetylcholine (ACH) is considered to be the gold standard in endothelial function assessment.[17,18] Normal epicardial and microvascular coronary arteries respond to this by an increase in diameter and blood flow. In subjects with endothelial dysfunction, ACH causes paradoxical vasoconstriction and a decrease in coronary blood flow due to the disruption of NO-dependent vasodilation.

Plethysmography. Venous occlusion plethysmography records changes in the forearm volume after occlusion of blood circulation to the hand. Thereby, changes in vascular resistance after intravascular administration of vasoactive drugs can be assessed as a measure of endothelial function. The method is accurate and reproducible, but it is semi-invasive and labor intensive, thus limiting its clinical utility.[19,20]

Noninvasive Assessment

Imaging

Noninvasive assessment of coronary artery endothelial function can be performed using positron emission tomography imaging or contrast ultrasound by measuring the change in myocardial blood flow in response to pharmacologic (e.g., adenosine, dipyridamole) and/or physiologic (cold pressor test) stimuli. This technique permits calculation of coronary flow reserve as a parameter reflecting vascular smooth muscle and endothelial contributions to microcirculatory vascular function.[21]

Peripheral Arteries

Several methods have been developed for the assessment of peripheral artery endothelial function as a surrogate marker of coronary arterial endothelial dysfunction. Indeed, measurement of the vascular response to reactive hyperemia after arterial compression has become the most popular approach for the assessment of it. Flow-mediated dilation (FMD) tests conduit artery function, while peripheral artery tonometry (PAT) tests microvascular function.

The FMD response is recorded by brachial artery ultrasound imaging (FIGURE 48.1). This comprises the current noninvasive gold standard method, one that is extensively validated, has a solid biologic foundation, and correlates with coronary endothelial function.[22,23] Yet, it is very operator-dependent, exhibits diurnal variation, and requires substantial experience in order to achieve reproducible results.[24] Nonetheless, it is the evaluative tool that has been most widely deployed and for which the most data exists. PAT, on the other hand, is virtually observer-independent and is performed using a system that calculates a reactive hyperemia index based on the contralateral finger serving as control. The device has been approved by the U.S. FDA and has been validated in different populations. PAT also correlates with coronary endothelial dysfunction and FMD, and assessment of vascular health using it has been demonstrated to be feasible in outpatient settings.[25,26] Therefore, it is emerging as a potential clinical tool to identify patients at high risk for future cardiovascular events (CVE).[26] The relative limitation of the latter approach is the high cost of consumables.

Controls

It is essential that these approaches be accompanied by similar evaluation of endothelial-independent vasodilation (e.g., in response to a NO donating drug) so that the meaning of observations is not misinterpreted.

Clinical Utility of Vasoregulatory Assessment

Endothelial dysfunction is understood to be the earliest detectable vascular abnormality in the natural history of atherosclerosis and atherothrombosis and, therefore, is believed to have predictive value.[27] It is closely associated with the presence of traditional cardiovascular risk factors.[28] For example, even in the absence of known atherosclerosis abnormal FMD is observed in smoking, hypercholesterolemia, obesity, diabetes, and hypertension, and FMD deterioration parallels accumulation of such risk factors (FIGURE 48.2). This has been interpreted as supporting the concept that the endothelium serves as the ultimate integrator of all cardiovascular risk inputs (environmental, genetic,

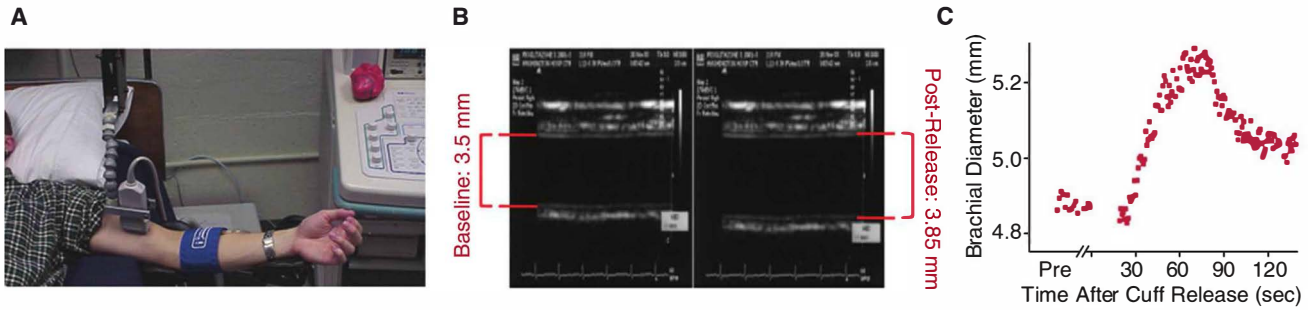

FIGURE 48.1 Measurement of FMD at the brachial artery. **A:** Placement of the ultrasound probe proximate to the site of transient arterial occlusion. (Kindly provided by Dr. Aaron Kelly, Pediatrics, University of Minnesota). **B:** Signal output of arterial wall diameter during rest **(left)** and postocclusion hyperemia **(right)**. (Reproduced from Barac A, et al. Methods for evaluating endothelial function in humans. *Hypertension* 2007;49:748–760, with permission from Wolters Kluwer Health.) **C:** Representative results from the multiple measures over time for a given patient. (Reproduced from Corretti A, et al. Guidelines for the ultrasound assessment of endothelial-dependent flow-mediated vasodilation of the brachial artery; a report of the International Brachial Artery reactivity task force. *J Am Coll Cardiol*, 2002;39:257–265, with permission from Elsevier.)

unknown) and, thus, provides a meaningful way to identify overall risk even in patients not having classical atherosclerotic risk factors.[18,29]

Endothelial dysfunction identified by aberrancy of endothelial-dependent vasodilation predicts future disease progression and is independently associated with future CVE.[18,29,30] In established coronary artery disease (CAD), it can predict future acute vascular events.[18,29] The major extant issue regarding the clinical applicability of FMD is that virtually all data are from cohort studies, such that applicability to the individual patient has not been robustly and prospectively studied. Yet, lending support to the belief that it meaningfully reflects biologic endothelial dysfunction is the improvement of FMD by therapeutic interventions that improve cardiovascular prognosis[32] such as statins,[18] weight loss,[33] smoking cessation,[34] and control of hyperglycemia[35] and hypertension.[36]

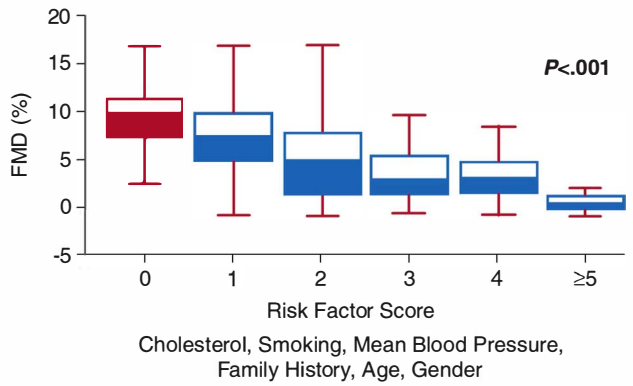

FIGURE 48.2 Inverse relationship between FMD and accumulating coronary risk factors in asymptomatic adults. Presence of hypercholesterolemia, smoking, hypertension, family history, age, and gender are represented by a proportionate, composite risk score. (Adapted from Celermajer DS, et al. Endothelium-dependent dilation in the systemic arteries of asymptomatic subjects relates to coronary risk factors and their interaction. *J Am Coll Cardiol* 1994;24(6): 1468–1478, with permission from Elsevier.)

Aside from atherosclerotic disease, abnormal FMD was observed in patients who had previously developed idiopathic venous thrombosis,[37] as well as in those with antiphospholipid antibody syndrome.[38] In patients with systemic lupus erythematosus, FMD has been observed to be[39] and to not be[40] abnormal, although blood biomarkers of endothelial dysfunction do tend to be abnormal (see below).

Caveats

Evaluation of FMD has been performed mostly in chronic conditions in which endothelial dysfunction would be strongly expected given the clinical context. Its potential value in many nonatherosclerotic disease settings, for example, sepsis, is a largely unstudied possibility, and interpretative caution is necessary, as FMD can be transiently diminished by unrelated concurrent situations (e.g., an acute viral illness).[31] Abnormal FMD has interestingly been reported in some unexpected situations, for example, migraineurs,[41] Alzheimer disease,[42] children of hypertensive parents,[43] rheumatoid arthritis,[44] and sarcoidosis.[45] It is reported to be alleviated by aromatherapy for night-shift workers.[46] It is not yet clear whether such observations reflect the substantial issues regarding test performance[47] or its specificity or the nascence of biomedical understanding of some pathophysiologies. The major source of variability in FMD measurement is between subjects, and the normal range is sufficiently large that definitive identification of endothelial dysfunction in an individual patient is difficult.

SOLUBLE MARKERS OF ENDOTHELIAL DYSFUNCTION

Direct, specific, and quantifiable detection of endothelial surface molecule expression on the activated/dysfunctional endothelium *in vivo* in clinical settings eventually will likely be achieved through engineering advances in reporter nanoparticles and imaging technologies. In lieu of such definitive testing, states of endothelial activation or dysfunction currently are often inferred from the increased levels of the soluble forms of these endothelial-derived molecules in the blood.

General Cautions

Substantial caveats apply to examination of circulating biomarkers. Of those used to probe endothelial cell function, only E-selectin is endothelial-specific; all others can be derived from other cellular sources and, therefore, reflect the biology of those as well. The usual reported levels of blood biomarkers derived from endothelial cells are based on plasma samples that do not distinguish between their truly soluble versus MP-bound forms. Levels of biomarkers in human disease overlap with their normal ranges, so data on their clinical instructiveness often have been derived from comparison of ends of the value spectrum (e.g., lowest versus highest quintiles). Additionally, virtually all studies rely upon single measurement at any given point of time, so that they are affected by normal variability, including diurnal variation for some. Although patients with documented endothelial dysfunction (by FMD) tend to have blood elevations of endothelial-derived biomarkers, there has been no comprehensive examination of the robustness of their independent association with documented endothelial dysfunction.

In general, these issues render biomarker measurements more useful for large patient studies than for application to the individual patient. Moreover, some biomarkers appear to retain sufficient functional characteristics so as to actively influence disease pathobiology. Thus, clinical correlates with biomarker elevations potentially can be different in different disease contexts. Nonetheless, they have been widely used, and some do have predictive value.

Endothelial Adhesion Molecules

The vascular endothelium exhibits carefully orchestrated modulation of its surface to govern its coordinated interactions with circulating blood cells. This involves multiple adhesion molecules, cytokines/chemokines and other mediators.[48] The principal endothelial molecules are P- and E-selectins that mediate initial tethering/capture/rolling, and VCAM-1/ICAM-1 that enforce stronger and stationary adhesion. Experimental studies have revealed that increased endothelial expression of such molecules is a typical and participatory feature in the development of atherosclerosis.[49–52] For example, knockout of either E- or P-selectin renders mice less susceptible to atherosclerosis, and knockout of both has additive benefits.[53,54]

Of note, however, blood levels of endothelial adhesion molecules do not necessarily quantitatively reflect the phenotype of the endothelial surface *in situ* because the levels of these soluble forms mostly reflect activation of the differing mechanisms causing their specific shedding (i.e., a cleavage event, shedding of MP, or release of an alternatively spliced variant). Thus, biomarker elevations in blood can occur in parallel with reciprocal diminished expression on the cell surface, and sometimes are seen even in the context of their concurrently diminished transcription. Due to such regulated shedding, their soluble forms (sP-selectin, sE-selectin, sVCAM-1, sICAM-1) are typically—but variably—increased in states of endothelial activation and dysfunction, and they have often been used to presumptively identify such states.

So, within the data set from a study focused on a specific disease context, a higher level of soluble endothelial adhesion molecules can be associated with worse endothelial dysfunction (as documented by FMD),[55,56] although this discrimination can require the within-study empirical identification of a high/low cutoff point. Conversely, soluble adhesion molecules can be elevated in active vascular disease absent abnormal FMD, as reported for lupus patients,[57] emphasizing that such elevations can reflect endothelial activation without actual (apparent) dysfunction, as narrowly defined by abnormal FMD. The resulting levels of these molecules tend to track together,[58] so sorting out their independent predictive value for future trouble even in the context of endothelial dysfunction can only be done via large studies (Table 48.1).

Endothelial Selectins

E-selectin has the greatest degree of endothelial specificity, it is not constitutively expressed normally, and it becomes expressed on the endothelial surface upon activation in the inflamed endothelium.[50] Yet, sE-selectin has been disappointing as a biomarker for prediction of future CAD in prospectively evaluated healthy subjects.[58] It may or may not be useful to indicate injury responses or cardiac disturbances.[59–61] Of interest, sE-selectin was observed to be elevated in lupus vasculopathy patients having thrombotic risk.[62]

P-selectin is stored in Weibel-Palade bodies and is constitutively expressed on endothelial cells at extremely low levels. It is also expressed in megakaryocytes and is stored in the alpha granules of platelets. Its surface expression on the endothelium and appearance in the blood (perhaps due to both cleaved and alternatively spliced forms[63]) can robustly increase in response to varied stimuli,[50] so plasma sP-selectin often parallels endothelial activation/dysfunction. However, utility vis-à-vis endothelial status is negated by the nonspecificity of its origin (i.e., from platelets also). Elevated sP-selectin can add confirmatory information in acute thrombosis and has predictive value in terms of recurrent deep vein thrombosis and future venous thromboembolism in patients with and without cancer.[64] However, a large prospective trial did not support any value for sP-selectin in predicting future CVE in patients with CAD[58] (Table 48.1).

Endothelial Cell Adhesion Molecules

The elaboration of soluble forms of endothelial CAMs by inflammatory cells confers some ambiguity upon interpretation of their typically elevated levels in inflammatory disease contexts. Endothelial VCAM-1 plays a prominent role in initiation and progression of atherosclerotic lesions.[49,50,65,66] Yet elevated sVCAM-1 levels had no predictive value for subsequent development of CAD or events (CVE) in prospective studies of healthy men[58,67,68] (Table 48.1). On the other hand, acute elevations predictably occur in acute coronary syndromes (ACS) in which higher levels may identify those having increased risk for future adverse CVE.[69,70] In type 1 diabetics, higher sVCAM-1 levels were associated with subsequent development of retinopathy, albuminuria, and cardiovascular disease.[71]

Endothelial ICAM-1 plays a similar pathogenetic role in atherosclerosis and is similarly released by nonendothelial cells in inflammatory states.[49–51] Yet, elevated sICAM-1 levels do appear to have value for assessing endothelial dysfunction in the atherosclerosis context (Table 48.1), in which they are tightly associated with levels of both C-reactive protein (CRP) and vWF.[58] Three large prospective studies of healthy men demonstrated that the highest elevations of sICAM-1 predict future CAD or CVE, independent of CRP or traditional risk factors.[58,67,72] Oddly, a large prospective study of healthy women found that

Table 48.1

Predictive value of circulating endothelial-derived adhesion molecules for cardiovascular disorders

Author [Citation]	Subjects	Follow-up	Predictive Value

ACS, acute coronary syndromes (acute MI or unstable angina); CABG, coronary arterial bypass graft; CAD, coronary artery disease; CVD, cardiovascular disease; CVE, cardiovascular event; HS, healthy subjects; HM, healthy men; HW, healthy women.

while higher sICAM-1 levels predicted CAD progression and even the need for coronary bypass, they did not predict CVE.[73] Increased sICAM-1 levels predicted subsequent stroke risk in type 2 diabetes[74] but not in healthy white women.[75] Thus, the utility of elevated sICAM-1 levels may be context dependent. Interestingly, temporally increasing sICAM-1 levels were associated with all-cause mortality for men and women older than 64 years.[76] In systemic lupus erythematosus, sICAM-1 elevations predict future first cardiac events.[77]

In ACS setting, sICAM-1 levels are elevated and parallel the increased expression of the monocyte receptor CD11b[78] and higher CRP and titers of antibody to oxidized low-density lipoprotein.[79] After an acute MI, higher levels of sICAM-1 measured 7 days or 10 weeks later predicted subsequent coronary symptoms and events.[69,80,81] Similarly, for hypertensive type 2 diabetes patients, sICAM-1 level paralleled degree of atherosclerosis.[82] However, data are not uniform, as studies following up ACS[70] or coronary bypass grafting[83] observed no predictive value of sICAM-1 for subsequent CVE.

Perhaps most strongly supporting the value of sICAM-1 measurement, its elevation correlated with impairment of FMD in obese hypertensive children and adolescents,[84] and even in apparently healthy adolescents.[85] The elevated sICAM-1 level in smokers decreases upon smoking cessation, perhaps bolstering its value as a meaningful marker.[86]

Conclusions Regarding Endothelial Adhesion Molecules

Thus, taken together these data identify elevated sICAM-1 levels as having considerable potential as a useful prognostic marker for increased risk of CAD and future CVE, but broader application to clinical predictions in endothelial dysfunction generally is not known. So overall, more study of its value in the clinical setting is necessary. The other candidate markers (sVCAM-1, sE- and sP-selectin) can all be elevated in endothelial activation states (with sVCAM-1 being the most commonly used indictor), but they cannot be relied upon to distinguish between activation and dysfunction. Indeed, the usefulness of soluble adhesion molecules, either independently or in various combinations, for predicting or quantifying measured FMD has not been comprehensively studied.

Hemostasis and the Maintenance of Blood Fluidity

Endothelial integrity is fundamental for separation of blood components from thrombogenic subendothelial materials, and the luminal surface of the healthy endothelium itself is anticoagulant and antithrombotic[1,2,10] (see Chapter 42). For example, it displays thrombomodulin (TM) and the endothelial protein C receptor (EPCR), a glycocalyx carrying antithrombin (AT) and

tissue factor pathway inhibitor (TFPI); it elaborates tissue-type plasminogen activator, along with low levels of PAI-1; and it has an absence of TF. Further, the endothelium produces molecules that impede platelet reactivity, particularly NO. These prominent antithrombotic characteristics can be challenged during endothelial activation and are typically changed dramatically in damaged or dysfunctional endothelium.[10] However, few of the consequent blood alterations are sufficiently dominated by endothelial biology so as to offer utility in detecting endothelial status vis-à-vis activation and/or dysfunction.

Thrombomodulin

Although TM is also expressed by monocytes and other nonendothelial cells, its thrombin-stimulated conversion of protein C to activated protein C (APC) is understood to be predominantly endothelial in location, where this is robustly augmented by its companion molecule, EPCR. Inflammatory mediators (particularly tumor necrosis factor α [TNFα]) elevate blood sTM levels but conversely diminish endothelial TM expression, thereby lowering APC generation capability. The latter is observed in a number of inflammatory vascular syndromes associated with endothelial dysfunction, sepsis perhaps being the paradigmatic example,[9] but others include vasculopathies, diabetic angiopathy, and acute respiratory distress syndrome.[87,88] Yet no direct comparison to measured global endothelial dysfunction (e.g., by FMD) has been reported. Moreover, protein C biology is heavily influenced by endothelial-independent events and activities.

Nevertheless, low APC levels are independently associated with increased risk of CAD and some CVE,[89] and deficient conversion of protein C to APC characteristically identifies adverse prognosis in sepsis syndromes and reperfusion injury.[90,91] Conversely, increased plasma levels of sTM are associated with increased mortality from trauma and acute respiratory distress syndrome.[87] In sepsis patients, in whom APC generation is variably impaired,[9,91,92] higher sTM levels presage development of DIC (disseminated intravascular coagulation), multiorgan failure, delayed recovery, and mortality.[87,93] For apparently healthy subjects not having CAD, higher sTM levels identified diminished risk for future coronary and cerebrovascular events.[94] Yet in those having established CAD, higher sTM identified enhanced risk for future CVE.[95]

It has consequently been suggested that sTM level possibly has varying implications depending upon the specifics of the extant vascular biology in different clinical contexts. Possibly additionally contributing to biologic heterogeneity, multiple TM cleavage sites underlie sTM release. Some, but not all, of the resulting fragments retain anticoagulation activity.[96] The extent to which different TM fragments (retaining varying functional domains) impact differentially upon biology requires exploration. Whether elevated sTM levels can generally assist with the fine distinction between endothelial activation and dysfunction is debatable, yet their association with certain catastrophic endothelial failures is clear.

Von Willebrand Factor

Plasma vWF levels are mostly endothelial in origin, despite some contribution from platelets.[97] Release of stored high molecular weight (HMW) forms via Weibel-Palade body exocytosis[98,99] is an immediate-early endothelial response prompted by a spectrum of (patho)physiologic biologic mediators. Thereafter, its functional biology is dominated by anchorage to membrane P-selectin[100] and cleavage by liver-derived ADAMTS-13 (A Disintegrin And Metalloproteinase with a Thrombospondin type 1 motif)[101] to preempt the strong prothrombotic effect of HMW vWF.[102] Therefore, the largest forms of vWF are observed in plasma only under certain disease conditions,[103–106] and analysis of the vWF size distribution has not been found to be of value in assessment of endothelial function. On the other hand, high plasma vWF levels are associated with increased prospective risk for arterial thrombosis,[107] CAD,[108] and stroke[109] in the healthy population, and for future CVE in angina patients.[110] However, risk defined by vWF tracks closely with that defined by traditional risk factors and Framingham risk calculation, so it adds little value beyond classical risk assessment.[108,111] Interestingly, while vWF elevations in the atherosclerosis context are accompanied by inflammatory markers (e.g., sICAM-1, CRP), similar elevations in the apparently healthy that predict venous thromboembolism are not associated with these.[112] This may be an important clue vis-à-vis potential utility of vWF assessment more broadly in consideration of thrombotic risk.

Although measurement of plasma vWF has been used very widely to evaluate endothelial function, sometimes as the sole basis for assignment of "endothelial dysfunction," its utility is perhaps compromised by being too sensitive as a biomarker. Elevation of plasma vWF is probably a universal feature of endothelial dysfunction,[113] in part because the associated deficiency of endothelial NO production is the major endogenous inhibitor of Weibel-Palade body exocytosis.[98] Experimentally, pathologic vWF release and a consequent thrombotic renal microangiopathy occur in a relatively pure model of endothelial dysfunction, the eNOS knockout mouse.[114] Consistent with this illustrative association between vWF release and endothelial dysfunction, vWF elevations independently correlate with deficient brachial artery FMD in ACS,[115] hypertension,[116] and congestive heart failure[117] (FIGURE 48.3). However, elevated vWF levels are equally predictable in the disparate situations involving inflammatory activation since vWF behaves like an acute phase reactant.[113,118] It is further noteworthy that vWF levels vary with age, gender, race, and, in particular, genetics.[107] Overall, it seems improbable that vWF levels can distinguish between endothelial activation and dysfunction, although this issue certainly deserves more thorough clinical correlation and experimentation.

Other Biomarkers

Asymmetric Dimethylarginine

Plasma ADMA level, derived from multiple cell sources, is an emerging and unusual biomarker vis-à-vis endothelial status because it is a known inducer of endothelial dysfunction (as a competitive inhibitor of eNOS).[119] Elevated ADMA levels can be associated with deficient FMD,[120,121] and they seem to predict the future development of this even in healthy young subjects.[122] ADMA is proposed as an independent risk factor/indicator for CAD.[122] It predicts future adverse CVE in patients with established CAD[123] in high-risk CAD populations such as ACS,[124,125] hemodialysis and renal failure,[126–128] and in surgical[129] and critically ill[130] patients. In aggregate, these reports support the value of ADMA measurement, although much work is needed to examine its utility in additional clinical settings.

C-Reactive Protein

Derived from liver and blood monocytes, CRP is an acute phase protein that predictably is elevated in inflammatory states

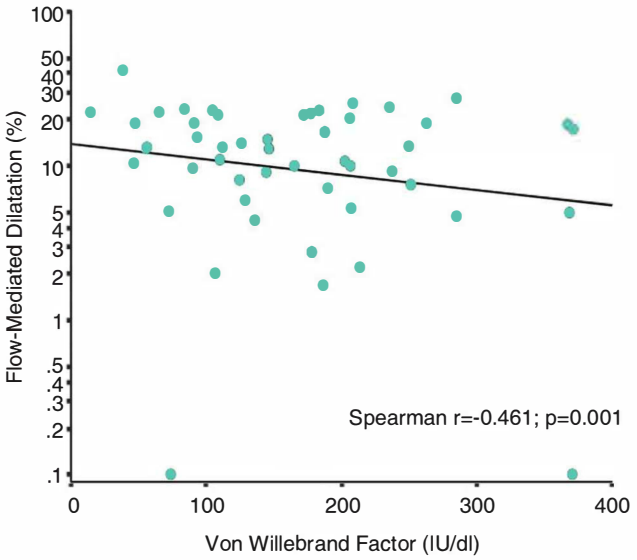

FIGURE 48.3 Flow mediated dilation is correlated with vWF level. These data are from patients with stable CAD. (Reproduced from Chong AY, et al. Endothelial dysfunction and damage in congestive heart failure: relation of low-mediated dilation to circulating endothelial cells, plasma indexes of endothelial damage, and brain natriuretic peptide. *Circulation* 2004;110:1794–1798, with permission from Wolters Kluwer Health.)

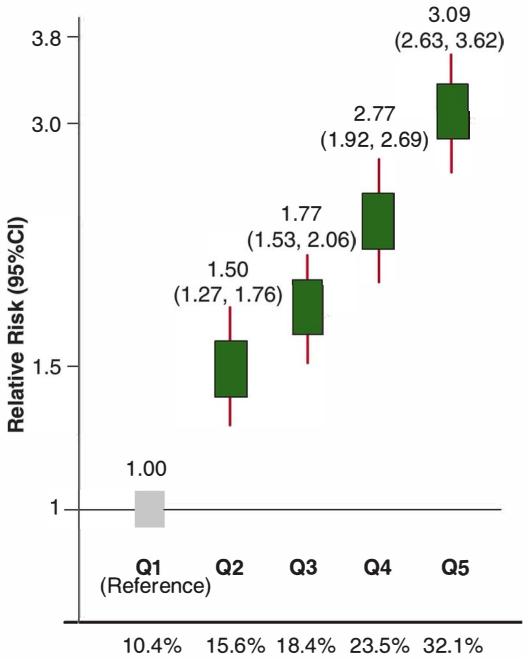

FIGURE 48.4 Relative prospective coronary risk increases in parallel with CRP concentration quintile. Numbers underneath the graph indicate what proportion of subjects falls into each of the quintiles of CRP level. However, enthusiasm regarding the utility of this relationship is mixed (see text). Critical appraisal of CRP measurement for the prediction of coronary heart disease events: new data and systematic review of 31 prospective cohorts. *Int J Epidemiol* 2008;38:217–231, with permission of the International Journal of Epidemiology.)

generally, to approximately 500 mg/L in some cases, rendering it unusable as an endothelial biomarker in such contexts.[131] In the normal general population, baseline high sensitivity CRP (hsCRP) levels are divided roughly into thirds: <1, 1 to 3, and >3 mg/L. hsCRP measurement has emerged as a clinically useful biomarker in the subtle, subclinical inflammatory context of atherosclerosis natural history because of its amenability to precision measurement at low levels and its reportedly robust association with—and ability to predict—CAD.[131–134] Conversely, achievement of lower hsCRP levels using statin therapy is associated with lower incidence of recurrent events in CAD,[135] as well as diminished occurrence of venous thromboembolism[136] and CVE[137] in the apparently healthy. Many have argued that hsCRP level helps in cardiovascular risk stratification (FIGURE 48.4).

However, enthusiasm for this robustness of hsCRP is by no means uniform.[138] Levels of hsCRP are tightly associated with some classical CAD risk factors.[131] So while hsCRP elevation may be an independent indicator of endothelial dysfunction[139] and cardiovascular risk,[88,138] some have found that the hsCRP effect is actually less strong than that of traditional cardiovascular risk factors and, indeed, provides little if any incremental risk information.[138,140] Whether its measurement is truly of added clinical value in the patients who would benefit the most, those of intermediate cardiovascular risk, continues to be considered.

Further complicating interpretation, human CRP gene promoter polymorphisms that establish chronic elevations of plasma CRP are not associated with alteration of cardiovascular risk.[140,141] Thus, CRP by itself is probably not a biologic inducer of vessel wall disease, despite a variety of experimental observations finding that it induces predictably relevant adverse changes in monocytes and endothelium *in vitro*.[142–149] In this regard, three observations are most ominous. CRP triggers TF expression and procoagulant activity by monocytes *in vitro*,[143] eNOS uncoupling and impairment of endothelial-dependent vasodilation *in vivo*,[148] and *in vitro* degradation of the endothelial glycocalyx, a critical layer that normally preserves endothelial homeostasis.[149] Indeed, it has been argued that endothelial glycocalyx thinning is closely linked generally to endothelial dysfunction.[150] Among many effects, this results in release of proteins normally embedded in glycocalyx such as AT and TFPI.[151]

In summary, extant data argue against CRP being a pathogenic factor in and of itself, but hsCRP level does independently indicate future cardiovascular risk. How robust this association is, and whether it adds predictive value, remain to be settled. Clearly, hsCRP requires further study to examine any potential utility as a biomarker of endothelial dysfunction in nonatherosclerosis contexts.

Lipoprotein-Associated Phospholipase A2

Lipoprotein-associated phospholipase A2 (Lp-PLA_2) is derived from nonendothelial cells but is nevertheless an emergent biomarker that appears to be a strong, independent predictor of endothelial dysfunction in the atherosclerosis context.[152] Despite being an inflammatory responsive molecule, its association with endothelial dysfunction is reported to be independent of CRP, suggesting that Lp-PLA_2 deserves wider study as an endothelial biomarker.

ENDOTHELIAL MICROPARTICLES

The blood carries MP derived from platelets (PMP), monocytes (MMP) or other leukocytes, red cells (RMP), and endothelial cells (EMP). PMP are usually the most prevalent type, but the numbers of each type vary enormously depending upon clinical context and thereby exhibit some very interesting associations with vascular disease.[153] The various MP source types can be distinguished by their retention of some features of their cell of origin, enabling a focus upon EMP, which, are figuratively summarized in FIGURE 48.5.[154]

Most data merely emphasize EMP enumeration and its associations with pathophysiology. The extent to which EMP phenotype accurately reflects the extant phenotype and activation state of the source cell remains to be documented. Proteomic studies illustrate that EMP composition can vary depending upon the type of stimulus that promotes their formation,[155] but it is not known if phenotype acquisition precedes onset of the shedding process. Nonetheless, this approach may have the potential to offer more detailed and precise information about the functional status of the endothelium *in situ* than is presently obtainable outside of the research laboratory. At present, however, there are still substantial caveats regarding attainment and interpretation of such data, which are most properly regarded as identifying potential rewarding areas for clinical research development.

Definition and Formation of MP

Circulating MP are defined as small (0.1 to 1.0 μM in diameter), anucleate, phospholipid vesicles formed by exocytotic budding from activated/perturbed cells. They are distinguished from smaller exosomes (<100 nm) and from larger apoptotic bodies containing nuclear material (>1.5 μM). Shedding of MP is an orchestrated response to cell activation, one that involves multiple intracellular events.[156] Of total circulating MP, most bind annexin V, reflecting the externalization of procoagulant phosphatidylserine (PS) that typically accompanies their formation. On the other hand, the single study that examined it reported that even so, a substantial portion of MMP and EMP actually were annexin V negative.[157] The significance of this is unknown. The risk of misidentifying annexin V-positive apoptotic bodies or even small platelets as MP can be limited by application of rigorous methods. Although EMP derived from activation

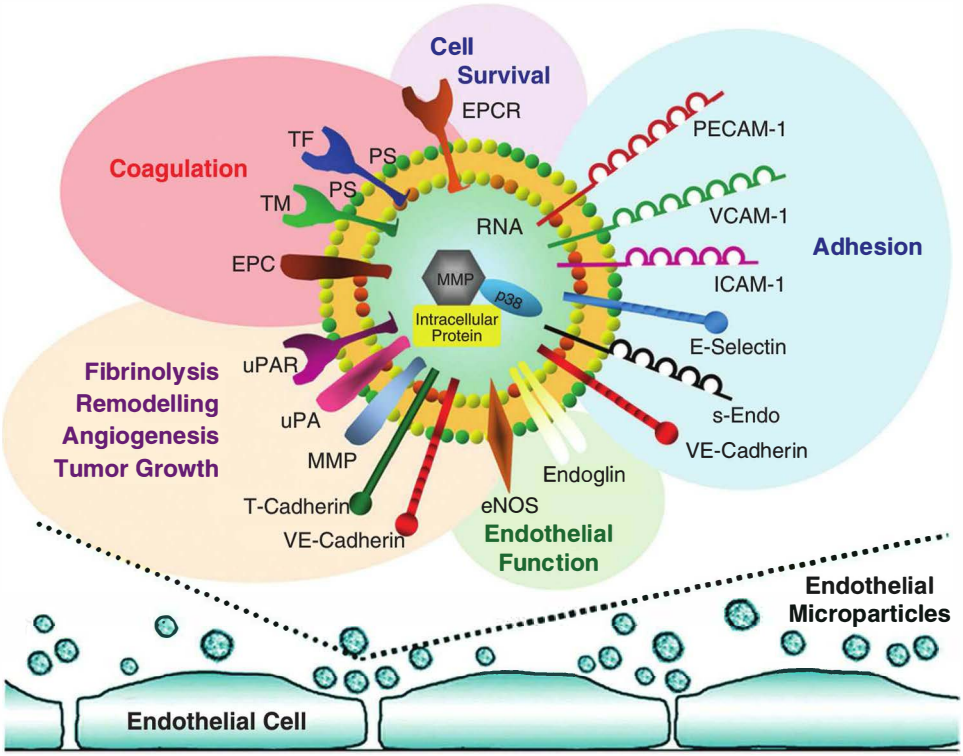

FIGURE 48.5 Depiction of a circulating endothelial-derived microparticle (EMP) showing many of the features reported for this type of MP. EMP features can include cytoplasmic components and surface features: endoglin (CD105); eNOS, endothelial NO synthase; EPC, endothelial protein C; EPCR, endothelial protein C receptor; E-selectin (CD62E); ICAM-1, intercellular cell adhesion molecule-1 (CD54); MMP, matrix metalloproteases; PECAM-1, platelet endothelial cell adhesion molecule-1 (CD31); PS, externalized phosphatidylserine; S-Endo/P1H12, melanoma cell adhesion molecule (CD146); TM, thrombomodulin; uPA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor; VCAM-1, VCAM-1 (CD106); VE-cadherin, vascular endothelial cadherin (CD144). Not shown on the EMP cartoon: α_v component of the vitronectin receptor (CD51); tissue factor (CD142). (Figure created and kindly provided by the laboratory of Dr. Francoise Dignat-George.) (Reproduced from Dignat-George F, et al. The many faces of endothelial microparticles. *Arterioscler Thromb Vasc Biol* 2011;31:27–33, with permission from Wolters Kluwer Health).

versus apoptosis of cultured cells can be distinguished experimentally,[158] it is unclear that this distinction can be made in clinical samples. Shedding of EMP is initiated by thrombin, TNFα, endotoxin, CRP, aberrant shear stress, and other pathobiologic stimuli. Thus, elevations of circulating EMP are associated with a variety of vascular disorders (Table 48.2).

Structure and Phenotype of EMP

From the background total MP, identification of EMP is enabled by probing for surface proteins constitutively expressed by endothelial cells, for example, PECAM-1, endoglin, VE-cadherin, MelCAM (S-Endo–1, P1H12), and the vitronectin receptor[154,159]; P1H12/S-Endo–1 (CD146) or VE-cadherin are used most commonly. Additional rigor is provided by documentation of more than one endothelial marker, as well as negativity for markers of monocytes and of platelets. When EMP have been probed for phenotype in relevant clinical contexts (Table 48.2), they have displayed inducible endothelial markers, such as the CAMs and selectins. EMP expression of TF was observed in sickle cell anemia,[157] a disease that entails ongoing coagulation activation.[6] Interestingly, an unrelated proteomic evaluation of EMP obtained from cultured cells was interpreted to suggest that they comprise a circulating, storage pool of bioavailable TF.[160] In addition, EMP have been reported to carry/express oxidized lipids, transcription factors, mRNA, microRNA, matrix metalloproteinases, NADPH oxidase, CD39, protein C, EPCR, TM, plasminogen activator and its receptor, and other moieties.

An illustrative example of the potential robustness of circulating MP analysis is displayed in FIGURE 48.6.[157] These data from patients with sickle cell anemia (obtained using a rigorous method having outstanding specificity) demonstrate that a varying clinical context within a single disease can be associated with temporal changes in total MP number, proportionate contributions of the different source cells, and MP tissue factor antigen positivity.

Functions of EMP

Circulating MP can exhibit functionality. Therefore, it has been suggested that the EMP's surface composition of endothelial-derived molecules could function as a biologic address mechanism, resulting in targeting of EMP to specific locations defined by, for example, cognate receptor expression. Thus, it is relevant to consider which endothelial functions have been found for EMP.

Procoagulant

Like other MP types, EMP have procoagulant potential due to their externalized PS that facilitates prothrombinase assembly/activity. The paradigmatic example of this property is, of course, provided by the exuberant generation of PS-positive PMP during platelet activation. Likewise, MP bearing TF are understood to play a prominent role in thrombosis.[161,162] It has been proposed that the procoagulant activity of circulating MP varies with their phenotype: $PS^+/TF^+ > PS^-/TF^+ = PS^+/TF^- > PS^-/TF^-$.[163,164] Conversely, EMP can be positive for EPCR and APC,[165] for urokinase-type plasminogen activator (u-PA) and u-PA receptor (uPAR),[166] or CD39,[167] and exhibit corresponding antithrombotic and anti-inflammatory activities. The pro- or anticoagulant function of MP may well vary with context and cell of origin, something requiring much additional research attention.

Table 48.2

Circulating EMP (endothelial-derived microparticles) in human vascular disease

Condition	Endothelial MP
Atherosclerotic Risk and Disease	
Hypertension	↑ CD31+CD42-MP[186]
Diabetes	↑ CD144+ MP[188] ↑ CD51+ MP[189] ↑ CD31+CD42- MP[189]
Obesity	↑ CD31+CD42b- MP[187]
CAD	↑ CD51+ MP[186] ↑ CD31+CD42- MP[186] ↑ CD144+ MP[188] ↑ CD31+ MP[171]
LV dysfunction	↑ CD31+ MP[190]

Nonatherosclerotic Vascular Diseases Having Increased Risk for Thrombosis	
Sickle cell anemia	↑ CD144+MP[157,196] ↑ CD144+CD142+MP[157] ↑ CD105+[196] ↑ CD105+ CD54+ MP[196]
Paroxysmal nocturnal hemoglobinuria	↑ CD105+ MP[196] ↑ CD105+CD 54+ MP[196] ↑ CD144+ MP[196]
Acute phase TTP	↑ CD31+CD62E+CD42b-, & ↑ CD54+CD62E+ & ↑ CD144+ & ↑ CD62E+vWF+ MP[158]
SLE +aPL ± thrombosis	↑ CD51+ MP[184]
Pre-eclampsia	↑ CD31+CD62E+ MP[199]

aPL, antiphhospholipid antibody; LV, left ventricle; MP, microparticles; SLE, lupus erythematosus; TTP, thrombotic thrombocytopenic purpura. For EMP features, CD designations are defined in legend to Figure 5. Features used to exclude PMP: CD41, GPIIb; CD42b, GPIba.

Endothelial NOS Impact

MP can impair eNOS function, as shown *ex vivo* by the adverse impact of EMP derived from cultures,[168] from renal failure patients,[169] and from CAD patients having myocardial

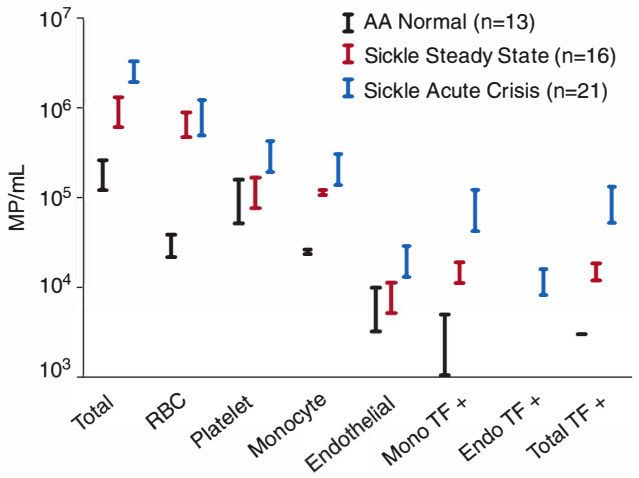

FIGURE 48.6 Example of circulating microparticle (MP) survey showing tissue factor (TF) positive MP. These data are from African American control subjects (*black bars*) and from sickle cell anemia patients either in "steady state" (*red bars*) or during an acute vaso-occlusive crisis (*blue bars*). These two sickle contexts are associated with chronic coagulation and platelet activation, which increase in the acute crisis state. Here, MP were defined rigorously: <1 μm in size plus positivity for annexin V binding plus ability to be pelleted out by ultracentrifugation. This had outstanding specificity but not optimal sensitivity (see text). Results indicate that (a) MP number varies widely in terms of cell-of-origin type, (b) MP type and number both vary with specific clinical context even within this single disease, and (c) additional instructive phenotype information can be identified and linked to cell-of-origin. (Data for this figure were derived from Shet AS, Aras O, Gupta K, et al. Sickle blood contains tissue factor-positive microparticles derived from endothelial cells and monocytes. *Blood* 2003;102(7):2678–2683.)

ischemia (but not those without ischemia)[170] upon endothelial-dependent dilation of rodent vascular rings. In the renal study, this adverse effect was not observed for EMP derived from healthy subjects.[169] Significantly, in patients with renal failure,[169] CAD,[171] and type 2 diabetes[172] brachial artery FMD correlated inversely with the elevated number of EMP[169,171,172] (FIGURE 48.7A,B). The renal failure study additionally noted that MP from nonendothelial sources (largely PMP outnumbering EMP by ~5:1) did not exhibit this correlation with FMD.[169]

In a low-disease burden model, enforced physical inactivity prompted EMP increases in normal volunteers,[173] interesting because lower levels of spontaneous physical activity induce a decrement in endothelial function (by FMD).[174] Thus, the data, albeit limited, suggest that elevated EMP levels not only result from endothelial dysfunction but also may promote it. The extent to which EMP induction of depressed FMD (an indicator of eNOS function) is accompanied by broader facets of endothelial dysfunction (e.g., inflammatory and prothrombotic phenotype) is not known and should be assessed. Whether this EMP response/effect is generally true in disease states is not known, although it does not escape attention that both EMP increases (Table 48.2) and depressed FMD seem to appear concurrently in multiple inflammatory states.

Other Signaling Effects and Biologic Roles

It is beginning to be apparent that the process of MP formation involves a degree of selective sorting of source cell molecules. This has been interpreted to raise the possibility that MP comprise a system of biologic cross-talk between cells, perhaps an orchestrated shuttling mechanism. Some studies have confirmed that MP can serve as messengers, transferring proteins and RNA/microRNA between cells.[175–178] Biologic roles for EMP in atherogenesis and atherothrombosis have been envisioned in terms of both pathogenic and protective mechanisms.[179,180] Likewise, participatory roles for MP in general have been proposed for sepsis,[181] angiogenesis,[182] thrombosis,[183] and the antiphospholipid syndrome in lupus.[184] Such proposals generally emphasize the roles of (higher numbers of) PMP and MMP, although sorting out which MP subpopulations (e.g., EMP vs. the others) contribute what to biology will be a formidable challenge.

Clinical Associations

Atherosclerosis Correlates

Although data are limited, and no comprehensive study has been done, studies in aggregate are beginning to indicate that EMP number may roughly parallel the natural history of atherosclerosis development and its characteristic deficient endothelial-dependent vasodilation. Elevated number of EMP is associated with abnormal arterial elasticity in apparent normals[185] and with severity of hypertension.[186] EMP count correlates inversely with FMD in various risk factor states such as obesity[187] and type 2 diabetes,[188,189] as well as in established CAD[171] (FIGURE 48.7B). Likewise, elevations of EMP count are associated with various cardiovascular complication events.[190–196] Finally, a study of 488 consecutive cardiology patients documented that EMP level roughly paralleled disease advancement in terms of risk/stage/acuity (FIGURE 48.7C), added further value to Framingham risk estimates, and predicted increased occurrence of subsequent CVE (FIGURE 48.7D).[197] Attainment of the latter observation specifically was perhaps predictably prejudiced by study design, but others similarly have argued that EMP count may assist in risk stratification.[198]

Other Disorders

Elevated EMP numbers also have been reported in thrombotic thrombocytopenic purpura (TTP), antiphospholipid syndrome, lupus anticoagulant, vasculitis, chronic venous insufficiency, venous thromboembolism, sickle cell anemia, paroxysmal nocturnal hemoglobinuria, eclampsia/preeclampsia but not gestational hypertension, and in a variety of inflammatory conditions including sepsis. A number of these are already known to be associated with abnormal FMD.

Conclusions Regarding MP

Methodology remains the greatest impediment to broad application of MP profiling by fluorescence-activated cell analyzer/sorter (FACS). The usable, gold-standard, but excessively cumbersome approach required a decade ago[157] (FIGURE 48.6) fortunately has been supplanted by multiple improvements.[154]

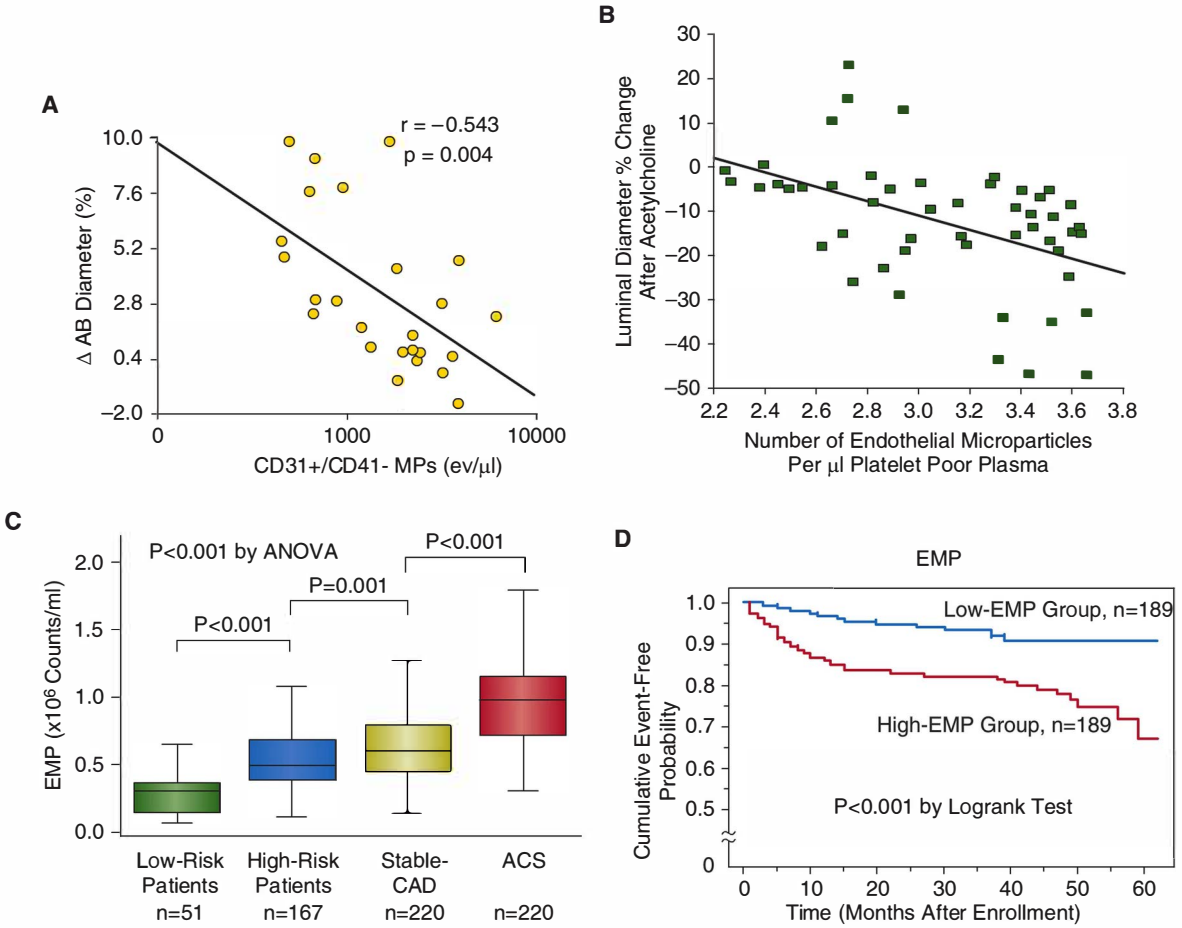

FIGURE 48.7 Relationship between EMP and endothelial function and coronary disease status. Flow mediated dilation (FMD) at the brachial artery (vertical axis) is inversely related to EMP count in end stage renal failure patients **(A)** (Reproduced from Amabile N, et al. Circulating endothelial microparticles are associated with vascular dysfunction in patients with end-stage renal failure. *J Am Soc Nephrol* 2005;16:3381, with permission from the American Society of Nephrology.) and CAD patients **(B)** (Reproduced from Werner et al. Circulating CD31+annexin V+ apoptotic microparticles correlate with coronary endothelial function in patients with coronary artery disease *Arterioscler Thromb Vasc Biol* 2005;26:112–116, with permission from Wolters Kluwer Health.) **(C)** In consecutive patients, number of EMP increases in parallel with coronary disease status. (Reproduced from Nozaki et al. Significance of a multiple biomarkers strategy including endothelial dysfunction to improve risk stratification for cardiovascular events in patients at high risk for coronary heart disease. *J Am Coll Cardiol* 2009;54:601–608, with permission from Elsevier.) **(D)** For the same CAD patients, those with higher EMP counts at presentation (*red*) had higher occurrence of subsequent CVE.

Nonetheless, ongoing attempts to achieve a consensus operational definition of MP and a standardized methodologic approach have been disappointing, as there are many issues that can impact results that still need to be standardized or solved.[154] The predominant challenge is presented by accurate assessment of the lower half of MP size spectrum (<500 nm), so many studies to date have focused only upon MP > 500 nm in size. Yet for optimal clinical utility, it seems probable that the full size range should be included (recognizing that MP of different sizes might have different phenotypes, functions, or disease associations), along with positivity/negativity for annexin V binding, at least two markers of parent cell of origin, and the desired markers of activation/functional status. Hopefully, the evolving availability of abundant fluorochrome choices, multiplex platforms, and latest generation of FACS hardware will allow such optimization to be achieved, in which case a wealth of clinically useful information may be obtainable.

A critical unsolved question is whether the phenotype of circulating EMP accurately reflects the extant features of the parent endothelium *in situ*, or whether it is established by the biologic process of MP formation itself. The available data (Table 48.2) are most consistent with the former. But if the latter is true, then EMP phenotyping will perhaps be disappointing as a "biopsy" of the endothelial surface *in situ*. Clearly, this critical issue requires research focus. Nonetheless, EMP enumeration plus phenotyping would seem to offer the greatest potential of all the blood biomarkers for eventual ability to glean multifaceted, clinically instructive information.

CIRCULATING ENDOTHELIAL CELLS

The CEC evident in fresh blood most likely have become detached from vascular walls, as evidenced by their recipient origin in subjects having previously undergone gender mismatched marrow transplantation.[200] They are identifiably endothelial by their positive staining for multiple endothelial markers and their inclusion of Weibel-Palade bodies.[154] The normal number of CEC (≤10/mL blood in virtually all normals, and <5 in most [Table 48.3]) comprises only approximately 10^{-11}% of the adult's total number of vessel wall endothelial cells. It is not known if their presence serves some biologic function, but suggestions that they may serve to "resurface" denuded vessel wall are perhaps whimsical. On the other hand, the worrisome implication of their appearance in blood lies in the presumed reciprocal existence of denuded vessel wall. The number of CEC in the normal total blood volume corresponds to an estimated <0.5 cm^2 of total denuded surface area, presumably an unconcerning amount. However, the CEC levels observed in pathologic states are sobering. The approximately 50 CEC/mL reached in sickle disease[201] and the approximately 200/mL reached in TTP[202] would correspond roughly to reciprocal denudation of approximately 7.5 cm^2 and approximately 30 cm^2, respectively—presumably not trivial. Whether this interpretation is actually realized in vascular biology is not known and deserves research attention.

CEC Detachment

The detachment mechanisms undoubtedly are complex and multifactorial but uniformly must involve impairment of endothelial cell anchorage to subendothelial matrix and adjacent cells. This event could be explained by various inciting processes including actual dislodgement by mechanical stress and a lifting response to biologic mediators such as TNFα,[203] inflammatory leukocyte proteases,[204] metalloproteases released from dysfunctional endothelial cells,[205] endothelial apoptosis that is hypothesized to be a prominent aspect of some vascular pathobiologies,[206] or the vanishingly slow turnover of the normal vascular wall endothelium. The latter may account for the tiny number of CEC found in normal individuals, but the inciting mechanism underlying abnormally increased CEC levels in disease undoubtedly varies amongst vascular disorders.

An increased number of CEC is usually assumed to reflect elevated generation, but in fact it is not known if CEC level is actually dominated by changes in clearance rate, a distinct possibility. It has been shown that infused autologous canine blood outgrowth endothelial cells are removed with probable single-pass kinetics,[207] which might imply that the CEC observable in fresh blood have very recently appeared. The balanced contributions of production and clearance also may well be different in different clinical disorders.

CEC Methodology

The rarity of CEC presents an enormous challenge to their enumeration and phenotyping.[154] Although prohibitively cumbersome, the gold standard method for CEC counting (direct manual immunofluorescent microscopic examination of an entire known amount of blood) has virtually 100% sensitivity and specificity.[201] Prior to this step, however, most studies have employed some form of centrifugation and/or enrichment using immunobeads carrying antibody to CD146 (either PIH12[201] or S-Endo-1[208]), although this results in loss of about 20% of CEC. Encouragingly, it may be possible to achieve acceptable specificity and reasonable CEC counts via direct FACS analysis without the immunobead step,[209] suggesting that FACS approaches to multiparameter phenotyping will enhance the potential utility of CEC assessment. A caveat is that depending upon the clinical context, serial observations should be considered. Longitudinally measured CEC counts in sickle patients, for example, varied significantly and rather chaotically depending upon clinical specifics.[201]

Information Derivable from CEC Analysis

While CEC enumeration and phenotypic profiling has by no means been done systematically or comprehensively, the accumulated reports focused upon single issues offer encouragement that this approach may have potential for obtaining clinically useful information.

Enumeration

CEC numbers are significantly increased in vasculotrophic infections, inflammatory vasculopathies, and atherosclerosis risk/disease. Such reports are summarized in Table 48.3 along with notations regarding ancillary findings of interest. Interestingly, elevations of CEC number have been observed to parallel increases of disease activity in systemic sclerosis,[210] systemic lupus erythematosus,[211] Mediterranean fever,[212] Kawasaki disease,[213] acute rejection of renal transplant,[214] and sickle cell anemia.[201] CEC level is reported to offer prognostic information in septic shock,[215] and it seems to predict risk for future CVE in hemodialysis[216] and ACS patients.[217]

Apoptotic Versus Viable CEC

CEC can be dead/necrotic cells (loss of permeability barrier), apoptotic cells (annexin V binding or TUNEL positivity), or still-viable cells[218] that exhibit very limited expansion potential if cultured[200]. These distinctions may well be indicative of the underlying disorder. Since endothelial cells are intolerant of loss of anchorage to survival-signaling matrix proteins, loss thereof triggers apoptosis pathways exhibiting (in cultured cells) a 10-hour half-time to death[219]. Thus, CEC should necessarily reside somewhere in the evolution of this process. Those dislodged most recently would have greater likelihood of being viable, so perhaps this could be an indicator of active dislodgement.

Yet even this is not so simple. For example, it was found that patients with sickle cell disease have an aberrantly higher proportion of CEC that are viable (64% vs. 30% in normals) rather than apoptotic,[220] seemingly implying that detachment is accelerated in this disease, especially since acute vaso-occlusive crises are associated with spikes in CEC count.[201] However, this unusually higher viability of CEC correlated with concurrent elevation of plasma levels of vascular endothelial growth factor (VEGF), a survival signaling growth factor,[220] so evaluation of CEC viability may not be a reliable indicator of blood residence time, at least in some cases. Despite this caveat, some enlightening results have been reported. For example, most CEC in antineutrophil cytoplasmic antibodies-associated small-vessel vasculitis are necrotic.[221] Apoptotic CEC dominate in many inflammatory disorders such as rheumatoid arthritis, whilst a

Table 48.3

Disorders with significantly elevated numbers of CECs*

Condition	CEC/mL nL	CEC/mL Cases	Noteworthy Special Observations
Atherosclerotic Disease and Risk-Related			
Coronary angioplasty [208]¶,§	<3	6–10	
ACS			↓ CD36 + CEC; some tissue factor + but generally

* Results shown as mean values, but greater information is derivable from the range of values within each disorder; citations are indicated by brackets. The symbol ∝ indicates "proportionate to". Methods vary: enrichment step utilized standard centrifugation (†) or density centrifugation (#) or immunobead enrichment (¶); counting/phenotyping utilized microscopy (§) or FACS (‡).
Abbreviations: ACS, acute coronary syndrome(s); BMT, bone marrow transplantation; CVE, cardiovascular events; ESR, sedimentation rate; FMD, flow mediated dilation as a direct indicator of endothelial dysfunction; PAH, pulmonary arterial hypertension.

temporal increase of the viable CEC was observed in patients with septic shock.[215]

Putative Vascular Origin of CEC

Actualization of identifying region of CEC detachment has been prevented by the unavailability of region-specific endothelial markers. It has been noted that CEC in sickle disease and in ACS are predominantly CD36 positive[201] and negative,[222] respectively, consistent with their respective natures as microvascular and macrovascular occlusive diseases.

Phenotype

An undetermined issue is whether CEC phenotype actually mimics that of the endothelium *in situ*. CEC activation phenotypes have been reported for a variety of disorders (Table 48.3). CEC examination also has been used to diagnose rickettsial disease[212] and to document therapeutic effect of attempted inhibition of endothelial inflammatory transcription.[223] Of present interest, TF (CD142) positive CEC have been detected in sickle disease[224] (FIGURE 48.9), in small vessel vasculitis,[221] and in acute myocardial infarction.[222]

CEC vis-à-vis Endothelial Dysfunction

CEC numbers are elevated in multiple clinical states known to involve endothelial dysfunction, including atherosclerosis risk/disease and sepsis (Table 48.3). In chronic heart failure[117] and in systemic lupus erythematosus[209] CEC levels were found to correlate inversely with FMD (FIGURE 48.8), but this correspondence has not been widely studied. Because of the seemingly dire implication of the presumed reciprocal denuded area indicated by CEC elevations, it seems reasonable to assume that these reveal existence of chronic endothelial dysfunction, but there is no specific proof of this. Whether this is true—and whether it is accompanied by untoward hemostatic activation—must be determined.

CONCLUSIONS

CEC can provide useful information if assessed manually (FIGURE 48.9), but if multiparameter profiling by FACS can be used accurately and reproducibly for this, much broader application will be enabled. However, CEC assessment needs to advance from essentially anecdotal descriptions of scantily profiled cells to a more systematic, rigorous, and critical assessment of the issues directly related to the believability of the information that their analysis yields. There are two fundamental issues that must be addressed if CEC evaluation can hope to advance from its current status as a boutique test of somewhat ambiguous meaning. To what extent does CEC phenotype mimic that of endothelium *in situ*, as opposed to being dominated by the (likely) temporally evolving state of their advancement toward apoptosis? If CEC phenotype is influenced by the evolution of apoptosis, can phenotyping still be informative, for example, by simultaneous, cell-by-cell documentation of viability status? Without answers to these questions, assessment of CEC will remain more of a curiosity than a biomarker of significance.

