The P-domain is named because it contains a major polymerization pocket. Before structure determinations of this part of fibrinogen, short peptides containing the Gly-Pro-Arg sequence, the *N*-terminal end of the α-chain of fibrin, were found to bind to fibrinogen and to be effective polymerization inhibitors.[27] Such peptides were incorporated into crystals of the γC-module and fragment D and were identified in the binding pocket of the P-domain.[28] There are only subtle changes in the conformation of the P-domain upon peptide binding.[29] The binding sites for the peptide are present on three extended loops that form a cavity with many negatively charged side chains complementary to the peptide amino acids. Residues in contact with the peptide are Gln329, Asp330, His340, and Asp364.

Peptides with the sequence Gly-His-Arg, corresponding to the *N*-terminus of the β-chain, also inhibit polymerization, but to a lesser extent.[27] In contrast to Gly-Pro-Arg binding to the γ-module, binding of Gly-His-Arg to the β-module results in a major conformational change.[29,30] Specifically, two carboxylates from BβAsp398 and BβGlu397 rotate inward to complete formation of the β-module P-domain–binding pocket.

There is one strand of β-sheet near the *C*-terminal end of the γ-chain that is inserted into the central B-domain. This strand can be pulled out of the γ-module without destroying its compact structure, which could be significant for FXIIIa-induced cross-linking and for the mechanical properties of fibrin.[31,32]

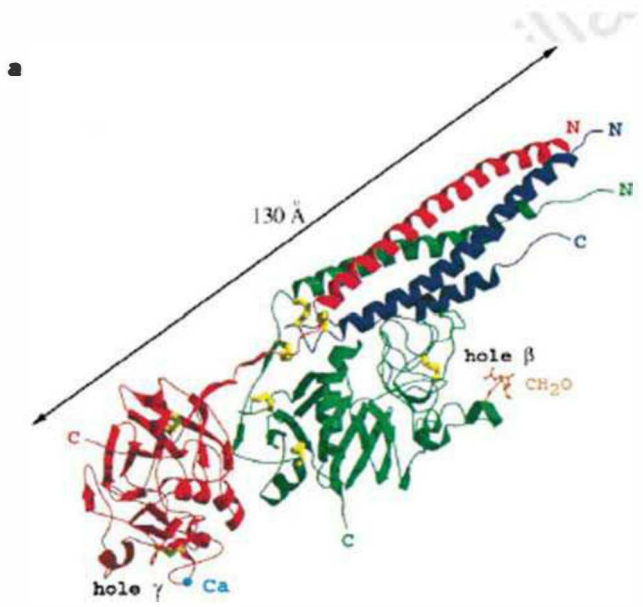

FIGURE 16.4 Crystal structure of fragment D. The Aα-chains are *blue*, the Bβ-chains are *green*, and the γ-chains are *red*. The four-stranded α-helical coiled coil is visible and the γ- and β-modules, with corresponding holes "a" (labeled hole γ) and holes "b" (labeled hole β). The *N*- and *C*-terminal ends of the polypeptide chains are indicated as is the carbohydrate-binding site (labeled CH_2O). (From Spraggon G, Everse SJ, Doolittle RF. Crystal structures of fragment D from human fibrinogen and its cross-linked counterpart from fibrin. *Nature* 1997;389:455–462.)

Structure of the Central Region of Fibrinogen

The central region contains portions of all six chains tightly folded into a compact structure held together by disulfide bonds.[4] In addition, there is an extensive "handshake" interface with many noncovalent interactions (FIGURE 16.5). Neither the A nor B fibrinopeptides (Fps) are visible in the crystal structure nor is the larger *N*-terminal end of the Bβ-chain. On one face of the central region, the Aα- and Bβ-chains from the two half molecules form a funnel-shaped domain with a hydrophobic core, while on the opposite face, the *N*-terminal γ-chains form a separate domain. Although the two halves of the molecule are identical in amino acid sequence, a pair of adjacent disulfide bonds constrain the two γ-chains to adopt different conformations. The resulting asymmetry of the molecule may be responsible for the twisting of oligomers and protofibrils.[33,34]

Coiled Coils

The central and end regions of fibrinogen are joined by α-helical coiled coils that are principally responsible for fibrinogen's elongated shape. Although the coiled coils represent only 30% of its molecular mass, fibrinogen was one of first proteins in which

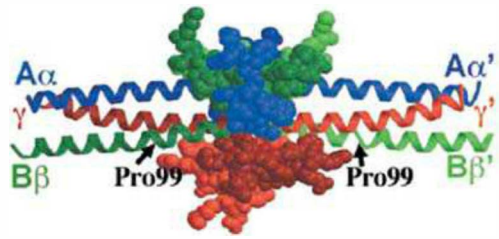

FIGURE 16.5 Crystal structure of fragment D. The Aα-chains are *blue*, the Bβ-chains are *green*, and the γ-chains are *red*. The central region is shown as a space-filling model while the three-stranded coiled coils are shown as ribbons. (From Madrazo J, Brown JH, Litvinovich, et al. Crystal structure of the central region of bovine fibrinogen E5 fragment at 1.4 Å resolution. *Proc Natl Acad Sci U S A* 2001;98:11867–11972.)

this structural element was identified from wide-angle x-ray diffraction patterns.[35] There are 111 or 112 residues in each of the three chains that form the coiled coils that are bounded at each end by disulfide rings. The amino acid sequences are largely consistent with those of typical coiled coils with nonpolar residues pointing inward forming a hydrophobic core shielded from solvent and charged residues exposed to solvent on the outside; there are specific interactions between the chains.[36,37] Near the middle of the coiled coil, there are residues less consistent with the canonical sequence, giving rise to a kink in the molecule.[38] This region is susceptible to proteolytic attack and is a major site of cleavage during fibrinolysis. The distal portion of the coiled coil has a fourth strand of α-helix formed from the *C*-terminal part of the Aα-chain.[39]

The coiled coils provide the length needed for fibrin polymerization and for the platelet cross-linking responsible for platelet aggregation. The coiled coils are stable and relatively rigid structures whose mechanical properties are likely critical for the overall viscoelastic behavior of fibrin clots. Although force spectroscopy experiments have suggested that the coiled coils may unfold,[40,41] the situation now appears to be much more complex. The γ-modules appear to unfold first, with the coiled coils acting as molecular capacitors, reversibly stretching to buffer the unfolding transitions of the γ-module.[32] The coiled coils also provide a surface containing some specific motifs for binding of other proteins.

Structure of the αC Region

Each αC region is made up of a relatively compact or globular region, the *C*-terminal portion of which is called the αC-domain and the extended *N*-terminal region, called the αC-connector. Together, the two αC regions comprise about 25% of the total mass of fibrinogen. The αC-domain has a β-hairpin turn and another loose β-hairpin turn, yielding a mixed parallel/antiparallel β-sheet structure.[42–44] The αC-connector is highly variable in different species of fibrinogen and is partially made up of 10 tandem repeats of 13 amino acids, each containing a characteristic Trp residue and rich in Gly, Ser, Thr, and Pro residues. Such sequences are found in extended poly-L-proline type II helices, which are left-handed with three residues per turn.[45] It is possible that the αC-connector also has such a structure, since these helices are highly hydrated, are stabilized by hydrogen bonds with water molecules, and tend to form interdomain links or "sticky arms."

In fibrinogen, the two αC regions interact with each other intramolecularly.[46–48] Following cleavage of the Fps, particularly FpB, the αC regions dissociate and interact intermolecularly. The αC regions interact specifically to form long, branching polymers, closely related to structures formed in fibrin clots.[46,49] In addition, these conformational changes on conversion of fibrinogen to fibrin expose binding sites for various ligands that are otherwise cryptic[49,50] (Tsurupa, 2009 #2483).

Structure of the AαE-Domain

A less common variant of the Aα-chain, called AαE, has an additional 236 amino acids at its *C*-terminal end.[51,52] Unlike the more common *C*-terminus of the Aα-chain, the AαE-domain does show significant homology to the β-module and the γ-module. In contrast to these structures, however, the binding cleft of the AαE-domain is essentially neutral and is not likely to bind Gly-Pro-Arg or Gly-His-Arg, suggesting that it does not participate directly in polymerization.[53] It has been proposed that this domain may act as a lectin-like carbohydrate-binding receptor.[53]

BIOSYNTHESIS AND METABOLISM

Gene Regulation

The three fibrinogen genes, *FGA*, *FGB*, and *FGG*, are expressed coordinately, such that the relative proportion of mRNA for the three chains is nearly equal.[54] They share common regulatory mechanisms, with cis-acting regulatory elements upstream of sites of transcription initiation.[55] However, a TATA-like sequence, a CAAT-like sequence, and a USF-binding site control liver-specific expression of FGG. In contrast, liver-specific expression of FGA and FGB is controlled by other transcription factors, such as hepatic-specific nuclear receptor.

Fibrinogen is an acute-phase protein whose levels increase in response to injury and the accompanying release of cytokines.[54] Upregulation of fibrinogen expression is controlled by interleukin 6 (IL6) through type II IL6-response elements in the 5'-flanking regions of all three fibrinogen genes. Fibrin(ogen) degradation products stimulate monocytes/macrophages to produce IL6 and hence upregulate fibrinogen synthesis. A glucocorticoid response element also upregulates fibrinogen expression.

There are also negative regulators of transcription, including the cytokines IL4, IL10, IL13, and transforming growth factor-β (TGF-β). In addition, TGF-β antagonizes IL6 induction of fibrinogen mRNA at late, but not early times, after IL6 treatment. The combined early and late effects of these cytokines may be responsible for the coordinate regulation of fibrinogen synthesis during inflammation.

Synthesis and Secretion

The polypeptide chains of fibrinogen are assembled in an ordered fashion in the rough endoplasmic reticulum of the liver.[56] Newly synthesized human Bβ-chains are secreted and used more rapidly than the other two chains that accumulate in intracellular pools. The interchain disulfide bonds at the ends of the coiled coil, the coiled coils themselves, and some disulfides between the two halves of the molecule are important for proper assembly of the molecule.

Tissue-Specific Synthesis

Most fibrinogen is synthesized in the liver, with a steady-state rate of production of 1.7 to 5.0 g per day and a large reserve capacity of up to 20-fold.[57] The half-life of circulating fibrinogen is 3 to 5 days, with the mechanism of turnover largely unknown. Coagulation and lysis accounts for only 2% to 3% of the total catabolism, and the classic catabolism pathways for plasma proteins do not apply.[58] Fibrinogen, but not the γ-chain variant, is present in platelet α-granules and appears to be taken up by the granules *via* receptor-mediated endocytosis. Fibrinogen synthesis, albeit in lower amounts, has been detected in tissues other than the liver, suggesting that it may function in structural or adhesive capacities in the extracellular matrix.[59]

FIBRIN POLYMERIZATION

Fibrinopeptide Release

Fibrin polymerization is initiated by the enzymatic cleavage of the Fps from fibrinogen by thrombin, yielding fibrin monomer. Specific Arg-Gly bonds are hydrolyzed in the Aα- and Bβ-chains, in part arising from a set of hydrophobic residues in FpA that bind to a complementary apolar region on thrombin, but other distinct regions of FpA are also involved in binding and catalysis.[60] FpB is released at a considerably slower rate than FpA. The ordered release of the Fps is dictated by the specificity of thrombin for its substrate[61] since replacement of FpB with a FpA-like sequence results in nearly equal rates of Fps release. As polymerization proceeds, the rate of FpB release increases greatly, suggesting that either it is preferentially released from polymers[62] or that conformational changes resulting from polymerization facilitate its release.[63,64]

Oligomer Formation

Although the Fps are small, their release has profound effects on the solubility of the molecule as a result of exposure of previously buried binding sites. The Fps mask knobs "A" that are complementary to holes "a" that are always exposed (FIGURE 16.6),[1,65] although the Fps and knobs are not visible in x-ray crystallographic structures of fragment E.[4] On the other hand, crystal structures of fragment D with peptides representing the *N*-terminal sequences of fibrin's α- and β-chains have demonstrated peptide-binding pockets in the γC- and βC-modules,[26,29,66,67] providing strong evidence that these are holes "a" and "b" respectively. It is not yet known if each peptide represents an entire knob, but it is likely that there are more extensive regions involved. Thus, two fibrin monomers thus interact with each other in a half-staggered manner, so that knob "A" fits into hole "a."[68,69] Because of the dimeric nature of the molecule, there are two "A"–"a" knob–hole interactions holding the two monomers together (FIGURE 16.6). However, it should be noted that fibrinogen can bind to fibrin monomer because fibrinogen has holes that can accept the exposed knobs on fibrin monomer. These fibrinogen–fibrin complexes are present most of the time and represent an important buffer mechanism to prevent the polymerization of small amounts of fibrin that is generated in the blood.[70,71] Additional monomers add longitudinally to the fibrin dimer forming larger oligomers (FIGURE 16.3B), which lengthen into protofibrils, defined as oligomers that are long enough to aggregate (~0.5 μm).[62,72] The "A"–"a" knob–hole interactions are sufficient to make fibers and a branched clot network.[73,74]

FpB cleavage exposes the knobs "B," but the functional consequences of this event are not clear. FpA cleavage alone produces clots made up of thinner fibers than those initiated by cleavage of both Fps. This led to the hypothesis that knob "A"–hole "a" interactions are responsible for the interactions within a protofibril, while knob "B"–hole "b" interactions are responsible for lateral aggregation.[75] However, lateral aggregation of protofibrils and fiber formation can occur without FpB cleavage, which is not consistent with this hypothesis.[73,74] Moreover, knob "B"–hole "b" interactions are potentially problematic because holes "b" are not at the ends of the molecule but 8 to 9 nm away. Although conformational changes accompanying conversion to fibrin could potentially shorten that distance, this effect is not likely to be substantial because the band pattern of fibrin indicates that the β-nodule has nearly the same spatial relationship to the γ-nodule in fibrin as in fibrinogen (FIGURE 16.3C).[9] On the other hand, the *N*-termini of the β-chain could be highly extended and act as "crab claws" to reach the holes.[76,77] Evidence that knob "B"–hole "b" interactions can actually occur in fibrin come from the dysfibrinogenemias Metz and Frankfurt XIII in which all fibrinogen molecules are homodimers from which FpB, but not FpA, can be cleaved yielding clots with thin fibers at low temperature.[74,78] In addition, recombinant mutants of γ364 that have no functional holes "a" form clots slowly with thrombin but not with reptilase.[79] Thus, it appears that B:b bonds can occur at least when A:a interactions are compromised, but their role under physiologic circumstances remains unclear. There is no evidence for A:b or B:a interactions in fibrin polymerization.[80,81]

Addition of a third molecule to a half-staggered fibrin dimer produces an end-to-end junction where the ends of two molecules abut each other. This D–D interface is an important feature of most of the known crystal and microcrystal forms.[26,38,82] At this interface, γArg275 makes contact with γTyr280 and γSer300. These interactions produce a broad interface that is likely to be similar to that at the end-to-end junction between monomers in protofibrils.

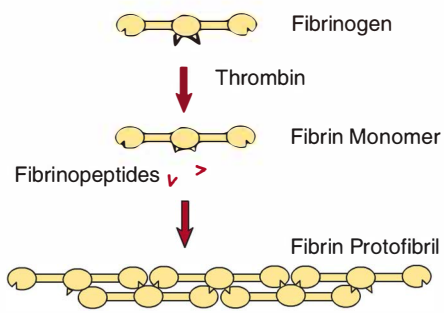

FIGURE 16.6 General schematic diagram of complementary binding sites or knob–hole interactions in fibrin polymerization. Fps in the central region cover knobs that are complementary to holes that are always exposed at the ends of the molecule. When the knobs are removed by fibrin, knob–hole interactions occur, giving rise to the two-stranded protofibril made up of half-staggered fibrin monomers. (From Weisel JW. Fibrinogen and Fibrin. *Adv Protein Chem* 2005;70:247–299.)

Protofibril Growth by Lateral Aggregation

The existence of a structure, called the protofibril, was based on the observation that oligomers must reach a certain length before they can aggregate laterally, so protofibrils are essentially longer oligomers.[68] Structurally they are two-stranded structures made up of half-staggered fibrin monomers. Protofibrils are twisted structures, with a long pitch.[34,69]

Protofibrils associate with each other laterally to make fibers (FIGURE 16.7). Because protofibrils do not associate until they reach a length of at least 0.5 μm,[62,72] it is likely that the interactions responsible for lateral aggregation are weak and additive over the length of the protofibril. However, little is known about the nature of these interactions or their localization. Potential clues come from the analysis of interactions between D fragments in crystals (FIGURE 16.8).[76] Although there is as yet no evidence that the crystallographic contacts are present in fibrin, structural proteins that self-assemble do tend to use similar

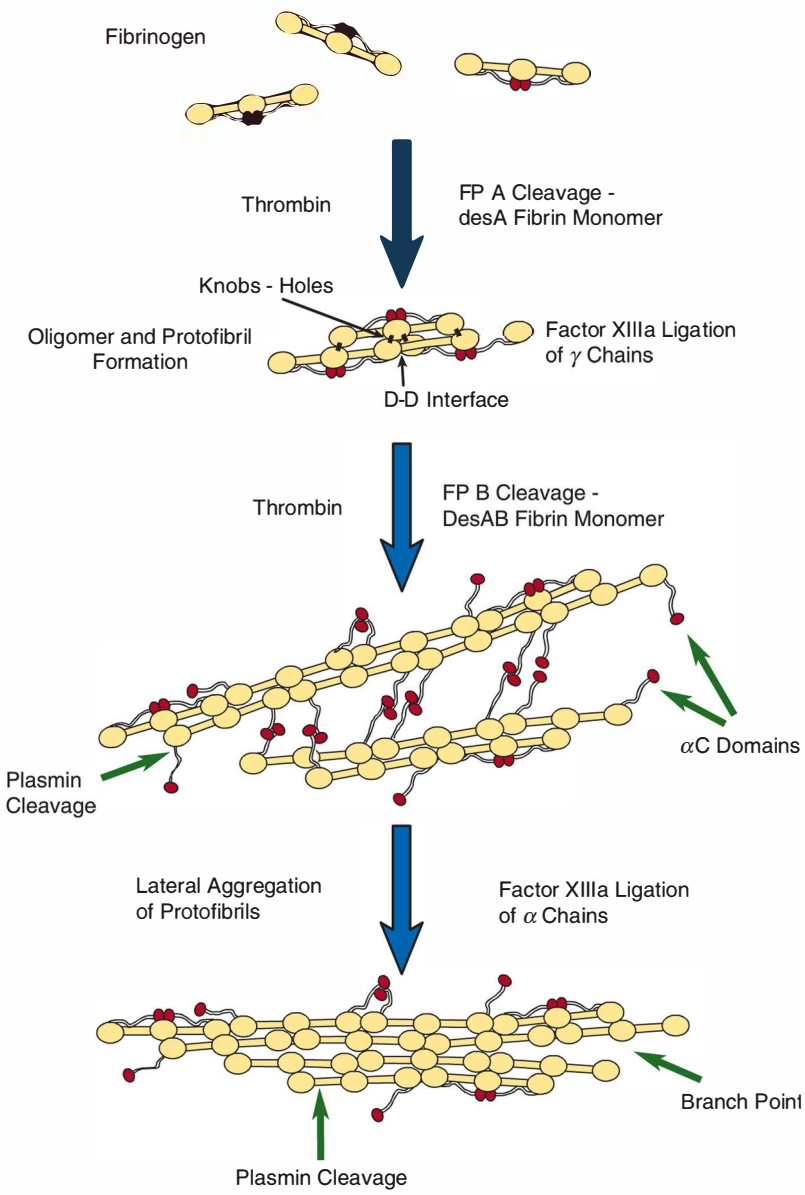

FIGURE 16.7 Schematic diagram of fibrin polymerization. FpA is cleaved first, producing desA fibrin monomers, which aggregate *via* knob–hole interactions to make oligomers. The D–D interface between the γ-modules of two fibrin monomers is shown. The oligomers elongate to make protofibrils. FpB is cleaved primarily from polymeric structures. Protofibrils aggregate laterally to make fibers, enhanced by interactions between αC regions. Factor XIIIa cross-links γ-chains more rapidly than α-chains. Plasmin cleaves the αC regions and at β42 and then cuts across fibrin in the middle of the coiled coil. At the bottom of this figure, a branch point has been initiated by the divergence of two protofibrils. (From Weisel JW. Fibrinogen and fibrin. *Adv Protein Chem* 2005;70:247–299.)

binding interactions *in vitro*.[82,83] In this scheme, the D regions of two laterally aligned protofibrils interact, such that residues γ350-360 and γ370-380 are shielded from water. In addition, the αC regions of fibrin interact with each other intermolecularly and enhance lateral aggregation (FIGURE 16.7).[47–49,84] Although they are not required for lateral aggregation, clots made from fibrinogen missing the αC regions are made up of thinner fibers.

Although such binding interactions may be present in fibrin, packing in fibrin is not crystalline, but paracrystalline.[85,86,87] Consequently, fibrin molecules are in good register in the longitudinal direction but are less well ordered across the fibers.[88] In addition, the twist present in protofibrils leads them to twist around each other to make twisted fibers (FIGURE 16.3B).[34] Because the periodicity of 22.5 nm is maintained as new protofibrils are added (FIGURE 16.3C), they must be stretched as their path length increases as fibers grow thicker. It has been proposed that fibers stop growing laterally when the energy necessary to stretch an added protofibril exceeds the energy of bonding.

Fibrin Branching

Fiber branching is necessary to produce a three-dimensional network. Although little is known about mechanisms of branching, one clue comes from the fact that fiber ends are seldom observed in an undamaged clot. Thus, it is likely that protofibrils do not add to a growing fiber with their ends in register but with random longitudinal spacing and that protofibrils of different lengths and smaller oligomers add to the growing fiber.

Nearly all branch points in fibrin clots are trifunctional, in other words, a junction of three fibers.[89] Observations of branching by either scanning electron microscopy or transmission electron microscopy of negatively contrasted specimens show that the diameters of all three fibers at a branch point are often, but not invariably, similar (FIGURE 16.9). There

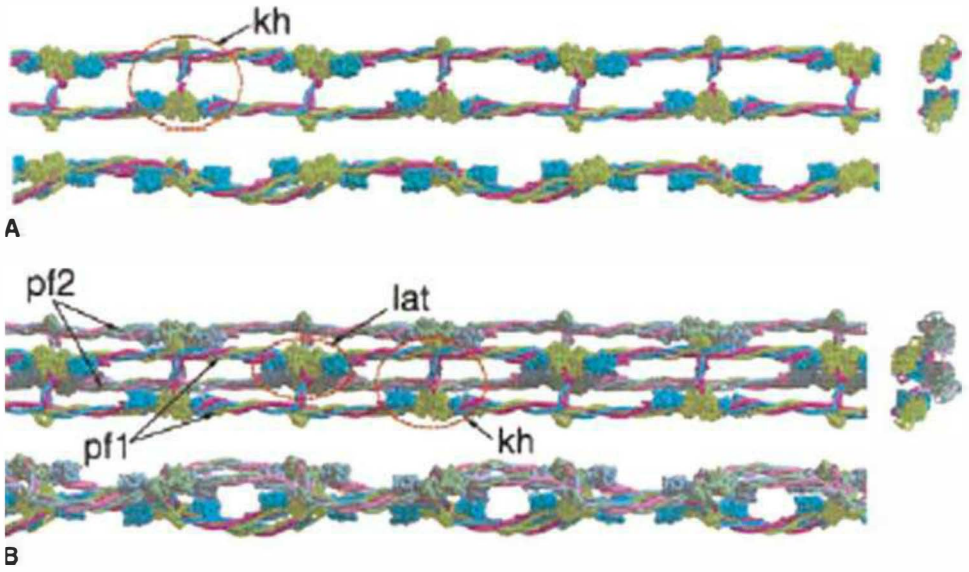

FIGURE 16.8 Potential model of protofibril structure and lateral aggregation from crystal structure packing. Space-filling models of the x-ray crystallographic structure of fibrinogen (missing some parts) were used together with knowledge about fibrin interactions to make a theoretical model for a protofibril and lateral aggregation between protofibrils. This model also uses contacts between fragments D that have been observed in the crystals, assuming that such interactions may also be present in fibrin. **A:** Top, side, and end-on views of a two-stranded protofibril, with the *red oval* outlining the knob "A"–hole "a" (kh) interactions that are responsible for fibrin polymerization. Note that the structure of the holes is known from the crystallographic data but not the knobs. **B:** Top, side, and end-on views of two protofibrils (pf1 and pf2) with presumed interactions between them. One *red oval* outlines the knob–hole interactions (kh) within a protofibril and the other *red oval* outlines lateral (lat) interactions between protofibrils. (From Yang Z, Mochalkin I, Doolittle RF. A model of fibrin formation based on crystal structures of fibrinogen and fibrin fragments complexed with synthetic peptides. *Proc Natl Acad Sci U S A* 2000;97:14156–14161.)

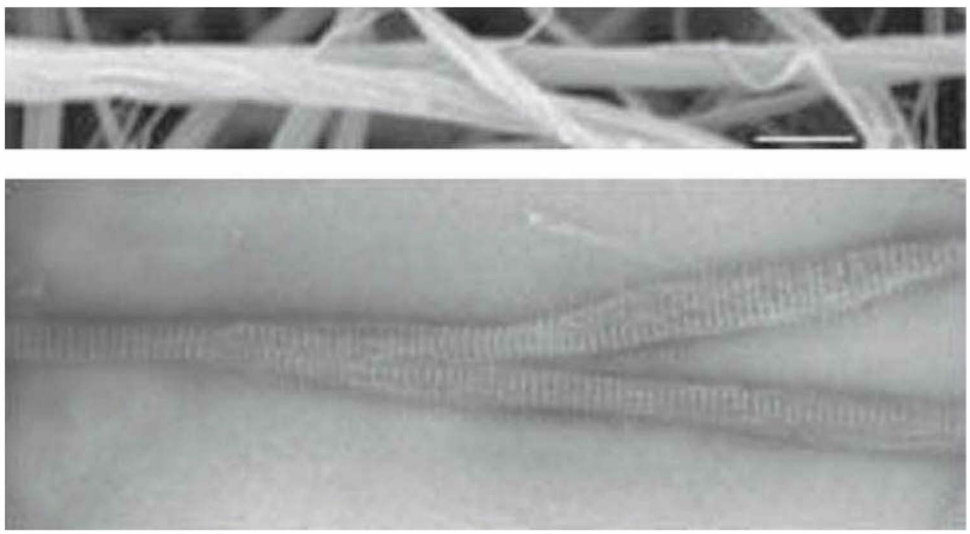

FIGURE 16.9 Electron microscope images of fibrin branch points. Nearly all branch points observed by electron or light microscopy are trifunctional, that is, they are formed by the junction of three fibers. The fibers can be of different or similar diameters. **Top:** Scanning electron micrograph of branch point. Note that the images show that fibers are made up of protofibrils that twist around each other. **Bottom:** Transmission electron micrograph of negatively contrasted fibrin fibers at a branch point. Note that the band patterns of the three fibers are aligned with each other. (From Weisel JW. The mechanical properties of fibrin for basic scientists and clinicians. *Biophys Chem* 2004;112:267–276.)

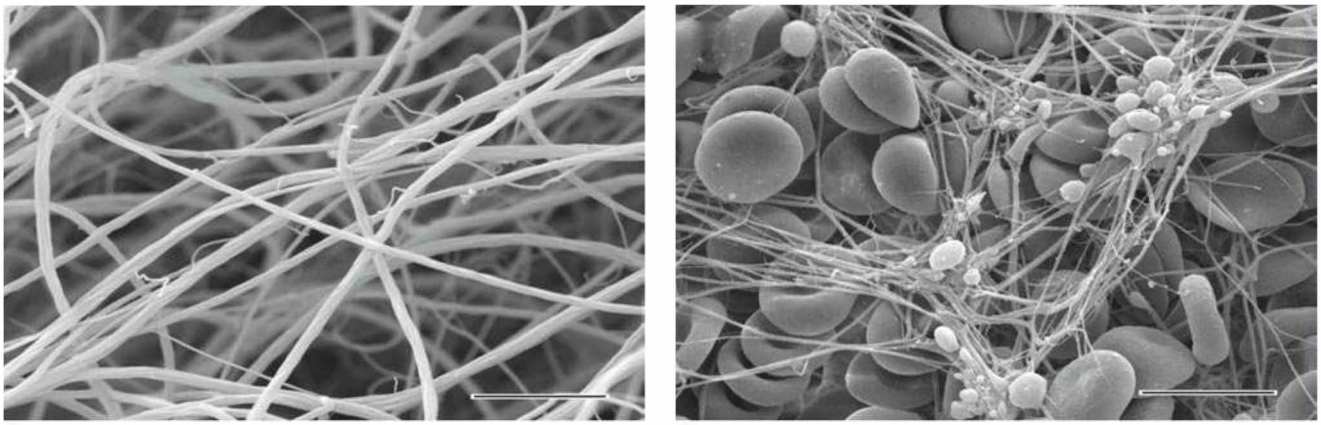

FIGURE 16.10 Scanning electron microscope images of clots. **A:** Clot formed by the addition of thrombin to purified fibrinogen. Note that in such images it is sometimes difficult to distinguish between true branch points and fibers crossing at different depths in the clot. Magnification bar, 5 μm. **B:** Whole blood clot made from freshly drawn blood with no additions. Fibrin fibers commonly originate from platelet aggregates, and red and white blood cells are trapped in the meshwork. Magnification bar, 10 μm. (From Weisel JW. Fibrinogen and fibrin. *Adv Protein Chem* 2005;70:247–299.)

is a general correspondence between numbers of branch points and fiber diameter; as the number of branch points increase, the fiber diameters decrease.[89] Together, these observations suggest that branching and lateral aggregation are opposite sides of the same coin, that is, conditions that favor lateral aggregation tend to produce clots with thick fibers and few branch points, while conditions that inhibit lateral aggregation tend to yield clots made up of thin fibers with many branch points.

At the molecular level, branches could result from two protofibrils that associate over part of their lengths and then diverge from each other or from the addition of two fibrin monomers that diverge from each other at the end of an individual protofibril.[90]

Fibrin Structure and the Gel Point or Clotting Time

Once the branching fibers form a space-filling, three-dimensional network, a clot or gel exists (FIGURES 16.10 and 16.11). The gel point or clotting time has been used as an indication of altered or pathologic coagulation. The gel point occurs relatively early in polymerization, perhaps when only 10% of the fibrinogen has been incorporated into the gel. Under standard conditions, however, it is a sensitive measure of the overall kinetics of the clotting cascade, and hence an indicator of abnormalities. Although there are correlations between gel time and final clot structure,[91] the complete and final network is generally not established at the gel point, with new fibers and branch points still being established after the gel point has been reached.[92]

The structure of a clot can be characterized by fiber diameter, density, number and nature of the branch points, distances between branch points, and the size of the pores (FIGURE 16.10). Although diffusion of proteins is rarely affected by the fiber network, perfusion of fluid through the gel is a sensitive measure of pore size and hence clot structure.[93]

Role of Calcium in Fibrinogen Structure and Function

Calcium binding to fibrinogen is important for its structural stability and function. X-ray crystallography has revealed one calcium ion in the γ-module and two in the β-module.[25,26] Specific residues in the calcium-binding loop, γ311-336 (as

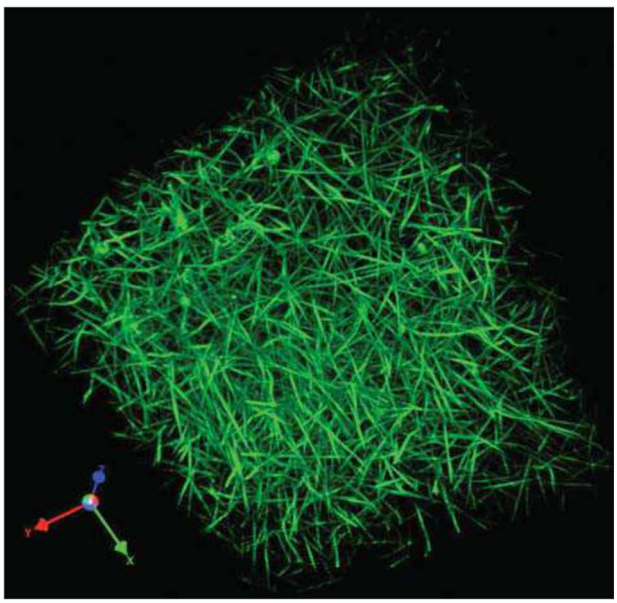

FIGURE 16.11 Three-dimensional structure of a hydrated fibrin clot. Three-dimensional reconstruction of optical sections by confocal microscopy of a fibrin clot made by the addition of thrombin to plasma, spiked with fluorescently labeled fibrinogen. (From supplementary online materials of Brown AE, Litvinov, RI, Discher, et al. Multiscale mechanics of fibrin polymer: gel stretching with protein unfolding and loss of water. *Science* 2009;325:741–744.)

well as corresponding residues in the βC-module), together with two strongly bound water molecules, form a high-affinity calcium-binding site that differs from a classic EF hand. Since the dissociation constant for calcium ion binding to these sites is much lower than the free calcium ion concentration in plasma, the sites should normally be fully occupied in fibrinogen. Physiologic concentrations of calcium are important for maintaining the stability of fibrin(ogen), protecting against plasmin digestion and denaturation by heat and high temperature, as well as the extent of reduction of disulfide bonds.[94–96]

There are also lower affinity calcium-binding sites that may have regulatory roles, some of which may bind to sialic acid.[15] Several lower affinity calcium-binding sites are associated with interactions of the βC-module with the coiled coil.[29,67,97] A movable flap made up of β397Glu and β398Asp is pinned back to the coiled coil with a calcium bridge until the GHR peptide occupies the βC-module–binding pocket.

There is no effect of calcium on thrombin-catalyzed Fp release, but it does have effects on subsequent polymerization step(s). Key calcium-binding residues in the γC-module appear to be necessary for protofibril formation.[98] Calcium increases the rate and extent of lateral aggregation, such that thicker fibers are formed at higher calcium ion concentrations. There is a calcium-dependent conformational change in fibrin that is correlated with the release of FpB,[99] and simultaneously, two calcium-binding sites shift from low to high affinity,[100] which may be related to the structural changes observed by x-ray crystallography.[29,67]

The peptide representing the knobs "B," GHRP, binds 10 times more strongly to hole "b" in the presence of 2 mM calcium than in its absence. Correspondingly, the βC-modules have low-affinity binding sites,[66] and mutation of one of them resulted in increased lateral aggregation, consistent with a role for knob "B"–hole "b" interaction involvement in lateral aggregation.[97]

Factor XIIIa–Catalyzed Cross-Linking of Fibrin

FXIIIa facilitates clot stability by catalyzing the formation of covalent by Nε-(γ glutamyl) lysine bonds between fibrin molecules. FXIIIa also cross-links other proteins, including α_2-antiplasmin, plasminogen activator inhibitor-2 (PAI-2), and fibronectin, to fibrin. FXIII is discussed in detail in Chapter 17, but several aspects of FXIII relevant to fibrin properties are discussed here.

γ-Chain Cross-Linking

Fibrinogen γ-chains are cross-linked more rapidly than α-chains and γ-chains are cross-linked more rapidly in fibrin than in fibrinogen. The latter results from the physical proximity of the acceptor and donor sites in fibrin.[101] Residues γGln398/399 and γLys406, located near the *C*-terminal end of the γ-chain, are cross-linked.[102] The three-dimensional structure of the cross-links is yet unknown, since the crystal structure of cross-linked human D-dimer does not show the region where the cross-links are present, likely because of the flexibility of the end of the γ-chains. However, half of one cross-link is visible in the crystal structure of lamprey D-dimer.[103] There is still controversy about whether the γ-chains of fibrin are cross-linked longitudinally or transversely; evidence for both viewpoints is summarized elsewhere.[104–107] The slow formation of γ-chain multimers confers greater resistance to fibrinolysis.

α-Chain Cross-Linking

Cross-linking *via* α-chains occurs more slowly, with multiple bonds per molecule. The α-chains contain potential glutamine acceptor sites at residues 221, 237, 328, and 366 and lysine donor sites at residues 508, 539, 556, 580, and 601.[102,108] The noncovalent association of αC regions brings acceptor and donor sites in proximity, facilitating the formation of the isopeptide bonds catalyzed by FXIIIa. The result is a network of αC regions, called αC polymers.

MECHANICAL PROPERTIES OF FIBRIN

The unique mechanical properties of fibrin are essential for its functions in hemostasis and wound healing since fibrin must be rigid enough to stop bleeding and yet open for perfusion of liquid and penetration of cells. The mechanical properties of fibrin in a thrombus will determine how it responds to flowing blood.[109] Reversible elastic deformation, irreversible plastic deformation, and embolization are all responses that can have serious clinical outcomes. Clots of low stiffness may lead to bleeding, while stiff clots are associated with premature coronary thrombosis.[110] Moreover, the effects of nearly all therapeutic regimes involving clots or thrombi, including thrombolysis, percutaneous coronary interventions, and surgery, are dependent on these mechanical properties.

Fibrin forms a branched three-dimensional network that is a viscoelastic polymer.[109] Finite stiffness is first established when a continuous network is established at the gel point and the stiffness increases over time as polymerization proceeds. Stiffness is also increased by the formation of covalent bonds introduced by FXIIIa, making the gel more stable mechanically and more resistant to proteolytic digestion. The viscoelastic properties determine how the clot responds to the forces to which it is subjected, such as flowing blood or contraction of muscle. A stiff clot will deform less than a softer one with the same applied stress. A clot with a larger inelastic or viscous component will incur more irreversible deformation than one with a smaller inelastic component.