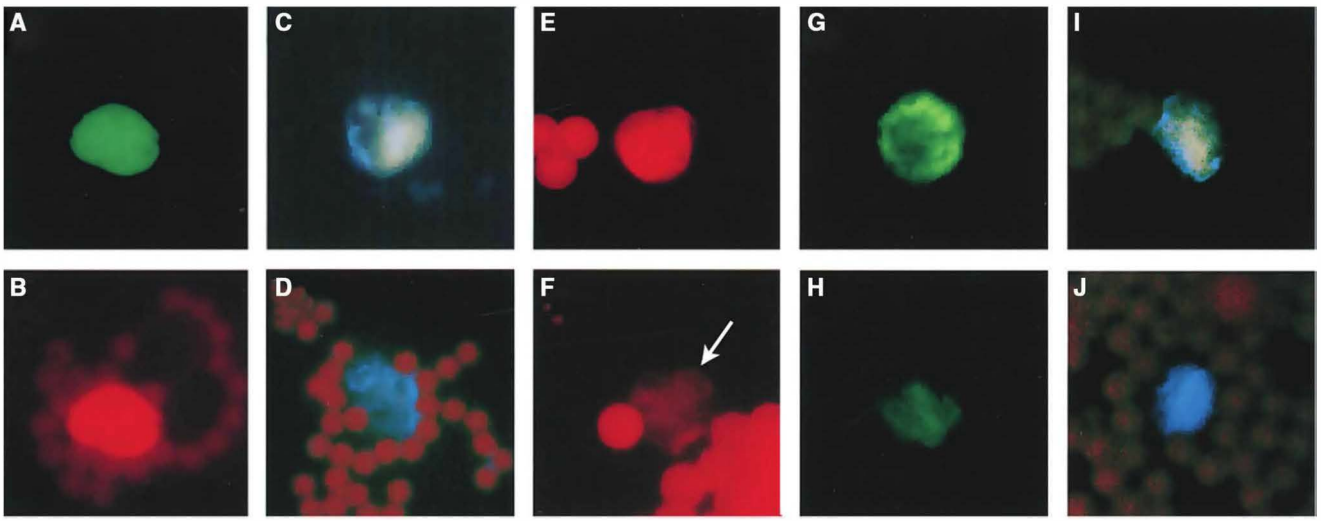

FIGURE 48.8 Assessment of circulating endothelial cell (CEC) tissue factor (TF) positivity. All panels show CEC obtained from sickle patients (smaller objects are the beads used for CEC enrichment). Panels are paired vertically to illustrate points. A single CEC is shown as positive for P1H12 **(A)** and TF antigen **(B)**. In **(C)**, a CEC that is P1H12 positive (*blue*) shows hybridization with antisense probe to TF mRNA (*yellow*), while panel **(D)** shows a control CEC having no hybridization using the control probe. **E:** A CEC stains positively with an antibody to factor VII/VIIa. **F:** That binding is abolished with a blocking antibody to TF (the faint CEC indicated by the arrow). **G:** A CEC incubated with factors VIIa and X exhibits factor X activation, as detected by a chromogenic substrate sensitive to factor Xa. **H:** That activity is abolished by a blocking antibody to TF. **I:** A CEC identified by P1H12 positivity (not shown) exhibits simultaneous expression of TF antigen (*blue*) and TF mRNA (*yellow-green*). **J:** The control CEC is positive for TF antigen (*blue*) but is negative for hybridization with the yellow control probe. Cells illustrated were representative of the sample slides from which they were selected. (Reproduced from Solovey A, et al. Tissue factor expression by endothelial cells in sickle cell anemia. *J Clin Invest* 1998;101:1899–1904] with permission of the American Society for Clinical Investigation.)

Endothelial dysfunction and damage in congestive heart failure: relaxation of flow-mediated dilation to circulating endothelial cells, plasma indexes of endothelial damage, and brain natriuretic peptide. *Circulation* 2004;110:1794–1798, with permission from Wolters Kluwer Health.) **B:** In patients with ACS, CEC count correlates directly with plasma tissue factor content. (Reproduced from Lee KW, et al. Interrelationships of indices of endothelial damage/dysfunction (circulating endothelial cells, vWF and FMD) to tissue factor and interleukin-6 in acute coronary syndromes. *Int J Cardiol* 2006;111:302–308, with permission from Elsevier.)

ENDOTHELIAL PROGENITOR CELLS

Despite recent attempts to link varied levels of EPCs in blood with endothelial dysfunction, this cannot be recommended as a useful biomarker. Many "EPC" studies have utilized ambiguously defined and incompletely characterized cells and/or have assigned the term "progenitor" to what, in fact, are actually the outgrowth progeny of (possible) progenitors. Indeed, the universally cited seminal papers identifying "EPC" in blood[238] and using colony forming units ("CFU-Hill") to count them[239] both utilized a flawed methodology that actually detects a population of peripheral blood monocytes that undergo partial transdifferentiation in an environment rich in endothelial growth factors.[240,241] They thereby acquire some endothelial markers, but they retain myeloid markers and exhibit extraordinarily limited expansion potential; they are neither endothelial nor related to true endothelial progenitors. Fewer studies have actually directly or indirectly focused upon the circulating endothelial lineage cells that actually are capable of transplantation and high-fold expansion, their progeny usually referred to as blood outgrowth endothelial cells or late outgrowth endothelial cells.[200,240,241] Whether the parent cells of these are true progenitors, as is believed, has not been formally proven but is consistent with available evidence. Evidence is reasonably compelling for their residence and source being bone marrow,[200] but it alternatively has been suggested to be the blood vessel wall;[242] it could, of course, be both.

SUMMARY AND CONCLUSIONS

Despite the central role played by endothelial biology in physiologic homeostasis and its complex contributions to disease pathophysiology, there are no fully validated and universally applicable tests to document endothelial dysfunction generally in clinical medicine. The most specific available test is measurement of endothelial-dependent FMD at the brachial artery, an approach having clearly documented utility and unambiguous meaning in the setting of atherosclerosis and its risk factors. However, in endothelial dysfunctional states inferred from extant functional aberrancies causing clinical risk/harm, there are no comparable unambiguous biomarkers. The most generally useful biomarkers seem to be plasma levels of vWF and sICAM-1. Others, CRP and ADMA, are robust but probably have limited context specificity. Perhaps most intriguing are two emerging approaches, enumeration and phenotyping of CECs and blood MP. The latter would seem to offer the greatest promise for providing the richest (and real-time) insight into the functional status of endothelium *in situ*.

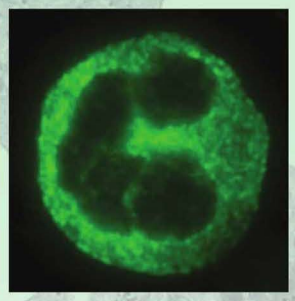
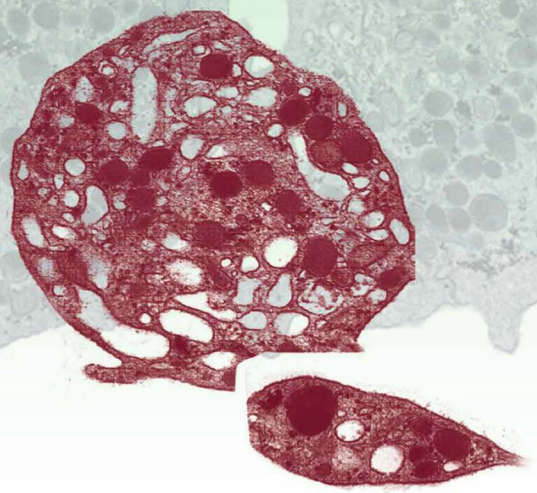
PART III





Disorders of Coagulation, Platelets, and Vessel Wall

SECTION A: BLEEDING DISORDERS OF COAGULATION AND FIBRINOLYSIS

CHAPTER 49

Overview of Inherited Hemorrhagic Disorders

GILBERT C. WHITE, II, HAROLD R. ROBERTS, AND VICTOR J. MARDER

The focus in Section A of Part III of this book is on inherited hemorrhagic disorders that result from deficiencies or abnormalities of the blood coagulation factors. Acquired hemorrhagic disorders, such as liver disease and diffuse intravascular coagulation (DIC), are presented in Part V of the text. Bleeding disorders from platelet defects are presented in the section on platelets (Section C, Part III) and bleeding disorders due to disorders that affect blood vessels are presented in the section on vascular defects (Section D, Part III). Altogether, worldwide, inherited hemorrhagic disorders due to deficiencies or abnormalities of blood coagulation factors number approximately 250,000. Thus, these are relatively rare but clinically important disorders.

Inherited disorders of blood coagulation have been known since antiquity. FIGURE 49.1 illustrates a passage from the Babylonian Talmud.[1] Rabbi Judah the Patriarch, redactor of the Mishnah, the second century compendium of Judaism's oral law, writes this passage which translates to: "If she circumcised her first child and he died, and a second one also died, she must not circumcise her third child." This demonstrates knowledge of the inherited nature of the bleeding disorder we now know as hemophilia and also demonstrates knowledge of the sex-linked nature of the disease as well as the clinical penetrance. General knowledge of inherited bleeding disorders such as hemophilia was further amplified when the daughters of Queen Victoria of England, a silent carrier for hemophilia A, married into a number of royal houses in Europe, including Russian, German, and Spanish royalty. The story of Princess Alexandra and her hemophilic son, Alexis, who was cared for by the mad monk Rasputin, is well known and was chronicled by Robert Massie, who was himself the father of a hemophilic son.[2]

Hemophilia in America goes back a long way too—relatively speaking—to the early colonial days in New England (FIGURE 49.2). John Oliver, the first known hemophiliac in the new world, was born in 1613 in London and came to Plymouth, MA, in 1639 on the ship, Jonathan, eventually settling in Ipswitch, MA. A daughter, Mary Oliver, was born in 1640. In 1656, Mary, an obligate carrier for hemophilia A, was married to Samuel Appleton and they proceeded to have eight children, three daughters and five sons. One son, Oliver Appleton, born in 1677, had hemophilia. Oliver lived to an advanced age and had three daughters. The oldest married Thomas Swain, Sr., of Reading, MA, and had seven children, two boys and five girls. The two sons both had hemophilia and bled frequently but became physicians, lived into their 30s, and had families. Dr. Thomas Swain, Jr., had a daughter who had three sons, two reported to be bleeders. Dr. Oliver Swain had three normal sons and a daughter who had three sons, all with hemophilia. A daughter of Thomas Swain, Sr., married John Bachilor and had three sons with hemophilia. Dr. Oliver Swain's daughter, Mary Swain, married Jeremiah Hartshorne in 1786 and gave birth to three sons with hemophilia. The Hartshorne family lived in Wakefield, MA, and, as it happened, next door to Dr. John Hay, a fellow of the Massachusetts Medical Society. Upon learning of the family history and after caring for the Hartshorne children, Dr. Hay published an *Account of a Remarkable Hemorrhagic Disposition Existing in Many Individuals of the Same Family* in the New England Journal of Medicine in 1813.[3,4] Coincidentally, a descendent of Thomas Swain, the New England landscape artist R. Swain Gifford, is an ancestor of the brother-in-law of one of the authors of this text.

Inherited disorders of blood coagulation range from the relatively common von Willebrand disease (vWD) to rare disorders such as factor XIII deficiency and multiple coagulation factor deficiencies (MCFD), from autosomal to X-linked in inheritance, and from severe to mild in clinical manifestations. Table 49.1 presents some of the distinguishing characteristics of each. The differential diagnosis of hemorrhagic disorders, both clinical and laboratory aspects, is discussed in Chapter 50. Specific coagulation tests are available for each factor, making unequivocal diagnosis of inherited deficiencies relatively easy, and industries to procure and sell specific clotting factor-deficient plasmas for specific assays exist, providing standardized substrate for the assays. Both immunologic and functional assays are available for most factors, enabling the diagnosis of both *quantitative*, defined as a proportional reduction in clotting factor protein and activity, and *qualitative*, defined as a reduction in clotting factor activity in excess of protein, disorders. The basis for clotting factor assays and how preanalytical variables can affect their accuracy is described in detail in Chapters 50 and 58. In general, the assays are sensitive to clotting factor activity, especially to levels of 20% of normal and lower, and are specific, making the diagnosis of most cases relatively straightforward. Where the diagnosis becomes difficult is with mild deficiencies, when clotting factor levels begin to blur with normal individuals, and in cases of general inhibitory substances, such as anti-phospholipid or so-called lupus-like antibodies, where multiple clotting factors may appear to be deficient. For example, the current difficulty with the diagnosis of mild type 1 vWD is well known and is discussed in detail in Chapter 52 by Sadler and Lillicrap on vWD.

While deficiency of procoagulants leads to bleeding, the clinical symptoms vary considerably (Table 49.1) and may provide a clue to the diagnosis. Hemophilia A and B are the most severe of the inherited bleeding disorders and have a curious predilection for bleeding into joints that is still poorly understood. As described in Chapter 51, this recurrent bleeding in joints leads to a chronic and progressive form of arthropathy that characterizes

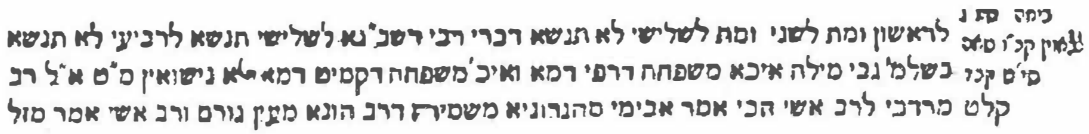


FIGURE 49.1 Hemophilia in Antiquity. A familial bleeding disorder, probably hemophilia, is described in the Babylonian Talmud, written by Rabbi Judah the Patriarch, redactor of the Mishnah, in the second century compilation of Jewish law. The translation is: "For it was taught: If she circumcised her first child and he died, and a second one who also died, she must not circumcise her third child. However, Rabbi R. Simeon b. Gamaliel said: She circumcises the third, but must not circumcise the fourth child."

the disorder and has some similarity to rheumatoid arthritis. The pathophysiology of the inflammatory changes that lead to the chronic arthropathy is reasonably well understood, but why bleeding occurs in the joints remains a mystery. It has been stated that factors VIII and IX must have some function supporting joint vessels. Bleeding from delicate mucous membranes is a feature of von Willebrand factor (vWF) deficiency (Chapter 52), suggesting that vWF-mediated platelet adhesion is particularly important in these tissues. Joint bleeding may occur in vWD but usually correlates with the level of factor VIII deficiency. Factor XIII deficiency has a high rate of intracranial bleeding, leading clinicians to emphasize the importance of prophylaxis in this disorder. Surprisingly, complete deficiency of fibrinogen (Chapter 54) produces a less serious bleeding disorder than might be expected from the deficiency of the protein that actually produces the clot. Why don't patients with afibrinogenemia bleed continuously? This is a question that is frequently asked by students and practitioners. In newborns with afibrinogenemia, bleeding from the umbilical stump is common. In children and adults, bleeding is typically in soft tissues and organs, but joint bleeding is not common. Other deficiencies (Chapter 53) are less common, and some, like factor XI deficiency, may be more variable in their bleeding but no less important if encountered. Despite the significant prolongation of the partial

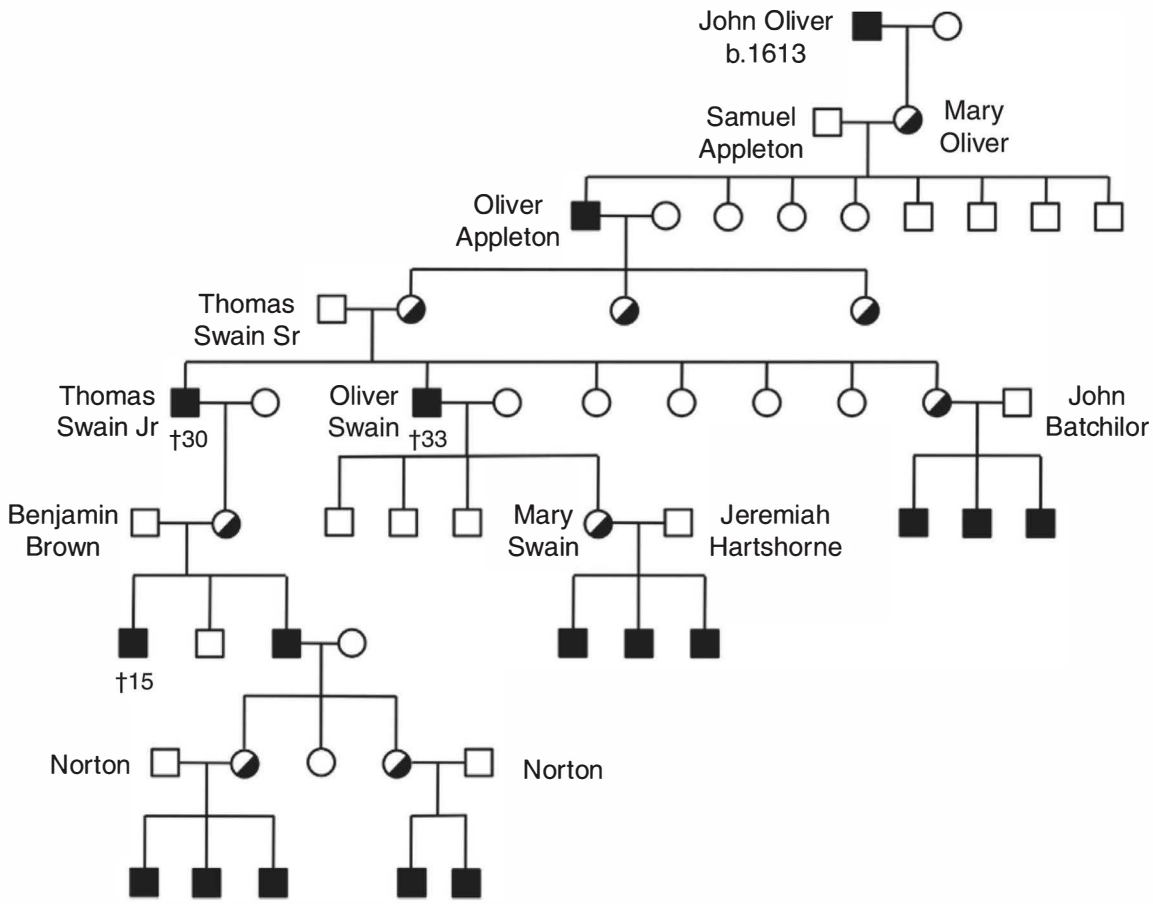

FIGURE 49.2 *Hemophilia in the New World*. Pedigree of first reported family with hemophilia in North America, as reported by Hay in 1813.[3] (The figure is reconstructed from descriptions in Hay's publication, in part.)

Table 49.1

Inherited hemorrhagic diseases

Defect		Frequency	Inheritance Pattern	Bleeding Manifestations	Diagnostic Testing			
					PT	PTT	TCT	BT
Fibrinogen abnormalities	Afibrinogenemia		Autosomal	Severe, but less so than severe hemophilia A and B	Infinite	Infinite	Infinite	Prolonged
	Dys-fibrinogenemia		Autosomal	Variable bleeding and/or clotting	Prolonged	Prolonged	Prolonged or shorten-ed	Normal
Prothrombin deficiency			Autosomal	Varies with prothrombin levels	Prolonged	Prolonged	Normal	Normal
Factor V deficiency			Autosomal	Mild-moderate	Prolonged	Prolonged	Normal	Prolonged
Factor VII deficiency			Autosomal	Moderate-severe	Prolonged	Normal	Normal	Normal
Hemophilia A			X-linked recessive	Variable, depending on factor VIII level	Normal	Prolonged	Normal	Normal
Hemophilia B			X-linked recessive	Variable, depending on factor IX level	Normal	Prolonged	Normal	Normal
Factor X deficiency			Autosomal	Variable, depending on factor X level	Prolonged	Prolonged	Normal	Normal
Factor XI deficiency			Autosomal	Variable, but not dependent on Factor XI levels	Normal	Prolonged	Normal	Normal
Deficiency of factor XII			Autosomal	None	Normal	Prolonged	Normal	Normal
Deficiency of prekallikrein			Autosomal	None	Normal	Prolonged	Normal	Normal
Deficiency of high molecular weight kininogen			Autosomal	None	Normal	Prolonged	Normal	Normal
Factor XIII deficiency			Autosomal	Severe	Normal	Normal	Normal	Normal
vWD		1:1,000,000	Autosomal; usually recessive; more rarely dominant	Moderate to mild, depending on level of deficiency and defect; predilection for mucous membranes	Normal	Normal or prolonged	Normal	Normal or prolonged
Deficiency of α_2 plasmin inhibitor			Autosomal	Moderate	Normal	Normal	Normal	Normal
Deficiency of PAI -1			Autosomal	Moderate	Normal	Normal	Normal	Normal

thromboplastin time (PTT) that occurs with deficiencies of factors XII, high molecular weight kininogen, and prekallikrein, there is no bleeding tendency. These proteins are important, though, providing, along with activated protein C, connections between the coagulation and inflammation pathways.

Deficiency of the regulators of fibrinolysis can also result in bleeding (Chapter 56). For example, in the absence of α_2-antiplasmin, the production of plasmin is less regulated, leading to enhanced fibrinolysis and a tendency to bleed. This is typically mild but can be severe. The diagnosis is suspected when a patient gives a lifelong history of bleeding, often after trauma, and when the usual screening tests of coagulation are normal and procoagulant levels are all normal. Similarly, deficiency of plasminogen activation inhibitor (PAI) can result in a bleeding tendency because plasminogen activation becomes unregulated, leading to increased plasmin levels. Symptoms and coagulation screening tests are similar to those seen in antiplasmin deficiency.

Bleeding tendency generally correlates with coagulation factor levels, but at a given level, there can be considerable variation in symptoms. For example, among patients with severe hemophilia A, the clinical symptoms can range from weekly bleeding to bleeding less than once a month; joint involvement can range from all joints to single joints. Even individuals with the same molecular defect can have varied symptoms. This has led to a search for so-called modifier genes, genes that can affect the frequency and severity of bleeding. Interestingly, prevalent gene defects associated with an increased risk of venous thrombosis do not appear to modify bleeding disorders, based on the evidence in hemophilia. Neither factor V Leiden nor the prothrombin 20210 polymorphism have been shown to consistently affect the annual bleed frequency, factor utilization, and/or arthropathy in hemophilia A,[5,6–15] even though hemophilic plasma with factor V Leiden generate more thrombin *in vitro* than hemophilic plasma with normal factor V.[16] This suggests that the balance between bleeding and clotting is not simple and may not reflect the sum of procoagulant and anticoagulant factors. Nevertheless, the strongest evidence that modifier genes do exist and do influence clotting are ABO blood group substances and their effect on vWF levels and on factor VIII levels, where vWF levels in individuals with type O blood (x = 74%) average 30% less than individuals with type A (x = 105%), B (x = 117%), or AB (x = 123%) blood.[17] The effect of blood group substances is believed to be through an effect on carbohydrate structure and vWF clearance. New genetic approaches such as genome wide association scanning (GWAS) and whole genome sequencing promise to make the search for meaningful modifiers more productive. This interest in identifying modifier genes in hemophilia stems in part from a desire to not only understand the difference in severity between individuals but also explore potentially new approaches to treatment. For example, there is currently strong interest in the pharmaceutical industry in the potential use of inhibitors of tissue factor pathway inhibitor as an approach to modify the bleeding risk in hemophilia, an approach that is supported by animal models.[18,19,20,21,22,23,24]

Multiple clotting factor deficiencies (Chapter 55) are among the most interesting deficiencies. Although clotting factor deficiencies may be coinherited, there is now evidence that these proteins may share common production pathways that create mechanisms for multiple deficiencies. One of the first of these to be described was the common deficiency of the vitamin K-dependent coagulation factors, factors II, VII, IX, X, protein C and protein S, initially called the Borgschulte-Grigsby syndrome.[25] Described clinically before molecular biology was understood, subsequent work has shown that two hepatic enzymes can produce this syndrome: γ-glutamyl carboxylase and vitamin K-epoxide reductase.[26,27] The former, cloned in 1991,[28] is responsible for posttranslationally converting glutamic acid to γ-carboxyglutamic acid at up to 12 sites in the carboxyterminal end of the vitamin K-dependent coagulation factors, thus enabling the factors to bind to phospholipid surfaces when the clotting reactions take place. The latter, cloned in 2004,[27,29] is responsible for an obligate oxidation and reduction of vitamin K to render it able to catalyze vitamin K carboxylase. Interestingly, the initial patient with combined vitamin K-dependent coagulation factor deficiencies has no detectable abnormality in either γ-glutamyl carboxylase or vitamin K epoxide reductase, spurring a search for a possible third gene that might lead to a Borgschulte-Grigsby-like syndrome. A second multiple clotting factor deficiency involves the deficiency of factors V and VIII. These are highly homologous cofactors in the process of blood coagulation. Both are transported from the endoplasmic reticulum to the Golgi by a specific calcium-dependent cargo receptor protein complex that includes LMAN1 (also called ERGIC53) and MCFD2. Abnormalities of either protein results in combined deficiency of both factors due to inefficient ER-to-Golgi transport.[30,31] The clue that combined V-VIII might be present is the finding of mild-moderate factor VIII deficiency that is inherited in an autosomal manner. Other multiple clotting factor deficiencies appear not to be coinherited and therefore represent other as yet undefined pathways that affect multiple factors and therefore represent common or shared mechanisms of synthesis or catabolism. Overall, multiple clotting factor deficiencies are uncommon causes of bleeding, but they emphasize the important point that defects outside the clotting factor genes can influence levels. Understanding the pathways in other forms of multiple clotting factor deficiencies will lead to a better understanding of the biology of coagulation.

Antibodies to clotting factors, called inhibitors because they inhibit the participation of the target clotting factor in the coagulation process, can occur. These may occur in individuals with inherited clotting factor deficiencies, or they may be spontaneous, in individuals with no underlying clotting defect. The former are considered alloimmune disorders; the latter are autoimmune disorders. In both situations, antibodies to coagulation factor VIII are most common. The development of an inhibitor is a serious occurrence and warrants considerable attention. Fortunately, effective treatments now exist that can either bypass the inhibitor to induce thrombin formation[32,33] or induce immunologic tolerance with disappearance of the antibody.[34,35,36] The ability to induce lasting tolerance is especially important as this is the only disorder known for which true tolerance can be induced. If the mechanism of tolerance in hemophilia can be understood mechanistically, it may be possible to apply the principle of tolerance to other immunologic disorders such as lupus and rheumatoid arthritis. In the 35 years since the discovery that prolonged

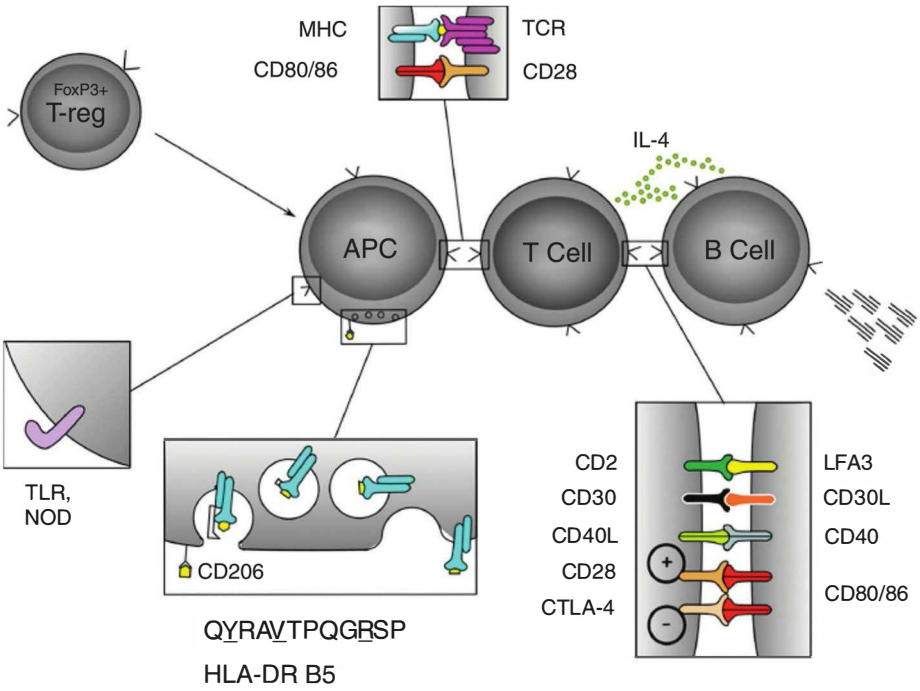

FIGURE 49.3 *Immunologic cellular cascade from APC to T-lymphocyte (T-cell) to antibody-producing B-lymphocyte (B-cell).* Peptide antigens such as FVIII are taken up by APCs. CD206, the macrophage mannose receptor, may be the endocytic receptor for factor VIII and mannose residues on VIII carbohydrates may mediate the binding to APCs (Dasgupta S Navrete A, Bayry J, et al. A role for exposed mannosylations in presentation of human therapeutic self-proteins to CD4+ T-lymphocytes. *PNAS* 104:8965, 2007.) After binding, VIII is internalized in endocytic vesicles where it is presented to MHC (major histocompatibility complex) class II molecules. The recognition of a given factor VIII peptide by an MHC molecule is specific and depends on the class II genotype of the individual. Once assembled, antigenic peptide-class II complexes are transported to the cell surface for presentation to helper T-lymphocytes. Antigenic peptide-class II complexes on the surface of APCs interact with the TCR on helper T-lymphocytes resulting in the generation of signals that result in T-cell activation and upregulation of surface molecules, including CD2, CD30, CD40L, and CD28. At the same time, synthesis of cytokines occurs. In Th1 helper cells, there is elaboration of cytokines such as interferon-γ and interleukin (IL)-2, which stimulate cell-mediated cytotoxicity. Th2 cells elaborate cytokines IL-4, IL-10, and IL-13, which stimulate antibody-producing B cells. Activated T-helper cells then activate B-cell clones through surface-mediated interactions and cytokines. These interactions stimulate B-cell growth, proliferation, and differentiation. TLRs and NOD-like receptors on APCs can enhance the process and increase the immune response. FoxP3 positive regulatory T-cells can down-regulate the process and decrease the immune response. (copyright G. C. White, from White et al.[40])

administration of factor VIII could induce tolerance in many individuals, significant advances in the immunology field have resulted in an increase in knowledge regarding the molecular events around antibody formation. The cellular cascade from antigen presenting cell (APC) to T-lymphocyte (T-cell) to antibody producing B-lymphocyte (B-cell) and the signals involved in these cellular interactions are known[37,38,39] (see FIGURE 49.3) and current efforts are aimed at understanding modulatory effects such as regulatory T-cells (Tregs).[41] and toll-like receptors (TLRs).[42] Knowledge gained over the past decade or two of the mechanisms involved in immunologic responses to peptide antigens such as the coagulation factors provides new directions for inducing tolerance. For example, the productive activation of T-cells by APCs requires an interaction between the MHC-peptide complex on APCs and the T-cell receptor (TCR) as well as a costimulation event, classically between CD80/86 on the APC and CD28 on T-cells. By blocking the costimulatory event, one can induce tolerance to antigen. Similarly, blocking interactions between T-cell and B-cell by, for example, blocking the CD4-L-CD40 interaction can inhibit the development of an antibody response. These various steps in the immune process represent novel targets for clinical therapy of inhibitors in hemophilia and in other disorders in which antibodies to coagulation factors arise. The characteristics of inhibitors and their diagnosis and treatment are covered in Chapter 57.

Overall, inherited hemorrhagic disorders are among the most important disorders in the field of thrombosis and hemostasis. Although even hemophilia is relatively uncommon, the proper diagnosis and treatment of these disorders requires knowledge

Table 49.2

Defects in soluble coagulation factors—clinical pearls

- The most common hereditary bleeding disorder is vWD with type 1 vWD as the most common subtype
- vWD is inherited as an autosomal dominant trait and is expressed in the heterozygous state
- Bleeding in this disorder resembles the type of bleeding seen with thrombocytopenia, with bruising and hemorrhage from mucous membranes
- Menorrhagia is common, and women with this common complaint should be screened for vWD
- The only two soluble clotting factors deficiencies that are inherited as sex-linked recessive characteristics are hemophilia A and B, resulting from defects in factors VIII and IX, respectively
- The occurrence of severe bleeding in men, especially associated with hemarthropathy, is strongly suggestive of one of these disorders
- Hemophilia A and B can be clinically indistinguishable, but classic hemophilia is much more common than hemophilia B
- Inhibitor antibodies occur more frequently in hemophilia A, and patients with such inhibitors are resistant to treatment and have increased morbidity and mortality
- The other deficiencies of soluble clotting factors are inherited in an autosomal recessive fashion, and bleeding occurs when the patient is homozygous or a combined heterozygote
- Deficiencies of factors XII, PK, and HK are not associated with bleeding, even after trauma or surgery
- A prolonged PT with a normal PTT and TCT suggests factor VII deficiency, whereas a prolonged PTT with a normal PT and TCT in a patient who is bleeding suggests a factor VIII or IX deficiency if the bleeding is confined to men or factor XI deficiency if the bleeding is mild and occurs in both sexes
- If all screening tests of coagulation are normal, deficiency of factor XIII, α_2-plasmin inhibitor or PAI-1 should be suspected, although these are very rare disorders
- When both the PT and PTT are prolonged, one should suspect deficiency of either factor V or factor X; bleeding from prothrombin deficiency and combined factor deficiencies can also present with these laboratory values, but these cases are more rare and can be easily diagnosed with assays for individual factors
- When the TCT as well as the PT and PTT are prolonged, dysfibrinogenemia should be suspected; when no clot is detected, afibrinogenemia is likely
- Acquired bleeding disorders can be confused with hereditary defects but are usually not lifelong and can be distinguished by a careful medical history

vWD, von Willebrand disease; PK, prekallikrein; HK, high molecular weight kininogen; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time; PAI-1, plasminogen activator inhibitor 1.

of the distinguishing clinical and laboratory features of each. In this section, the various inherited bleeding disorders involving blood coagulation factors are presented along with various approaches to treatment. Table 49.2 gives a salient summary and clinical pearls regarding defects in soluble clotting factors.

CHAPTER

50 Differential Diagnosis of the Bleeding Patient

JILL M. JOHNSEN AND BARBARA A. KONKLE

The hematologist is often faced with the question of whether a patient has an underlying bleeding disorder. This may be in the setting of unexplained bleeding, either spontaneous or with minor or major trauma or procedures. Or, the hematologist may be asked to evaluate a person's risk of bleeding with an upcoming procedure, particularly in cases of a personal or family history of bleeding or screening laboratory results that suggest a bleeding risk. This chapter reviews key points to help determine whether an underlying bleeding disorder is present, first focusing on the history and physical examination. Basic screening laboratory tests usually available at the time of evaluation are reviewed, including the platelet count, prothrombin time (PT), also expressed as the international normalized ratio (INR), and activated partial thromboplastin time (aPTT). Laboratory tests useful in pinpointing specific hemostatic abnormalities are then discussed. Many of the disorders highlighted here are presented in more detail in other chapters in this text.

Bleeding disorders are classically divided into those of primary or secondary hemostasis. Disorders of primary hemostasis include those that affect initial platelet plug formation and typically result in mucosal bleeding, usually the result of a platelet or von Willebrand factor (VWF) disorder. Disorders of secondary hemostasis involve disorders of fibrin formation and often manifest as soft tissue or joint bleeding. [This is commonly due to specific coagulation factor deficiencies, notably factor VIII (FVIII) and factor IX (FIX) (hemophilia A and B, respectively)]. However, there is considerable overlap in symptomatology.[1] Thus, although the pattern of bleeding is an important clue to its etiology, a comprehensive approach is necessary to correctly identify the bleeding patient's underlying hemostatic defect.

THE BLEEDING HISTORY

From a detailed personal and family history, the clinician should have a good idea of whether (a) a bleeding disorder is present; (b) the disorder is inherited or acquired; (c) the pattern of bleeding suggests a primary or secondary hemostatic defect (or combination); and (d) a person's propensity to bleed has been enhanced by an underlying medical condition or exposure to medications or dietary supplements.

A history of bleeding is the most important predictor of future bleeding risk. In evaluating a patient for a bleeding disorder, a history of hemostatic challenges should be assessed. Does the patient have a history of spontaneous or trauma- or surgery-induced bleeding? What is the nature and timing of the bleeding? Was the bleeding severe enough to necessitate medical intervention or treatment for acute or chronic blood loss?

A negative bleeding history is reassuring, but should not be used alone as the basis for dismissing a bleeding disorder, particularly if the person has never experienced a significant hemostatic challenge. Assessing a positive bleeding history can also be challenging, particularly in milder cases, as normal individuals can respond positively when questioned about specific signs or symptoms, particularly easy bruising or menorrhagia. Bleeding score questionnaires have been developed by several groups in an attempt to quantify bleeding in inherited bleeding disorders.[2] These instruments may be useful as a guide to the type of questions to ask in a targeted bleeding history, but their utility in initial bleeding evaluations or scoring the severity of disease remains to be seen. Thus, a careful and thoughtful investigation of the bleeding history is critical in guiding any clinical evaluation of the bleeding patient.

Mucosal Bleeding

Epistaxis

Epistaxis is a common symptom, particularly in children and in dry climates, and may not reflect an underlying bleeding disorder. Clues that epistaxis is a symptom of an underlying bleeding disorder include lack of seasonal variation and bleeding of prolonged duration (>10 minutes), bleeding which requires medical attention, or frequent bleeding episodes.

Oral Mucosal Bleeding

Excessive bleeding or swelling after episodes of minor oral trauma may be a clue to an underlying bleeding disorder. Bleeding with eruption of primary teeth is seen in children with more severe bleeding disorders, such as moderate and severe hemophilia, but is uncommon in children with mild bleeding disorders. Spontaneous gum or cheek bleeding resulting in blood blisters, frankly bloody secretions, or profuse bleeding after tooth brushing in the absence of gum disease are also suggestive of an underlying bleeding disorder, especially disorders of primary hemostasis.

Dental extraction, particularly of molars or premolars, represents a significant hemostatic challenge. The limitations on wound closure imposed by the bony tooth socket and the presence of profibrinolytic enzymes in saliva and at the mucosal surface contribute to difficulties in achieving hemostasis. Excessive bleeding and/or recurrent bleeding after tooth extractions or other oral surgeries, or increased bleeding after dental cleaning, can be suggestive of an underlying bleeding disorder.

Gynecologic and Obstetrical Bleeding

Gynecologic and obstetrical bleeding are common presentations in women with underlying bleeding disorders (reviewed in Ref.[33]). Menorrhagia is a common symptom, but the history can be difficult as a complaint of heavy menses is subjective and

has a poor correlation with excessive blood loss. The diagnosis of menorrhagia is supported by anemia, soaking through a pad or tampon within 1 hour, or flooding at night.[4] Additionally, women with underlying bleeding disorders are more likely to have other bleeding symptoms and are much more likely to have menorrhagia beginning at menarche than are women with menorrhagia due to other causes (reviewed in Ref.[55]).

Postpartum hemorrhage is a common symptom in women with underlying bleeding disorders. This occurs most commonly in the first 48 hours after delivery but may also be manifest by prolonged, recurrent, or excessive bleeding after discharge from the hospital. Women with a history of postpartum hemorrhage are at an increased risk of recurrence in subsequent pregnancies. Women presenting with rupture of ovarian cysts along with intra-abdominal hemorrhage are also more likely to have an underlying bleeding disorder.[3]

Other Mucosal Bleeding

Gastrointestinal (GI) bleeding is usually due to underlying anatomic pathology and not a hemostasis defect. However, von Willebrand disease (VWD), particularly acquired VWD and types 2 and 3, can be associated with angiodysplasia of the bowel resulting in GI bleeding.[6] True hematuria is more likely to be due to an underlying urologic or renal problem and not a bleeding diathesis.[7] Rarely, recurrent hematuria of unclear etiology can occur in moderate and severe hemophilia.

Easy Bruising

The development of bruises (ecchymoses) after trauma is normal; however, an exaggerated response to trauma may be an indication of an underlying bleeding disorder. Ecchymoses presenting without known trauma, particularly on the trunk, and/or especially large (>3 cm in diameter) or palpable ecchymoses may be a sign of an underlying bleeding disorder. A lifelong history of significant ecchymoses suggests a congenital hemostatic defect, while the sudden development of new or multiple ecchymosis may reflect an acquired disorder. In pediatric and other vulnerable populations, ecchymoses can raise concerns for physical abuse, and the hematologist may be asked for an assessment of an underlying bleeding disorder (reviewed in Ref.[88]).

Minor Trauma

Bleeding after minor trauma is also normal. However a persistent history of excessive or prolonged bleeding after minor wounds, such as small sharp cuts from razors, paper, or knives, particularly bleeding which lasts >5 minutes or cannot be managed by the patient themselves, may suggest an underlying bleeding disorder. The hospitalized patient undergoes minor trauma with high frequency due to phlebotomy and the placement of intravascular catheters in addition to other procedures. The unexpected requirement for application of prolonged pressure or intervention at phlebotomy sites, vascular access sites, or after other minor procedures may be a sign of defective hemostasis.

Joint and Muscle Bleeds

Hemarthroses and spontaneous muscle or soft tissue hematomas are characteristic of moderate or severe congenital factor deficiencies, most commonly FVIII or FIX deficiency. It can also be seen in moderate and severe deficiencies of fibrinogen, prothrombin, and FV, FVII, and FX.[1] Spontaneous hemarthroses occur rarely in other bleeding disorders except for severe VWD, which can be associated with FVIII levels <5%. Bleeding into a joint results in severe pain and swelling, as well as loss of function, but is rarely associated with discoloration from bruising around the joint. The first bleeding episode into a joint is accompanied by considerable swelling, but as bleeding recurs and joint destruction progresses, swelling may be less prominent while pain and loss of movement may worsen. In patients without a diagnosis of hemophilia, joint bleeding may go unrecognized as such by the patient or family. The clinical history, therefore, should specifically include questions about symptoms of severe joint pain and swelling.

Excessive Traumatic or Surgical Bleeding

Hemorrhage in the setting of severe trauma can be due to a combination of the trauma injury itself, surgical bleeding, medications, underlying comorbidities, and acquired coagulopathies, which can have components of both transfusion-related coagulopathy (discussed below) and trauma-related coagulopathy. Trauma-related coagulopathy itself is multifactorial and can result from shock and resulting tissue hypoperfusion and organ dysfunction, hypothermia, acidemia, dilution, consumption of clotting factors, and injured tissue-mediated activation of anticoagulant and fibrinolytic factors. Not surprisingly, trauma patients with underlying coagulopathies have worse outcomes.[9]

Significant surgical bleeding can occur during surgery or in the postoperative period. A comprehensive assessment of sites of bleeding, procedures, and local measures to stop the bleeding is critical. Different procedures pose different hemostatic challenges that must be considered in the bleeding evaluation. Tonsillectomy is a significant hemostatic challenge from both the surgery and mucosal injury. Bleeding may occur early after surgery or more than a week postoperatively with loss of the eschar at the operative site.[10,11] Surgeries also inherently incur different degrees of blood loss in the normal patient. Some vascular or orthopedic procedures, such as spinal surgery, are bloody surgeries and can require transfusion support even in the hemostatically normal patient. On the other hand, other general surgeries, such as laparoscopic intra-abdominal procedures, can generally be performed with minimal blood loss. A number of major surgeries, such as coronary artery bypass grafting or aortic procedures, are often performed while the patient is exposed to one or more anticoagulant medications, which increases blood loss from the surgical sites and exacerbates bleeding from any other underlying anatomic defects.

Hemorrhagic events often occur in patients with comorbidities and/or multiple confounding factors. For example, the medical patient with liver failure (acquired factor deficiencies) being treated for infected ascites (risk for disseminated intravascular coagulation [DIC], antibiotic effects) may bleed briskly from esophageal varices (anatomic site) resulting in hypotension (tissue shock response) and a need for multiple transfusions (dilutional coagulopathy). However, even in cases instigated by a seemingly simple anatomic event, such as cleaning a penetrating wound with excessive bleeding requiring transfusion, factors can rapidly compound to a multifactorial coagulopathy. The approach to complex bleeding patient requires an open mind to reevaluate the history of the patient and periodic reassessments both for clinical and laboratory response to interventions and for new developments that may contribute to bleeding. Ongoing laboratory assessments in such patients should include at least a PT, aPTT, platelet count, and fibrinogen. Further laboratory

analyses will depend on laboratory results and underlying disorders. As patients with liver disease can have laboratory findings consistent with low-grade DIC, a diagnosis of DIC may require serial testing to show evidence of ongoing fibrinogen consumption.

Patients with underlying bleeding disorders are at higher risk to bleed in the setting of trauma or surgery. The hematologist should take into account the nature of the trauma or procedures performed and consider the opinion of the surgeon in assessing if the patient is bleeding excessively for the hemostatic challenge.

Transfusion-Related Coagulopathy

Transfusion-related coagulopathy occurs in the setting of large-volume transfusion replacing acute blood loss (reviewed in Ref.[109]). The primary cause is dilution and failure to adequately replace plasma coagulation factors or platelets in proportion with the number of red cell units transfused. Replacement can be guided by closely following the platelet count, PT/INR (for plasma), or fibrinogen levels (for fibrinogen concentrates or cryoprecipitate). In high-volume, rapid transfusion, the need for these blood components can generally be anticipated by the number of red cell units infused. Massive transfusion also results in infusion of significant doses of citrate with the blood products. Iatrogenic hypocalcemia, reflected by low ionized calcium levels, may also contribute to clinical bleeding. Citrate chelates calcium, an essential cofactor for clotting and for multiple other essential biologic processes, including nerve conduction and muscle contractility.

Underlying Systemic Disease and Bleeding

Acquired bleeding disorders are commonly secondary to, or associated with, systemic disease. The clinical evaluation of a patient with a bleeding tendency must therefore include a thorough assessment for evidence of underlying medical disorders. Bruising or mucosal bleeding may be the presenting complaint in liver disease, severe renal impairment, hypothyroidism, and conditions causing bone marrow failure. Less prevalent disorders, such as paraproteinemias or amyloidosis, occasionally also present in this fashion. In DIC, presentation may be with symptoms of bleeding and/or microvascular thrombosis, and the underlying trigger for the consumptive coagulopathy is not always immediately obvious,[12] such as in cases of occult malignancy.

Other Conditions Presenting with Signs or Symptoms of Bleeding

Medical conditions in which there is no coagulopathy or defect of primary hemostasis can present with signs or symptoms, which may suggest a bleeding disorder, but are instead caused by abnormalities of blood vessels or their supporting tissues. For example, in inherited collagen disorders, such as Ehlers-Danlos or Marfan syndrome, there is frequently a history of easy bruising or prolonged posttraumatic bleeding. However, other clues in the history and physical point to the underlying congenital defect, such as skin hyperelasticity or joint hyperextensibility and body habitus. Endocrine disorders (such as Cushing syndrome) or chronic exogenous corticosteroid exposure can result in changes in the skin and subcutaneous tissues that result in more pronounced subcutaneous bleeding in response to minor trauma. The bleeding is generally more superficial than in true ecchymoses. Senile purpura, common with advancing age, is also very superficial, usually occurs on sun-damaged skin, most commonly on the hands and forearms, and can also be mistaken for ecchymoses. Some autoimmune disorders can present with vasculitis reminiscent of petechiae and skin findings suggestive of bruising. Joint pain and swelling due to an acute arthritic flare, crystal arthropathy, or septic joint can mimic hemarthroses. These are often able to be differentiated from a true joint bleed by the history, an important distinction as suspicion for these other inflammatory conditions may lead to arthrocentesis, a procedure that generally should be avoided in patients with a hemarthroses related to an underlying bleeding disorder.

Medications and Dietary Supplements

A complete medication list, including both short-term and chronic medications and all herbal or supplement use, is essential and should be temporally correlated to the onset of bleeding. A common but sometimes overlooked contributor to bleeding is the use of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs). These drugs inhibit both cylooxygenase-1 (COX-1) and COX-2 pathways. Inhibition of COX-1 impairs primary hemostasis and can exacerbate bleeding from another cause or even unmask previously occult mild bleeding disorders. NSAIDs selective for the COX-2 enzyme have little platelet inhibitory effect and should not enhance or precipitate bleeding, but have instead been associated paradoxically with increased risk for thrombotic events.[13] However, all NSAIDs can precipitate GI bleeding by direct action at the GI mucosa, which may then be more severe in patients with underlying bleeding disorders. The aspirin effect on platelet function is permanent and can persist for up to 7 days as assessed by platelet aggregometry, although it frequently returns to normal by 3 days after the last dose.[14] The duration of the effect of other NSAIDs on platelets is shorter, because the inhibitor effect is reversible and depends on the half-life of the agent.

Other causes of drug-related bleeding range from the obvious, such as hemorrhage complicating thrombolytic therapy or bleeding in the setting of thrombocytopenia after chemotherapy, to the more diagnostically challenging, such as bleeding secondary to impaired platelet function in subjects on high-dose intravenous penicillin or caused by a combination of a qualitative platelet defect and moderate thrombocytopenia secondary to anticonvulsant therapy with sodium valproate (see Chapter XX for further discussion of drug-induced qualitative platelet defects). Furthermore, exposure to multiple medications contributes to the risk of adverse drug–drug or drug–supplement interactions, which can lead to altered drug levels and toxicity.

Use of alternative medicines and herbal supplements is commonly practiced and must be asked about specifically. Popular herbal supplements, such as gingko, ginseng, and garlic, are associated with altered hemostasis[15] (Table 50.1). Fish oil or concentrated omega 3 fatty acid supplements can also impair platelet function. Herbal supplements may also alter hemostasis indirectly by interacting with other drugs, particularly warfarin. In addition to these concerns, loose regulatory oversight of the supplement industry raises concerns for quality control of the products consumed. Herbal supplements may contain variable (or no) detectable amounts of the active agents claimed on the packaging, while other unlisted ingredients can be present due

Table 50.1

Herbal supplements associated with increased bleeding

Herbs with Potential Antiplatelet Activity
Ginkgo (*Ginkgo biloba*)
Garlic (*Allium sativum*)
Bilberry (*Vaccinium myrtillus*)
Ginger (*Zingiber officinale*)
Dong quai (*Angelica sinensis*)
Feverfew (*Tanacetum parthenium*)
Asian ginseng (*Panax ginseng*)
American ginseng (*Panax quinquefolius*)
Siberian ginseng/eleuthero (*Eleutherococcus senticosus*)
Turmeric (*Curcuma longa*)
Meadowsweet (*Filipendula ulmaria*)
Willow (*Salix alba*)
Coumarin-Containing Herbs
Motherwort (*Leonurus cardiaca*)
Chamomile (*Matricaria recutita, Chamaemelum nobile*)
Horse chestnut (*Aesculus hippocastanum*)
Red clover (*Trifolium pratense*)
Fenugreek (*Trigonella foenum-graecum*)

to poor manufacturing processes, misidentification, or substitution. NSAIDs are a common contaminant, particularly for those formulations claiming pain relief,[15] and warfarin was repeatedly identified in formulations of PC-SPES, a dietary supplement.[16]

Social History

The bleeding history must take into account the patient's exposure to hemostatic challenges in their daily lives. This includes assessing both common daily activities and the history of the individual's participation in sports or other vigorous physical activities. The lifestyle of an office worker or low-impact exerciser provides fewer opportunities for incidents of trauma compared to individuals who have physically demanding occupations or engage in contact sports. In the same vein, an infant who cannot walk would not be expected to exhibit the minor ecchymoses commonly found on the normal toddler. This history will help guide the clinician in assessing if bleeding symptoms, particularly ecchymoses or bleeding with minor trauma, seem excessive for the patient's circumstances.

FAMILY HISTORY

Young age at presentation, prolonged duration of symptoms, failure of previous hemostatic challenges, and positive family history can be indicators of an inherited disorder. The pattern of inheritance in families is also informative. VWD is generally inherited in an autosomal dominant pattern (except for types 2N and 3, which are recessive), but can have variable penetrance and expressivity (particularly type 1). Factor deficiencies in FVIII and FIX are sex linked, and as such affected males present with more severe disease. Thus, the presentation of a male newborn with umbilical stump bleeding and a family history of hemophilia in a maternal uncle are strongly suggestive of an inherited factor deficiency. On the other hand, an elderly patient with no previous history of excessive bleeding despite surgical challenges who presents with recent onset of massive bruising and forearm compartment syndrome is much more consistent with an acquired bleeding diathesis. Diagnostic difficulties arise, however, when a mild familial disorder is present in a patient who previously has not been challenged because of young age, previous good health, or when the bleeding symptoms are highly variable within families, as can occur with mild disorders.

The positive family history may be informative, but a negative family history does not necessarily rule out a genetic disorder. Up to one-third of cases of hemophilia A and B arise as a result of new mutations, and the family history will be negative for abnormal bleeding. Because most new mutations causing hemophilia will manifest first in the carrier female,[17,18] she may present with symptoms due to a decreased FVIII or FIX level without a diagnosis of hemophilia in the family. Alternatively, she may not have bleeding symptoms depending on her baseline factor level, which would vary by degree of random X chromosome inactivation (the Lyon hypothesis).[19] Bleeding in patients with FXI deficiency occurs most commonly in those with severe deficiency, although severely affected individuals may be asymptomatic. Most heterozygotes are asymptomatic. However, the relation between the FXI level and bleeding is not clear-cut,[20,21] and some heterozygotes bleed excessively after trauma. In patients where there is suspicion for an inherited bleeding disorder, gene mutation studies in family members may be helpful in confirming the diagnosis.

PHYSICAL EXAMINATION

The physical examination can provide helpful clues as to the etiology of the bleeding disorder, although many patients with mild bleeding disorders will have normal examinations. The skin, mucosa, and sites of skin compromise, such as vascular access sites or surgical or traumatic wounds, should be examined for ecchymoses, petechiae, oozing, and associated soft tissue hematomas. Palpable or larger ecchymoses (>3 cm), particularly in the absence of apparent trauma or on the trunk, are suggestive of an underlying disorder. Petechiae can be distinguished from small vasculitic, infectious, or embolic lesions in that they are never palpable, do not blanch, and tend to be distributed over the extremities, particularly the lower legs. Petechiae or mucosal purpura are seen in severe thrombocytopenia, but not usually in thrombocytopathies. On musculoskeletal examination, abnormal joint appearance and/or a loss of normal range of motion is suggestive of past hemarthroses, while active joint bleeding manifests with significant monoarticular arthralgia and effusion. Some rare disorders are associated with particular findings, such as abnormalities of the forearm in thrombocytopenia with absent radii, or defects in skin pigmentation in patients with syndromes associated with platelet granule or storage pool

tahir99-VRG & vip.persianss.ir

disorders. The physical examination of all systems should be thorough in search of signs associated with systemic conditions that may predispose to bleeding, such as liver or kidney disease, malignancy, infection, autoimmune disease, or collagen–vascular disorders.

LABORATORY EVALUATION

Careful history taking and clinical examination are essential components in the assessment of bleeding risk. The use of laboratory tests of coagulation and hemostasis cannot substitute for clinical assessment. Indeed, ample evidence exists that screening tests are unhelpful in the prediction of bleeding risk, especially when applied indiscriminately.[22–24] Although there is much interest in developing a global assay of hemostasis, to date there is no single assay that can predict bleeding or thrombosis. The clinician must frequently use the results of several assays combined with the clinical presentation to arrive at a diagnosis or an assessment of bleeding risk. The primary use of coagulation testing should be to confirm the presence and type of bleeding disorder in a patient with a suspicious clinical history. An exception may be the preoperative assessment in infants and young children, in whom the clinical history is less likely to be informative.

Because of the nature of coagulation assays, proper sample acquisition and handling is critical to obtaining valid results. In patients with abnormal coagulation assays and no bleeding history, properly performed repeat studies are often normal. Most coagulation assays are performed in sodium citrate–anticoagulated plasma that is recalcified for the assay. Because the anticoagulant is in liquid solution and needs to be added to blood in proportion to the plasma volume, incorrectly filled or inadequately mixed blood collection tubes will give erroneous results. Other patient factors can influence laboratory results. An elevated hematocrit (>55%) can result in an incorrect coagulation measurement because of a decreased plasma-to-anticoagulant ratio. An accurate result is obtained by adjusting the amount of sodium citrate solution added to the blood on the basis of the estimated plasma volume, using the formula:

$$\frac{(100 - \text{Hematocrit}) \times (\text{total tube volume})}{(595 - \text{Hematocrit})} = \text{Volume of Na Citrate (3.2\%) required}$$

Complete Blood Count and Peripheral Smear

The complete blood count (CBC) is a necessary component of the evaluation of the bleeding patient and is often instrumental in identifying an underlying platelet defect or evidence of chronic or ongoing blood loss. However, artifacts are common, and verification by repeat or manual testing is warranted in patients with a newly identified CBC abnormality. Thrombocytopenia is often first identified by automated cell counting. An assessment of reticulated platelets or estimation of average platelet size from the mean platelet volume can also be useful clues to the underlying cause of thrombocytopenia. New diagnoses of thrombocytopenia should be verified by examination of the peripheral smear to evaluate the quantity and morphology of the platelets, to look for abnormalities in other blood cells, and to exclude pseudothrombocytopenia. A common cause of pseudothrombocytopenia is platelet clumping in the blood collection tube as a result of either the anticoagulant ethylenediaminetetraacetic acid (EDTA)-induced platelet clumping or specimen mishandling. Pseudothrombocytopenia may also result from the failure of the automated cell counter to identify morphologically abnormal platelets, as in the case of hereditary platelet disorders or acquired bone marrow diseases.

Red cell indices and morphology may exhibit abnormalities relevant to the bleeding patient. Hypochromia and microcytosis may be evidence of iron deficiency and suggest chronic blood loss, while schistocytes reflect an underlying microangiopathy (such as DIC). Abnormal leukocyte counts and morphology can be clues to underlying bone marrow disorders or rare congenital syndromes.

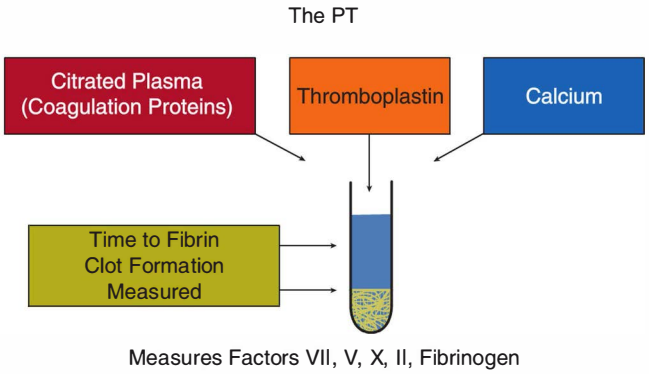

FIGURE 50.1 Elements of the PT are shown.

Prothrombin Time

The PT, developed by Quick et al.[25] in 1935, assesses the classic extrinsic coagulation system, including FI (fibrinogen), FII (prothrombin), FV, FVII, and FX (see FIGURE 50.1). The PT measures the time for clot formation of the citrated plasma after recalcification and addition of thromboplastin (reviewed in ref.[26]). Thromboplastin is a combination of tissue factor, the membrane receptor for FVII and FVIIa, and phospholipids. The speed of the PT reaction is influenced not only by the plasma concentrations of the extrinsic and common pathway clotting factors but also by the concentration and properties of the tissue factor.[27] The sensitivity to different factor deficiencies and coagulopathies varies by the source of thromboplastin. Human recombinant tissue factor, relipidated with natural or synthetic phospholipids, is now generally used.[28]

The degree of prolongation of the PT is dependent on the thromboplastin in the reaction as well as on the instrument used for the assay. In the past, the use of various thromboplastins and instruments resulted in varying levels of anticoagulation when the PT ratio was used to target warfarin therapy. To adjust for this variability, the overall sensitivity of different thromboplastins to reduction of the vitamin K–dependent clotting factors (FII, FVII, FIX, and FX) in anticoagulated patients is now expressed as the international sensitivity index (ISI).[29,30] This is determined by calibrating the thromboplastin against a standard thromboplastin, generally a well-characterized secondary WHO International Reference Preparation. An inverse

tahir99-VRG & vip.persianss.ir

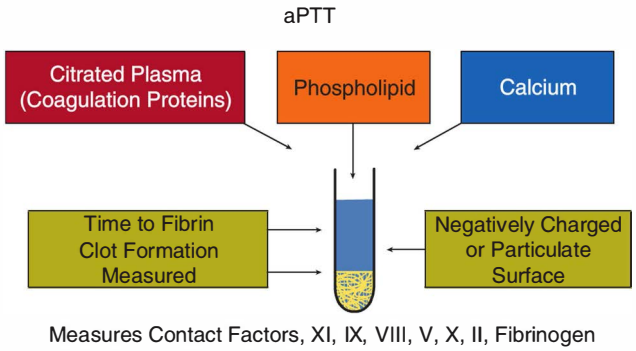

FIGURE 50.2 Elements of the activated partial thromboplastin time (aPTT) are shown. Contact factors are FXII, kininogen, and prekallikrein.

relation exists between ISI and thromboplastin sensitivity. The INR is then determined based on the formula:

$$\text{INR} = \left(\text{PT}_{\text{patient}} / \text{PT}_{\text{normal mean}}\right)^{\text{ISI}}$$

Although the INR was developed to assess anticoagulation due to reduction of vitamin K–dependent coagulation factors, it can be helpful in the evaluation of patients with liver disease, particularly when comparing values from testing performed at different laboratories. However, because progressive liver failure is associated with variable changes in coagulation factors, the degree of prolongation of either the PT or the INR is not necessarily associated with bleeding risk.[31] The INR is also generally not a reliable measure of warfarin anticoagulation in patients with an elevated baseline INR, such as in the case of antiphospholipid antibodies directed against prothrombin, which can prolong the PT at baseline.[32]

Activated Partial Thromboplastin Time

Like the PT/INR, the aPTT is performed on recalcified citrated plasma (see FIGURE 50.2, reviewed in Ref.[26]). It assesses the intrinsic and common coagulation pathways and was originally described as a "partial thromboplastin" time because the reagents did not induce hemophilic plasma to clot in a normal period of time as do "complete" thromboplastins.[33] The aPTT reagent contains phospholipids, derived from either animal or vegetable sources that function as a platelet substitute in the coagulation pathways. The aPTT test system also includes an activator of the intrinsic coagulation system, such as nonparticulate ellagic acid or the particulate activators kaolin, celite, or micronized silica. These provide a large surface area and increase the precision and reproducibility of the test.