Clots are highly extensible, meaning that they can be greatly stretched before breaking.[111] At least part of the reason for this behavior is the great extensibility of individual fibers making up the clot,[112,113] but the structural rearrangements that occur with stretching also play a role.

For small strains over short times, many clots are highly elastic with little inelastic component,[114] meaning that stiffness remains the same under a variety of conditions during the application of force, which can be quite different depending on whether the clot is arterial or venous. The origins of the inelastic component of fibrin are unknown, but it has been suggested that protofibrils may slide past each other, or knob–hole bonds may be broken and reformed, or certain domains of the fibrin may unfold.[109] In contrast to most nonbiologic polymers, fibrin exhibits strain stiffening or hardening, which means that the stiffness increases with increasing strain.[115–117] This nonlinear elasticity is probably important to prevent damage to clot structures at high strains.

The viscoelastic properties of clots can only be understood by integration of their material properties over all levels of structure, including macroscopic, network, fiber, and molecular. The imposition of stress on a clot causes distinctive changes at each level of structure. Initially, fibers align

along the direction of strain, bundling fibers into higher order structures. Then, fibers become aligned as a result of the strain, stretching, which causes unfolding of some domains, exposing buried hydrophobic residues, which aggregate and expel water.[111]

The bundling of protofibrils into fibers also makes their response to large strains unique with a built-in stress response, which has been used in a hierarchical model for clot mechanical properties.[118] There is also evidence that the αC region of fibrinogen is the origin of the low modulus, high extensibility, and strain stiffening that characterizes fibrin fibers.[119,120]

Variation in Fibrin Clot Structure and Properties

The complexity of fibrin polymerization and the ordered sequences of steps results in the possibility of a variety of clot structures and properties that are unequaled by any other biologic polymer. The factors that affect clotting can be divided into four general categories: (a) variations in protein structure; (b) environmental conditions of polymerization; (c) the presence of cells; and (d) fluid flow.

Splice variants, single-nucleotide polymorphisms, and an array of modifications to various parts of the molecule, including carbohydrate, proteolytic digestion, phosphorylation, tyrosine sulfation, oxidation, nitration, proline hydroxylation, asparagine or glutamine deamidation, glutamine cyclization, and acetylation, result in clots of different structure. Nearly all dysfibrinogenemias have effects on fibrin polymerization.

Ionic conditions, including pH and ionic strength, as well as albumin and other proteins present in plasma, have effects on clot structure. Thrombin concentration has a profound effect, with high concentrations producing clots made up of many thin fibers, many branch points, and small pores and lower concentrations producing clots composed of fewer thick fibers, fewer branch points, and large pores. Many proteins bind specifically to fibrin(ogen) and affect polymerization. Most of these observations are accounted for by the effects on the kinetics of fibrin polymerization and the effects on individual steps of polymerization.[121]

Physiologic clots contain variable numbers of platelets, which have a profound effect on clot structure. Clots formed in platelet-rich plasma contain platelet aggregates surrounded by dense networks of fibers that are thinner than other fibers in the clot; many radiate out from the platelets (FIGURE 10B).[122] Other intravascular and extravascular cells also have effects on the fibrin formed in their vicinity.[123,124] The effects of erythrocytes are complex. Depending on the number incorporated into a clot, they affect fiber thickness, alter mechanical properties, and increase heterogeneity (FIGURE 10B).[125]

Clots or thrombi formed in the vasculature experience the effects of blood flow. Clotting *in vitro* ceases when all fibrinogen is converted to fibrin and polymerizes. In normal plasma containing about 2.5 g/L of fibrinogen, such clots will contain only 0.25 g/100 mL, or 0.25% protein. In contrast, flow *in vivo* continually brings more fibrinogen to the forming clot, which can as a consequence be much more dense. In addition, the dynamics of flow results in heterogeneity throughout the thrombus, with a platelet-rich head upstream and fibrin-rich tail downstream. Flow can also cause orientation of the fibrin fibers.[126,127]

INTERACTION OF FIBRIN(OGEN) WITH OTHER PLASMA PROTEINS

Thrombin

Fibrin contains two classes of thrombin-binding sites that differ in location and affinity. The anion-binding exosite I of thrombin interacts with a negatively charged surface in the central region of fibrinogen such that its catalytic triad can engage FpA.[128,129] Two thrombin molecules can bind simultaneously to one fibrinogen molecule. The exosite II of thrombin recognizes sulfated tyrosines at γ418 and γ427.[60,130,131] Optimum high-affinity binding requires both exosites.[132]

Thrombin binds strongly enough to fibrin that most thrombin is sequestered in clots or thrombi. Thus, what had been called antithrombin I is actually fibrin.[133,134] There are important clinical consequences for thrombin binding to fibrin, in that it limits the extent of clotting. For example, individuals with fibrinogen mutations that impair thrombin binding tend to have serious thromboembolic disease.[135,136]

Factor XIII

The affinity of FXIII for fibrinogen (K_d 10 nM) is such that nearly all circulating FXIII zymogen circulates as a FXIII–fibrinogen complex. Interactions of fibrin(ogen) with FXIII, thrombin, and calcium generate active FXIIIa *via* thrombin cleavage of FXIII, followed by calcium-dependent release of active α_2-subunits. FXIII binds strongly to the γ form of fibrinogen and is most likely the carrier of the zymogen in blood.[137,138,139] In the ternary complex of fibrin–thrombin–FXIII, FpA is cleaved more than 40× faster than FXIII activation, likely reflecting the difference in concentration of the two thrombin substrates.[140]

Fibronectin

The adhesive protein fibronectin not only binds to cells *via* integrins but also to a number of proteins, including fibrinogen, collagen, and gelatin, that play important roles in cell adhesion and wound healing.[141] Fibronectin binds to fibrinogen and is covalently cross-linked by FXIIIa.[142] Fibronectin binding affects fiber diameter and density in clots, with the magnitude determined by the concentration of fibronectin and whether or not it cross-linked to fibrin.

Thrombospondin

Thrombospondin stabilizes platelet aggregates by binding to fibrinogen and platelet integrins.[143,144] Thrombospondin binds to fibrinogen[145] and causes a decrease in fiber diameter and increase in the number of fibers in clots.[121,146] The thrombospondin-binding regions of fibrinogen are the αC region[147] and/or in the middle of the Bβ- and γ-chains.[144]

von Willebrand Factor

von Willebrand factor (vWF) binds noncovalently to fibrinogen, but can be cross-linked to it by FXIIIa.[148,149] High molecular weight multimers of vWF released from endothelial cells bind to fibrin. vWF primary function is to anchor platelets to fibrin under high shear conditions and also in the formation of the platelet–fibrin thrombus.

Fibulin

The extracellular matrix protein, fibulin-1, was first isolated as a complex with fibrinogen, can bind to the *C*-terminal end of the Bβ-chain with high affinity, and is incorporated into clots and thrombi-containing fibrin.[150] Fibulin-1 supports platelet adhesion to the extracellular matrix under flow *via* fibrinogen bridges.[151]

Heparin

Heparin binding to fibrinogen may modulate the procoagulant activity of thrombin or the fibrinogen binding to cell surfaces. The heparin-binding site has been shown to be β15 to 57. However, the intrinsic dimeric structure of fibrin(ogen) is essential for high-affinity heparin binding.[152]

Growth Factors

The provisional fibrin matrix localizes growth factors to the site of injury, thereby enhancing cellular processes for repair and regeneration. Thus, fibroblast growth factor-2 binds to fibrin at two sites,[153,154] whereas IL-1β, but not IL-1α, binds to fibrinogen and fibrin at the same or similar sites.[155] Similarly, vascular endothelial growth factor binds to two classes of sites on either fibrinogen or fibrin.[156]

INTERACTION OF FIBRINOGEN AND FIBRIN WITH PROTEINS OF THE FIBRINOLYTIC SYSTEM

Plasmin(ogen) and t-PA

Both fibrinogen and fibrin are degraded by plasmin. In this context, fibrin acts as cofactor in tissue-type plasminogen activator (tPA)-induced plasminogen activation, thus linking fibrin formation and fibrin proteolysis.[157] However, the role of fibrinogen and fibrin as substrates for plasmin is independent of the cofactor function of fibrin in plasminogen activation.[157]

tPA is produced as a fully active enzyme and is constantly released into circulation by endothelial cells,[158] although its release is strongly increased by venous stasis[159] or other causes of endothelial activation. Enhancement of tPA-induced plasminogen activation requires binding of both tPA and plasminogen to specific binding sites on fibrin that are generated by conformational changes that occur when fibrinogen is converted to fibrin.[160,161] Fibrinogen is largely inert, limiting the action of tPA to fibrin, where it is dependent upon the interaction of two D regions of adjacent fibrin units with a fibrin E region within the polymer.[162] Fibrin formation results in an approximately 1,000-fold enhancement of plasminogen activation rate[163] and has been utilized for development of an assay system for the measurement of soluble fibrin.[164]

Two fibrin(ogen)-binding sites for plasminogen and tPA have been identified: γ312 to 324, and Aα148 to 160.[165] These sites are cryptic in fibrinogen and fibrin monomers,[50] and their exposure is linked to fibrin polymerization.[166] The γ312-324–binding site is located adjacent to parts of hole "a," whereas Aα148-160 is buried by the β-module and the fourth helix of the Aα166-195 region.[50] The conformational changes leading to exposure of both sites are induced by the binding of knobs "A" to holes "a."[167]

Additional binding sites for tPA and plasminogen are present in the αC region of fibrinogen.[168] More binding sites are formed in the course of fibrin degradation by exposure of *C*-terminal lysine residues at plasmin cleavage sites, further enhancing plasminogen activation and fibrin degradation. The stimulatory effect of soluble fibrin complexes on tPA-induced plasminogen activation is lost upon fibrin cross-linking.[169] tPA binding to fibrin is inhibited by lysine.[170]

Fibrin proteolysis is not limited to particulate fibrin clots, but also applies to soluble fibrin complexes. At high levels of plasmin, proteolysis may extend to fibrinogen, resulting in fibrinogenolysis and the formation of fibrinogen degradation products. Such high levels of plasmin are observed during infusions of streptokinase[158] and during treatment with thrombin-like snake venom enzymes, such as ancrod.[171,172] It can also be seen with trauma[173] and in some cases of disseminated intravascular coagulation.

During fibrin proteolysis, thin fibers are dissolved more rapidly than thick fibers,[174,175] although in fibrin clots, plasmin appears to move laterally across fibers, the rate of lysis being faster for clots made up of thicker, rather than thinner, fibers.[175,176] Plasmin proteolysis releases large fibrin fragments from fibrin clots.[175,177] Further degradation of these fragments is dependent upon the availability of active plasmin. Consequently, a considerable proportion of the fibrin degradation products found in clinical blood samples have a higher molecular weight than the terminal fibrin degradation products generated during *in vitro* fibrin proteolysis.[178] Therapeutic fibrinolysis caused by infusion of profibrinolytic agents proceeds from the surface of the clot.[176]

PAI-1

PAI-1 is the primary inhibitor of tPA and is produced by many cell types, including endothelial cells and hepatocytes. It is released from platelets following platelet activation, resulting in high PAI-1 concentrations in platelet-rich clots.[179] Binding to fibrin protects tPA from PAI-1 inhibition.[176]

TAFI

TAFIa (thrombin-activated fibrinolysis inhibitor a) is an antifibrinolytic enzyme that is converted from a proenzyme by thrombin bound to thrombomodulin[180,181]; it can also be activated by plasmin.[182] TAFIa is a carboxypeptidase that cleaves lysine residues exposed by plasmin proteolysis, reducing the cofactor effect of fibrin on tPA-induced plasminogen activation, thereby inhibiting further proteolysis by plasmin.[183] Conversion of TAFI (the procarboxypeptidase) to TAFIa (the active carboxypeptidase) requires a high concentration of thrombin. TAFI is a FXIIIa substrate and is covalently bound to fibrin.[184]

α_2-Antiplasmin

α_2-antiplasmin, the main inhibitor of plasmin in blood,[179,185] is covalently linked to fibrin,[162,186–188] as well as to fibrinogen, by FXIIIa.[189] Cross-linking to fibrin is strongly enhanced by cleavage of an *N*-terminal 12-residue peptide from Met-α_2-antiplasmin secreted from the liver cells by antiplasmin-cleaving enzyme.[190] The resulting Asn-α_2-antiplasmin is cross-linked to fibrin 12-fold faster than Met-α_2-antiplasmin. Fibrin-bound α_2-antiplasmin renders the fibrin more resistant to plasmin proteolysis.[189] Thus,

the antifibrinolytic effect of FXIIIa is fully explained by the covalent incorporation of α_2-antiplasmin into the clot.[189]

Prior to this covalent incorporation, α_2-antiplasmin is noncovalently adsorbed to polymeric fibrin, as well as surface-adsorbed fibrinogen and fibrin.[191] Binding occurs to the D and the αC regions of fibrinogen and fibrin molecules with plasminogen enhancing binding to the D region. The binding sites are cryptic in fibrinogen, but become accessible upon formation of polymeric fibrin and upon surface adsorption of fibrinogen (both mechanisms, fibrin polymerization and surface adsorption, evidently leading to similar conformational changes).[191]

α_2-antiplasmin is cross-linked to lysine Aα303 in the *C*-terminal part of the Aα-chain of fibrinogen and fibrin.[192] It has been hypothesized that under certain circumstances, such as low α_2-antiplasmin levels, covalent binding of α_2-antiplasmin to fibrin clots may be reversible[193] with FXIIIa-dependent release of free α_2-antiplasmin. It also has been shown that FXIII may covalently link α_2-antiplasmin to fibrinogen.[194]

PAI-2

PAI-2 is also covalently attached to fibrin by FXIIIa.[195] PAI-2 is produced by monocytes and placental trophoblast cells and is released in response to stimulation by thrombin.[195] PAI-2 is attached to lysine residues within the Aα-chain of fibrin(ogen).[196]

PLASMIN DEGRADATION

Fibrinogen

Plasmin has trypsin-like specificity, with an affinity for the hydrolysis of lysyl and arginyl bonds, although only 50 to 60 of the potential 362 lysine and arginine residues of fibrinogen are cleaved, 10% rapidly and the remainder more slowly.[197] Degraded fibrinogen can be separated by ion-exchange chromatography into five fractions (A, B, C, D, and E), of which fragments D and E are the major end products of the original molecule.[198] The identification and characterization of the intermediate fragments X and Y[199,200] provided the insight into the asymmetric scheme of fibrinogen degradation[201] (FIGURE 16.12, **left**). The cleavages responsible for these fragments and their composition have already been described above ("*Structural Insights from Limited Proteolysis of Fibrinogen*" section). Fragment X is slowly coagulable by thrombin, but fragments Y and D have potent antipolymerizing effects, mostly a result of disruption of the proper alignment of fibrin protofibrils

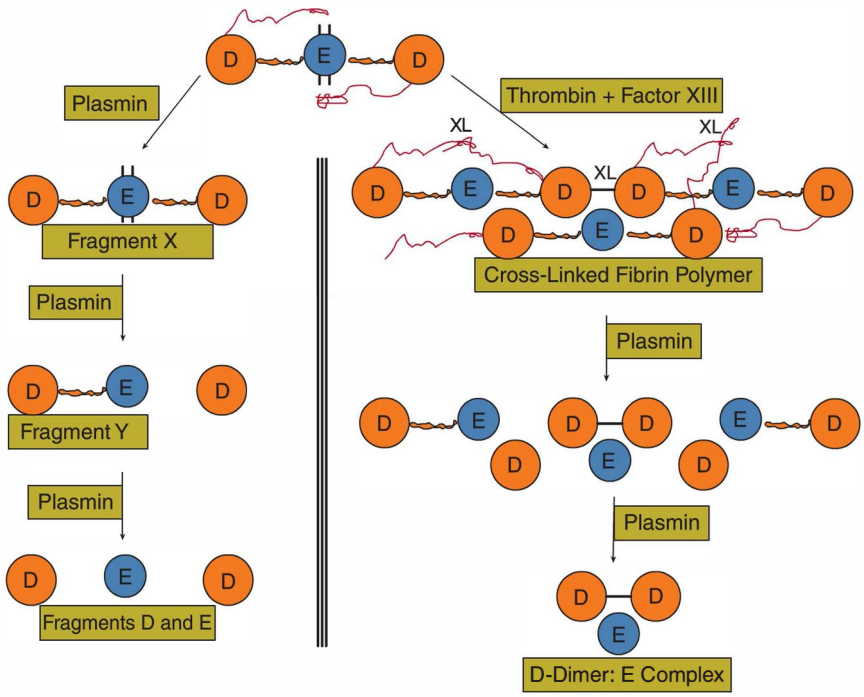

FIGURE 16.12 Plasmic degradation of fibrinogen and of cross-linked fibrin by plasmin. The principal structures of fibrinogen **(top)** are three globular regions from which degradation fragments D and E derive, the α-helical coiled coils that connect them, and Aα-chain extensions from the carboxy-terminal region of the D regions. Shown on the **(left)**, fibrinogen is degraded asymmetrically[201] by cleavage of the coiled coils. Intermediate degradation fragment X consists of all three nodules connected by coiled coils, but lacks the Aα-chain extensions and the Bβ1-42 sequence. Fragment Y consists of the central E region connected by a coiled coil to a fragment D region. Formation of cross-linked fibrin from fibrinogen is shown schematically on the right, by enzymatic actions of thrombin and factor XIIIa. Thrombin liberates Fps from the E region, and factor XIII cross-links (XL) fibrin longitudinally between D regions and in a less well-defined manner between the α-chain extensions. Plasmic cleavage of the two-stranded protofibrils removes the cross-linked α-chains first and then cleaves the coiled coils to liberate a series of complexes, the smallest of which is DD/E. Complexes that are larger than DD/E (such as DY/YD) also are liberated from cross-linked fibrin, but they are subsequently degraded to the DD/E moiety.

through competing for fibrin knobs.[200–202] Fragment E contains the amino-terminal portion of all six polypeptide chains.[200] In the presence of physiologic concentrations of calcium,[203–205] the molecular weight of fragments D and E varies from M_r 85,000 to 100,000 and M_r 35,000 to 50,000, respectively.[201,206–208] Under denaturing conditions[209] or with limited calcium content, fragment D can be further degraded to M_r 46,000. The late cleavages of fragment E disrupt binding sites involved in fibrin monomer polymerization, bonds that are probably critical for complex formation with D-dimer as well[210,211] (FIGURE 16.12, **right**).

Fibrin

With plasmin digestion of fibrin, initially very large pieces of fibers are released and then they are subsequently broken down into smaller fragments.[212] However, plasmic degradation of non–cross-linked fibrin results in a pattern of bands on gel electrophoresis under reducing conditions identical to that of fibrinogen, supporting the view that there is little structural change during polymerization.[213,214] On the other hand, cross-linked fibrin is degraded by plasmin more slowly, and the FXIIIa-mediated cross-link isopeptide bonds result in significantly different degradation products.[215–217] Prolonged exposure of fibrin to plasmin *in vitro* produces a unique fragment (D-dimer), consisting of two fragment D moieties from adjacent fibrin monomers, covalently bound by cross-links between their γ-chain remnants[11,218,219] (FIGURE 16.12, **right**). These D-dimers are very important clinically in the diagnosis of a variety of conditions as described below. Fragment E exists in both free and noncovalent complex with D-dimer (DD/E complex).[220,221] The derivation of this complex from degraded fibrin can be envisioned on the basis of the two-stranded, half-staggered overlap structure of the fibrin protofibril, and these structures have been confirmed by electron microscopy studies.[212] A variety of large degradation products are released by plasmin from cross-linked fibrin.[75,215,216,222–224] These noncovalently bound complexes represent ever-longer stretches of the two-stranded, half-staggered fibrin protofibril,[216] each of which is held in apposition with the same noncovalent bonds that influenced fibrin polymer formation. The smallest complex is DD/E, with larger forms being longitudinal strings of the DD/E complex held together by uncleaved coiled coils.[216] The structure of the DD/E complex provided evidence for the half-staggered organization and knob–hole interactions of fibrin monomers in the clot. The entire sequence of derivatives, such as DY, YY, DXD, and YXD, arises directly from the specific cleavages in the middle of the coiled-coil regions and the half-staggered arrangement in fibrin protofibrils and has been identified in the blood of patients with thrombotic and thrombolytic disorders.

INTERACTIONS OF FIBRIN WITH PLATELET, ENDOTHELIAL CELL, AND LEUKOCYTE RECEPTORS

Fibrin(ogen) binds specifically to integrins and other receptors on platelets, endothelial cells, and other cells. These binding events are important for platelet aggregation and wound healing where fibrin(ogen) serves as a bridge between cells and as a scaffold for cell migration. Fibrin also promotes physiologic inflammation and angiogenesis through interactions with leukocytes and endothelial cells.

Fibrinogen is the primary adhesive protein necessary for platelet aggregation. Fibrinogen binds to the activated conformation of the integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) *via* residues located in the *C*-terminus of the γ-chains, bridging platelets because of the dimeric nature of fibrinogen molecule (FIGURE 16.13). Human fibrinogen also has two pairs of RGD sequences, one in the coiled-coil region and a second in the *C*-terminal regions of the Aα-chains. However, these do not appear necessary for fibrinogen-mediated platelet aggregation.[225,226] However, these RGD sequences do appear necessary for clot retraction and hence may be involved in the interaction of $\alpha_{IIb}\beta_3$ with fibrin.[227,228] Other sequences in fibrin(ogen) have also been identified as sites of potential interaction with $\alpha_{IIb}\beta_3$.[229,230]

Endothelial cells adhere to fibrin or surface-immobilized fibrinogen *via* the integrin $\alpha_v\beta_3$, ICAM-1 (intracellular adhesion

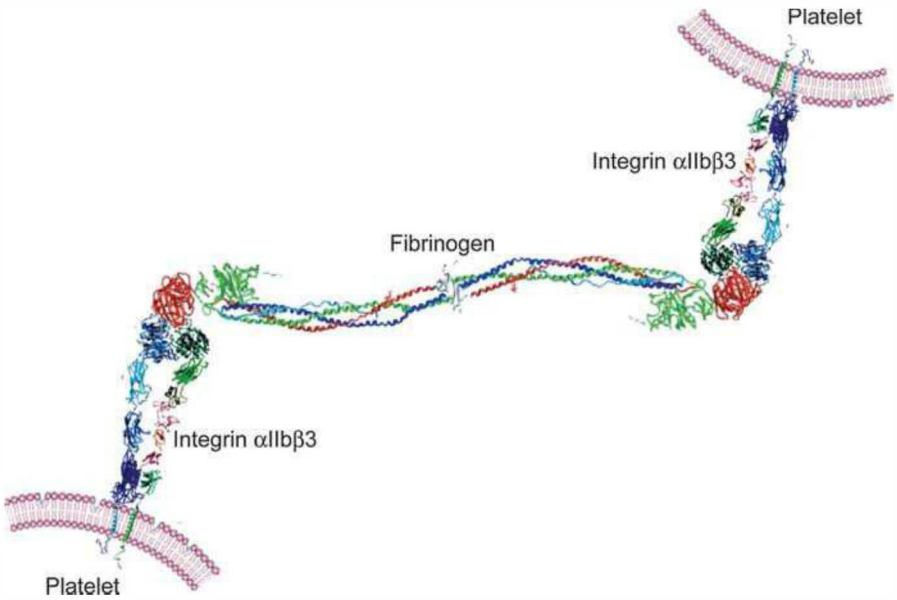

FIGURE 16.13 Binding of fibrinogen to the platelet integrin $\alpha_{IIb}\beta_3$. Ribbon diagrams of the structures of fibrinogen and the ectodomain of $\alpha_{IIb}\beta_3$ were combined in the orientation shown by electron microscopy of the rotary shadowed complexes. (The specific representation of fibrinogen was taken from Brown AEX, Litvinov RI, Discher DE, et al. Forced unfolding of coiled coils in fibrinogen by single molecule AFM. *Biophys J* 2007;92:L39–L41 and that of $\alpha_{IIb}\beta_3$ was from Rocco M, Rosano C, Weisel JW, et al. Integrin conformational regulation: uncoupling extension/tail separation from changes in the head region by a multiresolution approach. *Structure* 2008;16:954–964.)

molecule 1), and VE-cadherin (vascular endothelial cadherin). Integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$, present on platelets and endothelial cells, bind fibrinogen in part through the RGD sequences in the *C*-terminal region of the α-chain of fibrin(ogen)[231–233] and can be covalently cross-linked, possibly by endothelial cell transglutaminase.[234] Additional binding sites for $\alpha_v\beta_3$ are located in the region of γ190 to γ202 and γ346 to γ358, both in the γ–module. A binding site for $\alpha_5\beta_1$ is located in the region of γ370 to γ383. Fibrin promotes the formation of capillary tubes by interactions of two β*N*-domains of fibrin with the third extracellular domain of VE-cadherin.[235] β_1 and β_3 integrins on smooth muscle cells also mediate interactions with fibrin and contraction of fibrin clots.

Fibrinogen binds to leukocytes *via* the integrin $\alpha_M\beta_2$. This interaction is important, attracting leukocytes to sites of injury. The I-domain of the α_M–subunit of $\alpha_M\beta_2$ binds to the γ-module with a complex binding site made up of the P1- and P2-domains including γ228 to 253.[236,237,238] Binding only occurs when fibrinogen is bound to a surface or to fibrin.

EVOLUTION OF FIBRINOGEN

Fibrin polymerization catalyzed by thrombin cleavage of Fps is common to all extant vertebrates; the fibrinolysis system is present as well. The amino acid sequences of large portions of the Aα-, Bβ-, and γ-chains are homologous to each other, indicating that they evolved from a common ancestor.[239,240] The homologies extend to the genomic sequences, with two intron/exon boundaries being conserved in all three chains and another one being common to the Bβ- and γ-chains.[241] Evidence suggests that there were a series of gene duplications and inversions starting about a billion years ago. The current hypothesis is that an ancestral gene duplicated at around that time to produce the α-chain and a pre-β–γ-gene, and then the pre-β–γ-gene duplicated about 500 million years ago to make the β-gene and the γ-gene.[239,240]

Protochordates do not have clotting systems like vertebrates, but whole genome searches have revealed sequences of several related proteins. There are sequences in *C. intestinales* that are homologous to fibrinogen's γC- and βC-modules and that are flanked by sequences predicted to form coiled coils of about the same length, with disulfide rings at either end similar to those of fibrinogen.[242] Finally, the location of many introns in the *C. intestinales* protein is the same as that in fibrinogen's β- and γ-genes, suggesting the possibility of alternative splicing to yield a shorter polypeptide chain similar to that of the most common variant of the γ-chain. An intriguing possibility is that the middle portion of this gene was either deleted in the lineage on the way to vertebrates or inserted on the way to tunicates.

Studies of invertebrate genomes have identified high numbers of fibrinogen-related loci, suggesting important and perhaps diverse unknown functions. The functions of vertebrate fibrinogen may provide some clues to potential roles in invertebrates. Invertebrates do not have coagulation systems that use fibrinogen or a homologous protein. However, invertebrates do have many proteins containing fibrinogen-related domains. Many of the proteins have been linked to defense, self/nonself recognition, and innate immunity. The fibrinogen-related protein (FREP) gene family, also known as fibrinogen domain immunolectin, is a common pattern receptor gene family in invertebrates. Invertebrates use FREPs in defense against bacteria and other parasites.[243] Many of these proteins contain one or more Ig superfamily domains combined with a domain homologous to the fibrinogen β-module or γ-module. The fibrinogen-related domains bind to the parasite or to excretory products of the parasite, targeting them for elimination. In some cases, FREPs are specifically expressed and greatly diversified in response to infections.

In evolutionary terms, we may generalize the function of FREPs. The knob "A"–hole "a" strong binding may be considered a prototypical example of specific and tightly controlled interactions. Fibrinogen is also a fibrous adhesive protein with specific binding to cells.

SURFACE-ADSORBED FIBRINOGEN

Fibrinogen adsorbs to various foreign surfaces. Surface adsorption, for example, to polystyrene or glass, leads to conformational changes of the fibrinogen molecule. Depending on the fibrinogen concentration, adsorption may occur horizontally, with the whole fibrinogen molecule in contact with the surface, or vertically, with only a portion of the D region in contact with the surface.[244,245] Conversion to fibrin enhances surface binding.[246] Adsorbed fibrinogen develops functional properties otherwise unique to fibrin, such as the promotion of platelet adhesion.[247–249] In addition, adsorbed fibrinogen may provide a surface for FXII-related contact phase activation.[250]

FIBRINOGEN THERAPY

Fibrinogen is present in a variety of therapeutics, including whole plasma (fresh frozen plasma), various virus-inactivated whole plasma products, cryoprecipitate, and platelet-rich plasma. However, the most efficient means for therapeutic application of fibrinogen are purified fibrinogen concentrates. In patients with severe trauma, fibrinogen levels have been identified as a major predictor of blood loss and death,[251] and application of fibrinogen concentrate may be sufficient to restore hemostasis.[252] Therapeutic success is directly proportional to the fibrinogen levels achieved.

A logical indication for fibrinogen concentrate is treatment of patients with congenital afibrinogenemia, especially for perioperative management or in case of trauma or severe hemorrhage.[253] Some cases of dysfibrinogenemia are also associated with bleeding and may require treatment with fibrinogen concentrate.

Low levels of fibrinogen are observed in patients with massive blood loss, for example, in trauma or obstetrical complications, as well as in patients with hyperfibrinolysis.[254] In trauma patients, treatment with fibrinogen concentrate or other fibrinogen-containing blood products has been found to be highly efficient. Current protocols for massive transfusion combine erythrocyte concentrates with plasma or other fibrinogen-containing preparations.[251] Relevant amounts of fibrinogen are found in plasma, platelet concentrates, and cryoprecipitate. Fibrinogen concentrates (currently, only plasma-derived fibrinogen concentrates are available) allow rapid fibrinogen replacement without the risk of volume overload anticipated when using plasma. In cardiopulmonary bypass surgery, intraoperative treatment with fibrinogen concentrate aiming at a fibrinogen level in the high normal range leads to significantly reduced blood loss.[255]

Target fibrinogen levels in replacement therapy appear to be above 2 g/L, as lower levels lead to impaired clot properties.[256] Higher levels further improve the mechanical stability of

clots.[257] Levels below 1 g/L lead to the prolongation of clotting time in prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays.[257]

Fibrinogen also is a component of various pharmaceutical products used in surgery. Current fibrin adhesives consist of a fibrinogen solution and a thrombin solution, plus calcium and other components.[258,259] Methods have been developed for generation of fibrin sealants from autologous plasma. Novel technologies include use of recombinant fibrinogen and thrombin. In addition, dry preparations are available or under development, which are directly applied to wounds and do not require reconstitution with a buffer solution or water.

FIBRINOGEN-RELATED LABORATORY DIAGNOSTICS

Fibrinogen Assay Systems

Fibrinogen levels are measured using a variety of assays, including functional assays and assays detecting the total amount of fibrinogen by immunologic or precipitation procedures. The earliest assays were based on precipitation by heat or various chemical agents.[260,261]

Measurement of the total clottable protein involves incubation of a fibrinogen-containing sample with thrombin or a thrombin-like enzyme, extraction of the resulting fibrin clot, washing the clot to remove nonfibrin(ogen) protein, and measurement of the amount of protein incorporated into the clot by clot weight,[262] by photometric methods, using UV adsorption or other methods for quantitating proteins.[262,263] Such assays will detect all functionally intact fibrinogen, including slow-clotting variants of fibrinogen, but not nonclottable fibrinogen, as observed in some dysfibrinogens. Also, some fibrin derivatives, such as high molecular weight soluble fibrin complexes, might become incorporated into a clot, resulting in overestimation of the fibrinogen level.

Immunoassays using polyclonal antisera detect the total amount of fibrinogen antigen, including fibrinogen degradation products, fibrin complexes, and fibrin degradation products.[264] Assays available are based on various technologies, including radial immunodiffusion, microtiter plate ELISAs, as well as optical assays based on turbidity generated by aggregation of fibrinogen by free or microbead-bound antibodies. In healthy subjects, the amounts of fibrin(ogen) derivatives are low; therefore the total fibrinogen antigen approximates the amount of fibrinogen detected by total clottable protein or other functional assays. Patients with nonclotting abnormal fibrinogens display higher levels of fibrinogen antigen, compared to the functional levels. Similarly, discrepant values are found in subjects with thrombosis, disseminated intravascular coagulation, trauma, hyperfibrinolysis, or other conditions, leading to high plasma levels of fibrinogen or fibrin degradation products. Assays for intact fibrinogen have been developed, based on monoclonal antibodies against epitopes removed from the fibrinogen molecule early in the process of fibrin formation and plasmin proteolysis.[265–267]

In the clinical setting, fibrinogen levels are, in most cases, measured by clotting time assays, and by the PT-derived fibrinogen method.[268] For clotting assays, biologic samples are mixed with a high concentration of thrombin or a thrombin-like enzyme.[269] If samples are diluted with buffer, clotting time is mainly dependent on the fibrinogen concentration of the sample, with lower fibrinogen concentration leading to slower clotting.[270] Fibrinogen concentration is determined using a reference curve based on serial dilutions of a sample of known fibrinogen concentration.

Clot formation can be detected by mechanical or optical methods. A threshold is used for turbidity in optical clot detection. Clot formation may also be continuously monitored in optical assays.[271] In a modification of the kinetic method, thrombin is replaced by a thrombin-like snake venom enzyme to eliminate the influence of heparin and other thrombin inhibitors.[272] As some earlier automated coagulation analyzers were not capable of adequately diluting samples, an alternative method was developed that uses undiluted samples, but prolongs the time to clotting by adding an inhibitor of fibrin polymerization. In this assay, the effect of anticoagulants and other compounds present in the samples is expected to be considerably greater than in the original method involving sample dilution.

Clotting time assays and kinetic methods are potentially influenced by the presence of substances that impair fibrin polymerization and lead to underestimation of fibrin concentration.[273] Nonclotting or slow-clotting fibrinogen variants (including a large proportion of known dysfibrinogens) also result in low fibrinogen levels in clotting assays. A large discrepancy between the clotting assay and immunologic fibrinogen assay results is a strong indicator for a dysfibrinogen.[274] In contrast, low fibrinogen levels in both clotting and the immunologic assays indicate hypo- (or a-) fibrinogenemia. The influence of fibrinogen degradation products on the clotting time assays appears to be small. An overestimation of fibrinogen levels may occur in patients with high concentrations of soluble fibrin complexes. Soluble fibrin complexes may increase the rate of fibrin formation, leading to shorter clotting time (and faster increase of turbidity in assays involving optical detection). There is some evidence that high levels of high molecular weight fibrinogen, as observed during inflammatory conditions as part of the acute-phase response, result in a moderate overestimation of fibrinogen concentration due to more rapid clotting of high molecular weight fibrinogen compared to the lower molecular weight variants.[275]

The PT-derived fibrinogen assay is based on the observation that the final turbidity of the clot generated during measurement of the PT correlates with the amount of fibrinogen present in the original plasma sample. Fibrinogen levels are generated as a by-product of PT measurement at no additional cost.[268,276] The assay can only be performed with platelet-poor plasma using optical detection systems. As an endpoint method, the assay does not result in an underestimation of fibrinogen levels by circumstances leading to slow clotting. Recent results indicate that slow-clotting dysfibrinogens actually lead to an overestimation of fibrinogen levels in PT-derived fibrinogen.[277–279] Similarly, anticoagulant drugs that result in lower levels of active thrombin lead to the generation of fibrin clots with higher turbidity and an overestimation of fibrinogen levels. Inhibitors of fibrin polymerization also may lead to increased clot turbidity and overestimation of fibrinogen concentration.[280] Samples are not diluted for measurement of the PT. Anticoagulants, fibrin polymerization inhibitors, and other compounds have greater influence in PT-derived fibrinogen than in the majority of clotting time assays. If PT-derived fibrinogen is used as screening method, a large proportion of dysfibrinogens may escape detection because clot turbidity may be normal or increased (despite or because of the delayed fibrin formation).[280] Treatment with

hydroxyethyl starch and other plasma expanders may lead to overestimation of fibrinogen levels in PT-derived fibrinogen assays, probably by volume exclusion mechanisms.[280,281] PT-derived fibrinogen assays display a rather small measuring range that cannot be extended by dilution.

Various coagulation assays that are influenced by fibrinogen concentration include the PT, aPTT, thrombin time, batroxobin time, thromboelastography, and rotational thromboelastometry, as well as clotting-based assays for monitoring of anticoagulants. Prolongation of the PT occurs at fibrinogen levels below approximately 1 g/L.[257] At very low fibrinogen levels (below 0.25 g/L), clot formation may be below threshold for detection of the clotting time, resulting in "infinite" PT or aPTT. In thrombelastography, fibrinogen deficiency leads to reduced maximum amplitude of the tracing, indicating reduced clot stability. Thrombelastography and related methods may serve as an alternative for the detection of fibrinogen deficiency under certain circumstances.[282–285]

ASSAY SYSTEMS FOR FIBRINOPEPTIDE A AND SOLUBLE FIBRIN

Apart from fibrinogen, clinical blood samples contain a variety of fibrinogen derivatives, including fibrin complexes, fibrin degradation products, and fibrinogen degradation products. The presence of fibrin complexes, as well as fibrin degradation products, indicates *in vivo* fibrin formation. Whereas fibrin complexes generally are derived from intravascular coagulation processes, fibrin degradation products (and especially lower molecular weight fibrin degradation products) may stem from extravascular sources, such as sites of tissue injury. Fibrin degradation products are generated by a combination of coagulation activation (leading to the production of thrombin) and activation of fibrinolysis. Fibrinogen degradation products are generated by proteolysis of fibrinogen by plasmin (or other enzymes) without prior action of thrombin.