The phospholipid composition of different aPTT reagents varies considerably and influences the sensitivity of individual reagents to clotting factor deficiencies and to inhibitors, such as heparin and antiphospholipid antibodies. Therefore, aPTT results will vary from one laboratory to another, and the normal range in the laboratory where the testing occurs should be used in the interpretation. The aPTT reagent will also vary in sensitivity to individual factor deficiencies. It usually becomes prolonged with individual factor deficiencies of 30% to 50%, but the coagulation laboratory should determine the sensitivity of the reagent it is using for each coagulation factor. The aPTT is commonly prolonged in patients with antiphospholipid antibodies, and reagents vary widely in their sensitivity to these antibodies. A clue that a prolonged aPTT is due to an antiphospholipid antibody can be variable aPTT results on samples between assays performed in different laboratories.[34] Heparin contamination is another common iatrogenic or artifactual cause of a prolonged aPTT, particular in hospitalized patients, where it also may be monitored by its anti-Xa activity (reviewed in Ref.[35]).

Thrombin Clotting Time

Thrombin clotting time (TCT), or simply thrombin time, is a simple test that measures the time for clot formation to occur in citrated plasma after the addition of thrombin.[36,37] It therefore reflects the action of thrombin on fibrinogen with the formation of fibrin. During this process, thrombin cleaves the α and β chains of fibrinogen at their amino-termini, releasing fibrinopeptides A and B. The residual fibrin monomer of one fibrinogen molecule interacts with others to form polymerized fibrin.

A prolonged TCT is caused by a deficiency or structural abnormality (dysfibrinogenemia) of fibrinogen or by the presence of an inhibitor of the thrombin–fibrinogen reaction. It is abnormal in patients with familial hypofibrinogenemia or dysfibrinogenemia and in patients with acquired deficiencies of fibrinogen (as in decreased production due to liver dysfunction, increased consumption due to DIC, or acquired dysfibrinogenemia). Fibrin-degradation products, common in DIC or acute thrombosis, can interfere with the assay. Monoclonal gammopathies, particularly IgM and IgA isotypes, also interfere with fibrin polymerization both in the TCT and *in vivo*. Clinically, the most important inhibitor causing prolongation of the TCT is unfractionated heparin.[38] Unexplained prolongations of the aPTT and TCT warrant evaluation for heparin exposure in the patient or contamination of the clinical test sample.

The TCT is also sensitive to direct thrombin inhibitors (DTIs) and correlates directly with plasma concentration. With modification, the TCT can be used to detect and monitor the IV thrombin inhibitors argatroban, lepirudin, and bivalirudin even in the setting of prolongation of the baseline aPTT, such as lupus anticoagulants and vitamin K deficiency.[39] TCT is very sensitive to the oral DTI dabigatran. At therapeutic dabigatran levels, the TCT displays a linear dose-response curve, while a normal TCT can be used to exclude the presence of dabigatran in the sample.[40] Low molecular weight heparins have a less potent effect on thrombin and exert relatively greater inhibition of FXa, with less, if any, effect on the TCT.

Ecarin Clotting Time

Ecarin is a metalloprotease isolated from the viper *Echis carinatus* that cleaves prothrombin to generate meizothrombin, a proteolytically active intermediate form of thrombin. DTIs inactivate meizothrombin, preventing the conversion of fibrinogen into fibrin and prolonging the ecarin clotting time (ECT). Although not widely available, the ECT can be used to detect and monitor all of the DTIs. However, the ECT is insensitive to heparin, which is unable to interact with meizothrombin due to steric interference by the heparin–antithrombin complex.[40,41]

tahir99-VRG & vip.persianss.ir

Reptilase Time

The snake venom reptilase (from *Bothrops atrox*) induces fibrin clot formation in plasma by a direct action on fibrinogen. In contrast to the action of thrombin, which cleaves fibrinopeptides A and B, reptilase cleaves only fibrinopeptide A.[42] Unlike the TCT, the reptilase time is unaffected by heparin and can be used as a quick way to rule out heparin contamination.[43] The reptilase time is generally more sensitive to dysfibrinogenemias than is the thrombin time.

Mixing Studies

Mixing studies are used to evaluate a prolonged aPTT, or less commonly PT, to distinguish between a factor deficiency and an inhibitor. In this assay, normal plasma and patient plasma are mixed in a 50:50 ratio, and the aPTT or PT is determined immediately after incubation at 37°C at varying time points, typically 30 minutes, 60 minutes, and/or 120 minutes. With isolated factor deficiencies, the aPTT will correct with mixing and stay corrected with incubation. With aPTT prolongation due to an antiphospholipid antibody, the mixing and incubation will show no correction.[34] In acquired neutralizing factor antibodies, such as an acquired FVIII inhibitor, the initial assay may or may not correct immediately after mixing but will prolong or remain prolonged with incubation at 37°C. Failure to correct with mixing can also be caused by the presence of other inhibitors or interfering substances, such as heparin, fibrin split products, and paraproteins.

Specific Clotting Factor Assays

Decisions to proceed with specific clotting factor assays will be influenced by the clinical situation and the results of coagulation screening tests. When bleeding is severe, specific assays are often urgently required to guide appropriate therapy. Following factor levels can permit a safe and logical approach to replacement therapy, preventing both undertreatment (which may result in adequate control of bleeding) and overtreatment (which may paradoxically increase risk of thrombosis).

One-stage assays are commonly used for the quantitation of specific clotting factors participating in both the extrinsic and intrinsic coagulation pathways. These tests are modifications of the aPTT or PT, in which the patient plasma is serially diluted in specific factor-deficient plasma. The concentration of the patient's clotting factor is calculated using a standard curve generated by re-reconstituting the deficient plasma with known quantities of the clotting factor.[37] An activity level can be assigned only if the values from the serial dilutions fall on a straight line and the line formed by the test plasma is parallel to that of standard normal plasma. Nonparallel plots usually result from an inhibitor in the patient plasma or, occasionally, from an unrecognized deficiency of another factor in the substrate-deficient plasma. A two-stage assay, based on the thromboplastin generation test, can also be employed and would be appropriate either as initial coagulation factor testing or for follow-up when the bleeding history is suspicious but disproportionate to the one-stage test result. Indeed, 5% to 10% of patients with mild hemophilia A have a normal one-stage FVIII measurement but a low two-stage FVIII measurement more consistent with the bleeding history.[44] Chromogenic substrate assays, which mimic the cleavage site on the natural substrate for the clotting factor being tested,[45] and less commonly protein quantification by enzyme-linked immunosorbent assay (ELISA), may be employed in the assessment of a factor deficiency.

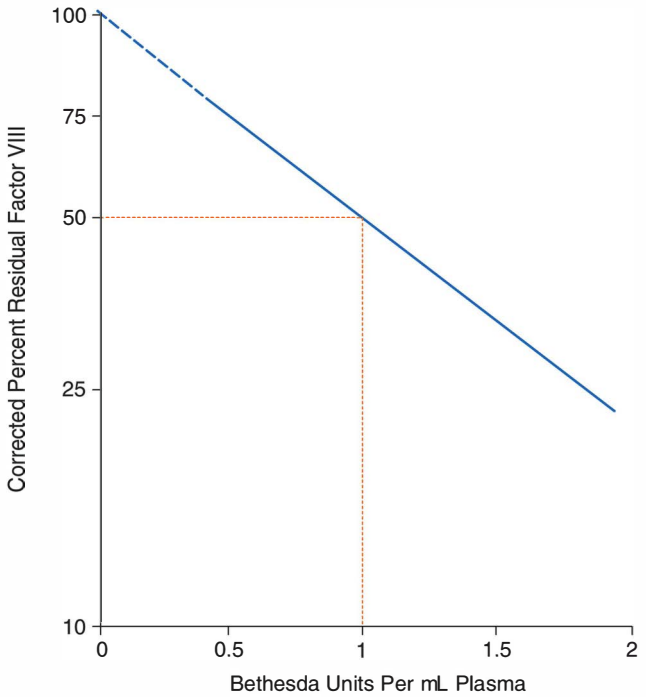

FIGURE 50.3 Bethesda assay for FVIII inhibitor quantitation. Relation between corrected residual FVIII activity and Bethesda titer is shown. If the result is <25%, serial dilutions of the patient's plasma are tested until the result is between 25% and 75%. The result is multiplied by the dilution to assign the Bethesda titer. One Bethesda unit is defined by a corrected residual FVIII of 50% in the assay (*dotted line*).

The Bethesda Assay for Factor VIII Inhibitor Quantitation

The Bethesda assay is used to detect and quantitate FVIII inhibitors[46] and is based on the ability of patient plasma to inactive FVIII in normal plasma. In this assay, patient plasma is serially diluted in normal plasma and residual FVIII activity measured after incubation for 2 hours at 37°C using a one-stage assay. The assay is controlled for normal FVIII decay using normal plasma diluted in buffer or FVIII-deficient plasma (Nijmegen modification). Percentage residual factor (corrected for control) is plotted on a logarithmic scale against units of inhibitor on a linear scale (see FIGURE 50.3). One unit is the amount of antibody that destroys 0.5 U of FVIII after incubation at 37°C for 2 hours. This assay can be adapted for inhibitors against other clotting factors, including porcine FVIII.

Factor XIII

FXIII deficiency cannot be detected by abnormalities in any of the routine coagulation screening tests. A high index of clinical suspicion is required for its recognition, and when it is suspected, a specific screening test for FXIII deficiency should be performed. The most commonly used procedure is a clot

tahir99-VRG & vip.persianss.ir

solubility test, which is based on the fact that non–cross-linked fibrin (due to FXIII deficiency or rarely, inhibitors to FXIII or fibrin) will be soluble in 5 M urea, 1% monochloroacetic acid, or 2% acetic acid. Functional and immunologic assays to quantitate FXIII are available.[47,48]

Fibrinogen

Fibrinogen is assessed in both quantitative and qualitative assays.[49,50] Clottable fibrinogen is determined similarly to the one-stage assay used for other clotting factors using either the TCT (Clauss method) or the PT as the basic assay method to determine fibrinogen activity. Immunologic methods are used to quantify the fibrinogen protein. A dysfibrinogenemia is diagnosed when the measurement of the total clottable fibrinogen is <80% of the immunologic fibrinogen in a sample.

Assessment of Fibrinolysis

There are a variety of immunologic, functional, and chromogenic tests for the determination of the components of the fibrinolytic system. The measurement of fibrin degradation is routine in patients suspected of having DIC or consumptive coagulopathies. D-dimers are the specific product of fibrin degradation formed through digestion of cross-linked fibrin by plasmin.

Enhanced fibrinolytic activity can be detected by the euglobulin clot lysis time (ECLT), a global test of fibrinolysis.[37] In this assay, plasma is treated by dilution to a low ionic strength and acidification to precipitate the euglobulin fraction, containing fibrinogen and plasminogen activators; fibrinolytic inhibitors such as plasminogen activator inhibitor (PAI-1) are partially precipitated. The euglobulin fraction is dissolved and the fibrinogen clotted; clot lysis is then timed. The ECLT is dependent on the activity of both tissue plasminogen activator (tPA) and PAI-1.[51] Short lysis times are indicative of increased fibrinolysis. Specific α_2-antiplasmin and PAI-1 assays are available, with the caveat that some assays are designed to detect elevations in these fibrinolytic factors and therefore limited in their sensitivity for detecting deficiencies.

Choice of testing for disorders of fibrinolysis is directed by the clinical suspicion of the underlying cause. Acquired states of accelerated fibrinolysis may contribute to bleeding that accompanies acute promyelocytic leukemia, carcinoma of the prostate or with prostatectomy, and end-stage liver disease. The latter is due to lack of clearance of fibrinolytic enzymes by the diseased liver. In these cases, measurement of the affected factors (fibrinogen, fibrin/fibrinogen degradation products, and D-dimers) to guide replacement is generally sufficient.

Familial bleeding disorders attributed to excessive fibrinolysis have been reported rarely, but include the autosomal recessive disorders of α_2-antiplasmin deficiency,[52] in which bleeding occurs because of the proteolytic digestion of procoagulants by plasmin, and deficiency of PAI-1,[53] the major inhibitor of tPA. High clinical suspicion would warrant specific factor testing.

von Willebrand Disease Testing

Both immunoassays and functional assays are available for the measurement of VWF in plasma. VWF protein antigen level (VWF:Ag) is measured by ELISA. VWF activity is measured by assays that test the interaction of VWF with its ligands, either platelets or collagen.[54,55] Ristocetin is an antibiotic that causes platelet agglutination by mediating an interaction between VWF and GPIb on the platelet surface. The ristocetin cofactor test (VWF:RCo) uses this interaction *in vitro* to assess the ability of VWF to bind platelets. Different concentrations of ristocetin are added to patient and control plasma in the presence of formalin-fixed platelets and platelet agglutination quantified. Decreased agglutination is indicative of low VWF activity, although a common polymorphism has also been described which decreases the affinity of VWF for ristocetin without perturbing its hemostatic function.[56]

The ristocetin-induced platelet aggregation (RIPA) also uses the platelet-agglutinating properties of ristocetin, but is less sensitive to mild deficiencies in VWF. In the RIPA, ristocetin is added to the patient's own platelets and plasma and platelet aggregation is measured. This test is useful to detect type 2B VWD and pseudo-VWD, in which the patients exhibit increased agglutination due to gain-of-function mutations in VWF or platelet GPIb respectively. The RIPA is decreased in Bernard-Soulier syndrome (GPIb deficiency) in addition to other forms of VWD. Alternative methods of quantifying the ristocetin-mediated interaction between VWF and GPIb have been developed, including ELISA and flow cytometry–based assays, although VWF:RCo remains the main benchmark of assessing VWF–platelet activity.

Collagen binding is assessed by ELISA and can vary depending on the type of collagen used to coat the plate. Collagen binding appears to be influenced by VWF multimer structure and has been previously suggested as a possible surrogate for disproportionate shifts in VWF multimer structure. However, genetic defects have been described in the VWF molecule that can affect collagen binding,[57] and therefore collagen binding assays are not always a surrogate for VWF multimer structure.

VWF structure should be assessed by a VWF multimer analysis in which VWF multimers are visualized on an unreduced low percentage (1% to 2%) agarose gel. Abnormalities in VWF multimer structure, such as changes in the abundance of high molecular weight multimers or alteration of the VWF triplet structure (a reflection of VWF proteolysis), are useful clues to the subtype of VWD.

Tests of Platelet Function

Assessment of platelet function should be performed in patients with a history suggestive of a disorder of primary hemostasis for which there is no obvious cause, such as VWD, thrombocytopenia, use of platelet inhibitory medications, or renal failure. Results of platelet function testing are highly dependent on sample handling and processing and are best performed in an experienced laboratory within 2 hours of sample collection. Ideally, the patient, rather than the blood sample, should go to the laboratory for on-site testing to attempt to optimize standardization of the procedure.

Platelet Aggregometry

Platelet function testing is commonly performed by platelet aggregometry, which is technically challenging and widely variable in execution. Despite these limitations, platelet aggregometry can be very useful when performed rigorously with validated standards in patients with a history of bleeding.[44] Although

tahir99-VRG & vip.persianss.ir

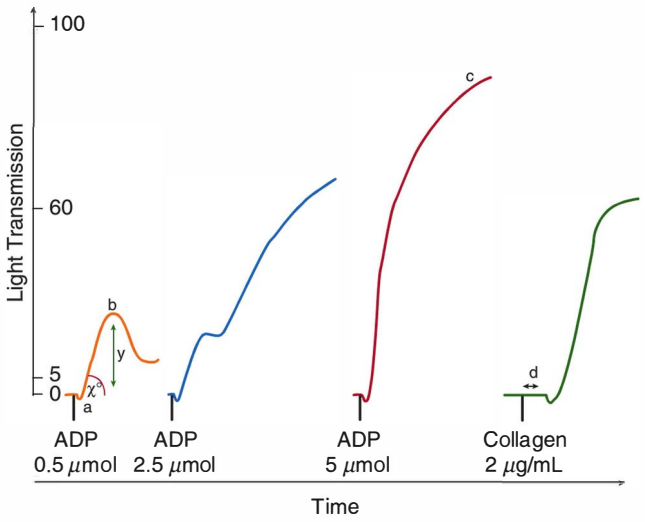

FIGURE 50.4 Typical traces obtained during platelet-rich plasma aggregation. *a*, shape change; *b*, primary wave aggregation; *c*, secondary wave aggregation; *d*, lag phase; χ°, angle of ascent of aggregation trace; *y*, height of aggregation trace; ADP, adenosine diphosphate.

other methods have been employed in the assessment of primary hemostasis, platelet aggregometry remains the gold standard in the diagnosis of platelet function defects.

Platelet aggregometry is performed *ex vivo* by light transmission aggregometry. Upon the addition of most aggregating agents, platelets change shape from discs to a more rounded form with pseudopods, resulting in a transient, small decrease in light transmission that is followed by increased light transmission as the platelets aggregate (see FIGURE 50.4).[58] Platelet aggregometry should always be performed with reference to a control sample and should take into account the patient's platelet count. The most commonly used agonists are ADP, epinephrine, collagen, arachidonic acid, and ristocetin (which is not a true platelet agonist, see VWF testing above), although other agents are sometimes used. ADP and epinephrine are weak agonists compared to collagen or thrombin. Aggregation with these agonists, particularly at low concentrations, will begin with a primary, reversible phase of aggregation, followed by a secondary irreversible phase. The secondary phase is dependent on thromboxane formation and release of granule content. Drugs that inhibit thromboxane formation, such as aspirin, will prevent the secondary phase of aggregation. Thus, the common agonists ADP, epinephrine, and collagen can all be helpful in identifying a platelet disorder.[59] Although platelet aggregometry is only modestly sensitive in identifying platelet disorders, bleeding disorders are likely if an aggregation defect is detected, particularly with two or more agonists.

As useful adjuncts to platelet aggregometry, the platelet release reaction and platelet granule content can be assessed using lumiaggregometry to measure the adenosine triphosphate (ATP) released after different agonists are added. The firefly enzymes luciferin and luciferase produces light proportional to the concentration of ATP, and the light is quantified in a luminometer.[60] Specific testing for platelet glycoproteins (such as the GPIb/V/IX complex or GpIIb/IIIa), analysis by electron microscopy to identify the ultrastructural defects associated with many inherited platelet disorders, and highly specialized testing of platelet granule components may be employed to further classify the nature of the defect in a suspected platelet disorder.

PFA-100

Different methods and instrumentation have been developed in an effort to globally assess platelet and VWF function. The PFA-100 (Siemens Diagnostics) measures the time to clot formation (and aperture closure) of citrated whole blood under flow in a membrane coated with collagen and either adenosine diphosphate (C/ADP) or epinephrine (C/EPI). The PFA-100 is rapid and easy to perform, but demonstrates wide variation between laboratories and is vulnerable to artifact during blood sampling and handling. The PFA-100 has varying sensitivity to VWD depending on the subtype and VWF levels, but it has low sensitivity for type 1 VWD and has limited sensitivity and specificity for common platelet disorders. Furthermore, the PFA-100 does not predict bleeding risk. Thus, the PFA-100 does not appear to be a useful general screening tool for bleeding disorders and is of limited utility in the evaluation of specific disorders of primary hemostasis.[61,62] Numerous other devices have been developed with the potential to measure primary hemostasis. However, most were developed to monitor antiplatelet therapies, are either investigational or of limited availability, and have not been validated in clinical practice.

Bleeding Time

The skin bleeding time is mentioned here for historical reference only. It previously was commonly employed in the bleeding evaluation in an effort to detect disorders of primary hemostasis. However, it is prone to operator error, insensitive, poorly reproducible, poorly predictive of bleeding, and invasive,[61,62] making it of limited clinical utility.

Genetic Testing

As the spectrum of mutations associated with defective hemostasis continues to expand, genetic testing may offer some assistance in the evaluation of a suspected inherited bleeding disorder. Gene mutations in many congenital coagulation factor deficiencies, such as FVIII, are well characterized, and the mutations almost always directly affect the clotting factor gene itself. Most subtypes of VWD have an identifiable mutation in the *VWF* gene, although about half of type 1 VWD patients do not.[63] Mutations in multiple genes have been associated with platelet defects, although many inherited platelet disorders remain molecularly unexplained.[64] Genetic testing is not widely available for many inherited bleeding disorders, but the field is rapidly evolving. Consideration of genetic testing should be based upon a high clinical index of suspicion and corroborating laboratory data, and only be performed in the setting of appropriate individualized genetic counseling before testing is performed and, if the patient is agreeable, again after the results are received.

CONCLUSION

Evaluation of the patient with bleeding requires careful attention to history and physical examination. Acquired perturbations of hemostasis resulting in coagulation factor deficiencies (such as

Table 50.2

Inherited disorders of hemostasis, relative prevalence, and inheritance patterns

Disorders of Primary Hemostasis	Relative Prevalence[a]	Inheritance Pattern
VWD	More common	
Type 1 VWD		Autosomal dominant
Type 2 VWD		Autosomal dominant
Type 3 VWD	(Rare)	Autosomal recessive
Platelet disorders	Less Common[b]	
Glanzmann thrombasthenia	(Rare)	Autosomal recessive
Bernard-Soulier syndrome	(Rare)	Autosomal recessive
Platelet granule disorders (storage pool, gray platelet, etc.)		All patterns
Defects of secretion/signal transduction		All patterns
Defects in cytoskeletal proteins (MYH9-related, Wiskott-Aldrich, etc.)		All patterns
Disorders of secondary hemostasis		
FVIII deficiency (hemophilia A)	More common	X-linked recessive
FIX deficiency (hemophilia B)	More common	X-linked recessive
FI (fibrinogen) abnormalities	Less common	
Afibrinogenemia		Autosomal recessive
Hypofibrinogenemia		Autosomal dominant or recessive
Dysfibrinogenemia		Autosomal dominant or recessive
FII (prothrombin) deficiency	Rare	Autosomal recessive
FV deficiency	Less common	Autosomal recessive
FVII deficiency	Less common	Autosomal recessive
FX deficiency	Less common	Autosomal recessive
FXI deficiency	More common in Ashkenazi Jews, otherwise rare	Autosomal recessive
FXIII deficiency	Less common	Autosomal recessive
Combined factor deficiencies	Rare	
Combined FV and FVIII deficiency		Autosomal recessive
Combined FII, FVII, FIX, and FXI deficiency		Autosomal recessive
α_2-Antiplasmin deficiency	Rare	Autosomal recessive

[a]"More common" = prevalence of > 1:50,000; "less common" = prevalence < 1:50,000 but >100s; "Rare" = hundreds of families or less.
[b]Overall prevalence of platelet disorders has not been well characterized.

DIC, liver disease, warfarin, autoimmune disease) or platelet defects (aspirin, GPIIb/IIIa inhibitors, clopidogrel) are generally more common than congenital disorders of hemostasis, and thus must be considered in the differential diagnosis of the bleeding patient. However, inherited disorders, even when individually rare, are collectively common. Therefore, careful attention should be paid to clues of a congenital coagulation defect, such as early age of onset or a positive family history. Table 50.2 categorizes congenital bleeding disorders by their tendencies to present with a primary or secondary hemostatic defect, prevalence, and inheritance pattern. Logical use of screening and specialized coagulation testing will guide the diagnosis and lead to appropriate treatment to stop or prevent bleeding. Table 50.3 summarizes conditions known to contribute bleeding and their commonly associated PT and/or aPTT abnormalities, conditions that may result in abnormal PT and/or aPTT in patients without a bleeding history, and a list of conditions associated with thrombocytopenia. In conjunction with a thorough history and physical examination, these tables are a general guide to narrow the differential diagnosis of the bleeding patient. More specific information on the diagnosis and treatment of specific bleeding disorders can be found in other chapters of this book. Many of these conditions may present together or present with considerable heterogeneity, providing a seemingly daunting complex hemostatic picture at the outset. Through careful dissection of the data, the cause of the patient's hemostatic defect(s) and underlying bleeding risk should be able to be discovered and thoughtfully addressed.

tahir99-VRG & vip.persianss.ir

Table 50.3

Assembling the bleeding history, inheritance, and the aPTT and PT

Symptoms and Laboratory Findings	Inheritance Pattern	
Bleeding Patient	**Congenital**	**Acquired**
Normal PT, normal aPTT	VWD (with mild ↓ or normal FVIII), platelet disorders, FXIII deficiency, fibrinolytic factor defects (α_2-antiplasmin, PAI)	Acquired platelet dysfunction (medications, uremia), thrombolytics
Normal PT, prolonged aPTT ("extrinsic pathway")	Factor deficiencies (FVIII, FIX, FXI), VWD (due to lower FVIII)	Acquired inhibitor (e.g., FVIII), acquired VWD, heparin
Prolonged PT, normal aPTT ("intrinsic pathway")	Factor deficiency (FVII), fibrinogen defect	Vitamin K deficiency or warfarin, acquired inhibitor, antiphospholipid antibodies, liver disease (factor and fibrinogen defects)
Prolonged PT, prolonged aPTT (common pathway)	Factor deficiency (fibrinogen, prothrombin, FV and FX)	DIC, severe vitamin K deficiency/warfarin, severe liver disease, paraproteinemia, antiphospholipid antibodies (prothrombin), acquired FV inhibitor, amyloidosis (adsorption of factors, especially FX)
Asymptomatic Patient		
Normal PT, prolonged aPTT ("intrinsic pathway")	Factor deficiency (FXII, prekallikrein, kininogen, FXI)	Antiphospholipid antibodies
Prolonged PT, normal aPTT ("extrinsic pathway")	FVII deficiency, fibrinogen defects	Acquired fibrinogen defect, liver disease, warfarin/vitamin K deficiency, antiphospholipid antibodies
Prolonged PT, prolonged aPTT (common pathway)	Factor deficiency (fibrinogen, prothrombin, FV and FX)	Antiphospholipid antibodies, FV inhibitors
Thrombocytopenic Patient		
Thrombocytopenia	Congenital thrombocytopenia/syndrome, type 2B VWD	Platelet production defect (medications, sepsis/shock, bone marrow disease, autoimmune), consumption (hypersplenism, DIC, thrombosis, thrombotic thrombocytopenic purpura, HELLP [hemolysis, elevated liver enzymes, and low platelet] syndrome), dilutional (iatrogenic, pregnancy), immune mediated (underlying autoimmune disease, medications, immune thrombocytopenic purpura, antiphospholipid antibodies)

CHAPTER

51

Clinical Manifestations and Therapy of Inherited and Acquired Hemophilia

EDWARD G.D. TUDDENHAM, PETER W. COLLINS, AND T.T. YEE

HISTORICAL INTRODUCTION

Knowledge of a congenital bleeding disorder affecting male infants can be inferred from rulings in the Babylonian Talmud[1] compiled about 500 CE. A dispensation was given to forgo circumcision in brothers and cousins of affected boys who had died after the ritual was carried out (presumably from bleeding), showing that the Rabbis recognized inheritance of a bleeding tendency through carrier females. Abu al-Qasim Khalaf ibn al-Abbas Al-Zahrawi, known as Albucasis (936–1013), the great Moorish surgical writer of 10th-century Spain, wrote of a certain village where boys and men suffered excessive bleeding after minor injury. He also gave the first practical advice for treating such bleeding by means of cautery, the success of which he observed. We can now interpret this report as referring to moderately severe hemophilia with a local founder effect.

The curious word for an abnormal inherited bleeding tendency which we use today—hemophilia (literally blood lover)—was introduced by Hopff in his doctoral thesis delivered at Wurzburg in 1828.

The medical literature of the 18th and 19th centuries on hemophilia was gathered in a monumental review published in 1911 by the Francis Galton Laboratory for National Eugenics of the University of London (now abbreviated to The Galton Laboratory). The review[2] described clearly all the clinical features that are seen today in untreated cases of hemophilia. However, they failed to recognize the key feature of X-linked inheritance—daughters of affected males are obligate carriers of the mutant gene. The correct theoretical explanation of chromosomal sex determination and of sex-linked inheritance in mammals had only just been proposed and had evidently not come to their notice. Notably absent from the nearly 1,000 pedigrees of hemophilic families illustrated in the review was that of the most famous hemophilic family in history, namely the descendants of Queen Victoria, who was an obligate carrier on pedigree evidence (FIGURE 51.1). In addition to her British descendants, she transmitted hemophilia to three other European Royal families through dynastic marriage alliances. No antecedents of Queen Victoria had a bleeding tendency, so it is likely that she inherited a new mutation in one or other of the parental gametes, as is the case for a third of carriers of hemophilia. Three of her daughters were carriers of the hemophilic gene and her youngest son Leopold had clinically severe hemophilia. The mutant gene then made its way into the German, the Spanish, and most famously the Russian Royal families. Leopold's daughter, the Princess Alice, was an obligate carrier and had two affected sons who died in childhood. The German affected boys also died young, but the Spanish princes with hemophilia survived into their 20s before succumbing to trauma-induced bleeding. Alexey Romanov, the Tsarevich (heir to the throne of Russia), was affected with severe hemophilia. Alexey was murdered on Lenin's orders with his family at Yekaterinburg during the civil war following the Bolshevik revolution. Hence by 1938, there were no surviving male descendants of Queen Victoria with hemophilia. In 1952, it emerged that there are two types of hemophilia—A and B. The question then arose, whether the "Royal disease" was type A or type B. It became a long-standing historical puzzle which was finally solved almost 60 years later, by a tour de force of forensic genetics, in favor of hemophilia B,[3] by genomic analysis of the Imperial family's bones, recovered from unmarked graves near Yekaterinburg (FIGURE 51.2).

GENETICS AND BIOCHEMISTRY OF HEMOPHILIA

The X-linked inherited bleeding disorders, hemophilia A and B, are due respectively to mutations at the factor VIII (FVIII) locus (*f8*) or the FIX locus (*f9*), both situated on the long arm of chromosome X at Xq2.8 and Xq2.6, respectively. The *f8*-linked condition, caused by deficient synthesis of coagulation FVIII, is known as hemophilia A, whilst the *f9*-linked condition, due to deficient synthesis of coagulation FIX, is called hemophilia B or Christmas disease (after one of the first described sufferers). The clinical features of the two conditions are indistinguishable, and they were not separated until complementation studies in 1952 uncovered the fact that blood from a majority of patients with X-linked hemophilia (type A) could correct the coagulation defect in blood from a minority (type B) and vice versa. FIX itself was discovered as a result of these studies, being called at first Christmas factor[4] to distinguish it from antihemophilic factor, the name already assigned to the putative entity lacking in the blood of type A patients. Biochemically, FVIII and FIX function together as a binary enzyme (FIXa) cofactor (FVIIIa) complex whose substrate is FX.

The incidence ratio of hemophilia A to B is about 5 to 1, and both conditions are rare: hemophilia A affects 1 in 5,000 males at birth whereas hemophilia B affects only 1 in 25,000 males at birth. Contrary to the commonly held belief that carriers are unaffected, about a third of females who are heterozygous for mutations at either locus manifest mild hemophilia due to skewed X inactivation.

Acquired hemophilia A is a rare autoimmune disorder caused by failure of self-tolerance toward FVIII occurring in later life, with production of antibodies neutralizing the activity of the patient's own FVIII. Hemophilia A and B are treated together in the following discussion of the pathology, clinical features, and treatment of the two disorders, only noting differences where relevant.

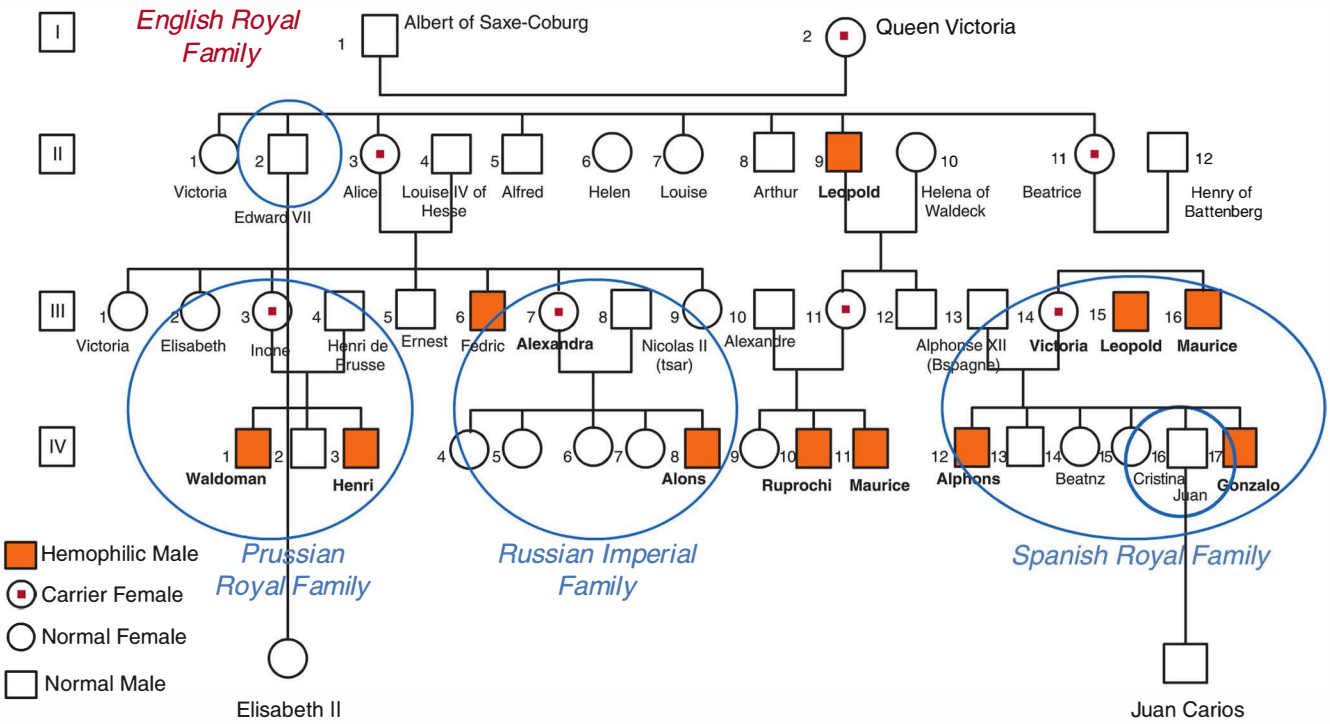

FIGURE 51.1 Queen Victoria's pedigree. The Royal disease is an X-linked recessive bleeding disorder that, until resolved by modern genetic analysis, could have been either hemophilia A or B as every affected male had died before blood tests could have decided the issue in 1950. Obligate carriers on pedigree are represented by a *circle* with a *red dot* in its centre. Affected males are shown as *red squares*. Of the four royal families afflicted by the disease (*blue circles*), the most tragic was the Russian. Alexei met his end by murder as did his sisters and parents. One of his sisters was a carrier according to the forensic analysis, probably Anastasia (FIGURE 51.2). (Reproduced from Lannoy N, Hermans C. The "royal disease"—haemophilia A or B? A haematological mystery is finally solved. *Haemophilia* 2010;16(6):843–847, with permission.)

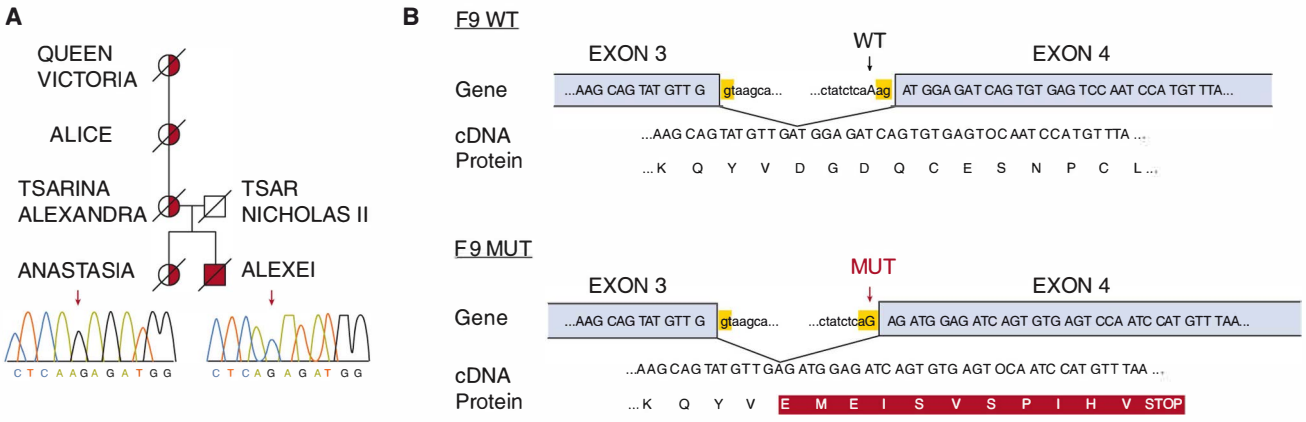

FIGURE 51.2 The Royal disease was caused by a point mutation in *F9*. **A**: Partial pedigree of the Royal family, showing transmission of the mutation from Queen Victoria to Empress Alexandra and from Alexandra to Prince Alexei, her haemophilic son. Alexei was hemizygous for the mutation, whereas Alexandra and one of her daughters, putative Grand Duchess Anastasia, were heterozygous carriers. **B**: The A-to-G mutation occurs just upstream of exon 4 in the F9 gene and is predicted to create a new splice acceptor site that could lead to production of a truncated factor IX protein. WT indicates wild type. (Reproduced from Rogaev EI, Grigorenko AP, Faskhutdinova G, et al. Genotype analysis identifies the cause of the "royal disease". *Science* 2009:326(5954):817, with permission.)

PATHOPHYSIOLOGY AND PRINCIPLES OF TREATMENT

All clinical features of hemophilia A and B are due to deficiency of FVIII or FIX respectively, with consequent failure to generate adequate thrombin in response to injury and hence failure to form a stable hemostatic plug at sites of vascular damage. Correction of the defect by intravenous infusion of the relevant missing factor completely normalizes thrombin generation, since all other factors required for hemostasis are present in normal amounts. Several circumstances conspire to frustrate our efforts to normalize clotting in a hemophilic person's blood. FVIII and FIX are scarce proteins which are difficult to purify and difficult to make by genetic engineering. Hence, the cost of clinical factor concentrates is extremely high. Given a supply of factor concentrate, it still has to be introduced into the circulation by intravenous infusion. Vascular access is therefore critical for hemophilia care lifelong. Most problematic of all is the short half-life in the circulation of infused factor—8 to 12 hours for FVIII and 15 to 20 hours for FIX. In fact, four out of five hemophiliacs worldwide have little or no access to replacement therapy at all. Treatment regimens discussed below are a compromise designed to maximize the benefit of scarce resources and minimize the dire effects of bleeding, which if left unstaunched leads to progressive damage wherever bleeding is prone to occur.

If left without effective treatment the natural history of hemophilia is progressive loss of mobility from joint and muscle bleeding and early death due to exsanguination or uncontrolled internal bleeding, most often intracranial. Prior to the advent of factor concentrates in the 1970s, the most severely affected hemophiliacs died before the age of 20. In contrast to that dire prognosis, modern comprehensive hemophilia care, supported by the resources of an economically advanced state, can normalize life span and limit or eliminate tissue damage.[5] Adequate supplies of virus safe FVIII and FIX first became widely available in the 1990s; hence most hemophiliacs born before 1985, even in economically advanced countries, are living with the long-term effects of undertreatment in childhood and infection by hepatitis C and HIV, which were present in factor concentrates up to 1986.

GENETICS AND DIAGNOSIS OF HEMOPHILIA A AND B

Since there is no heterozygote advantage to carrying defects at the *f8* or *f9* loci and since the hemizygous male has severely limited reproductive fitness (absent treatment), the frequency of "hemophilic" gene defects in the population must be maintained by new mutations. Consequently and as predicted by Haldane (op. cit.), the mutations are highly diverse.

Usually genetic analysis is carried out following the measurement of blood factor level establishing the diagnosis in the affected male, but putative carriers of hemophilia A or B often have no living affected relative, due to early death. Alternatively they may be carriers of a recent mutation. To help such women with establishment of carrier status and genetic counseling, it is then necessary to sequence their *f8* and/or *f9* genes. Detection of a heterozygous mutation already noted in the databases associated with hemophilia, or (if not previously reported) plausibly causative of deficient/functionally defective FVIII or FIX, then confirms carrier status. The nature of the mutation can also predict the severity of the disorder. Severe gene lesions such as stop codons, large deletions, or the prevalent inversion in hemophilia A not only cause severe disease with no circulating factor but are also associated with high risk of neutralizing antibody (inhibitor) development after substitution therapy. Missense mutations on the other hand are usually associated with moderate (residual factor level 1% to <5%) or mild (residual factor > 5%) bleeding tendency.

In laboratory diagnosis of hemophilia A and B, the standard screening tests show a prolongation of activate partial thromboplastin time (APTT) with normal prothrombin time (PT). If this is the case, then specific factor assays to quantify FVIII and FIX are performed. Traditionally, residual FVIII or FIX <1% is defined as severe. However, the lower detection limit for both assays is about 1% and a residual level below 1% but above absolute zero can make some difference to bleeding frequency, that is to say—the clinical phenotype. This is notable when one compares the bleeding frequency of subjects with a null mutation against those with a missense mutation but factor level <1% who may even have no spontaneous bleeding.[6] Although uncommon, patients with multiple defects in their hemostatic system are also found.

An assay capable of detecting antibodies to FVIII or FIX is also a mandatory part of the laboratory workup. In hereditary hemophilia A and B antibodies only develop after treatment and may do so promptly thereafter. Inhibitors may develop after many years of treatment, as recent data from the UK national database show.[7] Thus, regular inhibitor testing is part of routine follow-up care in hemophilia.

There are two different ways of measuring FVIII activity, the one-stage clotting assay and the two-stage clotting assay. Ideally, both assays should be performed on all patients because many patients with mild hemophilia A have a much lower two-stage assay level than one-stage assay level. The clinical bleeding tendency is better predicted by the two-stage assay result. There are even a few patients who have normal one-stage assay result but clearly abnormal two-stage assay.[8]

THE CLINICAL PHENOTYPE IN HEMOPHILIA A AND B

A guide to bleeding frequency can be derived from the residual factor level in the patient's blood[9] (FIGURES 51.3A,B). Subjects whose residual level is <1% can attract clinical attention at birth, with bleeding complications of delivery or within a few months with spontaneous bruising, bleeding after circumcision, from primary dentition or hemarthrosis. Throughout life, such patients bleed apparently spontaneously, but also after minor trauma about once or twice a week in the most severe cases.

Patients whose residual level is 1% to <5% are said to have moderate hemophilia. Typically, they present at age 2 to 5 years with bleeding after significant trauma that has sufficiently intrigued a medical attendant to request a blood test including screening for coagulation disorders. If the residual level is over 5%, then the patient is said to have mild hemophilia. Bleeding only occurs in such cases after significant trauma or surgery. Patients with mild hemophilia are often first diagnosed in middle or late life and then only after severe trauma or major surgery brings the bleeding tendency to light. The diagnosis can

Clinical severity of haemophilia A: does the classification of the 1950s still stand? *Haemophilia* 2011;17(6):849–853, with permission.) **B**:Annual number of joint bleeds according to factor VIII activity in the same cohort as in FIGURE 51.3A. Of note, there were no joint bleeds in patients with a baseline level above 12 IU/dL. (Reproduced from Den Uijl IE, Mauser Bunschoten EP, Roosendaal G, et al. Clinical severity of haemophilia A: does the classification of the 1950s still stand? *Haemophilia* 2011;17(6):849–853, with permission.)

go undetected for many years; as in one extreme example noted by one of us (ET), a 90-year-old gentleman was found to have 5% FIX that came to light because he bled around the site of catheter insertion for coronary angiography.

The anatomical structures most frequently affected by hemophilic bleeding are the major load-bearing joints in the order of ankles>knees>elbow>shoulders. The hips are often spared. A target joint is one where repeated bleeding is occurring, without fully recovering between bleeds. Such joints go on to develop progressive painful, deforming, and motion-restricting arthropathy until they become fixed by reactive fibrosis. Blood within a joint capsule is highly irritant and provokes proliferative synovitis with erosion of cartilage, formation of bone cysts and deformity, and progressive fibrosis.[10] The progress of such damage to joints is monitored for purposes of assessing response to treatment by standardized scales based on range of movement and function, radiology, or MRI.[11–14]

Muscles develop bleeding after direct trauma or exercise or spontaneously. If the blood is confined within a muscle capsule, pressure can build up until compartment syndrome develops. This is a surgical emergency since it can lead to ischemic necrosis and contracture with loss of all function. An incision in the fascia surrounding the affected muscle combined with adequate replacement therapy is muscle saving in such circumstances, though not without risk of continued bleeding.

Bleeding into deep muscles such as the iliofemoral muscles can occur in all severity levels of hemophilia. Hip flexion, abdominal pain, and femoral nerve entrapment symptoms should lead to suspicion of this site of bleeding.

Renal tract bleeding presenting with hematuria is common and often not related to any detectable renal tract disease.

Intracerebral bleeding has been the commonest cause of death in hemophilia, even to the present.

Bruising is commonly observed in hemophilic children on the legs, trunk, and arms but is not usually a cause of concern and does not need treatment if superficial and painless.

THE SEVEN AGES OF HEMOPHILIC MAN

Conception

The ethical choice not to have a hemophilic child is one that many carriers have made, in view of their first-hand observation of the suffering of their father or (N.B. not "and") brothers. Recently, preimplantation genetic diagnosis has made it possible to select embryos, obtained by in vitro fertilisation (IVF), for transfer according to their genetic status, and this technique has been successful for hemophilia.[15]

In Utero

Prenatal diagnosis, undertaken either to terminate an affected conceptus or to guide subsequent management of labor and delivery, is widely practiced by means of chorion villus biopsy. This allows direct access to tissue and therefore DNA of fetal origin, at 10 to 12 weeks, which can be tested for linkage to or directly for the specific mutation present in the family of the carrier.

Noninvasive testing for fetal DNA present in maternal blood has been developed using digital quantitative polymerase chain reaction (PCR).[16] From as early as the 11th week of gestation, it is now possible to determine by analysis of maternal blood not only the sex of the conceptus but also whether it is or is not affected. When the fetus is affected, the quantity of DNA bearing the mutation in the maternal plasma is increased above the level due to the maternal heterozygosity in a ratio that is high enough to enable perfect discrimination from the ratio when the male

tahir99-VRG & vip.persianss.ir

fetus is unaffected. Either the specific mutation or a linked informative single-nucleotide polymorphism may be used.

In utero bleeding is extremely rare in a hemophiliac fetus, suggesting that it is highly protected against trauma whilst in the womb.

Delivery of Affected Males

Passage through the birth canal of a term infant can only be achieved with considerable compression of the skull and deformation of the brain. At least 5% of hemophilic infants develop clear neurological signs of progressive bleeding requiring treatment. If the diagnosis of hemophilia has been made already, then the baby can be closely monitored and treated at the first sign of such bleeding. Tragedies occur when the diagnosis has not been expected, which is true of about one-third of such deliveries due to new mutations (see section on Genetics above). Current guidelines advise against prolonged labor, instrumental delivery, and use of scalp monitoring.[17] There should be a low threshold to proceed to cesarian section if labor is not progressing and difficulties in the birth canal are likely. A sample of cord blood should be taken to confirm or exclude hemophilia. FVIII may be boosted by the stress of birth such that an elevated level may be present in mild but not in severe hemophilia. FIX levels are reduced in normal term and more so in preterm cord blood. However, absent or very low levels are clearly indicative of hemophilia B.

The Infant

In neonates with severe hemophilia, the decision to infuse prophylactic concentrate at birth is controversial. Some authorities recommend replacement therapy without evidence of active bleeding whilst others wait for evidence of bleeding. The recommended practice in Europe and North America is to delay the start of regular prophylaxis until the infant starts to crawl and has his first joint or muscle bleed. This will vary from 12 to 18 months. To secure venous access, an indwelling port may need to be inserted and the parents trained in its use so that a regular program of prophylaxis can be maintained. This standard of treatment is now producing for the first time children and young men with severe hemophilia who have never had a serious bleed and who have normal joints. However, there is now also an increased incidence of inhibitory antibody development in children with severe hemophilia A, occurring within the first 50 infusions.

The School Years

Since the practice of early and continuous prophylaxis was instituted, hemophilic children have been able to attend mainstream schools and take part in all activities with the exception of violent contact sports. With maturity, the hemophilic child is encouraged to take responsibility for his condition and to self-administer concentrate. Most children with hemophilia can achieve this by the age of 10.

Adolescence and Transition to the Adult Center

There comes a time when the boy is reaching adolescence and should have his care transferred to an adult centre. When this time is reached varies, as does the timing of puberty. Special sensitivity to the patient's and parents' needs will ease this transfer, which should be managed formally according to a scheme that ensures none of the patient's needs are overlooked. Risk taking may manifest during adolescence, but if good habits of treatment and prophylaxis have been ingrained in childhood, then most young men with hemophilia can cope with the added stress of the teen years without losing control of their hemophilia.

Early Adulthood and Career

Hemophilia is no longer a bar to any level of educational attainment. Nor is it a bar to entry to any trade or profession, with the exception of front-line military and police work. No doubt, those bars too will be lifted one day, either by very long-acting preparations or by gene therapy (see section on Gene Therapy below).

Reproductive fitness of hemophilic males is now similar to that of other males. However, the question of inheritance does arise and is best dealt with in the context of a genetic counseling clinic with trained counselors, geneticist, and hematologist, roles that may be combined in one or two people. The obligate carrier daughter will herself in due course need genetic counseling. Numbers of carrier females and of affected male infants born to them are on the rise, thanks to improved therapy.

Middle Years

Men with severe hemophilia who have survived to the age of 35 and over have all been infected with hepatitis C, and most have also been infected with HIV in childhood. They may also have badly damaged joints with progressive arthropathy due to inadequate on-demand treatment of bleeding in their early years. Their medical needs contrast dramatically with those of the younger well-treated generations now reaching maturity. In those who have failed to clear hepatitis C, there is the potential for progression to cirrhosis with increasing risk of hepatocellular carcinoma and of terminal liver disease. These patients benefit from liver transplantation as the last resort, which also cures hemophilia A and B. Multiply disabled hemophiliacs (older men in developed countries and younger subjects from developing nations) depend for their mobility on the help of skilled orthopedic surgeons to replace joints and specialized physiotherapists to maintain function.

Later Life

For the first time in history, significant numbers of men with severe hemophilia are reaching their 6th, 7th and even 8th decades. A particular puzzle arises in relation to arterial degenerative disease and hemophilia. Although the rate of coronary thrombosis is reduced in hemophilia, due to the permanent state of anticoagulation that is characteristic of the condition, arterial disease itself continues unabated and often leads to the need for arterial stenting or bypass with subsequent requirement for antiplatelet agents. The compromise that may be recommended is to use lower doses of antiplatelet agent whilst maintaining prophylaxis of the hemophilia at a slightly higher level than usual for the patient.[18,19]

Old Age and Death

Whilst hemophilic life span, in those who are not subject to the dire effect of chronic viral infection, or of resistant inhibitors, is now approaching the norm for the general population, there still remains an excess of deaths due to intracerebral hemorrhage.[5] Prophylactic regimens do not deliver a normal level of FVIII or FIX all or even most of the time. Therefore, all patients spend most of their lives with subnormal thrombin generation.

tahir99-VRG & vip.persianss.ir

Perhaps, the aging arteries in the brain, which become more fragile with age, finally start to leak, and the absence of adequate hemostasis at that time and place is fatal.

One British hemophiliac has died who was found to have variant Creutzfeldt-Jakob disease (vCJD) prion in his spleen postmortem,[20] as a result of receiving concentrate made from blood products contaminated with the agent. All hemophiliacs who received concentrate made from UK plasma in the relevant period are deemed at risk to develop or transmit vCJD.

TREATMENT OF UNCOMPLICATED HEMOPHILIA A AND B

Mandatory normal hemostasis must be secured for treatment of head injury/intracranial hemorrhage, major trauma, impending compartment syndrome, exsanguination, and surgery. Normal hemostasis, that is, FVIII or FIX level maintained at 100% ± 5%, is most securely and economically achieved by continuous infusion. High-purity plasma-derived and recombinant factors may be used in continuous infusion; for this, purpose a suitable dose is made up and delivered by syringe pump at a rate of about 1 U/kg/h after a bolus dose has been delivered to raise the level rapidly to 100%. Interval assay levels, throughout the period where normal hemostasis is required, should be used to adjust the infusion rate.

Undertreatment is the commonest mistake made in hemophilia care. An example of the consequences of undertreatment may be seen in the recent analysis of outcomes of knee joint replacement.[21] Centers that covered surgery with normalization of factor level for 2 weeks followed by gradual reduction had a zero complication rate and centers using less factor had poor outcomes in up to 20% of patients. This is in keeping with laboratory studies in hemophilic mice.[22]

Formulae for Calculating Bolus Doses to Achieve 100%

FVIII dose in units = patients weight in kg × percent rise required to reach 100% × 0.5
FIX dose in units = patients weight in kg × percent rise required × 1.0
The same formulae are used to calculate any other desired target level as suggested in treatment plans below.

On-Demand Treatment of Joint and Other Bleeds

Treating a bleed at the earliest opportunity when it occurs is referred to as on-demand treatment. Provided the patient has his supply of treatment at home and can self-administer the drug intravenously, bleeding is minimized and the rate of joint damage progression is slowed. Due to lack of supply, on-demand treatment made available at a medical centre is the norm for severely affected patients in most of the world, although this is clearly a suboptimal approach to treating hemophilia.[23] Moderate and mildly affected patients are managed mainly with on-demand treatment. Self-therapy is always preferable as it enables the patient to take charge of his own treatment and eliminates delays. A general rule for hemophilia is "when in doubt treat with factor."

Dosage recommended for on-demand treatment is largely empirical with little in the way of trial data to support particular regimens. A common policy is to give a fairly small dose for an uncomplicated joint bleed if treated early and to follow with a second dose in 6 hours if the problem is not resolving rapidly. In hemophilia A, that would be a dose of 15 to 30 U/kg body weight. In hemophilia B with the somewhat lower recovery, 20 to 40 U/kg is suggested. For a more severe bleed induced by trauma or not responding to a lower dose of therapy, the recommended range is increased to 20 to 40 U/kg (hemophilia A) or 30 to 60 U/kg (hemophilia B).

Prophylactic Treatment for Hemophilia

The aim of prophylaxis is to convert the individual from a severe to a moderate bleeding phenotype and so decreasing or preventing musculoskeletal damage.[24] Prophylactic treatment has been shown to prevent joint damage and musculoskeletal disability in long-term retrospective cohort studies.[25,26,27] A prospective randomized clinical trial of prophylaxis versus enhanced on-demand therapy in young children showed reduced radiological joint damage in the prophylaxis arm.[23] On the basis of these studies, prophylaxis is now the recommended treatment for children with severe hemophilia and is being increasingly used in adults.[28] In addition to its proven role in reducing arthropathy, it is likely that prophylaxis reduces the risk of other severe bleeds, such as intracranial hemorrhage.

There is some controversy about the optimal dose and frequency of prophylactic infusions, and no studies have directly compared regimens. The regimen that was used in young children in the prospective randomized trial was 20 to 40 IU/kg on alternate days,[23] a regimen based on that pioneered in Sweden,[25] and many experts would now consider this to be the gold-standard prophylactic regimen in young children. However, similar long-term outcomes have been reported with lower dose regimens in the range of 10 to 15 IU/kg.[29] The use of 3 days a week regimen is no longer considered optimal therapy because of the 3-day gap that this entails and low FVIII levels during the third day before a dose[28,30] (FIGURE 51.4).

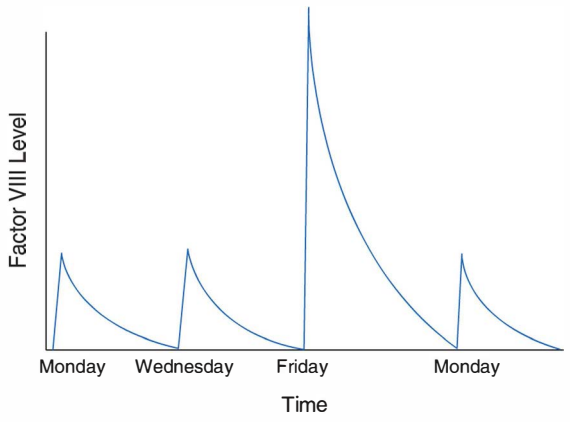

FIGURE 51.4 Implications of Monday, Wednesday, and Friday dosing. Illustration of the dose increment required to provide an equivalent trough level on Monday morning compared with the rest of the week for patients taking prophylaxis on Monday, Wednesday, and Friday. Assuming a 12-hour half-life, a fourfold dose increase on Friday morning compared to Monday and Wednesday would be required. The factor VIII scale is arbitrary. (Reproduced from Collins PW, Fischer K, Morfini M, et al. Implications of coagulation factor VIII and IX pharmacokinetics for clinical practice in the prophylactic treatment of haemophilia. *Haemophilia* 2011;17(1):2–10, with permission.)

tahir99-VRG & vip.persianss.ir

There is good evidence to show that prophylaxis should be started early in children with severe hemophilia.[23,26] In long-term follow-up studies, the best joint status is preserved if prophylaxis is started before recurrent bleeds have occurred,[26,31,32] and guidelines recommend starting prophylaxis at the latest after the first joint bleed.[28] Some hemophilia centers start prophylaxis before the first joint bleed, if venous access permits. There is no consensus on how prophylaxis should be initiated. Some experts recommend starting once-weekly prophylaxis with rapid escalation to full-dose regimens if bleeds occur and as the child becomes more active, whilst others prefer to introduce full-dose regimens as soon as prophylaxis is started. There are no convincing data to favor either view. The use of implanted central venous catheters may be required to allow prophylaxis in young children.

Prophylactic regimens should be tailored to the individual's bleeding pattern and activity and also take into account the patient's and their family's choices. Although the use of trough FVIII levels to adjust prophylaxis is often considered, the time spent per week with a low level may be more important than the trough level itself.[33] There are some data to suggest that dosing prophylaxis based on the patient's half-life to target a desired trough levels may lead to more cost-effective treatment, but this approach needs to be addressed in clinical trials before being widely adopted[34] (FIGURE 51.5).

Some centers are now using prophylaxis daily in very active patients or in those with problematic bleeds. The use of daily treatment results in much higher trough levels whilst using the same overall amount of FVIII or FIX as in less frequent regimens.[35] Daily treatment is a highly effective way to provide prophylaxis in the short or long term.