Fps may be detected by various methods, including immunoassays.[286,287] Current immunoassays available for measurement of FpA require removal of fibrinogen from the plasma samples by precipitation or adsorption, for example, to bentonite.

Various assay systems have been developed for the detection of soluble fibrin.[288] The earliest systems were based on precipitation or "paracoagulation" of fibrin complexes upon addition of ethanol[289] or protamine.[290,291] These assays were found to be quite specific, but not very sensitive in the diagnosis of disseminated intravascular coagulation.

Fibrin monomers may bind to insolubilized fibrinogen attached to microbeads, chromatography media, or other media such as sheep erythrocytes. In the assay using fibrinogen adsorbed to sheep erythrocytes, fibrin complexes are detected by observing aggregation of the modified erythrocytes.[292]

Fibrin complexes act as cofactors in tPA-induced plasminogen activation. If tPA and plasminogen are added to a diluted plasma sample, the amount of plasmin formed is primarily dependent upon the amount of fibrin present in the sample. The resulting plasmin may be detected photometrically, by adding a chromogenic substrate.[164] The sensitivity of the assay may be increased by the addition of mini-plasmin rather than full-size plasmin, or by the addition of an antiserum neutralizing the α_2-antiplasmin present in the sample.[293]

Release of Fps leads to the generation of neoepitopes, directly related either to Fp release or to conformational changes induced by Fp release or fibrin polymerization. The earliest assays used monoclonal antibodies against the neo-*N*-terminus of the fibrin α-chain.[294–296] Detection of this epitope is difficult due to the fact that it is part of the fibrin polymerization site knob "A" and therefore participates in the interaction between the fibrin monomer units, making the epitope inaccessible for antibodies.[295,296] Incubation of samples with denaturing agents such as thiocyanate strongly enhances detection due to disaggregation of the fibrin complexes, but also expands assay reactivity to include various fibrin degradation products. The enzyme immunoassay using monoclonal antibody 2B5 directed against the peptide sequence NH2-GPRVVER-X as capture and tag antibody and potassium thiocyanate sample treatment was therefore found to be a global assay for fibrin.

New assays are based upon latex-enhanced photometric immunoassay technology, using fibrin-specific monoclonal antibodies attached to latex microbeads. The monoclonal antibody IF-43 reacts with fibrin monomer units within a fibrin complex.[297,298] The epitope is located within the *N*-terminal α-chain (α 17 to 78), but reactivity of the antibody requires fibrin complex formation. MAb F405 is specific for a neoepitope at the neo-*N*-terminus of the fibrin α-chain NH2-GPRVVERHQ-X, but in contrast to MAb 2B5, binding of the antibody does not seem to be impaired by fibrin polymerization, presumably because the epitope does not involve the *N*-terminal three amino acids.[299] A different approach was selected in the development of MAb J2-23. This monoclonal antibody reacts with an epitope within the *C*-terminal Aα-chain of fibrinogen (Aα502 to 521), which is not accessible in fibrinogen, but becomes accessible after FpA release due to conformational changes related to the "handshake domain" of the fibrinogen molecule.[297,298] In native fibrinogen, the *C*-terminal Aα-chain region positioned close to the central region of the fibrinogen molecule. After FpA cleavage, the "handshake domains" dissociate from the central region and from each other. As the *C*-terminal Aα-chains are degraded early in the course of plasmin proteolysis, thus eliminating the antigenic site detected by MAb J2-23. Therefore, the assay is highly specific for non–plasmin-degraded fibrin complexes and displays no reactivity with fibrin degradation products or fibrinogen degradation products. Covalent linkage of α-chains by FXIIIa also appears to eliminate reactivity in the assay, restricting reactivity to non–cross-linked and nondegraded fibrin complexes.

Assays for soluble fibrin complexes may be used for diagnosis of intravascular coagulation processes, but due to heterogeneity of assay systems and lack of clinical trials, these assays have not yet gained widespread clinical use. Another reason might be the ubiquitous availability of D-dimer assays.

ASSAY SYSTEMS FOR D-DIMER ANTIGEN

Immunization of laboratory animals with the fibrin fragment D-dimer can yield antibodies specific for the dimerized D regions.[300,301] These antibodies are fibrin specific, since the epitope is not found in fibrinogen or in proteolytic fragments of fibrinogen.[300] The antibodies react with conformational epitopes induced by covalent linkage of the D regions.[302]

D-dimer assays not only react with the D-dimer fragment, but also with larger molecules containing the dimerized D regions, including freshly formed cross-linked fibrin complexes, as well as larger proteolytic fragments of cross-linked fibrin (D-dimer antigen).[303,304] These proteolytic fragments may be

derived from fibrin clots, but also from "soluble" fibrin formed in the flowing blood. As formation of D-dimer antigen involves at least two enzymatic processes (thrombin releasing FpA and FXIIIa inducing covalent bonds between adjacent D regions of fibrin monomer units within a fibrin polymer), it seems to be more robust toward preanalytical errors than other assays for fibrin-related markers. Assay systems for D-dimer include enzyme-linked immunoassays, latex-enhanced photometric immunoassays, fluorogenic assays, membrane-based assays, and other assay formats including point-of-care assays performed with whole blood.[305]

Many D-dimer assays display a high degree of sensitivity for the exclusion of acute deep vein thrombosis and pulmonary embolism.[306–310] In patients with high clinical probability, further diagnostic procedures should be performed even if D-dimer levels are normal.[311,312]

Apart from venous thrombosis, D-dimer antigen may reflect other diseases associated with fibrin formation, such as disseminated intravascular coagulation, trauma, pregnancy complications, malignant disease, or vascular abnormalities including aortic aneurysm or hemangiomas. Therefore, elevated D-dimer antigen levels have to be interpreted in the context of possible underlying diseases and clinical symptoms. Negative or low D-dimer antigen levels may be used for exclusion of clinical disease states typically associated with fibrin formation. For example, acute aortic dissection causes intense chest pain, which may be quite similar to the chest pain of patients with acute coronary syndromes. The pain is caused by rupturing of the vascular intima of the aorta, often in the context of preexisting atherosclerotic lesions. Both aortic dissection and aortic aneurysms cause local formation of fibrin, but some fibrin appears in the flowing blood and may be detected in the venous blood sample as D-dimer antigen. In contrast to patients with acute coronary syndromes, which generally display normal range D-dimer levels initially,[313] patients with aortic dissections or aortic aneurysms display massively elevated D-dimer antigen levels.[314,315]

ASSAY SYSTEMS FOR FIBRINOGEN AND FIBRIN DEGRADATION PRODUCTS

Specific assays for fibrinogen degradation products are currently not in widespread clinical use. Peptides released from the *N*-terminus of the Bβ-chain, including peptide Bβ1-42,[316] may serve as specific markers for plasmin proteolysis of fibrinogen. Fragment D may stem from fibrinogen, as well as from fibrin, as not all D regions within fibrin are cross-linked by FXIIIa. Fragment E also is generated both by proteolysis of fibrinogen and fibrin, but currently no assays specific for fibrinogen fragment E are commercially available.

There are assay systems for fibrinogen/fibrin degradation products in general, based on monoclonal antibodies specific for plasmin action, but independent of fibrin cross-linking, which may distinguish between fibrinogen degradation products and fibrin degradation products.[317,318] The advantage of such assays over D-dimer assays has not been proven.

Other enzymes, including leukocyte elastase, may degrade fibrinogen and fibrin. Differences in substrate specificity result in formation of specific fibrin derivatives not generated by plasmin proteolysis. These products may be detected with specific monoclonal antibodies.[319–321] Assay systems for elastase-related fibrinogen/fibrin degradation products may be helpful in sepsis and other inflammatory conditions, but additional clinical trials are necessary.

CHAPTER

17 Factor XIII

CÉDRIC DUVAL, HELEN PHILIPPOU, AND ROBERT A.S. ARIËNS

Factor XIII (FXIII) is an unusual blood coagulation factor, circulating as a heterotetramer composed of two catalytic A-subunits and two noncatalytic B-subunits. It is a plasma transglutaminase (TG), mostly associated with fibrinogen, which is activated by thrombin in the presence of calcium in the final stages of the coagulation cascade. It acts by stabilizing the clot through the covalent cross-linking of polymerized fibrin chains and the incorporation of fibrinolysis inhibitors into the fibrin clot. Genetic polymorphisms in FXIII are associated with cardiovascular diseases (CVD), including coronary artery disease (CAD), stroke, and deep vein thrombosis (DVT). FXIII deficiency leads to severe bleeding, impaired wound healing, and recurrent miscarriages.

In this chapter, we review the basic functions of FXIII and focus on the most recent findings highlighting the role of FXIII in cardiovascular disease, in particular an emerging link to thrombosis. We use the detailed recommended FXIII nomenclature published in 2006 by the Scientific and Standardization sub-Committee of the International Society on Thrombosis and Haemostasis.[1]

DISCOVERY OF FACTOR XIII

The original discovery of a blood protein that makes fibrin chemically resistant to dissolution was made in the 1940s by two independent scientists. In the United States, Robbins[2] described a serum factor that stabilizes fibrin during his PhD studies at the University of Illinois. At the same time, in Hungary and later in the UK, Lorand made similar discoveries of a blood protein involved in fibrin formation[3,4] and discovered that the protein involved was from plasma rather than serum.[5] Over the years, several names have been given to this factor including fibrin-stabilizing factor, Laki-Lorand factor, fibrinoligase or fibrinase. During meetings of the International Society on Haemostasis and Thrombosis in the 1950s and early 1960s, it was decided that the name FXIII should be used, based on its main function, that is the stabilization of fibrin, and its position in the coagulation cascade.

FXIII was first purified from blood plasma by Lorand[5] and later to further homogeneity by Loewy[6–8] and Schwartz. It was discovered that FXIII is composed of two A-subunits and two B-subunits, arranged in a heterologous tetrameric structure.[9–11] Discoveries of the first patient with FXIII deficiency and the fact that lack of FXIII leads to a serious bleeding disorder were made in Switzerland in 1960 by Duckert et al.[12] The primary amino acid sequences for both the A- and B-subunits and the structure of the A-subunit gene have been elucidated by Ichinose and others,[13,14,15,16–18] and, more recently, the crystal structure of the FXIII A-subunit (FXIII-A) dimer has been resolved at high resolution by Yee et al.[19] and Weiss et al.[20] These studies have paved the way for a profound understanding to be developed of the biology, structure, and function of this intriguing coagulation factor.

FACTOR XIII TETRAMER STRUCTURE

Cellular FXIII is composed of a dimer of A-subunits. FXIII in plasma is, however, composed of two A- and two B-subunits[9–10] (FIGURE 17.1). Binding to the B-subunits is necessary to provide stability to the hydrophobic A-subunit in the aqueous environment of the blood; without FXIII B-subunit (FXIII-B) the A-subunit is unstable as demonstrated by the absence of FXIII-A in blood plasma in patients with congenital B-subunit deficiency.[21] The structure of FXIII-A_2B_2 is that of a heterologous tetramer, with a molecular weight of 325.8 kDa.[22] FXIII-A forms a dimer with a central axis of symmetry, and the two monomers aligned in opposite *N*- to *C*-terminal orientation as characterized by x-ray crystallography[19,20] (FIGURES 17.1 and 17.2). The tertiary structure of FXIII-B and that of the tetramer remains, however, unknown. The closest information we get on the structure of the FXIII-A_2B_2 tetramer is that obtained by rotary-shadowed FXIII analyzed by electron microscopy (EM).[23] This study showed that FXIII-A_2 demonstrates a globular structure, whereas FXIII-B in isolation is a monomer and demonstrates a flexible strand-like structure. It has been suggested that the two B-subunits wrap around the globular A-subunit dimer in a protecting manner.[23] However, the resolution is too low to conclude with confidence on the structure for the FXIII-A_2B_2 tetramer, and future studies of higher resolution will be needed to determine the structural requirements for interaction between the A- and B-subunits. FIGURE 17.1 shows a schematic representation of the FXIII-A_2B_2 tetramer for illustration purposes; the conformation of FXIII-B in this structure in particular is hypothetical.

FXIII-A is produced as a typical cytoplasmic protein by monocytes, macrophages, and megakaryocytes.[24–26] The protein has no leader sequence for the classical secretion pathway.[14,17] Recent evidence suggests the existence of nonclassical secretion mechanisms for FXIII-A from macrophages.[27] FXIII-B on the other hand is synthesized in the liver and secreted via the classical secretion pathway from hepatocytes.[28] At which site the FXIII-A_2B_2 tetramer is assembled, and by which mechanism, remains unknown. As FXIII-B is normally secreted and circulates in excess, one line of thought is that FXIII-B could be delivered to the site of synthesis for FXIII-A and that it might be required to aid the release of FXIII-A from the cell. Phenotype changes for FXIII-A after bone marrow transplantation, and for FXIII-B after liver transplantation, suggest that these two organs are the main sites of synthesis for the FXIII subunits.[29]

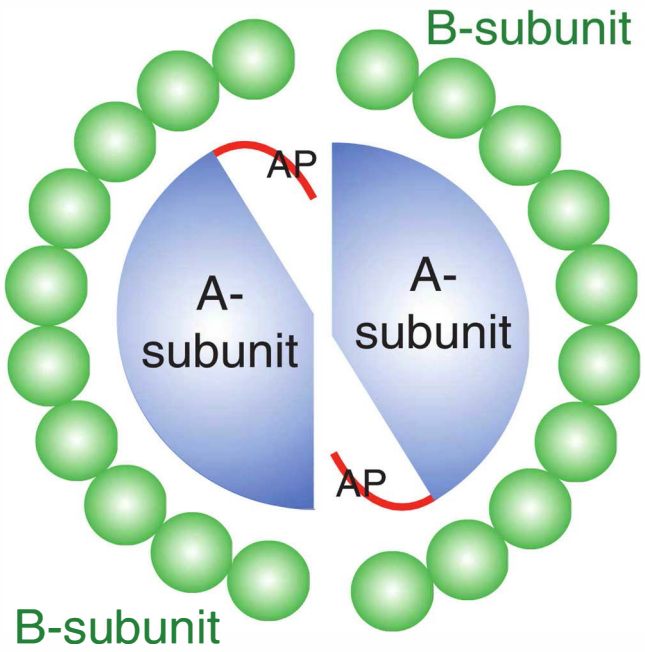

FIGURE 17.1 Schematic representation of FXIII A_2B_2 tetrameric structure. Two FXIII-A molecules (*blue*) are aligned in opposite *N*- to *C*-terminal orientation around a central axis of symmetry. The flexible, strand-like B-subunits (*green*) are thought to wrap around the hydrophobic A-subunits. The conformation of the B-subunits in this representation is hypothetical and based on previous EM studies.[23] The FXIII activation peptides (APs) are depicted in *red*.

FACTOR XIII A-SUBUNIT, CATALYTIC TRIAD, AND CALCIUM BINDING

The gene for the FXIII-A is located on chromosome 6 bands p24–25.[30,31] It contains 15 exons that code for a 731–amino acid mature protein.[17] The FXIII-A gene shows significant sequence homology with those of the other TGs, in particular keratinocyte TG 1 and tissue TG 2.[32–34] However, while most TG genes are <30 to 40 kb in size, the FXIII-A gene spans more than 160 kb, due to the large size of the introns in this gene. The FXIII-A gene shows linkage with other genes on chromosome 6 including the human leukocyte antigen genes of the major histocompatibility complex[31] and the plasminogen gene at bands q26–27.[35]

The mature FXIII-A protein has a molecular weight of 83.2 kDa[22] and is composed of five structurally and functionally distinct regions, which from *N*- to *C*-terminus include an activation peptide (AP) (residues 1 to 37), a β-sandwich domain (38 to 184), the catalytic core (185 to 515), a β-barrel domain 1 (516 to 628), and a β-barrel domain 2 (629 to 727)[19] (FIGURE 17.2). The catalytic triad involved in transamidation is composed of Cys314, His373, and Asp396.[19] FXIII-A_2 is a dimer of two subunits in antiparallel orientation. The AP from one subunit crosses the interface and interacts with the second subunit (FIGURES 17.1 and 17.2). FXIII-A shares its basic domain structure with many other members of the TG enzyme family. However, most other TGs lack an AP and do not form a dimer.[36,37] It has been suggested that dimerization of FXIII-A enhances substrate specificity of this enzyme by increasing the surface available for substrate binding.[36]

FXIII-A contains nine cysteine residues, none of which are disulfide bonded. Oxidation of the active site Cys314 leads to loss of enzyme activity. In the catalytic core of the zymogen, Cys314 is sandwiched between another cysteine residue (374) and an aromatic tyrosine residue (560) to protect it from oxidation.[19,20] Tyr560 is located in β-barrel domain 1, and hence removal of this residue from the active site by a conformational change of β-barrel 1 could play an important role in the exposure of Cys314 for interaction with the substrate. A conformational change that leads to β-barrel 1 separating from the catalytic core is exactly what happens when tissue TG is activated,[37] and it is therefore possible that a similar conformational change is involved in FXIII activation. Evidence for large conformational changes during the activation of FXIII-A is still scant. An x-ray crystal structure of activated FXIII-A did not show any major conformational changes compared with

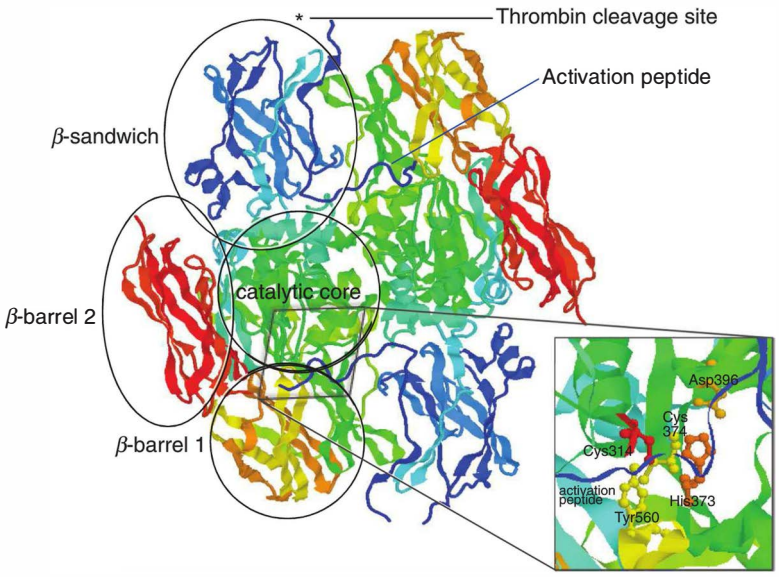

FIGURE 17.2 Tertiary structure of the FXIII A_2 dimer. FXIII-A forms a dimer of two subunits in antiparallel orientation. Each A-subunit is composed of (from *N*- to *C*-terminus) an AP that is cleaved by thrombin at peptide bond Arg37–Gly38 (indicated by an *asterisk*, not resolved on the crystal structure), a β-sandwich domain, a catalytic core, a β-barrel 1 domain, and a β-barrel 2 domain. The **inset** shows a zoom in on the catalytic core, with the catalytic triad, Cys314, His373, and Asp396 highlighted in *red*, *orange*, and *ocher*, respectively. Residues Tyr560 from the β-barrel 1 domain and residue Cys374, which protect the active site Cys314 from oxidation, are highlighted in *yellow*. Image was drawn using RasMol 2.7.5 and the crystal structure coordinates from Weiss MS, Metzner HJ, Hilgenfeld R. Two non-proline *cis* peptide bonds may be important for factor XIII function. *FEBS Lett* 1998;423(3):291–296 (PDB file 1F13).

FXIII-A zymogen.[38] However, studies of solvent accessibility of residues in FXIII-A by chemical labeling of surface exposed cysteines and lysines did indicate that conformational changes of FXIII-A are likely to play an important role in activation.[39] Feasible conformational changes in FXIII-A during activation have recently been modeled based on the x-ray crystal structure of active tissue TG.[40]

Calcium plays important roles both in FXIII activation and in the catalytic mechanism (see below). The main calcium binding site in FXIII-A is composed of residues Asn436, Asp438, Ala457, Glu485, and Glu490 of the catalytic core region.[41] Mutations at Glu485 and Glu490 significantly reduced catalytic activity of activated FXIII (FXIIIa), in agreement with a major role of these residues in calcium binding.[42] This calcium binding site can be found at the dimer interface and is located very close (<10 Å) to β-barrel domain 1. Its location close to β-barrel domain 1 suggests that calcium binding may be involved in the conformational change that removes β-barrel domain 1 and Tyr560 away from the catalytic core during activation.[41] Location of the calcium binding site at the dimer interface may also account for the allosteric effects of calcium binding on the exposure of the catalytic site for substrate interaction in both subunits, even if only one of them has been cleaved by thrombin, as reported by Hornyak and Shafer.[43]

Another structurally important characteristic of FXIII-A, which could be involved in conformational changes of the catalytic domain during activation, involves the presence of two nonproline *cis*-peptide bonds in FXIII-A at Arg310–Tyr311 and Gln425–Phe426, an uncommon feature in protein structures.[20] These nonproline *cis*-bonds, together with the Gly410–Pro411 *cis*-bond, could be involved in a major conformational "switch" in the catalytic core when it is transformed into an energetically favorable transconformation.[20] In agreement with this, mutations in either Arg310 or Tyr311 have been shown to result in an inactive FXIII molecule, indicating the potential importance of one of the two nonproline *cis*-bonds in FXIII activation.[44]

FACTOR XIII B-SUBUNIT STRUCTURE AND FUNCTION

The gene for FXIII-B is located on chromosome 1 bands q32–32.1 and is 28 kb in size.[45] It contains 12 exons separated by 11 introns and codes for a 641–amino acid mature protein.[46] The FXIII-B gene is part of a cluster of homologous genes located at bands q31–32 on chromosome 1, including the genes of five complement regulating proteins, factor H,[47,48] C4 binding protein,[49] C3b/C4b receptor,[50] decay accelerating factor,[51] and membrane cofactor protein.[52] The products of the genes at this locus contain a varying number of short consensus repeats called Sushi domains.[15,53,54] Sushi domains are typically involved in protein–protein interactions, and the FXIII-B protein is entirely composed of 10 Sushi domains with a 20–amino acid leader sequence for secretion and a short 11–amino acid *C*-terminal sequence.[15] Each Sushi domain contains four cysteine residues that participate in two disulfide bonds that provide stability to the structure of the domain. In total, there are therefore 20 disulfide bonds in FXIII-B. The tertiary structure of FXIII-B is hitherto unknown; however, FXIII-B appears as a long filament, or as "beads on a string," when imaged by EM.[23] Using recombinant FXIII-B and truncations of the molecule, it has been suggested that the first Sushi domain is responsible for binding FXIII-A and that the fourth and ninth Sushi domains are responsible for binding to another B-subunit.[55]

The B-subunit plays a number of roles in FXIII physiology. First, two B-subunits bind two A-subunits to form the heterologous tetramer that provides stability to the protransglutaminase in blood plasma. Whether FXIII-B also somehow aids the secretion of FXIII-A from its source of production is unknown, but it has been suggested that some hepatoma cell lines (PLC/PRF/5) are capable of expressing both FXIII-A and FXIII-B and that they secrete intact FXIII-A_2B_2.[56] Second, the dissociation of the B-subunit from FXIII-A is a critical event in the activation of FXIII (see below). FXIII-B may also play an important role in the interaction of FXIII with fibrinogen γ' (see below), thereby directing the cross-linking activity of FXIIIa to one of its major substrates. It is not known if FXIII-B is involved in other protein interactions.

FACTOR XIII ACTIVATION

FXIII-A_2B_2 is converted into its active form by a two-stage process (FIGURE 17.3). The first step involves the cleavage of the Arg37–Gly38 peptide bond by thrombin that results in the release of an *N*-terminal AP of 37 amino acids to generate FXIII-A′, followed by the second step of calcium-dependent dissociation of the B-subunits from the cleaved A-subunits.

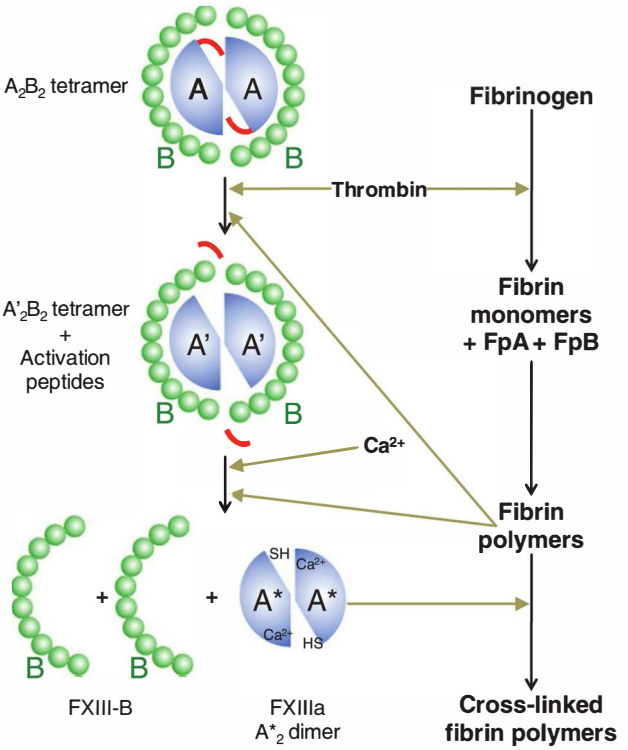

FIGURE 17.3 Activation of FXIII. FXIII is activated in a two-step process: in a first step thrombin cleaves the AP from FXIII-A, and in a second step the B-subunits dissociate from the active A-subunit dimer in the presence of calcium. Both steps are enhanced by the presence of the main substrate of FXIIIa in plasma, fibrin. Polymerizing fibrin increases cleavage of FXIII-A by thrombin as well as subunit dissociation. Fibrin formation and FXIII activation are therefore closely regulated to occur at the same time.

The cleaved A'-subunits in the absence of the B-subunits adopt an active conformation in the presence of calcium, FXIIIa.[57,58] As a consequence of FXIII activation, the active site cysteine, which is usually buried and inaccessible, is unmasked allowing access to potential substrates. Under physiologic circumstances thrombin is not able to cleave FXIII without the presence of the cofactor, fibrin.[59] Fibrin has been shown to enhance both steps of FXIII activation (FIGURE 17.3). Polymeric fibrin I and II (des-A- and des-A, B-fibrinogen) enhance the rate of thrombin cleavage of the A-subunits by approximately 80-fold. Fibrin I and II reduce the Michaelis constant (K_m) for thrombin during the activation of FXIII by forming a ternary complex with thrombin and FXIII, enabling activation to occur under physiologic conditions of clot formation.[59,60,61] The fibrin enhancement effect on thrombin cleavage only occurs with FXIII-A_2B_2 and not cellular FXIII-A_2.[62,63] Fibrin also accelerates the rate of A- and B-subunit dissociation following thrombin cleavage and it has been reported that the α-chains of fibrin play a role in this.[64] Calcium is essential for enabling the dissociation of FXIII-A from FXIII-B by modulating the conformation of FXIII-A´.[39,65] Fibrin enhancement of FXIII activation ensures that the formation of FXIIIa only occurs at the site of a forming fibrin clot, where FXIIIa cross-linking activity is required.

A second thrombin cleavage site (Lys513–Ser514) has been identified in the FXIII-A.[16] This site is not considered to play an important role *in vivo* because its cleavage is only observed *in vitro* when thrombin is incubated with FXIII in the absence of calcium, but not in its presence.[66]

TRANSGLUTAMINASE REACTION

Unlike the other eight members of the TG family mainly found in tissues, FXIIIa is a plasma-specific endo-γ-glutamine:ε-lysine transferase enzyme that plays an important role in the formation of fibrin gels.[7] It catalyzes protein cross-linking reactions by specifically replacing the ammonia of a glutamine residue[67,68] with an amino group from a lysine residue,[69,70] therefore creating a covalent isopeptide bond between these two amino acids. Upon activation by thrombin, FXIIIa cross-links adjacent fibrin molecules and induces stabilization of the fibrin clot.

The first step of the most common fibrin γ-chain cross-linking process is the reaction of the thiol group of factor XIIIa active site Cys314[71] with the carbonyl of the γ-glutamine residues (398/399) of a fibrin molecule (Table 17.1, FIGURE 17.4), resulting in the generation of an acyl enzyme intermediate and release of ammonia (FIGURE 17.5). The second step requires the recognition of a closely located Lys406 from an adjacent fibrin molecule (Table 17.1) aligned during fibrin polymerization, and the subsequent formation of an isopeptide bond between the ε-amino group of the lysine and the γ-glutamine residue, resulting in the cross-linking of γ-chain fibrin and the release of FXIIIa (FIGURE 17.5). If the appropriate lysine substrate is not available, the glutamine residue can then be deaminated (Fibrin-$(CH_2)_2$-CO-S-F_{XIII} + H_2O ↔ F_{XIII}-SH + Fibrin-$(CH_2)_2$-COOH), or linked to a substrate primary amine, the latter resulting in a peptide bond (Fibrin-$(CH_2)_2$-CO-S-F_{XIII} + H_2N-Amine ↔ F_{XIII}-SH + Fibrin-$(CH_2)_2$-CONH-Amine).[72]

The amino acid sequences surrounding both glutamine and lysine residues play some role in substrate recognition. This peptide sequence specificity is particularly important for recognition of glutamine by FXIIIa. Studies have shown that FXIIIa only recognizes specific glutamine residues,[73] and that the peptide sequence surrounding this amino acid plays a role in substrate recognition.[74] The latter study, using amino acid substitution, highlighted the requirement of leucine (pos−4), lysine (pos+2), valine (pos+3), and leucine (pos+4) residues in the vicinity in order for the glutamine residue (pos0) to be recognized by FXIIIa. The nature of the amino acids preceding the lysine residue is less influential on the cross-linking reaction. A comprehensive study has shown that on one hand, valine, arginine, and phenylalanine have a favorable effect to substrate reactivity, with serine, alanine, leucine, tyrosine, and asparagine also promoting cross-linking. On the other hand, glycine, aspartic acid, or to a lesser extent proline, histidine, and tryptophane have an adverse effect on creating an isopeptide bond between lysine and glutamine.[75] It is possible that tertiary structure surrounding the glutamine and lysine residues plays a more important role in substrate recognition for FXIIIa than primary structure. Future structural studies on the interaction of FXIIIa with different substrates will be required to elucidate this further.

Although fibrin γ-chain dimerization is the major product of FXIIIa enzymatic activity, fibrin α-chains cross-linking putatively occurs at Gln221, 237, 328, and 366, and Lys208, 219, 224, 418, 427, 429, 448, 508, 539, 556, 580, 601, and 606 (Table 17.1, FIGURE 17.4) at a much slower rate and results in highly cross-linked α-chain multimers.[76–78] Fibrin α–γ hybrid heterodimers and multimers[79] and γ-chain trimers/tetramers[80] have also been documented but are normally not a major product of FXIIIa-induced cross-linking.

To date, no human isopeptidase has been identified that is capable of disrupting the covalent ε(γ-glutamyl)lysyl bond created during fibrin cross-linking, but FXIIIa itself has been reported to display effective isopeptidase activity *in vitro*, with K_m values of 10^{-4}–10^{-5}.[81] However, the physiologic relevance of this reaction and the mechanisms by which it occurs remain unclear.

HOMOLOGY WITH OTHER TRANSGLUTAMINASES

TGs are a family of ubiquitous enzymes, with presence in bacteria, plants, and animals. They are part of a superfamily of enzymes that are classified as *R*-glutaminyl-peptide:amine γ-glutamyltransferases (EC 2.3.2.13).[82] The reactions catalyzed by the EC 2.3.2.13 enzyme family include transamidation or cross-linking, deamidation, and amine incorporation.[83] The biologic functions of TGs span a plethora of different activities, from involvement in egg fertilization, semen coagulation, cell death, and epidermal and hair structure to blood coagulation.

In humans, besides FXIII, there are at least eight other TGs (Table 17.2). These include keratinocyte TG or TG1 involved in epidermis formation,[84] tissue TG or TG2, a ubiquitous enzyme involved in a variety of cell functions including cell death,[85–87] TG3 involved in hair follicle stabilization,[88] TG4 with unknown function in the human prostate,[89] TG5 involved in epidermal differentiation,[90] TG6 and TG7 with unknown functions,[91] and erythrocyte protein 4.2 that plays a role in erythrocyte membrane integrity.[92] The genes of the TG family demonstrate significant sequence homology, and the proteins show remarkable structural similarity with a basic domain structure that includes a β-sandwich domain, and a catalytic core followed by two β-barrel domains. The catalytic core regions of

[a]Gln2 and Gln 14 relate to the same glutamine residue from the short and long forms of α_2-AP respectively.

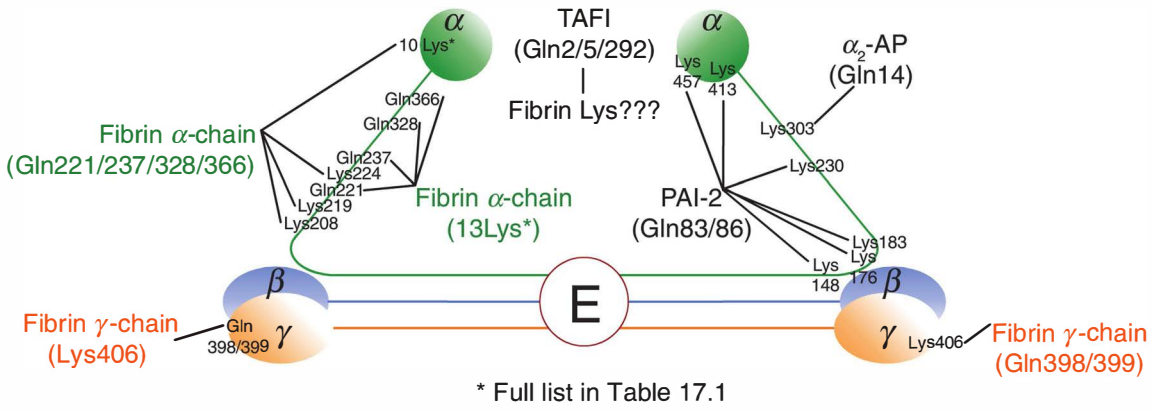

FIGURE 17.4 Fibrin cross-linking sites. Schematic of the fibrinogen molecule, with the central E-region, coiled coil region, and two distal D-regions. The sites where FXIIIa introduces cross-links are indicated in the fibrinogen molecule. The γ-chain (*orange*) of fibrin is cross-linked at residues Lys406 and either Gln398 or 399. The α-chain (*green*) has known cross-linking sites for fibrinolysis inhibitors such as α_2-AP and PAI-2, and many sites have been reported to be involved in α–α cross-linking.

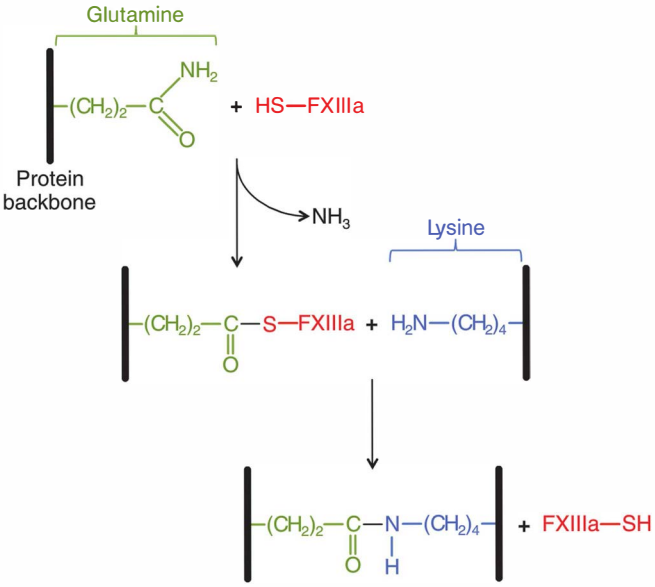

FIGURE 17.5 Transglutaminase reaction by FXIII. FXIIIa active Cys314 reacts with a substrate glutamine to generate an acyl enzyme intermediate and release a molecule of ammonia. The acyl enzyme then reacts with a lysine substrate, resulting in the formation of covalent ε(γ-glutamyl)lysyl bond and release of FXIIIa.

TGs are significantly conserved, with a 75% sequence homology between the active site of TG2 and FXIII-A for example.[82] The only member of the TG superfamily that does not contain a functional active site is erythrocyte protein 4.2.[93] This protein, although not active as a TG, is very abundant in the human red blood cell membrane where it plays a significant role in membrane stability through interactions with CD47, band three, and ankyrin, as demonstrated by hereditary spherocytosis (a form of hemolytic anemia) caused by protein 4.2 deficiency.[94]

FXIII has several unusual characteristics compared with other TGs. Whereas FXIII-A (the TG part of the proenzyme) forms a heterologous tetramer with FXIII-B, most other TGs exist in the form of a monomer. The only other TG that is not a monomer is rat TG4 that has been reported to form a homodimer, similar to FXIII-A.[83] Another uncommon feature of FXIII is that its activation involves proteolytic cleavage by thrombin in the presence of calcium. Most other TGs are activated by the presence of calcium alone, but there are two other exceptions to this. TG3 is activated by proteolytic cleavage by dispase that leads to a 50 kDa *N*-terminal fragment containing the catalytic core and a 27 kDa *C*-terminal fragment.[95,96] The activation of TG1 is also regulated by an additional mechanism, but unlike FXIII-A and TG3 not by limited proteolysis. Activation of TG1 in the absence of extracellular calcium is regulated by conformational changes induced by interaction with tazarotene-induced gene 3 (TIG3).[97,98] TIG3 is also a substrate for TG1, hence it is interesting to compare its stimulatory effect on TG1 activation with the enhancing effect that fibrin has on FXIII activation (see above).