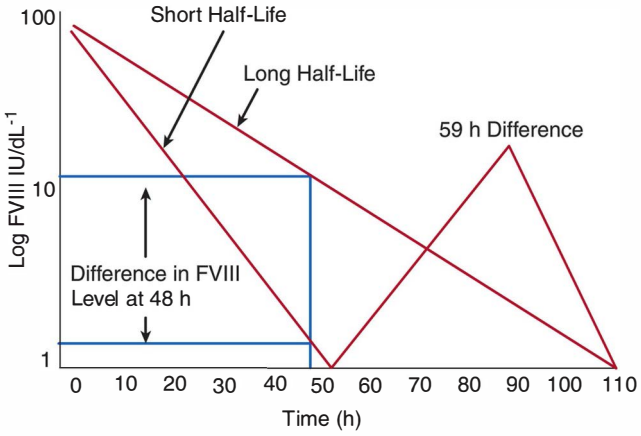

FIGURE 51.5 Effect of half-life on factor (FVIII) level following a bolus infusion. Illustration of the time taken for FVIII to reach 1 IU/dL in patients aged 10 to 65 years following an infusion of 30 IU/kg depending on variation in half-life within the normal range. Also illustrated is the variation in FVIII level at 48 hours depending on half-life. A short half-life is the 5th percentile and a long half-life is the 95th percentile of the normal range. This demonstrates that following a standard weight–based infusion, the time taken to reach 1 IU/dL varies by 59 hours depending on half-life. (Reproduced from Collins PW, Fischer K, Morfini M, et al. Implications of coagulation factor VIII and IX pharmacokinetics for clinical practice in the prophylactic treatment of haemophilia. *Haemophilia* 2011;17(1):2–10, with permission.)

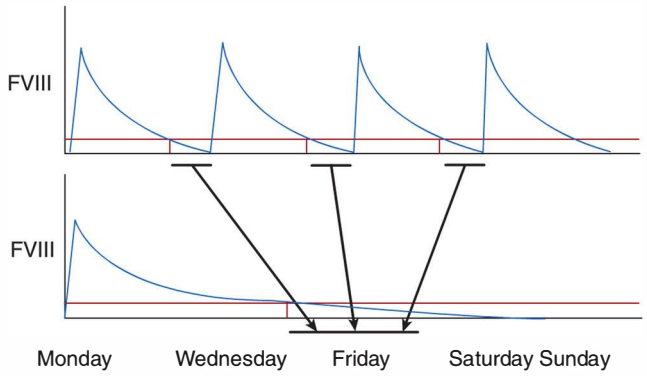

FIGURE 51.6 Potential implications of prolonged acting factor VIII (FVIII). Illustration of the length of time FVIII is below an arbitrary level assumed appropriate for an individual comparing standard FVIII infused on alternate days (*upper panel*) and a hypothetical prolonged acting FVIII infused once a week (*lower panel*). Patients on the prolonged acting FVIII spend more time per week below a specified level, and this is spread across both day and night as opposed to just during night as seen with alternate-day dosing. The FVIII scale is arbitrary. (Reproduced from Collins PW, Fischer K, Morfini M, et al. Implications of coagulation factor VIII and IX pharmacokinetics for clinical practice in the prophylactic treatment of haemophilia. *Haemophilia* 2011;17(1):2–10, with permission.)

Regimens for delivering prophylaxis will need to be revised if studies with longer acting FVIII and IX are successful. These products may allow less frequent infusions, but the effect of this strategy on bleeding needs to be closely studied because patients will spend longer with low levels than with conventional regimens (FIGURE 51.6).

There is debate about whether it is appropriate to stop prophylaxis when the patient has reached adulthood, but there are very limited data available. Observational studies have shown that, in the highly selected group of patients who decide to stop prophylaxis of their own accord, between 22% and 35% were able to continue with on-demand therapy without significant joint damage after 4 years follow-up.[36,37] The majority of patients, however, need to return to prophylaxis. In general, until new evidence is available, guidelines suggest that prophylaxis should be continued long term.[28]

Prophylaxis started in adulthood will reduce or even prevent bleeding, but the long-term effect on established musculoskeletal damage is unknown.[38,39] The cost of prophylaxis in adults is high; however, studies suggest that the use of pediatric regimens (e.g., 20 to 40 IU/kg) may not be appropriate for older patients because the coagulation factors have longer half-lives in adults. Hence, considerably lower infusion regimens will sustain a trough above 1 IU/dL and potentially allow much more cost-effective regimens to be used.[35]

TREATMENT OF INHIBITORS IN CONGENITAL HEMOPHILIA

With the introduction of concentrates that are safe from the risk of transfusion-transmitted infection, the development of an inhibitory antibody to infused FVIII or FIX is the most serious adverse event associated with replacement therapy.

tahir99-VRG & vip.persianss.ir

High-titer inhibitors are defined as >5 Bethesda units (BU)/mL and high-responding inhibitors are defined as an increase in titer to above 5 BU/mL after exposure to concentrate. Patients with a Bethesda titer above 5 BU/mL do not, in general, respond to factor concentrate and bypassing agents are usually required. (1 BU is the amount of inhibitor capable of neutralizing 0.5 units of FVIII after 2 hours incubation.)

Most inhibitors develop early during a patient's treatment history after a median of about 10 exposure days; emerging evidence suggests that the incidence of inhibitors increases again in later life.[7] Risk factors for the development of inhibitors include severe hemophilia, especially caused by null mutations and a positive family history of inhibitors. Peak treatment moments defined at 5 or more consecutive days of treatment are also associated with inhibitor development.[40] The relative risk of inhibitor formation with plasma-derived and recombinant FVIII is debated, but systematic reviews suggest that the incidence of inhibitor formation is similar with both types of concentrate.[41,42]

Inhibitor Eradication

Treatment to eradicate an inhibitor by immune tolerance induction (ITI) should be undertaken unless the inhibitor is low titer and transient.[43] Based on registry data, it is common practice to delay the start of immune tolerance until the inhibitor titer has declined to below 10 BU/mL because this is associated with a higher chance of eradication.[44] It is also common practice to use rFVIIa to treat bleeds whilst waiting for the inhibitor to decline to reduce the risk of an anamnestic response. Other features associated with successful immune tolerance are less well established but a high historic peak titer and a short time between inhibitor development and ITI have been suggested as being important. Complete remission after ITI is reported to be between 60% and 80%, dependent on the risk factors of the patients studied.

ITI for patients with hemophilia A, an inhibitor titer below 10 BU/mL and a historical peak titer <200 BU/mL, has been the subject of a prospective randomized trial.[7] The regimens compared were 200 IU/kg daily versus 50 IU/kg on alternate days, and results show that the two arms were similar in terms of the proportion of patients who achieve a complete remission, but the patients treated on the low-dose arm took longer to achieve remission and had significantly more bleeds.

The type of FVIII that should be used for ITI is controversial. Retrospective, uncontrolled data suggest that plasma-derived concentrate with a high von Willebrand factor (vWF) content may be more efficacious than recombinant FVIII.[45] However, as yet, this has not been confirmed in well-designed clinical trials, and many clinicians prefer to use recombinant FVIII for first-line ITI.

Patients who not achieve inhibitor eradication with first-line ITI are a difficult group to treat. Anecdotal reports and uncontrolled case series suggest that a proportion will respond to changing to a plasma-derived concentrate with a high vWF content, and many clinicians will attempt a second ITI with these products.[45] A prospective trial is underway to investigate this question.[46] There has been recent interest in the use of immune suppression with the anti-CD20 agent rituximab in this group. Although a proportion of patients appear to respond sufficiently well for some to be treated with FVIII rather than bypassing agents, a durable complete remission is uncommon.[47]

Hemostatic Treatment of Bleeds

The management of bleeds in patients with hemophilia A and inhibitors depends on the bleed site and severity and the characteristics of the inhibitor.[42] Low-titer inhibitors may be overwhelmed with high and frequent doses of FVIII and, if adequate FVIII levels are achieved, good hemostatic effects can be expected. Patients with low-titer, low-responding inhibitors can be treated with FVIII for most bleeds, but if the inhibitor is high responding then many clinicians reserve FVIII for major bleeds.

High-titer inhibitors (>5 BU/mL) do not usually respond to FVIII and a bypassing agent is the treatment of choice. At the time of writing, the two available bypassing agents are recombinant FVIIa (rFVIIa, Novo Nordisk) and the plasma-derived activated prothrombin complex concentrate FEIBA (Factor Eight Inhibitor Bypassing Activator, Baxter Inc.). These agents have been shown to have similar haemostatic efficacy when used to treat hemarthroses at home.[48,49] Both agents appear to have a low risk of thrombosis when used in patients with congenital hemophilia.

The standard dose of rFVIIa is 90 μg/kg every 2 hours initially, with decreased frequency as the bleed is controlled. Most hemarthoses can be controlled with 1 to 3 doses if treated early. The use of 270 μg/kg as a single dose has been shown to be as efficacious as 3 doses of 90 μg/kg when treating hemarthroses, and this is an option for some patients.[49,50] This higher dose of rFVIIa has not been studied in other types of bleeding, and caution is required in patients with risk factors for arterial thrombosis.[51] FEIBA is generally used at a dose of 25 to 100 U/kg 8 to 12 hourly to a maximum dose of 200 U/kg in 24 hours. The length of treatment with either agent depends on the site and severity of the bleed, and some situations require a period of prophylactic treatment after the initial bleed has been controlled to prevent recurrence of bleeding. Some centers have reported successful treatment with immunoadsorption and infusion of FVIII.[52] This treatment modality is not widely available but can be useful in unresponsive patients.

In the past, porcine FVIII has been used to treat bleeds associated with inhibitors because the cross-reactivity of antihuman FVIII antibodies with porcine FVIII is low. Good hemostatic response was reported in most patients, but this product is no longer available. Clinical trials with a recombinant B-domain delete porcine product are underway (Inspiration Biotech Inc. company sponsored trial), and safety and efficacy data are awaited.

Surgery

Surgery in hemophilia patients with high-titer inhibitors is a high-risk undertaking since neither bypassing agent has consistent and predictable hemostasis efficacy. All surgery should be performed in centers with experience in treating this patient group. Both FEIBA and rFVIIa have been used successfully for surgery, and both seem to offer effective hemostasis in 80% to 90% of patients.[53,54] The optimal regimen for rFVIIa and FEIBA in surgery remains to be established, and a number of treatment schedules have been published. rFVIIa has been successfully used as a continuous infusion.[55] Protocols using rFVIIa in the initial perioperative period with switch to FEIBA for extended postoperative rehabilitation have been reported.[56]

tahir99-VRG & vip.persianss.ir

Prophylaxis

Patients with severe hemophilia and inhibitors are at high risk of developing disabling arthropathy, and as a result interest has been increasing in the role of prophylaxis in this patient group. In most inhibitor patients, FVIII cannot be used for prophylaxis because the half-life of circulating FVIII is too short or an anamnestic response may be provoked.

There are a number of published case reports and cohort studies that suggest bypassing agents reduce the number of bleeds in patients with inhibitors, but there is a high chance of a positive reporting bias and the studies need to be interpreted cautiously. Regimens tend to be either rFVIIa at 90 μg/kg daily or FEIBA 50 to 100 IU/kg alternate day. Some reports describe daily FEIBA prophylaxis.[57–61]

A prospective study has investigated rFVIIa given at 90 μg/kg daily for 3 months in patients who were experiencing very high numbers of hemarthroses. Although the number of bleeds during prophylaxis fell by 45% to 59% compared with on demand, the study design lacked a control arm and so it is not clear whether the reduced number of bleeds was the effect of the rFVIIa or partly due to the natural variation in bleeding over time seen in many patients with hemophilia. Furthermore, despite the statistically significant reduction in bleeds, the actual number of bleeds (mean 2 to 3 a month) remained high[59] and the clinical benefit of this is unclear.

A prospective randomized crossover study of FEIBA prophylaxis given at 85 U/kg 3 days a week also enrolled patients with significant numbers of bleeds.[62] The bleed rate on prophylaxis fell, but again the actual number of bleeds (median 3 hemarthroses in 6 months) remained high. At the present time, there is more published experience with FEIBA and the longer half-life of this product may make it a more practical option for many patients. It is, however, associated with anamnesis and should be avoided in those where ITI is planned. Patients who are proceeding to ITI should be managed with rFVIIa. A common initial dose is 90 μg/kg once daily. If bleeds continue despite this treatment, dose escalation has been shown not to be effective[59] and increasing frequency to twice daily is a more logical option.

Inhibitors in Mild Hemophilia

Patients with mild hemophilia A have a lower prevalence of inhibitors than those severely affected. Inhibitors in patients with mild hemophilia B are extremely rare. Inhibitors developing in mild hemophilia have been associated with intensive treatment especially at the time of surgery, and close surveillance of patients at this time is required.[63]

Some inhibitors cross-react with the patient's native FVIII and reduce their baseline FVIII level, resulting in a more severe bleeding phenotype. In these patients, bypassing agents are often required to manage bleeds. In patients in whom the antiFVIII antibody does not cross-react and whose baseline FVIII level is stable, a clinically useful response may be achieved with an infusion of Desmopressin, leading to the release of endogenous FVIII.[64]

There are limited data on inhibitor eradication in patients with mild hemophilia.

Factor IX

Treatment of patients with FIX inhibitors is complicated because allergic reactions to infused FIX are reported, and in some cases these can be very severe.[65] Furthermore, infused FIX is associated with the development of nephrotic syndrome.[66] FIX can be used in patients with a low-titer FIX inhibitor who do not experience allergic reactions. In patients with high-titer inhibitors, rFVIIa or FEIBA can be used. In patients with a history of allergic reactions to FIX, rFVIIa is the treatment of choice because FEIBA contains FIX. In general, patients with inhibitors to FIX respond less well to ITI than those with FVIII inhibitors, and the risk of nephritic syndrome is high.

CLINICALLY SIGNIFICANT INFECTIOUS COMPLICATIONS OF HEMOPHILIA TREATMENT

The availability of clotting factor concentrates (CFCs) made from large plasma pools from the mid-1970s changed the lives of hemophilia patients and the health care professionals involved in their care. There was tremendous mood of optimism as the modern replacement therapies alleviated the many of the worst problems of hemophilia, and the life expectancy for a man with hemophilia in the developed world had increased from 40 years in the 1960s to 69 years by 1980.[67] But effective treatment is rarely free from adverse effects, as the emergence of infectious complications of blood products and development of FVIII/FIX inhibitory antibodies became the next tragedy and clinical challenge for the hemophilia community.

HIV Infection

Hemophilia individuals have a significant risk of acquiring an infection from plasma even if the agent has a low prevalence rate as CFCs are produced from large plasma pools. Prior to 1985, there was no blood screening programs and no viral inactivation methods applied to the production of CFCs, and the true impact of transfusion-transmitted viral infections was not appreciated until the magnitude and consequences of the HIV epidemic in hemophiliacs became evident in the mid-1980s.

The first reports of *Pneumocystis carinii* pneumonia among patients with hemophilia appeared in the Morbidity and Mortality Report in 1982,[68] and only in April 1984 the major breakthrough for the discovery of HIV came about with the isolation of a human T lymphotropic retrovirus from cultured T lymphocytes of two brothers with hemophilia B.

The first HIV seroconversion in the United Kingdom in a man with hereditary bleeding disorder was in 1979,[69] and since 1986 no HIV infection has occurred through infusion of plasma-derived CFCs. The percentage of patients infected with HIV differs widely from country to country, and approximately 80% of severe hemophilia A patients were infected with HIV in the United States,[70] whereas in the United Kingdom during 1969 to 1985, 4,865 hemophilia individuals of all severity received nonheat-treated blood products and approximately 25% were infected with HIV.[71]

Initial treatment for HIV with azidothymidine monotherapy for patients with AIDS and AIDS-related complex[72] became available in 1987, but management of HIV was revolutionized with the advent of combination called highly active antiretroviral therapy (HAART) in 1996. Many hemophilic men died before HAART, and in the United Kingdom the death rate rose steeply from 8/1,000 in 1985 to 1992 in seronegative individuals to 81/1,000 in 1991 to 1992 in seropositive individuals.[73] The increased survival

tahir99-VRG & vip.persianss.ir

conferred by HAART has led to an increased risk of noninfectious comorbidities such as cardiovascular disease, diabetes mellitus, bone fractures, and renal failure seen as part of the metabolic toxicities of antiretroviral medications.[74]

HCV Infection

Hemophilia individuals who received CFCs during the 1970s and early 1980s before heat treatment was applied became infected with HCV on the first exposure, and these small cohort studies have shown that over 90% of individuals treated with nonvirus inactivated large pool concentrates became infected with HCV.[76,75,77]

HCV infection is self-limited in about 15% of cases where HCV PCR is negative in the setting of anti-HCV antibody positivity. The remaining 85% develop chronic hepatitis with viremia and abnormal liver function. Majority of hemophilia patients are infected with HCV genotype 1 infection, and current standard therapy achieves 50% sustained virological response for genotype 1 and 80% for genotype 2 and 3. There is encouraging evidence from phase 2/3 trials, indicating that the addition of a protease inhibitor (e.g., telaprevir and boceprevir) to pegylated interferon-α/ribavirin substantially improves sustained virologic response rates in both treatment-naïve and treatment-experienced patients with HCV genotype 1.

Yee et al.[78] have shown HIV-HCV coinfected patients have a progression of 19% to liver-related death after 25 years and HCV monoinfection has a slow progression rate of 3% to a liver-related death. As hemophilia patients continue to grow older, clinicians will be challenged with end-stage liver disease, hepatocellular carcinoma, and the need for liver transplantation. Consequently, eradication of these hepatitis viruses with antiviral agents and chemoprevention methods may decrease the risk of end-stage liver disease and hepatocellular carcinoma.

HIV-HCV coinfection is not a contraindication for liver transplant, and recent data from a London liver transplant unit revealed the median age for liver transplant in 18 HCV infected hemophilia patients was 52 years and the median survival of patients with and without HIV coinfection was 26 and 118 months, respectively.[79]

HBV Infection

Most individuals treated before the introduction of donor screening for hepatitis B virus (HBV) in 1972 were exposed to HBV (MRC report BJH 1974), and about 2% of HBV-exposed hemophilia patients developed persistent HBs Ag-positive infection.[80] Routine HBV and HAV vaccines are given to all patients diagnosed with a bleeding disorder.

Parvovirus Infection

Parvovirus B19 is a ubiquitous DNA virus infecting up to 50% of people by the age of 15 years. This prevalence, combined with its small size, which makes filtration difficult, and its resistance to inactivation by available virucidal processes, has led to the transmission of Parvovirus B19 by plasma-derived factor replacement products used to treat hemophilia.[81] Parvovirus B19 has been found in recombinant (non–plasma-derived) FVIII products as well, most likely introduced by the albumin used as a stabilizer.[82] Continued surveillance and studies are warranted to reduce the risk of Parvovirus B19 being spread by blood products.

Variant Creutzfeldt-Jakob Disease

vCJD is caused by a prion protein (PrP) and manifests as the human counterpart of bovine spongiform encephalopathy (BSE). The BSE incidence peaked in 1993, and its rapid spread throughout United Kingdom resulted in clinical cases of vCJD attributable to dietary exposure. It is from a group of individuals harboring asymptomatic subclinical vCJD infection donating blood that the risk of secondary transmission arises for the individuals with bleeding disorders receiving blood and blood products. To date, there have been no cases of transmission of vCJD by blood products in the United States and no case of clinical vCJD has been identified in any hemophilia patients who have received implicated batches of UK plasma products. Recent detection of PrP in the spleen of a patient with hemophilia who had received implicated UK sourced FVIII concentrates but showing no evidence of a neurological disorder has raised anxiety in the hemophilia cohort. As there is no validated screening test for vCJD and the prevalence of subclinical vCJD infection in the general population remains unknown, continued surveillance of individuals "at risk" and widespread public health measures need to continue.

ORGANIZATION OF HEMOPHILIA CARE

By localizing hemophilia care at treatment centers, a sufficient critical mass of patients is gathered to attract and justify the specialized attention of a range of health care professionals. The first and minimal requirement for such a center is an interested physician with access to a laboratory capable of making accurate diagnosis with specific factor assays. Once a location for a hemophilia centre has been established and the patient register started, it is time to support the physician with specialist nursing and physiotherapy professionals and therapeutic factors. Other professionals whose services to the hemophiliac and his family are needed include orthopedic surgery, infectious disease, hepatology, psychology, and genetics. In the United Kingdom, such facilities are designated "comprehensive care centres" if they have registered a target number of severely affected patients (at least 40) and offer a full range of staff and services. A hub and spoke model of centre organization serves to facilitate access for patients living across a geographically dispersed region. Central collection of national statistics of hemophilia treatment enables planning at government level of service delivery and enables monitoring of progress in hemophilia care.

NEW THERAPEUTIC AGENTS IN DEVELOPMENT

The golden era of cloning the genes for the coagulation factors spanned the 1980s with FVIII cloned in 1984, FIX in 1983, and FVII in 1986. There is now a ferment of activity in the area of hemostatic drug development with biosimilar and modified versions of all three factors on trial. These products include versions of FVIII and FIX with prolonged half-life obtained by addition of polyethylene glycol to the protein, or fusion of the clotting factor with albumin or with Fcγ. The best prolongation of half-life has been reported for glycopegylated FIX with a half-life of over 90 hours. If such a product can be used safely for prophylaxis then regimes of dosing every 3 weeks become possible[83,84] (FIGURE 51.6).

tahir99-VRG & vip.persianss.ir

Another route to hemostasis in hemophilic blood would be to reduce the strength of natural coagulation inhibitors that shut down the extrinsic pathway, in particular tissue factor pathway inhibitor, since this pathway is normal in hemophilia A and B. Proof of concept for this approach has been obtained in *ex vivo* studies,[85] but human trials have not been started at the date of this writing.

GENE THERAPY FOR HEMOPHILIA

Hemophilia was seen as early as the 1980s to be a suitable target for gene therapy, because the missing protein only has to be produced in low amounts that do not need tight regulation to achieve a beneficial effect. Mice and dogs with both hemophilia A and B have been successfully cured of hemophilia using a variety of gene vectors.[86] Clinical studies of gene therapy in humans with hemophilia have been safe but not efficacious until this year when an Anglo-American group reported on a study in hemophilia B using an adeno-associated virus vector.[87] Of the first six subjects so treated, who each had severe hemophilia B, all have been converted to moderate or mild hemophilia B phenotype. Correction of bleeding tendency has been sustained for up to 18 months due to a rise in steady-state level of FIX in the range of 2% to 6%, achieved without serous toxic side effects.

CHAPTER

52

von Willebrand Disease: Diagnosis, Classification, and Treatment

J. EVAN SADLER AND DAVID LILLICRAP

von Willebrand disease (vWD) was discovered by Erik von Willebrand,[1,2] a Finnish internist who investigated a family living in Föglö, one of the Åland Islands in the Gulf of Bothnia, separating Sweden and Finland. The proband was a 5-year-old girl with a severe bleeding tendency. Four of her affected sisters died of hemorrhage before the age of 4 years, and the proband herself died at the age of 13 years with her 4th menstrual period.[3] The parents and several other relatives of both sexes had mild bleeding symptoms, suggesting autosomal inheritance. The severity of bleeding was variable throughout this large pedigree, and some obligate heterozygous individuals were asymptomatic. The most common sites of bleeding were skin, uterus, and mucous membranes rather than deep tissues. Patients had a prolonged bleeding time, but had normal coagulation time, clot retraction, and platelet count. von Willebrand distinguished this condition from hemophilia and Glanzmann thrombasthenia but was unable to determine whether the defect lay in the blood, the vasculature, or the platelets.

Considerable progress has been made in understanding the pathophysiology of vWD. In the 1950s, patients with vWD were reported to have low levels of blood clotting factor VIII (FVIII), and transfusions with plasma fractions from healthy individuals or patients with hemophilia were shown to correct the bleeding tendency in vWD.[4–8] These observations suggested that vWD was caused by abnormalities in a plasma protein, now known as von Willebrand factor (vWF). In 1972, vWF was purified,[9] and genetic variants of vWD were identified and correlated with structural differences in vWF.[10] The development of multimer gel electrophoresis[11,12,13] uncovered additional heterogeneity in vWD. In 1985, the structure of vWF was determined by protein sequencing and cDNA cloning.[14–17] This was followed almost immediately by the characterization of mutations that cause severe vWD.[18,19] Today, hundreds of mutations in many subtypes of vWD have been described.[20,21] An online database of vWD mutations is maintained by the International Society on Thrombosis and Haemostasis at the University of Sheffield and is accessible at http://www.vwf.group.shel.ac.uk/index.html.

We now understand many aspects of vWF biosynthesis, structure, and function, as discussed in Chapter 13. vWF is a multimeric blood protein that performs two major roles in hemostasis; it mediates the adhesion of platelets to sites of vascular injury and it is a carrier protein for FVIII. These activities require the assembly of vWF into large multimers and interactions with several ligands. Inherited defects in vWF may interfere with biosynthetic processing, or disrupt specific ligand-binding sites, thereby causing bleeding by impairing either platelet adhesion or blood clotting. Depending on the disease mechanism, vWF mutations may cause autosomal dominant or recessive vWD. This knowledge provides a framework to understand the pathogenesis and classify the many variants of vWD.

DIAGNOSIS AND CLASSIFICATION OF VON WILLEBRAND DISEASE

Three major categories of vWD are distinguished: partial quantitative deficiency (type 1), qualitative deficiency (type 2), and total deficiency (type 3) (see Table 52.1).[22,23] Qualitative type 2 vWD is divided further into four variants (2A, 2B, 2M, and 2N) on the basis of details of the clinical phenotype. These six categories correspond to distinct pathophysiologic mechanisms and they correlate with distinct clinical features and therapeutic requirements, as discussed in a subsequent section. The laboratory features of vWD subtypes are summarized in Table 52.2.

von Willebrand Disease Type 1

vWD type 1 includes partial quantitative deficiency of vWF and is commonly inherited as an autosomal dominant trait. vWD type 1 accounts for more than 70% of all vWD, although the prevalence of vWD type 1 is not known precisely. Symptomatic vWD that leads to medical treatment affects approximately 35 to 100 per million individuals, which is comparable to the prevalence of hemophilia A.[24] Screening programs often identify many more individuals with low vWF and mild symptoms and suggest that vWD could have a prevalence of approximately 1%,[25] but very few patients identified by population screening subsequently have significant bleeding.[26] Finally, screening patients attending the offices of primary care physicians has indicated a prevalence of symptomatic vWD of approximately 1 in 1,000.[45] vWD type 1 includes variants previously designated as type IA[27]; type I-1, I-2, and I-3[28]; type I-platelet normal and type I-platelet low[29]; and vWD Vicenza. vWD Vicenza was formerly classified as vWD type 2M, but the consensus now favors classifying it as vWD type 1. Most studies indicate that vWF Vicenza has a normal vWF function/antigen ratio (vWF:RCo/vWF:Ag),[30,31] but some suggest the protein is dysfunctional.[32]

Many factors make vWD type 1 difficult to diagnose with confidence. Mild bleeding symptoms are sufficiently common that coincidental association with low vWF levels also is frequent, even when patients have a positive family history of bleeding.[33] Furthermore, bleeding symptoms are not specific for vWD, and apparent transmitters of low vWF or a bleeding phenotype may themselves be phenotypically normal. Therefore, the criteria used for diagnosis are important determinants of the apparent prevalence of vWD type 1.

tahir99-VRG & vip.persianss.ir

Table 52.1

Classification of vWD

Type	Description
1	Partial quantitative deficiency of vWF
2	Qualitative vWF defects
2A	Decreased vWF-dependent platelet adhesion and a selective deficiency of high molecular weight vWF multimers
2B	Increased affinity for platelet GPIb
2M	Decreased vWF-dependent platelet adhesion without a selective deficiency of high molecular weight vWF multimers
2N	Markedly decreased binding affinity for FVIII
3	Virtually complete deficiency of vWF

vWF, von Willebrand factor.
From Sadler JE, Budde U, Eikenboom JC, et al. Update on the pathophysiology and classification of von Willebrand disease: a report of the Subcommittee on von Willebrand factor. *J Thromb Haemost* 2006;4(10):2103–2114.

Bleeding Symptoms

Few large studies of symptoms in vWD have been published, and they rarely distinguish among subtypes of vWD. For example, the extensive compilations of Silwer[34] and of Buchanan and Leavell[35] include patients with all variants of vWD. Because other variants are relatively uncommon, these surveys remain useful guides to the clinical features of vWD type 1. The most common symptoms (see Table 52.3) are epistaxis, skin bruises, hematomas, prolonged bleeding from trivial wounds, oral cavity bleeding, and excessive menstrual bleeding. Gastrointestinal bleeding appears to be relatively rare, but may be serious when it occurs.

Epistaxis may be severe and prolonged. Easy bruising is common in vWD. Prolonged bleeding after minor trauma to skin or mucous membranes is characteristic of vWD. Severe hemorrhage after major surgery may continue for several weeks. Prolonged oral bleeding is common from gums, or with biting of the tongue or lips. Heavy bleeding is also common after tooth extraction or other oral surgery such as tonsillectomy and adenoidectomy. Menorrhagia is a typical presenting symptom in women with vWD, but is also frequent in otherwise healthy women.[34]

Coexistent conditions or drug interactions can strongly influence the severity of symptoms in vWD. Bleeding may be exacerbated by the use of aspirin or corticosteroids and decreased by the use of oral contraceptives. Treatment with sodium valproate for epilepsy can lower the level of vWF and induce bleeding.[36] The risk of hemorrhage may be increased by liver disease, uremia, defects in connective tissue such as Ehlers-Danlos syndrome,[37] hypothyroidism,[38] and focal lesions such as gastric or duodenal ulcers, or gastrointestinal angiodysplasia.[39]

Standardized questionnaires have been developed to describe and quantitate bleeding symptoms.[40,41] These assessment tools are being refined and validated for prospective use with pediatric and adult patients to diagnose vWD.[42,43–45] These tools may help direct the intensity of laboratory investigation and also facilitate communication of the bleeding severity between health care professionals.

Laboratory Testing

The goal of laboratory testing in vWD type 1 is to exclude other causes of bleeding, document vWF deficiency, and exclude qualitative vWF defects. As a complete laboratory evaluation for vWD is quite elaborate, the efficiency of testing can be increased by using initial screening tests for vWD. vWF levels vary with physiologic

Table 52.2

Selected laboratory features of vWD subtypes

vWD	FVIII	vWF:Ag	vWF:RCo or vWF:CB	RIPA	Multimer Structure
Type 1	Decreased	Decreased	Decreased	Decreased	Normal in plasma and platelets
Type 2A	Decreased or normal	Decreased or normal	Decreased relative to vWF:Ag	Decreased relative to vWF:Ag	Large and intermediate multimers absent from plasma; variable in platelets
Type 2B	Decreased or normal	Decreased or normal	Decreased or normal	Increased at low ristocetin concentration	Large and intermediate multimers absent from plasma; normal in platelets
Type 2M	Decreased or normal	Decreased or normal	Decreased relative to vWF:Ag	Decreased relative to vWF:Ag	Large and intermediate multimers present in plasma and platelets
Type 2N	Moderately decreased (<20 IU/dL)	Normal	Normal	Normal	Normal in plasma and platelets
Type 3	Moderately decreased (<20 IU/dL)	Absent or trace	Absent	Absent	None or trace in plasma or platelets

vWD, von Willebrand disease; vWF, von Willebrand factor; RIPA, ristocetin-induced platelet aggregation.

[c]For women older than 15 years.

stress, and where possible, tests should not be performed in proximity to hemorrhagic events, pregnancy, acute infection, or strenuous exercise. Optimal testing strategies have not yet been validated experimentally, and the approach described here is an attempt to synthesize various expert opinions.

Initial tests for any hemostatic disorder include a complete blood count with platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT). Additional tests specific for vWD include ristocetin cofactor activity (vWF:RCo), collagen-binding activity (vWF:CB), vWF antigen (vWF:Ag), and FVIII level.

vWF:RCo is a useful initial assay for vWF concentration and platelet-binding function,[25] but the test is difficult to standardize and is not very precise. Therefore, vWF:Ag may be used to confirm low values for vWF:RCo. Like the vWF:RCo test, vWF:CB also depends on vWF concentration but measures the interaction of vWF with immobilized collagen. vWF:CB tests are not as widely available as vWF:RCo, but are useful for a comprehensive evaluation of vWF functional defects.[46,47]

Discrepancies between vWF:RCo and vWF:Ag, or between vWF:CB and vWF:Ag, suggest a qualitative vWF defect that should be investigated along with other tests, as discussed in the section, *von Willebrand Disease Type 2*. However, some common vWF sequence variations affect the vWF:RCo assay. For example, African Americans have relatively decreased vWF:RCo, and this variation is explained by differences in the frequency of the vWF Asp1472His polymorphism. vWF 1472His has normal hemostatic function but decreased vWF:RCo compared to vWF 1472Asp. vWF 1472His occurs in 19% of whites and 62% of African Americans, which accounts for the observed differences in vWF:RCo/vWF:Ag between these populations and can lead to the overdiagnosis of vWD type 2M.[48] The vWF mutation Pro1467Ser also profoundly decreases vWF:RCo/vWF:Ag (<0.1) with no impairment of hemostasis.[49] Conversely, the polymorphism Ala1381Thr modestly increases vWF:RCo.[50] Mutations associated with vWD type 2B Malmö/New York may also belong to this category.

tahir99-VRG & vip.persianss.ir

vWF levels may be normal intermittently in vWD, and abnormal results should be confirmed.[51] For example, the PT, aPTT, FVIII, and vWF tests may be repeated after an interval of 2 weeks. If the results are inconsistent, they may be performed again. Unfortunately, such repeated testing is impractical or not feasible for many patients. With the limitations discussed in the subsequent text, vWD is excluded by arriving at repeated normal values of FVIII and concordant vWF:RCo, vWF:CB, and vWF:Ag on serial testing. If these initial tests are abnormal, other tests are indicated.

An abnormal aPTT is evaluated in concert with the FVIII level. An FVIII that is disproportionately lower than the vWF:Ag would suggest either hemophilia A, a defect that impairs vWF ability to bind FVIII (vWF:FVIIIB) as occurs in vWD type 2N, or another cause of FVIII deficiency such as an antibody against FVIII. If the FVIII is normal, then other causes of a prolonged aPTT should be considered.

Low values for vWF by any test can be hard to evaluate because the range of normal values for plasma vWF concentration is very broad. vWF levels also depend on ABO blood type (see Table 52.4), and the mean vWF:Ag level is approximately 25% lower for individuals of blood type O compared to other blood types.[52] Some additional variation has been attributed to the secretor locus that specifies some oligosaccharide antigens of the Lewis blood group system.[53,54] However, most of the variation in vWF levels is due to unknown factors other than either vWD or blood type. The problem is illustrated in FIGURE 52.1, using data for blood type O. For this population of normal type O blood donors, the mean level of vWF:Ag was 86 IU/dL, with a range (±2 SD) of 41 to 179 IU/dL.[52] Therefore, blood type O alone can cause vWF levels low enough to suggest the diagnosis of vWD. By halving the values for this normal population, the distribution for individuals of blood type O and only one functional vWF allele can be estimated to have a mean vWF:Ag of 43 IU/dL (see FIGURE 52.1), but there is considerable overlap with the normal distribution. Because individuals heterozygous for vWD mutations constitute much <1% of the population,[24]

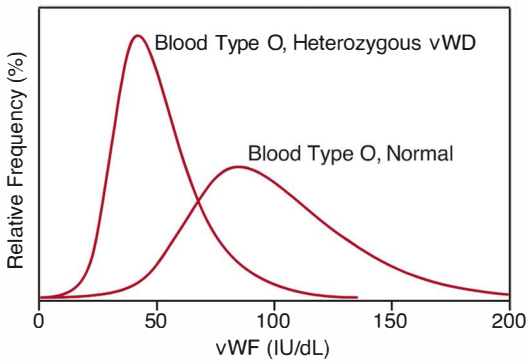

FIGURE 52.1 Distribution of vWF:Ag levels in normal blood donors of blood type O and hypothetical distribution of vWF:Ag levels in individuals of blood type O who are heterozygous for vWF null alleles. The reference normal value of 100 IU/dL is based on the World Health Organization standard pooled plasma. (Adapted from tabulated data of Gill JC, Endres-Brooks J, Bauer PJ, et al. The effect of ABO blood group on the diagnosis of von Willebrand disease. *Blood* 1987;69:1691–1695.)

Table 52.4

Influence of ABO blood groups on vWF:Ag in volunteer blood donors

		vWF:Ag (Percentage of Pooled Normal Plasma Standard)	
ABO Type	n	Geometric Mean IU/dL	Geometric Mean ± 2 SD IU/dL
O	456	86	41–179
A	340	121	55–267
B	196	134	65–275
AB	109	141	73–271

The groups were statistically different from each other as follows: O versus A, B, and AB, $P < 0.01$; A versus AB, $P < 0.01$; B versus A, $P < 0.05$.
vWF, von Willebrand factor.
Modified from Gill JC, Endres-Brooks J, Bauer PJ, et al. The effect of ABO blood group on the diagnosis of von Willebrand disease. *Blood* 1987;69:1691–1695. The modified table includes vWF:Ag values converted to WHO international units per deciliter (IU/dL).[23]

moderately low vWF levels cannot reliably identify patients with vWD type 1. Whether blood type–adjusted means should be used routinely remains controversial, but it seems increasingly likely that the ABO blood type is one of perhaps many genetic modifiers that influence vWF plasma levels. In these initial tests, comparison of functional assays with the level of vWF:Ag must not suggest a qualitative abnormality of vWF, as discussed in the section on vWD type 2. If available, ristocetin-induced platelet aggregation (RIPA) should not indicate abnormal sensitivity to ristocetin, and the plasma vWF multimer distribution should have a normal complement of large multimers.

The template bleeding time has been used to diagnose vWD, but its value for this purpose is difficult to demonstrate. A prolonged bleeding time is not specific for vWD, and does not predict bleeding at surgery.[55–57] The bleeding time is subject to even greater normal variation than vWF levels, has poor reproducibility, and often is normal in vWD.[51] The test can distinguish populations that are defined independently, but generally it is not useful when applied to individuals. The bleeding time may be helpful for assessing the efficacy of therapeutic interventions in selected patients with vWD, but it does not appear to have sufficient sensitivity or reproducibility to contribute strongly to the diagnosis or exclusion of vWD. With all of these considerations, performance of the bleeding time has now been discontinued in many institutions.

A platelet function analyzer (PFA)-100 has been developed to test platelet plug formation *in vitro* by forcing a sample of citrated whole blood at high shear through a porous membrane coated with collagen plus adenosine 5′-diphosphate or collagen plus epinephrine. Normal platelets become activated upon contact with the membrane and form occlusive aggregates. The time required for blood flow to stop is termed the closure time, which is prolonged by defects in vWF or platelet function. The PFA-100 has been proposed as a sensitive and reproducible alternative to the bleeding time, but lack of specificity remains a concern and the clinical utility of PFA-100 testing remains uncertain.[58–60] As previously reported for the bleeding

tahir99-VRG & vip.persianss.ir

time,[55–57] a prolonged PFA-100 closure time was not found to predict increased surgical bleeding.[61]

Other vWF tests may be performed in specialized diagnostic or research laboratories. Approximately 15% of vWF in the blood is located within the α-granules of platelets and is secreted upon platelet activation.[62] Platelet vWF can be assayed by methods similar to those used for plasma vWF, and the results can help identify some variants of vWD type 1.[29] Botrocetin is a snake venom protein that binds vWF.[63,64] Like ristocetin, botrocetin induces high-affinity binding to platelet glycoprotein (GP) Ibα. Tests of botrocetin-induced platelet aggregation or "botrocetin cofactor activity" have been developed that are analogous to vWF assays employing ristocetin, although botrocetin and ristocetin affect vWF function by distinct mechanisms.[65] A variant of the vWF:RCo assay has been described that replaces platelets with recombinant, gain-of-function GPIbα immobilized on microtiter plates. This enzyme-linked immunosorbent assay style test is very precise and sensitive compared to conventional vWF:RCo assays[66] but is not yet available commercially.

Criteria for Diagnosis of von Willebrand Disease Type 1

No matter what criteria are used, the extreme range of normal vWF levels complicates the diagnosis of vWD type 1, and a satisfactory general answer to this dilemma has not yet been devised. Because of this diagnostic uncertainty, the risk and benefit of specifically diagnosing vWD type 1 should be balanced for each patient.

The diagnosis of vWD type 1 is easy to make when the patient has significant mucocutaneous bleeding, the vWF level is clearly low (e.g., <30 IU/dL), and the family history is strongly positive with high penetrance. Such families usually show clear coinheritance of low vWF with bleeding symptoms, and usually, mutations in the vWF gene can be found.[29,67–69,70–74] For these patients, a diagnosis of vWD type 1 seems appropriate because they often can benefit from changes in lifestyle, or from specific treatment to prevent or control bleeding. Also, genetic counseling is straightforward when the inheritance of the disorder can be predicted with confidence. Unfortunately, this combination of features is relatively rare.

More commonly, patients have a medical history of only menorrhagia or other infrequent mild bleeding, their vWF levels are borderline low (e.g., 30 to 50 IU/dL), and their family members do not consistently have either low vWF or bleeding symptoms. In such cases, low vWF level and bleeding are likely to associate coincidentally rather than causally.[33] Family studies usually show that bleeding symptoms and low vWF levels are not coinherited, and linkage to the *vWF* gene cannot be demonstrated.[26,41,70–74,75,76] vWF levels that are slightly more than 2 SD below the population mean confer a relatively small relative risk of menorrhagia or other bleeding[33,77,78] and do not correlate with increased bleeding at surgery.[79] To label these patients as vWD type 1 has little clinical utility. It may, in fact, harm them by affecting their relationship with employers and insurance providers, by causing unnecessary changes in lifestyle, and by inducing unjustified fear of transmitting a genetic disease. A modestly low vWF level may be treated instead, as a biomarker for modestly increased bleeding risk. Empiric therapy to raise vWF may be considered for these patients with low vWF if they should bleed.

Molecular Defects in von Willebrand Disease Type 1

Recent studies have indicated that vWD type 1 is associated with candidate mutations at the *vWF* locus in approximately 65% of cases.[71,73,74] There is significant allelic heterogeneity, with >100 different mutations being documented to date. Missense mutations predominate, with the Tyr1584Cys substitution being the most frequent variant reported, showing a prevalence of 5% to 15% in different populations.[71,73,74] This mutation is associated with a mild phenotype (vWF:Ag ~40 IU/dL in heterozygotes), usually accompanies blood type O, and has a penetrance of approximately 70%.[80]

vWD type 1 can occasionally be caused by frameshifts, nonsense mutations, or deletions that are similar or identical to mutations found in patients with vWD type 3.[81–83] As first shown by Erik von Willebrand, some heterozygous members of such families may not have bleeding symptoms, so that possession of a single such mutant allele does not consistently cause bleeding symptoms. Variation in symptoms may be due to chance coinheritance of a second mutated vWF allele. For example, in two families in the Netherlands, compound heterozygosity for vWD type 1 and vWD type 2N was found in patients with substantial bleeding, whereas relatives with either single mutant allele were asymptomatic.[84]

vWD type 1 sometimes is inherited as an autosomal dominant trait with very high penetrance, and this strongly dominant phenotype is usually associated with missense mutations.[70–74] Many of these missense mutations cause intracellular retention of mutant vWF subunits.[85] In one family, a Cys1149Arg missense mutation was identified that caused the retention of mutant subunits in the endoplasmic reticulum and also inhibited the secretion of normal vWF subunits, possibly by causing the intracellular retention of heterodimers between mutant and normal subunits.[86,87] Another missense mutation at a cysteine residue, Cys1130Arg, was found in two other families with a similar dominant phenotype, although the effect on vWF biosynthesis was not reported.[86] Two independent mutations that cause the heterozygous deletion of vWF exons 4 to 5 were shown to dominantly inhibit the secretion of normal vWF.[88] This dominant mechanism provides a plausible biochemical explanation for the transmission of exceptionally low vWF levels and bleeding symptoms with high penetrance.

Quantitative vWF deficiency also can be caused by mutations that lead to the increased clearance of vWF from the blood, provided that the clearance mechanism does not exhibit a strong preference for large multimers.[89,90,91] For example, the mutation Arg1205His causes vWD Vicenza, which is characterized by vWF:Ag < 15 IU/dL and plasma vWF multimers that are sometimes even larger than those found in normal plasma. vWF Vicenza appears to be cleared from the blood approximately fivefold more rapidly than normal vWF.[31] It has been proposed that these accelerated clearance variants, which comprise approximately 15% of type 1 vWD cases, be subclassified as vWD type 1c.[89]

Other mutations resulting in vWD type 1 may be located in *vWF* introns or in distant regulatory elements. Furthermore, the results of a large genome-wide association study meta-analysis indicate that several genes involved in storage organelle formation and protein clearance functions are strongly associated with plasma vWF levels.[92] Variation at these novel loci may act as primary causative mutations or genetic modifiers in vWD type 1.

von Willebrand Disease Type 2

For vWF to perform its hemostatic functions, it must be assembled into large multimers, and functional binding sites must be constructed for FVIII, for platelet receptors, and for ligands in

tahir99-VRG & vip.persianss.ir

connective tissue. Mutations in vWD type 2 can disrupt any of these properties, and vWD type 2 accounts for between 7% and 30% of all vWD in various reports. Such qualitative abnormalities of vWF often are associated with discrepancies between the level of vWF:Ag and functional assays such as vWF:RCo, vWF:CB, or vWF:FVIIIB. Four subtypes are currently recognized (Tables 52.1 and 52.2). The prevalence of the subtypes appears to be increasing as awareness of them increases, although the distribution of subtypes differs considerably among treatment centers. A survey in France found that patients with vWD type 2 were divided as 30% type 2A, 28% type 2B, 8% type 2M (or unclassified), and 34% type 2N.[93] A similar study in Germany found 74% type 2A, 10% type 2B, 13% type 2M, and 3.5% type 2N.[94]

Discrimination between qualitatively normal vWF and abnormal vWF can be difficult by laboratory testing, especially because vWF:RCo assays become somewhat unreliable when the vWF:Ag level is <20 IU/dL. A common strategy is to compare values obtained in functional assays (vWF:RCo, vWF:CB, vWF:FVIIIB) with vWF:Ag; a ratio <0.6[95] or <0.7[96,97] is inferred to be abnormal, and a ratio larger than the selected value is interpreted as normal. This approach seems reasonable, although the sensitivity and specificity of a particular ratio would depend on the performance characteristics of the individual assays. The discriminant power of vWF multimer analysis is also a significant determinant of vWD type 2 diagnosis.

von Willebrand Disease Type 2A

A disproportionately low vWF:RCo or vWF:CB, relative to vWF:Ag, may reflect decreased affinity of vWF for platelets or collagen, respectively. The most common cause of this defect is the absence of large vWF multimers (see FIGURE 52.2), which is characteristic of vWD type 2A. This subtype can be diagnosed by the combination of markedly reduced vWF:RCo or vWF:CB and compatible multimer gel analysis (FIGURE 52.2). vWD type 2A appears to account for most of vWD type 2.[98] vWD type 2A includes variants previously designated as type IIA[12]; type IIA-1, IIA-2, and IIA-3[28]; type I-platelet discordant[29]; type IB[27]; type IIC[99]; type IID[100]; type IIE[101]; type IIF[102]; type IIG[103]; type IIH[104]; and type II-I.[105]

vWD type 2A usually is a dominant disorder and is caused in approximately 80% of cases by single amino acid substitutions in or near domain A2 (residues 1,480 to 1,672) of the mature vWF subunit[20] (see FIGURE 52.3). These mutations lead to the absence of large vWF multimers either by impairing intracellular multimer assembly or by promoting intravascular proteolysis of vWF.[106] Some mutations may cause vWD type 2A by a combination of these mechanisms. Defects in multimer assembly produce an absence of large multimers in both plasma and platelet vWF. In contrast, increased susceptibility to proteolysis selectively depletes the large multimers of plasma vWF because

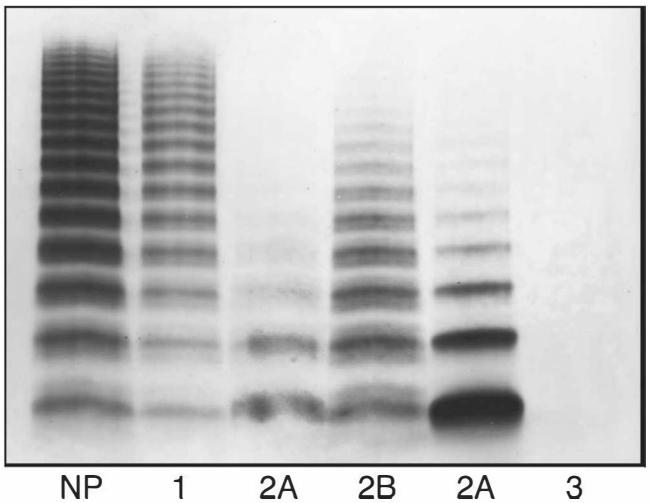

FIGURE 52.2 Multimer patterns in vWD. Samples of plasma from a normal individual (*N*) and from patients with vWD type 1, type 2A (two unrelated patients), type 2B, and type 3 were electrophoresed through a 1.3% agarose/sodium dodecyl sulfate (SDS) gel and von Willebrand factor (vWF) was detected by Western blotting. (Reprinted from Sadler JE. von Willebrand disease. In: Bloom AL, Forbes CD, Thomas DP, et al., eds. *Haemostasis and thrombosis*, 3rd ed. Edinburgh, UK: Churchill-Livingstone, 1994:843–857, with permission.)

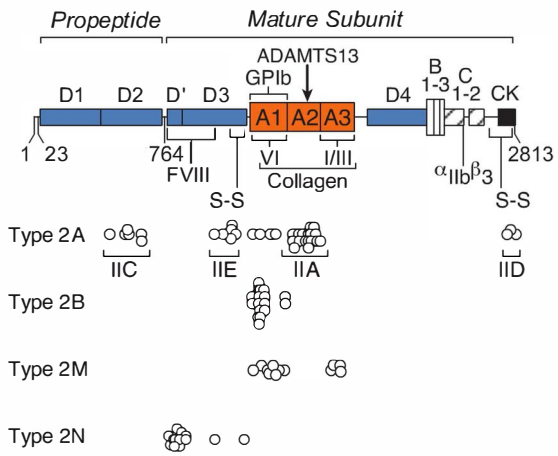

FIGURE 52.3 Mutations in vWD type 2. Amino acid residues are numbered by codon number 1 to 2,813 for prepro-vWF. The signal peptide contains residues 1 to 22, the propeptide contains residues 23 to 763, and the mature subunit contains residues 764 to 2,813. The locations of conserved structural domains (A, B, C, D, and CK) are indicated. Intersubunit disulfide bonds (not shown) connect CK to CK domains and D3 to D3 domains. The locations of binding sites are indicated for FVIII, platelet glycoprotein (GP)Ib, collagen, and platelet $\alpha_{IIb}\beta_3$. The metalloprotease ADAMTS13 cleaves a Tyr–Met bond in domain A2 (*arrow*). *Circles* mark the positions of mutations that cause the vWD phenotypes noted at the left. For vWD type 2A, the *labeled brackets* show the location of mutations that correspond to variants with characteristic multimer patterns discussed in the text. These include variants with increased sensitivity to proteolysis (*IIA*) or defective multimer assembly due to mutations in the propeptide (*IIC*), the D3 domain (*IIE*), or the CK domain (*IID*). References to the individual mutations can be found in the database of vWD mutations[20] maintained by the International Society on Thrombosis and Haemostasis at the University of Sheffield and accessible at http://www.shef.ac.uk/vwfvwf.group.shel.ac.uk/index.html. (Adapted from White GC II, Sadler JE. Von Willebrand disease: clinical aspects and therapy. In: Hoffman R, Benz EJ, Shattil SJ, eds. *Hematology: basic principles and practice*, 4th ed. Philadelphia, PA: Elsevier Churchill Livingstone, 2005:2121–2136, with permission.)

tahir99-VRG & vip.persianss.ir

platelet vWF is relatively protected from proteolysis. The plasma metalloprotease, a disintegrin and metalloprotease with thrombospondin type 1 motifs member 13 (ADAMTS13), cleaves the Tyr1605–Met1606 bond within domain A2 of vWF,[107,108] and this cleavage accounts for the major proteolytic fragments of the vWF subunit that are found in plasma vWF.[109] Mutations that increase the susceptibility of vWF to ADAMTS13 cause the loss of large, hemostatically effective multimers from plasma and result in bleeding. Conversely, deficiency of ADAMTS13 causes thrombotic thrombocytopenic purpura associated with unusually large vWF multimers, as discussed in Chapter 99.

A similar dominant phenotype is caused by mutations within the cystine knot motif at the carboxyl terminus of the vWF subunit. These mutations disrupt the initial dimerization of pro-vWF subunits in the endoplasmic reticulum. The mutant subunits remain capable of forming disulfide bonds in the Golgi apparatus, and the vWF found in the blood consists of small multimers comprised mainly of an even number of subunits, with prominent abnormal intermediate bands composed of an odd number of subunits.[110–113] vWD type 2A caused by mutations in the cystine knot domain corresponds to the variant originally named "type IID" (FIGURE 52.3).[100,114]

vWD type 2A also may result from defective multimerization within the Golgi. Mutations in the D3 region can cause a dominant phenotype characterized by small multimers that are indistinct or "smeary," suggesting heterogeneity of the disulfide bond arrangements that probably is caused by disruption of normal intersubunit disulfide bond formation.[94,111,113] These mutations correspond to the variant, originally named "type IIE" (FIGURE 52.3).[101] A recessive form of vWD type 2A is caused by mutations within the vWF propeptide that impair the assembly of disulfide bond–linked multimers (FIGURE 52.3).[113,115–118] The small plasma vWF multimers in these patients are characterized by an exceptionally clean appearance, lacking the usual intermediate or "satellite" bands that are associated with proteolysis *in vivo*; these mutations correspond to the variant originally named "type IIC."[99,101]

These studies indicate that vWD type 2A can be caused by several distinct defects in vWF biosynthesis or proteolytic susceptibility, and some can be distinguished by multimer gel electrophoresis. These various defects are united, however, by a common mechanism of impaired hemostasis resulting from the absence of large vWF multimers, and currently, they cannot be distinguished clinically by differences in severity of bleeding or response to therapy.

von Willebrand Disease Type 2B

The mutant vWF in vWD type 2B has increased affinity for binding to GPIbα on platelets.[12] This defect causes spontaneous binding of large vWF multimers to platelets *in vivo*, followed by removal of the large vWF multimers and a variable decrease in the platelet count. The remaining small multimers are not hemostatically effective, and patients with vWD type 2B have a bleeding diathesis that may seem disproportionately severe for their vWF level. Thrombocytopenia in vWD type 2B can be intermittent and is frequently exacerbated by stress factors, such as infection or pregnancy.[119–124] vWD type 2B has been misdiagnosed and treated as autoimmune thrombocytopenia.[120–122,124–127] vWD type 2B includes variants previously designated as vWD type IIB,[12] type I New York,[128] and Malmö.[129]

The results of initial laboratory tests may be difficult to interpret in vWD type 2B. vWF levels occasionally are in the normal range, but vWF:Ag usually is decreased.[12] vWF:RCo is usually decreased more than vWF:Ag, suggesting a diagnosis of vWD type 2A. Less commonly, vWF:Ag and vWF:RCo are decreased proportionately, which suggests a diagnosis of vWD type 1. In most cases of vWD type 2B, the plasma vWF lacks the largest multimers, and multimer gels do not reliably distinguish vWD type 2B from vWD type 2A (FIGURE 52.2).

The diagnosis of vWD type 2B depends on the results of RIPA. In platelet-rich plasma (PRP) from normal controls, RIPA requires vWF and exhibits a characteristic dose response to ristocetin (see FIGURE 52.4). In vWD type 2B, brisk platelet aggregation occurs at low concentrations of ristocetin that has little or no effect on PRP from normal controls.[12] Positive results in this test are found in one other rare disease, platelet-type or pseudo-vWD, in which mutations in platelet GPIbα cause a gain-of-function phenotype very similar to vWD type 2B. Increased RIPA at low ristocetin concentrations is sensitive and fairly specific for vWD type 2B. The RIPA test is not sensitive to moderate decreases in vWF concentration[130] and therefore is not an effective screening assay for other subtypes of vWD.

In the absence of RIPA data, the only sign pointing to vWD type 2B may be thrombocytopenia. For patients misdiagnosed as vWD type 1, the correct diagnosis of vWD type 2B may be discovered accidentally by finding that thrombocytopenia develops or is markedly worsened by desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP).[119] For this reason, the platelet count should be followed in all patients who receive their first diagnostic or therapeutic trial of desmopressin.

The binding site on vWF for platelet GPIbα is within vWF domain A1, between amino acid residues 1,226 and 1,479. At least 25 mutations are known to cause vWD type 2B, and all of them are within domain A1 (FIGURE 52.3). The crystal structure of a complex between vWF domain A1 and a fragment of GPIbα suggests that large conformational changes occur in both proteins when they bind.[131] The locations of vWD type 2B mutations indicate that they are likely to stabilize the bound conformation of domain A1, which could allow binding to platelet GPIbα in the absence of vascular injury and thereby cause the observed dominant, gain-of-function phenotype.[131]

vWD type 2B Malmö/New York merits special consideration. This variant of vWD type 2B is characterized by abnormal RIPA—consistent with a diagnosis of vWD type 2B—but a normal vWF multimer pattern and normal platelet count, even after administration of DDAVP.[128,129] Patients with this phenotype rarely have significant bleeding,[132] suggesting that vWD type 2B Malmö/New York is either an extremely mild form of vWD type 2B or a normal vWF variant in which specific sequence changes cause increased RIPA *in vitro* without affecting hemostasis *in vivo*. The mutations associated with vWD type 2B Malmö/New York are Pro1266Leu, Pro1266Gln, and Arg1308Leu. These mutations also occur in the vWF pseudogene that is located on chromosome 22, and their occurrence in the vWF gene on chromosome 12 appears to be a consequence of recombination between these loci.[133]

von Willebrand Disease Type 2M

vWD type 2M ("M" for "multimer") includes variants in which platelet adhesion is impaired but the vWF multimer distribution is normal. This phenotype may be produced by mutations that inactivate specific binding sites for ligands on platelets or in connective tissue.[22] For example, many patients

tahir99-VRG & vip.persianss.ir

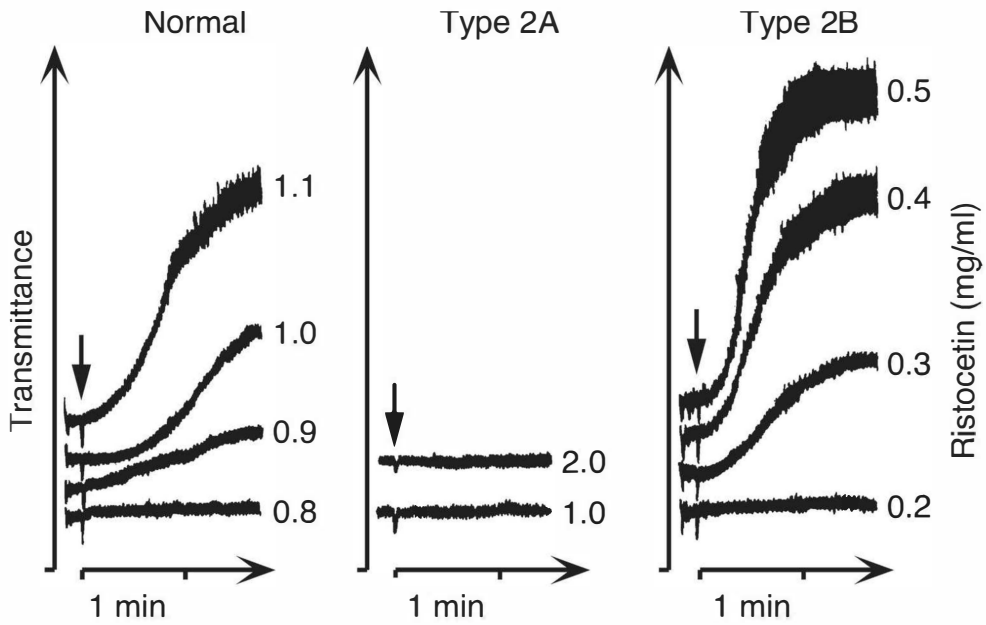

FIGURE 52.4 RIPA in a healthy control and patients with vWD type 2A and type 2B. Stirred samples of PRP were supplemented at the time marked with the *arrow* (↓) with the indicated concentrations of ristocetin, and light transmission was recorded as a function of time. Normal samples always required more ristocetin than did vWD type 2B samples to achieve comparable rates of platelet agglutination. (Adapted from Ruggeri ZM, Pareti FI, Mannucci PM, et al. Heightened interaction between platelets and factor VIII/von Willebrand factor in a new subtype of von Willebrand disease. *N Engl J Med* 1980;302:1047–1051.)

with vWD type 2M have been described with mutations in vWF domain A1 that impair binding to platelet GPIbα (FIGURE 52.3).[93,113,134–136] Only four mutations that impair binding to collagen have been reported in vWF domain A3,[137–139] although the apparent low prevalence of domain A3 mutations might reflect the relatively limited use of vWF:CB assays compared to vWF:RCo assays. Screening laboratory results generally are similar to those in vWD type 2A (Table 52.2), but multimer gel analysis shows that large multimers are present. vWD type 2M includes variants previously designated as type B,[140] type IC,[141] and type ID.[142]

von Willebrand Disease Type 2N

The FVIII-binding site on vWF is near the amino-terminus of the mature subunit. Missense mutations that selectively inactivate this binding site (FIGURE 52.3) produce an interesting autosomal recessive vWD phenotype in which the platelet-dependent functions of vWF are preserved and the multimer pattern appears normal, but FVIII levels are low, usually between 5 and 25 IU/dL.[143,144] This autosomal mimic of hemophilia A is named vWD "type 2N" after "Normandy," the birth province of one index case. The correct diagnosis is made either by demonstrating that the patient's vWF has markedly decreased binding affinity for FVIII in vWF:FVIIIB assays or through the demonstration of *vWF* mutations known to result in this phenotype.

The prevalence of vWD type 2N is not known, but it might be higher than currently appreciated. For example, 31 affected families were identified between 1990 and 1995 in France, where only two centers perform vWF:FVIIIB assays.[145] Some of these patients with vWD type 2N had been misdiagnosed with hemophilia A or as carriers of hemophilia A. Screening of patients with hemophilia A has shown that a small percentage of those with apparent mild hemophilia A may instead have vWD type 2N.[146]

Although vWD type 2N superficially resembles mild hemophilia A, or a hemophilia carrier state with low FVIII levels due to extreme lyonization, the therapeutic requirements in vWD type 2N are quite distinct. In particular, highly purified or recombinant FVIII preparations give poor FVIII recovery and survival *in vivo* because the patient's endogenous vWF cannot stabilize it normally.[147,148] For the same reason, treatment with desmopressin often does not effectively increase plasma FVIII levels.[148] Desmopressin may produce acceptable results in milder forms of vWD type 2N (e.g., Arg854Gln) but is unlikely to be beneficial in cases with more severe 2N mutations (e.g., Arg816Trp). Importantly, genetic counseling for an autosomal recessive disease is very different from that for an X chromosome–linked disease. Because of these issues, the differential diagnosis of vWD type 2N versus hemophilia A should be considered in any patient with low FVIII levels in whom the evidence for X-linked inheritance is incomplete, or in whom initial therapy with desmopressin or pure FVIII gives unexpectedly poor results.

von Willebrand Disease Type 3

vWD type 3 is a recessive disorder in which vWF protein is essentially absent. Total deficiency of vWF causes a secondary deficiency of FVIII, and such patients have a severe combined defect in platelet adhesion and blood clotting. Laboratory testing shows undetectable vWF:RCo and vWF:Ag, as well as a prolonged aPTT that is explained by a low FVIII level. If the

tahir99-VRG & vip.persianss.ir

condition is congenital, other testing is not usually necessary to make the diagnosis.

Heterozygous relatives of patients with vWD type 3 usually are phenotypically normal, but may sometimes have mild bleeding symptoms and meet criteria for vWD type 1.[149–152] Review of published data for 117 obligate heterozygotes indicated that they had a mean plasma vWF level of 45 IU/dL with a range of 5 to 130 IU/dL; some had mild bruising, epistaxis, menorrhagia, or bleeding after tooth extraction.[33] Such variability was evident in the first report by von Willebrand—the proband was one of five siblings with vWD type 3 and both parents had mild symptoms, but several relatives who could transmit the disease appeared to be unaffected.[1] Similar variability in symptoms is evident in many other families in whom mutations have been characterized. vWD type 3 appears to be caused mainly by deletion, frameshift, and nonsense mutations,[20,81–83,152] but approximately 25% of mutations are missense. The mutation in the original Åland Islands families studied by von Willebrand was shown to be a single-nucleotide deletion in exon 18, causing a frameshift and premature termination within the propeptide.[153]

Questions regarding the "expressivity" or "penetrance" of vWD in the relatives of type 3 patients are related to questions concerning the pathophysiology of vWD type 1. For example, the prevalence of vWD type 3 is reported to be 2.5 to 3 per million in Scandinavian countries and is 0.1 to 1.6 per million in many counties of Europe and the Middle East.[154] An intermediate prevalence of approximately 1.5 per million was reported for the United States and Canada.[155] These figures provide approximate values for q^2, where q is the gene frequency for type 3 alleles; therefore, the prevalence of heterozygous individuals ($2pq$) is 660 to 3,400 per million. The prevalence of heterozygotes could be even higher because of the shortened life expectancy in vWD type 3. However, the prevalence of symptomatic vWD type 1 appears to be <10% of these values. Therefore, a single nonfunctional vWF allele may sometimes be associated with vWD type 1, but rarely is sufficient to cause disease.

DIFFERENTIAL DIAGNOSIS OF VON WILLEBRAND DISEASE

vWD type 2 and type 3 are relatively easy to diagnose and appear at present to be genetic diseases of a single locus, the *vWF* gene. The most common variant, vWD type 1, often is difficult to diagnose and appears to involve factors other than mutations in the *vWF* gene. vWD must be distinguished from other inherited or acquired disorders of platelet function or FVIII deficiency. A few conditions are characterized by laboratory features that are remarkably like certain vWD subtypes and therefore pose special diagnostic challenges.

Acquired von Willebrand Syndrome

Acquired von Willebrand syndrome (AVWS) refers to vWF deficiency that is not inherited but is secondary to another cause. AVWS is usually a chronic condition in which patients may have mucocutaneous bleeding symptoms and laboratory parameters consistent with the diagnosis of vWD. Although the incidence of AVWS is unclear, a survey of 260 patients with myeloproliferative or lymphoproliferative disorders identified 25 patients with a ristocetin cofactor activity of <40 IU/dL, eight of whom had evidence of a vWF inhibitor.[156] In many cases, a multimer pattern consistent with type 2A vWD was identified, suggesting an increased effect on high molecular weight multimers. AVWS typically is caused by one of three mechanisms: autoimmune clearance, proteolysis induced by increased fluid shear stress, or binding to cell surfaces.[157,158]

Autoimmune clearance probably accounts for the common association of AVWS with monoclonal gammopathy of unknown significance (MGUS). Other conditions thought to induce immune clearance of vWF include lymphoproliferative diseases such as non-Hodgkin lymphoma and multiple myeloma and autoimmune diseases such as systemic lupus erythematosus and autoimmune thyroiditis. Antibodies to vWF have been demonstrated in a few patients tested, suggesting the assays are insensitive or the mechanism of disease may not always involve circulating antibodies.[157,158]

Cardiovascular conditions with pathologically increased fluid shear stress will promote the cleavage of circulating large vWF multimers by ADAMTS13, thereby causing AVWS. A classic presentation of AVWS is associated with aortic stenosis and bleeding from intestinal angiodysplasia. The AVWS and bleeding resolve upon surgical replacement of the stenotic valve.[159] AVWS also has been described in patients with mitral valve prolapse, pulmonary hypertension, ventricular septal defect, and patent ductus arteriosus.[157,158,160–162]

AVWS caused by increased vWF binding to platelets has been described in reactive thrombocytosis and in thrombocytosis associated with myeloproliferative diseases including essential thrombocythemia, polycythemia vera, and chronic myelogenous leukemia. The platelet count correlates inversely with the level of large vWF multimers, and reducing the platelet count can restore a normal vWF multimer distribution.[163,164] vWF binding to malignant lymphocytes and other cancer cells has also been described, sometimes associated with the expression of platelet GPIbα or other vWF-binding proteins on the tumor cell surface.[157,158]

Hypothyroidism may sometimes cause decreased vWF levels attributed to decreased vWF synthesis, and the levels return to normal with thyroid replacement therapy.[38] Certain drugs including sodium valproate[36] and ciprofloxacin[165] are reported to be associated with AVWS.

Platelet-Type Pseudo–von Willebrand Disease

vWD type 2B is characterized by exaggerated affinity of plasma vWF for GPIbα on platelets. The vWD type 2B phenotype is mimicked closely by an analogous but relatively rare gain-of-function defect in platelet GPIbα that is referred to as "platelet-type" or "pseudo" vWD.[166–168] Both vWD type 2B and platelet-type pseudo-vWD are associated with decreased plasma vWF and FVIII, increased sensitivity to ristocetin in the RIPA assay, the absence of the largest vWF multimers from plasma, and the presence of all sizes of multimers within platelets. Furthermore, administration of desmopressin to patients with either disorder can cause transient thrombocytopenia and spontaneous platelet aggregation.[119,169] Platelet-type pseudo-vWD can be distinguished from vWD type 2B by suitable mixing experiments: addition of normal vWF (e.g., in normal plasma) to patient platelets causes platelet aggregation in platelet-type pseudo-vWD, but not in vWD type 2B.[167,169,170] Four mutations in the platelet GPIbα subunit have been described in patients with platelet-type pseudo-vWD: Gly233Val,[171] Gly233Ser,[172] Met239Val,[173] and a 27 bp deletion

tahir99-VRG & vip.persianss.ir

in the macroglycopeptide-coding region of the gene.[174] The affected residues in the missense mutants are located in a small region that changes structure and adopts a β-sheet conformation upon binding to vWF domain A1. The mutations that cause platelet-type pseudo-vWD appear to enhance the affinity of binding, by stabilizing this β-sheet conformation.[131]

Hemophilia A

As discussed in the preceding text, vWD type 2N may be misdiagnosed as hemophilia A, particularly if the family history does not provide clear evidence for X chromosome–linked inheritance of FVIII deficiency. Conversely, patients with hemophilia A who also have platelet dysfunction, commonly caused by aspirin use, can have mucocutaneous bleeding similar to that of patients with vWD.[175]

Other Disorders

Because patients with vWD type 2B may present with thrombocytopenia, this subtype of vWD has been misdiagnosed as autoimmune thrombocytopenia in adults and infants.[120–122,124–127]

TREATMENT OF VON WILLEBRAND DISEASE AND ACQUIRED VON WILLEBRAND SYNDROME

Although the bleeding in vWD is usually mild, particular care to achieve adequate hemostasis should always be taken in patients undergoing invasive procedures and in those with trauma. In addition to the severity of bleeding (or potential surgical bleeding), treatment is guided by the vWD subtype, so that whenever possible the correct subtype should be established prior to therapy. Because the bleeding time is a poor reflection of bleeding risk and other laboratory testing such as the vWF:Ag and vWF:RCo levels may be difficult to obtain in a timely fashion, intervention may be guided by clinical criteria. In general, with appropriate therapy, adequate hemostasis should be obtained so that surgical procedures may be safely undertaken in all forms of vWD.

Agents Used in the Treatment of von Willebrand Disease

Desmopressin

Desmopressin (DDAVP) is a synthetic analog of vasopressin that has <1% of the pressor effect of the natural hormone. Originally used as replacement therapy for central diabetes insipidus, this agent was shown to successfully treat bleeding in hemophilia A and vWD.[176,177,178] Administration of desmopressin results in a rapid increase in plasma levels of FVIII and vWF in normal individuals and those with type 1 vWD. The rapid rise suggests an effect on preformed vWF that is released from the Weibel-Palade bodies of the endothelium, but the mechanism of this effect is uncertain.

Surgical prophylaxis and treatment of minor bleeding can usually be accomplished with desmopressin. Desmopressin may be administered intravenously, subcutaneously, or as an intranasal spray. When given intravenously, the usual dose is 0.3 μg/kg diluted in 50 mL of 0.9% sodium chloride and infused over 30 minutes. The maximal response in the vWF levels occurs in 30 to 60 minutes and generally persists for at least 6 hours. When indicated, repeat doses are usually given every 12 to 24 hours.[177,179,180] The response is consistent in any one individual and usually results in a twofold to fourfold increase in vWF. Some vWD type 1 variants, such as vWD Vicenza (Arg1205His), are associated with a much greater initial response (up to 10-fold increment in vWF), but by 4 hours the vWF levels have returned to baseline. This reflects the accelerated clearance of these variants and emphasizes the importance of obtaining a vWF level at >2 hours after desmopressin administration. Several early reports suggested that patients developed tachyphylaxis (decreased response) to repeated doses of desmopressin, and this is thought to be caused by depletion of vWF from its storage sites. On an average, the increment in vWF is approximately 30% less with a second dose given 24 hours subsequent to the initial dose, but the response was not reduced further after one or two additional doses.[181] Repeated dosing at intervals of <24 hours is also more likely to cause tachyphylaxis. Three to four days after desmopressin is stopped, a full response can again be anticipated with readministration of the drug. If suitably concentrated preparations of injectable desmopressin are available, a subcutaneous dose is approximately as effective as the same intravenous dose and suitable for home therapy.[182]

In some countries, a highly concentrated form of desmopressin containing 1.5 mg/mL (Stimate, CSL Behring) is available as an intranasal spray. The recommended adult dose is 300 μg given in divided doses, 150 μg in each nostril. In children and adults weighing <50 kg, the recommended dose is 150 μg. Note that preparations of intranasal desmopressin used for diabetes insipidus or enuresis are too dilute as intranasal therapy for bleeding in vWD. The therapeutic levels achieved with intranasal desmopressin are similar to a dose of approximately 0.2 μg/kg intravenous desmopressin.[177] For patients with type 1 vWD, peak responses in vWF activity occur in 1 to 2 hours and the plasma concentrations of vWF generally are not as high as with intravenous desmopressin. The responses are also less predictable than with intravenous therapy.[183] Nevertheless, this approach is useful for patients who are in remote settings or who require treatment of minor recurrent bleeding (e.g., menorrhagia). The medication should be stored under refrigeration but appears stable for up to 3 weeks when stored at room temperature for use during travel.

Because the response to desmopressin varies among individuals, a trial dose should be evaluated before any therapeutic or prophylactic use of desmopressin. Blood samples are obtained for baseline measurement of vWF:Ag, vWF:RCo (or vWF:CB), and FVIII. Then a single dose of desmopressin, 0.3 μg/kg in 50 mL of normal saline, is given intravenously over 30 minutes. The subject should be monitored for vital signs, flushing, and headache. Additional samples for measurement of vWF:Ag, vWF:RCo, and FVIII should be obtained at 1 hour and 4 hours after the start of the infusion. Values at 1 hour represent the maximum response. Values at 4 hours allow calculation of the circulatory half-life of the released factors.

Target plasma levels of vWF and FVIII depend on the hemostatic challenge. Minor bleeding and minor surgical procedures may be covered satisfactorily with increases of vWF and FVIII to at least 30 IU/dL at 1 hour after desmopressin, provided the half-life is normal. Major bleeding and major surgery may require levels >100 IU/dL that remain >50 IU/dL before the next dose.

Useful responses to desmopressin are common in vWD type 1 and rare in vWD type 2 variants.[178] Almost all patients with type 3 vWD are insensitive to desmopressin and do not have

tahir99-VRG & vip.persianss.ir

a therapeutically useful response. The percentage of patients with vWD type 1 that responds to intravenous desmopressin varies from 90%[179] to approximately 30%.[32] Some of this variation reflects different definitions of response. Some patients with vWD type 2A, type 2M, or type 2N have a useful response to desmopressin, and these patients may be identified by their response to a test dose.[184,185] Administration of desmopressin to patients with vWD type 2N is associated with the expected twofold to threefold increase in vWF:Ag and vWF:RCo, but patients with severe FVIII-binding defects often have a small and transient response in FVIII level with a half-life of only 2 to 3 hours.[143,186] In contrast, patients with the relatively common mutation Arg854Gln have a mild FVIII-binding defect with higher baseline FVIII levels of 21.8 ± 9.8 IU/dL[145] and frequently have a useful FVIII response to desmopressin.[32,186]

When given to patients with vWD type 2B, desmopressin increases the levels of vWF and FVIII, but also causes or exacerbates thrombocytopenia. For this reason, plasma-derived FVIII/vWF products are generally recommended for use in vWD type 2B (Table 52.5). Nevertheless, a few patients have received desmopressin with good hemostatic responses and no unexpected bleeding or thrombosis.[187,188] Therefore, if plasma product therapy must be avoided, desmopressin could be considered.

It is generally recommended that a test dose of intranasal desmopressin also be evaluated before the clinical use of this form of the drug, even in patients who have previously responded to intravenous desmopressin.

The most common adverse reaction to intravenous desmopressin, occurring in up to 10% of patients, is vasodilatation with facial flushing and, less commonly, headache and mild hypotension. Extending the period of infusion from 30 to 60 minutes generally lessens these side effects as does administering the drug by the subcutaneous route. Intranasal desmopressin is associated with similar reactions and may also be associated with local reactions including nasal congestion, rhinitis, and upper respiratory symptoms. Hyponatremia, the result of the antidiuretic effect of desmopressin, tends to occur in children younger than 2 years, and in elderly patients who have received several doses. Hyponatremia has been described with either intravenous or intranasal desmopressin and, when severe, may cause seizures.[180,183] Monitoring of the serum sodium level and fluid restriction should be instituted for patients receiving more than two to three doses. Hyponatremia resolves rapidly after desmopressin is discontinued. There have been several isolated reports of stroke and myocardial infarction among patients receiving desmopressin. However, a retrospective review of patients receiving desmopressin for major surgery found no difference in thrombotic events between patients who did and did not receive the drug.[189] Most cases of thrombosis have been described in older men who have other thrombotic risk factors so that a concern remains in these patients requiring therapy.

Unlike vasopressin, desmopressin does not appear to cause uterine contractions. Nevertheless, because of the concern over a possible oxytocin-like effect, desmopressin is not often used during pregnancy, but may be administered as soon as the baby is delivered. Safety in nursing mothers has not been defined.

Plasma-Derived von Willebrand Factor

Cryoprecipitate is prepared from plasma and is enriched in FVIII, vWF, and fibrinogen. Blood collected for the preparation of cryoprecipitate is screened for a number of infectious agents including human immunodeficiency virus (HIV), hepatitis B, and hepatitis C, but at present is not virucidally treated. Therefore, a small risk of viral contamination remains, similar to that of red cell transfusions. One unit of blood yields approximately 8 to 10 mL of cryoprecipitate containing 100 to 150 IU of vWF. When prepared from single donors and processed individually, cryoprecipitate has a vWF multimeric structure similar to that found in plasma.[190] Cryoprecipitate is given as an intravenous infusion, and a typical dose is 1 to 2 "bags" per 10 kg of body weight. Matching for ABO type is not necessary, and the product does not need to be given through a leukocyte-depleting filter. Cryoprecipitate was once the preferred plasma-derived product for the treatment of bleeding in vWD. However, concern over viral transmission has led to the abandonment of cryoprecipitate in favor of virucidally treated FVIII/vWF concentrates in almost all circumstances.

FVIII/vWF-containing products are either derived from plasma or prepared as a recombinant product from cultured cells. Plasma-derived products are virucidally treated, and available data suggest that the risks of transmitting HIV, hepatitis B, and hepatitis C have been essentially eliminated. Highly purified or "monoclonal" plasma FVIII concentrates and recombinant FVIII products lack sufficient vWF to be useful in the treatment of any form of vWD. In contrast, plasma-derived FVIII/vWF concentrates that contain 15 to 200 IU FVIII per mg protein (commonly described as "intermediate purity") also contain substantial amounts of vWF. Because these products are virucidally treated, they have become the preferred products for the treatment of vWD.

For patients who do not tolerate or respond adequately to desmopressin, treatment with a plasma-derived FVIII/vWF concentrate such as Humate-P may be necessary. When examined by gel electrophoresis, the vWF present in plasma-derived FVIII concentrates shows some evidence of limited degradation compared to fresh plasma vWF. Nevertheless, these products can correct the hemostatic defect in patients with vWD.[191,192] Humate-P (CSL Behring) is one of the most extensively utilized FVIII/vWF concentrates. This concentrate appears effective for the prevention of bleeding perioperatively and for the treatment of other bleeding episodes. Each vial of Humate-P is labeled with both FVIII units and vWF units (ristocetin cofactor units) so that particular attention is paid to this information to ensure correct dosing. Examples of treatment guidelines are summarized in Table 52.5. Monitoring of vWF activity may be helpful to reduce the hemostatic risk of underdosing and the extra cost of overdosing.[193] Humate-P is generally well tolerated with few adverse events.[193] Continuous infusion of Humate-P may be considered because this appears effective and consumes approximately one-half of the total dose required when given by intermittent bolus injection.[194]

Data with Alphanate (Alpha Therapeutics) and other plasma-derived FVIII/vWF concentrates suggest that these products are also effective in correcting the vWF activity level and therefore may be considered for use in vWD.[191,192] Because the concentration of vWF in these products is not yet standardized in the United States, dosing is determined in units of FVIII activity. Initial treatment with 40 FVIII IU/kg intravenously every 12 hours is usually sufficient to maintain the vWF activity level >50 IU/dL.

Concentrates that contain both vWF and FVIII have the potential to cause disproportionately high plasma FVIII

tahir99-VRG & vip.persianss.ir

Table 52.5

Usage of plasma-derived FVIII/vWF concentrates in the treatment of vWD

Hemostatic Challenge	Therapy
Major surgery or bleeding	50 IU FVIII or vWF:RCo/kg body weight, followed by 25 to 40 IU/kg every 12 or 24 h, adjusted to keep the nadir level of FVIII or vWF:RCo >50 IU/dL until healing is progressing, typically for 5 to 10 d
Minor surgery	40 IU FVIII or vWF:RCo/kg body weight every 24 or 48 h, adjusted to keep the nadir level of FVIII or vWF:RCo >30 IU/dL until healing is progressing, typically for 2 to 4 d
Dental extraction	30 IU FVIII or vWF:RCo/kg body weight as a single dose, to maintain the level of FVIII or vWF:RCo >50 IU/dL for 12 h
Spontaneous minor bleeding	25 IU FVIII or vWF:RCo/kg body weight every 24 h to keep the nadir level of FVIII or vWF:RCo >30 IU/dL until bleeding stops, usually for 2 to 4 d
Labor and delivery	40 IU FVIII or vWF:RCo/kg body weight daily, adjusted to maintain the FVIII or vWF:RCo >50 IU/dL h on the day of delivery and for 3 to 4 d postpartum

Doses may be increased 20% for subjects younger than 18 years, to compensate for their increased plasma volume.
FVIII, factor VIII; vWF, von Willebrand factor.
Adapted from Mannucci PM, Chediak J, Hanna W, et al. Treatment of von Willebrand disease with a high-purity factor VIII/von Willebrand factor concentrate: a prospective, multicenter study. *Blood* 2002;99:450–456.

levels when administered to patients with vWD. Both the transfused FVIII and endogenously synthesized FVIII are stabilized by binding to the transfused vWF, and after several days of therapy the vWF level may be normal but the FVIII level may exceed 400 IU/dL.[178] These levels of FVIII may be associated with venous thrombosis and pulmonary embolism in patients with vWD exposed to other thrombotic risk situations,[178,195,196] and standard measures for thromboprophylaxis should be considered.

A virucidally treated, highly purified vWF concentrate that contains little FVIII has been used successfully to increase the levels of vWF in patients with vWD.[191,192,197,198] This product is not yet available in the United States. Because the FVIII content is so low, the normalization of FVIII levels depends on endogenous FVIII production and may require 12 hours in patients with severe vWD. Therefore, prophylactic treatment with purified vWF should be given 12 to 24 hours before any elective procedure, and acute correction of both FVIII and vWF levels requires concomitant treatment with a source of FVIII.

A recombinant human vWF concentrate is currently undergoing clinical trial evaluation (Baxter Healthcare). This concentrate also contains recombinant FVIII, and thus immediate replacement of FVIII is also provided by this product. This concentrate has previously been evaluated in dog models of vWD, and it appears to be safe and effective.[199]

Alloantibody inhibitors of vWF are rare complications of transfusion therapy in vWD type 3, reportedly occurring in 3% to 10% of patients.[200,201] Large vWF gene deletions appear to correlate with the risk of developing inhibitors.[201] With one possible exception, the few inhibitors that have been characterized were polyclonal Ig (immunoglobulin) G antibodies.[201] Patients with vWF inhibitors often have severe allergic reactions to transfused vWF that can include back pain, abdominal pain, hypotension, and anaphylaxis.[200,202]

Antifibrinolytic Agents

Tranexamic acid and ε-aminocaproic acid (Amicar) inhibit fibrinolysis and may be used alone or in combination with other hemostatic agents. These agents are most useful in oropharyngeal bleeding and menorrhagia. They are generally contraindicated in urinary tract hemorrhage because of the risk of a fibrin clot obstructing the urinary outflow tract. Tranexamic acid (10 to 15 mg/kg every 8 to 12 hours) or ε-aminocaproic acid (50 to 60 mg/kg every 4 to 6 hours) may be given orally or by intravenous infusion.[203] These agents may also be used as a mouthwash for oral bleeds or dental procedures. Tranexamic acid mouthwash, 10 mL of a 4.8% solution given as a "swish and spit," may be better tolerated than ε-aminocaproic acid in some patients.[180,204]

Platelet Transfusions

Some patients with vWD type 3 have had a rapid improvement in the bleeding time after platelet transfusion despite an incomplete response to a prior infusion of plasma-derived vWF.[205] Both platelet and plasma vWF contribute to hemostasis,[206] and platelet transfusion (e.g., a plateletpheresis collection of 4 to 5×10^{11} platelets) may be considered as adjunctive therapy for bleeding that is refractory to treatment with FVIII concentrate.[207]

Platelet transfusions are not likely to be helpful in the treatment of thrombocytopenia associated with type 2B vWD.[208]

Other Therapy

Short courses of conjugated estrogens have been used in surgical prophylaxis and for treatment of bleeding associated with angiodysplasia.[209] A short course of corticosteroids may be effective for hematuria.

Patients with vWD type 3 and alloantibodies to vWF have been treated with purified plasma or recombinant FVIII that contains no vWF. The infused FVIII is cleared rapidly, but therapeutic

tahir99-VRG & vip.persianss.ir

levels (40 to 60 IU/dL) can be maintained by administering FVIII at a total dose of 700 to 900 IU/kg/d intravenously by continuous infusion or bolus infusions every 4 hours.[210,211] Recombinant FVIIa (NovoSeven) also has been used to treat surgical or postpartum bleeding in these patients by continuous infusion (approximately 20 μg/kg/h) or bolus infusion (~90 μg/kg every 4 hours).[211,212]

Therapy for Problems Specific to Women with von Willebrand Disease

The incidence of symptomatic vWD in women is disproportionate as compared to that in men, representing approximately two-thirds of all patients,[34,75] although autosomal inheritance requires an equal frequency of mutant gene transmission to both sexes. The increased impact of vWD on women of childbearing age is a consequence of the repeated hemostatic challenges of ovulation, menstruation, pregnancy, and delivery. Bleeding into the corpus luteum may occur after ovulation, and midcycle pain may be severe enough to prompt surgical exploration.[34,213] The prevalence of menorrhagia in vWD is not known precisely because few studies have used quantitative measures of blood loss, and bias in patient selection is possible. With these limitations in mind, approximately 65% of women with vWD appear to have menorrhagia (>80 mL blood loss per menstrual cycle), compared to 9% to 14% of controls, and menorrhagia for women with vWD often begins at menarche.[34,214,215]

Conversely, approximately 6% to 13% of women with unexplained menorrhagia have vWF levels more than 2 SD below the mean.[214,216] Independent of whether subjects meet criteria for diagnosing vWD, a low vWF level appears to be a modest risk factor for menorrhagia, with a relative risk of approximately 2 to 4 for vWF levels below approximately 50 IU/dL.

Excluding patients with vWD type 3, intranasal desmopressin every 12 to 24 hours for up to 3 days may be effective for menorrhagia in vWD, if the side effects can be tolerated.[217] Two randomized placebo-controlled trials in a total of 44 women, approximately half with vWD, reported a trend in favor of desmopressin for menstrual bleeding, but the differences between the two arms were not statistically significant.[214,218] A larger open-label study in 90 women, many with vWD, reported shortened or decreased bleeding in 88% of treated menstrual cycles.[219]

Menorrhagia in all types of vWD may be treated successfully with hormonal therapy (danazol, progesterone, or combined oral contraceptive pills).[215,220] In appropriate patients, desmopressin and hormonal therapy can be combined.

Antifibrinolytic agents can be very effective for menorrhagia,[221,222] and, although experience is limited in vWD, case reports suggest these agents could be useful alone or as adjuncts to other treatments.[223] Tranexamic acid has been used at 1 g every 6 hours for 5 days,[221] or 4 g in a single daily dose for 3 to 5 days.[223] ε-Aminocaproic acid has been used at dosages of 5 g three times daily for 5 days,[224] or 3 g every 6 hours for 3 to 5 days.[225] ε-Aminocaproic acid is thought to reduce fertility by inhibiting embryo implantation although the data are scanty. For this reason, antifibrinolytics generally are not recommended during the first trimester of pregnancy or for patients considering pregnancy.

Pregnancy usually is tolerated well by patients with vWD.[226] In most patients, except for those with vWD type 3, vWF levels increase during the third trimester and protect against hemorrhage late in pregnancy. However, miscarriage or therapeutic abortion early in pregnancy, while vWF and FVIII levels are low, carries an increased risk of maternal hemorrhage.[227,228] Provided the levels of both vWF and FVIII are >50 IU/dL, the risk of hemorrhage during labor and delivery does not appear to be increased. Exceptions to this generalization may occur for patients with vWD type 2. Retrospective series that include both vWD type 1 and type 2 suggest that primary postpartum hemorrhage (>500 mL blood loss in the first 24 hours) occurs in approximately 16%[229] to approximately 18.5%[228] of patients. After delivery, the levels of FVIII and vWF fall rapidly over several days, and secondary postpartum bleeding (bleeding after 24 hours in excess of "normal" lochial loss) may occur with an incidence of 20%[228] to 25%.[229] Therefore, patients should be monitored for at least 1 week postpartum, and they should be advised that bleeding may occur up to 3 weeks after delivery.

Progressive pregnancy-associated thrombocytopenia is common and may be the presenting manifestation of vWD type 2B.[122] Increased bleeding has not been reported to accompany pregnancy-associated thrombocytopenia in vWD type 2B. Patients with vWD type 2B Malmö/New York do not develop thrombocytopenia when given DDAVP or during pregnancy.[129,132]

Maternal hemorrhagic complications can be minimized by prophylactic therapy to raise factor levels to >50 IU/dL at delivery and to maintain them at that level for 3 to 4 days postpartum.[200,228,230] Factor levels >50 IU/dL appear to be sufficient to administer epidural anesthesia safely.[228,231] In general, FVIII/vWF concentrates are used prior to delivery, switching to desmopressin if appropriate after delivery. FVIII/vWF concentrate may reverse the thrombocytopenia and correct the bleeding tendency of vWD type 2B for delivery.[124] In all patients, complete uterine evacuation and contraction after delivery are important to prevent bleeding.[230]

Treatment of Acquired von Willebrand Syndrome

Treatment of AVWS involves consideration of both the underlying disease and the bleeding disorder. Because the mechanism of AVWS is variable, identifying effective therapy can be difficult.[157]

The optimal treatment of AVWS associated with autoimmune disease is yet to be defined. Immunosuppressive therapy with oral prednisone, 1 mg/kg/d, or intravenous cyclophosphamide, 700 mg/M² monthly has been used successfully.[232,233] For patients with malignant lymphoproliferative disorders such as non-Hodgkin lymphoma or multiple myeloma, successful treatment of the underlying disease with cytotoxic chemotherapy or surgical removal of the tumor typically results in resolution of the AVWS. In a few cases, the return of AVWS heralded a relapse.[234–237] For patients with MGUS, treatment of the associated clonal lymphoid disorder with cytotoxic or immunosuppressive chemotherapy usually does not alter the course so that prevention and treatment of bleeding represents the mainstay of therapy.

Intravenous immunoglobulin (IVIG) was first proposed in 1976 for the treatment of AVWS,[238] and many reports describe the success of this approach for patients with AVWS caused by immune-mediated clearance of vWF.[157,234,239–243] Active bleeding may be treated with IVIG 1 g/kg/d for 1 to 2 days with resolution of the hemorrhage within several days of the infusion. Repeated prophylactic infusions of IVIG 1 g/kg every 3 to 4 weeks have been used successfully in the prevention of bleeding.[242,243] IVIG

tahir99-VRG & vip.persianss.ir

appears to be more effective for patients with IgG than IgM MGUS.[242] Patients in whom no underlying disease is identified may respond to IVIG, suggesting that an underlying immune-mediated disorder may be responsible.

Desmopressin or FVIII/vWF concentrate is effective in up to one-third of patients with AVWS associated with MGUS or malignant lymphoproliferative diseases, although the primary mechanism of disease is increased clearance. A test dose of desmopressin can be helpful to identify responsive patients.[157]

For patients with myeloproliferative disease or solid malignancies, treatment of the underlying disease with surgery or chemoradiation therapy appears to be effective. Control of the platelet count in myeloproliferative disease seems to be effective in increasing the plasma concentration of large vWF multimers.[244,245] An unusual association of AVWS with Wilms tumor has been described, and the bleeding disorder resolved with the successful treatment of the malignancy.[246] Cases of AVWS associated with medications resolve when the drug has been discontinued, and those associated with hypothyroidism resolve with thyroid hormone replacement therapy.[38]

Patients with AVWS caused by increased fluid shear stress generally do not respond to desmopressin, FVIII concentrates, or IVIG, but require correction of the underlying cardiovascular abnormality to normalize vWF function.[157] For example, AVWS associated with aortic stenosis typically resolves upon successful repair of the defective valve.[159]

Rare Inherited Coagulation Disorders Other than Hemophilia

PIER MANNUCCIO MANNUCCI, FLORA PEYVANDI, AND MASSIMO FRANCHINI

The rare inherited coagulation disorders (RICDs), usually transmitted in an autosomal recessive fashion, represent 3% to 5% of all the inherited deficiencies of coagulation factors and include fibrinogen, factor (F)II, FV, FV+FVIII, FVII, FX, FXI, FXIII, and the multiple deficiency of vitamin K–dependent factors.[1,2] Their distribution is variable in the world, with a prevalence in the general population of the presumably homozygous forms ranging from approximately 1 in 2 million for prothrombin (FII) to 1 in 500,000 for FVII deficiency (the most common) (Table 53.1).[3] In countries with large Jewish communities, FXI deficiency is more prevalent. In Middle Eastern countries and Southern India, where consanguineous marriages are customary, autosomal recessive traits occur more frequently in the homozygous state.[4]

Data on the distribution of patients affected by RICDs are limited. Given their rarity, few centers have the possibility to follow and manage a consistent number of patients, so that scientific reports are usually limited to small numbers. Two recent large registries help to derive the worldwide distribution of RICDs: one by the World Federation of Haemophilia (WFH, www.wfh.org) and the other by the International Rare Bleeding Disorders Database (RBDD, www.rbdd.org).[5] The WFH database, which started in 1998 but collected information since 2004, includes information from 108 countries (2008 update), while the RBDD, developed in 2004, reports data from 68 countries. According to these registries, FXI and FVII deficiencies are the most prevalent RICD worldwide, with frequencies of 29% and 33% of the total RICDs, followed by FX (9%), fibrinogen (8%), FV (8%), FXIII (6%), and combined FV+FVIII (5%) and FII deficiencies (2%) (FIGURE 53.1).[6] These results were also confirmed by smaller national registries, such as those of Central and South America, Egypt, France, India, Iran, and the United Kingdom.

There are considerable variations in bleeding patterns among patients with RICDs, but on the whole, bleeding manifestations affecting critical organs such as the central nervous and musculoskeletal systems appear to be less frequent than in hemophilia A and B.[7] The laboratory diagnosis of RICDs is carried out by means of screening tests such as the activated partial thromboplastin time (APTT), the prothrombin time (PT), and the thrombin time (TT) in subjects reporting a clinical and family history of bleeding (Table 53.1).[4] Abnormal results of screening tests should be followed by coagulation factor assays, in order to specify the diagnosis. Molecular diagnosis is based on the search of mutations in the genes encoding the corresponding coagulation factors. Exceptions are the combined deficiency of FV and FVIII, caused by mutations in genes encoding proteins involved in the intracellular transport of FV and FVIII (multiple coagulation factor deficiency 2 [MCFD2] and lectin mannose binding protein 1 [LMAN1]), and the combined deficiency of vitamin K–dependent proteins (FII, FVII, FIX, and FX), caused by mutations in genes that encode enzymes involved in posttranslational modifications and in vitamin K metabolism (γ-glutamyl carboxylase [GGCX] and vitamin K epoxide reductase [VKOR]). Genetic analysis is important mainly for prenatal and preimplantation genetic diagnosis, especially in countries with a high rate of RICDs and consanguinity.[8] Because it is not always clear whether or not the identified mutation is the cause of the deficiency of a clotting factor, family history associated with allele frequency in the general population is important to rule out that the identified mutations are common polymorphisms.[7]

Treatment of RICDs is a difficult task, because information on the clinical management of RICDs is often scarce and replacement therapy of coagulation factors may require unlicensed products that are not readily available.[9,10] The patients' personal and family history of bleeding are important guides for management.[9] Dosages and frequency of replacement therapy with products containing the deficient factor depend on the minimal hemostatic level of the factor, its plasma half-life, and the type of bleeding episode. Unfortunately, information on the safety and efficacy of the few available products is scarce and experiences from their use are significantly more limited than those available for congenital hemophilia. Other treatments in RICDs are nontransfusional adjuvant drugs (i.e., antifibrinolytic amino acids, estrogen–progestogen).[10]

After these general statements on RICD, the next section will deal specifically with each factor deficiency.

FIBRINOGEN DEFICIENCY

Fibrinogen is a 340 kDa protein synthesized in the liver, with a plasma concentration of approximately 1.5 to 3.5 g/L and a half-life of approximately 4 days (Table 53.1). The fibrinogen molecule is a homodimer, each half consisting of the three nonidentical polypeptide chains Aα, Bβ, and γ. The genes encoding fibrinogen Bβ (*FGB*), Aα (*FGA*), and γ (*FGG*), ordered from centromere to telomere, are clustered on chromosome 4 in a region of approximately 50 kb (Table 53.1). Fibrin is produced by proteolytic cleavage of fibrinogen by thrombin, with the release of fibrinopeptides A and B and generation of insoluble fibrin monomer followed by polymerization. Fibrinogen is also important in primary hemostasis through its ability to support normal platelet aggregation.[9]

Fibrinogen deficiency is heterogeneous and two main phenotypes can be distinguished. In some cases, plasma and platelet levels of the protein are not measurable or very low, leading to afibrinogenemia and hypofibrinogenemia. In other cases,

low clottable fibrinogen contrasts with normal or moderately reduced fibrinogen antigen, causing dysfibrinogenemia and hypodysfibrinogenemia.[3]

Mutation Analysis

A homozygous deletion of approximately 11 kb of the *FGA* as a cause of inherited afibrinogenemia was for the first time identified by Neerman-Arbez et al.[11] in four members of a Swiss family. Since then many other mutations have been identified in afibrinogenemia (in homozygosity or in compound heterozygosity) or hypofibrinogenemia.[8] While the majority of mutations are in the *FGA* gene, missense mutations leading to complete fibrinogen deficiency appear to be clustered in the highly conserved *C*-terminal globular domains of the Bβ and γ chains. Recent functional studies of these mutations in transfected cells have demonstrated either impaired assembly or secretion of the fibrinogen hexamer. To date, only two missense mutations located at the start of the coiled coil in *FGA* (Cys64Phe and Met70Arg) were found in fibrinogen deficiency.[12,13]

Besides the large number of rare, individual mutations identified in congenital afibrinogenemia, two common mutations were found in individuals of European origin, both in *FGA*: the Asp153SerfsX4 mutation and the *FGA* 11-kb deletion, both on multiple haplotypes. Two further residues of interest in screening for dysfibrinogenemia are residue Arg16 in exon 2 on *FGA*, which is part of the thrombin cleavage site in the fibrinogen Aα chain, and residue Arg275 in exon 8 on *FGG*, which is important for fibrin polymerization.[14]

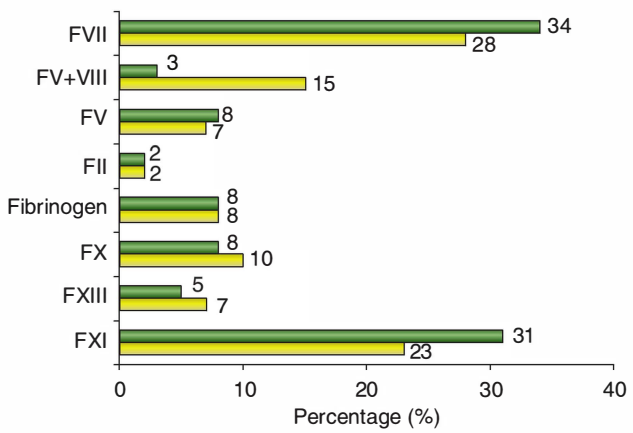

FIGURE 53.1 Prevalence of RICDs derived from RBDD (*green-filled bars*) and WFH (*yellow-filled bars*) registries.

Clinical Phenotype and Treatment

Whereas the majority of patients with dysfibrinogenemia do not bleed at all, afibrinogenemic patients have a bleeding tendency that may manifest in the neonatal period, with 85% of cases presenting with umbilical cord bleeding.[15] Bleeding may also occur in the skin, gastrointestinal tract, or central nervous system, while recurrent joint and muscle bleeding leading to persistent damage to the musculoskeletal system is less frequent. Clinically milder symptoms such as epistaxis and menorrhagia are also frequent. First trimester abortion is common in afibrinogenemic women, less common in dysfibrinogenemia, and not reported so far in hypofibrinogenemia.[16,17] Postpartum bleeding is relatively frequent when no prophylactic replacement therapy is given. On the whole, bleeding problems are often not dramatic in patients with afibrinogenemia, despite the fact that screening coagulation tests (PT, APTT) usually result in no clot formation and that the skin bleeding time is prolonged.[2]

tahir99-VRG & vip.persianss.ir

Both arterial and venous thromboembolic complications have been reported in afibrinogenemic patients, in spite of the fact that in the majority of patients no traditional thrombotic risk factors were present. One possible but as yet unproven explanation for this predisposition is that even in the absence of fibrinogen platelet aggregation does occur due to the action of von Willebrand factor. Moreover, in contrast to hemophiliacs, afibrinogenemic patients are able to generate thrombin, both in the initial phase of limited production and in the secondary burst of greater thrombin generation.[2]

Pertaining to replacement therapy, four products are available: fresh-frozen plasma (FFP), cryoprecipitate, virus-inactivated FFP, and fibrinogen concentrate. Safety commands avoidance of the first two if possible, because they are not virus inactivated. The latter is the treatment of choice, because it is virally inactivated and thus safer than cryoprecipitate or FFP and does not cause volume overload.[18,19] The conventional mode of treatment delivery is episodic and on demand, with fibrinogen administered as soon as possible after onset of bleeding. Long-term secondary prophylaxis (made possible thanks to the relatively long half-life of fibrinogen) with administration of fibrinogen every 7 to 14 days (particularly after central nervous system hemorrhages) has been proposed (Table 53.2). Prophylactic therapy also appears to be necessary for successful completion of pregnancy: fibrinogen replacement must begin at least at 5 weeks gestation to prevent abortion and to maintain fibrinogen

Table 53.2

Treatment of inherited coagulation disorders

Deficient Factor	On Demand	Surgery	Long-term Prophylaxis
Fibrinogen	SD-treated plasma (15–20 mL/kg) Fibrinogen concentrate (50–100 mg/kg) Target level: 50–100 mg/dL	Fibrinogen concentrate (50–100 mg/kg) Minimum level: 100 mg/dL	Fibrinogen concentrate (30–100 mg/kg every week) Target level: 50–100 mg/dL
Prothrombin	SD-treated plasma (15–20 mL/kg) PCC (20–30 U/kg) Target level: 20%–30%	SD-treated plasma (15–20 mL/kg) PCC (20–30 U/kg) Minimum level: 20%–40%	PCC (25–40 U/kg every week) Target level: 20%–30%
Factor V Factor V+VIII	SD-treated plasma (15–20 mL/kg) Target level: 10%–20%	SD-treated plasma (15–20 mL/kg) Minimum level: 25%	No data available
Factor VII	FVII concentrate (30–40 mL/kg) PCC (20–30 U/kg) rFVIIa (15–30 μg/kg every 4–6 h) Target level: 10%–15%	FVII concentrate (30–40 mL/kg) PCC (20–30 U/kg) rFVIIa (15–30 μg/kg every 4–6 h) Minimum level: 10%–15%	FVII concentrate (30–40 mL/kg, three times per week) rFVIIa (10–20 μg/kg, two to three times per week) Target level: 10%–15%
Factor X	SD-treated plasma (10–20 mL/kg) PCC (20–30 U/kg) FX/FIX concentrate (10–20 U/kg) Target level: 10%–20%	SD-treated plasma (10–20 mL/kg) PCC (20–30 U/kg) FX/FIX concentrate (10–20 U/kg) Minimum level: 10%–20%	PCC (30–40 U/kg, two to three times per week) FX/FIX concentrate (20–40 U/kg, one to two times per week) Target level: 10%–20%
Factor XI	SD-treated plasma (15–20 mL/kg a.d.) FXI concentrate (15–20 U/kg a.d.) Target level: 15%–20%	Antifibrinolytic agents (250 mg/d) SD-treated plasma (15–20 mL/kg a.d.) FXI concentrate (15–20 U/kg a.d.) Minimum level: 15%–20%	No data available
Factor XIII	SD-treated plasma (3 mL/kg) FXIII concentrate (10–20 U/kg) Target level: 2%–5%	SD-treated plasma (3 mL/kg) FXIII concentrate (10–20 U/kg) Minimum level: 5%–10%	SD-treated plasma (15–20 mL/kg every 4–6 wk) FXIII concentrate (10 U/kg every 4–6 wk) Target level: 2%–5%
VKCFD	Vitamin K (10 mg i.v. or s.c.) SD-treated plasma (15–20 mL/kg) Target level: 20%–30%	Vitamin K (10 mg i.v. or s.c.) SD-treated plasma (15–20 mL/kg) Minimum level: 20%–30%	Vitamin K (10 mg orally every week)

levels at >1.0 g/L throughout pregnancy (a level of >1.5 g/L is recommended for delivery).[17]

PROTHROMBIN DEFICIENCY

Prothrombin (FII) is a 72 kDa single-chain glycoprotein synthesized by the liver. It is one of the vitamin K–dependent coagulation factors and requires posttranslational carboxylation to become functionally active. Prothrombin consists of four domains—the Gla domain, kringle 1 and kringle 2 domains, and a serine protease domain—and is encoded by a gene of approximately 21 kb located on chromosome 11. FXa activates prothrombin on the surface of platelets in the presence of FV and calcium. During prothrombin cleavage, the activation peptide fragment 1 + 2 is released.[20]

Prothrombin deficiency is probably the rarest inherited bleeding disorder, with an estimated prevalence of 1:2,000,000 in the general population.[4] Based on the measurement of prothrombin (FII) activity and antigen level in plasma, two main phenotypes are distinguished: hypoprothrombinemia (both levels are concomitantly low) and dysprothrombinemia (normal or near normal synthesis of a dysfunctional protein).[20] No living patient with undetectable plasma prothrombin has been reported so far, consistent with the demonstration that in mice complete prothrombin deficiency by gene knockout is incompatible with life, resulting in embryonic or neonatal lethality.[21]

Mutation Analysis

Genetic variants were identified all along the prothrombin gene, although frequently they involve the catalytic site, consistent with the fact that they affect the enzymatic activity of the protein.[22] Mutations in different exons may cause similar phenotypic expression of prothrombin. Most of the mutant prothrombins derive from missense mutations (80%), although insertion/deletions (10%), nonsense (6%), and splice-site (4%) mutations have also been described. The abnormalities may be classified according to the site of the defects: (a) in the activation mechanism or (b) in the protease activity of thrombin. The latter can in turn be subdivided into two subtypes: one in which there is defective amidolytic activity and another in which there is a defective interaction of thrombin with substrates because of mutations in the molecular recognition domains.[23] Other mutations indirectly affect the catalytic activity of thrombin, by perturbating of the Na^+ binding site of the enzyme. However, while *in vitro* Na^+ binding seems to play a major role in thrombin activity, the natural mutant prothrombins with altered Na^+ binding described so far (Arg517Gln and Lys556Thr, in exon 13 and 14, respectively) had only a mild hemorrhagic phenotype.[24] Recent biochemical characterization of the mutants Des-Lys9/10 and Phe299(7)Val revealed an important role of the A-chain for a correct function of the catalytic B-chain of thrombin. Perhaps these natural mutations affect the interaction of divalent metals with thrombin, recently localized at the interface between the A- and B-chain that seem to stabilize the active conformation of thrombin.[25,26]

Clinical Phenotype and Treatment

Clinically, heterozygotes with prothrombin deficiency are usually asymptomatic, while homozygotes with activity levels <10% of normal experience severe bleeding manifestations, such as spontaneous hematomas and hemarthroses, intracerebral bleeding, and gastrointestinal hemorrhages. In homozygous women, menorrhagia is frequent.[24,27]

Patients with a prothrombin coagulant activity above 20% usually do not require replacement therapy, but antifibrinolytic agents may be considered.[28] Replacement therapy is needed only in homozygous patients, in case of bleeding or to ensure adequate prophylaxis of bleeding before surgical procedures. Since no prothrombin concentrate exists, prothrombin complex concentrates (PCCs) are used to treat patients (Table 53.2),[20] because in several clinical settings, higher levels of prothrombin may be achieved with PCCs without the harm of potential volume overload induced by FFP. However, all PCCs contain other vitamin K–dependent coagulation factors, which increase unnecessarily in plasma of patients with normal levels and could potentially cause thrombotic complications.

FACTOR V DEFICIENCY

FV is a large glycoprotein of 249 kDa, encoded by a gene on chromosome 1, synthesized by hepatocytes and megakaryocytes (Table 53.1). FV and FVIII have approximately 40% amino acid homology in their respective A and C domains and their overall protein domain structures are identical.[29] Platelets contain approximately 20% of total circulating FV.[30] FV is activated by thrombin and the resulting heterodimer FVa acts as a cofactor for FXa in the conversion of prothrombin to thrombin.[29] FV also contributes to the anticoagulant pathway by downregulating FVIII activity, so that FV deficiency also may rarely result in a thrombotic tendency.[31,32] The majority of FV deficient cases are characterized by the concomitant deficiency of FV activity and antigen levels (type I deficiency), but approximately 25% of them have normal antigen levels, indicating the presence of a dysfunctional protein (type II deficiency).

Mutation Analysis

Studies of the molecular basis of severe FV deficiency started in 1998 with the identification of the first causative mutation.[33,34] So far, a total of 56 genetic defects have been identified.[29] Of them, 48 seem to be responsible for the type I deficiency, only one being recurrent (Tyr1702Cys, repeatedly found in Italians), confirming the remarkable allelic heterogeneity of the disease. A mild type I deficiency has also been associated with two FV variants: the functional Met2120Thr polymorphism, which causes about 25% reduction in FV levels, and the HR2 haplotype defined by a group of more than 10 polymorphisms. Among them, the dominant contribution of the Asp2194Gly variant was demonstrated by expression experiments in eukaryotic cells.[35] Only one genetic defect associated with type II deficiency Ala221Val has been reported so far.[29]

A genotype/phenotype discrepancy can be observed in FV deficiency because, despite carriership of the same mutations, some patients often present a more severe bleeding pattern than others. The possibility that severe FV-deficient phenotype may be modulated by a concomitant procoagulant defect was investigated by Duckers et al.[36] showing that congenital FV deficiency associated with reduced plasma levels of tissue factor pathway inhibitor—which decrease the FV requirement for minimal thrombin generation to <1%—perhaps protects patients from severe bleeding.

tahir99-VRG & vip.persianss.ir

Clinical Phenotype and Treatment

Frequent symptoms in patients with FV deficiency are epistaxis and menorrhagia, which occur in approximately 50% of cases. Other less common symptoms include hemarthroses and hematomas, which occur in about 25% of patients, whereas life-threatening episodes in the gastrointestinal tract and in the central nervous system are rare (6%).[37]

There is no FV concentrate available and FV is not present in significant amount in cryoprecipitate nor in PCCs.[38] Thus, replacement therapy of FV is only achieved through FFP, preferably virus-inactivated (Table 53.2).[2] Platelets contain FV, so that platelet transfusions have been sometime used therapeutically, particularly in patients with FV deficiency owing to the development of a specific inhibitor. In FV deficiency, this limited availability of therapeutic weapons should prompt pharmaceutical companies to develop and make available plasma-derived or recombinant FV products.

COMBINED DEFICIENCY OF FACTOR V AND FACTOR VIII

Combined FV and FVIII deficiency is an autosomal recessive bleeding disorder with an incidence of about 1 in million, and it is a clinical entity distinct from FV deficiency and FVIII deficiency[8] that are transmitted with different patterns of inheritance (autosomal recessive for FV, X-linked for FVIII) and involve proteins encoded by two different genes. The molecular mechanism of the combined deficiency (F5F8D) was not understood until 1998,[39] when it was causally associated with mutations in the *LMAN1* (previously named as *ERGIC-53*), encoding a 53 kDa type-1 transmembrane protein chaperoning the intracellular transport of both factors.[40,41] In 2003, another locus associated with F5F8D was identified in about 15% of affected families with no mutations in *LMAN1*: the *MCFD2* that encodes the MCFD2 protein acting as a cofactor for LMAN1 through the recruitment of correctly folded FV and FVIII in the endoplasmatic reticulum.[42,43]

Mutation Analysis

LMAN1 is encoded by a gene of approximately 29 kb located on chromosome 18 and containing 13 exons, while MCFD2 is encoded by a shorter gene of approximately 19 kb located on chromosome 2 and containing 4 exons. To date, a total of 48 mutations are described (32 in *LMAN1* and 16 in *MCFD2*). All the *LMAN1* mutations reported so far are null mutations, with the exception of a cysteine-to-arginine mutation that disrupts a disulfide bond required for oligomerization and destabilizes the protein. In contrast, both null and missense mutations have been identified in *MCFD2*. In particular five of six reported missense mutations (Asp81Tyr, Asp89Ala, Asp122Val, Asp129Glu, and Ile136Thr) disrupt LMAN1 binding, indicating that LMAN1 and MCFD2 must function as a unit to transport FV and FVIII.[43] Zhang et al.[44] have performed a genotype–phenotype analysis to evaluate if mutations in the two different genes are associated with differences in FV and FVIII plasma levels. Mean plasma levels in patients with MCFD2 mutations were significantly lower than those in patients with LMAN1 mutations, suggesting that MCFD2 may play a primary role in the export of FV and FVIII from the endoplasmatic reticulum. The *MCFD2* IVS2+5G>A appears to be one of the most common mutation causing F5F8D, being identified in at least 13 unrelated families from different geographic regions (India, Italy, United States, Serbia, and Germany).[7]

Clinical Phenotype and Treatment

Combined F5F8D is characterized by concomitantly low but measurable levels (usually 5% to 20%) of the two coagulation factors, both as coagulant activity and antigen. The concomitant presence of two coagulation defects does not appear to enhance the hemorrhagic tendency observed in each defect separately. Thus, symptoms are usually mild, with a predominance of easy bruising, epistaxis and bleeding after dental extractions.[45] Menorrhagia and postpartum bleeding are also reported in some affected women. More severe symptoms (such as hemarthroses, gastrointestinal, central nervous system, and umbilical cord bleeding) occur very seldom. Soft tissue hematomas are also unusual.[45]

As there are no FV concentrates available, replacement of FV and FVIII can currently be achieved only through the use of FFP, preferably virus-inactivated,[38] which contains both. For FVIII replacement, a large number of products are available: the synthetic hormone desmopressin (DDAVP) can be successfully used for minor bleeding episodes to raise FVIII only.[10]

FACTOR VII DEFICIENCY

Factor VII is a vitamin K–dependent glycoprotein of approximately 50 kDa that circulates in plasma in two forms, the majority as a single-chain inactive form (with a concentration of 0.5 μg/mL) and in a much smaller amount as the active two-chain form. The FVII gene maps to chromosome 13, spans approximately 12 kb of DNA, and consists of nine exons encoding a mature protein of 406 amino acids. Through its interaction with tissue factor, FVII is fundamental for the initiation of coagulation.[46]

FVII deficiency is the most common RICD (1:500,000).[47] Plasma levels of FVII coagulant activity (FVII:C) and FVII antigen (FVII:Ag) are influenced by a number of genetic and environmental factors (sex, age, cholesterol, and triglyceride levels) and by *FVII* polymorphisms.[48] The majority of patients have concomitantly low levels of FVII:C (measured with functional assays) and FVII:Ag (measured with immunologic assays), but several cases are characterized by normal or low borderline levels of FVII:Ag contrasting with lower levels of FVII:C.[49]

Mutation Analysis

The molecular basis of FVII deficiency is more extensively characterized than those of other defects, owing to the relatively high frequency of this defect and small size of the gene.[50] Numerous mutations (available at online database http://europium.csc.mrc.ac.uk) are described. Missense mutations are the most frequent (70% to 80%), and splice-site changes are also well represented, while nonsense mutations and small deletions are rare, particularly in the homozygous condition.[50] Mutations are located throughout the gene, suggesting that all domains are important in maintaining the structure and function of FVII. The severely deficient cases are either homozygous or double heterozygous for mutations that disrupt the expression of the protein (e.g., deletions, insertions, splice-site and promoter mutations), resulting

tahir99-VRG & vip.persianss.ir

in FVII:C levels typically <1% of normal. Individuals with a mild/moderate clinical phenotype are homozygous or doubly heterozygous for missense mutations; however, some missense mutations are also associated with a severe phenotype.[51,52]

The most frequently reported mutations (Ala294Val, Ala294Val, 11125delC, Arg304Gln, and Cys310Phe) are associated with all ranges of clinical severity. Neither FVII:C nor gender provides an explanation for this heterogeneity, suggesting that other modifying factors may influence the different clinical manifestations in patients carrying the same mutation. FVII levels are modulated by *FVII* polymorphisms that are associated with up to fivefold differences in mean FVII levels. Tightly linked polymorphisms in the 5′ regulatory region regulate FVII levels and differential promoter activity *in vitro*. The Arg353Gln substitution in the catalytic domain, tightly associated with the decanucleotide insertion (g.–323–324insCCTATATCCT) and with the −401T allele in the promoter region, decreases FVII secretion, thereby reducing plasma levels. The same effect is given by the g.11293–11294insAA polymorphism in the 3′ untranslated region of a *FVII*, which negatively affects the steady state of mRNA levels and leads to a reduction of FVII mRNA by 40%, which in turn reduces FVII protein levels.[53] An additional polymorphism, located in intron 7 of *FVII* and characterized by the presence of a variable number of 37–base pair (bp) repeats, is associated with variable rates of FVII transcriptional activity.[50]

Clinical Phenotype and Treatment

The severity of symptoms of FVII deficiency is quite variable. Some patients with severe deficiency do not bleed at all after major challenges of hemostasis. Life- or limb-endangering bleeding manifestations are relatively rare, the most frequent symptoms being epistaxis and menorrhagia.[54] The high incidence of central nervous system bleeding (16%) reported by Ragni et al.[47] in a series of 75 patients affected by FVII deficiency was not confirmed by two subsequent large series of Italian and Iranian patients.[51,55] Thrombotic episodes (particularly deep vein thrombosis), have also been reported in 3% to 4% of patients with FVII deficiency, particularly at the time of surgery and replacement treatment, but spontaneous thrombosis may also occur.[56] The mechanism of these complications is obscure.

Current therapeutic options include, PCCs, plasma-derived FVII concentrates, and recombinant FVIIa (Table 53.2),[46] because, the very short half-life of FVII makes it difficult to use FFP without causing volume overload. Recombinant FVIIa is the optimal replacement therapy, since it can be used at a very low dosage (10 to 20 μg/kg).[57] Pregnancy does not require special precautions and uncomplicated delivery is possible with no prophylaxis. However, all postpartum bleedings reported so far occurred in women with relatively low FVII coagulant activity (<15 IU/dL) not on replacement therapy. Therefore, delivery should take place under the coverage of short-term replacement.[46] It must be noticed that rFVIIa given for inherited FVII deficiency has sometime caused formation of a specific inhibitor.