Most TGs are intracellular, cytoplasmic proteins, apart from FXIII-A and TG2 both of which are secreted. TG1 is anchored to the cell membrane via palmitate and myristate linkages at a cluster of five cysteine residues in the *N*-terminus of the protein.[99] TG2 demonstrates guanosine triphosphate (GTP) hydrolizing activity in addition to its cross-linking activity.[100,101] This GTPase activity competes with cross-linking activity in TG2, as binding of GTP inhibits the cross-linking function of TG2.[102] Cross-linking by FXIIIa is however unaffected by GTP,[102] indicating that FXIII does not support GTPase activity.

INTERACTIONS WITH FIBRIN(OGEN) AND ROLE OF FIBRIN α-CHAIN

As mentioned above, the fibrin α-chain contains several potential cross-linking sites, and its cross-linking by FXIIIa leads to high molecular weight polymers. All the α-chain cross-linking sites are located in the *C*-terminal half of the chain (αC), which contains many protein binding sites and plays an important role in lateral aggregation of fibrin.[103] The cross-linking of this chain by FXIIIa therefore contributes to the stability of the laterally aggregated fibrin fiber.

Several studies have been performed to elucidate the interactions of various forms of FXIII with fibrinogen and fibrin. Greenberg's group showed that nonactivated FXIII-A_2B_2 bound specifically to fibrinogen via the FXIII-A_2 subunits with an equilibrium constant (K_D) of 10 nM[104] and identified that FXIII-A_2B_2 binding also occurred with fibrinogen polymerized with protamine sulfate, fibrin I produced with reptilase and fibrin II, indicating that binding of FXIII is not dependent on thrombin or the release of fibrinopeptides.[105] The authors went on to propose a model wherein FXIII zymogen reversibly binds to fibrinogen (via the A-subunits), remaining there after cleavage of fibrinopeptide A, which is cleaved from the fibrinogen α-chain by thrombin during the conversion of fibrinogen to fibrin. At this point the AP of the A-subunits of FXIII is cleaved by thrombin during the formation of fibrin II polymers. Once the A-subunits of FXIII are cleaved, the B-subunits are able to dissociate in the presence of calcium to form FXIIIa.[105] Hornyak and Shafer[63] compared thrombin-cleaved, nonactivated platelet FXIII-A and nonactivated FXIII-A_2B_2 for binding to fibrin. The thrombin-cleaved FXIII-A′ bound with a higher affinity to fibrin (K_D = 2.1 μM) compared to noncleaved FXIII-A subunit (K_D = 14 μM). However, the tetramer FXIII zymogen (A_2B_2) bound to fibrin with a much greater affinity (K_D = 0.2 μM) than either form of the A-subunit preparations. These authors saturated fibrin with plasma FXIII zymogen, and this did not modify the interaction of thrombin-cleaved FXIII-A subunit, suggesting FXIII zymogen and FXIIIa bind to separate sites on fibrin.

Lorand's group established that residues 242 to 424 of the fibrin α-chain play a role in enhancing the dissociation of the A- and B-subunits of FXIII-A_2B_2 following thrombin cleavage.[64] This work therefore indirectly infers that these residues of the α-chain are involved in the binding of thrombin-cleaved FXIII-A_2B_2, which is likely to involve the A-subunit. Subsequent work by Greenberg's group[106] showed, using immunoblotting techniques, that binding of FXIII-A took place on the carboxy-termini of the α- and β-chains, but not on the E fragment (which is the central fragment of the molecule that contains the *N*-termini of all the chains) of fibrinogen (see FIGURE 17.4 for diagram of fibrinogen structure). Procyk et al.[107] found that thrombin-activated FXIII-A subunit bound to residues 389 to 402 of the α-chain, by competing the binding of FXIIIa to fibrin columns with antibodies directed against this

sequence of the fibrin α-chain. More recently, taking a direct approach of recombinant expression of truncated fibrinogen α-chains and using surface plasmon resonance to study the interaction of FXIIIa to these α-chain fragments, FXIII-A was found to bind to residues 233 to 425 in the αC with a K_D of 2.4 μM and this interaction was further localized to αC residues 389 to 403. Using a site-directed mutagenesis approach, it was found that mutation of the single residue Glu396 of the αC-chain abolished the binding to FXIIIa.[108]

ROLE OF FIBRIN(OGEN) γ CHAIN

The fibrin γ-chain is one of the preferred substrates for FXIIIa; its cross-linking is rapidly completed (5 to 10 minutes) after clot formation. FXIIIa cross-links the γ-chains between Lys406 and one of two tandem glutamine residues situated at position 398 and 399.[109,110] Cross-linking occurs when two γ-chains are lined up, the D-regions (which contain the *C*-terminal domains of both the γ- and the β-chains of fibrin) facing each other, in the half-staggered D-E-D fibrin protofibril arrangement of fibrin (see FIGURE 17.4 for diagram of fibrinogen structure). Two γ-chain cross-links are introduced in this assembly across the D-dimer interface in an antiparallel orientation.[111]

In agreement with the structural orientation of the γ-chain at the D–D interface, fibrin γ-chain cross-linking does not normally lead to higher molecular weight complexes, such as those formed during cross-linking of the α-chains, but leads to the formation of γ-chain dimers.[112] When cross-linked fibrin is digested by plasmin, proteolysis of the coiled coils on either side of the cross-linked D-regions leads to the formation of D-dimers.[113–115] Mutation of Lys406 in the fibrinogen γ-chain modifies the topology of fibrin cross-linking by FXIIIa with the production of γ-α hybrid cross-links.[116] Similar γ-α hybrid cross-links are also found when fibrin is cross-linked by

TG2,[117,118] suggesting that Lys406 is a specific acyl-acceptor for FXIIIa and not for TG2.

Some studies have suggested that the γ-chain cross-links introduced by FXIIIa show a different configuration than the longitudinal orientation of antiparallel cross-links across the D–D interface. Mosesson suggested that γ-chain cross-links show a transverse orientation, spanning from one γ-chain in one protofibril across to a second in another protofibril, suggesting that this agrees with fiber extensibility upon stretching of the fiber, which has lead to some debate on this topic in the literature.[119,120] Recent data from atomic force microscopy studies of fibrin fibers at stretch, however, has provided further evidence for the γ-chain longitudinal cross-linking model[121] in agreement with previous x-ray crystallography[122] and EM studies.[123]

Cross-linking of the fibrin γ-chains is inhibited by a monoclonal antibody against the *C*-terminal region of the γ-chain[124] and by clumping factor A from *Staphylococcus aureus* that binds to the same region.[125] Residue Ile387 of the fibrin γ-chain seems to be important for the interaction of the γ-chain with FXIIIa, as mutation of this amino acid impairs γ-chain cross-linking.[126]

It has been suggested that FXIIIa binds to the fibrinogen γ-chain *C*-terminal region. In particular, a splice variant of the γ-chain, fibrinogen γ′, has been reported to interact with FXIIIa. Studies using zymogen FXIII-A_2B_2 suggested that the γ′-chain of fibrinogen was responsible for binding FXIII-A_2B_2, as FXIII-A_2B_2 copurifies with γA/γ′ but not γA/γA fibrinogen. Contrary to this work, studies by Lord's group, using recombinant expression of γA/γA and γA/γ′ fibrinogen, found similar binding affinities for FXIII-A_2B_2, regardless of the presence of γ′.[127] Fibrinogen γ′ is caused by alternative polyadenylation,[128] which leads to two messengers differing at the *C*-terminus. For the γ′-chain, the last 4 residues are replaced by 20 different residues.[129] FXIII copurifies with the fibrinogen γ′-chain, and this effect is due to the B-subunit, as A-subunit on its own does not coelute.[130,131] These findings suggest that FXIII-B may bind to the γ′ sequence, which is negatively charged and also contains a thrombin-binding site.[132–134] FXIII also binds to a γ′ peptide, which competitively inhibits binding of FXIII to fibrinogen.[135] Fibrinogen γ′ has been shown to associate with increased activation of FXIII.[136] The mechanisms behind the γ′/FXIII interaction remain largely unknown and further studies will be needed to characterize the physiologic relevance of these findings.

CROSS-LINKING OF INHIBITORS OF FIBRINOLYSIS

FXIIIa cross-links several protease inhibitors to fibrin, in order to protect the clot from breakdown (fibrinolysis) (Table 17.1, FIGURE 17.4). Plasmin is the main protease responsible for fibrinolysis, and its major inhibitor is the serine protease inhibitor α_2-antiplasmin (α_2-AP). Deficiencies and abnormalities in plasma α_2-AP result in severe hemorrhagic disorders,[137–146] characterized by increased susceptibility to fibrinolysis, which can be reverted *in vitro* by addition of purified α_2-AP to plasma from deficient patients.[147] FXIIIa is able to cross-link Gln2/14, 21, 419, 447 of α_2-AP[148–150] to Lys303 of α-chain fibrin.[151] Circulating free α_2-AP inhibits tissue plasminogen activator (tPA)-induced fibrinogenolysis,[152] whereas FXIIIa-mediated cross-linking of α_2-AP to fibrin results in inhibition of fibrinolysis.[153] Plasmin bound to fibrin is protected from inhibition by α_2-AP.[154,155] There are two forms of α_2-AP circulating in human plasma. The native α_2-AP is secreted as a 464–amino acid protein with amino-terminal methionine (Met–α_2-AP) that can be cleaved between Pro12–Asn13 in the circulation to form a 452–amino acid protein with asparagine at the amino-terminus (Asn–α_2-AP).[156,157] The enzyme responsible for this cleavage has been characterized as antiplasmin cleaving enzyme (APCE).[158,159] Both forms of α_2-AP have similar inhibitory activity toward plasmin,[158] but the major form (70%) Asn–α_2-AP is more rapidly cross-linked to fibrin than the Met–α_2-AP form (30%), and the plasma clot lysing time increases with Asn–α_2-AP/Met–α_2-AP ratio.[158] It appears therefore that the *N*-terminal 12–amino acid sequence is inhibitory toward the cross-linking of α_2-AP by FXIIIa. Recently, a single nucleotide polymorphism (SNP) has been shown to affect the sixth amino acid of α_2-AP, Arg6Trp.[160–162] The arginine and tryptophane alleles have a frequency of 79.5% and 20.5%, respectively.[163] Also, this Arg6Trp SNP results in an altered ability of the Met–α_2-AP(Trp6) to be cleaved by APCE, compared to Met–α_2-AP(Arg6), with potential effects on fibrinolysis.

Plasminogen activator inhibitor-2 (PAI-2), which inhibits the conversion of plasminogen into plasmin by urokinase plasminogen activator and tPA,[164,165] is also a substrate of FXIIIa for cross-linking to fibrin. PAI-2 reacts with FXIIIa through putative Gln83 and 86,[166] and is cross-linked to Lys148, 176, 230, 183, 413, and 457 of the fibrin α-chain.[167,168] The inhibitory effects of PAI-2 are not affected by cross-linking,[166] and PAI-2 cross-links with fibrin at sites different to that of α_2-AP, resulting in an increased stabilization of the fibrin clot. Although α_2-AP circulates in the plasma, PAI-2 is not detected in normal plasma; it is mainly secreted into the matrix of tissues,[169,170] and could play an important role in reducing fibrinolysis during wound/tissue repair.[171] Its incorporation into fibrin may also play a role during pregnancy, as circulating PAI-2 levels are elevated throughout pregnancy, and during the first few days postdelivery, before returning to undetectable levels.[172] Unlike α_2-AP, no polymorphism in the PAI-2 gene that affects cross-linking to fibrin has been reported to date.

Another inhibitory protein of the fibrinolytic pathway, thrombin-activatable fibrinolysis inhibitor (TAFI),[173,174] was also identified as a FXIIIa substrate, with residues Gln2, 5, and 292 participating in the cross-linking to fibrin,[175] although the reactive lysine residues have yet to be identified. Pro-TAFI is activated through cleavage by thrombin at Arg92,[173,174] resulting in the release of the AP and the loss of two major cross-linking sites (Gln2 and 5). Activation of TAFI may therefore result in the release of the inhibitor from its cross-linked position in fibrin, leading to fibrin-localized antifibrinolytic activity. TAFI is a plasma carboxypeptidase B,[173,174] of which the antifibrinolytic activity is associated with the removal of *C*-terminal arginine and lysine from fibrin, resulting in a decreased binding of plasminogen to fibrin, and therefore a reduced conversion of plasminogen to plasmin on the fibrin clot.[176] In the last decade, SNPs have been shown to play a role on TAFI-related inhibition of fibrinolysis; Ala147Thr and Thr325Ile polymorphisms play a role on TAFI level in plasma,[177,178] and the Ile325 variant shows greater activity than the Thr325 variant.[179] The Ala147Thr polymorphism is in linkage disequilibrium with a promoter-C1 542G polymorphism that strongly affects the level of TAFI expression,[180] and C1542G and Thr325Ile are related to different types of acute coronary syndrome.[181] The Thr325Ile polymorphism is also strongly associated with risks of stroke,[182] coronary

heart disease,[183] venous thromboembolism,[184] and restenosis.[178] Despite its link with TAFI levels, the Ala147Thr polymorphism did not show any association with stroke,[182] acute coronary syndrome,[181] or aneurysmal subarachnoid hemorrhage.[185]

ROLE OF CROSS-LINKING BY FACTOR XIII IN FIBRIN STRUCTURE AND ELASTICITY

One of the main functions of cross-linking of fibrin by FXIIIa is to increase the stiffness of the blood clot. Fibrin clots demonstrate both elastic and viscous properties. Fibrin has unique properties amongst biologic polymers in that it can be stretched several times without damage to its structure.[186] The viscoelastic properties of fibrin can be attributed to its properties at the molecular level, with unfolding of domains providing a basis for stretching of the molecule,[121,187] and at the level of individual fibers,[188] as well as to structural characteristics at the level of the whole clot.[189]

Cross-linking by FXIIIa increases the storage modulus (stiffness) of fibrin, and decreases the loss tangent or amount of energy dissipated during deformation.[190] This occurs in purified systems as well as in plasma.[191] The elastic modulus of individual fibrin fibers is increased significantly by cross-linking as analyzed by optical tweezers and atomic force microscopy.[121,188,192] The strength of branch points is also increased by cross-linking, resulting in a reduction of ruptured branch points from 70% to 40% when branched fibers are stretched using the atomic force microscope.[193] The stiffness of fibrin increases when the clot is stretched, a phenomenon that is called strain hardening.[194] Cross-linking by FXIIIa has been shown to reduce strain hardening by around 50%.[121] Permanent deformation of fibrin structure at strain is reduced by cross-linking; therefore, the elastic properties of cross-linked fibrin gels are maintained at higher strain than those that are not cross-linked.[195]

It has been described that the timing of the increase of fibrin stiffness during clot formation correlates more closely with the formation of α-chain cross-links, rather than with the earlier formation of γ-chain cross-links, suggesting that the increase in stiffness is largely due to α-chain cross-linking.[196] Studies using an autoantibody that inhibited primarily α-chain cross-linking, appeared to confirm that the increase of fibrin stiffness is largely due to α-chain cross-linking and the formation of highly cross-linked polymers.[197] However, more recent studies of fibrinogen with mutations in the γ-chain cross-linking sites showed that γ-chain cross-linking also significantly contributes to clot stiffness, with a 40% increase in the storage modulus due to γ-chain dimerization by FXIIIa.[116] The same study also showed that α–γ hybrid cross-links were least effective in enhancing fibrin stiffness.[116] It has been suggested that the αC-region, which extends between protofibrils, mediates the extensibility of fibrin.[192] Cross-linking in this region by FXIIIa may reduce the effective length of the αC-region link between protofibrils and hence reduces the length by which fibrin can be stretched.[121]

Besides its role in fibrin elastic properties, FXIIIa has been suggested to modulate the structure of the fibrin clot. One study indicated that cross-linking by FXIIIa did not introduce gross changes in fibrin clot architecture, but that it reduced fiber diameter by around 10% to 20%.[198] Other studies on FXIII-A Val34Leu polymorphism found that the Leu34 allele associates with thinner fibrin fibers and smaller clot pores,[199] and that these changes are dependent on fibrinogen concentration.[200] Fibrin formation is a dynamic process, as fibrin fibers continue to grow and rearrange themselves long after the initial gel point.[201] FXIII activation is regulated by fibrin formation as described above. Hence, the architecture of the clot is determined by the conditions that regulate the kinetics of fibrin formation and those of FXIII activation.

FACTOR XIII AND PLATELETS

Before forming the circulating heterotetramer form of FXIII, both subunits A and B are synthesized and secreted by different cell types. The B-subunits are synthesized by hepatocytes,[29,202] whereas macrophages and monocytes[25,203,204,205,206] are a source of catalytic A-subunits. FXIII-A is mainly synthesized by megakaryocytes[207] and stocked in the cytosol of nascent platelets,[208–211] where it reaches concentrations estimated at 100- to 150-fold higher than in the blood plasma.[212] Some heterodimeric form of FXIII is also taken up into the platelet α-granules by endocytosis, but its amount is negligible when compared with that of cytosolic FXIII-A.[213] The role of this platelet FXIII-A pool in contributing to plasma FXIII levels remains to be clarified. An initial study showed that plasma FXIII-A levels correlated to platelet counts but not monocyte counts,[214] and the authors concluded that platelets contribute significantly to plasma FXIII-A levels. However, other factors could contribute to this correlation and FXIII-A plasma levels. In a more recent study, platelet counts were not altered in two transgenic mice lines displaying thrombocytopenia through decreased platelet life span and megakaryocytes generation.[27] Although these latter findings cannot exclude the existence of compensatory mechanisms, they indicate that platelets are not the major source for plasma FXIII-A. Also, unlike FXIII-B, the A-subunit does not contain an endoplasmic reticulum signal sequence,[14,17] crucial for integration in the ER–Golgi secretion pathway, and therefore cannot be secreted. Further studies will be required to unequivocally identify the source of plasma FXIII-A, and the mechanism by which its levels are maintained. FXIII-A appears to be associated with peripheral Golgi proteins,[27] highlighting a possible release of FXIII-A through a nonclassical secretion pathway identified for the secretion of other proteins.[215]

In addition to the documented extracellular role of FXIIIa in fibrin clot stabilization and tissue repair, intracellular FXIII-A plays a role in cytoskeletal remodeling. Upon activation of platelets, cytoplasmic calcium concentration increases, leading to intracellular FXIII-A activation through a nonproteolytic process.[212] FXIII-A plays a role in cytoskeletal reorganization, associated with platelet activation, through the cross-linking of various substrates (Table 17.1). Actin[216,217] and myosin[218], playing a major role in cell migration, are cross-linked to each other by FXIII-A, resulting in stabilization of the cytoskeleton. Furthermore, vinculin[219] that plays a role in linking the cytoskeleton to the plasma membrane, and heat-shock protein 27[220] that regulates actin polymerization, are also FXIII-A substrates. Since it plays a role in cytoskeleton remodeling and platelet contraction plays a role in clot retraction,[221] a recent study investigated the role of FXIII-A on this process *in vivo*.[222] FXIII-A knock-out mice were found to have impaired clot retraction, but the relevance of cross-linking of cytoskeletal proteins by FXIIIa in this process remains to be fully explored.

FXIII is also present on the surface of activated but not resting platelets,[223–226] through binding to glycoprotein (GP) IIb/IIIa (integrin $\alpha_{IIb}\beta_3$)[226,227] (Table 17.1). Platelets activated by a mixture of collagen and thrombin, known as COAT platelets,

secrete many procoagulant proteins, such as fibrinogen/fibrin and α_2-AP, from the α-granules,[228] which are then bound to the cell surface in a FXIII-dependent manner.[228] In this study, the authors also highlighted the necessity of serotonin cross-linking to these proteins for cell surface binding. Although serotonin is a TG substrate,[228] further studies are required to assess the role of FXIII in the serotonylation of the α-granule proteins, and to identify the serotonin receptor. In addition to binding platelets, FXIII-A mediates the binding of these platelets to endothelial cells, through the dual binding of FXIII to platelet GP IIb/IIIa and endothelial cell integrin $\alpha_V\beta_3$.[229,230] This FXIII-dependent adhesion of platelets to endothelial cells could play a role during tissue repair following vascular injury.

HETEROGENEITY OF FACTOR XIII A-SUBUNIT

The gene coding for FXIII-A is highly polymorphic, as first established by agarose gel electrophoresis.[231] Two common alleles have been described by isoelectric focusing, FXIIIA*1 and FXIIIA*2. Further isoelectric focusing analysis showed that these two isoforms could be split into four subtypes, FXIIIA*1A, FXIIIA*1B, FXIIIA*2A, and FXIIIA*2B.[232] The four allele subtypes were later identified as product of two SNPs, A614T and C1894T,[233] resulting from four combinations of the two sets of different amino acids coded by these SNPs.

The most studied SNP in FXIII-A is a prevalent G103T mutation resulting in amino acid change Val34Leu.[234] In white populations, the frequency of the Leu34 allele ranges from 24.5% to 28.8%.[235,236,237–242] This frequency is lower in black[238,241] and Asian Indian[237] communities, and extremely rare in these Japanese population.[241,243]

The FXIII Leu34 variant is more quickly activated by thrombin,[199,240,244] and the resulting clots have thinner fibers and smaller pores.[199] The higher activation rate of this variant is related to the fact that the SNP is located only four amino acids away from the cleavage site (Arg37–Gly38) by thrombin. The substitution of valine with leucine at residue 34 leads to improvements in both the K_m and catalytic constant (k_{cat}) during thrombin cleavage of Arg37–Gly38.[245] Once fully activated, there is no influence of this polymorphism on FXIIIa specific activity.[244]

FXIII Val34Leu has been associated with a wide range of CVD. Despite contradicting individual studies, meta-analysis studies have concluded that Leu34 allele is associated with a protective effect on CADs,[246] myocardial infarction (MI),[247] and DVT,[248] but studies of the role of FXIII Val34Leu in stroke has produced inconsistent data,[242,249–253] and no effect was observed on peripheral artery disease (PAD).[250] FXIII Val34Leu has also been associated with increased risk of aneurysmal subarachnoid hemorrhage[185] and thrombotic microangiopathies,[254] and worse efficacy of thrombolytic therapy.[255–257] Interestingly, an association between Val34Leu polymorphism and Alzheimer disease has been documented.[258] Although the mechanisms linking FXIII to Alzheimer disease are still unclear, TG activity is documented to be responsible for cross-linking of amyloid β-peptides,[259] and FXIIIa has been detected in reactive microglia and macrophages of various neurologic disorders, including Alzheimer disease.[260]

Two other common SNPs in FXIII-A, an A614T substitution and a C1894T point mutation resulting in Tyr204Phe[243] and Pro564Leu[233] respectively, have been studied to a lesser extent. The Phe204 allele is associated with decreased plasma FXIII level and activity, whereas the Leu564 allele is associated with lower level and higher activity.[261,262] Only a few studies have linked these polymorphisms to CVD. Variant Phe204 may be a marker of susceptibility to ischemic stroke (IS),[263,264] but does not seem to affect risks of MI.[250,265] Leu564 allele is associated with slightly increased risk of MI in younger women[265] and smaller venous ulcer surface.[266] Although this variant did not influence the risk of IS,[250,264] concomitant presence of the Leu34 allele was associated with an increased risk of IS.[267] Two recent studies are in contradiction regarding a link between Leu564 and aneurysmal subarachnoid hemorrhage.[185,268]

Other SNPs, such as Val650Ile and Glu651Gln,[13,14] have been described (FIGURE 17.6), but their roles in CVD are unknown. A study using 201 dizygotic twin pairs showed that Val34Leu, Tyr204Phe, and Pro564Leu, but not Val650Ile or Glu651Gln, polymorphisms are associated to levels of FXIII activation.[269] In this study, Val34Leu was found to be the main functional SNP influencing FXIII activation.

HETEROGENEITY OF FACTOR XIII B-SUBUNIT

The noncatalytic FXIII-B is a highly polymorphic blood protein, like FXIII-A. Three main isoforms were identified by agarose gel electrophoresis and isoelectric focusing experiments.[270–272] These alleles, FXIIIB*1, FXIIIB*2, and FXIIIB*3, are related to European, African, and Asian populations respectively, with a clear segregation of the alleles between the continents.[273] Other less frequent isoforms include FXIIIB*4, FXIIIB*6, and FXIIIB*13 to 15.[274–276] Hitherto, two major SNPs have been identified (FIGURE 17.6), His95Arg (FXIIIB*2),[277] and C29756G ([IVS11]+144C>G) change in intron 11 (FXIIIB*3), generating a new splice variant.[278,279]

There have been a few studies on the functional characteristics of FXIII-B His95Arg and its associations with thrombosis. In the first study, plasma FXIII-B dissociation from the tetrameric form was found to be increased for Arg95 variants, which could be associated with increased FXIIIa enzymatic activity.[277] In this study, *in vitro* steady-state binding experiments did not confirm these results, so further investigations are required to fully understand the effects of His95Arg polymorphism. Although very few studies have investigated the role of FXIII-B polymorphisms in relation to CVD, carriers of the Arg95 variant of FXIII-B may have an increased risk of IS,[264] DVT,[277] and aneurysmal subarachnoid hemorrhage,[268] but this variant may not affect risks of MI.[265,280] Interestingly, combination of both FXIII-A Leu34 and FXIII-B 95Arg alleles reduced MI risk by 70% in women in estrogen therapy.[281]

The 29756G allele, mainly found in Asian population, results in a splicing variant coding for a 15–amino acid longer B-subunit at the carboxy-terminus compared to the wild-type protein.[278] Although this isoform presents a different isoelectric point,[278] the location of these extra amino acids is thought to not influence the Sushi-domain structure of the protein.[279] Together with another extremely rare Glu368Val polymorphism (FXIIIB*4),[278], the biochemical and clinical properties of this splicing variant remain to be further investigated.

FACTOR XIII DEFICIENCIES

Congenital FXIII deficiency is a rare autosomal recessive disorder,[282–288] first documented in 1960 in Switzerland,[12] with a frequency of 1 per 2 million and a higher prevalence in areas of high rate consanguinity.[289] The disease was initially classified as one of two subtypes, type 1 and type 2, which were characterized

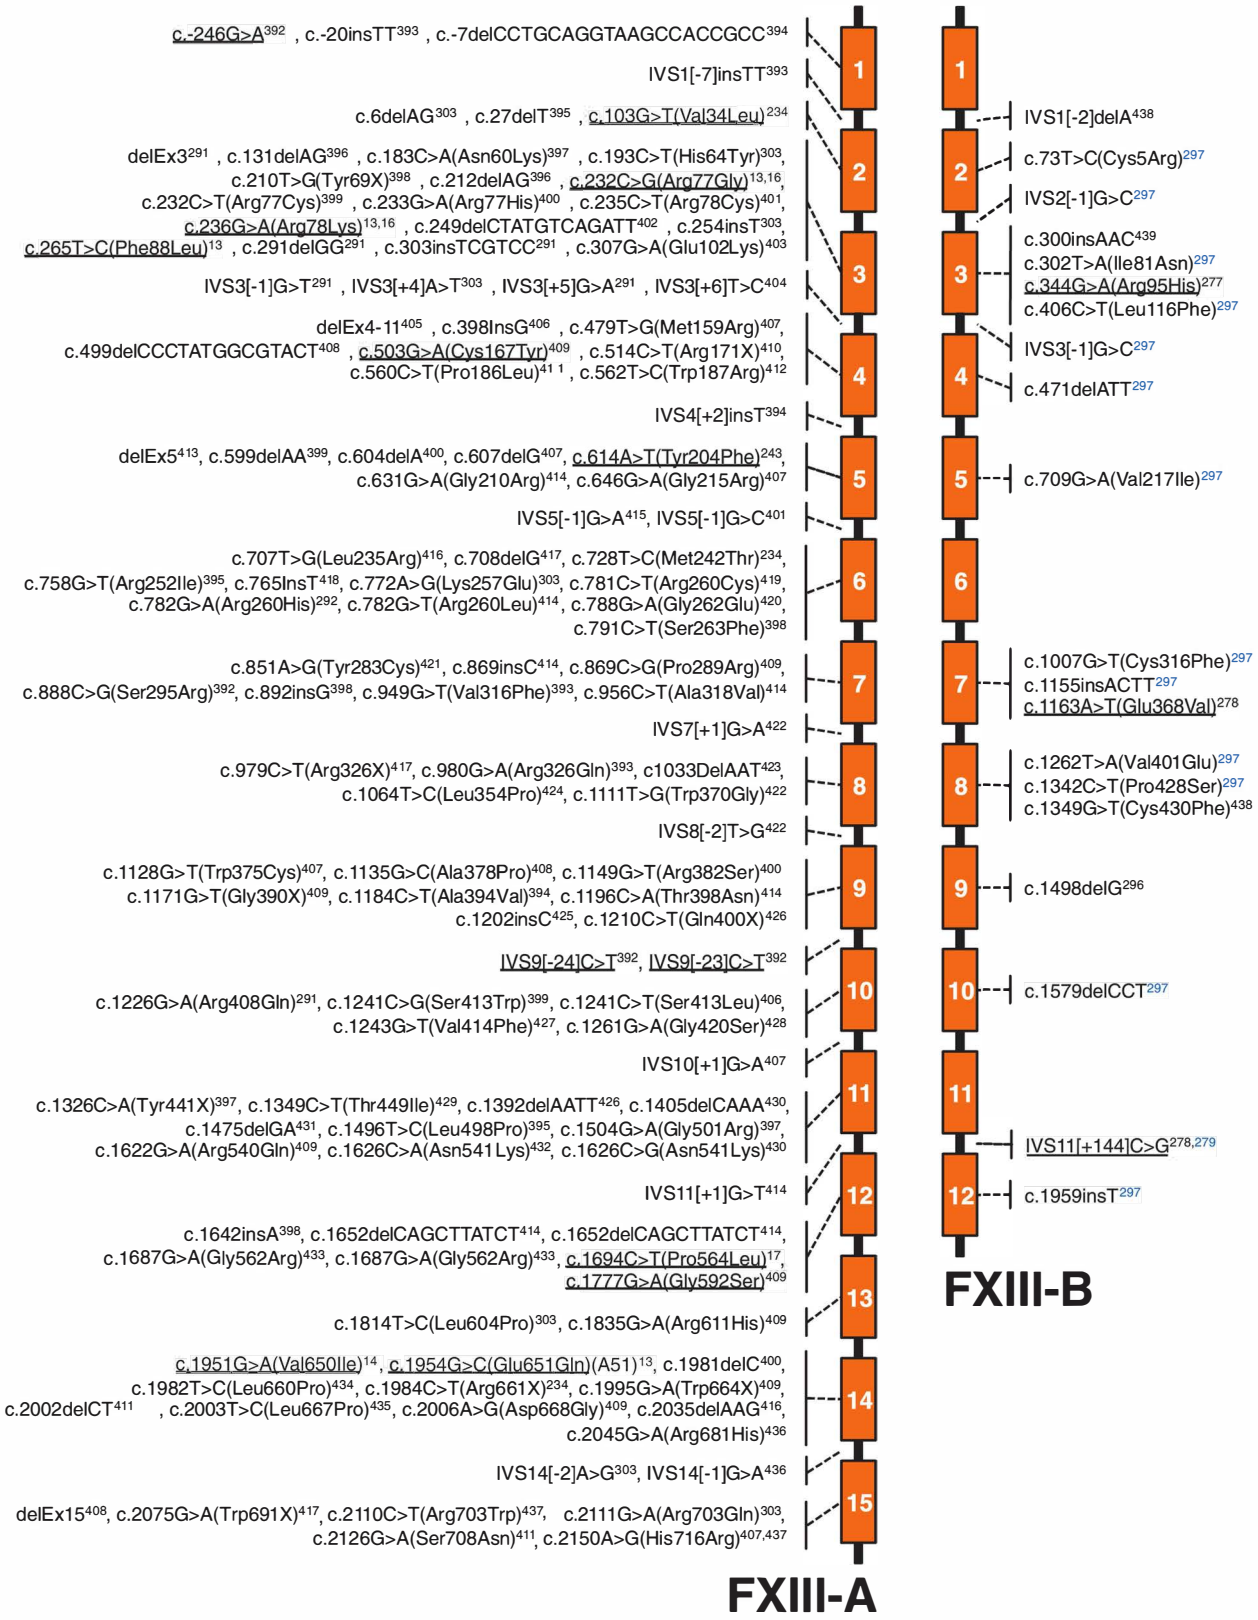

FIGURE 17.6 Genetic mutations of FXIII A- and B-subunits. Common polymorphisms in FXIII are underlined, and the remaining mutations have been identified in FXIII deficient patients. Nucleotides are numbered from the published cDNA sequences of FXIII-A[17] and FXIII-B,[46] with nucleotide one corresponding to the A of methionine-coding ATG translation initiation codon. (Modified and updated from Karimi M, Bereczky Z, Cohan N, et al. Factor XIII deficiency. *Semin Thromb Hemost* 2009;35(4):426–438.)

by the absence in the circulation of both FXIII-A and -B or the absence of FXIII-A alone, corresponding to FXIII-B deficiency (type 1) and FXIII-A deficiency (type 2) respectively.[290]

Genetics of Factor XIII-A Deficiency

FXIII-A deficiency is the most frequently described (>95% of cases) of the two subtypes, with 54 missense, 9 nonsense, 14 splice-site, 23 deletion, and 9 insertion mutations leading to this type of deficiency reported up to December 2010 (listed in FIGURE 17.6). Mutations in FXIII-A associated with deficiency are mainly located in exons 3 to 15. So far, none has been reported in the catalytic triad (Cys314, His373, and Asp396), but mutations within the active domain, such as Arg408Gln,[291] have been reported and could grossly affect the activity of the protein. In many studies, FXIII-A mRNA levels were unchanged in patients suffering from this deficiency, but intracellular proteins could not be detected, indicating that these mutations lead to the formation of unstable proteins that are degraded within the cell.[292–294]

Genetics of Factor XIII-B Deficiency

FXIII-B deficiency is the less common type (<5% of cases). Up to December 2010, eight missense, three splice site, three deletion, and three insertion mutations have been reported to be responsible to this disease (FIGURE 17.6). Similarly to FXIII-A deficiencies, FXIII-B mutations result in decreased ability of the protein to be secreted from cells,[295,296] and decreased protein stability.[297] Despite FXIII-A synthesis being unaffected in this particular subtype, the lack of B-subunit results in an unstable plasma A-subunit, which will affect its functions.[298] Similarly, FXIII-$B^{-/-}$ mice exhibit decreased FXIII activity and A-subunit levels. Injection of recombinant B-subunit in the FXIII-$B^{-/-}$ mice resulted in an increase in both cross-linking activity and FXIII-A antigen levels, highlighting the importance of the B-subunit in stabilizing the A-subunit in the plasma.[299]

Clinical Phenotypes

The main clinical symptoms of FXIII-A deficiency are severe bleeding, recurrent miscarriages, and impaired wound healing. In 70% of cases, umbilical cord bleeding is reported, and most patients will exhibit ecchymoses, hematomas, and prolonged bleeding.[300–303] Intracranial hemorrhage is observed in 30% of FXIII-A deficient patients.[300–303] The other main sites of bleeding are mouth and gums, muscles and joints, mucous membranes, peritoneum, and sites of surgery.[300–303] FXIII-$A^{-/-}$ mice were also described to present subcutaneous, intraperitoneal, and intrathoracic hemorrhage.[304] Since the first case of recurrent miscarriage in a FXIII deficient patient was reported,[305] all subsequent studies reported that women with this deficiency suffer from recurrent pregnancy loss, although the causes are still unknown.[306] The level of FXIII required for carrying pregnancy to term is around 10%.[307] FXIII-$A^{-/-}$ mice exhibited vaginal bleeding, placental hemorrhage, detachment, and necrosis.[308] Impaired wound healing has been reported in up to 30% of FXIII-A deficient patients,[300,301,303] and FXIII-$A^{-/-}$ mice also showed impaired wound and cardiac healing.[309–311] All cases of FXIII-B deficiency reported to date showed milder bleeding symptoms, which are mostly caused by trauma, surgery, and delivery,[297] but successful pregnancies can be observed.[297,298] FXIII-$B^{-/-}$ mice also exhibit milder phenotype of FXIII deficiency.[311] A likely reason for the milder phenotype of FXIII-B deficiency is the normal presence of intracellular FXIII-A, which, through the contribution of platelet FXIII-A at the site of injury, may contribute to fibrin cross-linking and local wound healing.

Diagnosis

Because of the high level of mortality and morbidity in FXIII deficiency when left untreated, it is important that the deficiency of this coagulation factor is correctly diagnosed. Diagnosis is complicated by the fact that routine coagulation test (activated partial thromboplastin time, prothrombin time, thrombin time) parameters are unaffected by FXIII deficiency. For a long time, it was common practice to base the diagnosis of FXIII deficiency on a qualitative test of clot solubility in strong urea or acid.[312] However, a recent study showed that this test may only detect very severe FXIII deficiencies, is characterized by poor reproducibility, interlaboratory variability, and poor sensitivity, and it was therefore not recommended as a screening test for this deficiency.[313] The correct diagnosis of FXIII deficiency requires a quantitative activity assay followed by antigen assays, in order to classify the type of deficiency. Several quantitative activity assays have been reported that are commonly based on the measurement of ammonia released in the first step of cross-linking, or on the measurement of the cross-linking of a biotinylated amine substrate into a protein substrate, the latter usually coated on a microtiter plate. In ammonia release assays,[314–316] the amount of free ammonia released by FXIII-dependent cross-linking of substrates is proportional to the amount of NAD(P)H consumed by glutamate dehydrogenase (NH_3 + α-ketoglutarate + NAD(P)H → glutamate + NAD(P)). The decrease in NAD(P)H is then measured spectrophotometrically by absorbance at 340 nm. Automated assays are available commercially, showing similar sensitivities.[317] In amine incorporation assays, the amount of labeled amine substrate bound to glutamine substrate,[318–325] in the presence of FXIII, is measured by fluorescence, radioactivity, or colorimetry.[318–325] Automated microtiter plate tests are available using the following reaction: fibrinogen + 5-(biotinamido)pentylamine (BAPA) → fibrinogen-BAPA + NH_3. Bound BAPA is then chromogenically measured. This type of assay has been shown to efficiently detect FXIII deficiency.[326] Research and development is still ongoing in order to increase the sensitivity of these techniques.[327–329] ELISA-based antigen assays have been developed,[261,330–333] which may be used to quantify FXIII A-subunits, B-subunits and A_2B_2 heterodimers, determining the type of FXIII deficiency.

Treatment

Patients suffering from FXIII deficiency are currently treated with a number of sources for FXIII supplementation. The three main types of supplementation are fresh-frozen plasma, cryoprecipitate, and pasteurized plasma FXIII concentrate. Lifelong prophylactic therapies are commonly used in FXIII deficient patients due to high risks of spontaneous hemorrhage. Since fresh-frozen plasma and cryoprecipitate present high risks of transmission of blood-borne diseases, viruses-inactivated plasma concentrate is the most commonly used source of FXIII. This treatment does not present major inconvenience to patients due to the long half-life of plasma FXIII (around 12 days),[334] and many reports have

indicated efficient prophylaxis for 10 to 20 U/kg in 4 to 6 weeks interval over periods of 5 to 20 years.[335–337] More recently, human recombinant FXIII-A_2 homodimer concentrate has been produced from *Saccharomyces cerevisiae*.[338] In phase I trials, rFXIII-A_2 was shown to associate with endogenous B-subunit, and normalize clot solubility. The heterodimer A_2B_2 half-life was 8.5 days, and no safety issue (yeast antibodies formation, clinical parameters) was observed. A preliminary clinical report using such rFXIII-A_2 showed that 35 U/kg may be the appropriate dose for pre/postoperative replenishment of FXIII-A in cardiopulmonary bypass.[339] To prevent abortion in FXIII deficient woman, plasma FXIII level must be maintained above 10% by replacement therapies, preferentially using pasteurized plasma FXIII concentrate.[307] To maintain this 10% level, recommended doses are 250 U/kg every 7 days in early gestation and 500 U/kg every 7 days after 23 days.[307] In order to prevent delivery-triggered hemorrhage, the levels of plasma FXIII should be higher than 30%, which can be achieved with a booster dose of 1,000 U/kg prior to labor.[307]

ACQUIRED FACTOR XIII DEFICIENCY

Acquired FXIII deficiency can occur as a consequence of an autoimmune response,[340,341] or as a secondary event to an underlying disease state where there is decreased synthesis and/or increased consumption of FXIII. Examples of the latter include disseminated intravascular coagulation, certain inflammatory diseases (e.g., Crohn disease and ulcerative colitis), leukemia, myelodysplasia, myeloproliferative disorders, and liver disease.[21] Acquired FXIII deficiency also occurs perioperatively. Here, it has been shown that early substitution of FXIII levels during surgery benefits patients.[342] Phase III clinical studies are underway to investigate the benefits of recombinant FXIII-A therapy in patients undergoing heart surgery.

It is interesting that in the cases of acquired FXIII deficiency even mild levels of deficiency are able to cause bleeding problems, unlike conditions of hereditary deficiency where apparently moderate levels of deficiencies can be tolerated.[342] Therefore, it is important to be able to diagnose cases of acquired FXIII deficiency with sensitive enough assays to allow treatment of patients under appropriate circumstances.[317]

FACTOR XIII AND THROMBOSIS

Cardiovascular disease is the most common cause of morbidity and mortality globally, causing 17.1 million deaths every year, rising to an estimated 23.6 million by 2030 (World Health Organization). In these patients, thrombotic complications such as MI, IS, PAD, DVT, pulmonary thromboembolism (PE), and coronary sclerosis (CS) are the ultimate cause of death.[343]

The role of fibrin clot in relation to thrombosis and thrombolysis is still poorly understood. Sustained presence of fibrin clot could play a major role in the formation and maintenance of the thrombus, therefore highlighting a potential role of FXIII in this process. Two initial studies highlighted the potential role of FXIII in thrombosis. The first study, using a canine model of coronary thrombosis, showed that inhibition of FXIII increased endogenous thrombolysis, and decreased reperfusion time.[344] In the other study, inhibition of FXIII activity increased emboli lysis in a ferret model of PE.[345]

Clinical studies suggest that FXIII could play a role in thrombosis, although the mechanisms involved remain unclear. FXIII activity and antigen levels have been investigated in many thrombotic diseases. Patients with PAD show elevated activity and antigen levels.[346–348] Female but not male patients show increased risks of CAD, such as MI and CS, when FXIII levels are increased.[349] Patients diagnosed with IS show elevated FXIII-B, but not A-subunit, levels,[350,351] whereas patients suffering from DVT and PE show decreased FXIII-A levels.[352,353]

As described earlier in this chapter, the first step of FXIII activation consists of cleaving the AP by thrombin. A recent study showed that AP is released from FXIIIa following activation, and a specific ELISA method was developed to detect this peptide in the plasma.[354,355] The authors propose FXIII AP as a possible marker for acute thrombotic events, prior to the formation of a thrombus.

Studies of genetic polymorphisms also highlighted a potential role for FXIII in thrombosis. Both FXIII A- and B-subunit polymorphisms have been associated with various thrombotic diseases (see above). The effects of FXIII polymorphisms can be modulated by other factors influencing the risk of arterial thrombosis, such as fibrinogen concentration and insulin resistance. FXIII-A Leu34 variant was associated with increased risks of CAD when fibrinogen concentrations were low, whereas high concentrations resulted in decreased risk.[200,356] Similarly, in the Hungarian population, high fibrinogen concentration was associated with a protective role of Leu34 against CS and MI.[357] This association between the FXIII Val34Leu polymorphism and fibrinogen concentration was also reported for risk of DVT associated with Leu34 polymorphism.[358,359] In another study, the protective effects of Leu34 on CAD were lost in patients with insulin resistance.[360]

Treatment of certain thrombotic events consists of inhibiting thrombus formation with oral anticoagulants such as warfarin, however this approach does not affect fibrinolysis of already formed thrombi, and requires regular monitoring of coagulation parameters. Fibrinolytic agents may be used in certain acute situations of MI or IS, but they can induce severe complications such as fatal bleeding.[361,362] It is therefore primordial to develop techniques allowing diagnosis of early thrombus formation. Fibrin-based contrast agents have been developed for *in vivo* thrombus visualization by magnetic resonance imaging (MRI) in animal models,[363–370] and one human study using such approach indicated a potential use of this method in humans.[371] New probes have been developed based on the finding that factor XIIIa ability to cross-link α_2-AP into thrombi declines with time,[372] therefore allowing the detection of newly formed thrombi. These probes are based on the N_{13}QEQVSPLTLLK$_{24}$ sequence of α_2-AP, required for cross-linking to fibrinogen by FXIII. Two probes, A14 and A15, were developed for use in near-infrared fluorescence (NIRF) and MRI, respectively.[373] NIRF probe A15 successfully visualized newly formed intravascular thrombi in mouse models by intravital fluorescence microscopy (IVM),[374,375] although this type of probe might not be useful in human studies due to the limited penetration depth of IVM. MRI techniques using contrast agents related to A14 have now been optimized in mouse models of thrombosis.[376–378] These peptides may provide useful future tools for potential early diagnosis of thrombotic events in humans, and for the study of the relevance of FXIII to thrombosis *in vivo*.

CONCLUDING REMARKS

In more than six decades of FXIII research, a great deal has been learnt about this clotting factor. We know that FXIIIa stabilizes the fibrin clot by the formation of covalent isopeptide bonds. The gene and protein structures of the catalytic subunit have been deciphered, and we know that both FXIII subunits are highly polymorphic. FXIII deficiency is associated with severe bleeding, poor wound healing, and pregnancy loss. Yet, FXIII continues to intrigue the scientific community and many novel aspects of FXIII physiology and pathology are continuously being discovered in new studies.

We are only recently beginning to understand the molecular mechanisms involved in the interaction of FXIII with its main substrate, fibrin, which not only acts as a substrate but also regulates FXIII activation. FXIII interacts with both fibrin α- and γ-chains and recent studies have focused on elucidating the relative roles of these two interactions in FXIII activation and function. The fibrin clot has a remarkable elasticity, and the role of α- and γ-chain cross-linking in the regulation of this aspect of fibrin formation is beginning to be understood. The molecular structure of FXIII has only been partly characterized. While the detailed structure of FXIII-A is known, the structure of FXIII-B remains to be discovered at atomic level. Also the structure of the tetramer complex is poorly described and the mechanism by which the FXIII-A_2B_2 zymogen is secreted remains to be fully elucidated.

One of the main features of the FXIII subunits is their heterogeneity, which has lead to major discoveries about the role of FXIII in disease. Common genetic variants of FXIII have been discovered, which are functional and associate with atherothrombotic disease. The role of FXIII in thrombosis is however still controversial and the mechanisms that are involved remain to be fully elucidated.

It has been known for some time that congenital deficiency of FXIII, with FXIII levels of <5%, leads to a severe bleeding disorder. However, recent findings of acquired deficiency indicate that also moderately decreased levels associate with a risk for bleeding, suggesting that the association between FXIII and bleeding is not a threshold relationship but could be more gradual. While FXIII-A deficiencies have been described more extensively, recent studies have also found increasing evidence for FXIII-B deficiencies. FXIII deficiency may currently be underdiagnosed as routine coagulation screening assays do not readily detect it and specific assays need to be performed for accurate diagnosis.

While many of the features of FXIII have been detailed, others are still elusive and remain to be discovered. The intriguing possibilities of developing new diagnostic tools based on FXIII and those of designing new drugs that modulate FXIII function for the treatment of disease are a major motivator for such future studies of this remarkable clotting factor.

CHAPTER

18 Antithrombin and the Serpin Family

SUSAN C. BOCK

ANTITHROMBIN III

Overview

Antithrombin III (ATIII) is a plasma proteinase inhibitor that inactivates thrombin and the enzymes responsible for the generation of thrombin. This combination of properties makes ATIII a very powerful and important endogenous anticoagulant molecule and explains why patients with even modest ATIII deficiencies experience clinical thrombosis. The anticoagulant activity of pharmaceutical heparins derive from their ability to potentiate the inhibitory activity of ATIII by mechanisms that are similar to physiologic activation of ATIII by vessel wall heparan sulfate proteoglycans (HSPGs). In addition to its well-known anticoagulant activity, ATIII also has anti-inflammatory, antiproliferative, antiangiogenic, and antiviral properties that are related to its ability to block noncoagulant as well as coagulant functions of thrombin and to its ability to assume a variety of protein conformations.

Biochemistry

The plasma concentration of human ATIII[1] is about 2.4 μM (i.e., 140 μg/mL).[2] It circulates as two glycoforms: the predominant ATIII-α glycoform accounts for more than 90% of the ATIII in plasma, whereas the minor ATIII-β variant represents <10% of ATIII concentration.[3] Both isoforms have an identical polypeptide backbone, for which the complete amino acid sequence is known.[4,5] Disulfide bonds link cysteines 8 with 128, 21 with 95, and 247 with 430.[5] The major α-ATIII isoform is modified with four identical sialylated, biantennary complex oligosaccharides on asparagines 96, 135, 155, and 192,[6,7] and these account for 15% of the total mass of 58,000 Da. The minor β-ATIII isoform is not glycosylated on asparagine135, and some of its properties are distinct from those of the α-isoform, as discussed in the section on β-antithrombin. Both ATIII isoforms adopt several different protein conformations, which have distinct physical and functional properties. Crystal structures are available for several conformations and have considerably advanced the understanding of ATIII mechanism and regulation.[8–14]

The enzymes that are targets of ATIII inhibitory activity mediate blood coagulation, platelet activation, protease-activated receptor (PAR) signaling, and cell proliferation (see FIGURE 18.1). The name "antithrombin" is somewhat misleading because it suggests that ATIII is primarily an inhibitor of thrombin, when in fact, it has broad inhibitory activity for many different factors in the coagulation cascade. ATIII serves as an important regulator of hemostasis and thrombosis at several levels by blocking: (a) thrombin-mediated fibrin clot formation, (b) common pathway factor Xa (FXa)-mediated thrombin generation, and (c) coagulation factors that are higher up in the intrinsic and extrinsic pathways (factors IXa, XIa, XIIa [and its fragments], and plasma kallikrein [high molecular weight kininogen] and factor VIIa–tissue factor [TF]). ATIII inhibition of thrombin also serves to regulate its noncoagulant functions that mediate platelet activation and vascular cell signaling and proliferation (FIGURE 18.1).

Serpin Inhibition Mechanism

ATIII exhibits sequence, structural, and functional homology to members of the serpin (*ser*ine *p*roteinase *in*hibitor) gene family.[5,15] Many different serpins are present in blood and contribute to the regulation of the coagulation (ATIII), vascular remodeling (heparin cofactor II [HcII]), complement (C1 inhibitor), fibrinolytic (plasminogen activator inhibitor-1 and α_2-antiplasmin), and inflammatory (α_1-antitrypsin [α_1-proteinase inhibitor]) pathways. Serpins inhibit their target enzymes *via* a suicide-substrate inhibition mechanism that requires full function of the target proteinase catalytic apparatus and involves the formation of a covalent complex between the enzyme active site serine and the serpin.[16] Serpins are globular molecules with protruding reactive center loops (RCLs) containing substrate-like sequences that serve as "bait" for their target enzymes (FIGURE 18.2A). Inhibitory complex formation begins when a target enzyme cleaves the scissile P1–P1′ bond (nomenclature of Schechter and Berger[17]) of the RCL. This generates an acyl–enzyme complex in which the P1 residue is covalently linked to the target proteinase active site serine, and in which the polypeptides generated by reactive loop cleavage become mobile and are rearranged.[18,19] The P1-containing polypeptide incorporates as strand 4A in central β-sheet A of the serpin, translocating the covalently bound target enzyme approximately 70 Å to the opposite pole of the inhibitor.[20] Structures of the canonical serpin α_1-antitrypsin in inhibitory complexes with trypsin[21] and elastase[22] (FIGURE 18.2B) show that inhibitory complex formation results from critical protein conformational changes in both the inhibitor and the target enzyme. The P1–P1′ bond of the RCL is cleaved by the target enzyme, which promotes a large-scale protein conformational change, wherein the stressed, five-stranded A-sheet metastable conformation relaxes into a hyperstable, six-stranded A-sheet conformation in which the acylated enzyme is translocated to the opposite pole of the serpin. The translocated target enzyme molecule is crushed against the hyperstable serpin molecule in such a way that distortion of catalytic triad geometry prevents deacylation and regeneration of active proteinase.

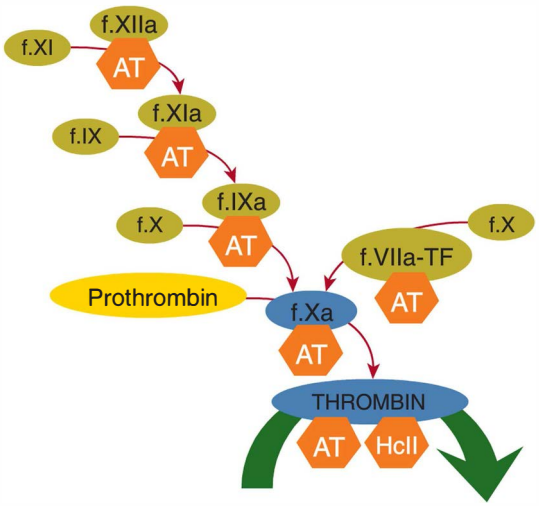

FIGURE 18.1 ATIII and HcII inhibition of coagulation pathway enzymes. ATIII inhibits coagulation factors in the intrinsic, extrinsic, and common pathways. ATIII and HcII inhibit thrombin, which has coagulant and noncoagulant functions.

Heparin Cofactor Activation of Antithrombin III

ATIII exhibits the general serpin structural and mechanical features described above, but it is somewhat unusual in being a considerably less efficient inhibitor than typical members of this family. Whereas rate constants for target proteinase inhibition by most serpins are in the 10^6 to 10^7 M^{-1} sec^{-1} range, the values for ATIII inhibition of its target enzymes are approximately three orders of magnitude lower. In contrast to other serpins, which have fully exposed RCLs, native ATIII circulates in a conformation in which the amino-terminal end of its RCL is partially inserted into its central β-sheet A[12,14] (see P14 residue S380 of *orange* RCLs of native and intermediate ATIII in panels a and b of FIGURE 18.3). RCL insertion was originally thought to reduce ATIII inhibition rates by limiting target enzyme access to the arginine393 P1–P1′ scissile bond (*blue* sphere on *orange* RCL).[23] However, it is now appreciated that native conformation presentation of an exosite (*cyan* surface under *orange* RCL in FIGURE 18.3), which comprises elements that positively and negatively influence interactions with factors Xa and IXa, contributes substantially to reduced ATIII inhibition rates in the absence of cofactor heparin.[24,25]

Heparin and HSPGs containing a very specific pentasaccharide sequence serve as pharmaceutical and physiologic cofactors for ATIII and activate it to achieve inhibition rates comparable to those that most other serpins are capable of without cofactors. The specific pentasaccharide sequence[26,27] that mediates high-affinity binding and activation of ATIII has the structure illustrated in FIGURE 18.4. This pentasaccharide is present in the approximately 30% of pharmaceutical heparin molecules having anticoagulant activity[28] and in vascular wall and matrix HSPGs, which are endogenous ATIII receptors and activators.[29,30]

ATIII thrombin, FXa, and FIXa inhibition rates are accelerated up to several thousand-fold by a combination of heparin-dependent conformational change and bridging mechanisms. The relative importance of the conformational change and approximation mechanisms varies with the target enzyme.

A bridging effect is the most important factor in the activation of thrombin inhibition. Thrombin inhibition is accelerated just twofold by pentasaccharide, whereas pentasaccharide-containing heparin chains of >18 sugar units in length accelerate the rate of inhibitory complex formation by more than 1,000-fold, using an approximation mechanism wherein different regions of the same extended heparin chain bind to the pentasaccharide-binding site on ATIII and to anion-binding exosite II on thrombin.[31,32]

In contrast, an allosteric induced fit conformational change mechanism plays an important role in the acceleration of ATIII FXa and FIXa inhibition by heparin. Pentasaccharide alone accelerates rates of FXa and FIXa inhibitory complex formation by approximately 300-fold.[28,33,34] In the presence of Ca^{2+}, full-length heparin produces further inhibition rate increases, revealing that in addition to the primary conformational change-based mechanism of FXa and FIXa activation, there are also template contributions to full-length heparin cofactor-mediated inhibition of these targets.[33–35] The FXa/FIXa exosite has been mapped to a region of β-sheet C (*cyan* in FIGURE 18.3) located under the RCL loop (*orange* in FIGURE 18.3). The protein conformation of the exosite as it is presented in native ATIII is unfavorable for interactions with the target enzymes. However, cofactor binding to the heparin-binding site of ATIII induces long-range allosteric conformational changes that expose exosite features that promote recognition and interaction with factors Xa and IXa and minimize repulsive interactions that were present in the native conformation exosite.[24,25,36,37]

As illustrated in FIGURE 18.3, the ATIII pentasaccharide-binding site is located at the junction of the *N*-terminal polypeptide (*ruby*) with helices A (*light yellow*) and D (*pink*), some 30 Å distant from the RCL (*orange*). The pentasaccharide is drawn in stick representation with *blue* carbon, *red* oxygen, *yellow* sulfur, and *dark blue* nitrogen atoms. Crystal structures of AT*H5 complexes[8,9,12] allowed direct identification of ATIII surface residues that contact the cofactor and largely confirmed heparin-binding site residue assignments previously made on the basis of early chemical modification studies and the analysis of naturally occurring, thrombosis patient ATIII mutants with heparin-binding defects. Detailed information about the roles of specific residues and their quantitative contributions to the binding of the heparins and to the stabilization of the high-affinity AT*H complexes have more recently become available from investigations of recombinant mutant ATIIIs.

Heparin binding to and activation of ATIII has been described in terms of the two-step, three-state mechanism presented in FIGURE 18.5.[38] An initial weak binding complex, AT–H, forms first. Then, in a second step, a protein conformational change converts the AT–H intermediate to the activated, high-affinity AT*H complex that is competent for rapid FXa and FIXa inhibition. The overall affinity (K_d) of antithrombin for heparin results from the combined effects of the K_1 binding and k_{+2} and k_{-2} rate constants defined in the two-step mechanism. K_1 represents the dissociation equilibrium constant for formation of the initial weak binding complex, AT–H. k_{+2} measures the rate for

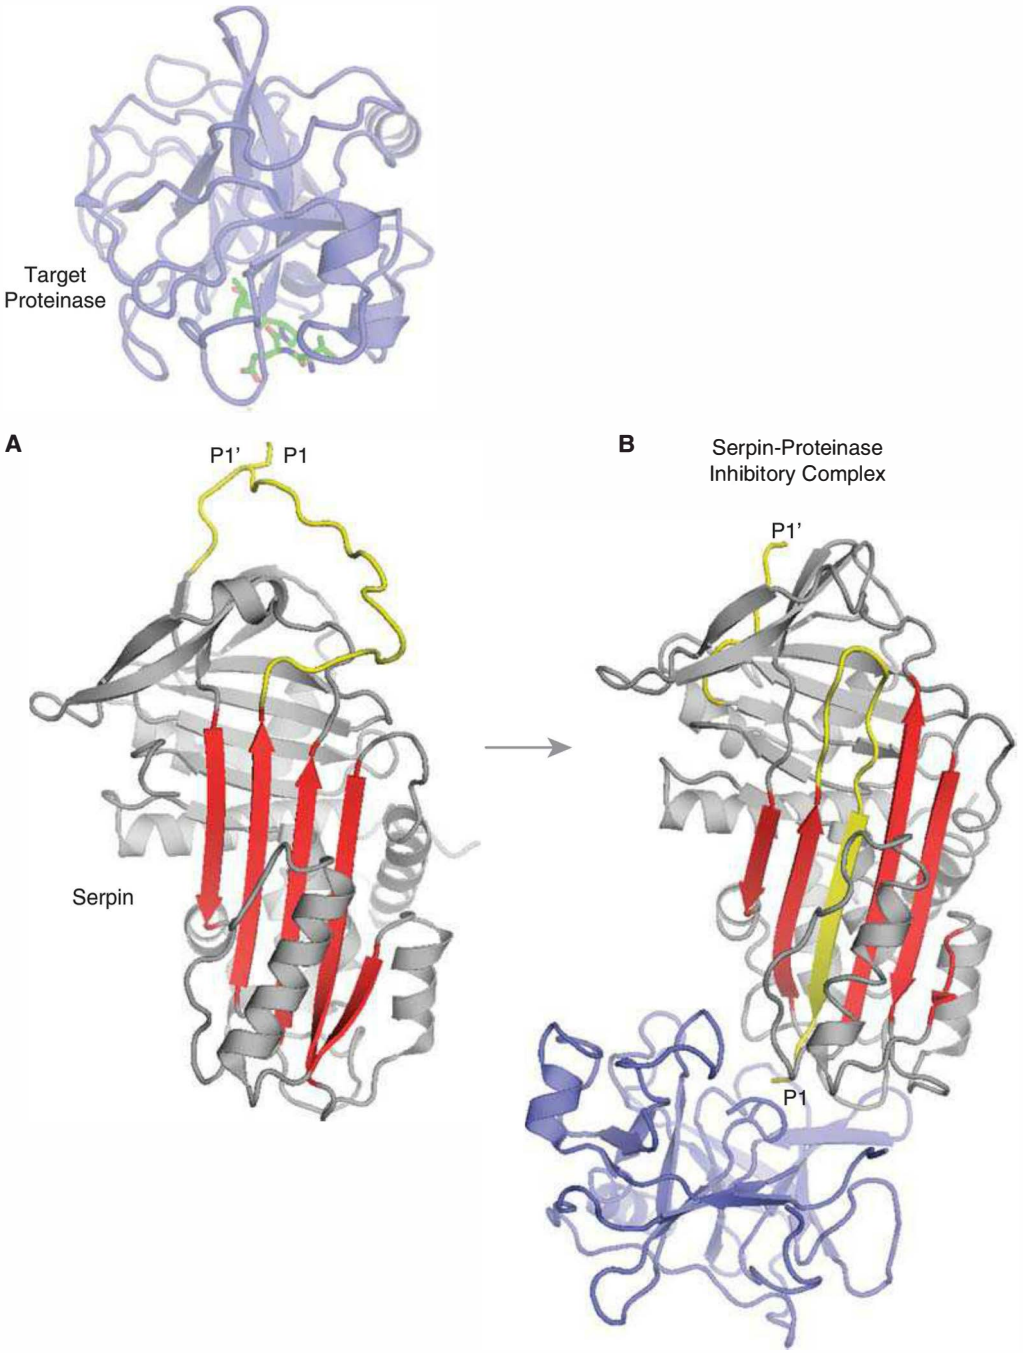

FIGURE 18.2 Serpin inhibition mechanism. **A**: The native serpin has a five-stranded central β-sheet A (*red*) and an exposed RCL (*yellow*). A substrate-like sequence in the RCL is recognized by a target enzyme (*blue*), which initiates cleavage of the P1–P1′ scissile bond. **B**: Formation of an inhibitory complex between the serpin and target proteinase involves (a) recognition and cleavage of the P1–P1′ peptide bond in the RCL polypeptide, (b) formation of a covalent acyl linkage between the serpin P1 residue and the enzyme active site serine, (c) expansion of the serpin central β-sheet by incorporation of the cleaved RCL polypeptide as a 6th strand, (d) translocation of the P1 residue and covalently bound enzyme from the north to the south pole of the serpin molecule, and (e) deformation of active site geometry in the translocated proteinase, which prevents deacylation and regeneration of active enzyme. Drawings were generated from native α1-proteinase inhibitor (1HP7.pdb), pancreatic elastase (1H9L.pdb), and covalent α1-PI–PPE covalent complex (2D26.pdb) structures using PyMol.

Drawings were generated from the indicated pdb files using PyMol. *Color coding*: β-sheet A is *slate blue* and the RCL is *orange*. P1 Arg-393 and P14 Ser-380 residues of the RCL are indicated by a *marine blue* sphere and a *marine blue* side chain, respectively. The β-sheet C region comprising the ATIII exosite for factors IXa and Xa is *cyan*. Structural elements forming the heparin-binding site are drawn in shades of reds and yellow: helix D *pink*; helix P *magenta*; *N*-terminal polypeptide *ruby*; *C*-terminal helix-D extension polypeptide *red*; helix A *light yellow*. Side chains of basic residues of the heparin-binding site are shown as *green-element* sticks. Pentasaccharide is drawn with *blue-element* sticks.

(Continued on page 290)

conformational conversion of initial weak AT–H complex to the high-affinity AT*H complex. Finally, k_{-2} represents the reverse rate of the conformational change (i.e., the stability of the AT*H complex). The extent to which individual ATIII residues and pentasaccharide components contribute to each of the above steps was determined by measuring the binding equilibrium and kinetic constant values for ATIII mutants and truncated pentasaccharides and by comparing them to those of ATIII and pentasaccharide controls.

K_1 analysis showed that initial recognition and low-affinity binding of the pentasaccharide to native ATIII is mediated by its DEF nonreducing end (see FIGURE 18.4), which interacts with K125 from helix D and K11 in the *N*-terminal polypeptide.[39–43] Side chains of the two basic residues that participate in the initial binding step are drawn and labeled in the native structure of FIGURE 18.3A.

The weak binding interaction of the first step leads to conformational adjustments in both the pentasaccharide and the antithrombin molecules. Pentasaccharide DEF complementarity with ATIII is enhanced and creates a complementary secondary site for binding a preferred conformer of the GH disaccharide.[40,41] On the antithrombin side, the protein conformational change converting AT–H to AT*H requires K114, K125, and F122,[39,44,45] which make the largest contributions to k_{+2} and mediate the formation of a new helix P (*magenta* in FIGURE 18.3) when pentasaccharide is bound. The activated AT*H complex that forms is stabilized by interactions requiring F122, R129, and, especially, K114, as evidenced by large increases in k_{-2} when these residues are mutated.[39,44,45] Side chains of basic residues that participate in the second binding step leading to further increases in heparin affinity, and ultimately long-distance conformational changes that mediate exosite presentation, are drawn and labeled in the intermediate structure of FIGURE 18.3B.[39–43]

Helix-D elongation (see *red* polypeptide at the *C*-terminal [top] end of helix D [*pink*] in FIGURE 18.3) also contributes to increased affinity for heparin and allosteric activation of FXa inhibition. ATIII mutants in which helix-D elongation is inhibited by deletion(s)[46] or by proline introduction[47] in the elongated helix-D region exhibit decreased pentasaccharide- and heparin-binding affinities and cannot be fully activated for FXa inhibition. Conversely, replacement of helix-D residue Y131 with a leucine produces 30-fold activation of FXa inhibition in the *absence* of cofactor and increased affinity for heparins.[48] Thus, the rotation of helix-D residue Y131 (compare positions of *yellow* Y131 side chain in panels a to d of FIGURE 18.3), caused by occupancy of the heparin-binding site or by Y131 phenol side chain substitution with smaller, nonphenyl groups, contributes to allosteric activation of ATIII by promoting consolidation of the hydrophobic core underlying central β-sheet A and long-range protein conformational changes that are associated with rearrangement of bonding networks formed by residues in the A-sheet, the hF arm, and the reactive loop polypeptide,[9,49] and more favorable presentation of the exosites for factors Xa and IXa recognition. FIGURE 18.3D shows the crystal structure for the encounter complex of S195A FIXa (*green* heavy chain, *pink* light chain) with H5-activated ATIII. Note that pentasaccharide binding has induced activating protein conformational changes that elongate helix-D and rotate tyrosine-131 to promote closure of central β-sheet A, P14 S380A expulsion, and favorable interactions of the exosite surface and key residue Y253[36,50] with arginine-150 of FIXa, and P1 arginine393 with the S195A-FXa "catalytic" triad.[10]

The K_1 binding and k_{+2} and k_{-2} rate constants from the two-step mechanism of FIGURE 18.5 together determine the overall affinity of the ATIII–pentasaccharide interaction. At physiologic pH and at ionic strength, the K_d for binding of the major α-ATIII isoform of human plasma to pentasaccharide and longer chain high-affinity (i.e., pentasaccharide-containing) heparin molecules are approximately 50 and 20 nM, respectively, as determined by both binding equilibrium and binding kinetic measurements.[51] Measurements of the free energy of binding with pentasaccharide for mutants of key heparin-binding site residues have determined that lysine114 and phenylalanine122 make the greatest contributions to the binding energy.[39,45] Lysine125 and arginine129 also make significant contributions,[42,44] whereas lysine11 and arginines13 and 47 make only small contributions.[43,52] Analysis of binding energy losses across the mutant series also indicates that cooperative interactions between combinations of the previously described residues contribute to high-affinity cofactor binding.[53]

The binding of pentasaccharide and ATIII is mediated by ionic as well as by nonionic interactions. From the salt dependence of the K_d, it has been determined that ionic interactions of the pentasaccharide and the six basic residues on ATIII are responsible for approximately 40% of the free energy of binding.[28,32,39,42–44,52] Nonionic interactions (i.e., hydrogen bonds and van der Waals and hydrophobic interactions) contribute approximately 60% of the binding free energy, with centrally

(Continued) Conformational changes induced by H5 binding to antithrombin can be visualized by comparing ***panels a, b,*** *and* ***c:***

Native ATIII (a) is a poor inhibitor due to suboptimal presentation of FXa/FIXa exosites (*cyan*) and the presence of repulsive sites in the surface surrounding the RCL (*orange*). Heparin allosterically activates ATIII by binding to site that is on the other side of the molecule. The cofactor initially binds to K11 and K125 of the native conformation (*green side chains* in **panel a**). Induced-fit conformational changes in *both* the H5 and ATIII molecules promote K114, R13, R46, R47, and R129 interactions with the cofactor and the formation of helix P (*magenta*) (see **panel b**). These binding interactions extend helix D at its *C*-terminal end (*red*), which causes tyrosine-131 rotation (compare positions of yellow Y131 side chain in **panels a, b,** and **c**). Exposure of buried Y131 ring leads to consolidation of the serpin core and long-distance changes in the electrostatics and H-bond network of the surface that underlies the RCL. The ATIII exosite for FXa and FIXa (*cyan*) is rearranged in a way that promotes favorable interactions and alleviates negative interactions with these target enzymes. See chapter text for greater detail.

Structure of encounter complex of S195A-FIXa with H5-activated ATIII:

FIXa heavy chain is *green* and light chain is *pink*. Pentasaccharide binding has induced activating protein conformational changes that elongate helix D and rotate tyrosine-131 to promote closure of central β-sheet A, P14 S380A expulsion, and favorable interactions of the exosite surface and key residue Y253 (*cyan* side chain) with R150 (*blue* side chain) of FIXa, and P1 arginine393 (*blue* sphere) with the S195A-FXa "catalytic" triad.

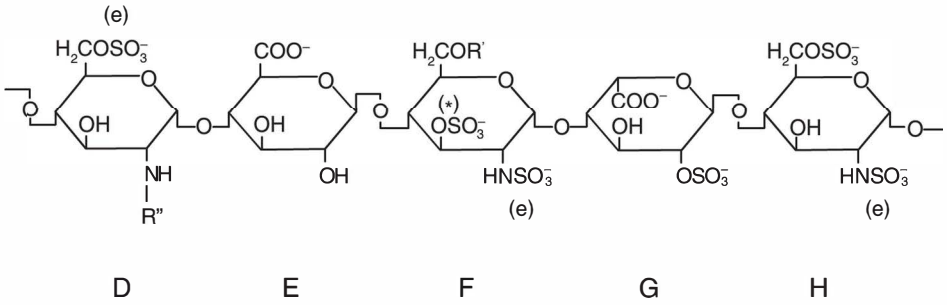

FIGURE 18.4 Structure of the heparin pentasaccharide that binds ATIII with high affinity and activates it for efficient target proteinase inhibition. Structural variants are indicated by R′ (–H or $–SO_3^-$) and R″ ($–SO_3^-$ and $–COCH_3$). The 3-*O*-sulfate group marked by an *asterisk* is unique to the antithrombin-binding region of the heparin molecule. In addition, the three sulfate groups indicated by (e) are essential to the high-affinity binding of antithrombin. (Modified from Tollefsen, DM, *Arterioscler Thromb Vasc Biol* 2007;27:456, with permission.)

located phenylalanine122 being responsible for a substantial share by positioning R47 and K114 for extensive contact with the cofactor and bridging structural elements involved in forming and stabilizing the high-affinity conformation.[45]

Endogenous Activation of Antithrombin III

As previously noted, native conformation ATIII molecules circulating in the blood have limited inhibitory activity. They become activated, however, upon binding to vessel wall $HSPG^{act}$ molecules (3-*O*-sulfated pentasaccharide-bearing anticoagulantly active HSPGs), which serve as the physiologic cofactor of ATIII. $HSPG^{act}$ is present on vascular endothelium and in the underlying matrix and serves to localize and concentrate activated antithrombin on and in the vessel wall. It is generally believed that activated ATIII molecules bound to vascular surface $HSPG^{act}$ receptors contribute substantively to the anticoagulant and antithrombotic properties of the endothelium by inhibiting free thrombin, FXa, and other activated coagulation-factor molecules that are generated by membrane-bound activation complexes and released into the diffusion layer at the blood vessel–wall interface.

Physiologic activation of ATIII by a vascular component was initially investigated in a rat hindlimb quarters model perfused with ATIII and thrombin. A tightly bound, heparinase-sensitive component accelerated the rate of thrombin–antithrombin complex formation 15- to 19-fold.[30] Further studies with normal versus mast cell–deficient mice established that the accelerating vascular component was $HSPG^{act}$ rather than a mast cell–derived heparin species.[54] This anticoagulantly active $HSPG^{act}$ species constitutes about 5% of the total HSPG associated with rat microvascular endothelial cells.[55] The integral membrane proteins ryudocan and syndecan serve as core proteins for both $HSPG^{act}$ and $HSPG^{inact}$ (anticoagulantly *in*active HSPG).[56] Ryudocan and syndecan have, respectively, three and five extracellular serine attachment sites that are posttranslationally modified with glycosaminoglycans (GAGs) composed of alternating *N*-acetylglucosamine and glucuronic acid/iduronic acid residues. The copolymer is further modified by multiple sulfation reactions to generate heparan sulfate chains with regions of varying structure. The presence of chains bearing pentasaccharide sequence(s) with essential 3-*O*-sulfation (See FIGURE 18.4) confers $HSPG^{act}$ status on a small subset of HSPG molecules.