FACTOR X DEFICIENCY

Factor X occupies a key position in the coagulation cascade, as its activated form is the first enzyme in the common pathway of thrombin formation.[58] The gene for FX is 22 kb long, is located on chromosome 13 and encodes a protein of 59 kDa. FX synthesis occurs in the liver and circulates in plasma at a concentration of 10 μg/mL as a two-chain molecule (Table 53.1). Activation of FX occurs by means of a tenase complex consisting of tissue factor, FVIIa, calcium ions, and a suitable phospholipid surface. FXa is the most important activator of prothrombin and the presence of the prothrombinase complex (FXa, FVa, calcium ions, and a suitable negatively charged phospholipids membrane) accelerates 280,000-fold the conversion of prothrombin to thrombin.[59] Severe (homozygous) FX deficiency is inherited as an autosomal recessive disorder with an incidence of 1:1,000,000 in the general population. The clinical phenotypes of FX deficiency are characterized by concomitantly low levels of coagulant activity and antigen but also by low coagulant activity contrasting with normal or low borderline antigen values.[60]

Mutation Analysis

To date, 105 mutations including 85 missense, 14 insertion/deletions (3 gross deletion + 11 micro insertions/deletions), 6 splice sites, 2 nonsense, and 1 in the 5′ flanking region, are reported. Although most mutations are in exon 8, the number of mutations located in each exon is proportional to the length of the exon itself, indicating the absence of a hotspot region on *FX*. Among the reported mutations, only one (C61X) was identified in the homozygous state in three unrelated patients. Moreover, only a few of the entire group of missense mutations were found in more than one family. In particular the Arg-1Thr, associated with a severe phenotype (FX:C <1%), was identified in homozygous state in four unrelated patients from Iran, while the Gly380Arg, associated with intracranial hemorrhages, was identified in six homozygous patients from Costa Rica. The Pro343Ser (FX Friuli), associated with reduced FX:C (4% to 9%), was identified in more than 10 patients coming from Northern Italy. Other mutations such as Gly-20Arg, Gly94Arg, and Gly222Asp, all associated with a severe laboratory phenotype, were reported from different countries.[58] No association was found between polymorphisms located in the promoter region and FX plasma levels.[61]

Clinical Phenotype and Treatment

Severely affected individuals (FX:C <1 IU/dL) sometimes present in the neonatal period with umbilical-stump bleeding. The most frequent symptom in FX deficiency is epistaxis, seen with all severities of deficiency. Menorrhagia occurs in half the women of reproductive age. Hemarthroses, severe postoperative hemorrhage, and central nervous system hemorrhage have also been reported.[62–64]

The treatment of FX deficiency patients is based upon the administration of FFP and PCCs (Table 53.2).[58] However, PCCs may be associated with thrombotic complication owing to the attainment of high concentrations of FII, FVII, and FIX after PCCs preparations. To overcome this problem, a freeze-dried human coagulation FIX and FX concentrate (Factor X P Behring, CSL Behring) with specified amounts of FX (and FIX) has been developed. Even though pregnancy is accompanied by increased concentrations of FX, women with severe FX deficiency and a history of adverse pregnancy outcomes (such as abortions, placental abruption, or premature births) may benefit from prophylactic replacement therapy.[65]

FACTOR XI DEFICIENCY

FXI is a homodimeric serine protease mainly synthesized in the liver and encoded by the 23 kb long *FXI* located on chromosome 4.[66] The disease is characterized by a decrease of the functional activity of this plasma protein, usually accompanied by correspondingly low FXI:Ag. More rarely, normal or borderline level of plasma FXI:Ag is associated with a dysfunctional form of the protein. The estimated prevalence of the severe FXI deficiency in most populations is about 1:1,000,000, but prevalence is much higher in Ashkenazi Jews, heterozygosity for FXI gene mutations and the corresponding mild FXI deficiency being as high as 8%.[67]

Mutation Analysis

Up to date, more than 180 mutations affecting *FXI* have been identified (available online: http://www.isth.org/default/index.cfm/publications/registries-databases/mutations-rare-bleeding-disorders/factor-xi/). The high allelic heterogeneity of FXI deficiency is highlighted by the distribution of genetic defects throughout the whole gene. Missense mutations represent more than 60% of all variants, only seven of them leading to the dysfunctional form of the deficiency.[68]

Only two mutations are responsible for most cases of FXI deficiency in Ashkenazi Jews, while mutations are more individual and private in non-Jews.[68,69] The type II Jewish mutation is a stop codon in exon 5, compatible with the observation that patients homozygous for this defect usually have undetectable levels of FXI. The type III Jewish mutation is a missense mutation in exon 9, leading to the substitution of phenylalanine at position 283 with leucine.[70,71] The mutation causes defective secretion of the protein from cells, but some FXI is ultimately produced so that these patients have measurable levels of FXI (at ~10%). Type II/III compound heterozygosity is the commonest cause of severe to moderate FXI deficiency in Ashkenazi Jews.[71]

Clinical Phenotype and Treatment

In comparison with hemophilia A or B, bleeding manifestations in FXI deficiency are much less predictable, even in severe deficiency, because bleeding is poorly related to FXI:C levels but rather to the site of injury. Thus, when a site of injury with local high fibrinolytic activity is involved (e.g., urogenital tract, oral cavity after dental extraction, or tonsillectomy), the risk of bleeding is increased (49% to 67%) in comparison to sites with less local fibrinolytic activity (1.5% to 40%).[72] Usually patients with severe FXI deficiency (1% or less) are mildly affected and most bleeding manifestations are injury related. Surprisingly patients with low but measurable levels of FXI are also mild bleeders, so that clinical phenotypes are not strikingly different in these two groups.[66,73] Women with FXI deficiency are prone to excessive bleeding during menstruation, but case series of women affected by severe FXI deficiency showed that 70% of pregnancies were uneventful despite no prophylactic treatment.[74–76] Also patients with alloantibodies that inhibit FXI do not bleed spontaneously, but only during surgery or trauma.[66] The Glu117stop mutation predisposes to the development of inhibitors.[77]

Treatment is based upon the use of antifibrinolytic agents, FFP, FXI concentrate, and low-dose recombinant FVIIa, but attention should be paid in order to reduce the risk of thrombotic complications (especially when FXI concentrates are employed), volume overload, allergic reactions, and development of anti-FXI inhibitors.[66] As surgery or trauma can be associated with excessive and prolonged bleeding unless adequately treated, a careful evaluation of patients with severe FXI deficiency is recommended prior to surgery, as well as meticulous planning of the procedure and the postsurgical course.[78] FXI has a relatively long half-life (40 to 70 hours), so that the infusion of 15 to 20 mL/kg virus-inactivated FFP on alternate days should be sufficient to keep FIX at trough hemostatic levels of 15% to 20% (Table 53.2).

FACTOR XIII DEFICIENCY

FXIII, also called fibrin-stabilizing factor, is the final enzyme in the blood coagulation pathway and functions to cross-link α- and γ-fibrin chains, resulting in a stronger clot with an increased resistance to fibrinolysis. The plasma factor consists of two catalytic A subunits (FXIII-A) and two carrier B subunits (FXIII-B). FXIII-A is synthesized in cells of bone marrow origin, while FXIII-B is produced in the liver. The corresponding genes are located on chromosomes 6 and 1.[79,80]

Inherited FXIII deficiency is an autosomal recessive disorder with a frequency of approximately 1:2,000,000 in the general population. In FXIII deficiency, plasma levels of FXIII-A, measured as functional activity or immunoreactive protein, are usually extremely reduced, whereas the FXIII-B subunit is reduced but always at measurable levels.[79] In 1999, the Scientific and Standardization Committee of the ISTH approved a new classification at the DNA level: FXIII-A deficiency (former type II deficiency), FXIII-B deficiency (former type I deficiency), and a possible combined deficiency FXIII-A and FXIII-B.[80]

The diagnosis of FXIII deficiency is made after the demonstration of increased clot solubility in 5 M urea, monochloroacetic acid, or acetic acid. FXIII activity may also be determined quantitatively by measuring the incorporation of fluorescent or radioactive amines into proteins.[81] Specific ELISA tests have been developed to measure FXIII-A and FXIII-B antigen levels.[82] It must be emphasized that the accuracy of functional FXIII assay is at the moment rather limited and hence it is not easy to diagnose partial factor deficiencies and assess their clinical significance.

Mutation Analysis

More than 70 mutations within *FXIII-A* have been published to date and most of them are missense/nonsense point mutations. An updated listing of mutations is available (http://www.f13-database.de). Multiple missense/nonsense mutations were also reported for a number of codons (77, 260, 326, 413 and 541) with codon changes AAC-AAA and AAC-AAG.[79] In the review by Ivaskevicius et al.[83] the two most frequent mutations affecting *FXIII-A* were the IVS5-1 G>A splice-site and the Arg661stop mutations. Mutations are scattered throughout the *FXIII-A* and in a few studies the mutant proteins were expressed in cultured mammalian cell lines, showing that the introduction of the mutation often caused destabilization of the protein structure and intracellular degradation.

On *FXIII-A* several polymorphisms have been identified. The most common are Val34Leu, Tyr204Phe, Pro564Leu,

tahir99-VRG & vip.persianss.ir

Val650Ile, and Glu651Gln.[83] The Val34Leu variant is the most studied, with the amino acid substitution occurring in the activation peptide sequence, three amino acids upstream from the thrombin cleavage site. The Leu34 allele variant promotes accelerated cleavage of the activation peptide once activated by thrombin and has been associated with a decreased risk of myocardial infarction, although its role in coronary artery disease is still debated.[84] In *FXIII-B*, only four mutations are identified to date: a single-nucleotide deletion at the acceptor splice junction of intron A/exon 2 (IVS1(-2)delA), a Cys430Phe missense mutation, a G deletion in exon 9, and an AAC triplet insertion within codon Tyr-80 in exon 3.[83]

Clinical Phenotype and Treatment

Individuals with FXIII deficiency have an increased tendency to bleed.[85] Animal models of factor XIII deficiency (FXIII-A knockout mice) present with intrathoracic, intraperitoneal, and subcutaneous hemorrhage.[86] In humans, bleeding from the umbilical stump in the first few days of life is common. Intracranial hemorrhage, hematomas, and prolonged bleeding following trauma are also characteristic.[87] Delayed wound healing is reported in approximately 30% of FXIII-deficient patients, while hemarthroses are less common than in hemophiliacs.[83] In a recent study made on the largest group of patients with severe FXIII deficiency (93 Iranians), the most frequent mucosal tract bleeding symptom was bleeding in the oral cavity (lips, tongue, gum) followed by menorrhagia and epistaxis.[87] Twenty percent of patients in the reproductive age had intraperitoneal bleeding that occurred at the time of ovulation, while 50% of pregnant women had at least one miscarriage.[87] The same patterns of symptoms, including the threat of intracranial bleeding in untreated patients, was also recently shown by Ivaskevicius et al.[83] in the frame of an international registry based mostly upon European data.

The clinical severity of FXIII deficiency, and particularly the high risk of intracerebral bleeding prompts regular prophylaxis.[79] This mode of treatment is facilitated by hemostatic levels of FXIII as low as 2% to 5% and the very long plasma half-life of infused FXIII (11 to 14 days), so that replacement material can be infused at longer intervals (20 to 30 days) (Table 53.2).[88] During pregnancies, monthly prophylactic infusions of FXIII concentrate are necessary to prevent abortions. There are three types of FXIII-containing products: FFP (preferably virus-inactivated), a plasma-derived, virus-inactivated FXIII concentrate, and a recombinant FXIII-A2 concentrate that contains no human or mammalian products and is manufactured in *Saccharomyces cerevisiae* (ZymoGenetics, Inc. Seattle, Washington, USA).[89] Recombinant FXIII-A2 homodimers associate in plasma with the endogenous FXIII-B to form the stable heterotetramer FXIII-A2B2. In a phase I clinical trial, recombinant FXIII-A2 was found to have a half-life similar to that of native FXIII and appeared to be safe.[89]

VITAMIN K–DEPENDENT COAGULATION FACTORS DEFICIENCY

Coagulation FII, FVII, FIX, and FX require γ-carboxylation of critical glutamic acid residues within their Gla domains to enable binding of calcium and attachment to phospholipid membranes.[90,91] The γ-carboxylation reaction is catalyzed by the hepatic enzyme GGCX that requires reduced vitamin K (KH2) as a cofactor. During the γ-carboxylation reaction, KH2 is converted to vitamin K epoxide, which is recycled to KH2 by the VKOR enzyme complex.[92,93] Inherited dysfunction of GGCX or the VKOR complex results in the secretion of poorly carboxylated FII, FVII, FIX, and FX that have poor hemostatic function. The γ-carboxylation of glutamic acid residues is also required for the activities of the anticoagulant proteins C, S, and Z.[90] The GGCX and VKOR proteins are encoded by two genes: the *GGCX* (13 kb—15 exons) located on chromosome 2 and the *VKORC1* (5,126 bases—3 exons) located on chromosome 16.

Mutation Analysis

The vitamin K–dependent coagulation factor deficiency (VKCFD) is a rare autosomal recessive bleeding disorder that arises from point mutations in either the *GGCX* (type I) or *VKOR* (type II) genes, the only exception being a kindred with a 14 bp deletion in intron 1 of *GGCX*.[92] To date a few mutations have been described for the type I disorder: Asp31Asn, Trp157Arg, Leu394Arg, His404Pro, Arg485Pro, Trp501Ser, and Thr591Lys, and two recently identified splice-site mutations: a G to T transversion of the first nucleotide of intron 2 (c. 1358+1G>T) and an A to G transversion of the third nucleotide of intron 11 (c. 10363+3A>G). The only mutation identified so far leading to type II is the homozygous Arg98Trp mutation.[94–96]

Clinical Phenotype and Treatment

Patients with severe VKCFD (i.e., factors levels below 5U/dL) are often symptomatic in the neonatal period, with umbilical stump bleeding or even intracranial hemorrhage.[97,98] Severely affected children may also have skeletal abnormalities such as nasal hypoplasia, distal digital hypoplasia, epiphyseal stippling, and mild conductive hearing loss. Older patients are usually less clinically severe and may show easy bruising and mucocutaneous or postsurgical bleeding.[99]

Treatment with oral or parenteral vitamin K1 (phytomenadione) should be started as soon as possible in all patients at diagnosis. However, large parenteral doses of vitamin K do not always correct FII, FVII, FIX, and FX activities, and there is clear biochemical evidence that the molecules are not fully carboxylated by such treatment.[90] Thus, in the group of patients with insufficient response following vitamin K1 administration, virally inactivated FFP could also be used in case of acute bleeding episodes or before surgery (Table 53.2). PCC is the alternative choice when a rapid increase of clotting factor levels is necessary. However, PCCs have been associated with thrombosis and disseminated intravascular coagulation (DIC), and therefore should be used with caution.[91]

GENERAL CONCLUSIONS

The clinical expression of the RICDs is more variable than that of hemophilia and may present challenges in both diagnosis and management. The unique proprietary nature of these mutations complicates the approach to the control of these diseases through prenatal diagnosis in families with affected members, because it renders necessary the actual identification of the underlying mutation in each kindred.

tahir99-VRG & vip.persianss.ir

The relation between genotype and phenotype is not always clear cut. Even though in general severe mutations predicting no protein production (stop codons, deletions, insertions, splicing abnormalities) are associated with more severe factor deficiencies and clinical phenotypes, there are a number of cases with severe factor deficiencies and phenotypes that are associated with missense mutations. However, missense mutations are usually associated with milder phenotypes in spite of undetectable factor levels, probably because some trace of protein is produced in these cases that cannot be detected with the currently available assays. The most severe RICDs are afibrinogenemia and severe FXIII and FX deficiencies, which present with the highest rate of life-threatening bleeding symptoms, whereas the least severe disease is FXI deficiency, with at least one third of patients remaining asymptomatic.

Treatment of RICDs consists in the use of the most purified blood product available that contains the deficient factor. Due to the rarity of each deficiency, specific factor concentrates are not often available as they are for hemophilia A and B. Dosages and frequency of treatment depend on the minimal hemostatic levels of the deficient factor, plasma half-life, and type of bleeding episode. General recommendations on treatment on demand, prophylaxis, and on surgery in patients with RICDs are summarized in Table 53.2. The avoidance of transmission of blood-borne infectious agents is the primary requisite in the choice of replacement material. Costs are also another important determinant. Virally inactivated factor concentrates are available for several deficiencies and should be preferred when virally inactivated plasma is not available or repeated infusions causing fluid overload are needed, as may occur at surgery or in cases of bleeding in the central nervous system. An updated registry of the available clotting factor concentrates, published by the WFH can be downloaded at the web address http://www.wfh.org/index.asp?lang=EN.

In conclusion, even though in the last few years substantially more knowledge on the prevalence, clinical manifestations, and genotype analysis of RICDs has been achieved, additional efforts are required to ameliorate the global care of RICD patients. Particular attention should be devoted to the health care status of women affected by RICDs. It is necessary to conduct appropriately designed studies for prompt diagnosis, prophylaxis, or on demand treatment that may significantly improve the usually poor quality of life of affected women. The pharmaceutical industries should devote more efforts to improve the availability of factor concentrates. An FV product and a prothrombin product are particularly needed. Finally, registries on RICDs should continue and should be funded by research and regulatory agencies, because they are the only weapons that can answer the many unsolved questions that pertain to the management of these very rare disorders[100].

CHAPTER

54 Afibrinogenemias and Dysfibrinogenemias

DENNIS K. GALANAKIS

Congenital fibrinogen disorders have provided novel insights into structure/function relationships and into the central role of fibrinogen in hemostasis. They are generally classified as quantitative (type I, a- or hypofibrinogenemia) and qualitative (type II, dysfibrinogenemia) groups. Afibrinogenemia was first reported in 1920,[1] hypofibrinogenemia in 1935,[2] and dysfibrinogenemia in 1958.[3] The first fibrinogen mutation (Detroit) was described in 1969[4] using protein sequencing, and use of DNA sequencing was first applied in 1989 to identify fibrinogens Hershey II and Leogan.[5] Subsequent application of mass spectrometry remains the preferred method to confirm results from genetic techniques. Aside from a 1974 compilation[6] and an updated listing in *http://www.geht.org/databaseang/fibrinogen/*, recent reviews provided detailed updates of this steadily expanding area of investigation.[7–10] To date, afibrinogenemia accounts for 23%, hypofibrinogenemia for 26%, and dysfibrinogenemia for 51% of all three. Estimated from the present selection of mutations, dysfibrinogenemia accounts for 51%, afibrinogenemia for 23%, and hypofibrinogenemia for 26%. This relative frequency and and the ~0.6% prevalence of apparent congenital hypofibrinogenemia among in a 5,746 Japanese patient population[11] suggest an over a prevalence of ~2% for all three disorders, and a possibly similar prevalence in other populations. Also, with the present selection of mutations, afibrinogenemia and dysfibrinogenemia are most frequently caused by FGA and FGG mutations, 38% and 35%, respectively as compared to 27% by FGB. Apart from its hemostatic functions, fibrinogen binds to vascular endothelial and other cells, interacts with many extracellular matrix components (see Chapter 16), and enables placentation from the middle of first trimester to full term.[12–14] Moreover, fibrin provides nonsubstrate binding for thrombin, serves as platform for assembly of fibrinolytic proteins, and is the preferred substrate for the protease plasmin.

AFIBRINOGENEMIA

Causative Mutations

This is an autosomal recessive disorder that often results from consanguinity. Mutations that cause afibrinogenemia (Table 54.1) are typically homozygous causing deficiency at the DNA or at the RNA level by affecting mRNA splicing or stability, or by affecting protein synthesis, assembly, or secretion.[10,15] Since the first mutation was identified in 1999,[16] more than 80 novel mutations have been described. Null mutations are most common and include frameshift or large deletions, and early truncating nonsense, or splice site mutations. Less frequently, missense or late-truncating nonsense mutations allow synthesis of the corresponding chain but impair intracellular fibrinogen assembly and/or secretion.

Clinical and Laboratory Manifestations—Hemorrhage

Hemorrhagic diathesis commences during the neonatal period and in some cases at a later age.[17] Umbilical cord bleeding occurs in up to 85%, and other common sites are gastrointestinal tract, skin, and genitourinary tract. There is an increased incidence of splenic rupture,[18] and intracranial bleeding is the major cause of death. Hemarthrosis and/or muscle hematomas are reported in about half. In menstruating women, menometrorrhagia is common and spontaneous first-trimester abortion is typical.[19] Predictably, clotting time is infinite, bleeding time is prolonged, and fibrinogen-dependent platelet aggregation is impaired.[20] Also, erythrocyte sedimentation rate is decreased,[21] and delayed hypersensitivity skin test reaction sites do not develop the normal induration.[22]

Thrombosis

Paradoxically, venous or arterial thrombosis occurs in some probands.[23] Thrombosis risks such as antithrombin III, protein C deficiency, or others, present in few probands,[24] are absent in most.[25] Among six unrelated probands,[25] arterial thrombosis sites included iliac, hypogastric, and other peripheral arteries. A prevailing explanation is that in the absence of fibrin, unsequestered thrombin induces vaso-occlussive platelet aggregate formation. This is based on evidence that fibrin sequesters thrombin,[26,27] and that in a fibrinogen knockout mouse model[28] spontaneously formed platelet aggregates embolized six times more frequently than those of wild-type controls and were often vaso-occlusive. Also, plasma levels of prothrombin activation peptides and of thrombin–antithrombin complexes are elevated in such probands, and both normalize following fibrinogen replacement.[29,30] Among eight unrelated probands with venous thromboembolism (VTE), the affected veins included portal vein, mesenteric vein, cerebral sinus, and others.[25] An intriguing feature is the association with fibrinogen infusion in five probands with venous and two with arterial thrombosis, suggesting a causative role by infused fibrinogen. Among possible explanations is substantial enrichment of plasma cryoprecipitate, and possibly other fibrinogen preparations, with soluble fibrin/fibrin(ogen) complexes[31,32] known to shorten fibrinogen clotting times.[33] Also, active thrombin was demonstrated in such complexes from a dysfibrinogenemic proband with recurring thrombosis.[34] Such thrombin may be released by proteolytic degradation of the complexes at the wound or other sites. Suggesting another possible mechanism, fibrinogen excess decreases plasminogen binding to fibrin polymers.[35]

tahir99-VRG & vip.persianss.ir

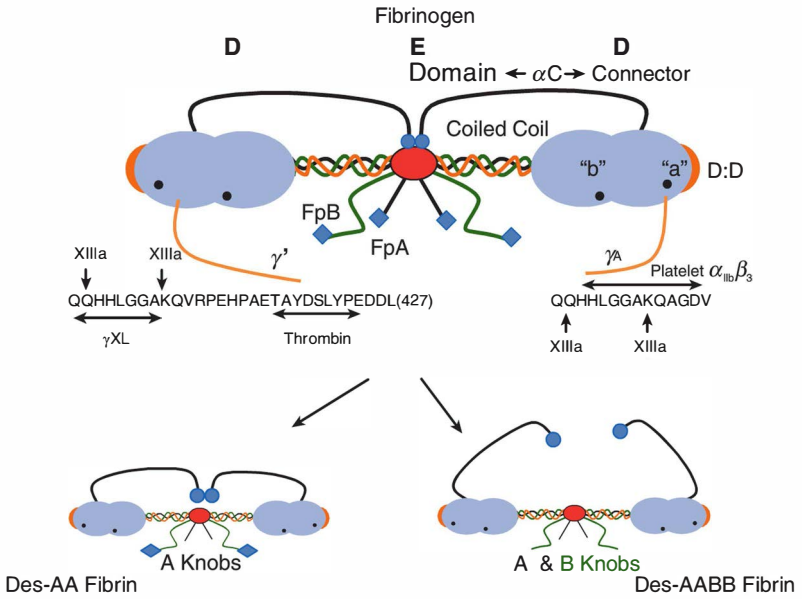

FIGURE 54.1 Schematic representation of functional regions of fibrinogen and fibrin. The C-terminal sequences of the γ_A and γ' chains are amplified for clarity, showing the high affinity thrombin binding, platelet interaction, and factor XIIIa catalyzed cross-linking (XL) sites. Elsewhere on the D region are the 'a' and 'b' pockets, and the D:D interface indicating the sites between D s of two molecules that associate during fibril elongation. The lower left panel indicates the slight weakening of αC tethering to the E region by FpA release, reflecting the contributing role to the tether by intact FpA.[131] The lower right panel illustrates the untethering and dissociation of αC s following FpB release.[128,132]

HYPOFIBRINOGNEMIA

Mutations that cause afibrinogenemia are usually homozygous and in a few cases compound heterozygous. They cause decreased plasma concentrations of normal fibrinogen when they are heterozygous (Table 54.2), often with decreased assembly and/or secretion of the variant fibrinogen. Substitutions Aα C36G or R[36] disrupt formation of Aα36C-Bβ65C and Aα36C-γ23C bonds,[37] while AαC45Y[36] and C45F[38] disrupt formation of the AαC45-γ23C bond.[39] As detailed elsewhere,[36] these confirmed experimental data showing that these bonds are required for hexamer assembly and/or secretion. Among mutations in the FGB gene two missense, R255H[40] and D346Y,[41] and one nonsense mutation, W470X,[42] result in changes in the β-domain of the distal D nodule of fibrinogen, suggesting impaired secretion. A second nonsense mutation, Y71X,[7] likely results in impaired assembly since the encoded chain lacks the β-domain of the distal D nodule. A single splice-site mutation at the 5′ site of FGB intron 6 (IVS6 + 1G > A) results in a frameshift after P319, adding 18 novel residues prior to a stop codon.[43] Like other mutations in this region (Table 54.2), variant fibrinogen may be assembled but is not secreted. Also not secreted is fibrinogen with γC153R.[44] In two unrelated probands with hemorrhagic diathesis,[45,46] substitution A82G is accompanied by a BβP265L in one and by an FGG splice-site mutation (IVS2 + 1G > A) in the other. Considered together, these γ chain variants are likely synthesized but not incorporated into hexamers.

Four mutations result in hypofibrinogenemia, *hepatocellular intracytoplasmic* inclusions, and progressive liver disease in the same proband (Table 54.2). Three include missense mutations, γG284R (Brescia),[47] γR375W (Aguadilla),[48] and γT314P (Al DuPont),[49] all occurring within or near the "a" pocket. Defective polymerization of fibrinogen Brescia was attributed to its hypersialylation, a characteristic of fibrinogen in liver disease.[50] The fourth, a γ346-350 del (Angers)[51] occurring within the five-stranded beta sheet of the γC, results from deletion of FGG nucleotides 7690A-7704G which deletes the splice site at position 7703. This generates a new (donor) splice site at position 7688, resulting in the in-frame deletion of five amino acids (GVYYQ) 346 to 350. Interestingly, other heterozygous mutations in these fibrinogen regions result in either assembly and secretion (dysfibrinogenemia) or selective secretion of only normal molecules (hypofibrinogenemia) but no intracellular accumulation.[52]

Clinical Manifestations

Hemorrhagic manifestations are common when plasma fibrinogen levels are in the range of 0.1 to 0.5 g/L[1] (normal 1.50 to 3.50 g/L[1]) by clotting assays. Symptoms include bruising, epistaxis, menometrorrhagia, miscarriage, and hemorrhage after trauma, surgery, or during pregnancy and parturition. By contrast, probands with plasma fibrinogen at diagnosis as low as 0.60 to 0.70 g L^{-1} are usually asymptomatic. The moderately prolonged thrombin (TT) and reptilase (RT) times are corrected by equal mixtures with normal plasma. Similar results may be obtained when a variant fibrinogen comprises a minor fraction of plasma fibrinogen (hypodysfibrinogenemia).

DYSFIBRINOGENEMIA

Dysfibrinogenemia is an autosomal dominant disorder that comprises mostly heterozygous mutations that result in both variant and normal fibrinogen in circulation. At least 500 families are known to date. Predictably,[53] plasma fibrinogen consists of normal and abnormal homodimers and of heterodimers, and its level by clotting assays is typically decreased, less than half that by antigen assay which is usually in the normal range. In a minor proportion of mutations (Table 54.2), fibrinogen is decreased by both assays and it is known as hypodysfibrinogenemia.

Defects that Impair Conversion of Fibrinogen to Fibrin

Following fibrinopeptide cleavage, fibrin monomers self-assemble to form protofibrils that polymerize by lateral contact to form fibers and networks (FIGURE 54.2). The specific interactions resulting in normal fiber formation have been elucidated in x-ray crystallographic structures of fibrinogen fragments D and factor XIIIa-cross-linked

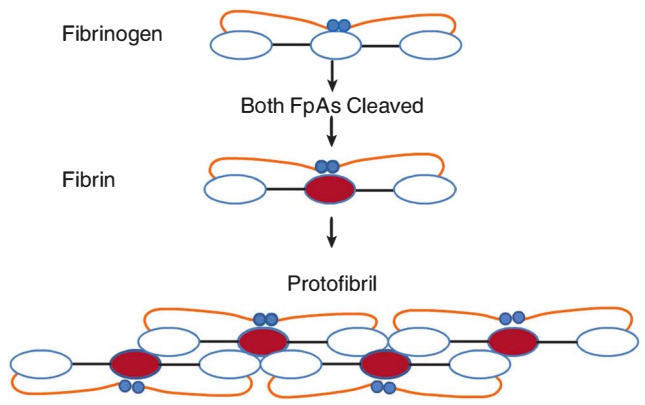

FIGURE 54.2 Schematic representation of fibrinogen and its conversion to fibrin. Release of FpA initiates polymerization. Each central (or E shown in red) fibrin region associates with the outer (or D) regions of two other molecules initiating a double stranded, half staggered, two molecule thick fibril, known as protofibril. As elongation progresses FpB release, significantly slower than that of FpA, is accelerated. Following FpA release, illustrated in Fig. 54.1, the αCs become untethered and dissociate. Each free αC associates with one or more counterpart(s) on neighboring fibrils (not shown) and in this manner promotes lateral assembly.

fragment D-D in the presence of peptides GlyProArgPro-amine (GPRPam) and GlyHisArgPro-amine (GHRPam), which mimic the *N*-terminal α and β sites of fibrin, respectively.[54–57] Substitutions occurring within these crystal structures have enabled correlations of clinical and biochemical data with the three-dimensional fibrinogen structure. Mutations in the E region (Table 54.2) impair one or more of the following functions: thrombin binding to fibrinogen, fibrinopeptide cleavage, and fibrin polymerization.

Defects in the "A" Knob

Variants include G17V (Bremen), P18L (Kanazawa and Kyoto II), R19S (Detroit), R19G (Oslo IV, Aarhus, Mannheim I, Matsumoto V, and Milano XIII), R19N (Munich I), and V20D (Canterbury). Structural data indicate that the free amino group of the "A" mimic (GPRPam) interacts directly with the side chain of residue γD364 in the "a" pocket, suggesting that the side chain is not critical.[54] Apparently, substitution of a Val for Gly17 impairs both thrombin-catalyzed fibrinopeptide A (FpA) release and polymerization since the peptide Val-Pro-Arg-Val partially inhibits fibrin polymerization.[58] Structure data also show that the positively charged side chain of R19 interacts with residues in the "a" site, such as γD330. Consequently, substitutions with Gly, Ser, or Asn will abolish these interactions. The substitution of Leu for Pro 18 likely alters the structure of the "A" knob and thereby impairs the strength of the "A":"a" interaction.

Unexpectedly, the heterozygous Aα V20D substitution[59] results in absence of residues Aα1-20, thus explaining the approximately half of normal amount of released FpA. This apparently reflects a new furin-susceptible Aα20-21 bond, which enables intracellular removal of the mutant peptide.

Defects in FpA Release

Substitutions at AαR16 are most frequent with over 80 unrelated families known to date. Most are heterophenotypic and asymptomatic. They include either AαR16H or AαR16C and one AαR16S family.[60] Unique to AαR16H is the slower FpA than fibrinopeptide B (FpB) release.[32] In contrast, thrombin does not cleave FpA from AαR16C fibrinogen, although it does from its modified (e.g., S-aminoethylated) isolated chains.[61,62] In the rare homophenotypic probands (i.e., all fibrinogen consists of abnormal homodimers) with either AαR16H[32,63] or AαR16C,[64–66] clotting times are prolonged by the former and infinite by the latter. In such AαR16C probands, this reflects fibrinogen incoagulability, since FpB is releasable, but no clot forms under physiologic conditions.[67] In the case of AαR16H, the reversed FpA/FpB release sequence results in clots formed when most if not all FpB and minor amounts of FpA have been released.

Substitutions of AαD7N, AαL9P, AαP11G, and AαG12V all display delayed FpA release, underscoring the importance of this region on FpA cleavage. Studies including nuclear magnetic resonance and crystallography demonstrate extensive interactions between this region and thrombin, including disruption of a critical electrostatic interaction by the AαD7N (Lille) substitution.[68] Introduction of Pro into the α-helical stretch between residues Aα7 and 10 (AαL9P, Magdeburg I) is believed to inhibit interaction with thrombin by altering conformation.[69] Similarly, the AαG12V (Rouen and Saint-Germain) substitution is predicted to disrupt the Aα1-12 β turn and slightly displace Gly13 and Gly14.[70] The Saint-Germain report also describes delayed FpB release.[71] In addition, AαE11G (Mitaka II) destabilizes the β turn and disrupts the salt bridge between fibrinogen Aα E11 and R173 of thrombin.[72]

Defects in FpB Release and B Knob

Only heterophenotypic Cys substitutions were identified at or near the Bβ14 thrombin cleavage site (Table 54.3). Cleavage of FpB exposes the *N*-terminal β chain site, "B" knob, which binds noncovalently to a complementary polymerization "b" pocket

tahir99-VRG & vip.persianss.ir

in the *C*-terminal region in the β chain (β397-432) of another fibrin(ogen) molecule. This interaction is modeled in the crystal structures obtained in the presence of GHRPam (see previous reviews[7,8]). Only one substitution has been found in the "B" knob: heterophenotypic Bβ G15C (Ise, Fukuoka II, Kosai, Ogasa, and Hamamatsu II). Functional studies showed normal FpA release, approximately 50% FpB release, impaired thrombin- and reptilase-catalyzed polymerization, and impaired desA- and desAB-fibrin monomer repolymerization.[73,74] In addition to impairing the function of "B" knob, these results suggest they impair that of the "A" knob whose second part[8] resides within β.15-42 The sulfhydryl group of each varied. Some formed complexes with albumin attributable to disulfide links via the albumin's solitary-free C34 sulfhydryl,[75] some formed fibrinogen–fibrinogen dimers, and some were free sulfhydryls. Three were asymptomatic and two were associated with thrombosis.

Among eight Bβ R14C unrelated probands (including those in the online registry, vide supra), six were associated with thrombotic events,[76,77] occurring at a young age in at least four, and in several probands in one family (Table 54.3). This association, however, has not occurred in every affected family and remains unclear. There was one proband with hemorrhage and one asymptomatic.[78] Release of FpA was normal and release of FpB was half-normal. Reptilase-induced polymerization (Seattle) was also impaired, suggesting that the mutation itself impairs polymerization.[78] Studies on fibrinogen Ijmuiden identified molecular species linked to albumin (40%), in free sulfhydryl form (36%), and as fibrinogen–fibrinogen dimers (30%).[77] Bβ R44C (Nijmegen, heterophenotypic) impaired fibrin polymerization. Its association with thrombosis contrasts with the same mutation in two unrelated and asymptomatic families (author's unpublished data).

Defects in Thrombin Binding

Three different Bβ chain substitutions resulted in delayed fibrinopeptide release linked to impaired thrombin binding. One was the homophenotypic Bβ A68T (Naples) substitution that impaired thrombin binding (<10%) to fibrin and markedly delayed FpA and FpB release.[79] Crystallographic data suggest that this substitution impairs interactions between fibrinogen and thrombin exosite I.[80] Other studies indicate that binding of thrombin to low-affinity sites (located in the E region) is abolished and high-affinity binding to the γ′ chain is impaired.[81] The second is a heterophenotypic fibrinogen (New York I) with a large deletion of residues Bβ9-72, encoded by FGB exon 2.[82] Its delayed FpA and FpB release is also attributable to diminished thrombin binding. A third substitution, a heterophenotypic Bβ A61K (Miami),[83] is associated with repeated spontaneous abortions and impaired polymerization. A reptilase-incoagulable subfraction (60% of plasma fibrinogen) displayed thrombin binding <10% of normal controls (author's unpublished data).

Defects that Impair Fibrin Polymerization

The intermolecular D:E interaction results in half-staggered, double-stranded fibrils (FIGURE 54.2) and lateral association of fibrils with fibers. More specific interactions have been elucidated in x-ray crystallographic structures of fibrinogen fragments D and FXIIIa–cross-linked fragment D-D in the presence of the peptides GPRPam and GHRPam, which mimic the *N*-terminal regions of the α and β chains of fibrin, respectively.[54,56,57,84] Identification of specific amino acids in these structures and their substituted counterparts caused by mutations enabled a correlation of corresponding biochemical data with the three-dimensional structure. Also, binding of calcium to high-affinity sites γAsp318, Asp320, Phe322, and Gly324[84] is impaired by mutations in this stretch.

Defects within the "a" Pocket

This pocket encompasses γ chain residues 337 to 379. Crystallographic studies showed that Q329 shifts on GPRPam binding; the substitution γQ329R (Nagoya) may disrupt this shift, thereby impairing polymerization.[85] Substitutions γD330V, Ales[86] and Milano I,[87] and D330Y, Kyoto III[88] disrupt ionic interactions with Aα R19. Biochemical analyses of these variants demonstrate that the Aα R19 residue is critical for polymerization.[86,88] Similarly, substitutions γD364 to His and Val, Matsumoto I[89] and Melun[90] respectively, disrupt ionic interactions with the free amino group of the "A" knob mimic, and both substitutions impair polymerization. A γ-chain insertion of 15 residues between γQ350 and γG351, with a concomitant G351S change (Paris I), was first noted in the protein[91,92] and later defined by genetic analyses.[93] The inserted segment has two Cys residues that likely form a disulfide bond, which alter conformation around residues γ350 and γ351. These alterations can account for the impaired polymerization, factor XIIIa cross-linking, and platelet binding.[94] A study of three γ364 substitutions, Ala, His, or Val, disclosed coagulability with normal FpA release but absence of "A": "a" interactions, implying that "B": "b" interactions enabled polymerization.[95] This is in general agreement with the polymerization behavior of homophenotypic Aα R16H (Kingsport).[32] Two polymerization-impairing mutations near the "a" pocket resulted in novel glycosylation γA327T (Tokyo V) and γK380N (Kaiserslautern I). Impaired polymerization by the latter with a new glycosylation site at N380 was corrected by desialylation, suggesting the extra sialylation impaired polymerization. Substitutions γA341D and γA341V[96,97] resulted in impaired "A":"a" interactions and impaired calcium binding,[98] implying that this residue is required for both functions. Two novel Cys substitutions within the "a" pocket were covalently linked to albumin, γY354C[99] (Homburg VII), and γS358C[100] (Milano VII). Both impaired polymerization, and this was not corrected by removal of albumin from Milano VII, suggesting it was attributable to γ358C *per se*.

Defects within the D:D Interface

This interface, first seen in the crystal structure of D:D,[84] encompasses γ275R-300S, near or within which many mutations with variable clinical presentation were reported. Among them are γG268E (Kurashiki), γR275C (numerous unrelated families), γR275H (numerous), γR275S (Kamogawa), γA279D (Auckland), γY280C (Banks Peninsula), γN308I (Baltimore III), γN308K (several), γ309D (Hillsboro), and γM310T (several). By scanning electron microscopy, γR275C (Tokyo II) clots displayed altered network structure,[101,102] which along with other studies underscores the importance of the D:D interface in polymerization. Similarly, impaired polymerization by γA279D and γY280C most likely reflects altered D:D interface, as suggested by evidence of a direct intermolecular γ280:γ275 interaction.[84] The crystal structure also shows γ308 and γ310 lying on the D surface juxtaposed to γ275, intimating altered D:D interface by each mutation. Consistent with this, electron microscopic analysis showed that the abnormal clot structure of γM310T is virtually normalized by enzymatic removal of the novel γ308N-linked carbohydrate cluster.[103]

[a]Accompanied by extra glycosylation detailed in the text.

[b]Decreased calcium binding and/or impaired protective effect of calcium on plasmic lysis.

[c]Of two Bβ mutations in different alleles in the family, the R255H segregated with hypofibrinogenemia, while the K148D segregated with normal fibrinogen (1.4 g L^{-1}) levels. Standard capital letter labels are abbreviations used in DNA and RNA sequences to denote nucleotides and in protein to denote amino acids.

tahir99-VRG & vip.persianss.ir

Defects in Other D Region Sites

The Bβ A335T[104] (Pontoise) substitution results in extra glycosylation in Bβ333N and a markedly prolonged clotting time. Causing impaired polymerization, an insertion of 12 residues at the *C*-terminus of the Bβ chain resulted when the normal stop codon at 462 was changed to encode Trp (Osaka VI).[105] The resulting single new cysteine formed disulfide-linked dimers of variant molecules. Clots of this variant had thinner fibers in a lacy meshwork with large pores and were more fragile and compressible than controls. The γG165R (Milano XII) mutation was copresent in heterozygosity with Aα R16C.[106] Circular dichroism analysis disclosed altered folding of the *C*-terminal part of the γ chain, likely because γG165R falls between disulfide-bound residues γ153 and γ182. Molecular modeling of γG292V (St. Gallen I)[107] suggested that (a) the Val substitution alters conformation so fibrin(ogen) γ302-γ303 is more accessible to plasmin and (b) it impairs polymerization by disrupting hydrogen bonds between γ297 and γ375, thus destabilizing "A": "a" interactions. The γC326S substitution displayed albumin bound to its unpaired Cys.[108] Both γM336I[99] (Hanover VI) and γN337K[109] (Bern I) are near the calcium-binding site and the "a" pocket and likely impair polymerization by altering both structures. Impaired polymerization by γN361K[110] (Poissy II) implies that residue 361 contributes to the "A": "a" interaction. Normalized polymerization by increased calcium concentrations also suggests that this mutation affects calcium binding. The γR375G (Osaka V) substitution was similar,[111,112] with impaired polymerization normalized by calcium, impaired protective effect of calcium on plasmin degradation, and reduced high-affinity calcium binding. These results indicated a role for γ375 in calcium binding and the "a" pocket functions.[112] Some γchain mutations impaired fibrinogen-dependent platelet aggregation.[113–115] Since platelets interact with the *C*-terminal γ400-411site and an auxiliary γ370-383 site,[116] the impaired platelet aggregation by these mutations possibly reflects allosteric effects.

Defects within the Coiled-Coil Region

Identified in wide-angle x-ray diagrams of fibrinogen fibers,[117] the D and E regions are joined by α-helical coiled-coil rods that encompass amino acids Aα50-166, Bβ81-191, and γ24-134. In the coiled-coil, most nonpolar residues point inward to form the core and the polar residues are exposed to the solvent on the outside. Evidence indicates that most of the elasticity of the molecule resides in its coiled coil.[118] Two single deletions, Aα80N del[119] (Caracas IV) and Bβ111S del[120] (Kyoto IV), occurred within the all-polar region near the carbohydrate attachment point at γ52N and are thought to disrupt α-helicity. The former decreased polymerization and clot stiffness and the latter enhanced lateral polymerization. This region is a touch point where the coiled coils from different molecules associate in an antiparallel fashion in the fibrinogen crystal and possibly in polymerized fibrin.[121] A Bβ N167-E171 deletion is associated with severe hypodysfibrinogenemia and undue bleeding.[122] Severe hypodysfibrinogenemia is also associated with a compound heterozygosity consisting of a missense Bβ L172Q, with a truncation resulting from exposure of a cryptic acceptor splice site in exon 4, and R17Stop.[123] Each of two other mutations, Aα R141S[124] (Lima) and a Bβ N160S (Niigata),[125] results in a consensus sequence enabling novel glycosylations. Impaired polymerization is not corrected by deglycosylation at residue 158, indicating it was attributable to the Ser substitution (Niigata). In contrast, deglycosylation of Aα N139 (Lima)[126] corrects the polymerization defect, suggesting the novel glycosylation impairs polymerization. Substitution of Bβ R166C (Longmont) resulted in disulfide-linked fibrinogen dimers[127] whose removal did not correct the impaired polymerization. Taken together, these data suggest steric hindrance or blocking of proper alignment of monomers into protofibrils, of protofibrils into fibers, or both. Lastly, afibrinogenemia was found in a compound heterozygote with Aα M51R in one allele and a stop Aα51 codon in the other,[127] intimating failure of intracellular assembly or secretion by each mutation. Normal/mutant heterozygosity of either mutation likely results in normal or decreased plasma fibrinogen (hypofibrinogenemia).

Defects in the αC Region

The αC region (residues Aα221-610) extends from the D region and folds back toward the center (E) region.[128] It includes a flexible segment (Aα221-391), the "αC-connector," and an independently folded compact segment (Aα392-610), the "αC-domain."[129,130] In fibrinogen, the two αC-domains interact with each other and with the E region (FIGURE 54.1) while in fibrin they switch to intermolecular interactions. FpA release weakens their E region tethering.[131] Following FpB release, αCs are untethered and dissociate from one another facilitating lateral assembly of protofibrils.[128,132] Most mutations within αC generally result in impaired polymerization. Aα S434N substitution[133,134] creates a consensus sequence enabling novel glycosylation. In two other single substitutions, Aα S532C (Caracas V) and Aα R554C (Dusart, Chapel Hill III, Nashville, and another unnamed), the novel Cys residue is covalently linked to albumin. Electron microscopy (Caracas V[135] and Dusart[136]) disclosed abnormal fibrin clot structures.

Seven mutations result in truncations in the αC region, ranging from a 56% truncation terminating at residue 271, Otago[137] to a 15% truncation terminating at residue 518, San Giovanni Rotondo.[138] The Otago truncation reflects a frameshift mutation encoding Aα R268QEP, is homozygous with severe hypodysfibrinogenemia, and suggests an αC role in fibrinogen assembly and secretion. Also suggesting such a role are truncations with similarly low levels of fibrinogen variants Keokuk (10% of normal, Aα Q328X in the simple heterozygote),[139] Marburg (10% to 20%, homozygous Aα K461X),[140] Lincoln (20%), a heterozygous frameshift mutation Aα A475+HCLAStop,[141] and Perth (15%), a heterozygous frameshift with addition of 23 novel residues after Aα494.[142] In sharp contrast, two homozygous truncations at Aα452 (GPD–>WS-Stop, Milano III)[143] and Aα454 (Nieuwegein)[144] circulate at normal levels (2.6 g and 1.7 g L^{-1}, respectively). These two dysfibrinogens differ from one another in their terminating residues. Milano III[143,145] is a frameshift change in which two novel residues, W453 and S454, follow the Aα G452 mutation before a stop codon. In the Nieuwegein[144] defect, a nucleotide insertion at P453 codon results in a premature stop codon at 454. Turbidity studies indicate that each of these truncations decreases lateral aggregation, consistent with the long-known αC enhancement of this process.[132] Studies with fibrinogen Lincoln[141] (frameshift at Aα475A which translates as four new residues before terminating at a new stop codon, 476HCLAStop) showed that despite the new Cys residue, the variant chain was not found in albumin-bound fibrinogen. Also unique, the Aα Q328X truncation (Keokuk) occurred in two compound heterozygotes, with an FGA (IVS1 + 4A > G)

tahir99-VRG & vip.persianss.ir

splice-site mutation that results in no viable Aα chains from the second allele, a known cause of afibrinogenemia in homozygotes.[10] Only the truncated Aα chain was found in circulating fibrinogen whose lateral fibrin aggregation was markedly decreased. In general, mutations with albumin-bound complexes indicate that absence of the specified αC segment, rather than the presence of albumin, leads to impaired polymerization.

Clinical manifestations. The plasma prothrombin time (PT) is more often prolonged than the activated partial thromboplastin time (aPTT), possibly because PT is performed without a preincubation step and is thereby more sensitive to time lag prolongation. Such prolongation may be masked by the preincubation, with activating agents during the aPTT test. TT and RT are characteristically prolonged. For plasma fibrinogen measurements, TT-based[146] assays are clearly more sensitive than those that are PT based,[147] particularly when fibrinogen levels by either assay are decreased. Abnormal thromboelastograms may also reflect hypo- or dysfibrinogenemia[148] and are particularly sensitive when the test is performed in the absence of platelets. That is, owing to platelet retraction the typically small proportion of normal molecules may be sufficient to result in a normal or near-normal signal graph, while without platelets this is insufficient to correct the altered signal graph caused by the preponderance of abnormal molecules. Most dysfibrinogenemia mutations are asymptomatic (Table 54.2). Among symptomatic probands, a common feature is that other affected family members are asymptomatic. For example, a massive single hemorrhagic event in the Fibrinogen Louisville, AaR16H, proband (Table 54.3) did not occur in other affected family members, suggesting other possible contributing factors. In a retrospective study of clinical manifestations among >260 dysfibrinogenemic probands,[149] 55% were asymptomatic, 20% presented with a thrombotic history or event, and 25% with a hemorrhagic history or event, and among 2,376 patients with deep vein thrombosis 0.8% had dysfibrinogenemia.

Association with thrombosis. Among probands with a thrombosis history or presenting event, other genetic/acquired risks of thrombosis were present in a relatively small number. Some examples[150–153] include heterozygous factor V_{Leiden} with γR375C (Cedar Rapids), γR275H (Crete) or γG200V (Columbus), and AαT312A on contraceptive medication. Mutations associated with thrombosis include a small number with both thrombosis and hemorrhage. In roughly half of the thrombosis group (Thrombosis U, FIGURE 54.3), the nature of the copresence or association is unclear, while in the other half (Thrombosis R) clinical and other data strongly suggest a relationship to the mutation (Table 54.4). There is a variety of mutation types (i.e., deletion, insertion, missense, frameshift, etc.) and they occur in many molecular sites (FIGURE 54.4). Two mutations (Champagne au Mont d'Or and Lozanne) associated with thrombosis were identified using electrophoretic screening of fibrinogen from 217 individuals with recurrent or early age thrombosis and normal clotting times.[154] Five others were identified by liquid chromatography and mass spectrometry analyses of fibrinogen from 33 patients with thromboembolism-related pulmonary hypertension.[155] Among these, finer fibrin network and hypofibrinolysis (in three) were shown by retrospective analyses. An additional two, fibrinogens New York I,[82] heterophenotypic, and Naples,[79] homophenotypic, were associated with recurring thrombosis in more than one family member with the same mutation. Each mutation resulted in markedly impaired thrombin binding (vide supra), implying a causative mechanism for thrombosis. The heterophenotypic substitution AαR554C was found in four unrelated families with recurring thrombosis

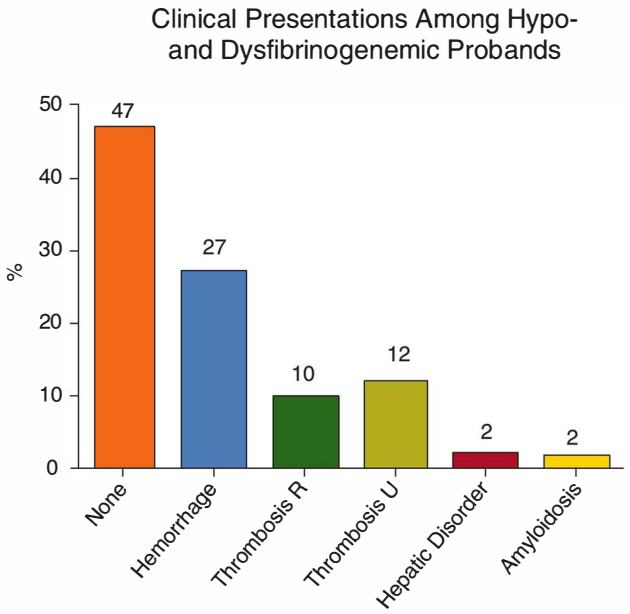

FIGURE 54.3 Clinical presentations among 194 probands with hypofibrinogenemia or dysfibrinogenemia. Numbers on top of each column reflect the % of the total in all columns.

in multiple affected members (Dusart, Chapel Hill III, Nashville, and one unnamed other).[156] The fine clot network (Dusart) was resistant to hypofibrinolysis.[8] This raises the possibility that the covalently linked albumin, relatively resistant to plasmin,[75] masks or blocks access to critical plasmin-susceptible bonds. Recurring thrombosis was also described in multiple probands in each family with heterophenotypic AαS532C,[157] AαQ328X (with Aα IVS4+1G >T),[139] and γD364V.[90]

Association with hemorrhagic diathesis. Including 4% with both thrombotic and hemorrhagic events, 27% of 194 mutations (FIGURE 54.3) are associated with hemorrhage, which is common among probands with fibrinogen levels of approximately 0.1 to 0.5 g L^{-1} by clotting assays. Frequent hemorrhagic events include recurring skin bruising with or without epistaxis. Unexplained and recurring miscarriage and/or hemorrhage during pregnancy including parturition are common.[158,60] However, undue hemorrhage during or following surgery, trauma, or minor injury is highly variable, suggesting that for a given mutation the threshold for undue hemorrhage in pregnancy is lower than in other clinical settings. Hemorrhagic diathesis from E region mutations is typical among homophenotypic AαR16H (two unrelated families, reversed FpA/FpB release sequence) and AαR16C[64,65] (three unrelated families, incoagulable fibrinogen at 37 degrees). In one AαR16H proposita (fibrinogen 0.61g L^{-1}), clot lysis by plasmin was accelerated[159] and likely contributed to the delayed FpA release-associated hemorrhagic diathesis. A similar presentation is associated with some heterophenotypic mutations within or near the "A" knob (vide supra). Most mutations within FpA are associated with hemorrhagic symptoms (Table 54.3), possibly reflecting both diminished thrombin binding and FpA release. Most polymerization defects are asymptomatic (Table 54.3). For those with a hemorrhagic history, the mechanism(s) is unclear, save fibrinogen Paris I with defective cross-linking of γchains and platelet interaction, those with severe hypodysfibrinogenemia, and those associated with defective α chain cross-linking.

Table 54.4

Mutations associated with thrombosis

Peptide Phenotype (Site)	Name[Reference], Mutation(s)	Presentation	Affected Family Prob.	Other Comments
Aα L69H (CC)	San Diego IV[155]	One of 5 in 33 patients with VTE-pulmonary hypertension	None	Detected by special screening (see text)
AαN106D (CC)	Plzen[274]	VTE	None	26-year-old proband
Aα272 in frame 39-residue duplication (αC-conn.)	Champagne au Mont d'Or[154], 117 bp ins	Recurring VTE, 42 y.o., plasma clotting tests normal	None	Detected by special screening (see text)
Homophenotypic AαQ328Stop both siblings (αC-conn.)	Keokuk[139], FGA codon 328 C>T (Stop)	Both siblings with severe hypod. and severe hem. diathesis. Male: Recurrent VT after cryoprecipitate infusion	Female: 6 Misc'ge	Both compound heterozygotes with IVS-4 + 1g > t (silent allele)
AαR454C (αC-dom.)	Bordeaux[281]	VTE at age 25	None	Normal plasma clotting times
AαI451Wfs, homoz. (αC-dom.)	Milano III[143,145]	VT at age 13	None	Impaired polym.
AαS532C (αC-dom.)	Caracas V[135]	VTE	Many	Hypofibrinolysis
Aα R554H (αC-dom.)	San Diego V[155]	One of 5 among 33 patients with VTE-pulmonary hypertension	None	Detected by special screening (see text)
AαR554C-alb (αC-dom.)	Dusart[156] (4 unrelated families)	Recurring VTE in young adults and children	VTE in many probands	Impaired polym. hypofibrinolysis
Heterophenotypic Bβ9-72 del (B knob, thr. bdg.)	New York I,[82] exon 2 del	Recurring VT	VT in others	Impaired thr. bdg., polym.
BβA59Pfs (Thr. bdg.)	3404del[239]	Thr. in infancy		Fs
Homophenotypic BβA68T (Thr. bdg.)	Naples[316], codon 68G>A	Recurring arterial and VT	VT in three homozygotic probands	Impaired thr. bdg. and polym.
BβP235L/γR375W(D:D) BβP235L/γY114H(CC), BβP235L (D)	San Diego I[155] San Diego II[155] San Diego III[155]	Three of 5 in 33 patients with VTE-pulmonary hypertension	None	All detected by special screening (see text)
Bβ236YStop (D)	Lozanne[154], 5909a>g	Recurrent VTE, clotting tests normal, age 31 y	Mutation in family members	Detected by special screening
γT314I (D)	Kagoshima[302]	VT, age 36 y		Postpartum hemorrhage
γD318V (D)	Caen[317], c.1031A>T	VT, age 5 y	None	
γD318G (D)	Giessen IV[317]	VT, child	None	
γA327T (D)	Tokyo V[308] hypod.	Recurrent VTE, age 43 y	None	Clot resists lysis
γD330V (D)	Ales[86]	Strokes, before age 36 y		Thrombotic strokes
γD364V ("a")	Melun[90]	VT and arterial thrombosis, miscarriage	VT in many siblings	Normal fibrin polym.

Homophenotypic: indicates that either genotypes were not reported (e.g., Detroit, Metz), were homozygotic, or were compound heterozygotic by allele analysis (e.g., Kingsport, Frankfurt XIII); Homoz., homozygous; Hypod., hypodysfibringenemia; Misc'ge, miscarriage; Ins, insertion; Fs, frameshift; Polym, polymerization; Thr. bdg., thrombin binding; Hem., hemorrhagic; VT, venous thrombosis; D, unspecified D region site(s); Dom.: domain, conn.: connector. CC, coiled coil; y, year old.
Criteria for inclusion: thrombosis at young age (<40 y), in multiple related and unrelated probands, and probands randomly discovered in a thrombosis population.

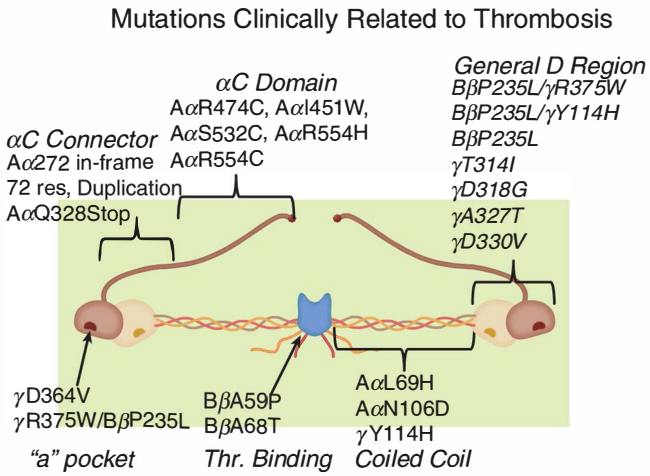

FIGURE 54.4 Schematic representation of molecular sites of fibrin(ogen) mutations whose clinical features strongly suggest a relationship to thrombosis as detailed in the text and Table 54.4.

Pregnancy complications. Although the precise frequency of miscarriage among afibrinogenemic fertile women is unknown, case reports indicate it is typical,[9,10,17,160] in general agreement with data from animal studies showing fibrinogen is required to maintain gestation to term.[12,13,14] Miscarriage is also frequent in pronounced hypo- or hypodysfibrinogenemia. Examples of mutations with dysfibrinogenemia and associated miscarriage include homophenotypic AαR16C (Metz,[161] Frankfurt XIII[64]), BβM118K (Lyon[162]), BβY236C (Paris IX[163]), γA82G (Hannover VII[164]), BβAsn137-Glu141del (Epsom),[122] AαH494P+23 res>517Stop (Manheim V),[165] and homophenotypic AαQ328Stop (Keokuk).[139] Many other reports in which the mutations were not identified[19,166] described miscarriage, bleeding during second or third trimester including the intra- and peripartal period, and abruption placenta. An unique example is perivillous placental thrombosis and recurring postpartum VTE along with intrapartal hemorrhage associated with the single pregnancy of the homophenotypic AαR16H proposita.[32]

Hereditary amyloidosis. A few mutations within the fibrinogen αC-domain are linked to hereditary amyloidosis, a protein misfolding disorder resulting in tissue deposition of insoluble fibrils containing peptides with the abnormal sequence. There are 25 known causative mutations among various proteins.[167] Renal involvement is typical, the most frequent lesion consisting of glomerular deposits. The typical presentation is nephrotic syndrome and hypertension with a median age of 55 years. The first report of amyloid identified fibrinogen peptides encompassing Aα499-580 with an AαR554L substitution.[168] Other mutations include AαE526V[169] and two frameshift mutations that encode truncations: a mutation at codon 524, resulting in termination at Aα548,[170] and one at codon 522, also resulting in termination at Aα548.[171] A possible explanation is intimated by the minor catabolic fraction of circulating fibrinogen that lacks intact αC.[172] The resulting free mutant αC peptides may form insoluble aggregates that are deposited in tissues and lead to amyloidosis. A retrospective DNA and tissue analysis of 350 cases of systemic amyloidosis disclosed 18 cases with renal amyloidosis due to the AαE526V mutation.[173] In a study providing new insights, among 22 patients with fibrinogen amyloid (21 with AαE526V and one R554L), all of whom received both renal and hepatic transplants,[167] coronary and systemic atheromas were found in 67% and 55%, respectively. Vascular atheromas and endocardial biopsies from these contained purely fibrinogen amyloid. Also, the combined liver/renal transplantation dramatically improved renal allograft survival.