The anatomic localization of $HSPG^{act}$ has been studied using immunohistochemistry and radiolabeled ATIII perfusion techniques. ATIII localization was investigated using immunohistochemistry techniques in biopsies of normal human hearts before transplantation.[57] Venous endothelium, but not capillary endothelium, stained positively for ATIII. ATIII was also present around smooth muscle cells and around intima of small arteries and arterioles, but not around large arteries, in apparent contradiction to the results of subsequent studies in which normal rat aorta was perfused with ^{125}I-labeled ATIII. These perfusion studies[29] demonstrated the presence of ATIII-binding $HSPG^{act}$ on and under the aortic endothelium. Small amounts of $HSPG^{act}$ (1%) were observed on the luminal side of aortic endothelial cells, whereas the subendothelial basement membrane and extracellular matrix on the abluminal side of the endothelium contained much greater amounts of ATIII-binding $HSPG^{act}$. The observed distribution suggests that luminal $HSPG^{act}$ may provide a basal level of activated ATIII for scavenger inhibition of activated coagulation enzymes exposed to the endothelium, and that these basal levels may be dramatically increased in injured regions following endothelial damage and liberation of the larger pool of abluminal $HSPG^{act}$ and its associated bound and activated ATIII.

The physiologic importance of ATIII binding to endogenous vascular surface $HSPG^{act}$ is supported by the occurrence of lethal thrombosis in mice homozygous for an ATIII mutation that reduces binding to heparin/HSPG.[58] Similarly, thrombosis was prevented in stents coated with the high-affinity, pentasaccharide-containing fraction of heparin (which binds antithrombin) but not in stents coated with low-affinity,

$$AT+H \underset{}{\overset{K_1}{\rightleftharpoons}} AT–H \underset{K_{-2}}{\overset{K_{+2}}{\rightleftharpoons}} AT^*H$$

FIGURE 18.5 Two-step mechanism for heparin binding to and activation of ATIII. AT, antithrombin III; H, heparin; AT–H, initial weak antithrombin–heparin intermediate; K_1, dissociation equilibrium constant for AT–H formation; AT*H, high-affinity antithrombin–heparin complex which is competent for rapid FXa inhibition; k_{+2}, rate of conformational conversion of the weak AT–H intermediate to the high-affinity AT*H complex; k_{-2}, reverse rate of the conformational change.

pentasaccharide-depleted heparin (which does not support ATIII binding).[59] Therefore, antithrombin–HSPG interactions play a crucial role in maintaining circulatory system patency. A previous contrary report based on the nonthrombotic phenotype of mice deficient for 3-OST-1[60] may reflect redundancy of enzymes that mediate 3-*O*-sulfation of the pentasaccharide sequence of HSPG.[61,62]

Finally, in addition to vascular HSPGs, the endothelial cell thrombin receptor thrombomodulin can bind ATIII and enhance its inhibition of receptor-bound thrombin by a factor of approximately 8.[63] This thrombin-specific effect is mediated by a highly sulfated chondroitin sulfate chain on thrombomodulin,[64,65] which interacts with both thrombin (at exosite II,[66]) and with ATIII. Chondroitin sulfate occupancy of exosite II of anticoagulant thrombin (i.e., thrombomodulin-bound thrombin) blocks heparin binding to the enzyme and precludes heparin/ATIII inhibition at the very rapid rates observed for procoagulant thrombin.[67]

Pharmacologic Activation of Antithrombin III

The clinical use of heparin as an anticoagulant began more than 60 years ago.[68] The name heparin derives from the fact that the anticoagulant was originally extracted from liver; however, commercial preparations are now usually obtained from pig intestinal mucosa or bovine lung, which are good sources of mast cells. Mast cell heparin proteoglycan is composed of a serglycin core protein modified with 60 to 100,000 Da heparin sulfate GAG chains.[69] The heparin proteoglycan polysaccharide chains are intracellularly cleaved to form smaller fragments (7,000 to 25,000 Da) that are present in pharmaceutical heparin. Standard pharmaceutical heparin is a heterogeneous mixture of polysaccharide molecules (average 15,000 to 18,000 Da). In addition to a high degree of size/length heterogeneity, there is also a significant amount of compositional heterogeneity. Typically, only one-third of the molecules in a standard pharmaceutical heparin preparation bear the ATIII-binding pentasaccharide sequence and exhibit anticoagulant activity.

Unfractionated heparin is used widely in clinical settings. It is given to prevent and treat venous thrombosis and for the management of arterial disease. Intravenous administration of heparin doses that prolong the activated partial thromboplastin time (aPTT) to 1.5 to 2.5 times control values is highly effective for the prevention and treatment of venous thrombosis.[70] Heparin is also widely utilized in extracorporeal circulation, for flushing indwelling catheters, for coating biomaterials and medical devices, and in many other hospital procedures. However, there are major drawbacks associated with the use of unfractionated heparin, including increased risk of hemorrhage and thrombocytopenia, variable patient response, and prolonged hospitalization because of the need for anticoagulant monitoring and dosing adjustments. In addition to inhibiting clotting enzyme function, heparin also interferes with platelet function, which contributes to its hemorrhagic side effects. On the basis of studies with size-fractionated heparins, which indicated that the high molecular weight fraction (average 20,000 Da) was considerably more active at inducing platelet aggregation than was the low molecular weight fraction (average 7,000 Da),[71] low molecular weight heparins (LMWHs) were suggested as a potentially advantageous alternative to standard heparin.[72]

Several LMWHs have been developed and evaluated in clinical trials and are now frequently used in hospital and outpatient settings. LMWHs are derived from unfractionated heparin by enzymatic or chemical cleavage. Their range of fragment size is from 1,800 to 12,000 Da, with an average of around 5,000 Da. As a result of their small fragment size and the cleavage into smaller pieces of most chains that were long enough (>18 sugars) to approximate (bridge) ATIII and thrombin, LMWHs preferentially inhibit factor Xa and have antifactor Xa to antithrombin ratios of 2:1 to 4:1 (vs. 1:1 for standard heparin). Compared with standard heparin, LMWHs have decreased affinity for endothelial cells[73,74] and exhibit reduced nonspecific binding to heparin-binding proteins.[75] These properties improve bioavailability and produce a more predictable dose response. The improved pharmacokinetic profile permits LMWHs to be administered subcutaneously once or twice daily on a weight-adjusted basis without laboratory monitoring. These attributes are an important advantage over standard heparin, which has a highly variable patient response that necessitates frequent laboratory monitoring, dose adjustment, and prolonged hospitalization. Clinical trials have established that for eligible patients with deep vein thrombosis, outpatient, unmonitored, subcutaneous, weight-adjusted LMWH is as effective and as safe as inpatient treatment with intravenous, unfractionated heparin and affords considerable cost reductions.[76]

A synthetic pentasaccharide, fondaparinux, has also been developed as an anticoagulant pharmaceutical.[77] Fondaparinux accelerates ATIII inhibition of FXa but has no activity against thrombin. It is believed that selective FXa inhibition may be advantageous because it targets amplification steps that generate large numbers of thrombin molecules through the common and intrinsic pathways while still permitting the trace thrombin that does form to facilitate hemostasis. The half-life of fondaparinux is approximately 17 hours and is dose independent, which allows for once-daily subcutaneous administration without monitoring of coagulation parameters. Fondaparinux has been approved for thromboprophylaxis after major orthopedic surgery. A concern with the use of fondaparinux is the lack of an antidote. Protamine sulfate is used to reverse the anticoagulant effects of unfractionated and LMWHs, but does not neutralize fondaparinux. However, a recombinant ATIII has recently been reported to reverse fondaparinux overdosing in a mouse model.[78] The antithrombin antidote to fondaparinux has (a) increased affinity for pentasaccharide in order to more effectively compete for fondaparinux binding and (b) a proline insertion in its RCL, in order to prevent formation of inhibitory complexes with coagulation enzymes, and exacerbation of bleeding.

Antithrombin III Inhibition of Target Enzymes Associated with Activating Complexes and Fibrin Clots

Freely circulating and purified thrombin and factor Xa are readily inhibited by ATIII and ATIII/heparin. However, when associated with the surface-activating complexes that generated the thrombin and FXa or with platelets or with fibrin clots, these target enzymes are resistant to ATIII and ATIII/heparin inhibition. Factor Xa in prothrombinase complexes formed by its addition to platelets or reconstitution with factor V, phospholipid, and

calcium is blocked from inhibition by ATIII.[79–82] Meizothrombin, a fragment-2–containing, fibrinogen-clotting intermediate in the generation of thrombin from prothrombin, is less susceptible to inhibition by ATIII and heparin than is thrombin. This effect is mediated by fragment-2 of prothrombin,[83] which interacts with the heparin-binding site of thrombin. The gradient of fragment-2 around a clot contributes to the reduction in ATIII inhibition of thrombin in the immediate vicinity of the clot and allows for more rapid thrombin inhibition at greater distances from the site of injury where fragment-2 concentrations are reduced.[83] Platelet-bound thrombin is protected from inactivation by ATIII/heparin by platelet GPIbα occupancy of its exosite II heparin-binding site.[84]

Clot-bound thrombin and thrombin bound to soluble fibrin-degradation peptides generated by tissue plasminogen activator–induced clot lysis are refractive to inhibition by ATIII/heparin.[85,86] Fibrin blocks ATIII/heparin thrombin inhibition by prior formation of ternary thrombin–fibrin–heparin complexes in which thrombin exosite I interacts with fibrin and thrombin exosite II binds the heparin molecule of the ternary complex (which is also connected to the ternary complex through the heparin-binding site of fibrin). Therefore, thrombin in the ternary complex is resistant to ATIII/heparin inhibition because the ATIII/heparin cannot access exosite II, which is occupied by the heparin molecule from the ternary complex.[87] Clot-associated factor Xa is also resistant to inhibition by ATIII/heparin.[88] Therefore, coagulation is difficult to regulate in the immediate microenvironment of a clot because clot-bound factor Xa is able to generate thrombin (and fragment-2—see the preceding discussion) from prothrombin, and, by binding to fibrin, the newly formed thrombin may also evade inactivation by ATIII/heparin.

In contrast to ATIII inhibition of factor Xa and thrombin, which is attenuated in activation complexes, ATIII inhibition of kallikrein and factor VIIa (FVIIa) is potentiated by the association of these intrinsic and extrinsic enzymes with activating surface-bound proteins. In the case of kallikrein, binding of high molecular weight kininogen promotes inhibition by ATIII/heparin through a bridging mechanism that involves binding of ATIII and kallikrein–kininogen to the same heparin molecule.[89] FVIIa also becomes more sensitive to ATIII inhibition when bound to its activating cofactor, TF.[90,91] In this case, increased reactivity of FVIIa with ATIII has been attributed to a conformational change in the enzyme active site that is induced by TF binding.

Antithrombin III as a Scavenger

As discussed in preceding text, native ATIII, HSPG^{act}-bound ATIII, and ATIII/heparin that are formed by administration of the pharmaceutical inhibit "free" factor Xa and "free" thrombin more efficiently than they inhibit factor Xa and thrombin located on activation surfaces and in fibrin clots. Hence, these forms of ATIII may serve as scavengers in the blood and on vascular surfaces and may neutralize thrombin and factor Xa molecules that have escaped from activation complexes and clots. In this capacity, ATIII would serve an important role in blocking coagulation and thrombin noncoagulant functions in uninjured areas, where they are less necessary.

ATIII may also play a role in regulating the low-level coagulation activation that occurs normally in the unperturbed circulation. ATIII regulation of TF-induced coagulation has been studied from several angles, and these investigations collectively suggest that there are multiple points at which ATIII may contribute to the control of coagulation initiation. ATIII inhibits FVIIa–TF complexes formed on OC2008 cells (which express TF and cell-surface GAGs constitutively) in the presence, as well as in the absence, of heparin.[91] ATIII in combination with tissue factor pathway inhibitor (TFPI) was also able to prevent the formation of prothrombinase activity in a model system containing FVIIa–TF, FVIII, FV, FIX, FX, and prothrombin reconstituted on phosphatidyl choline and phosphatidyl serine vesicles. This model procoagulant system contained physiologic concentrations of the listed components, but no heparin or HSPG. TFPI potentiated the action of ATIII by decreasing the rate of prothrombinase formation and by enabling ATIII to effectively scavenge the limited amounts of FIXa and FXa formed in the presence of TFPI.[92] Studies in a different model system reconstituted with zymogen FVII and human brain thromboplastin suggest that ATIII may also contribute to regulation of TF-induced coagulation through its ability, in the presence of heparin, to inhibit the activation of plasma FVII by FXa, thrombin, FIXa, and other proteinases.[93] Therefore, ATIII (in combination with TFPI) appears to play a crucial role in controlling low-level basal activation of the coagulation system that occurs in the normal circulation.

Antithrombin III Clearance

Different conformations and complexes of ATIII are cleared from the circulation by different pathways. High-affinity binding of the native conformation to vessel wall HSPG^{act} mediates its clearance from plasma into noncirculating vascular-associated and extravascular pools.[94,95] As will be discussed in the next section, the β-ATIII isoform clears from plasma 2.5 times faster than the α-ATIII isoform.[96] Thrombin–ATIII (TAT) inhibitory complexes (and, presumably, inhibitory complexes of ATIII with other target enzymes) are rapidly cleared from the circulation by the liver.[97] This clearance mechanism is specific for complexed ATIII, with TAT complexes being eliminated from the plasma many times more rapidly than native and cleaved ATIII.[98] Furthermore, clearance of ATIII inhibitory complexes exhibits competition with the clearance of other serpin complexes, indicating that serpin–enzyme complexes utilize a common clearance pathway.[97–99] The primary receptor for clearance of serpin–enzyme complexes is low-density lipoprotein receptor–related protein (LRP).[99] LRP is expressed by many tissues and cell types and is a prominent receptor in the liver. It interacts with numerous ligands, including serpin–enzyme complexes, and plays a key role in proteinase regulation and lipoprotein metabolism.

β-Antithrombin III

β-ATIII is a naturally occurring glycoform of ATIII that binds to heparin and HSPGs with higher affinity than the predominant ATIII isoform, α-ATIII.[3,51] β-ATIII synthesis is the result of inefficient utilization of the N-X-S–type consensus sequence specifying *N*-glycosylation of asparagine135.[100] Because of partial glycosylation at this site, plasma contains two ATIII glycoforms: α-ATIII, which is glycosylated at all four consensus sequences, and β-ATIII, which is glycosylated at only three consensus sequences (the asparagine135 N-X-S remains unmodified[101]).

β-ATIII binds heparin and pentasaccharide, respectively, six times and three times more tightly than does α-ATIII due to asparagine135 oligosaccharide effects on the formation of the initial AT–H intermediate, its conformational conversion to activated AT*H, and its stabilization of this complex.[51] The enhanced affinity of the β-isoform for heparin and its more rapid clearance from the circulation compared with α-ATIII suggest that β-ATIII, although a minor species in the plasma, may play an important role on the vessel wall.[96] β-ATIII associates 30% to 50% faster with uninjured aorta, and three times faster with deendothelialized aorta, than does α-ATIII, and approximately five times more β-ATIII than α-ATIII was recovered in detergent extracts of intima media from uninjured rabbit aortas.[102] Compared to plasma, a higher proportion of the ATIII in extracts of human organs is β-ATIII.[103] β-ATIII is also more effective than α-ATIII at inhibiting thrombin appearance on the wall of injured aorta.[104] Because it is believed that antithrombin molecules that are bound in an activated conformation to vessel wall HSPGs are crucial for efficient scavenging of activated thrombin and other coagulation factors, β-ATIII may represent a functionally important component in the physiologic regulation of coagulation enzyme activity, despite the fact that it is only a minor component in blood. Furthermore, according to this hypothesis, the apparently low content of β-ATIII (<10%) compared with α-ATIII (>90%) in plasma may actually reflect its increased binding and physiologic consumption on vascular surfaces.

Inherited Antithrombin III Deficiencies and Their Treatment

ATIII is an essential physiologic anticoagulant.[105] Its complete absence is incompatible with life, and its partial deficiency in mice[106] and humans increases the individual's risk for thrombosis. The prevalence of genetic ATIII deficiency in humans is approximately 0.02% to 0.05% (reviewed in Ref.[107]). However, this increases to approximately 5% for patients with a history of thromboembolic disease.[108]

The ATIII gene is composed of seven exons and six introns and spans 13,477 base pairs of genomic DNA[109] in the q23–q25 region of chromosome 1.[110] Genetic ATIII deficiencies, therefore, exhibit an autosomal dominant pattern of inheritance, with functional activity levels of the affected heterozygotes usually ranging from 40% to 60% of normal, and antigen levels varying according to the type of deficiency. Type I ATIII deficiencies result from failure of ATIII synthesis or from defective secretion of ATIII from hepatocytes and exhibit parallel reduction of functional activity and antigen levels to approximately 50% of normal values. Type I deficiencies are caused by a wide variety of mutations, including insertions and deletions, missense mutations, nonsense mutations, and the introduction of cryptic splice sites. Type II ATIII deficiencies are caused by missense mutations and *N*-glycosylation consensus sequence mutations that lead to the production of variant antithrombins with altered functional properties. ATIII antigen levels generally exceed ATIII functional levels in patients with type II deficiencies, and the characterization of numerous type II variant proteins has provided extensive ATIII structure–function information (reviewed in Refs.[107,111,112,113]).

There is great variability in the occurrence and severity of symptomatic thrombosis in individuals with genetic ATIII deficiencies. The onset of thrombotic episodes most often occurs in the third decade, but a considerable number of affected individuals reach old age without thrombotic problems, whereas some infants and children develop thrombosis early in life. Disease severity and age of onset are influenced by properties of the specific defective ATIII allele that is inherited, and by other factors that can decrease or enhance the thrombotic tendency caused by genetic ATIII deficiency. For example, protein C resistance secondary to the factor V_{Leiden} mutation (FV R506Q) has been shown to influence the expression of thrombosis in patients with genetic ATIII deficiencies. In a study of six families that segregated type I and type II ATIII defects and factor V_{Leiden}, the coinheritance of the factor V_{Leiden} allele with the ATIII alleles reduced the age of onset and increased the clinical severity of thrombosis.[114]

Thrombotic episodes in individuals with genetic ATIII deficiencies are mainly confined to the venous system. Common problems include recurrent episodes of deep vein thrombosis, mesenteric thrombosis, and/or pulmonary emboli. Similar to venous thrombosis occurring in persons without ATIII deficiency, precipitating factors in patients with ATIII deficiency include pregnancy, surgery, trauma, and infection. However, many episodes of thrombosis in genetically deficient persons appear to occur spontaneously, without a precipitating event. Pregnancy is a time of increased thrombotic risk in women with genetic ATIII deficiency. In a retrospective study, the incidence of thromboembolic complications during pregnancy in women with congenital ATIII deficiency has been estimated at about 70%. Prophylactic subcutaneous administration of heparin may be considered as soon as the pregnancy has been diagnosed, and supplementation with ATIII concentrates to normalize antithrombin levels during delivery and postpartum is also recommended.[115] As with any genetic disease, patient education is important because it enables the patient to avoid stimuli that are likely to induce thrombosis and to effectively recognize and to seek prompt treatment for thrombotic symptoms when they do occur.

Episodes of acute venous thromboembolism (VTE) in patients who have ATIII deficiency have been successfully managed by heparin alone or heparin in combination with antithrombin concentrates. Administration of ATIII concentrates together with heparin is considered the treatment of choice for patients with known hereditary ATIII deficiency and who present with massive and potentially life-threatening thromboembolic disease.[116] By increasing the plasma antithrombin concentration, it is believed that potential "heparin resistance" secondary to genetically low levels of ATIII can be overcome more readily, and clinical benefit can be achieved more rapidly. However, a retrospective study of Swedish patients with ATIII deficiency suggested that heparin resistance may not actually represent a substantial problem for most of these individuals because administration of heparin alone produced a more than 1.5 times prolongation of the aPTT in at least 90% of patients.[117]

Individuals with ATIII deficiency are at a high risk for postoperative and posttraumatic thrombosis, as well as thromboembolism during pregnancy and after delivery, and antithrombin concentrates have been used in combination with heparin for prophylaxis during surgery, delivery, and postpartum.[118–120] Although there are no randomized clinical trials establishing the efficacy of this approach, the preponderance of favorable outcomes reported in the literature suggests that prophylactic treatment with ATIII concentrates and heparin is helpful.

Prophylactic anticoagulation with vitamin K antagonists is sometimes prescribed for genetically deficient persons who have experienced recurring episodes of thrombosis. In contrast, prophylactic anticoagulation of asymptomatic carriers of ATIII deficiency genes is regarded as unnecessary and is not recommended.[121]

Estrogen-containing contraceptives and postmenopausal replacement therapies should be avoided by women with genetic ATIII deficiencies because estrogen usage has been associated with the development of thrombosis in normal women, as well as in ATIII-deficient females.[122,123] Progestogen-containing contraceptives, on the other hand, do not appear to lower ATIII levels.[124]

Acquired Antithrombin III Deficiencies

Acquired antithrombin deficiencies are encountered more frequently than genetic ATIII deficiencies. Acquired ATIII deficiencies occur in association with many conditions and procedures, including severe sepsis, trauma, burns, malignancies, extracorporeal circulation, and surgery. These disorders have consumptive coagulation and acute inflammatory components. Antithrombin levels decline because of stoichiometric consumption of ATIII during neutralization of activated coagulation enzymes. Additionally, in inflammatory settings, activated leukocytes release neutrophil elastase and matrix metalloproteinases that cleave the reactive loop of ATIII[125,126,127] and induce a functional activity deficiency.

Data from several studies suggest that a decrease in plasma ATIII concentration to below 60% to 70% of normal represents a crucial point in the pathogenesis of venous thrombosis. A study of patients with nephrotic syndrome reported that 8 of 11 patients with antithrombin concentrations of <70% developed thrombosis, whereas only 1 of 37 patients with ATIII concentrations of >70% experienced thrombosis.[128] Finally, in trials of antithrombin concentrate in patients undergoing hip or knee replacement, all patients with nadir ATIII concentrations of <60% developed thrombosis.[129]

ATIII levels decrease profoundly during cardiopulmonary bypass to 40% to 50% of preoperative levels and remain low even after protamine neutralization.[130] Several factors contribute to the development of ATIII deficiency during bypass including (a) hemodilution, (b) ATIII consumption by the formation of inhibitory complexes, and (c) increased systemic neutrophil elastase concentrations and the heparin-mediated elastase inactivation of ATIII.[131]

ATIII deficiency also develops in response to high-dose chemotherapy regimens used to prepare patients with hematopoietic malignancies for bone marrow transplantation (BMT). ATIII levels decline in parallel with albumin and prealbumin levels, suggesting that impaired hepatic synthesis and/or extravascular redistribution contribute to ATIII deficiency in BMT. Nadir ATIII levels typically occur at 2 to 3 weeks following the start of the preparative regimen and are correlated with the development of vascular occlusive disease of the liver, pulmonary dysfunction, and central nervous system dysfunction. Patients who developed multiorgan failure had lower ATIII levels than those who did not develop organ failure or who experienced single-organ failure.[132,133]

Localized ATIII deficiency has been observed in unstable cardiac allografts.[57] Immunohistologic studies on serial biopsies from donor and transplanted organs (for periods of up to a decade) have shown that clinically stable grafts maintain a normal pattern of vascular ATIII reactivity in contrast to grafts that fail. Interestingly, a proportion of late unstable allografts, which have progressed to the stage of losing normal venous and arterial ATIII reactivity and showing evidence of fibrin deposition, may go on to subsequently develop a system of ATIII-reactive capillaries. Appearance of these ATIII-reactive capillaries shifts the prognosis for graft survival from bad to good.

Antithrombin III Concentrates

ATIII concentrates have been produced by the blood plasma fractionation industry since the mid-1970s using heparin-affinity chromatography methods.[134] The manufacturing process also includes a heat treatment step to inactivate viral pathogens. ATIII concentrates are considered safe, and the transmission of HIV, hepatitis B, or non-A non-B hepatitis has not been reported in patient follow-up studies (reviewed in Refs.[119,135]). However, the pasteurization step used to inactivate viruses induces formation of aggregated protein and latent ATIII molecules, which are devoid of anticoagulant activity because of uptake of the RCL as a central 6th strand in β-sheet A. Sixteen to forty percent of the ATIII in five extensively analyzed batches of one antithrombin concentrate existed as inactive, latent molecules.[136] Another study of 23 lots of four different ATIII concentrates produced by four different manufacturers demonstrated the presence of denatured antithrombin in all preparations except in those that had received additional solvent/detergent treatment and further purification steps.[137] This study also found levels of TAT and cleaved antithrombin to be substantially elevated in concentrates relative to normal plasma. TAT increased 20- to 1,600-fold, whereas cleaved ATIII increased 50- to 230-fold. Therefore, elevated TAT and cleaved ATIII levels in patients who have received ATIII concentrates should be interpreted with caution.

In the United States, ATIII concentrates are mainly utilized for patients with genetic ATIII deficiencies, as discussed in a previous section. However, in some European countries and in Japan, ATIII concentrates are additionally administered to patients with acquired antithrombin deficiencies (e.g., disseminated intravascular coagulation, sepsis, trauma, hematopoietic malignancy) and to patients undergoing BMT, orthopedic surgery, and cardiopulmonary bypass and to obstetrics patients.

Although ATIII supplementation improved hemostatic parameters and survival in several animal models of sepsis (reviewed in Ref.[138]), the large double-blind, placebo-controlled, multicenter phase III KyberSept trial of human plasma-derived high-dose ATIII for patients with severe sepsis failed to show any benefit with respect to 28-day all-cause mortality.[139] The design of the KyberSept study did not exclude concomitant heparin, which was received by a large subset of the patients, and in retrospect heparin was speculated to have interfered with potential therapeutic benefits of the antithrombin. In a subsequent analysis, it was noted that for patients without concomitant heparin, 28-day mortality was lower for the antithrombin group compared to the placebo group, and that this trend continued through 90 days, whereas it was not observed with groups receiving heparin.[140]

A recombinant form of human antithrombin (rhAT) has been produced in the milk of transgenic goats.[141] Glycosylation of rhAT differs from that of the human plasma-derived protein,

leading to fourfold higher heparin affinity[141] and more rapid clearance and a shorter *in vivo* half-life than plasma-derived ATIII.[142,143] rhAT was approved in Europe for the prevention of VTE in patients with hereditary antithrombin deficiency in 2006, and the U.S. FDA similarly approved it for the prevention of perioperative and peripartum thromboembolic events in patients with hereditary antithrombin deficiency in 2009.[144]

Anti-Inflammatory Properties of Antithrombin III

ATIII exhibits anti-inflammatory properties that are both independent of, and related to, its ability to inhibit thrombin. Work in endotoxemia and ischemia/reperfusion models attributed ATIII anti-inflammatory effects on leukocyte accumulation, vascular permeability, and TNF-α and iNOS induction to endothelial prostacyclin release.[145–148] Prostacyclin administration mimicked the ATIII-mediated anti-inflammatory effects, whereas indomethacin pretreatment antagonized these responses to ATIII. Anti-inflammatory effects were lost in experiments using chemically modified and recombinant ATIIIs with reduced affinity for heparin, suggesting that anti-inflammatory effects require ATIII interaction with cell-surface HSPGs. ATIII has also been demonstrated to block thrombin-mediated, neutrophil-dependent ischemia-reperfusion damage. Postreperfusion treatment with ATIII attenuated the P selectin–mediated leukocyte recruitment response, and similar results were also observed in an *in vitro* model using human blood neutrophils and cultured endothelial cells.[149]

Direct ATIII effects on inflammatory responses of peripheral blood cells have also been demonstrated. ATIII inhibits chemokine-induced migration of neutrophils, lymphocytes, and monocytes, and, in the absence of chemokines, stimulates their migration.[150–152] In monocytes and endothelial cells, ATIII potently blocks activation of nuclear factor kappa beta (NFκB), a transcription factor involved in immediate early gene activation during inflammation.[153] ATIII-mediated NFκB downregulation also involves binding of ATIII to cell-surface HSPGs, and this interaction has been proposed to interfere with signal transduction leading to NFκB activation.

Therefore, on the basis of the recently described anti-inflammatory and the well-established anticoagulant properties of ATIII, ATIII supplementation has been proposed for clinical reversal of microvascular dysfunction in acute inflammatory disorders such as sepsis. High-dose ATIII failed to improve overall 28-day survival in severe sepsis patients of the KyberSept trial; however, decreased mortality was noted for patients who did *not* receive heparin.[139] It has been suggested that clinical benefit was observed in this subgroup because concomitant systemic heparin did not block the anti-inflammatory effects of ATIII.[151]

Antithrombin III—Antiproliferative and Antiangiogenic Activities

Independent of its anticoagulant and anti-inflammatory properties, ATIII also has antiproliferative and antiangiogenic activities. ATIII inhibits thrombin-induced proliferation of human arterial smooth muscle cells and human mesangial cells *in vitro*[154,155] and is also reported to inhibit rat spleen T-cell proliferation in a thrombin-independent manner.[156]

Several conformations of ATIII lack anticoagulant activity but exhibit antiangiogenic and antitumor growth properties that are of potential physiologic and therapeutic importance. These activities are not present in the native, inhibitory conformation of antithrombin, but are acquired after the protein undergoes structural conversion to cleaved and latent forms, which feature incorporation of the reactive loop polypeptide as strand four of the central A β-sheet.[157,158] A "prelatent" conformation of ATIII, which has undergone only limited conformational change and is still able to bind heparin and inhibit thrombin, also exhibits potent antiangiogenic and tumor inhibition activities.[159,160] Antiangiogenic forms of ATIII block FGF-2 and VEGF ligand-receptor signaling on endothelial cells by competing for binding to the heparan sulfate coreceptor, which then alters endothelial gene expression profiles in a manner that produces overall downregulation of proangiogenic functions and upregulation of antiangiogenic functions.[161,162]

HEPARIN COFACTOR II

Overview

HcII is a plasma serpin with 30% homology to ATIII. Compared with ATIII, there are similarities as well as differences in HcII interactions with coagulation enzymes and GAGs. Like ATIII, HcII inactivates thrombin; but unlike ATIII, it is not a broad-spectrum inhibitor of coagulation enzymes and does not inhibit FXa or other clotting factors. The circulating form of HcII, like the circulating form of ATIII, is an inefficient inhibitor of thrombin. Both are activated more than three orders of magnitude by heparin; however, the structural mechanisms for heparin activation of HcII and ATIII are distinct. Dermatan sulfate, which only minimally activates ATIII, is an efficient activator of HcII. Proposed physiologic roles of HcII include extravascular thrombin inhibition, inflammatory signaling, and thrombin regulation during pregnancy. In contrast to ATIII, HcII deficiency is not strongly associated with venous thrombosis but contributes to the prevention of arterial thrombosis.

Biochemistry and Molecular Genetics

HcII (also known as leuserpin 2 and SERPIN D1) is a 66-kDa glycoprotein with a pI of 4.95 to 5.15.[163] HcII contains approximately 10% carbohydrate, two sulfated tyrosine residues,[164] and three free sulfhydryls. The plasma concentration and plasma half-life of HcII are, respectively, approximately 1.2 μM (?80 μg/mL) and approximately 2.5 days.[165,166] The complete amino acid sequence of the 480-residue mature protein is known from complementary deoxyribonucleic acid analysis.[167,168] The serpin domain is approximately 30% homologous to ATIII and other serpins, uses leucine as its P1 residue, and is preceded by a unique *N*-terminal polypeptide sequence that contains two highly acidic hirudin-like repeats. In contrast to ATIII, which is a broad-spectrum inhibitor of thrombin, factor Xa, and other intrinsic and extrinsic pathway coagulation enzymes, HcII inhibition of clotting pathway enzymes is limited to thrombin (FIGURE 18.1). However, HcII also inhibits cathepsin G[169] and chymotrypsin[170] in accordance with its P1 leucine residue. HcII inhibition of thrombin, but not of chymotrypsin, is potentiated by heparin and dermatan sulfate.[170] HcII–thrombin inhibitory complexes are rapidly cleared by LRP,[99] which also clears ATIII inhibitory

complexes. The HcII gene spans 14 kb of DNA in the q11 region of chromosome 22 and has five exons and four introns.[171]

Target Enzyme Specificity and Mechanism of Glycosaminoglycan Activation

The leucine P1 residue of HcII confers primary specificity for inhibition of cathepsin G and chymotrypsin, which prefer medium-sized nonpolar residues, but not for thrombin, FXa, or related coagulation factors, which cleave arginine-containing substrate sequences. Despite having a nonarginine P1 residue, HcII inhibits thrombin, and this specificity is conferred by a GAG cofactor binding–dependent interaction between two negatively charged hirudin-like sequences in the amino-terminal domain of HcII and thrombin's anion-binding exosite I.

FIGURE 18.6A shows the 2.35-Å structure of native HcII.[172] As in native ATIII (FIGURE 18.3A), the RCL is partially inserted into central β-sheet A. Binding sites for heparin and dermatan sulfate occupy overlapping areas in the helix-D region, and most of the positively charged HcII residues that interact with these GAGs are located in homologous positions to basic residues of the ATIII heparin-binding site (FIGURE 18.3A,B). As

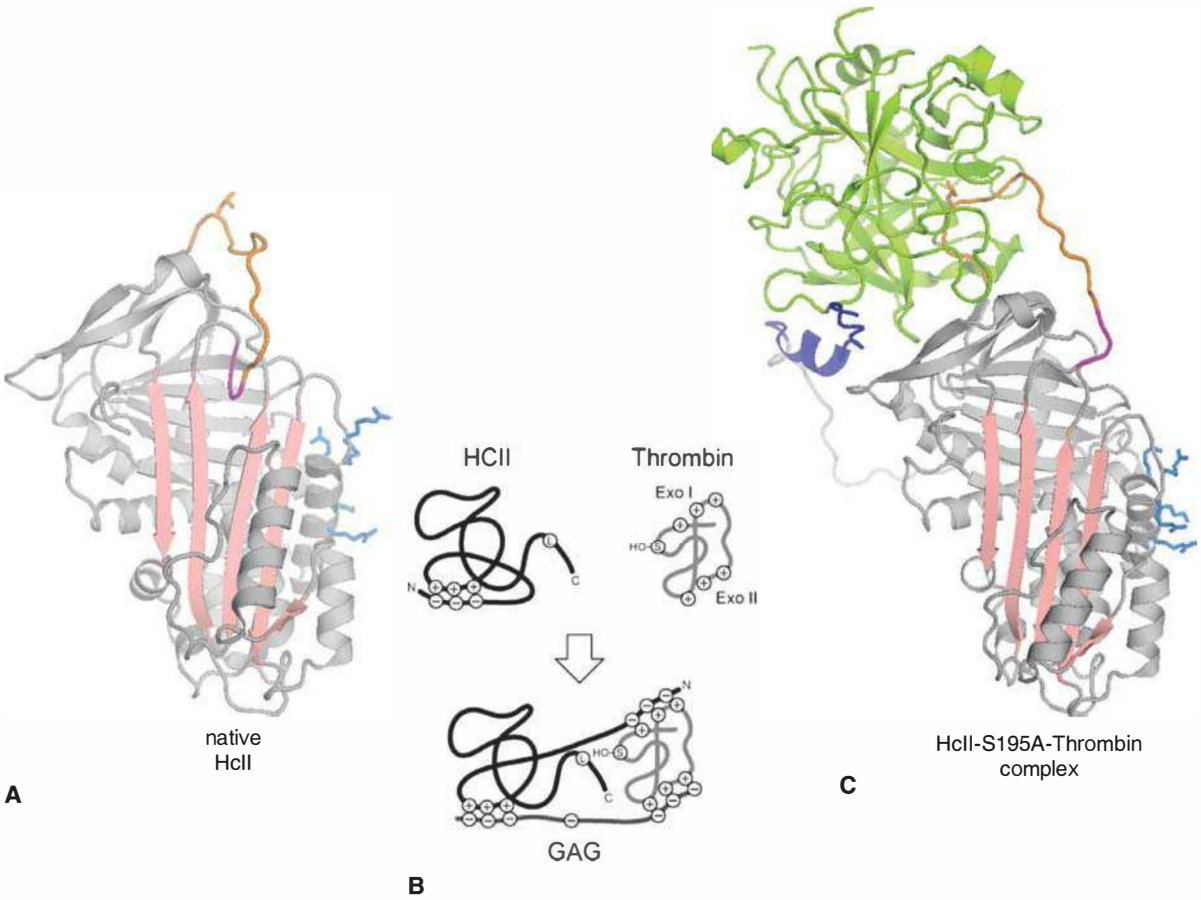

FIGURE 18.6 HcII inhibition of thrombin. **A**: *Native HcII*. The RCL (*orange* and *purple*) of native HcII is constrained due to incorporation of its *C*-terminal end (*purple*) into β-sheet A (*pink*). The leucine P1 residue of the RCL is drawn in *orange* sticks, and side chains of positively charged residues in the heparin- and dermatan sulfate–binding sites on helix D are drawn in *marine blue*. The *N*-terminal hirudin-like polypeptide of HcII was not visible in this structure because perturbations caused by intermolecular contacts in the dimeric native HcII crystal structure largely prevented assignment of its location. **B**: Cartoon model of native HcII shows intramolecular binding of its *N*-terminal, negatively charged hirudin-like and positively charged GAG-binding domains, as inferred from mutagenesis studies. Activation occurs when a heparin or dermatan sulfate GAG molecule binds HcII and competitively displace its *N*-terminal domain from its GAG-binding site. This uncoupling leads to (a) allosteric HcII conformational changes and (b) HcII *N*-terminal domain binding to the thrombin anion-binding exosite I, which together increase the specificity, rate, and strength of the inhibitory complex formation. **C**: *S195A-thrombin—HcII Michaelis complex*. In this structure, the *N*-terminal anionic binding site (*dark blue*) interacts with exosite I on thrombin (*green*), and the allosteric change leading to expulsion of the RCL (*purple* and *orange*) from the A β-sheet has occurred. (**Panels A** and **C** drawn from 1JMJ.pdb and 1JMO.pdb, respectively. Modified from Tollefsen, DM, *Arterioscler Thromb Vasc Biol* 2007;27:456, with permission.)

a result of perturbations caused by intermolecular contacts in the dimeric native HcII crystal structure, the location of the anionic hirudin-like *N*-terminal domain of HcII could not be assigned for the most part. However, from functional studies with HcII *N*-terminal anionic and helix-D GAG-binding region mutants, it is inferred that for the native molecule in the absence of GAG cofactors, there is intramolecular binding of the hirudin-like repeats with the positively charged GAG-binding region, as is schematically depicted in FIGURE 18.6B cartoon.[173–175] Upon exposure to dermatan sulfate or heparin, cofactor binding and occupancy of the GAG-binding site makes dual contributions to activating HcII for more efficient thrombin inhibition. First, GAG binding competitively displaces the hirudin-like amino-terminal polypeptide from the helix-D GAG-binding site, freeing it to interact with exosite I on thrombin,[176] as illustrated in the FIGURE 18.6B cartoon and in FIGURE 18.6C 2.2-Å crystal structure of the HcII–S195A–thrombin complex.[172] Second, by analogy to the mechanism for heparin activation of ATIII (FIGURE 18.3), the release of the binding interaction between the *N*-terminal hirudin domain and the helix-D GAG-binding domain through mutation,[173,176] or cofactor binding, is inferred to induce a long-range protein conformational change, which contributes to expulsion of the RCL from sheet A and improved reactivity with thrombin.[172] The binding sites for heparin and dermatan sulfate on HcII overlap, but are not identical (reviewed in Ref.[177]), and distinct protein conformational changes are induced by the GAGs.[178] In contrast to heparin cofactor inhibition of thrombin by ATIII, both heparin and dermatan sulfate primarily utilize an allosteric mechanism, rather than a template mechanism, to accelerate thrombin inactivation.[179] In the presence of heparin, large decreases in rates of HcII and ATIII inhibition of fibrin clot-bound thrombin occur as a result of the formation of thrombin–fibrin–heparin ternary complexes, which reduce the access of heparin–serpin complexes to the enzyme.[87] However, in the presence of dermatan sulfate, HcII inhibition of clot-bound thrombin remains almost as efficient as its inhibition of free thrombin because of the lack of dermatan sulfate–fibrin cross-linking in the DS–thrombin–fibrin complex that is formed.[180]

Biologic Role of Heparin Cofactor II

HcII participates in thrombin inhibition in the body as indicated by the presence of low levels of thrombin–HcII inhibitory complexes in normal plasma samples[181] and human organ extracts.[103] However, in contrast to ATIII deficiency, HcII deficiency in humans is not strongly associated with venous thrombosis and contributes to thrombotic risk only in combination with other deficiencies (reviewed in Ref.[182]). Furthermore, approximately 1% of apparently healthy individuals (no history of thrombosis) have HcII levels of <60%,[183] and the frequency of HcII deficiency is similar in the general population and venous thrombosis patients.

Recent clinical studies suggest that HcII contributes to the prevention of arterial, rather than venous, thrombosis. Elderly subjects with low plasma HcII activity have a higher incidence of in-stent restenosis after percutaneous coronary intervention,[184] increased carotid artery plaque thickness,[185] and increased prevalence of peripheral arterial disease.[186] These clinical observations imply that HcII protects against the pathologic remodeling response that is initiated by vascular injury and are consistent with results from mouse models of HcII deficiency.

The biologic consequences of HcII deficiency have been investigated in two independently generated mouse models.[187,188] Although there were notable differences in the phenotypes of the St. Louis and Tokushima mice, work with both supports the view that HcII attenuates the vascular injury–induced intimal hyperplasia and atherogenesis.[187,189] St. Louis HcII mice were fully viable and did not exhibit spontaneous thrombosis or other apparent abnormalities.[188] However, complete HcII deficiency in these (−/−) mice was associated with more rapid occlusion after carotid artery injury, and prevented by prior infusion of purified HcII.[188] Moreover, on an apolipoprotein E (apoE)–null genetic background and atherogenic diet, St. Louis HcII null mice exhibited accelerated atherogenesis and neointima formation compared to HcII wildtype mice with the same genetic background and diet.[190] In contrast to the normal viability and growth of the St. Louis HcII-null mice, Tokushima HcII-null mice were embryonically lethal.[187] However, in arterial injury models, heterozygous HcII Tokushima animals exhibited increased intimal hyperplasia and cellular proliferation compared to wildtype. On an apoE-knockout background, the heterozygous HcII deficiency also caused acceleration of aortic plaque formation with increased PAR-1 expression and oxidative stress. Vascular injury–induced intimal hyperplasia in Tokushima HcII$^{+/-}$ mice was abrogated by human HcII supplementation.

In conjunction with the aforementioned clinical observations, the results from the St. Louis and Tokushima mouse models of HcII deficiency imply that it plays a protective role against the pathologic consequences of vascular remodeling, including atherosclerosis. Vascular injury allows HcII molecules from circulating blood to enter the vessel wall, and there bind subendothelial dermatan sulfate, which activates HcII inhibition of thrombin. In this context, HcII serves to block the noncoagulant proliferative and chemotactic functions of thrombin, and thereby protect against intimal hyperplasia, plaque formation, and atherogenesis. This view is consistent with the original proposal of HcII as an extravascular thrombin inhibitor that is activated by fibroblast and smooth muscle cell dermatan sulfate proteoglycans.[191]

HcII has also been suggested to have a biologic role in thrombosis prevention during pregnancy. Dermatan sulfate proteoglycans (presumably of placental origin) increase in the maternal and fetal circulations during pregnancy,[192] and thrombin–HcII complexes are prominent in placental extracts.[103] Elevated HcII has been reported in pregnant women, with levels increasing to three times normal at term.[193,194] HcII levels have also been observed to decrease in preeclampsia patients.[195] However, the previously discussed mouse models of HcII deficiency are confusing with respect to the role of HcII during pregnancy and early development. St. Louis HcII (−/−) mice are born at the expected Mendelian frequency and are reproductively fit,[196] in contrast to Tokushima HcII (−/−) mice, which are embryonic lethal.[187] Thus, the role of HcII in pregnancy is not fully understood.

Finally, a role for HcII in inflammation, wound healing, and tissue repair has also been proposed, on the basis of the ability of proteolytically derived *N*-terminal peptides of HcII to act as leukocyte chemoattractants.[197]

CHAPTER

19

Protein C, Protein S, Thrombomodulin, and the Endothelial Protein C Receptor Pathways

LAURENT O. MOSNIER AND JOHN H. GRIFFIN

THE PROTEIN C PATHWAYS—OVERVIEW

Control of coagulation reactions is essential for normal hemostasis. As part of the tangled web of host defense systems that respond to vascular injury, the blood coagulation factors act in concert with the endothelium and blood cells, especially platelets, to generate a protective fibrin-platelet clot, forming a hemostatic plug. Pathologic thrombosis occurs *inter alia* when the protective clot extends beyond its beneficial size, when a clot occurs inappropriately at sites of vascular disease, or when a clot embolizes to other sites in the circulatory bed. For normal hemostasis, both procoagulant and anticoagulant factors must interact with the vascular components and cell surfaces, including the vessel wall and platelets. Moreover, the actions of the fibrinolytic system must be integrated with coagulation reactions for timely formation and dissolution of blood clots. The protein C pathways provide diverse important functions to maintain a regulated balance between hemostasis and host defense systems in response to vascular injury. On one hand, the anticoagulant protein C pathway is designed to regulate coagulation, maintain the fluidity of blood within the vasculature, and prevent thrombosis. On the other hand, the cytoprotective protein C pathway provides anti-inflammatory and cytoprotective activities and it acts to prevent vascular leakage. This chapter summarizes current knowledge of the protein C pathway components and their activities, with particular emphasis on the recently elucidated, novel direct cellular effects due to activated protein C (APC) and its cofactors, protein S, thrombomodulin (TM), and endothelial protein C receptor (EPCR). Several reviews are available on the biochemistry and clinical impact of the anticoagulant and cytoprotective protein C pathway.[1,2,3–5,6,7,8,9,10–12,13,14]

Thrombin is central to the protein C pathways. Thrombin that is generated by the blood coagulation pathways (see Chapters 8, 9, and 14) binds with high affinity to the cell-surface receptor, TM, and converts the protein C zymogen that is bound to EPCR to APC. For its anticoagulant activity, APC acts in concert with cofactors, including protein S, to inactivate factors Va and VIIIa, the major cofactors for thrombin generation. Cytoprotective APC activities that include antiapoptotic activity, anti-inflammatory activity, regulation of gene expression, and stabilization of endothelial barrier protection can be initiated when APC targets two key receptors, protease-activated receptor-1 (PAR-1) and EPCR.[6,15–17,18–20] Target cells for APC's cytoprotective activities are not limited to the endothelium but also include epithelial cells, various lymphocytes, dendritic cells, and neurons, and additional receptors may also play key roles.

Many questions arise related to APC's effects on cells, such as (a) what are the signaling pathways and/or molecular mechanisms underlying APC's cytoprotective effects on each type of cells; (b) what are the target(s) for APC's effects on cells that allow for APC's many pleiotropic properties; (c) to what extent are molecular mechanisms for APC's antiapoptotic activity, anti-inflammatory activity, regulation of gene expression, and endothelial or epithelial barrier protection shared, overlapping, or distinct; and, perhaps most critically for mechanistic insights, (d) what are the relative contributions of APC anticoagulant activity and APC's cytoprotective activities for the observed beneficial effects, including mortality reduction, in various *in vivo* injury models? Partial answers to these questions are provided in this chapter. Because of their critical roles in the body's host defense system, APC and the protein C pathway components are ideal targets for translational medicine research, and they provide opportunities for therapeutic treatment of complex and challenging medical disorders, including thrombosis, severe sepsis, and stroke among others.

IDENTIFICATION OF THE PROTEIN C PATHWAY COMPONENTS

Although protein C was originally identified as "autoprothrombin-IIa" more than 50 years ago, it was subsequently rediscovered by Stenflo and named "protein C" because of its elution in the third peak ("peak C") on an ion-exchange chromatogram.[21,22] The identification of TM, an endothelial cell cofactor for thrombin-catalyzed activation of protein C, provided a rationale for how a kinetically inefficient enzyme, such as thrombin, could be a physiologically significant activator of protein C.[23,24] The clinical importance of the protein C pathway was based on discovery of deficiencies in protein C or in protein S linked to thrombosis and, for severe or total deficiency, to inflammation.[25,26,27–29] Efforts to elucidate the molecular basis of the anti-inflammatory effects of APC were sparked by the identification of the EPCR.[30] The finding of the PROWESS trial in which recombinant APC (Xigris) reduced 28-day all-cause mortality in adult severe sepsis patients was a watershed event.[31] However, 10 years after that trial, in late 2011 APC's mortality reduction efficacy was not reproduced in the PROWESS-SHOCK trial, raising multiple questions about each trial and their comparisons. Nonetheless, many studies between 2001 and 2011 were driven by the PROWESS trial's success, including major breakthroughs in understanding APC cellular effects involving the direct action of APC on cells that induce signaling through activation

of PAR-1 when bound to EPCR and possibly other receptors.[16] Additional dimensions to studies on the protein C pathway include preclinical studies showing beneficial effects of second-generation recombinant APC mutants in sepsis and ischemic stroke, the generation of protein C– or protein S–deficient mice, and the findings that protein S can exert direct receptor-mediated effects on cells.[16,17,18–22,23,25,27–29,30,31,32–38,39,40,41,42,43–47]

Protein C

Protein C was discovered in search for vitamin K–dependent coagulation factors that are not detected by clotting assays.[21] The protein C gene (PROC) is homologous to the genes for factors VII, IX, and X and is comprised of nine exons and eight introns, located on chromosome 2q13-14 (Table 19.1).[48–51] After removal of the prepro leader peptide, mature protein C contains 419 amino acids (Mr ~ 62 kDa) (FIGURE 19.1) and is synthesized mainly in the liver. Protein C in plasma circulates at 70 nM (4 μg/mL) with a half-life of approximately 8 hours.[25] A significant posttranslational modification involves the cleavage of the zymogen between residues 157 and 158 by a furin-like enzyme, followed by the loss of the Lys156–Arg157 dipeptide connecting the light chain (residues 1 to 155; Mr ~ 25 kDa) to the heavy chain (residues 158 to 419; Mr ~ 41 kDa). As a result, 85% to 90% of human protein C is a two-chain form, linked by a single disulfide bond between Cys141 and Cys277. Other posttranslational modifications involve β-hydroxylation at Asp71, *N*-linked glycosylation at residues 97, 248, 313, and 329, and γ-carboxylation at the first nine Glu residues in the γ-carboxyglutamic acid (Gla) domain. The three subforms of the heavy chain, designated alpha (Mr ~ 41 kDa), beta (Mr ~ 37 kDa), and gamma (Mr ~ 32 kDa), represent tri-, di-, and monoglycosylated heavy chain due to partial glycosylation of Asn residues 329 and 248.[52] Ca^{2+}-binding sites that are located in the Gla domain are required for binding to phospholipids and EPCR, and such sites are also present in the first epidermal growth factor (EGF) domain and the protease domain.[53–55] The characteristic structural elements of protein C include an amino-terminal Gla domain (residues 1 to 37), an aromatic stack (residues 38 to 45), two EGF-like regions (EGF-1, residues 46 to 92 and EGF-2, residues 93 to 136), an *N*-terminal activation peptide (residues 158 to 169) on the heavy chain, and the serine protease domain (residues 170 to 419) (FIGURE 19.1).

Table 19.1

Characteristics of the protein C pathway components

Protein	Gene	Locus	cDNA	Residues	Theoretical Mass (kDa)	Observed Mass (kDa)	Plasma Concentration (nM)	$\varepsilon_{1\%;\ 1\ cm}$
Coagulation Factors								
Protein C	PROC	2p13-14	NM_000312	419	47	62	70	14.5
Protein S	PROS1	3q11.2	NM_000313	635	71	77	320[a]	9.5
FV	F5	1q23	NM_000130	2,196	249	330	25	8.9
FVIII	F8	Xq28	NM_000132	2,196	265	330	0.7	11.9
C4b-binding protein[b]	C4BPA	1q32	NM_000715	549	70	500–570[b]	260	14.1
	C4BPB	1q32	NM_000716[c]	235	45			
Cell Receptors								
TM	THBD	20p12-cen	NM_000361	557	60	75 (105)[d]	0.05[e]	9.2[f]
EPCR	PROCR	20q11.2	NM_006404	221	25	46	2.5[g]	11.3[f]
PAR-1	F2R	5q13	NM_001992[h]	400	47	65	n/a	ND
ApoER2	LRP8	1p34	NM_004631[i]	899	102	180	ND	24[f]

[a]The total protein S concentration (320 nM) includes free protein S (130 nM) and protein S in complex with C4BP (190 nM).
[b]C4BP contains two polypeptide chains in varying proportions and circulates in different isoforms, alpha-7-beta-1 being the most common. About 17% (45 nM) of C4BP contains only alpha-chains and lacks the beta-chain that binds protein S. The α_6, $\alpha_6\beta_1$, and α_7 isoforms have molecular weights of approximately 500, 530, and 570 kDa.
[c]C4BP beta-chain variants 1 (NM_000716), 3 (NM_001017365), and 5 (NM_001017367) encode for the longer isoform 1 but vary in the 5′-untranslated region, whereas variants 2 (NM_001017364) and 4 (NM_001017366) encode for isoform 2 with a shorter *N*-terminus due to an in-frame alternate splice site.
[d]The TM apparent molecular weight is dependent on the presence of the GAG attachment.
[e]Soluble TM is believed to be the product of proteolysis of TM on the cell surface and comprises different molecular forms (Mr 35–65 kDa) that lack the transmembrane sequence. The concentration of soluble TM in normal individuals is approximately 2 to 5 ng/mL but can increase many-fold under pathologic conditions. Increased soluble TM levels are regarded to be a sign of endothelial cell activation.
[f]Values are given for the soluble extracellular domain of the receptor. Soluble ApoER2 is truncated after EGF-like domain B but includes all seven ligand-binding domains.
[g]Soluble EPCR is derived from proteolysis of EPCR on the cell surface and lacks the transmembrane domain (Mr ~ 43 kDa).
[h]The reference sequence was adjusted in 2008 between revision 2 (NM_001992.2) and 3 (NM_001992.3), resulting in two amino acid changes compared to the sequence originally published for PAR-1.[284]
[i]Several cell-type specific ApoER2 isoforms are reported. Transcript variant 1 (NM_004631) contains all 19 exons, transcript variant 2 (NM_033300) lacks exons 5 and 6 encoding the ligand-binding domain (LBD) 4–6 and 7. Transcript variant 3 (NM_017522; e.g., found in endothelial cells [HUVEC]) lacks exon 5 (LBD4-6), exon 15 (*O*-linked sugar), and exon 18 (part of the intracellular domain). Transcript variant 4 (NM_001018054) is similar to full-length transcript variant 1 except for the lack of exon 18. In addition, U937 cells were found to express an additional transcript that lacks exons 5 and 18 but that contains exon 15.[43]

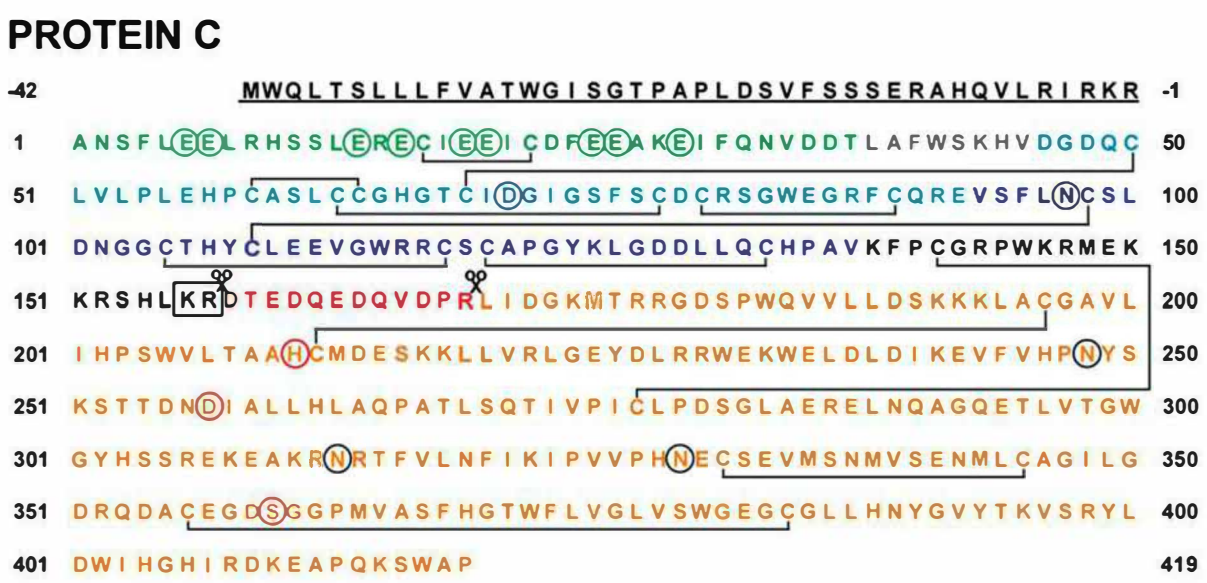

FIGURE 19.1 Amino acid sequence of protein C and ribbon polypeptide scheme of APC. Amino acids are numbered from the amino-terminus of the mature protein with the signal peptide sequence *underlined*. Specific domains are color coded as indicated in the *ribbon cartoon*. *Green circles* depict γ-carboxylation, *blue circles* depict β-hydroxylation, and *black circles* represent sites of *N*-linked glycosylation. Sites of proteolytic cleavage during posttranslational processing and protein C activation are indicated by the scissors. The dipeptide that is proteolytically removed during the posttranslational processing of most protein C molecules in the liver is identified by the box. The serine, aspartic acid, and histidine residues that constitute the active site triad are identified by *red circles*.

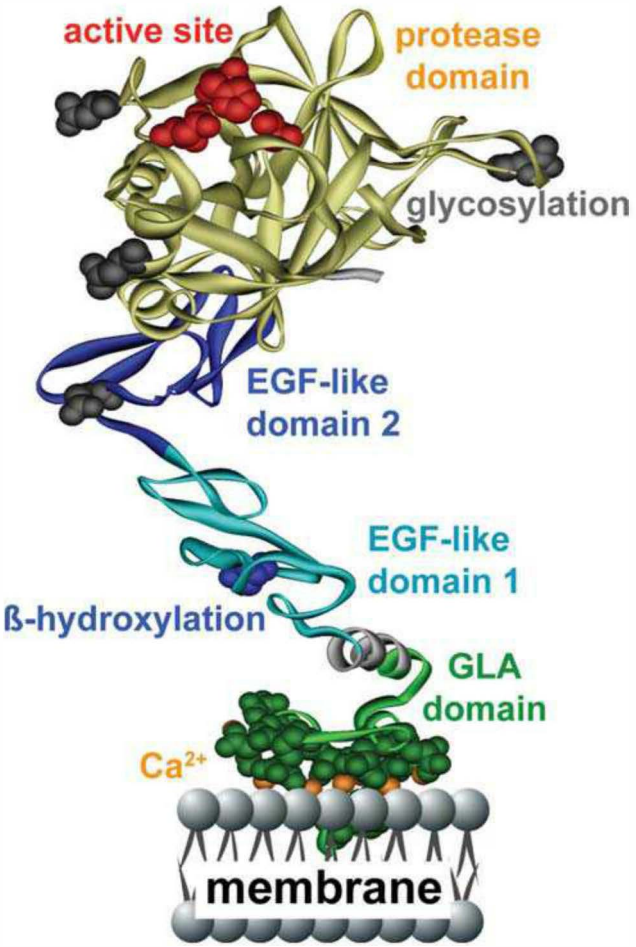

Thrombin cleavage of the zymogen at Arg169 removes the activation peptide and generates APC, a trypsin-like serine protease with a typical serine protease active site triad (His211, Asp257, and Ser360). Endogenous circulating levels of plasma APC are low (<40 pM), and inactivation of APC in plasma is driven by serine protease inhibitors (SERPINs) that contribute to a remarkably long circulation half-life of APC in man of approximately 20 to 25 minutes. Most important inhibitors of APC in plasma are protein C inhibitor (PCI) and α_1-antitrypsin and, to a lesser extent, α_2-macroglobulin and α_2-antiplasmin.

Protein S

Protein S, named after its birth city, Seattle, is a vitamin K–dependent plasma glycoprotein and is best known for its function as a nonenzymatic cofactor to APC in the inactivation of factors Va and VIIIa. The relatively large gene for protein S (PROS1) is located on chromosome 3 (3q11.2) and contains 15 exons (Table 19.1). Chromosome 3 also contains an inactive pseudogene for protein S (PROSP at location 3p21-cen). After removal of the prepro leader peptide, mature protein S contains 635 amino acids (Mr ~ 77 kDa) (FIGURE 19.2) and is predominantly synthesized in

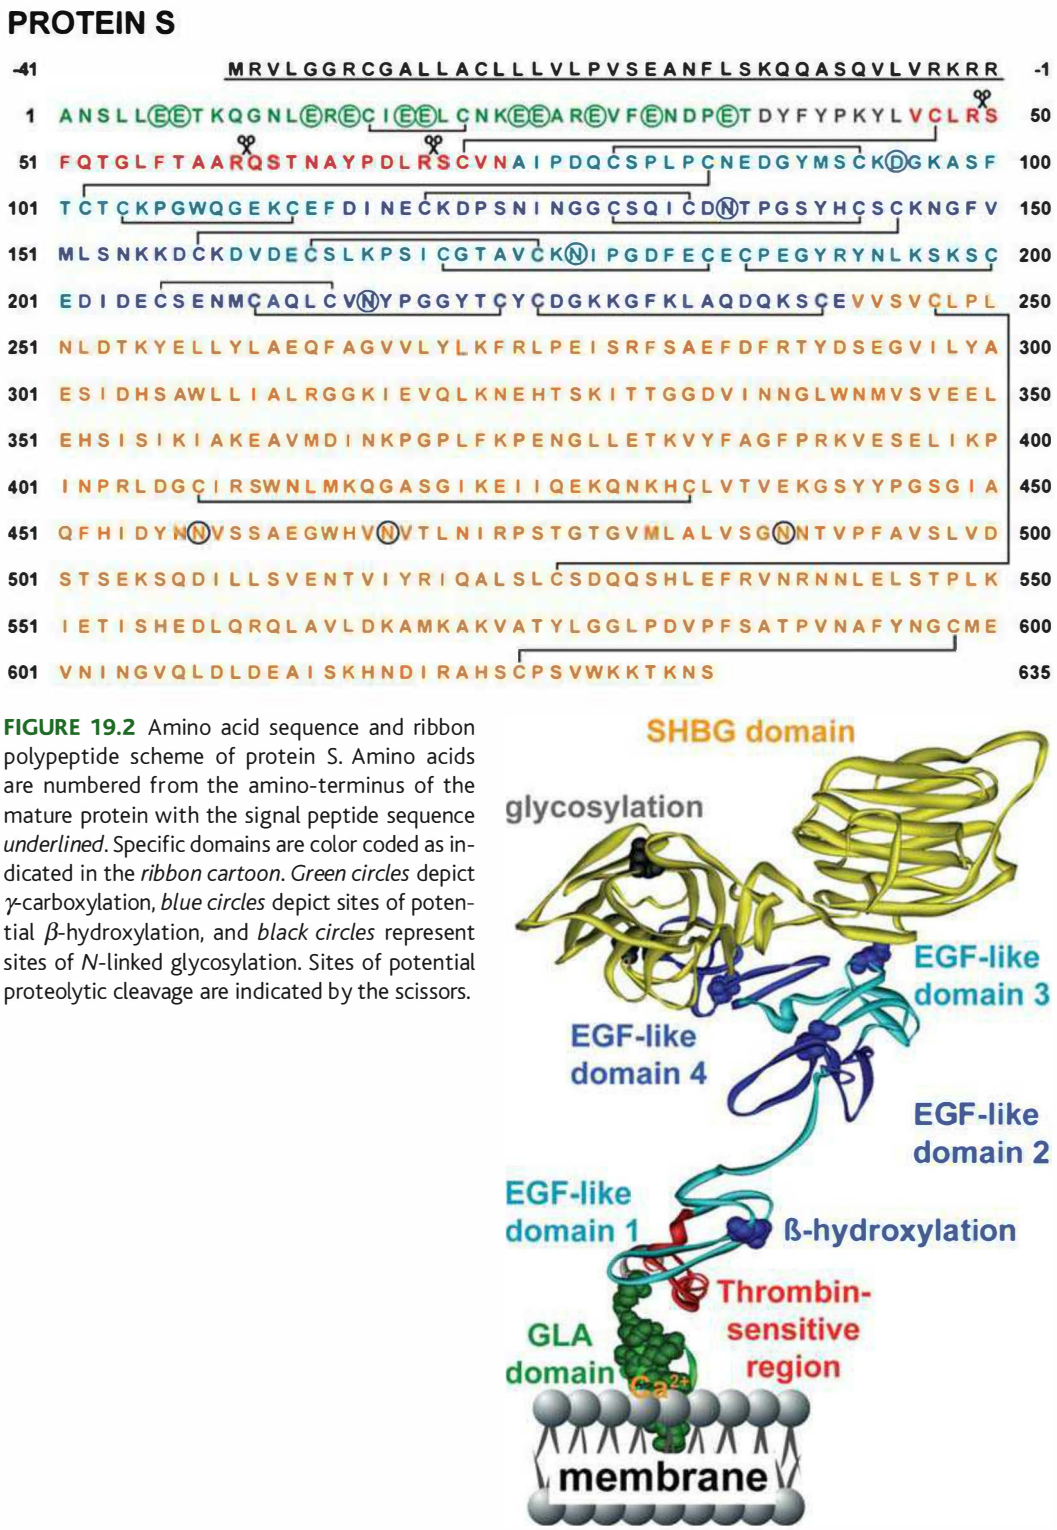

FIGURE 19.2 Amino acid sequence and ribbon polypeptide scheme of protein S. Amino acids are numbered from the amino-terminus of the mature protein with the signal peptide sequence *underlined*. Specific domains are color coded as indicated in the *ribbon cartoon*. *Green circles* depict γ-carboxylation, *blue circles* depict sites of potential β-hydroxylation, and *black circles* represent sites of *N*-linked glycosylation. Sites of potential proteolytic cleavage are indicated by the scissors.

the liver but is also made by endothelium and other cells. Protein S circulates in plasma at a total concentration of 320 nM, and approximately 60% of the protein S is noncovalently complexed with C4b binding protein (C4BP) such that free protein S is 130 nM in plasma.[56] C4BP is an octopus-like shaped glycoprotein of approximately 500 to 570 kDa and consists of six or seven disulfide-linked, identical alpha-chains and one smaller beta-chain (see Table 19.1).[57] C4BP regulates protein S functions by binding via the beta-chain.[58] Protein S binds to the C4BP beta-chain in a 1:1 stoichiometric complex with high affinity ($K_d \sim 0.1$ to 0.6 nM).[59] Although C4BP is an acute-phase response protein, only alpha-chains are increased causing the levels of free protein S levels to remain stable during an acute-phase response.[60]

Mature protein S has a defined structural organization consisting of five distinct domains, including an *N*-terminal Gla domain (residues 1 to 37) and aromatic stack (residues 38 to 45), an unique 29–amino acid sequence known as the thrombin-sensitive region (TSR; residues 46 to 74), a string of four EGF-like domains (EGF-1 [residues 75 to 115], EGF-2 [residues 116 to 159], EGF-3 [residues 160 to 201], and EGF-4 [residues 202 to 242]), and finally a large 393–amino acid domain on the *C*-terminus referred to as the sex hormone–binding globulin-like domain (residues 243 to 635) that is composed of two laminin G-type domains (FIGURE 19.2).

Thrombomodulin

The endothelial cell receptor TM (CD141) was discovered and named for its ability to modulate the protease specificity of thrombin (FIGURE 19.3).[24,61] The gene for TM (THBD) is on chromosome 20 (20p12-cen) and is intron-less (Table 19.1).[62,63] Based on its cDNA sequence, TM consists of 575 amino acids in

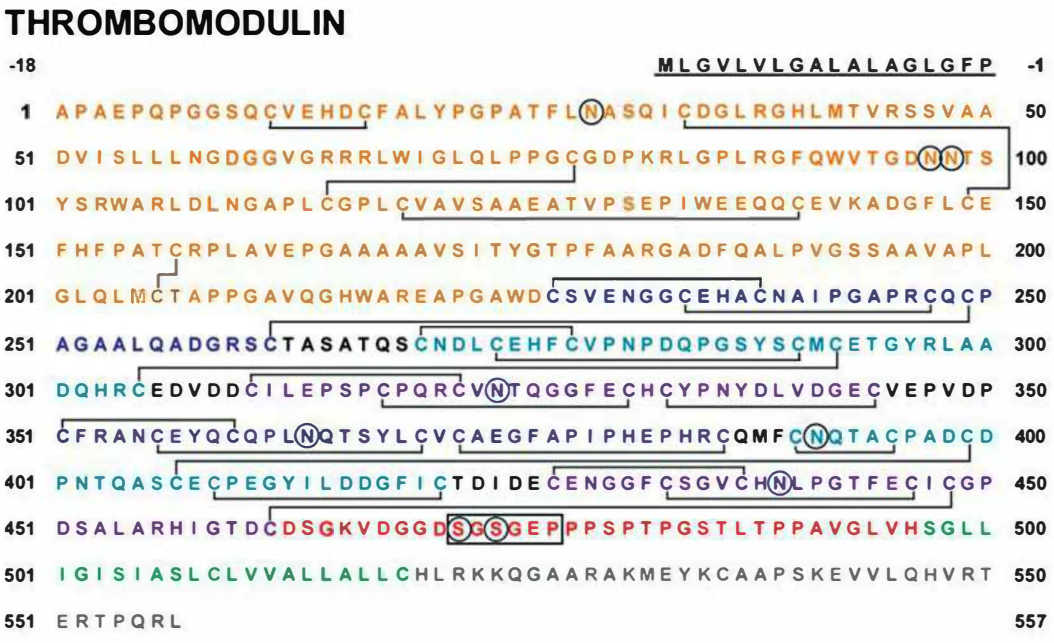

FIGURE 19.3 Amino acid sequence and ribbon polypeptide scheme of TM. Amino acids are numbered from the amino-terminus of the mature protein with the signal peptide sequence *underlined*. Specific domains are color coded as indicated in the *ribbon cartoon*. *Blue circles* depict sites of potential *β*-hydroxylation, *black circles* represent sites of *N*-linked glycosylation. The consensus sequence for the GAG attachment is *boxed*.

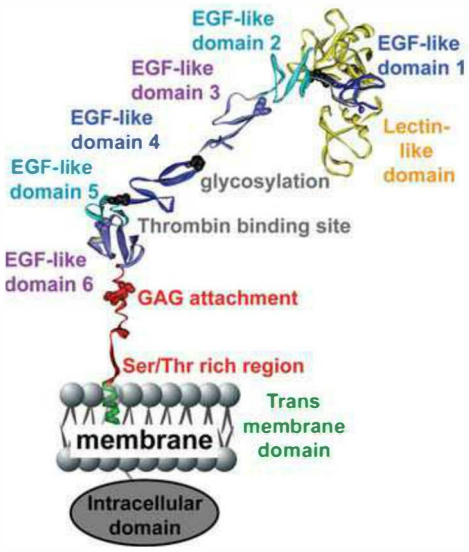

the form of a 60.3-kDa single-chain transmembrane protein.[63] Posttranslational *O*-linked and *N*-linked glycosylation accounts for approximately 20% of the apparent molecular weight of TM, and other modifications include covalently bound chondroitin sulfate moieties.[64]

Functionally, five regions of the mature TM can be identified (FIGURE 19.3)[63]: An *N*-terminal lectin domain (residues 1 to 226), a repeat of six EGF-like domains (EGF-1 [residues 227 to 262], EGF-2 [residues 270 to 305], EGF-3 [residues 311 to 344], EGF-4 [residues 351 to 386], EGF-5 [residues 390 to 421], and EGF-6 [residues 427 to 462]), a serine- and threonine-rich region (residues 463 to 496), a transmembrane region (residues 497 to 519), and finally a *C*-terminal intracellular tail (residues 520 to 557). The EGF-like modules 5 and 6 mediate thrombin binding, whereas EGF-like module 4 is required for interactions with protein C. The major site for the glycosaminoglycan (GAG) attachment is within the chondroitin consensus sequence of Ser472-Gly-Ser474-Gly-Glu-Pro at Ser472 or Ser474. GAG-containing TM has somewhat different properties than TM devoid of a GAG attachment as the presence of GAG increases the affinity for thrombin approximately 10-fold, reduces thrombin's ability to clot fibrin and to activate platelets, and modulates the Ca^{2+}-dependent profile of protein C activation. Furthermore, the GAG on TM can bind a second thrombin molecule and facilitate inactivation of thrombin by the SERPINs, PCI, and antithrombin (AT).[65] Besides promoting protein C activation by thrombin, TM also supports activation of a plasma carboxypeptidase, known as thrombin-activatable fibrinolysis inhibitor (TAFI). Activated TAFI is not only a potent attenuator of fibrinolysis but also an effective inactivator of a variety of proinflammatory peptides such as the activated complement components C3a and C5a, bradykinin, thrombin-cleaved osteopontin, and other peptides.[66] For a more detailed discussion of TAFI, see Chapters 20 and 21.

Low levels of soluble TM, generated by shedding from the endothelium due to proteolysis, circulate in plasma and are generally considered to be a marker of endothelial cell damage.[61] The functional significance of circulating TM is unknown, although variations in its plasma level arise in different clinical conditions.