Therapy

There are no controlled studies on fibrinogen replacement, but there is general agreement from case reports that at a mean weakly dose of 0.06 g/kg body weight it prevents/stops bleeding from fibrinogen anomalies,[10] notwithstanding that in one report frequencies of bleeding episodes between groups with and without prophylactic replacement were similar.[174] Cryoprecipitate (~0.25 g fibrinogen/container) is commonly used. Fresh-frozen plasma (0.5 to 0.75 g fibrinogen/container) is less frequently used owing to undesirable hemodynamic effects of its large volume. A fibrinogen concentrate[175] (that lacks the viral disease transmission risks) has also become available in United States. Numerous case reports clearly indicate that with a history of one or more miscarriages further miscarriage is prevented by fibrinogen replacement.[158] Similarly, undue bleeding or miscarriage after the first trimester can also be successfully treated/prevented. Suggested regimens (Table 54.5) reflect those in various reports.

Hyperfibrinogenemia

Circulating fibrinogen levels are determined partly (30% to 59%) by genetic[176–178] and partly by environmental factors.[23] The latter include the acute-phase response[179,180] during which the fibrinogen level is regulated by cytokines,[181–184] mainly IL-1 and IL-6. Underscoring genetic determinants, overexpression of all three fibrinogen genes was required to achieve fibrinogen levels of 1.4 to 1.7 times the normal level in an experimental mouse model.[185] Levels above the normal range are commonly associated with pregnancy, venous thrombosis, malignancies, and inflammation. Hyperfibrinogenemia is found in approximately 26% of patients with a large array of different malignancies.[186] Fibrinogen levels of >5g L^{-1} carry a nearly fourfold higher venous thrombosis risk than those of <3gL^{-1}.[187] Of considerable interest are levels within the upper part of normal range that are associated with FGB promoter region polymorphisms such as −854G>A, −455G>A, −148C>T, R/K448, and BclI.[188] Among these, −148T and −455A are associated with cardiovascular disease.[189] That is to say, fibrinogen levels in the upper tertile, relative to those in the lower tertile, are associated with a 2.3-fold greater risk of cardiovascular disease.[190,191] Cross-sectional prospective studies imply that such elevations are independent predictors of coronary artery disease, stroke, and peripheral artery disease.[191] Moreover, the magnitude of the increased fibrinogen levels correlates with the severity of peripheral arterial disease, with the extent of myocardial necrosis following infarct, and with cerebrovascular occlusions. Additionally, the disease risk is disproportionately increased in individuals with the highest fibrinogen levels indicating a threshold effect. Fibrinogen is a major determinant of blood viscosity whose increased level is also a strong predictor of cardiovascular events in hypertension, stroke, and diabetes.[192] Also, circulating soluble fibrinogen/fibrin complexes,[193] which are inherently viscid and procoagulant,[33] are likely to increase with increased fibrinogen and contribute

tahir99-VRG & vip.persianss.ir

Table 54.5

Recommended fibrinogen replacement during pregnancy

First Trimester	Third and Fourth Trimesters	During Labor or Caesarian Section
Afibrinogenemia		
As soon as gestation is established begin replacement and maintain plasma fibrinogen at ~1 g/L[1].	At least weakly infusions required, the amount required will increase two to three times by late third trimester.[318]	Infuse 5-g fibrinogen bolus; initiate a slow infusion to maintain 1.5 g L^{-1} for 24 h (will need ≥ 5g).
Dysfibrinogenemia		
Fibrinogen >0.6 and <1.5 g L^{-1} similar to pregestation levels, and no history of bleeding	Obtain levels every trimester.	Replacement need is unlikely, unless bleeding occurs before delivery.
Fibrinogen <0.6 g L^{-1} (bleeding risk is increased)	Follow replacement regimen as in afibrinogenemia.	Follow replacement regimen as in afibrinogenemia.
Hypofibrinogenemia		
Fibrinogen >0.6 and <1.5 g L^{-1} (bleeding risk is low)	Follow the dysfibrinogenemia procedure, if needed	Replacement as in afibrinogenemia may be needed.
Fibrinogen <0.6 g L^{-1} (bleeding risk is increased)	Follow replacement regimen as in afibrinogenemia.	Follow replacement regimen as in afibrinogenemia.

to the increased blood viscosity. Among the effects of elevated viscosity is increased blood flow shear stress[192] and thereby activation of endothelial cells[194,195] that leads to expression of various adhesion molecules such as intercellular adhesion molecule-1, $\alpha_v\beta_3$, and $\alpha_5\beta_1$.[196,197] All three are receptors for fibrinogen whose binding to each receptor results in multiple alterations of vascular function.[198] In other studies, histopathologic data indicate the presence of fibrinogen and its degradation products during the progression of atheroma,[199,200] and elevated fibrinogen levels are closely related to the enhanced rate of coronary calcification and increased media–intima thickness, both measures of premature atherosclerosis.[201] At the cellular level, fibrinogen favors permeability of endothelial cells, extracellular accumulation of low-density lipoprotein cholesterol, and formation of foam cells. Fibrinogen also induces migration of monocytes and vascular smooth muscle cells, increases platelet reactivity or aggregation, and enhances inflammation.[23,202] Also, elevated fibrinogen level is a major determinant of amount of formed thrombin.[203] A study using a transgenic mouse model[204] demonstrated that elevated fibrinogen augments fibrin deposition into specific organs, interacts with an unidentified and independent modifier of hemostatic activity that regulates fibrin turnover and deposition, and exacerbates neointimal hyperplasia under stasis-induced vascular remodeling conditions. In a study of a normal variant known as γ', (8%–15% of total fibrinogen), it is increased in stroke and coronary disease and this is independent of increased plasma fibrinogen.[205] This is a splicing variant with a longer γ chain[206] (FIGURE 54.1). Its last four C-terminal γ residues are replaced by a unique 20-residue extension[207] within which residues 414 to 427 possess the high affinity, noncatalytic thrombin-binding site.[208] Mediated by thrombin exosite 2, binding to this variant sequesters free thrombin and by limiting its catalytic potential regulates thrombin generation via the intrinsic pathway. Considered together, the foregoing observations intimate that elevated plasma fibrinogen contributes substantially to the development of the atheroma lesion.

Definitions

FpA: fibrinopeptide A. "A" knob: site exposed by FpA release, encompassing residues α17-19 (GlyProArg). "a" pocket: site interacting with "A" knob

FpB: Fibrinopeptide B. "B" knob: site exposed by FpB release encompassing Bβ15-19 (GlyHisProArg)

"b" pocket: Bβ397-432

αC: Aα chain region encompassing Aα 220-610

αC-domain: region encompassing Aα 372-610

αC-connector: region encompassing Aα 220-371

Heterozygous: mutation or polymorphism affecting one allele

Homozygous: mutation of polymorphism affecting both alleles

Heterophenotypic: expression of both alleles of a heterozygous proband

Homophenotypic: expression of both variant alleles of a homozygous proband or of only one of two variant alleles of a heterozygous proband (i.e. the second allele is not expressed).

CHAPTER

55 Familial Multiple Coagulation Factor Deficiencies

BIN ZHANG AND DAVID GINSBURG

The familial multiple coagulation factor deficiencies (FMFDs) are a group of rare inherited disorders characterized by a simultaneous decrease in the levels of two or more coagulation factors. Earlier reports of deficiencies in various combinations of coagulation factors prompted Soff and Levin[1] in 1981 to classify these disorders into six types (FMFD I to VI). Combined deficiency of FV and FVIII (F5F8D, or FMFD I) and combined deficiency of vitamin K–dependent clotting factors (VKCFD, or FMFD III) are the best known and comprise the vast majority of reported cases of FMFD. This chapter focuses on these two disorders. Little is known about other types of multiple coagulation factor deficiencies, as few new cases have been reported since 1981. As a consequence, this old classification is of limited relevance today and not generally used in practice.[2]

COMBINED DEFICIENCY OF FACTOR V AND FACTOR VIII

History

Combined deficiency of factors V and VIII (F5F8D) was first described in a pair of Swiss siblings in 1954.[3] Since then, more than 80 families with F5F8D have been identified around the world. As is the case for rare autosomal recessive disorders, F5F8D is often associated with consanguineous marriages. However, it is likely that F5F8D is underdiagnosed, in part due to its often mild bleeding manifestations. Some F5F8D patients may be misdiagnosed as having mild hemophilia A or parahemophilia (FV deficiency). F5F8D appears to be particularly prevalent among Middle Eastern Jews and non-Jewish Iranians, estimated at approximately 1:100,000 in these populations.[4,5,6] This high frequency is probably due, at least in part, to the prevalence of consanguineous marriages in these populations. The molecular basis of F5F8D was a mystery until 1998.[7] Initial speculation centered on a defect in a precursor protein for both factors V and VIII,[3] but no such precursor could be identified. A low level of protein C inhibitor activity in patient plasma was reported in 1980,[8] but was later found to be caused by an artifactual loss of protein C inhibitor in frozen samples.[9–12] Subsequent genetic studies identified the cause of this disorder as deficiencies in a unique secretory pathway shared by FV and FVIII.[13,14,15]

Genetics and Biology

Inheritance of F5F8D is autosomal recessive and distinct from the coinheritance of both FV deficiency and FVIII deficiency. Heterozygotes are asymptomatic and their plasma levels of FV and FVIII are indistinguishable from normal. Using homozygosity mapping and positional cloning approaches, the first gene for F5F8D was identified in 1998[13] as *LMAN1* (lectin, mannose-specific 1). The encoded protein (LMAN1, also referred to as ERGIC-53), though of previously unknown function, was known to localize to the endoplasmic reticulum (ER)-Golgi intermediate compartment (ERGIC).[16,17] Mutations in *LMAN1* account for approximately 70% of F5F8D patients. No *LMAN1* mutations could be identified in approximately 30% of affected families.[18,19] In 2003, the second cause of F5F8D was identified in the latter subset of families as mutations in *MCFD2* (multiple coagulation factor deficiency gene 2).[14] To date, at least 33 different *LMAN1* mutations[13,18–20,21] and 17 different *MCFD2* mutations[14,21,22,23] have been identified (FIGURE 55.1). The diverse nature of the mutations indicates multiple independent genetic origins. Haplotype analyses performed on two *MCFD2* mutations (c.149+5G>A and c.407T>C) that are identified in multiple distinct populations demonstrated multiple independent genetic origins for each mutation.[24] However, founder mutations may account for all or the majority of F5F8D in some isolated populations. For example, two mutations in *LMAN1* account for nearly all Jewish F5F8D patients. One of these mutations is prevalent in Jews originating from the island of Djerba in Tunisia, but not found among North African Jews.[25] The second *LMAN1* mutation is unique to Middle Eastern Jews.[13] Another notable mutation is the missense mutation abolishing the initiation codon (c.2T>C) of *LMAN1*, which has only been reported in families of Italian origin.[21,26]

Mean FV and FVIII levels are slightly but significantly lower in *MCFD2* patients compared to *LMAN1* patients. However, the levels in these two groups overlap extensively, and individual patients with *MCFD2* or *LMAN1* mutations are clinically indistinguishable.[21] Plasma FV and FVIII levels for a given patient are also significantly correlated, suggesting that deficiencies in either LMAN1 (ERGIC-53) or MCFD2 exert a similar impact on the secretion of both FV and FVIII.[21] Circulating FV exists in both plasma and the α-granules of platelets as a 330-kDa single-chain polypeptide. In humans, the platelet FV pool is thought to originate from endocytosis of plasma FV,[27,28] whereas in mice, platelet FV is derived exclusively from biosynthesis within the megakaryocytes.[29,30] Comparison of platelet FV levels in F5F8D patients and normal controls indicates that platelet FV and plasma FV are reduced to the same extent for both the *LMAN1* group and the *MCFD2* group.[21] Therefore, mutations in *LMAN1* or *MCFD2* similarly affect the steady-state levels of FV in both pools.

LMAN1 is a 53-kD homohexameric transmembrane protein that belongs to a conserved class of L-type animal lectins with homology to leguminous mannose-binding lectins.[31,32] The

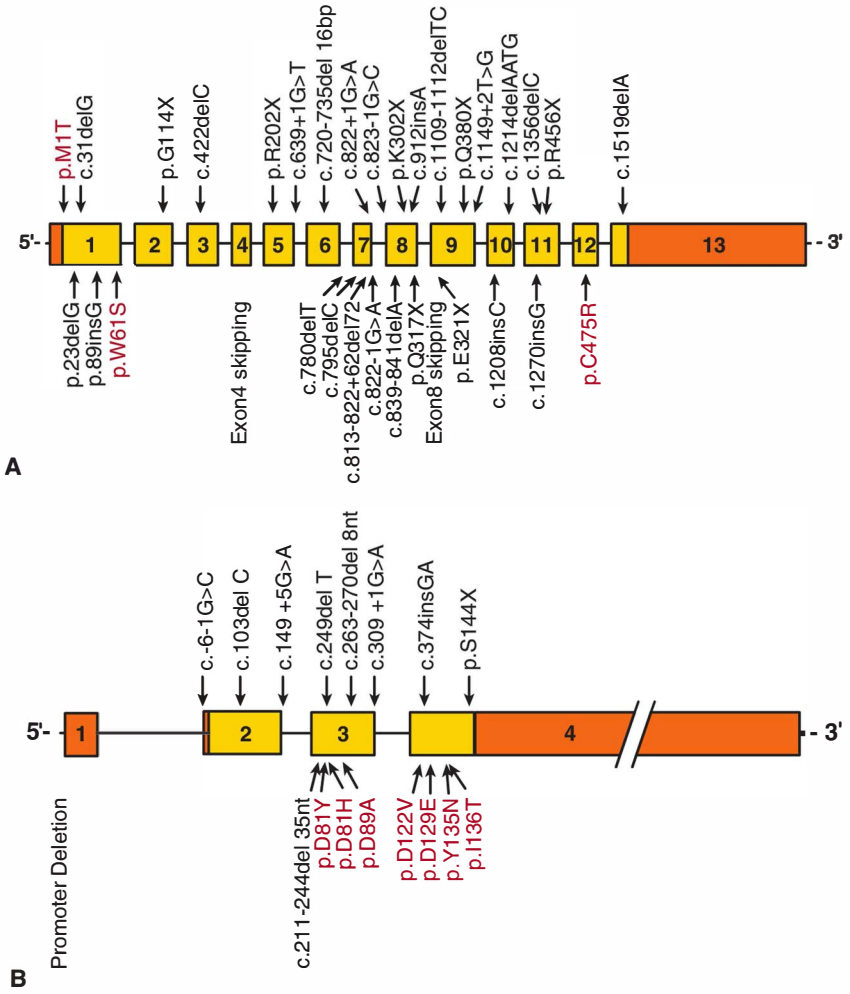

FIGURE 55.1 Structures of *LMAN1* and *MCFD2* genes and mutations identified in combined deficiency of factor V and factor VIII. **A:** Most mutations in *LMAN1* are predicted to result in complete loss of protein function. Three missense mutations, shown in *red*, also lead to loss of function. **B**: In addition to insertion, deletion, and splice site mutations in *MCFD2*, multiple missense mutations also occur in both EF-hand domains and were shown to abolish binding to LMAN1(14;21;37). Exons are numbered and drawn to scale. *Shaded rectangles* represent the coding regions of the genes, with the open portions of exons 1 and 13 in *LMAN1* and exons 1, 2, and 4 in *MCFD2* representing the 5′ and 3′ untranslated regions.

LMAN1 *C*-terminus is exposed to the cytoplasm and contains the ER exit and retrieval motifs. The ER luminal side of the protein contains a carbohydrate recognition domain (CRD) and a coiled-coil domain. MCFD2 is a 16-kDa soluble protein with two Ca^{2+}-binding motifs, known as EF-hand domains, at the *C*-terminus with a structure similar to that of calmodulin.[33] MCFD2 interacts with LMAN1 to form a stable Ca^{2+}-dependent complex with a 1:1 stoichiometry, and the two proteins colocalize in the ERGIC.[34] Crystal structure and cell biology studies indicate that the *N*-terminus of the LMAN1 CRD interacts with the EF-hand domains of MCFD2.[35,36] Only three missense mutations have been identified in *LMAN1*. The first missense mutation destroys the initiation codon of the gene. The other two mutations either destabilize the protein[24] or abolish MCFD2 binding.[20] Seven *MCFD2* missense mutations have been identified within the EF-hand domains, which disrupt the LMAN1-MCFD2 interaction, resulting in F5F8D.[14,21,37]

One of the central problems in cell biology is how newly synthesized proteins are sorted for transport to their final destinations. An increasingly accepted model envisions that "cargo receptors," localized to the ER membrane, selectively package secreted proteins into "vesicles" for transport to the Golgi body.[38,39] The finding of *LMAN1* gene mutations as a cause of F5F8D provided the first direct evidence for a mammalian ER cargo receptor, suggesting that LMAN1 mediates export of FV and FVIII from the ER to the Golgi (FIGURE 55.2). To date, the LMAN1-MCFD2 complex remains the only cargo receptor identified in higher eukaryotes,[38,39] though two other potential cargo receptors have been described in yeast.[40,41] LMAN1 and MCFD2 should act in concert to facilitate transport of FV and FVIII, since mutations in either gene lead to impaired secretion of FV and FVIII. However, the precise role of MCFD2 in cargo receptor function is still not clear. Both LMAN1 and MCFD2 have been shown to bind FV and FVIII directly,[14,34,37,42] with the sugar-binding site of LMAN1 and the EF-hand domains of MCFD2 important for these interactions.[37,42] The heavily glycosylated B domains of FV and FVIII may be important in mediating secretion through the LMAN1-MCFD2 pathway.[34,43,44] An interesting question is whether the ER to Golgi transport of other proteins is also altered in F5F8D patients. This seems likely, given the ubiquitous expression patterns of both LMAN1 and MCFD2,[14] as well as the presence of LMAN1 and MCFD2 orthologs in lower eukaryotes without a blood clotting system. Indeed, a number of other proteins have been identified to either interact with LMAN1 or exhibit delayed secretion in cultured cells with a

tahir99-VRG & vip.persianss.ir

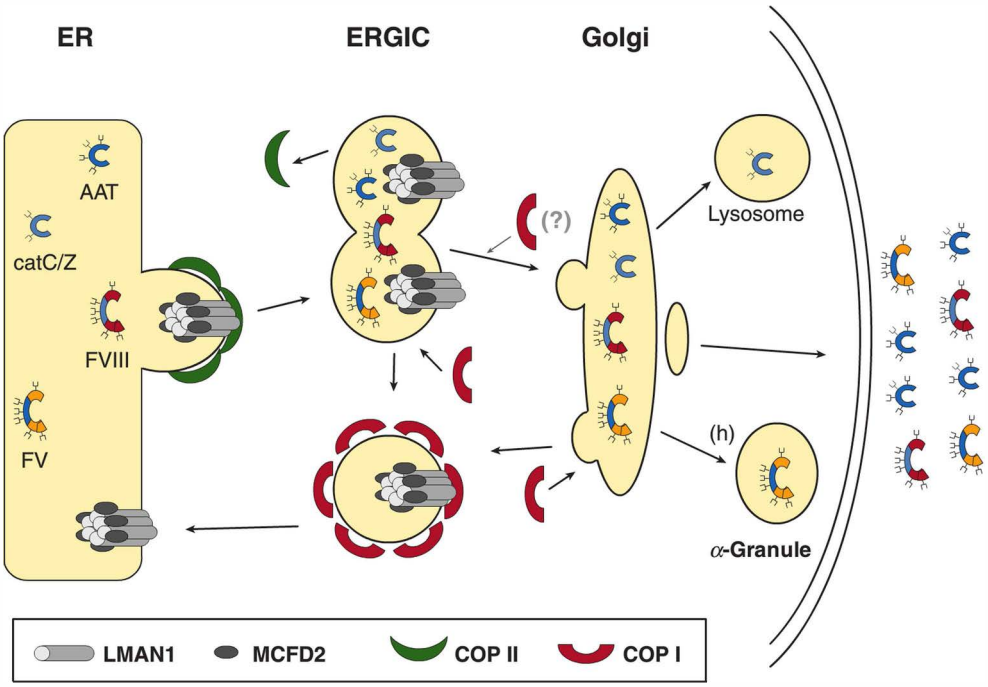

FIGURE 55.2 Model of receptor-mediated ER to Golgi transport of FV and FVIII and other potential cargo. Correctly folded FV/FVIII molecules are recruited to the COPII-coated vesicle budding from the ER by binding to the LMAN1-MCFD2 complex. Upon budding, these vesicles uncoat and fuse with each other to form the ERGIC. Release of FV/FVIII from LMAN1-MCFD2 occurs in the ERGIC. The LMAN1-MCFD2 complex is recycled back to the ER in COPI-coated retrograde vesicles as FV and FVIII are transported to the Golgi. Cargo proteins undergo further sorting and modifications in the Golgi. CatC and catZ are targeted to the lysosome. FV, FVIII, and α_1-antitrypsin (AAT) are secreted from cells, with the exception of megakaryocytes, in which FV is packaged into α-granules for storage. (Modified by permission from Baines AC, Zhang B. Receptor-mediated protein transport in the early secretory pathway. *Trends Biochem Sci* 2007;32:381–388, copyright (2007) Elsevier Ltd.)

dysfunctional LMAN1 (FIGURE 55.2).[45–48] However, transport deficiency in other proteins is likely to be at a level insufficient to produce a clinical phenotype, as no other abnormalities, aside from the deficiencies of FV and FVIII, have been identified in F5F8D patients.

Clinical Manifestations

Seligsohn et al.[4] studied 14 patients in 7 families of Middle Eastern Jews. Peyvandi et al.[5] and Mansouritorgabeh et al.[6] studied a total of 46 patients from 23 families of non-Jewish Iranians. In addition to these relatively large studies, a number of case reports have also been published.[23,26,49–76] Patients with this disorder exhibit plasma FV and FVIII activity level at approximately 10% of normal, with a range of 5% to 30%, though factor levels as low as 1% have been reported.[5,49] FV and FVIII clotting activity and antigenic level are both concordantly decreased.[1,67,77] Bleeding symptoms appear to be comparable to those observed in patients with single deficiencies of FV or FVIII.[4,5] No abnormalities outside of these hemostatic changes have been identified in F5F8D. Spontaneous bleeding symptoms are common, including easy bruising, epistaxis, and menorrhagia. Hemarthroses are less frequent, though reported in up to one-third of patients in some series.[5,6,49] In contrast, gastrointestinal bleeding, hematuria, and intracranial bleeding are only rarely observed. Excessive bleeding is particularly common during or after trauma, tooth extraction, surgery, or labor. Postcircumcision bleeding was reported to be common among Iranian patients,[5] but rare among Jewish patients,[4] possibly due to the age at which circumcision is performed (at birth among Jews and usually at 5 to 7 years of age among Muslims). In contrast to hemophilia A, the levels of FV and FVIII correlate poorly with bleeding severity.

Diagnosis and Differential Diagnosis

The diagnosis of F5F8D should be suspected in patients with a prolonged prothrombin time (PT) and partial thromboplastin time (PTT) and a history of mild to moderate bleeding beginning in childhood. Diagnosis is confirmed by the demonstration of FV and FVIII levels in the 5% to 30% range. A positive family history, if present, should be consistent with an autosomal recessive inheritance. All other routine laboratory results would be expected to be normal. Differential diagnosis includes coinheritance of hemophilia and parahemophilia, though this is extremely rare. Coinheritance of FV deficiency and type 1 von Willebrand disease (vWD) may be more common,[50,57] given the higher frequency of vWD.[78] von Willebrand factor levels could be determined to exclude this possibility.

tahir99-VRG & vip.persianss.ir

Treatment

Due to the small number of patients, only limited experience is available to guide therapy, though severe or life-threatening bleeding is fortunately rare. Fresh-frozen plasma has been effective in F5F8D in raising both FV and FVIII levels and should be used for the treatment of life-threatening hemorrhage, preparation for major surgery, and child birth.[79,80] Regular prophylaxis is generally not required.[81] DDAVP (1-deamino-8-D-arginine-vasopressin) has been used for mild to moderate bleeding, and results in an up to threefold increase in FVIII, but does not alter the FV level. DDAVP has also been used in combination with plasma infusion to compensate for the shorter half-life of plasma FVIII. Recombinant FVIII may also be combined with plasma infusion to raise FVIII level. Overall, treatment must be individualized to the specific patient and the severity of clinical bleeding.

COMBINED DEFICIENCY OF VITAMIN K–DEPENDENT CLOTTING FACTORS

History

The first case of VKCFD was described in 1966 in an infant girl who exhibited significant bleeding from the first week of life.[82] The proband was found to have low or undetectable levels of factors II, VII, IX, and X, with no evidence of hepatic disease or malabsorption. High doses of vitamin K partially restored clotting factor levels with clinical improvement.[83] Over 20 additional cases of VKCFD have been reported since that time.[84,85,86,87–103,104]

Genetics and Biology

γ-glutamyl carboxylase (GGCX) catalyzes a posttranslational modification of glutamate (Glu) residues into γ-carboxyglutamate (Gla) residues.[105–107] This carboxylation is required for the activities of coagulation factors II, VII, IX, and X, as well as the anticoagulant factors protein C, protein S, and protein Z.[108,109] Carboxylation occurs at Glu residues located in a homologous approximately 45–amino acid "Gla domain." The presence of Gla residues is thought to enable these proteins to adopt a calcium-dependent conformation that allows binding to phospholipids. Other proteins known to undergo γ-carboxylation include osteocalcin,[110] matrix Gla protein (MGP),[110] Gas6,[111] nephrocalcin A-D,[112] as well as several putative carboxylated proteins identified through nucleotide database screening (PRGP1, PRGP2, TMG3, and TMG4).[113,114] Vitamin K is an essential cofactor for γ-carboxylase. As carbon dioxide is added to Glu to form Gla, the reduced form of vitamin K (vitamin K hydroquinone) is oxygenated to form vitamin K 2,3-epoxide. Another enzyme, vitamin K epoxide reductase (VKOR), is required to regenerate the vitamin K hydroquinone, completing the so-called vitamin K cycle (FIGURE 55.3).

VKCFD is an autosomal recessive disorder characterized by deficiency of all VKCFDs. It is a heterogeneous disorder with two subtypes. VKCFD1 is defined by defective γ-carboxylase (GGCX) activity, first demonstrated in Devon Rex cats.[115] Nineteen different mutations in the *GGCX* gene have been reported in human families, the majority of which are missense mutations (FIGURE 55.4). Two different homozygous point mutations (L394R and W501S) were found in three consanguineous families.[86,88,91] Another patient of nonconsanguineous parents[97] is a compound heterozygote with a splice site mutation that

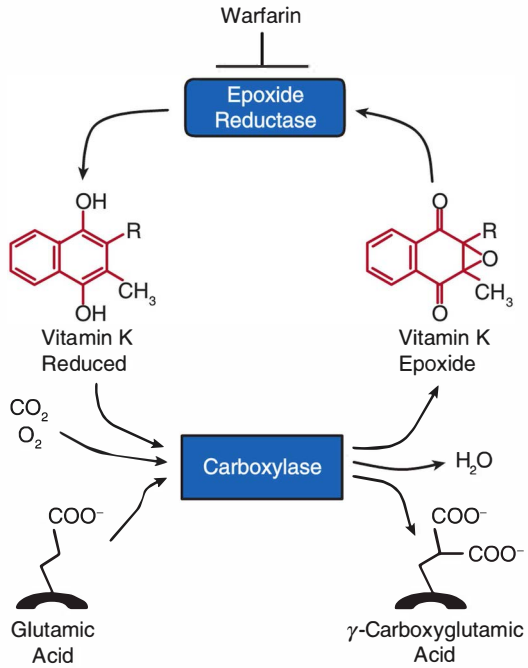

FIGURE 55.3 Vitamin K cycle. Vitamin K is an essential cofactor for γ-carboxylase (GGCX). GGCX adds a carbon dioxide to glutamic acid to form γ-carboxyglutamic acid at the same time that the reduced form of vitamin K (vitamin K hydroquinone) is oxygenated to form vitamin K 2,3-epoxide. VKOR is required to regenerate the vitamin K hydroquinone, completing the vitamin K cycle. Warfarin inhibits VKOR to limit the carboxylation of vitamin K–dependent coagulation factors. (Modified by permission from Sadler JE. Medicine: K is for koagulation. *Nature* 2004;427:493–494, Ref. [157], copyright (2003) Macmillan Publishers Ltd.)

results in early truncation of GGCX, and a missense mutation that changes a conserved arginine (R485P). GGCX carrying the L394R mutation demonstrated a threefold reduced activity compared with the wild-type protein.[86] L394 is in a 25–amino acid stretch of the enzyme that is highly conserved among all species with a known *GGCX* gene.[116] The primary defect associated with L394R appears to be reduced glutamate-substrate binding.[117,118] The W501S mutation appears to decrease the affinity of the carboxylase for the propeptide of its substrates.[88] The R485P mutation may affect vitamin K binding,[97] whereas the W157R and T591K mutations were shown to decrease carboxylase activity.[100] Other GGCX missense mutations have not yet been characterized in detail. In addition, splice site and intronic mutations have been reported.[92,97,101]

VKCFD2 results from functional deficiency of vitamin K 2,3-epoxide reductase (VKOR),[89,94] which is also the target of the oral anticoagulant warfarin.[119] VKOR activity was identified over 30 years ago.[120] However, the gene encoding the corresponding enzyme, vitamin K epoxide reductase complex subunit 1 (VKORC1), eluded identification until 2004.[121,122] Expression of *VKORC1* alone in insect cells confers warfarin-sensitive VKOR activity and the purified protein alone is sufficient for VKOR activity.[121,123] VKORC1 is a small protein of 163 amino acids (~18 kD) with four potential transmembrane domains.[124,125] Like γ-carboxylase, it is localized to the ER via

tahir99-VRG & vip.persianss.ir

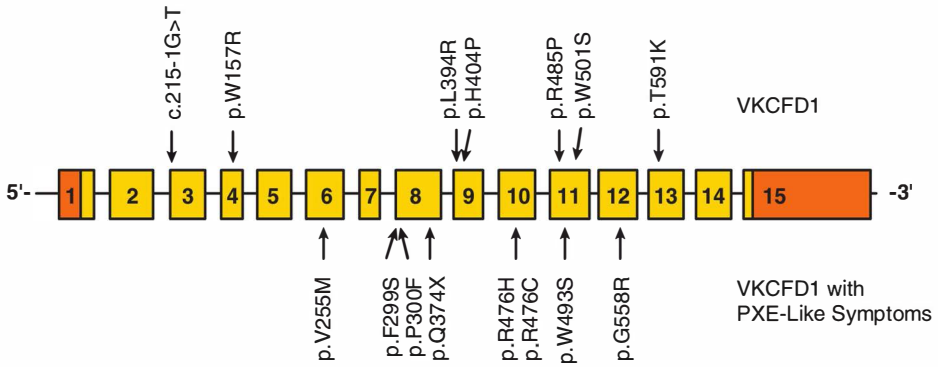

FIGURE 55.4 Structure of *GGCX* gene and mutations identified in VKCFD1. Mutations associated with VKCFD1 without the PXE-like phenotype are denoted above the gene. Mutations associated with the PXE-like phenotype are denoted below the gene. Exons are numbered and drawn to scale. *Shaded rectangles* represent the coding regions of the genes, with the open portions of exons 1 and 15 representing the 5′ and 3′ untranslated regions.

the *C*-terminal dilysine ER retention motif.[122] Current research is focused on identifying the redox partners of VKOR and the mechanism for electron transfer between VKOR and its partners.[126,127,128,129]

To date, only a recurrent homozygous *VKORC1* missense mutation (R98W) that decreases VKOR activity has been reported in families of distinct origins.[122,130] Multiple missense mutations were identified in warfarin-resistant rats and humans and shown to result in VKOR resistance to warfarin. Administration of warfarin during pregnancy results in warfarin embryopathy, characterized by a spectrum of birth defects including abnormal midfacial development, stippling of the epiphyses, and mental retardation.[89,131–133] Patients with *VKORC1* mutations do not resemble those of warfarin embryopathy, except for bone deformation in some patients.[89]

A subgroup of VKCFD with variable bleeding tendency is prominently associated with a pseudoxanthoma elasticum-like (PXE-like) phenotype, which is characterized by dystrophic mineralization of soft connective tissues, in particular the elastic fiber, skin, eye, and arterial blood vessels. Small yellowish papules coalesce on the skin, which also exhibits excessive folding with loss of recoil. Several mutations in *GGCX* (FIGURE 55.4) have recently been identified in VKCFD patients with PXE-like symptoms.[102,103,104] Decreased γ-carboxylase activity and accumulation of uncarboxylated MGP and osteocalcin, both of which are inhibitors of soft tissue calcification, have been documented in plasma and dermis.[102,103,134] It is not clear why only a subgroup of mutations in GGCX lead to a PXE-like phenotype.

The rarity of VKCFD and the fact that mostly missense mutations in GGCX and VKORC1 have been identified suggest that complete deficiency in either of these enzymes has more severe consequences. Indeed, deletion of the *GGCX* gene in mice results in partial embryonic lethality. Null mice surviving to term died uniformly of massive intra-abdominal hemorrhage at birth.[135] Similarly, *VKORC1* knockout mice died within 2 to 20 days after birth from extensive bleeding,[136] a lethality that can be rescued by the administration of vitamin K. These results exclude the existence of a redundant carboxylase pathway and indicate a role for γ-carboxylated proteins in early mammalian development.

Clinical Manifestations

Clinical symptoms of VKCFD vary widely, though they are roughly correlated with procoagulant protein levels.[94] Large amounts of vitamin K can partially correct the bleeding symptoms in most, but not all,[93,99] patients. Reported bleeding in VKCFD has included episodes of intracranial hemorrhage in the first weeks of life, sometimes leading to a fatal outcome. Hemarthroses and mucocutaneous bleeding may follow antibiotic therapy, due to decreased vitamin K production by gut bacteria. Skeletal defects have been reported in some probands, presumably resulting from undercarboxylation of bone Gla proteins.[84,89] Central nervous system abnormalities and mental retardation were also reported in some cases.[96,137]

Diagnosis and Differential Diagnosis

The hallmark of VKCFD2 is the simultaneous decrease of FII, FVII, FIX, and FX, though the levels range widely. Diagnosis of familial VKCFD2 requires differentiation from acquired forms of the disorder that can be caused by intestinal malabsorption of vitamin K or liver and renal dysfunction, or treatment with warfarin.

Treatment

Large doses of vitamin K (2 to 10 mg daily) are the standard treatment. Suspected patients should be started on vitamin K therapy as soon as possible. Response to vitamin K varies from complete correction to no effect. The underlying mechanism for this variability is unknown. Treatment with fresh-frozen plasma is the only alternative, if the response to vitamin K is inadequate. Large dose of vitamin K should be given to pregnant women suspected of carrying a fetus affected by VKCFD.

OTHER INHERITED DISEASES WITH MULTIPLE COAGULATION FACTOR DEFICIENCIES

Deficiencies of other combinations of coagulation factors have been reported,[1,59,138–152] most probably due to rare chance inheritance of two different disease genes[2,15,153] or occasionally due to chromosomal abnormalities as is the case of some combined

tahir99-VRG & vip.persianss.ir

FVII and FX deficiency.[153] However, several other inherited diseases may exhibit a secondary coagulation abnormality. Most notable are the congenital disorders of glycosylation (CDG), a rare but rapidly growing family of inherited diseases affecting many of the steps involved in glycosylation of proteins in the ER and Golgi.[154,155] CDG types 1a and 1b are associated with abnormal coagulation factor levels, including decreased activity of FXI and of the coagulation inhibitors antithrombin III and protein C,[156] probably due to hypoglycosylation of these factors.

CHAPTER

56 Clinical Disorders of Fibrinolysis

DAPHNE B. STEWART, CHARLES W. FRANCIS, AND VICTOR J. MARDER

Excessive promotion or inhibition of fibrinolysis interferes with the hemostatic balance and can lead to clinical bleeding or thrombosis. Hyperfibrinolytic mechanisms leading to premature lysis of hemostatic clots may result in significant bleeding disorders. Conversely, if impaired fibrinolysis slows clot dissolution, local clot formation occurs unimpeded, and a procoagulant state ensues. The importance of the fibrinolytic enzyme system is underscored by the observations that constitutional abnormalities in plasminogen,[1–3] plasminogen activators (PAs),[4] or their release,[5] are associated with an increased risk for thrombosis, whereas defects in PA inhibitors[6] and α_2-antiplasmin (AP)[7] are associated with an increased bleeding risk. Disorders impairing and promoting fibrinolysis occur as inherited disorders, which are rare and typically caused by a single molecular defect. Acquired disorders are more common, and heightened or impaired fibrinolysis may be the primary or contributing mechanism to bleeding or thrombotic events that occur in the course of an underlying systemic disorder or as the result of pharmacologic therapy. Clinical management requires an appreciation of the potential for pathologic bleeding or clotting; the use of appropriate, sensitive diagnostic tests; and rational use of medical therapies.

HYPERFIBRINOLYSIS WITH BLEEDING

Inherited Disorders of Fibrinolysis with Bleeding

α_2-Antiplasmin Deficiency

Inherited deficiency of α_2-AP is a rare autosomal recessive condition characterized by clinical bleeding due to premature dissolution of hemostatic plugs, typically seen as rebleeding following trauma or invasive procedures (Table 56.1).[8,9–11] AP inhibits fibrinolysis by forming a stable inactive complex with plasmin, by binding to the lysine-binding site of plasminogen and competitively inhibiting plasminogen binding to fibrin, and by covalent binding to fibrin via FXIIIa to prevent fibrinolysis by plasmin.[12] In patients with clinical evidence of the disorder, typical screening coagulation tests are normal, but the euglobulin clot lysis time (ECLT) is short due to uninhibited plasmin activity. A mouse knockout model of AP deficiency demonstrates enhanced endogenous fibrinolytic activity, but the mice, unlike humans, do not have an overt bleeding tendency, reflecting the presence of compensatory mechanisms.[13] The gene for AP has been mapped to chromosome 17,[14] and several mutations causing congenital deficiency have been elucidated.[15,16,17,18,19] Type I deficiency represents a quantitative disorder, with similar decreases in functional and immunologic assays, while type II deficiency results from a structural change causing lower activity than antigen concentration.[20]

Homozygous type I AP deficiency was first reported in 1978[8] in a patient with severe lifelong bleeding complications that included hemothorax, hemarthrosis, gingival bleeding, easy bruising, and prolonged bleeding after minor injury. Only 40 cases have been reported; the phenotype is variable, with the most severely affected patients symptomatic in childhood, even presenting with umbilical hemorrhage.[21] Intramedullary hematoma in the diaphyses of long bones represents a unique site of bleeding.[22] Individuals with heterozygous AP deficiency may be asymptomatic or exhibit a mild bleeding tendency that worsens with advancing age,[23–25] mostly following trauma, dental extraction, or surgery. Homozygous AP deficiency patients generally have <10% normal AP and heterozygotes have levels of 20% to 50%.[23,26]

Treatment with the antifibrinolytic agents tranexamic acid (TXA) or epsilon aminocaproic acid (EACA) can prevent bleeding during and after invasive procedures and is effective for treating acute bleeding episodes.[21,27,28] While no standard protocol exists, Morimoto et al. suggests using TXA 7.5 mg/kg orally 3 hours prior to dental extraction and then every 6 hours for 7 days. For dental extractions requiring gingival incisions or removal of bone, six patients were treated with infusion of TXA, 1.5 mg/kg/h followed by oral dosing once hemostasis was obtained.[27] Infusion of fresh-frozen plasma (FFP) provides adequate and lasting treatment levels, as the *in vivo* half-life is >20 hours,[28] although solvent or detergent treatment of plasma inactivates AP.[29]

Plasminogen Activator Inhibitor-1 Deficiency

Plasminogen activator inhibitor-1 (PAI-1) is the primary inhibitor of tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), physiologically limiting fibrinolysis to a thrombus by generating irreversible, inactive complexes. Congenital PAI-1 deficiency may be quantitative or qualitative and is characterized by recurrent bleeding, primarily after surgery or trauma.[30,31,32,33–35] As with AP deficiency, screening coagulation tests are normal; the ECLT is short (<2 hours); and fibrinogen, plasminogen, and AP levels are reduced to variable degrees. Diagnosis may be aided by demonstrating PAI-1 activity of <1 U/mL combined with elevated plasmin–AP complexes.[36]

Quantitative deficiency in a family of 26 affected individuals was linked to a frameshift mutation,[33] and those individuals who were homozygous for the mutation had mild to moderate bleeding symptoms (epistaxis, menorrhagia, bleeding following trauma), while heterozygotes tolerated surgery without bleeding.[33] The incidence is perhaps underestimated, as low PAI-1 levels (<1 U/mL) have been found in 23% of patients investigated for a bleeding tendency.[37] Bleeding can be treated effectively with antifibrinolytic medications.

tahir99-VRG & vip.persianss.ir

Table 56.1

Hyperfibrinolysis with bleeding

Inherited Disorders	Clinical Characteristics
AP deficiency	Premature lysis of hemostatic plugs Autosomal recessive, chromosome 17 Homozygous: severe bleeding Short lysis time, decreased plasmin–AP complexes, and fibrinogen Prophylaxis and treatment: FFP, antifibrinolytics
PAI-1 deficiency	Homozygous deficiency with moderate to severe bleeding Absent PAI-1, short lysis time, low fibrinogen, and plasminogen Increased plasmin–AP complexes Treat with antifibrinolytics
Elevated t-PA	Continuous plasmin activation Short lysis time, decreased fibrinogen Elevated circulating t-PA Treat with antifibrinolytics
Quebec platelet disorder	Excess u-PA in platelet granules released into hemostatic plugs causing premature lysis Increased copy number of u-PA gene Moderate to severe delayed bleeding Treat with antifibrinolytics
Factor XIII deficiency	Non–cross-linked fibrin undergoes premature fibrinolysis Increased clot solubility, low FXIII Severe delayed bleeding Prophylaxis and treatment: FFP, FXIII concentrate, antifibrinolytics
Acquired Disorders	
Cirrhosis	Hyperfibrinolysis exacerbates bleeding tendency, increases mortality Impaired clearance of t-PA Impaired synthesis of AP, PAI-1, TAFI Pronounced fibrinolysis during anhepatic phase of orthotopic liver transplant
Primary hyperfibrinolysis	Circulating t-PA due to endothelial release or infusion Rapidly cleared If DIC absent, may treat with antifibrinolytics
APL	Blasts release t-PA, u-PA, elastase Dense surface expression of annexin II on blasts enhances t-PA activation of plasmin ATRA decreases annexin II expression
Menorrhagia (normal uterine anatomy)	Increased t-PA in endometrium with high local fibrinolysis Antifibrinolytic treatment decreases bleeding Progesterone intrauterine device (IUD) decreases bleeding
FXIII deficiency	Consumption or immune clearance May be medication related: isoniazid (INH) Treat with: FFP, FXIII concentrate, antifibrinolytics, immune suppression
Trauma	Increased fibrinolysis with severe hypoperfusion Degree of fibrinolysis correlates with mortality Early volume resuscitation with FFP may benefit

FFP, fresh-frozen plasma; u-PA, urokinase plasminogen activator; AF, antifibrinolytics; TAFI, thrombin-activatable fibrinolysis inhibitor; DIC, disseminated intravascular coagulation; ATRA, all-trans retinoic acid.

tahir99-VRG & vip.persianss.ir

Increased t-PA

A congenital hemorrhagic disorder due to increased plasma levels of PA has been described in a few patients, including one with fatal intracranial hemorrhage.[6,38] Laboratory findings reflect continuous plasmin activation, as evidenced by elevated plasmin–AP complexes, shortened ECLT, low fibrinogen, and increased plasma t-PA that can be inhibited by specific antibodies.[38] Bleeding occurs after surgery, trauma, or dental extraction, although some family members have no clinical bleeding despite laboratory evidence of increased clot lysis. In one report, treatment with EACA or TXA resulted in improvement in laboratory markers of hyperfibrinolysis with normalization of clot lysis times and an increase in fibrinogen and α_2-AP.[38]

Quebec Platelet Disorder

The Quebec platelet disorder is an autosomal dominant condition characterized by moderate to severe delayed bleeding, typically starting at 12 to 24 hours after hemostatic challenge.[39] Affected individuals experience large bruises, joint bleeds, and local bleeding following dental extractions or trauma. The disorder was initially designated as *Factor V Quebec* because of deficiency in platelet factor V content.[40] Additional platelet defects include reduced count, defective platelet aggregation to epinephrine, and absence of α-granule contents and intrinsic membrane proteins.[39,41–43] Platelets of affected individuals show excessive α-granule protein degradation due to excess platelet u-PA, but external membrane, dense granule, and cytoplasmic platelet proteins are not affected.[39,41,44–46] The bleeding state is caused by the excess u-PA that is released into hemostatic plugs, and bleeding episodes may be treated with fibrinolytic inhibitors.[44,47]

Genetic marker analysis links the abnormality to the u-PA gene (PLAU) on chromosome 10; no point mutations have been found,[48,49] but an increased gene copy number likely accounts for the excess u-PA expression.[50] It is likely that testing for PLAU amplification will facilitate diagnosis in the future.

Factor XIII Deficiency

Activated factor XIII (FXIII) cross-links fibrin strands and AP to fibrin, thus contributing to fibrin clot stabilization and protection against premature fibrinolysis.[51] Congenital FXIII deficiency is associated with severe, lifelong bleeding due to rapid, plasmin-mediated lysis of hemostatic clots. The first described case was a young man with severe bleeding and normal coagulation assays, who had clots that lysed readily; addition of normal plasma corrected the laboratory abnormalities.[52] Approximately 160 cases have been reported.[53] FXIII is a tetramer, formed from dimerization of two A subunits associated with two B subunits (see Chapter 17). Deficient cases typically have absent A subunit in plasma. Patients typically present with delayed bleeding, even from the umbilical stump, and suffer a lifelong predisposition to subcutaneous, intramuscular, and intracranial bleeding; impaired wound healing; and spontaneous abortion.[54] Bleeding generally is delayed after trauma, compatible with lysis of clots after initial hemostatic plug formation. Intracranial hemorrhage is the most frequent cause of bleeding-associated mortality.[53]

Routine clotting time assays are normal. Diagnosis is based on solubility of clots in 1% monochloroacetic acid and 5 M urea, and by quantitation of FXIII activity in platelets and plasma. Treatment of acute bleeding episodes may be accomplished by infusion of small volumes of FFP, as control of hemorrhage requires raising plasma concentration by only a few percent.[53] The plasma half-life of FXIII is 11 to 14 days, so prophylactic doses may be infused every 6 weeks. Patients are generally treated with lifelong FFP prophylaxis, with fibrinolytic inhibitors, or with FXIII concentrates. A recombinant product, FXIII-A2 homodimer, has been developed though not yet approved by the FDA.[55] Inhibitors to FXIII resulting from replacement treatment have been reported.[56]

Acquired Disorders of Fibrinolysis with Bleeding

Cirrhosis

Severe liver disease is frequently complicated by clinically significant bleeding, due to a combination of decreased synthesis and/or clearance of coagulation factors and inhibitors, and thrombocytopenia caused by splenic sequestration and marrow insufficiency (Table 56.1). Accelerated fibrinolysis is common; in some cases this may represent the predominant hemostatic abnormality and is attributable to impaired clearance of t-PA and decreased synthesis of fibrinolytic inhibitors.[11] Although elevated plasma levels of D-dimer suggest disseminated intravascular coagulation (DIC), macrovascular and microvascular thrombosis is less common in advanced cirrhosis compared with other conditions associated with DIC.[57] Rather, an accelerated fibrinolytic state typically exists, identified by a rapid ECLT, increased plasma t-PA, and decreased AP and PAI-1.[58,59,60,61,62] Elevated D-dimer levels are likely the result of degradation of plasma-soluble cross-linked fibrin.[63] Chronic systemic hyperfibrinolysis is present in 30% to 46% of patients with cirrhosis and is more prevalent with greater severity of liver failure.[64] In a study of 112 cirrhotic patients with esophageal varices but without clinical upper gastrointestinal bleeding who were followed for 3 years, multivariate analysis indicated that elevated t-PA and D-dimer were the only markers predictive of bleeding.[65] In another study of 86 patients with cirrhosis, 31% showed a rapid ECLT, which was proportional to the severity of hepatic dysfunction.[66] Treatment with fibrinolytic inhibitors such as EACA and TXA may be useful in patients with cirrhosis, particularly those with mucosal or gastrointestinal bleeding, but there are no prospective controlled studies to validate clinical observations.

Pathologic hyperfibrinolysis may contribute to severe hemorrhage in some cases of orthotopic liver transplantation (OLT), especially during the anhepatic phase of surgery.[67,68] Accelerated fibrinolysis during OLT has been associated with increased plasma t-PA, depletion of fibrinogen and AP, and elevated fibrin degradation products.[69] Both systemic release and reduced hepatic clearance of t-PA contribute to accelerated fibrinolysis, which improves after revascularization of the transplanted liver. Treatment with fibrinolytic inhibitors can be useful. In a double-blind, randomized, placebo-controlled study of 45 patients, those who received TXA had less intraoperative blood loss and reduced intraoperative need for plasma, platelets, and cryoprecipitate.[70] Porte et al.[71] showed in a double-blind study of OLT recipients that treatment with aprotinin reduced blood loss with no increase in thrombosis or mortality.

Primary (Systemic) Hyperfibrinolysis

Primary systemic hyperfibrinolysis follows the widespread endothelial release or the exogenous infusion of t-PA, which leads to hemostatic plug dissolution and bleeding at sites of

tahir99-VRG & vip.persianss.ir

vascular injury. Disparate clinical conditions may cause systemic hyperfibrinolysis, for example, the bleeding symptoms of dengue infection in which plasminogen is activated by the virus[72,73] and heat stroke, characterized by an elevated body temperature, an exaggerated acute-phase response and multiorgan failure,[74] which may present as a hemorrhagic diathesis.[75] A similar transient clinical bleeding disorder may occur acutely after coronary artery bypass grafting surgery,[76,77] or following the infusion of t-PA to achieve therapeutic thrombolysis. Laboratory findings of hyperfibrinolysis, including increased t-PA and D-dimer, decreased plasminogen, and increased plasmin–AP complexes, likely reflect an exaggerated release of endothelial cell t-PA causing this primary hemorrhagic disorder, without the thrombotic events that characterize DIC syndromes (see Chapter 98). The hemorrhage may be transient and self-limited, reflecting clearance of t-PA, and in the absence of concomitant DIC, therapy may be limited to an antifibrinolytic agent and replacement of consumed factors, especially fibrinogen. In most cases, t-PA release is of limited duration, and therapeutic intervention is directed to the underlying condition.

Secondary Fibrinolysis in DIC: Microcirculatory activation of fibrinolysis may be a secondary response to the marked hemostatic activation and microvascular thrombotic occlusion of DIC and serves an important compensatory function in maintaining vascular patency (see Chapter 98). The bleeding that complicates DIC is primarily due to consumption of procoagulant factors and platelets, and this local fibrinolytic response usually does not reach the systemic level of primary hyperfibrinolysis. Pharmacologic inhibition of the compensatory fibrinolysis of DIC with antifibrinolytic therapy must be considered carefully, since local activation of fibrinolysis serves the crucial role of maintaining microvascular patency in patients with DIC. Fibrinolytic inhibition may exacerbate thrombosis and worsen or precipitate ischemic symptoms.[78,79]

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) represents a malignant clonal expansion of immature myeloid cells characterized by a balanced translocation, t(15;17), and the expression of a chimeric protein derived from the fusion of genes for the nuclear retinoic acid receptor on chromosome 17 and a transcription factor (PML) on chromosome 15.[80] Before the introduction of therapy with all trans-retinoic acid (ATRA), hemorrhage was a major cause of mortality, occurring in 14% of 268 patients during induction therapy.[81] Thrombocytopenia, DIC, and fibrinolysis may all contribute to the bleeding diathesis.[82,83] Leukemic cells contain t-PA, u-PA, and elastase, and elevated plasma levels of these proteins have been found in patients with accelerated fibrinolysis and APL.[84–87] Leukemic blasts also produce inflammatory cytokines (TNF-α, IL-1β)[88,89] that downregulate endothelial anticoagulant properties and upregulate procoagulant tendencies and express annexin II, a cofactor for t-PA-mediated activation of plasminogen to plasmin.[90,91] Surface annexin II, plasminogen, and t-PA may cause plasminemia and hyperfibrinolytic hemorrhage,[90] especially as plasmin present on cell surfaces is protected from inhibition by AP.[92]

Chemotherapy typically exacerbates bleeding,[79,93] but ATRA normalizes hemostatic abnormalities in the 1st week of therapy,[81] at least partly by downregulating surface expression of annexin II.[94] Although studies demonstrating the benefits of fibrinolytic inhibitors were published before the introduction of ATRA for induction therapy, contemporary treatment should focus on the optimal use of ATRA, and fibrinolytic inhibitors should be considered only in patients who are refractory to treatment and who have significant bleeding manifestations. A retrospective analysis of 30 patients with newly diagnosed APL observed that AP was a useful marker of fibrinolysis and hemorrhage risk and permitted treatment of higher risk patients with a coagulopathy protocol of low-dose heparin, EACA, and blood products.[95]

Menorrhagia

Up to one-third of women undergoing hysterectomy for menorrhagia have an anatomically normal uterus.[96,97] However, increased t-PA is present in the endometrium and menstrual fluid in women with menorrhagia, compared to women with normal menstrual blood loss,[98] likely explaining the excessive bleeding in some patients. A meta-analysis of seven trials of antifibrinolytic agents (vs. placebo) for menorrhagia found that treatment was associated with a considerable reduction in blood loss.[96] Antifibrinolytic agents compared to other nonsurgical therapies, including mefenamic acid, norethisterone, and ethamsylate, show a strong, though nonsignificant, trend in favor of antifibrinolytic agents in the participants' perception of improvement of menstrual blood loss. Increased fibrinolytic activity has been identified in the endometrium of women with an intrauterine device (IUD) associated with menorrhagia, and treatment with antifibrinolytic agents has been effective in reducing menorrhagia.[99] In contrast to standard IUD, those that release progesterone more effectively mitigate menorrhagia, as shown in a study of 41 women with menorrhagia treated with a levonorgestrel-releasing intrauterine system of whom 100% had resolution of their menorrhagia by 6 months. Endometrial sampling confirmed significant local increases in PAI-1 and endothelial expression of the u-PA receptor, without effect on systemic hemostasis.[100]

Amyloidosis

Patients with systemic, monoclonal light-chain amyloidosis may present with bleeding due to acquired factor X deficiency[101] or hyperfibrinolysis secondary to increased t-PA.[102,103] Hemorrhage in such patients has also been attributed to amyloid angiopathy, bleeding from the weakened walls of blood vessels infiltrated with amyloid fibrils.[104] The clonal plasma cells responsible for amyloidosis contain u-PA, in contrast to clonal plasma cells from multiple myeloma patients.[105,101] One report showed resolution of hemorrhage following treatment with nafamostat mesilate, a u-PA inhibitor,[105] and others relate hyperfibrinolysis primarily to deficiency of AP.[102,106,107] Patients with amyloidosis and hyperfibrinolysis often respond well to antifibrinolytic therapy.[101–103,106,107]

Acquired Factor XIII Deficiency

Acquired inhibitory IgG antibodies to factor XIII are associated with high morbidity and a case fatality rate of 50%.[108–111] Among the reported cases, six were temporally related to isoniazid, five occurred in the setting of active autoimmune disease, and three in patients with monoclonal gammopathy of unknown significance (MGUS),[108,109] with the cause of the remaining cases obscure. The cause of bleeding is the same as in congenitally deficient states: impaired cross-linking with premature fibrin lysis.[51] Diagnosis may be made by mixing patient plasma with

tahir99-VRG & vip.persianss.ir

normal plasma, with quantification of inhibitor by Bethesda assay, using an ECLT endpoint. Treatment of acute hemorrhage includes FFP or purified FXIII concentrate and antifibrinolytic therapy, plus targeted elimination of the inhibitor through steroids, immunoglobulin therapy, and immunosuppressive agents.

FXIIII can also be consumed, for example during extensive surgery, and subnormal levels may increase the rate of hemorrhage. An assessment of postoperative FXIII levels in normal individuals undergoing neurosurgery showed that 33% of patients with symptomatic intracranial hematoma had an FXIII level <60% compared with only 7% of patients who did not suffer hematoma formation.[112] Bleeding is treated with FFP.

Trauma

Trauma patients presenting with shock show a coagulopathy that is proportional to the degree of organ hypoperfusion and have a fivefold increase in mortality.[113] The coagulopathy of hypoperfusion suggests both DIC and secondary fibrinolysis and plasmin generation.[114] In a retrospective study of 314 severe trauma patients, of 55 nonsurvivors, 44 had laboratory parameters consistent with hyperfibrinolysis, the severity of which was predictive of massive bleeding and death within 4 hours.[115] A greater degree of hyperfibrinolysis confirmed by rotational thromboelastography also confers a greater risk of death.[116] A cohort of 208 patients presenting with systemic organ hypoperfusion following traumatic injury showed a more profound than anticipated activation of fibrinolysis, independent of acidosis or hypothermia.[117] Although not yet clinically proven, the study by Brohi et al. concluded that aggressive correction of hypoperfusion would be the most effective way to minimize the bleeding due to hyperfibrinolysis. The choice of resuscitation medium may also be relevant. Whole-blood dilution studies confirmed preservation of fibrinolysis following massive dilution with FFP versus saline[118] and suggest that early volume resuscitation with plasma after trauma may prevent excessive bleeding from hyperfibrinolysis.

HYPOFIBRINOLYSIS WITH THROMBOSIS

Inherited Hypofibrinolysis

The contribution of defective fibrinolysis to thrombotic disease has been difficult to evaluate because screening tests such as the ECLT are less sensitive to decreased activity than increased activity (Table 56.2). However, there is suggestive evidence that impaired fibrinolysis contributes to thrombosis in both inherited and acquired hypofibrinolytic states. The MEGA study (Multiple Environmental and Genetic Assessment of risk factors for venous thrombosis) analyzed ECLT in 2,090 patients with a history of deep vein thrombosis (DVT) and in 2,564 control patients and found that the lowest quartile of ECLT (e.g., most prolonged) was associated with a twofold increased risk of VTE.[119] In a separate cohort study of 770 patients after first venous thrombosis and 743 healthy controls, elevated levels of PAI-1 and thrombin-activatable fibrinolysis inhibitor (TAFI) were associated with thrombosis, each conferring a 1.6-fold increased risk,[120] suggesting that a hypofibrinolytic state is a predisposing factor for thrombotic disease. In a study of 897 patients with a first episode of venous thromboembolism, elevated PAI-1 was an independent risk factor for recurrence during 10 years of follow up.[121]

Plasminogen Deficiency

Plasminogen is the zymogen of the active fibrinolytic enzyme plasmin, and deficiency could be expected to result in impaired fibrinolysis and pathologic thrombosis. Functional plasminogen deficiency (50% of normal) was described by Aoki et al.[122] in a patient with recurrent venous thrombotic disease, the defect being an amino acid substitution occurring near to the active site histidine.[123,124] Several other plasminogen variants have been characterized by normal or slightly reduced antigen concentration with decreased functional activity.[3,125–127] A study in Scotland found familial plasminogen deficiency at a frequency of 2.9 per 1,000.[128] A common missense mutation (K19E) was found in most of the propositi, but none of the individuals developed venous thrombosis. In a large referral center, plasminogen deficiency was identified in 23 of 1,192 subjects, with a DVT prevalence of 2.2% and arterial events in 1.4%.[129] Of the 23 plasminogen-deficient individuals, eight had additional thrombophilic defects and four had relevant circumstantial risk factors. In a large database of 2,132 consecutive patients with venous thromboembolism, 16 (0.75%) had plasminogen deficiency.[130] The volume of evidence suggests that plasminogen deficiency is not a strong thrombotic risk factor when present as a single defect.

Although the association with thrombotic disease is tenuous, severe type I plasminogen deficiency is clearly associated with ligneous conjunctivitis, manifest by pseudomembranes developing on ocular and extraocular mucosa,[131–133] impaired wound healing, hyperviscous nasopharygeal and bronchial secretions, and hydrocephalus. The conjunctival lesions contain fibrin without plasminogen, suggesting that deficient fibrinolysis in tears is the likely cause of the fibrinous pseudomembranes, and a plasminogen knockout mouse model confirms this association.[134] Schott et al.[135] demonstrated that the ligneous lesions could be eliminated by plasminogen replacement, with normal anatomy restored after 2 weeks. Recurrence was prevented by daily injections of plasminogen sufficient to achieve plasma concentrations to approximately 40%. Treatment with topical plasminogen has also been successful,[136] and two women treated with oral contraceptives showed marked increase in plasminogen and some resolution of pseudomembranes.[137]

Dysfibrinogenemia

Dysfibrinogenemia is usually asymptomatic but may be associated with bleeding, pregnancy loss, or thrombotic disease (see Chapter 54). Of 250 cases of dysfibrinogenemia reported by Haverkate and Samama[138] in 1995, 20% had a thrombotic phenotype. Specific structural defects in fibrinogen may predispose to thrombosis, for example, those that impair interaction with fibrinolytic proteins or that polymerize to form a less porous clot, both effects serving to limit optimal fibrinolytic action. Fibrinogen Chapel Hill III[139] and Fibrinogen Dusart[140] have been associated with familial DVT, likely related to impaired fibrin lysis, secondary to decreased plasminogen binding and reduced t-PA–induced plasminogen activation.[141–143] Both conditions were characterized as a single-base change, AαArg554Cys.[144] Fibrinogen New York I has a deletion of residues 9 to 69 of the β chain (exon 2 for the gene)[145] and is associated with abnormal fibrinolysis and

tahir99-VRG & vip.persianss.ir

Table 56.2

Hypofibrinolysis with thrombosis

Inherited Disorders	Clinical Characteristics
Plasminogen deficiency	Venous thrombosis uncommon Ligneous conjunctivitis resolves with plasminogen replacement
Dysfibrinogenemia	Abnormal fibrinogen variants form lysis-resistant clots Treat thrombotic events with standard anticoagulation
Defective vascular response	Impaired endothelial release of t-PA in response to venous occlusion Associated with thrombotic disease No prospective evaluation for screening
Antifibrinolytic protein polymorphisms	Lead to higher levels of gene expression Associated with thrombotic events
Elevated TAFI	Increased risk of ischemic stroke Increased risk for recurrence after first thrombosis
Elevated PAI-1	Increased risk for pregnancy loss Impaired response to therapeutic thrombolysis Increased risk for recurrent venous thrombosis
Acquired Disorders	
Use of antifibrinolytic agents	Risk of thrombosis in patient with thrombogenic stimulus Avoid in DIC Higher mortality in patients treated with aprotinin
Atherothrombotic disease	Increased risk of reinfarction after MI Risk for progression of CAD after MI Lower rate of recanalization after therapeutic t-PA Elevated PAI-1 common
Postoperative thrombosis	Elevated PAI-1 Hypofibrinolysis contributes to thrombotic risk PCD stimulates local fibrinolysis
Pregnancy APS	Elevated PAI-1, TAFI impair fibrinolysis Risk for venous and arterial thromboses Elevated PAI-1 Production of antibodies against t-PA, plasmin Antibodies against annexin II Antibodies to β_2-glycoprotein plasmin activation

DIC, disseminated intravascular coagulation; CAD, coronary artery disease; MI, myocardial infarction; t-PA, tissue plasminogen activator; PAI-1, plasminogen activator inhibitor 1; PCD, pneumatic compression device.

defective potentiation of plasminogen activation by t-PA.[146] An example of abnormal polymerization leading to tight fibrin gels with fibrinolytic resistance is Fibrinogen Tampere.[147] Fibrinogen Caracas V occurred in a Venezuelan family with thrombophilia and exhibited prolonged thrombin and reptilase times[148] and a decreased capacity to accelerate t-PA–induced plasminogen activation, caused by an AαSer532Cys mutation.[149]

Those patients with identified dysfibrinogenemia without clinical bleeding should be treated with routine thromboprophylaxis during surgery or periods of immobilization.[150] Following a documented thrombotic event, patients should receive standard anticoagulation therapy, although the benefit of prolonged anticoagulation is not well defined.[150]

Defective Vascular Response

Defective endothelial release or low endothelial stores of t-PA would theoretically produce a local deficiency and impaired fibrinolytic response to incipient clot formation that could increase the risk of pathologic thrombosis. Impaired local fibrinolysis after a venous occlusion has been observed in patients with idiopathic DVT,[151] and Johansson et al.[152] noted reduced plasma fibrinolytic activity after venous occlusion or DDAVP infusion in 12 out of 13 family members with DVT.[152] A similar defect with a high incidence of venous thrombotic disease was described by Jorgensen et al.[153] in three generations of a family; six members studied showed a subnormal increase in fibrinolytic activity after venous occlusion or exercise and suffered recurrent venous thrombosis. A report by Stead et al.[5]

tahir99-VRG & vip.persianss.ir

described a family with five members in two generations in whom venous thrombosis developed at an early age, and whose plasma fibrinolytic activity after venous occlusion was markedly deficient. Because it was associated with a subnormal increase in von Willebrand factor (vWF), a combined endothelial cell defect in processing or storage of vWF and t-PA was suggested. A case study comparing patients with idiopathic DVT and unaffected relatives analyzed for t-PA release after venous occlusion and PAI-1 activity at rest demonstrated impaired release in 9% of patients with DVT (8 of 91). Six of eight of these patients underwent family analysis, and 50% of family members tested also demonstrated impaired t-PA release, suggestive of familial clustering.[154] Although this putative causative factor is intriguing, it has not been critically evaluated prospectively.

Antifibrinolytic Protein Polymorphisms

TAFI is activated by thrombin and protects nascent clot against fibrinolysis by impairing plasminogen and t-PA binding. High plasma levels of TAFI have been seen in patients with acute ischemic stroke compared with healthy controls.[155,156] Although no definitive association has been demonstrated between a high baseline TAFI concentration and venous thromboembolism,[157,158,159] >75th percentile TAFI was associated with a twofold higher risk for VTE recurrence.[160] *PAI-1* polymorphisms that lead to higher levels of gene expression may be associated with thrombotic disease. In a small study of white women suffering two or more spontaneous pregnancy losses, homozygosity for polymorphisms of PAI-1 (4G) or FXIII (34Leu) was associated with a twofold increase in relative risk for pregnancy loss,[161] and a lower rate of cerebral recanalization following thrombolytic therapy after acute ischemic stroke has been noted in patients with high plasma PAI-1 levels.[162] However, a large, prospective cohort study of women found the PAI-1 4G/4G was associated with a significantly lower risk of cerebrovascular mortality,[163] demonstrating that the role of polymorphisms in thrombotic disease remains controversial.

Acquired Hypofibrinolysis with Thrombosis

Administration of Fibrinolytic Inhibitors

Thrombosis due to excessive inhibition of fibrinolysis may result from administration of antifibrinolytic agents such as EACA to predisposed patients, including those with DIC or with the thrombophilia of malignancy (Table 56.2). Intravascular coagulation normally leads to activation of compensatory fibrinolysis, presumably due in part to stimulation of PA release from endothelial cells. This response contributes to the maintenance of vascular patency, and inhibition of fibrinolysis in patients with DIC or those developing thrombosis may disrupt the balance between thrombosis and fibrinolysis and exacerbate the thrombotic process with serious morbidity.[164–166] Because EACA is excreted in the urine and can inhibit normal urinary fibrinolysis, thrombosis may develop in the urinary collecting system in patients who have urinary tract bleeding and may result in ureteral obstruction; therefore, antifibrinolytic therapy must be used with great caution in patients with hematuria.[164] This is also true for patients with severe hemophilia.[164]

Aprotinin administration in the context of coronary artery bypass surgery has been associated with excess mortality, not noted for the other antifibrinolytic agents, although an excess of thrombotic disease has not been definitively proven. The BART trial (Blood Conservation using Antifibrinolytics in a Randomized Trial) compared aprotinin to the lysine analogs and concluded that aprotinin afforded patients a lower risk for massive hemorrhage, but greater risk for death,[167] suggesting the more powerful hemostatic effect could cause death through distant thromboses. Secondary thrombotic outcomes following treatment with antifibrinolytic agents during cardiac surgery have not been definitive. Although a large observational study showed a significantly increased incidence of myocardial infarction (MI) (55% increase) and stroke after use of aprotinin,[168] a meta-analysis reported no difference between aprotinin, TXA or EACA, or placebo in the risk of MI or stroke.[169]

Atherothrombotic Disease

In atherosclerotic disease, fibrin deposition occurs in the arterial wall, and thrombotic events resulting from plaque rupture lead to vessel obstruction. The fibrinolytic system is an important regulator of fibrin deposition, and hypofibrinolysis might be expected to increase fibrin deposition and promote thrombus formation. Patients with coronary artery disease have elevated PAI-1,[170] which is a risk factor for reinfarction in young survivors of MI.[171,172] Juhan-Vague et al.[173] found correlations of elevated PAI-1 with subsequent MI or sudden coronary death in 3,043 patients with angina pectoris. Similarly, there was a strong correlation between low plasma fibrinolytic activity and coronary artery disease in the Northwick Park Heart Study.[174] A Swedish case–control study found that high plasma PAI-1 concentration predicted the occurrence of the first MI,[175] and high plasma PAI-1 concentrations were also associated with progressive coronary artery disease in young men with a history of MI.[176,177] Elevated levels of t-PA have also been associated with the development and progression of coronary artery disease.[178] However, most t-PA in the circulation exists in a complex with PAI-1, and high t-PA levels likely reflect elevated PAI-1 levels.[175,179–183] The principal features of the "metabolic syndrome" include insulin resistance, hyperinsulinemia, impaired glucose metabolism, hypertriglyceridemia, low high-density lipoprotein-cholesterol concentrations, obesity, and hypertension,[184] and since the original description in 1983, high plasma PAI-1 concentrations have also found a place in this cluster. Glucose and insulin increase PAI-1 synthesis by endothelial cells,[185,186] unsaturated fatty acids and very low density lipoprotein (VLDL) increase endothelial cell secretion of PAI-1,[187,188] and VLDL increases the production of PAI-1 by hepatocytes.[189] These relations are the result of regulatory elements in the PAI-1 gene that are responsive to insulin, lipids, and estrogens.[190] Individuals homozygous for the 4G allele of PAI-1 have higher plasma concentrations and are more sensitive to upregulation by hypertriglyceridemia,[190,191,192] perhaps explaining the higher prevalence of the 4G allele with cardiovascular disease in some studies.[193–195] Patients undergoing thrombolytic therapy who fail to recanalize the obstructed vessel may have an excess of PAI-1. For example, 13 of 43 patients with acute stroke treated with thrombolytic therapy who failed to recanalize had higher PAI-1 levels than did patients who did recanalize,[162] and conversely, PAI-1 deficiency was predictive of intracranial hemorrhage following thrombolytic therapy.[196]

Postoperative Thrombosis

Surgical trauma results in rapid activation of hemostasis followed by a postoperative reduction of fibrinolytic activity related in part to an increase in PAI-1.[197–199] This pattern has clear benefit in preventing excessive bleeding at the surgical site, but may also contribute to the increased risk of postoperative venous thromboembolism. The development of postoperative venous thrombosis has been related both to preoperative deficiencies of fibrinolysis and to excessive inhibition of fibrinolysis postoperatively, although the association is not strong enough to be of clinical predictive value.[198–200] Stimulation of fibrinolytic activity may be one mechanism underlying the benefit of pneumatic leg compression for reducing the risk of postoperative venous thromboembolism.[201–207]

Pregnancy

Pregnancy induces significant changes in the hemostatic system with increases in procoagulants, decreases in free protein S, and alterations in fibrinolysis, all of which prepare for the hemostatic challenges of delivery but increase the risk of venous thromboembolic disease.[208–214] Although increases in PA levels occur during pregnancy, these are overwhelmed by greater increases in PAI-1 and PAI-2, the latter of which is produced by the placenta,[215–217] and by TAFI levels that progressively increase to a peak at 20 weeks of gestation.[218,219] Preeclampsia is associated with elevated PAI-1, in correlation with the severity of placental damage.[220–222]

Antiphospholipid Syndrome

The antiphospholipid syndrome (APS) is a hypercoagulable disorder characterized by arterial and venous thromboses and autoantibody production. Impaired fibrinolysis may be a central component of the clinical thrombotic disease, potential mechanisms being elevated PAI-1, anti-t-PA antibodies, antibodies against annexin II, and anti-β_2-glycoprotein-I that block activation of plasminogen by t-PA. Patients with asymptomatic APS have high levels of PAI-1 and diminished t-PA locally following venous occlusion, compared with healthy controls.[223] A common finding in APS is a high circulating level of lipoprotein (a), which competes with plasminogen for binding to fibrin, impairing plasmin-mediated fibrin degradation.[224] An observational study of 25 APS patients found 7 (28%) with IgG antiplasmin antibodies.[225] Another found that two patients with APS had anti-t-PA antibodies that blocked t-PA–mediated plasminogen activation,[226] and a third report found APS patients with antibodies to annexin A2 that correlated with the incidence of thrombosis.[227] Functional β_2-GP-I is a phospholipid-binding protein with a lysine-rich domain that is cleaved by plasmin to facilitate phospholipid binding.[228] This "nicked" β_2-GP-I binds plasminogen and inhibits activation to plasmin by t-PA.[229] While intact β_2-GP-I enhances t-PA–mediated plasminogen activation 20-fold,[230] depletion of intact β_2-GP-I, as with neutralization by autoantibodies in APS,[231] could diminish clot lysis by inhibiting t-PA function.

CHAPTER

57

Acquired Disorders of Coagulation: The Immune Coagulopathies

CHARLES R.M. HAY

The formation of a blood clot is the final result of a cascade of interactions among multiple plasma proteins that ultimately result in the conversion of fibrinogen to fibrin and the cross-linking of fibrin by activated factor XIII to form a stable clot. Quantitative or qualitative deficiencies of many of the coagulation factors involved in these reactions may be associated with a clinically significant bleeding disorder. Circulating immunoglobulin anticoagulants may arise in the plasma of individuals whose coagulation mechanism was previously normal. These inhibitor antibodies, usually but not exclusively immunoglobulin G (IgG), may function as a circulating anticoagulant when directed against a specific clotting factor protein. These are autoantibody inhibitors, in contrast to the alloantibody inhibitors, which arise in individuals with congenital factor deficiencies as a complication of replacement therapy.[1,2]

Although neutralizing autoantibody inhibitors have been described to neutralize each of the coagulation factor proteins, antibodies to factor VIII, von Willebrand factor (vWF), and factor X are rare, and autoantibodies to other clotting proteins are extremely rare. Nevertheless, when they do occur, they may produce life- and/or limb-threatening bleeding. Acquired hemophilia A (factor VIII:C deficiency) is the most common of the acquired autoantibodies against specific clotting factors but is much less prevalent than the lupus anticoagulant (LAC). In fact, the acquired autoantibody, which characterizes the LAC, is an *in vitro* anticoagulant only, and is actually associated with clinical hypercoagulability *in vivo*.

Autoantibodies targeting specific coagulation factor proteins are often associated with more severe bleeding manifestations and often demonstrate more complex pharmacokinetics and binding affinities than alloantibodies directed against the same protein. Although frequently found in subjects without any associated pathology, autoantibody inhibitors may arise in association with a number of benign diseases, such as autoimmune disorder, chronic inflammatory and infectious states, and in pregnancy. The development of autoantibody inhibitors may also complicate lymphoproliferative and, to a lesser degree, solid tumor malignancies. Incidental associations have also occurred in the context of certain antibiotics and bone marrow transplantation. Some associations are quite specific, for example, the association between myeloproliferative disease and hyperthyroidism and mild acquired von Willebrand disease (vWD) and the association between amyloid and factor X deficiency, but many patients have no obvious underlying pathology.

From a laboratory perspective, the diagnosis of autoantibody inhibitors is based on the inability of normal plasma to correct prolonged clotting assays produced by patient plasma in mixing studies. The potency of the inhibitor and the target of the inhibitor determine the mode of treatment of acute bleeding episodes.

ACQUIRED INHIBITORS TO FVIII

Acquired Hemophilia

Autoantibody FVIII:C neutralizing inhibitors appear spontaneously in subjects with previously normal hemostatic function causing *acquired hemophilia*.[1,2,3] This rare immune coagulopathy occurs with an incidence rate of 1.38 and 1.48 per 1 million per year in the only two studies of acquired hemophilia in which the patients are linked to a defined population.[4,5] The latter figure is as close to a true incidence as one can currently get, since it is based on a 2-year, cross-sectional, UK study in which considerable effort was expended to record all cases diagnosed in every hospital in the United Kingdom during that time. Even so, many low-titer (<5 BU) inhibitors may remain undetected unless patients experience severe bruising or bleeding after surgery or trauma. Some cases of mild disease may be missed because of the vagaries of diagnostic accuracy and the tendency for these patients to present to generalists, surgeons, and physicians. Acquired hemophilia is being diagnosed more frequently now that there is increased awareness that this syndrome complicates a wide variety of autoimmune and malignant diseases. Also, the availability of improved and specific treatment options for acquired hemophilia has increased the urgency of accurately diagnosing this potentially severe and morbid condition.

Epidemiology and Clinical Presentation

Acquired hemophilia has an equal sex distribution overall, though younger patients are more frequently female.[5] The condition may arise at any time in life but usually presents in the extremely elderly,[4,5,6,7,8,9,10,11] the median age at presentation having been reported by Collins to be 78 years (range 2 to 98 years).[4] Earlier series tend to report relatively younger patient groups, either because of recall, referral, and/or reporting bias[6,7] or because of the focus of the report is on the treatment of bleeding.[8,9] Presentation during childhood is exceptionally rare.[5,9,10]

In approximately 50% of individuals with auto antibodies to FVIII:C, there is no obvious underlying disease state ("idiopathic" inhibitors).[4,5,6,11] Older patients with acquired hemophilia are much less likely to have an associated disease state than younger patients.[5] Diseases associated with acquired hemophilia include autoimmune diseases, hematologic and nonhematologic malignancies, drug reactions, and pregnancy.[4,5,6] These are described in greater detail below:

tahir99-VRG & vip.persianss.ir

There is a strong inverse correlation between the age at presentation and the likelihood that the acquired hemophilia has arisen in relation to some underlying disease.[5] Collins found an underlying diagnosis in all five patients under the age of 40 years, 55% of those between 40 and 59 years, 42% of those between 60 and 79 years but only 23% of those aged 80 or over ($P < 0.01$).

Immune Disorders

Acquired hemophilia has not only been described particularly with chronic, long-standing, severe, rheumatoid arthritis, but also with other autoimmune disorders/collagen vascular diseases, including systemic lupus erythematosus (SLE), Sjögren syndrome, and less frequently with temporal arteritis, multiple sclerosis, myasthenia gravis, autoimmune hypothyroidism and hyperthyroidism, ulcerative colitis, graft versus host disease, and following vaccinations.[5,6,10–15] Autoimmune dermatologic diseases, including pemphigus and psoriasis have also been occasionally associated with acquired hemophilia. Individuals with autoimmune FVIII:C antibody inhibitors secondary to autoimmune disease usually have high-titer inhibitors (>5 BU) that do not usually resolve spontaneously and are commonly relatively resistant to treatment with corticosteroids.

Malignancy

Hematologic malignancies, usually but not exclusively lymphoproliferative malignancies, have also occasionally been associated with acquired hemophilia. These include chronic lymphocytic leukemia (CLL), non-Hodgkin lymphoma, multiple myeloma, Waldenstrom macroglobulinemia, myelofibrosis, and myelodysplastic syndromes.[5,6,17]

Solid tumor malignancies, including carcinoma of the prostate, breast, lung, stomach, pancreas, colon, head and neck, and renal cell[5,6,18] have all been associated with acquired hemophilia. Inhibitor antibodies secondary to solid tumors[17,18] tend to be of low-titer. There is no correlation between the titer of the autoantibody to FVIII:C and tumor size, aggressiveness, or likelihood of tumor response to chemotherapy or radiation. Acquired hemophilia complicating malignancy has a poor overall prognosis. Successful suppression of the autoantibody inhibitor occurs in only about 20% of these cases and may require tumor eradication.[17,18] If the autoantibody FVIII:C inhibitor does remit, it may recur and relapse of the inhibitor is not a reliable marker of tumor recurrence. Acquired hemophilia occurs much more frequently in association with lymphoproliferative malignancies than with solid tumors. CLL, non-Hodgkin lymphoma, multiple myeloma, and Waldenstrom macroglobulinemia are the most frequent hematologic malignancies associated with the development of autoimmune FVIII:C inhibitors. Although autoantibody and alloantibody inhibitors to FVIII:C are usually IgG, IgA and IgM monoclonal antibodies have been described in cases of multiple myeloma and CLL. Isolated cases of acquired hemophilia complicating myelodysplastic syndromes, myelofibrosis, and erythroleukemia, have also been reported.

Although acquired hemophilia has often been reported to follow drug administration, many of these drug associations may be coincidental and spurious.[5] Nevertheless, the literature lists associations with allergic diseases and drug reactions including asthma; allergies to penicillin, sulfonamides, phenytoin, chloramphenicol, and methyldopa; treatment with fludarabine, interferon-α; and antipsychotic medications.[19,20] Allergic reactions to medications, particularly sulfonamides, rarely penicillin and most recently clopidogrel,[29] have been implicated in the development of an autoimmune response to FVIII:C. The inhibitory antibody usually disappears shortly after withdrawal of the offending drug. Of interest is the fact that acquired inhibitors to FVIII:C have also been observed after treatment with medications known to interfere with the immune system, such as interferon-α and fludarabine.[19]

Pregnancy

The association between acquired hemophilia and pregnancy has been overstated in earlier publications in which pregnancy-associated acquired hemophilia accounted for up to 10% to 15% of total cases. This is probably accounted for by recall and reporting bias. The recent 2-year survey of Collins et al.[5] reported only three cases of pregnancy-associated acquired hemophilia (2% of the entire cohort and 4.3% of women reported). This represents 1 case per 350,000 births during that period. A similar incidence was reported from the Italian Registry.[23]

Acquired hemophilia arises in mostly primiparous women (80%), usually within 3 months postpartum, though cases have been described as late as 11 months postpartum, and presentation around the time of delivery or even antenatally is not uncommon.[5,8,9,22,24,26] Of the 42 cases of pregnancy-associated acquired hemophilia reported to the European acquired haemophilia (EACH2) registry, only 1 presented antenatally.[25] Late presentation may represent delayed diagnosis rather than late onset. Recurrence of the inhibitor in subsequent pregnancies has been reported but is not common, though mothers should be warned of this possibility. Although one study reported recurrence in four-sixth of subsequent pregnancies,[21] no relapses were reported in nine subsequent pregnancies in a further report[26] and no relapses were reported in the four patients reported in the Italian registry.[23] When acquired hemophilia occurs antenatally, transplacental transfer of IgG autoantibody may cause life-threatening bleeding in the baby.[23,27,28] Although spontaneous remission has been described in postpartum-acquired hemophilia patients, they usually require immunosuppressive therapy to achieve remission (see below). Severe uterine bleeding during labor or delivery may occur in those presenting antenatally and this sometimes requires hysterectomy. Nevertheless, the overall mortality of acquired hemophilia associated with pregnancy is relatively low (<5%).[22,26] These cases are usually sensitive to corticosteroids alone, though spontaneous remission may occur in up to 76%, if steroids are withheld. This contrasts with the relatively low spontaneous remission rate of <30% observed generally for autoimmune hemophilia.[22,23,24]

Spontaneous remissions of the autoimmune antibody inhibitor targeting FVIII:C is not uncommon, and may occur in approximately one-third of cases, usually after months to years of involvement.[6] More recent reports do not report spontaneous remission, because virtually all patients are offered immunosuppressive therapy to minimize the period during which they may be at hemorrhagic risk. Spontaneous remission in pregnancy-associated acquired hemophilia syndrome is said to be particularly common but, again, these women are usually offered immunosuppressive therapy to minimize the hemorrhagic risk.

Clinical Manifestations

The occurrence of an acquired inhibitor to FVIII:C typically is heralded by spontaneous, bruising and soft tissue bleeding in individuals who lack a previous bleeding history. Bleeding

tahir99-VRG & vip.persianss.ir

may sometimes be life- and limb-threatening. Hemarthrosis are unusual in acquired hemophilia, in contrast to congenital hemophilia. The commonest bleeding manifestation of acquired hemophilia is bruising, with often massive ecchymosis. Muscle bleeds occur in 40%, followed in frequency by gastrointestinal, urinogenital, and retroperitoneal bleeding. Spontaneous bleeding into the central nervous system is fortunately relatively infrequent.[5,6,7,8,9] Since the 1st obvious bleeding manifestation may be hematuria or melena, these patients may present to generalists and diagnosis may consequently be delayed, sometimes until after some surgical intervention.

Between 7.9% and 22% of cases have been reported to die from hemorrhage.[6,7,8,25] More recent studies reveal a trend toward decreasing hemorrhagic mortality, which may be related to the availability of improved management options.[8,9] However, the recent study of Collins et al. reported a 9.1% mortality rate from hemorrhage. Most hemorrhagic deaths are from gastrointestinal or retroperitoneal bleeding and occur within the 1st few weeks after presentation though patients remain at risk of life-threatening bleeding until the inhibitor has been eradicated.[5] Delayed diagnosis and inadvertent treatment, such as surgery, contribute significantly to the early high mortality rate, occurring mainly because these patients frequently present to surgeons and general physicians.[5,8]

Infectious complications, secondary to immunosuppressive therapy, account for most of the late deaths in patients with acquired hemophilia. Indeed, infection appears to be a commoner cause of death than hemorrhage in acquired hemophilia. Collins reported an 11% mortality rate from sepsis.[5] Indeed, 33% of patients from this cohort suffered from sepsis at some time in their course.

Although bleeding may be severe and life-threatening, the recent cross-sectional study of Collins showed that 34% of patients have only mild bleeding manifestations that did not require hemostatic replacement therapy.[4,5] This 2-year study attempted to capture all cases of acquired hemophilia presenting in any hospital in the United Kingdom during a 2-year period. This observation also accounts for the paradoxical observation that the prognosis for acquired hemophilia is better for patients managed outside a major teaching center because those with severe bleeding are more likely to be referred in to a teaching hospital.[5] Earlier reports tend to overstate bleeding severity either because of recall bias[6] or because they only report patients treated for bleeding.[8,9] Interestingly, at the time of presentation, neither the factor VIII level nor the inhibitor titer predicts the severity of subsequent bleeding events.[5,8] Patients who died from hemorrhage and those who required no hemostatic therapy at all had a similar presenting median (range) factor VIII level and inhibitor titer.[5]

Laboratory Diagnosis of Autoimmune FVIII:C Antibody Inhibitors

The clinical suspicion of acquired hemophilia, based on the recent onset of significant bruising or bleeding in a previously noncoagulopathic individual, is strengthened by the detection of a normal prothrombin time (PT) but prolonged activated-partial-thromboplastin time (aPTT). The aPTT initially corrects using 50:50 normal plasma, which suggests a factor deficiency, but the aPTT subsequently prolongs again on incubation at 37°C. An intrinsic factor screen will reveal a low factor VIII level, typically lower than 0.05 IU/dL, but may appear to show less dramatic reductions in factors XI, XI, and XII. This is a laboratory artifact caused by the inhibitor-depleting factor VIII from the XI-, XI-, and XII-deficient plasma used in these one-stage assays. Dilution experiments show an apparent increase in the concentration of factors IX, XI, and XII, whilst the factor VIII level remains low.[3,8,31,32] This may cause confusion with the LAC, which interferes nonspecifically with phospholipid-dependant one-stage assays but whose clinical presentation is dramatically different.[31] The diagnosis is confirmed using a formal Bethesda assay, possibly modified following the Nijmegen recommendations for low-titer inhibitors. Autoantibody factor VIII inhibitors in acquired hemophilia are usually polyclonal and have complex reaction kinetics. Consequently, patients with acquired hemophilia often have residual circulating factor VIII and the Bethesda assay is semiquantitative at best. This is linked with the clinical observation that bleeding severity is unrelated to the factor VIII level and inhibitor titer measured at the time of presentation. It is common practice to report the inhibitor titer based on the dilution closest to 50% inhibition. There have also been reports of anticoagulant treatment masking acquired hemophilia, possibly delaying diagnosis or being causally associated with the occurrence of acquired hemophilia. Patients on anticoagulants who present with bruising should therefore have both an aPTT and an International Normalized Ratio measured, for that reason.[33–35] An enzyme-linked immunosorbent assay (ELISA) assay may be useful in complicated cases.[3,30]

Immunochemistry of Autoantibody Inhibitors to FVIII:C

In contrast with the oligoclonal alloantibodies found in congenital hemophilia, and which are usually both IgG1 and IgG4, autoantibody inhibitors to FVIII:C is usually polyclonal IgG4. A further distinctive feature is that the autoimmune autoantibody inhibitors may rarely be monoclonal IgA or IgM antibodies and shifting immunoglobulin profiles have been observed, for example, shifting from IgM to IgG.[36]

Systematic epitope mapping has indicated that autoantibodies are usually directed against either the A2 or C2 domain of the FVIII:C molecule (62%) and much less frequently to both epitopes as observed with alloantibodies, which overwhelmingly interact with both A2 and C2 domains.[36,37] There appears to be preferential targeting of FVIII:C autoantibodies to the C2 domain (67%). The A3 epitope is targeted much less commonly. Both alloantibodies and autoantibodies bind to the same epitopes on the A2 and C2 domains. Autoantibodies may exert their inhibitory activity by interfering with thrombin cleavage sites on A2 or by impeding the interactions between FVIII:C and phospholipid or vWF protein on C2. This may result in increased FVIII:C catabolism and increased susceptibility of FVIII:C to degradation by activated protein C and factors IX and X.

Clinical Management

The management of acquired hemophilia involves treatment of any bleeding complications, simultaneous immunosuppression to abolish the inhibitor and investigation for and treatment of any underlying causative disorder. Patients with acquired hemophilia should be managed in or at least in collaboration with a hemophilia center experienced in managing the disorder, even if the initial presentation appears relatively benign. Invasive procedures and surgery should be avoided, if possible. Intramuscular injections should be avoided and venepuncture minimized since these can cause significant and troublesome

tahir99-VRG & vip.persianss.ir

bleeding. If procedures or surgery are unavoidable, they should be conducted in a hospital with an experienced hemophilia center and with adequate hemostatic cover. Patient education is also important, especially for patients managed as an outpatient. The patient and their relatives have to be made aware of the seriousness of the condition so that they present to hospital in a timely manner.[3,38,39]

Management of Bleeding Complications

FIGURE 57.1 shows an algorithm for treatment of bleeding complications.

Bleeding may be life- and limb-threatening. Morbidity and mortality are reduced by prompt and adequate hemostatic treatment supervised at an experienced hemophilia center. None of the hemostatic options available have predictable efficacy in acquired hemophilia. Neither the presenting inhibitor titer nor the residual factor VIII level, nor the factor VIII level achieved following the infusion of human or porcine factor VIII are predictive of clinical response.[3,8,9] Regular clinical review and appropriate imaging and laboratory monitoring are therefore vital when monitoring the efficacy of hemostatic therapy for this condition. An early assessment of hemostatic efficacy is very important so that if the treatment is not working a different agent may be tried with the minimum of delay. Dosing needs to be adequate and should continue for some time after bleeding is controlled, at a reducing dose, to optimize clinical response and minimize the risk of recurrent bleeding. This is particularly important for intracranial, intramuscular, and retroperitoneal bleeding. In contrast, many patients need no hemostatic treatment at all and subcutaneous bleeding and bruising can be managed conservatively, even if extensive. Mucosal bleeds may also benefit from the use of antifibrinolytic agents such as tranexamic acid or aminocaproic acid.

Bleeding is treated either with bypassing agents (currently, Factor Eight Inhibitor Bypassing Activity [FEIBA] (Baxter, Vienna) or NOVOSEVEN (rVIIa, Novo, Denmark) or with factor VIII-containing agents to raise the factor VIII level.[3] A recent survey from the EACH2 registry suggests that bypassing agents may be clinically more effective than factor VIII.[40,41] Porcine factor VIII has been unavailable for some years, however, and this comparison may have to be reevaluated when the current recombinant B-domain-deleted porcine factor VIII completes ongoing clinical trials in acquired hemophilia and gains a product license for this indication.

Factor VIII:C Concentrates

Previous reports of the treatment of bleeding in acquired hemophilia have shown that human factor VIII concentrate is the 1st agent used to treat bleeding in about one-third of cases.[6,8,9] The EACH2 registry data suggest that the response to factor VIII may be significantly worse than for bypass therapy in this group, probably because the half-life of factor VIII is severely curtailed in acquired hemophilia.[40,41] Human factor VIII may be used in large doses, when this is sufficient to overcome a relatively low-affinity inhibitor and an effective postinfusion factor VIII increment can be achieved. The use of factor VIII is, therefore largely limited to patients with low-affinity inhibitors. Although dose-calculating formula have been proposed, empirical dosing combined with close laboratory monitoring of the response and prompt dose adjustment is probably the best approach since the

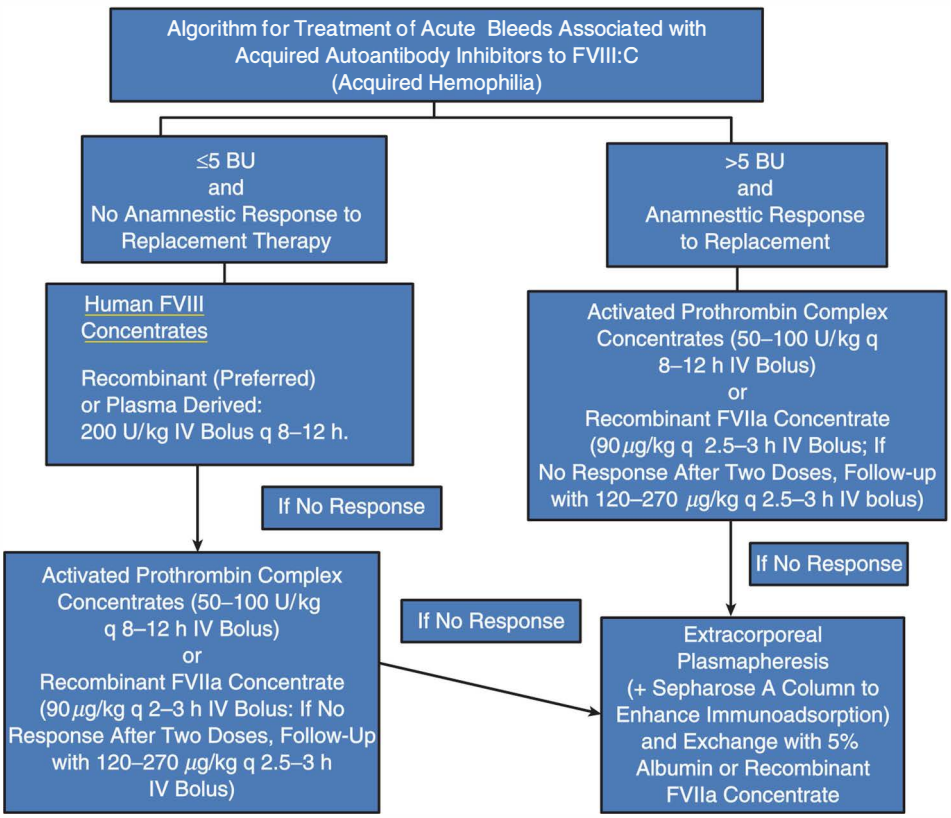

FIGURE 57.1 Algorithm for treatment of acute bleeds associated with acquired autoantibody inhibitors to FVIII:C. FIX, factor IX; BU, Bethesda units; rFVIIa, recombinant factor VIIa; PCC, prothrombin complex concentrate; DDAVP, 1-deamino-8-D-arginine vasopressin.

tahir99-VRG & vip.persianss.ir

Bethesda titer is not quantitative in this condition and therefore gives a poor guide to the likely response to factor VIII. Factor VIII replacement combined with immunoadsorption of the inhibitor antibody may also be effective, if this is available.[42,43] Human plasma-derived FVIII:C concentrates, which are characterized as being of intermediate purity by virtue of their substantial content of vWF protein, theoretically may be less susceptible to inactivation by the autoimmune FVIII:C inhibitor directed against the C2 domain[37]; however, this premise has not been confirmed in clinical studies. In contrast to congenital hemophilia, the use of factor VIII concentrate will not cause an anamnestic increase in the inhibitor titer.

Porcine Factor VIII

Another source of FVIII:C concentrate, which was very much more effective than human factor VIII, was porcine factor VIII concentrate. Cross-reactivity of antibodies in acquired hemophilia to porcine factor VIII was characteristically low, averaging 5% to 10%,[8,44,45] permitting porcine factor VIII to achieve hemostatic factor VIII levels in patients completely resistant to human factor VIII. Cross-reactivity varies considerably between individuals however, and so it is recommended to give an initial bolus of 75 to 100 IU porcine FVIII:C with subsequent dosing and dose intervals determined by the level of FVIII:C activity achieved and the durability of the response. FVIII:C levels of at least 30% to 50% are desirable, though clinical response has not been shown to correlate with the factor VIII level achieved.[8] Porcine factor VIII was reported to give a good or excellent response in 78% of 74 bleeds and failure in only 9%.[8] This response rate is comparable with that achieved using bypassing agents. More consistent high levels and improved pharmacokinetics may be achievable by administration using continuous infusion.[46] In contrast to congenital hemophilia, an anamnestic rise in the factor VIII inhibitor is not seen following exposure to factor VIII in acquired hemophilia. Specific antiporcine factor VIII antibodies may arise in 30% and these patients, however, rendering them resistant to porcine factor VIII.[45] Porcine factor VIII was manufactured from porcine plasma, which could not be rendered "virus free." Consequently, the product was withdrawn some years ago. An alternative, recombinant B-domain-deleted porcine factor VIII (Inspiration, California) has recently completed trials in congenital hemophilia[47] and multinational trials have begun in acquired hemophilia. This product looks very promising for the management of bleeding in acquired hemophilia but will probably not be available for general clinical use until 2013 to 2014.

Desmopressin (1-deamino-8-D-Arginine Vasopressin, DDAVP)

Administration of 1-deamino-8-D-arginine vasopressin (DDAVP) (Desmopressin) either intravenously or subcutaneously at the dose of 0.3 μg/kg induces a rapid rise of vWF and FVIII:C activities in normal individuals and those with mild uncomplicated hemophilia A and vWD.[47] DDAVP may also induce a rapid rise of FVIII:C in individuals with low-titer inhibitors, rendering the drug suitable for the treatment of minor, non–life-threatening bleeds or for prevention of potential bleeding secondary to mild surgical procedures in the context of acquired hemophilia.[48] The response is very variable, however. Of the 22 treatments reported, 11 patients with FVIII <5 IU/dL DDAVP resulted in an increase to between 15 and 140 IU/dL. Five patients with a Bethesda titer <2 BU/mL all responded with peak FVIII levels >80 IU/dL and a half-life of 4 to 6 hours. In contrast, no significant clinical response was reported for seven patients with a FVIII level <1 dL/mL.[48] The use of DDAVP in this condition is therefore very limited, and it should probably therefore be reserved for the treatment of minor bleeding in patients with a discernible circulating factor VIII level and low-level inhibitors.[3]

Bypassing Agents

At present the choice of bypassing agents is limited to FEIBA (Baxter Vienna) and Novoseven (recombinant activated factor VII, rVIIa, NovoNordisk, Denmark), although several manufacturers are currently developing analogs of rVIIa. Although non-activated prothrombin complex concentrates were used from the 1970s, these products have now largely fallen out of use for bleeding in acquired hemophilia. Both FEIBA and Novoseven have been shown to be effective in treating bleeding in acquired hemophilia.[9,40,41,49–51,52]

Although there are no direct comparative trials of FEIBA and Novoseven in acquired hemophilia, the data from the EACH2 registry and comparison of the published literature suggests that the two agents have similar efficacy.[9,40,41,49–51,52] National statistics suggest that FEIBA is used more frequently than Novoseven for acquired hemophilia, at least in the United Kingdom.[53] The choice of bypassing agent should depend, where possible, on the patient's previous response, the dosing schedule, and possibly cost. When first-line therapy fails, the alternative bypassing agent may be used. In cases of life- and limb-threatening bleeding, both bypassing agents may be used sequentially or together since they synergize and have greater hemostatic efficacy when used in combination.[53–54] The use of combination bypass therapy may be associated with an increased risk of both venous and arterial thrombosis, particularly in the elderly, and should therefore only be used for very serious bleeding, unresponsive to full doses of one or both bypassing agents.[3]

Both agents have been associated with a relatively small thrombotic risk.[39,52,56–60] Disseminated intravascular coagulation (DIC), myocardial infraction, and deep vein thrombosis have been associated with the use of FEIBA.[56] It is impossible to compare the thrombogenicity of the two products directly because most of the thrombotic events reported in relation to Novoseven are thought to relate to off-label use in nonhemophiliacs and FEIBA is currently only used in acquired and congenital hemophilia. However, the overall risk of thrombosis is low (~1 per 10^{4-5} infusions). Twelve (8.6%) of 139 patients with acquired hemophilia treated with rVIIa were reported to have had a thrombotic event, which was arterial in 10 cases.[52] Whether these events were directly related to rVIIa treatment is unclear and the authors point out that the methodology used would tend to overestimate the incidence of events.[52] EACH2 reported 8 (2.3%) arterial events amongst 337 patients.[40] One might expect that the thrombotic risk would be greater in patients with acquired rather than congenital hemophilia since the former are far more elderly and may have multiple risk-factors for arterial disease.

A limitation of bypassing agents is that they have no validated and readily available laboratory monitoring technique and dosing and dosing intervals must be adjusted based on clinical evaluation alone. Thrombin generation assays[60,61] and thromboelastography (TEG)[62,63] have both been used in a research

tahir99-VRG & vip.persianss.ir

setting to assess response and adjust dosage of bypassing agents. Neither is the test fully validated nor widely available and there are no published data in relation to the use of these tests to manage acquired hemophilia. It may not be possible to extrapolate evidence on the use of these tests from congenital to acquired hemophilia because of the differing immunochemistry and kinetics of the inhibitors involved. Further studies are required. Furthermore, preliminary evidence suggests that TEG does not predict clinical response consistently.[64]

FEIBA

The postulated mechanism of action of FEIBA is that of "bypassing" the obstruction to coagulation caused by the neutralizing inhibitor of FVIII:C. This is accomplished through their content of trace amounts of serine proteases (activated factors IX, X, VII, and thrombin). Retrospective analyses of patient cohorts with alloantibodies and autoantibodies have revealed efficacy rates of approximately 80% for both FEIBA (average dose of 70 IU/kg).[49] Furthermore, bolus doses higher than 200 IU/kg or frequent repeat dosing of activated prothrombin complex concentrates (aPCC) significantly increases the risks of thrombotic adverse events.[56] A more recent retrospective report of 34 severe and moderate bleeds treated mainly with 75 U/kg between 8 and 12 hourly reported an efficacy of almost 100% after a median of 6 infusions for moderate bleeding and 10 infusions for severe bleeding.[50] The EACH2 registry reported 94% efficacy for 64 bleeds treated with FEIBA.[40]

Recombinant FVIIa Concentrate

Recombinant FVIIa (rFVIIa, Novoseven) is generally administered as an intravenous bolus, resulting in supraphysiologic levels of FVIIa activity in blood. In individuals with normal coagulation, it is hypothesized that thrombin is generated after FVIIa interacts with tissue factor (TF) on mononuclear cell surfaces (monocytes and macrophages) and subsequently activates FX to participate in the tenase and prothrombinase complexes. This small quantity of thrombin is adequate only to activate platelets and to cleave vWF protein from FVIII:C, but this results in a self-amplification process in which rFVIIa binds to the surface of the activated platelet, activates FX in the presence of FVIII and FIX, and produces an extraordinary "thrombin burst" to affect fibrin formation.[65] Pertinent to the clinical situation with autoantibody FVIII:C or FIX inhibitors, large amounts of administered rFVIIa may bind nonspecifically to the platelet surface and activate FX in a TF-independent manner and in absence of FVIII:C and/or FIX.

Novoseven is normally given in a dose of 90 μg/kg, administered every 2 to 3 hours because of its short circulating half-life but a larger dose of 270 μg/kg has been shown to be safe and as effective as three 2-hourly doses of 90 μ/kg.[66,67] Once bleeding has stopped, the dose interval is lengthened but replacement therapy with rFVIIa should continue for several days to minimize the risk of re-bleeding. In the largest clinical trial in acquired hemophilia, rFVIIa, employed as first-line replacement therapy, reversed symptomatic bleeding 100% of the time, whereas rFVIIa, used as salvage or rescue therapy, yielded a 75% response rate.[25] A recent systematic review[52] reported a 95% efficacy for rVIIa, when used as first-line therapy for 103 bleeds. The EACH2 registry reported similar 91% efficacy for 170 bleeds treated with Novoseven as first-line therapy.[40] When used as second line therapy, the reported efficacy of Novoseven is lower at 86%.[52] The median duration of treatment has been reported to be 6 days (1 to 33).[52] If bleeding is not successfully stopped within the initial 24 hours of treatment with rFVIIa, the patient is likely to remain unresponsive to further rFVIIa and an alternative regimen should be considered.

Overall, very few side effects, including episodes of thrombosis, have been reported for rFVIIa concentrate use in autoimmune hemophilia. A finite risk does exist, however, and cases of myocardial infarction, DIC, and venous thromboembolism (VTE) have been reported.[40] No laboratory methods are available to monitor the hemostatic efficacy or safety of rFVIIa.

Immunosuppression Regimens

As soon as the diagnosis of acquired hemophilia has been established, the patient should be given some form of immunosuppressive treatment to eradicate the inhibitor.[3,30,38] Although up to 25% to 30% of patients may remit spontaneously,[22,23,24,68] they may suffer significant morbidity whilst awaiting spontaneous remission and are more likely not to remit. For that reason, the current consensus of opinion is that all patients with acquired hemophilia should be offered immunosuppressive therapy in the hope that this will not only optimize the remission rate but reduce the time taken to achieve remission, thus minimizing bleeding morbidity and mortality. However, when choosing an immunosuppressive regime, it should be remembered that infection is actually the commonest cause of death in acquired hemophilia[5] and aggressive immunosuppressive regimens may contribute to the morbidity and mortality associated with the condition. For this and other reasons, aggressive immunosuppressive regimens have fallen a little out of favor in recent years as a broad generalization. The options available for immunosuppression include administration of: corticosteroids alone; corticosteroids plus cyclophosphamide; rituximab (anti-CD20 monoclonal antibody); cyclosporin A; immunosuppression/immune tolerance induction regimens; high-dose intravenous immunoglobulin (IVIG); plasmapheresis/immunoadsorption; immune-tolerance regimens, and finally, corticosteroids combined with one or more cytotoxic agents cytotoxic agents (e.g., Cyclophosphamide, Azathioprine, Vincristine, 6-MP).

The various available regimens are difficult to compare directly because patient selection and end-points vary from report to report and most reports are of uncontrolled cohort studies. Almost all are case-reports, single center cohorts, or retrospective surveys. Furthermore, since most reports come from teaching centers, there is reporting bias toward more seriously affected cases. There may also be positive publication bias since failures are more difficult to publish.

Although there are no reports of relapse in older publications, patients with acquired hemophilia have presumably always relapsed and recent studies report a relapse rate of 10% to 20%.[5,69] Relapse occurred after a median of 7.5 months (0.25 to 14 months) in 20% of 102 patients.[5] This finding was reproduced in the EACH2 registry, which reported 18% relapse amongst those treated with steroids alone and 12% relapse in those treated with steroids and cyclophosphamide after a median of 4 months. All patients with acquired hemophilia therefore require long-term follow-up, even if they go into complete remission and should be warned of the possibility of recurrent bleeding symptoms. Furthermore, many patients require long-term maintenance immunosuppressive therapy to maintain remission or even partial remission and to prevent relapse.

Corticosteroids with/without Cytotoxic Agents

For many years it was thought that prednisolone combined with cyclophosphamide offered a slightly higher remission rate and more rapid response, though this has recently been challenged.[5] Recent data and reexamination of the literature led one to the conclusion that the combination had no advantages over prednisolone alone, however.[3,5,41] The only randomized comparison recruited only 31 patients and was therefore underpowered. The patients were treated with prednisolone 1 mg/kg/d for 3 weeks. The 21 nonresponders were then randomized either to continue prednisolone or to continue prednisolone combined with cyclophosphamide.[70] There was no difference between treatment arms, though the number of subjects was very small.

The UK prospective cohort study[5] permitted a prospective but nonrandomized comparison of patients treated with prednisolone or with prednisolone plus cytotoxic agents. The study design (an all-inclusive cohort study of all patients presenting in the United Kingdom over 24 months) should prevent selection bias. This showed that the 34 patients treated with prednisolone alone had a 76% complete remission rate after a median of 49 (31 to 62) days treatment, compared to a 78% complete remission rate after 39 (34 to 57) days for 45 patients treated with steroids and cytotoxics. Neither the remission rate nor the time to remission were significantly different, though the comparison is probably, again, statistically underpowered.

Aggregation of data from uncontrolled cohorts suggested similar results.[41] However, a systematic review[31] of 20 publications showed that there was a higher remission rate in patients treated with prednisolone combined with cyclophosphamide. This was not associated with a lower mortality rate, however, perhaps because of the greater toxicity of the combination than prednisolone alone.[31] An analysis of the 331 patients reported to the EACH2 registry has been conducted, in which the groups were matched for potential confounding variables such as age, gender, inhibitor titer, factor VIII level, and underlying etiology.[71] This group reported an odds ratio (95% CI) of 3.25 (1.51 to 6.96) $P < 0.001$ in favor of combination therapy. There were peculiarities in this data in that the remission rate for steroids alone was much lower, at 58%, than reported in the aggregate literature, whereas the 80% remission rate reported for combination therapy is comparable with what has been published before if not higher than average. This difference was not reflected in outcome. Mortality and sustained remission rate was similar in both groups.[5,31,71] This suggests that although combination treatments offer a better short-term remission rate they do not improve long-term outcome.[71] The median time to remission is reproducibly 5 weeks, so treatment must be given for more than 3 weeks before an assessment of success or failure may be made.

Rituximab

Rituximab (anti-CD20 antibody) has been a popular treatment for acquired hemophilia, particularly since the publication of a report of its use in three patients in combination with other drugs[72] and the first-line use of rituximab in 10 patients, of whom eight achieved rapid complete remission.[73] The remaining two patients responded to cyclophosphamide. A further study reported a complete remission rate of 100% in six patients treated with rituximab combined with prednisolone with or without cytotoxics after response times of 1, 2, 4, 8, 36, and 52 weeks, which are similar to those reported for other regimens.[74] Rituximab has proved to be a disappointing drug used as a second-line agent and there is no convincing evidence that is superior to other regimens.[31,75] Franchini[38] reviewed 71 patients with acquired hemophilia treated with rituximab, mostly in combination with a variety of other immunosuppressive agents. Although these authors reported a response rate in excess of 90% the data was difficult to interpret with confidence and they still suggested that rituximab should be used as a second-line agent in combination with steroids. The EACH2 data would support such a cautious approach since only 30 of the 51 patients (59%) treated with rituximab in combination achieved a stable remission, no better than steroids alone.[70] Only 42% of the patients treated with rituximab alone achieved remission.[70] Since rituximab is usually given in combination with one or more other immunosuppressive drugs, the data is difficult to interpret. However, there is no convincing evidence to suggest that it improves the remission rate or reduces the relapse rate and is therefore currently not recommended as first-line therapy.

Cyclosporine

This drug is used as a second-line agent, usually in combination with steroids, and there are a number of anecdotal reports of its successful use in inducing remission. [41,76,77]

Intravenous High-Dose Immunoglobulin

High-dose immunoglobulin enjoyed a vogue during the late 1980s and early 1990s, when reports of its successful use 1st appeared.[78] The early promise was never realized, however. A prospective study of 16 patients treated with IVIG reported that only three subjects (one also treated with steroids) achieved a remission and all three had inhibitor titers ≤1 BU/mL.[79] This 12.5% response rate is actually lower than the reported spontaneous remission rate.[68] Neither the UK Cohort study[5] nor the EACH2 registry nor the systematic review of Delgado et al.[31] show any additional benefit from including IVIG in the treatment regimen for acquired hemophilia and so high-dose immunoglobulin is currently not recommended for this condition.[3]

Extracorporeal Immunoadsorption

Forty-five patients were reported to have been treated with a combination of cyclophosphamide, prednisolone, IVIG, and daily immunoadsorption using a sepharose column combined with 200 IU/kg of factor VIII daily.[80] Bleeding was controlled rapidly and the inhibitor titer also declined rapidly achieving undetectable levels after a median of only 3 (95% CI 2 to 4) days. Remission was reported in 88% of patients after a median of 14 days. This is clearly a very effective approach to the management of bleeding, which may be useful in the treatment of resistant bleeding in centers equipped for immunoadsorption. The response remission rate is not convincingly superior to conventional therapy, however, and the observations are uncontrolled. The rationale for the use of the factor VIII in this regimen, other than to control bleeding is unclear. Since patients with acquired hemophilia do not usually elicit an anamnestic increase in their inhibitor following factor VIII infusion, it is difficult to understand in what way factor VII will act as an immunomodulatory agent in such a regimen.

Immune Tolerance Induction

The rationale for immune tolerance induction is that factor VIII may stimulate antibody-producing cells to divide, thus making them susceptible to cytotoxic immunosuppressants.[81] This

tahir99-VRG & vip.persianss.ir

hypothesis seems implausible given that the patient is making factor VIII constantly anyway and given that an anamnestic increase in inhibitor titer does not usually follow factor VIII infusion in acquired hemophilia. None of the studies of this approach were controlled and factor VIII was invariably administered in combination with an aggressive combination of cytotoxic immunosuppressive drugs and so the results are very difficult to interpret. Lian et al. reported a 92% remission rate in 12 patients treated with steroids, vincristine, and cyclophosphamide given thrice weekly with factor VIII after 1 to 3 cycles of this treatment.[79] This group subsequently reported very similar results (83% remission) in six patients treated with the same immunosuppressive regimen but without factor VIII.[82]

Nemes and Pitlik[83] reported on the use of a more aggressive regimen where factor VIII was administered daily (30 IU/kg) in a reducing regimen over 3 weeks combined with cyclophosphamide and methyl prednisolone. Although they reported a 93% remission rate after a median of 4.6 weeks compared to a 67% remission at a median of 28.3 weeks in six historical controls, the control group is inadequate since the number of subjects and controls is too small to provide an adequate comparison. The results of these studies do not provide sufficient evidence of additional benefit from the inclusion of factor VIII in the immunosuppressive regimen to recommend this approach.

In conclusion, although there is general agreement that all patients with acquired hemophilia should be offered immunosuppressive therapy to attempt to eradicate the inhibitor, in the absence of clinical trials, there is no consensus as to the best regimen to use. Furthermore, the choice of regimen does not appear to influence the prognosis. Prednisolone combined with cyclophosphamide is probably superior to prednisolone alone. Rituximab and cyclosporine are probably second-line approaches and combined cytotoxic regimens are probably third-line. A balance must be struck, in this predominantly elderly population, between adequate immunosuppression on the one hand and excessive treatment-related morbidity on the other.

INHIBITORS OF VON WILLEBRAND FACTOR PROTEIN

Acquired von Willebrand Disease

Autoantibodies to vWF protein give rise to a clinical disorder resembling congenital vWD, acquired von Willebrand disease or syndrome (AvWS). In the absence of any large prospective cross-sectional studies, the incidence of this condition is unknown and it is almost certainly also still under-diagnosed.[84,85] The condition may arise at any stage of life but occurs most frequently in the elderly at a median age of 62 years (range 2 to 96 years.[86] AvWS is usually, but not invariably, an epiphenomenon of an underlying disease, most commonly lymphoproliferative or myeloproliferative disorders, which account for between 48% and 63% of cases.[85,86,87,88,89–108] The condition is seen in a wide variety of lymphoproliferative disorders including lymphoma, monoclonal gammopathy of unknown significance (MGUS), myeloma, and Waldenstrom macroglobulinemia.[86,87,88,89–103] Mohri et al.[88] reported acquired hemophilia in 10% of 260 prospectively studied patients with hematologic disorders. AvWS has also been reported in association with autoimmune diseases such as SLE[85,86,109–112] and hypothyroidism,[86,113–117] cardiovascular disorders[86,118,119,–127] and solid tumors.[85,86,128–130] The association with cardiovascular disorders, in particular, has been increasingly recognized, accounting for 46% of cases in one recent retrospective study.[118] Since 1st being recognized in association with congenital heart disease,[119,120] AvWS has also been described in relation to a variety of acquired cardiac defects including aortic stenosis with gastric angiodysplasia (Heyde syndrome) and ventricular assist devices.[121–127]

Less frequent etiologic associations with AvWS have included chronic graft versus host disease post bone marrow transplantation[112]; post vaccination prodromes[16]; solid tumor nonhematologic malignancies such as Wilms tumors[128–131] and peripheral neuroectodermal tumors.[132] Finally, AvWS has iatrogenic associations with the use of valproic acid,[133,134] ciprofloxacin,[135] griseofulvin,[136] and hydroxyethyl starch.[137,138]

It is important to identify the underlying condition causing AvWS, not just because the condition may itself require treatment, but also because successful treatment of the underlying condition often leads to resolution of the acquired hemophilia. It seems likely that milder cases of AvWS may escape detection because they resolve when the underlying condition is successfully treated and may only come to light if the patient undergoes a surgical procedure prior to treatment of the underlying condition. It has therefore been argued that a bleeding history should be taken and appropriate tests conducted to exclude AvWS prior to surgical intervention in patients with myeloprololiferative and lymphoproliferative disorders and untreated hypothyroidism.

Clinical Presentation

The clinical presentation is very variable, reflecting the considerable heterogeneity of AvWS. Most individuals present with a mild bleeding pattern of easy bruising and epistaxis. In some cases abnormal bleeding may only be observed following surgery or injury, however. More severely affected individuals bleed spontaneously, with bruising and bleeding predominantly involving the gastrointestinal tract and other mucous membranes, such as epistaxis.[84] Bleeding may, occasionally, be life threatening.

Diagnosis

The diagnosis is based partly on the history of recent onset bleeding in a patient with no previous or family history of bleeding. The discovery of an "underlying disorder" may be coincidental however and, in order to distinguish AvWS from hereditary vWD it will sometimes be necessary to test not only the patients but their first-degree relatives.

The laboratory diagnosis of AvWS is based on measurement of factor VIII, von Willebrand antigen and activity (Ristocetin cofactor activity or collagen binding assay). Multimeric analysis in plasma and platelets and von Willebrand propeptide has also been used to diagnose AvWS. It is important always to test for anti-vWF antibodies, because this is of clinical importance.[86,88,118] This can be carried out by conducting mixing experiments, measuring von Willebrand activity before and after incubation at 37°C for 1 to 4 hours. Some sandwich ELISA assays have also been described.[86,140] This assay is sensitive but its specificity requires further evaluation. Tiede et al.[118] evaluated this diagnostic approach retrospectively in 35 patients, reporting a high (86%) sensitivity of vW mutimeric analysis for AvWS similar to the combination of all the other assays combined. Another way of looking at this would be to say that the other

tahir99-VRG & vip.persianss.ir

assays are diagnostically sufficient, particularly since most laboratories do not have ready access to multimer testing.

There is also an argument for taking a careful bleeding history and possibly testing asymptomatic individuals with high-risk disorders prior to surgical intervention.[141]

Pathophysiology

There are several, very different proposed mechanisms for the development of AvWS. The mechanism and even vW subtype cannot be reliably predicted by identifying the underlying disorder, though some disorders are more strongly associated with specific mechanisms and vW types than others. Indeed, more than one mechanism may be operating in an individual at any one time. In general, vWF is normally secreted in AvWS, the exception being hypothyroidism, which is associated with decreased synthesis or secretion. Various mechanisms result in increased clearance, either of the entire native vWF giving rise to type 1 vWD or to selective clearance of high molecular weight (HMW) multimers, giving rise to type 2A vWD, though type 3 vWD is also occasionally reported.[85,86,139] Type 3 AvWS is rare but has been observed in association with Wilms tumors and essential thrombocytosis. The etiologies for type III AvWS respond to chemotherapy and/or tumor resection.[93,120,122,142] The mechanisms underlying AvWS are as follows:

Immune-mediated