Endothelial Protein C Receptor

The EPCR (CD201[67]) was discovered in a search for the endothelial cell receptor responsible for binding of APC.[30] The gene for EPCR (PROCR) is on chromosome 20 (20q11.2) (Table 19.1).[68] EPCR is homologous to the CD1/MHC superfamily. MHC class I molecules are type 1 integral membrane proteins and consist of three extracellular domains, alpha-1, alpha-2, and alpha-3. The latter domain typically associates noncovalently with β_2-microglobulin. EPCR lacks the alpha-3 domain and thus does not associate with β_2-microglobulin; rather, in EPCR, the transmembrane domain is connected directly to the alpha-2 domain (FIGURE 19.4).[68] The alpha-1 and alpha-2 domains form a binding groove by each providing an alpha-helix that

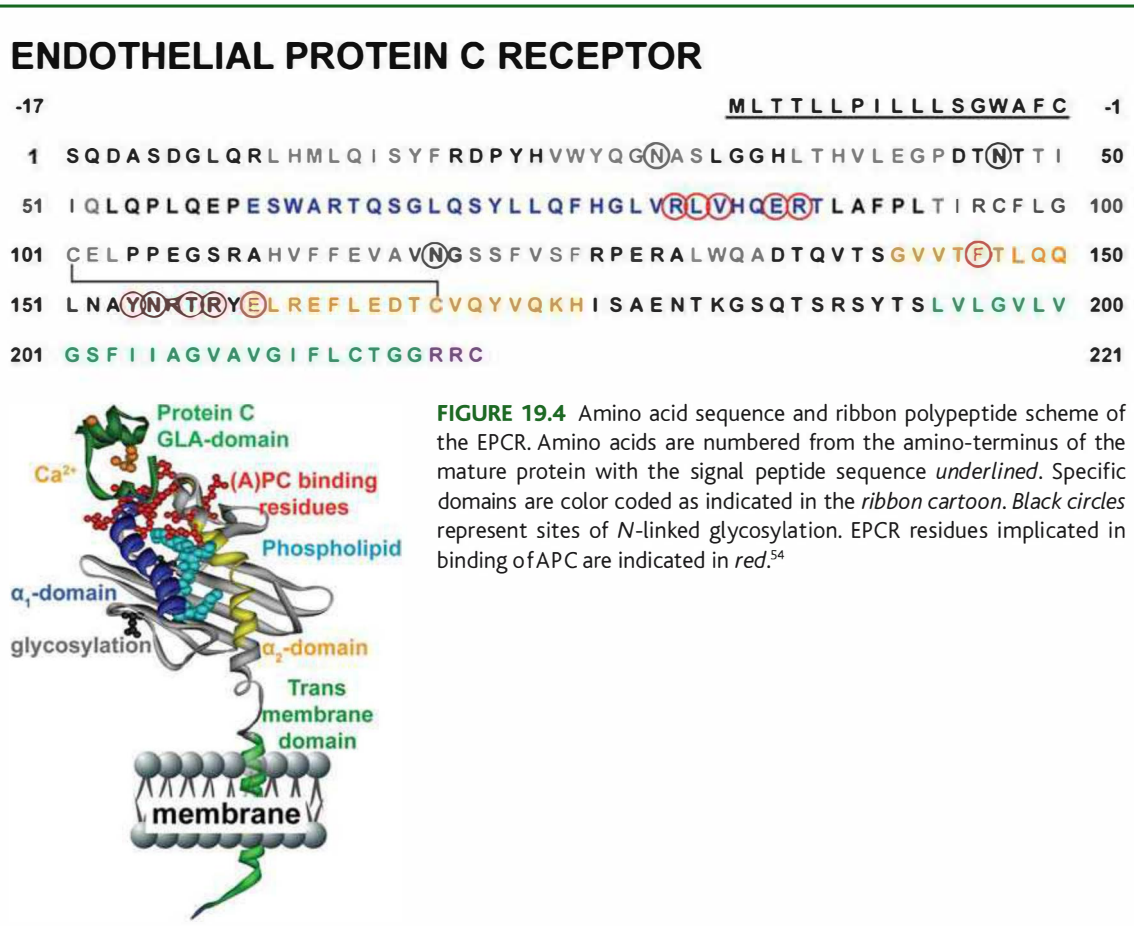

FIGURE 19.4 Amino acid sequence and ribbon polypeptide scheme of the EPCR. Amino acids are numbered from the amino-terminus of the mature protein with the signal peptide sequence *underlined*. Specific domains are color coded as indicated in the *ribbon cartoon*. *Black circles* represent sites of *N*-linked glycosylation. EPCR residues implicated in binding of APC are indicated in *red*.[54]

is located along opposing edges of a planar platform generated by an eight-stranded antiparallel beta-sheet. The crystal structure of soluble EPCR revealed that a phospholipid, most likely phosphatidylcholine, was bound in this groove between the two alpha-helices.[69,70] EPCR's short cytoplasmic tail (Arg–Arg–Cys–CO_2H) suggests that induction of direct cell signaling is unlikely and that palmitoylation of the *C*-terminal Cys residue may help localize EPCR to certain lipid rafts or caveolae and facilitate modulation of cell-signaling pathways that depend on EPCR.[71,72]

In addition to binding protein C and APC with similar affinity (K_D ~ 60 nM), EPCR also binds factor VII and factor VIIa to the same end of an EPCR alpha-helix that binds to the ligand's Gla domain (FIGURE 19.4). Although EPCR is named after its expression on endothelial cells, EPCR is also present on epithelial cells, monocytes, macrophages, neutrophils, eosinophils, natural killer cells, and in mice on specific bone marrow–derived dendritic cells.[30,73–79]

EPCR is susceptible to shedding of the EPCR ectodomain due to proteolysis in the region of residues 193 to 200, just above the transmembrane domain, by tumor necrosis factor-alpha (TNF-α)–converting enzyme/ADAM17 (TACE). Several proinflammatory cytokines, for example, TNF-α and interleukin-1β, induce soluble EPCR formation and increase soluble EPCR levels in mice exposed to endotoxemia; soluble EPCR is increased in plasmas of patients with a prothrombotic and proinflammatory tendency.[80–84]

THE ANTICOAGULANT PROTEIN C PATHWAY

The protein C system is a dual function cofactor-dependent system that exerts direct cytoprotective activities on cells as well as its well-studied anticoagulant activity anticoagulant. By targeting factors Va and VIIIa, major procoagulant cofactors for thrombin generation, APC regulates coagulation and prevents thrombosis. The physiologic importance of thrombosis prevention by the anticoagulant protein C system is evident from clinical observations of thrombotic complications in individuals with deficiencies of protein C and protein S.

Anticoagulant Protein C Pathway Defects and Thrombosis

Homozygous and compound heterozygous severe protein C deficiency typically presents itself as neonatal purpura fulminans, a rapidly progressing hemorrhagic necrosis of the skin due to microvascular thrombosis, inflammation, and disseminated intravascular coagulation (DIC).[85] Infants with severe protein C deficiency suffer massive thrombotic complications, and if they survive due to maintenance replacement therapy, they tend to present with mental retardation and/or visual impairment.[85–87] Replacement therapy with fresh-frozen plasma or with purified plasma protein C concentrate (CEPROTIN) is beneficial.[88–90] The incidence of clinically significant protein C deficiency carries a significantly increased risk for venous thrombosis (see Chapters 80 to 82).[91–93] Hundreds of mutations have been identified (see protein C mutation databases[92,94,95]), and the basis for hereditary protein C defects can most often be rationalized based on the structure of protein C.[96–98] Type I mutations, characterized by reductions of both antigen and activity, typically involve amino acid mutations that affect protein folding, secretion, or stability. In contrast, most type II mutations, characterized by reduction of anticoagulant activity but not antigen, involve residues that cause dysfunctional molecules either by affecting thermodynamic stability or by protein–protein interactions important for expression of anticoagulant activity. Acquired protein C deficiency occurs upon initiation of vitamin K antagonists (coumarin/warfarin) therapy due to the relatively short half-life of protein C ($T_{1/2}$ ~ 8 hours) compared to most procoagulant vitamin K–dependent factors ($T_{1/2}$ ~ 20 to 48 hours); this potential problem is addressed by using heparin during initiation of therapy, or even protein C concentrate for special circumstances.[99,100]

Severe (homozygous or compound heterozygous) protein S deficiency, although extremely rare, manifests with purpura fulminans in the neonatal period similar to severe protein C deficiency.[101–103] Hereditary protein S heterozygous deficiency conveys a significantly increased risk of thrombosis.[29,93,104–106] Due to the binding of protein S to C4b-binding protein in plasma, testing to establish protein S deficiency is challenging.[105] Deficiencies are classified as follows: type I, reduction of both free and total protein S antigen; type II or qualitative deficiency, functional protein S defect with a low functional activity but normal antigen level; and type III, with a low level of free protein S level but a normal level of total protein S antigen.[29,102,104–109] Mutations are found in the majority of patients and families with hereditary protein S deficiency (see Chapters 80 to 82 and protein S mutation databases).[105,110] Two polymorphisms causing deficiencies are known as protein S Heerlen (Ser460Pro), a type III defect among subjects of European ancestry, and protein S Tokushima (K196E), a type II defect.[111–116] Protein S Tokushima is a common risk factor for venous thrombosis among Japanese and is found in approximately 10% of venous thrombosis patients.[105,111,117–119] It is likely that the protein S Tokushima mutation of K196E (residue 155 in mature protein S) arose from a founder effect in Japan and is a balanced polymorphism, like factor V Leiden or prothrombin 20210A that carries a beneficial effect (e.g., prevention of excess fatal bleeding) and a mild risk factor for venous thrombosis. In contrast, the Heerlen polymorphism that alters glycosylation is not as obvious a risk factor. Acquired protein S deficiency is common during pregnancy and also may arise during the use of certain oral contraceptives, or after initiation of oral anticoagulant treatment.[120–124]

APC resistance conveys an increased risk for venous thrombosis and is defined as an abnormally reduced anticoagulant response of a plasma sample to APC. It can be caused by many potential abnormalities in the protein C anticoagulant pathway but among whites a mutation in factor V, which arose in a European ancestor involving an APC-cleavage site (Arg506Gln, factor V Leiden), is the most common cause for hereditary thrombosis.[38,39,125] Other known APC cleavage site mutations in factor V that contribute to an increased thrombotic risk are Arg306Thr (factor V Cambridge) and Arg306Gly (factor V Hong Kong).[126–131] APC resistance with no identifiable genetic or acquired abnormalities is well described in patients with venous and arterial thrombosis, and further studies are needed to identify the causes of APC resistance in such patients.[132–135]

TM genetic mutations may be associated with increased risk of arterial thrombosis and myocardial infarction, whereas there is less supportive data for association with risk for venous thrombosis.[61,136–142] Mutations in TM have also been linked to atypical hemolytic-uremic syndrome patients; this syndrome

is strongly linked to excessive complement activation.[143] The lectin-like domain of TM (FIGURE 19.3) can contribute to inhibition of complement activation and provide direct anti-inflammatory activity, although the molecular basis for this remains somewhat unclear.[144–147]

The potential association of EPCR defects with venous and arterial thrombosis remains a bit controversial and seems difficult to prove (see Chapters 81 and 82).[148–155] To date, four EPCR gene haplotypes have been characterized containing certain polymorphisms.[68] Interestingly, the H1 haplotype was associated with a reduced risk of venous thromboembolism and diminished risk of thrombosis in carriers of the factor V Leiden mutation.[156,157] In contrast, the H3 haplotype of EPCR that is characterized by a Ser219Gly mutation in EPCR causes enhanced EPCR shedding from the membrane, resulting in increased levels of soluble EPCR in the circulation, which might be associated with an increased risk of venous thrombosis.[81,156,158–160]

Protein C Activation

Activation of zymogen protein C by thrombin is due to cleavage at the Arg169–Leu170 peptide bond (FIGURE 19.1) in a reaction that is accelerated by TM and EPCR on the surface of the endothelial cells (FIGURE 19.5).[1,6,7,23,161,162] Binding of thrombin to TM shields thrombin's procoagulant exosite I and unveils its anticoagulant properties.[7,163–165] Subsequent activation of protein C by the thrombin–TM complex is facilitated by localization of protein C on the endothelial cell surface by binding to EPCR.[166,167] Available data suggest that EPCR and TM must be in close proximity on cell surfaces, though this has yet to be experimentally demonstrated. In blood vessels, TM is generally considered more abundant in the microcirculation while EPR is relatively more abundant in large vessels than in small vessels.[1,168,169]

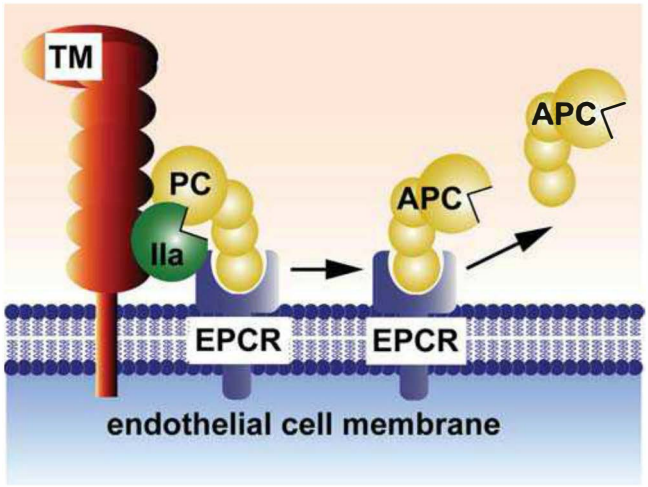

FIGURE 19.5 Protein C activation on endothelium. Physiologic activation of protein C (PC) by the thrombin (IIa)–thrombomodulin (TM) complex occurs on the surface of endothelial cell membranes. The most efficient activation of protein C occurs when protein C is bound to the endothelial receptor (EPCR). Since protein C and APC have a similar affinity for EPCR, after activation APC can either dissociate from EPCR to exert anticoagulant activity or remain bound to EPCR where it might express multiple direct cellular activities. (This scheme was originally published in *Blood*. Mosnier et al. The cytoprotective protein C pathway. *Blood* 2007;109(8):3161–3172. © the American Society of Hematology.)

APC is constantly generated in the resting state because APC is present at approximately 40 pM in all healthy human subjects' plasma. The concentration of zymogen protein C in plasma is an important determinant for circulating APC levels, reflecting the kinetics of the protein C activation on cultured cells *in vitro*.[166,167,170–177] An inverse correlation between circulating fibrinopeptide A and APC levels suggests that APC is a significant *in vivo* regulator of basal thrombin activity.[178–180] Impaired activation of protein C occurs in patients with inflammation and sepsis.[181] Protein C levels in patients with severe sepsis often are markedly decreased, due to a combination of protein C consumption, dysfunctional protein C synthesis in the liver, and/or reduced levels of TM or EPCR on the endothelium.

APC Anticoagulant Activity

Anticoagulant activity of APC involves proteolytic inactivation of factors Va and VIIIa (FIGURE 19.6).[182,183] Multiple cofactors, including protein S, negatively charged phospholipids, neutral glycosphingolipids, and high-density lipoprotein (HDL), are known to enhance APC's inactivation of factor Va and/or factor VIIIa.[184–188]

Factor Va is composed of a heavy chain (A1–A2, residues 1 to 709) and a light chain (A3–C1–C2, residues 1,546 to 2,196) that form a noncovalent heterodimeric complex.[189–195] In the prothrombinase complex, factor Va binds both the substrate prothrombin and the enzyme factor Xa on the surface of negatively charged phospholipids, thereby increasing the rate of thrombin generation by approximately 10,000-fold.[182,183,196] Inactivation of factor Va by APC effectively shuts down thrombin formation via a complex process involving three cleavages at Arg306, Arg506, and Arg679. Cleavage at Arg506 is rapid and much faster than cleavage at Arg306, but it only partially inactivates factor Va, whereas cleavage at Arg306 results in the complete inactivation of factor Va.[182,183,197] Cleavage of the connection between the A2 domain and the A1 domain at Arg306 results in the dissociation of the A2 domain fragment, whereas the A1 domain remains associated with the light chain.[198] Protein S might enhance the APC-mediated cleavage of factor Va by lowering the active site of APC closer to the membrane.[199] In addition, protein S is able to diminish the ability of factor Xa to protect factor Va from inactivation by APC when protein S, factor Xa, and factor Va are simultaneously present. Mutagenesis studies show that positively charged residues in exosites on the APC protease domain surface are required for rapid inactivation of factor Va.[200–205]

Although factors Va and VIIIa are generally homologous proteins with similar domain structure and procoagulant function, factor VIIIa, in contrast to factor Va, is quite unstable with a half-life of only 2 minutes due to spontaneous dissociation of the A2 domain (see Chapter 12). This is because factor VIIIa is a heterotrimer, whereas factor Va is a heterodimer due to different cleavage patterns that cause their respective activations.[206] Factor VIIIa, expressing full cofactor activity, enhances factor Xa formation by the tenase complex approximately 200,000-fold.[207]

The physiologic relevance of APC-mediated factor VIIIa inactivation was questioned due to the spontaneous inactivation of factor VIIIa; however, several arguments, including stabilization of factor VIIIa by factor IXa, support a role for APC in the inactivation of factor VIIIa.[208–210] Proteolytic inactivation

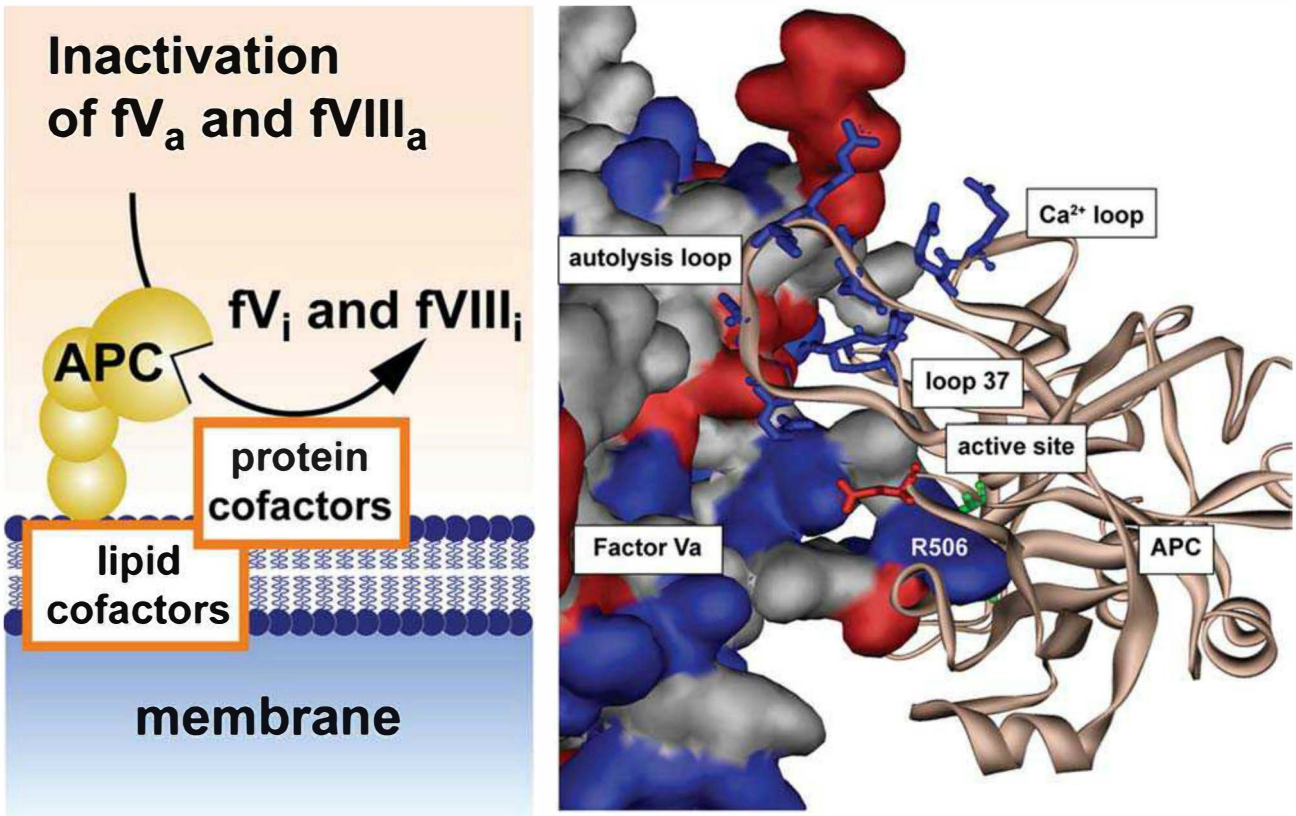

FIGURE 19.6 APC anticoagulant activity. Schematic model of mechanisms for APC anticoagulant activity **(left)**. APC anticoagulant activity involves proteolytic cleavages of the activated cofactors Va (FVa) and VIIIa (FVIIIa) to yield the inactivated cofactors, FVi and FVIIIi, when APC is bound to phospholipid surfaces. Different protein and lipid cofactors, for example protein S, factor V, and various lipids (e.g., phosphatidylserine, cardiolipin, glucosylceramide, etc.), enhance inactivation of factors Va and VIIIa by APC. A close-up scheme **(right)** of the exosite interaction between APC and factor Va. In this APC:FVa complex model (from Pellequer et al.[195]), exosite specificity is based on the juxtaposition of positively charged residues (*blue*) of APC in the autolysis loop, 37-loop, and calcium-binding loop near negatively charged residues (*red*) of FVa. These exosite interactions between APC and factor Va are required for positioning of Arg506 of factor Va in the active site pocket of APC and thus for cleavage of factor Va at Arg506 and for normal anticoagulant activity **(left)**. (This scheme was originally published in *Blood*. Mosnier et al. The cytoprotective protein C pathway. *Blood* 2007;109(8):3161–3172. © the American Society of Hematology.)

of factor VIIIa by APC occurs upon cleavage at Arg336 and Arg562, homologous to Arg306 and Arg506 in factor Va. Protein S only moderately enhances cleavage at Arg336 (~twofold), whereas it stimulates the cleavage at Arg562 only slightly more (~ fivefold).[210–212] Factor V can further enhance the APC cofactor effect of protein S.[213–215] Thus, factor V and protein S act as synergistic cofactors for factor VIIIa inactivation by APC.[213] It also appears that factor V promotes APC's inactivation of factor Va.[216] Because factor V Leiden lacks this APC cofactor activity, it was hypothesized that risk for thrombosis in factor V Leiden carriers is caused by both defective APC cofactor activity and resistance to APC inactivation, with each defective mechanism assumed to contribute equally to increased risk.[217–219]

Protein S Anticoagulant Cofactor Activity

The APC cofactor function of protein S involves a complex set of interactions of protein S with APC and with components of the prothrombinase complex, factor Xa, and factor Va.[220–227] Molecular mechanisms for enhanced APC-mediated cleavage of factor Va at Arg306 by protein S have been partially elucidated and involve a protein S-induced change in the geometry of APC relative to the membrane. Protein S binding lowers APC's active site closer to the membrane, presumably placing it in a better position to cleave Arg306.[199,228] In addition, protein S reduces the ability of factor Xa to protect factor Va from APC, based on the presumption that factor Xa blocks access of APC to factor Va and that protein S competes with factor Xa for binding to factor V.[223–226,229]

Protein S molecular regions (FIGURE 19.2) that bind APC are located in the Gla domain, the TSR, and in both EGF-1 and EGF-2 domains. The sequence in EGF-1 from Lys97 to Pro106 is thought to support direct interactions as well as a supporting structural role for the Gla domain, the TSR, and EGF-2.[222,230–232] The protein S–binding regions on the surface of APC (FIGURE 19.1) are thought to involve hydrophobic helix at the end of the Gla domain, several EGF-1 residues, and the *C*-terminus of the light chain, but such

interactions are speculative in the absence of better structural information.[233,234,235,236]

The protein S anticoagulant APC cofactor function is regulated by at least two mechanisms. First, noncovalent and reversible binding of protein S to C4BP results in the loss of protein S APC cofactor function, which enhances Arg506 cleavage in FVa. Protein S molecules bound to C4BP can still bind to phospholipid membranes, interact with APC, and enhance cleavage at Arg306; however, this cleavage is not well reflected in typical coagulation assays for APC anticoagulant activity.[220,237–241] Second, proteolysis of protein S in the TSR at Arg49, Arg60, and/or Arg70 reduces the affinity of protein S for calcium and phospholipids and causes loss of APC cofactor activity.[242–245] Patients with DIC showed markedly increased levels of cleaved protein S, indicating that cleavage of protein S in the TSR can occur under certain pathological conditions, although this has been labeled nonphysiologic due to inhibition of thrombin-mediated cleavage by calcium ions *in vitro*.[246]

APC-Independent Protein S Anticoagulant Activity

Protein S can directly exert anticoagulant activity independent of its role as an APC cofactor. Initial reports demonstrated that direct binding of protein S to factor Xa, factor Va, and factor VIIIa was responsible for inhibiting functional assembly of the prothrombinase and tenase complex. This activity of protein S was subsequently attributed as due to either an artifact involving protein S multimers or simply a competition of protein S for limited amounts of procoagulant phospholipid surfaces.[220,224,227,247–249] It has been debated whether protein S multimers are artifactual and created during protein S purification, or whether protein S multimers are physiologic and exist in plasma.[248–251] More recent research has provided some evidence for mechanisms by which protein S might directly inhibit thrombin generation, including protein S with tissue factor pathway inhibitor (TFPI), with Zn^{2+} ions, or with tissue factor; each of these interactions, in addition to APC enhancement, may contribute to the antithrombotic activities of protein S.[14,252–255] Few data are currently available to decipher the relative *in vivo* importance of these mechanisms.

Lipids and Lipoproteins

Negatively charged phospholipids, especially phosphatidylserine, markedly enhance both procoagulant and anticoagulant reactions in the test tube. However, certain phospholipids (e.g., phosphatidylethanolamine and cardiolipin) and sphingolipids (e.g., glycosphingolipids and sphingosine) enhance the anticoagulant APC pathway much more than the procoagulant pathways.[184–188,256–260] In particular, glucosylceramide (GlcCer) improves APC anticoagulant activity by enhancing the interaction of APC with phospholipid membranes, and remarkably, GlcCer deficiency is a biomarker and may be a potential risk factor for venous thrombosis.[186,187,259,261]

Most lipids in blood are in lipoproteins. HDL enhances the anticoagulant activity of APC, at least in part, by stimulation of APC's cleavage at Arg306 in factor Va that is protein S dependent.[188] HDL inhibits DIC induced by endotoxin infusion in baboons and inhibits ferric chloride–induced arterial thrombosis in rats.[262,263] The components responsible for this APC cofactor activity of large HDL but not small HDL particles have not been identified, in part, because HDL is extensively heterogeneous in both protein and lipid composition.[258] Moreover, the heterogeneous nature of purified lipoprotein particles makes them challenging for functional coagulation studies; notably, it is possible to draw invalid conclusions about HDL's enhancement of APC activity when studying HDL that was not properly handled or was frozen.[264] Although HDL can exert antithrombotic activity via multiple potential mechanisms, observations from clinical venous thrombosis cohorts are consistent with the hypothesis that deficiency of large HDL particles is a risk factor for venous thrombosis based on reports that recurrent venous thrombosis and venous thrombosis in males are associated with a pattern of dyslipoproteinemia and low HDL.[258,265–267]

In addition, hyperlipidemia and vascular disease can affect protein C activation in primates. Thrombin infusion into healthy animals always generates anticoagulant activity due to APC formation (FIGURE 19.5). But thrombin infusion into hyperlipidemic monkeys with atherosclerosis generates significantly less APC compared with infusion into normolipidemic control monkeys; moreover, hyperlipidemia causes a diminished *ex vivo* response of monkey plasma to APC, thereby showing that dyslipidemia affects the protein C systems *in vivo*.[174,268,269]

THE CYTOPROTECTIVE PROTEIN C PATHWAY

Control of coagulation reactions does not occur in the absence of an integrated host defense system which is comprised of multiple overlapping and integrated pathways, including inflammatory processes, blood coagulation reactions, fibrinolysis, and thrombotic processes (see reviews[1,6,7,161,265,270–272]). In addition to its anticoagulant actions, APC acts directly on cells to cause multiple cytoprotective effects including (a) antiapoptotic activity; (b) anti-inflammatory activities; (c) protection of endothelial barrier function; and (d) alteration of gene expression profiles (FIGURE 19.7). For simplicity of discussion below, these multiple, distinct actions are sometimes, collectively, referred to as APC's cytoprotective effects although the mechanism for each type of activity must involve distinct types of cell-signaling actions. Several components of the anticoagulant pathway, in addition to protein C itself, contribute not only to anticoagulant activity but also to cytoprotective functions and continue to stimulate new directions for the protein C cytoprotective pathway.

Mechanisms and Major Components

The currently best established paradigm for the direct cytoprotective actions of APC is that EPCR-bound APC activates PAR-1 to initiate signaling, and this is widely supported by both *in vitro* and *in vivo* evidence (see reviews[2,5,6,9,13,273,274]) (FIGURE 19.7). However, other receptors may mediate, directly or indirectly, APC-initiated signaling in various cells (see below). Such other receptors include sphingosine-1-phosphate receptor 1 (S1P1), apolipoprotein E receptor 2 (ApoER2), glycoprotein Ib, several integrins, PAR-3, Tie2, and epidermal growth factor receptor.[19,20,43,47,275–282]

APC proteolytic actions can also indirectly protect cells from the detrimental effects of histones or of neutrophil-derived histone–DNA complexes because APC can cleave extracellular histones, and this activity appears to protect against sepsis in mice.[283]

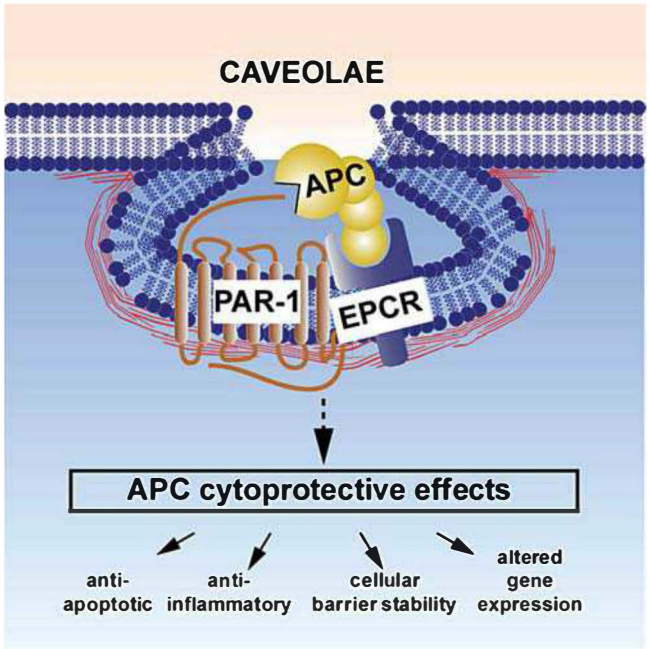

FIGURE 19.7 Beneficial direct effects of APC on cells. The cellular receptors EPCR and PAR-1 are required for APC's beneficial effects on endothelial cells. These activities include APC-mediated antiapoptotic activities, anti-inflammatory activities, protection of endothelial barrier functions, and alteration of gene expression profiles. This paradigm in which EPCR-bound APC activates PAR-1 to initiate signaling is consistent with many *in vitro* and *in vivo* data. Localization of APC signaling in the caveolin-1–rich microdomains (caveolae) may help differentiate mechanisms for cytoprotective APC signaling versus proinflammatory thrombin signaling.[72,311] Additional mechanisms for APC effects on cells may also involve other receptors. These effects include APC anti-inflammatory effects on leukocytes or cytoprotective effects on dendritic cells and neurons, and other receptors may include S1P1, apoER2, PAR-3, and specific integrins (e.g., CD11b). Transactivation of the S1P1 receptor by the PAR-1/EPCR/APC complex is required for APC's ability to protect endothelial barrier functions and EPCR coimmunoprecipitates with S1P1 in the presence of APC.

Protease-Activated Receptor-1

PAR-1 is a thrombin receptor that is the prototype of a four-member subfamily of protease-activated G-protein–coupled receptors (GPCRs).[284–290] Each PAR contains seven transmembrane helical domains and an extracellular *N*-terminal tail that upon cleavage by various proteases generates a new amino-terminus acting as a tethered ligand to trigger cell signaling, most often but not always via coupled G proteins.[285,291,292] The gene for PAR-1 (F2R) is on chromosome 5q13 and contains only two exons (Table 19.1), and its expression varies substantially among different cells and tissues.[284–290,293] Although thrombin activates human platelets via PAR-1 and PAR-4, curiously, murine platelet activation involves PAR-3 and PAR-4, but not PAR-1 which is lacking on murine platelets.[286,294,295]

Mechanisms for PAR-1–initiated signaling are complex and likely involve a spectrum of conformational states and a diverse family of agonists, partial agonists, coreceptors, and allosteric effectors that typify the complexity of a GPCR.[296–300] While EPCR acts as an essential cofactor for PAR-1 activation by APC, EPCR can also modulate PAR-1 activation *in vitro* by factor VIIa and factor Xa.[16,17,18,41,301–306]

Mechanisms on Endothelial Cells

A useful but incomplete paradigm for APC-induced signaling on endothelial cells is one in which EPCR-bound APC cleaves and activates PAR-1 (FIGURE 19.7), and extensive *in vitro* and *in vivo* data support this model (see reviews[6,15–17,42,71,274,276,307–309,310,311]). Yet, the puzzle remains of how PAR-1 can be activated by both APC and thrombin with contrasting outcomes.[2,71,72,311,312] Some suggest that PAR-1's signaling properties are altered in relationship to the localization of PAR-1 and EPCR in membrane rafts, specifically in caveolae (FIGURE 19.7).[71,311,313,314] Accordingly, localization of PAR-1 and EPCR in membrane rafts, possibly induced by occupancy of EPCR, is required for cytoprotective signaling properties via PAR-1 as APC's PAR-1 signaling but not thrombin's PAR-1 signaling is caveolin-1 dependent.[72] Furthermore, thrombin-cleaved PAR-1 is rapidly internalized, whereas APC-activated PAR-1 tends to remain on the cell surface, which could prolong signaling, by APC compared to thrombin.[72,315]

APC's cytoprotective effects are multiple and vary widely in nature (FIGURE 19.7). Certainly, the initiation and integration of signaling pathways that mediate each type of cytoprotective activity of APC are, at most, only partially overlapping. Much needs to be elucidated before even a partial picture emerges for intracellular mechanisms that mediate APC's various cytoprotective actions. It is unclear whether each of these activities is indeed almost completely separate or whether these activities are intimately intertwined and dependent on each other. For example, does APC mediate antiapoptotic activity because APC downregulates certain proapoptotic gene expression, or because it upregulates certain antiapoptotic gene expression, or because APC somehow intervenes more specifically at certain steps of the apoptotic transformation of the cell, or because of all of these?[15–17,276,316–318] Moreover, the mechanisms likely depend on the cell type and the context of cells, tissues, and organs.

Some insights into mechanisms for APC's ability to stabilize endothelial barriers and to minimize vascular permeability are available. Whereas thrombin-mediated PAR-1 activation results in activation of barrier disruptive RhoA, Rho kinase-mediated inactivation of myosin light-chain phosphatase, and actin–myosin contractility due to increased myosin light-chain phosphorylation, APC prevents such morphologic transformations and maintains endothelial barrier functions both *in vitro* and *in vivo*.[19,20,42,319–323] In reactions that require EPCR, PAR-1, S1P1, and caveolin-1, APC activates barrier-protective Rac1 via PAR-1, β-arrestin, and the dishevelled-2 scaffold.[72,311,312,324] APC's barrier protective effects via Rac1 activation are similar to endothelial barrier stabilization by S1P, an endogenous bioactive lipid, in that APC causes EPCR-dependent clustering and transactivation of the S1P1 in membrane lipid rafts and with potential sphingosine kinase 1 (SphK1) "inside-out" signaling by S1P.[19,20,323,325]

Mechanisms on Lymphocytes

Lymphocytes are an important target for APC's anti-inflammatory effects where APC can downregulate inflammatory mediator release and expression of procoagulant activity. Interestingly, the APC–PAR-1–EPCR signaling complex seems to play a less

tahir99-VRG & vip.persianss.ir

prominent role on lymphocytes. Instead, additional receptors and receptor complexes, including ApoER2, EPCR, integrins, or combinations thereof, have been implicated to play a role in mediating APC's anti-inflammatory activities. APC indirectly influences leukocytes by preventing expression of adhesion molecule expression (such as ICAM-1, VCAM-1, and E-selectin) on endothelial cells, resulting in downregulation of lymphocyte adhesion and tissue infiltration.

Integrins are important modulators of APC signaling and anti-inflammatory effects on lymphocytes. On macrophages, APC binds integrin CD11b/CD18 ($\alpha_M\beta_2$, Mac-1, CR3) within specialized membrane microdomains/lipid rafts where it presumably replaces the role of EPCR in initiating PAR-1–dependent signaling by APC. Enhanced production of barrier-protective S1P and suppression of the proinflammatory response of activated macrophages is dependent on CD11b/CD18 but not on EPCR.[282] Soluble EPCR and proteinase-3, a serine protease with elastase-like properties stored in granules of neutrophils, bind CD11b/CD18 on activated neutrophils. When soluble EPCR is bound to proteinase-3, soluble EPCR retains the ability to bind APC. Thus, although speculative at present, soluble EPCR may contribute to CD11b/CD18-mediated APC cellular signals and/or activation of protein C on leukocytes.[326] CD11b/CD18 is a ligand for ICAM-1 and plays a pivotal role in the adhesion and migration of leukocytes.[327,328] Accordingly, binding of soluble EPCR to CD11b/CD18 might interfere with leukocyte adhesion as an antibody that blocks β_2-integrin–mediated adhesion also inhibited soluble EPCR binding to CD11b/CD18.[326] An RGD (Arg–Gly–Asp) sequence is present in human protein C and APC has been implicated in binding β_1- and β_3-integrins and inhibiting neutrophil migration.[278] Furthermore, glycoprotein Ib and ApoER2 are also able to bind APC to cell surfaces.[275] With the arsenal of APC receptors on vascular cells expanding, it seems less and less likely that there is one unifying mechanism for each of APC's cytoprotective effects on various cell types. Instead, APC cellular activities and its underlying mechanisms seem to be dictated by cell-type specific expression of APC receptor complexes. Dendritic cells have been identified as mediating APC's EPCR-dependent ability to reduce mortality in endotoxemia.[79]

Mechanisms on Other Cells

The beneficial effects of APC on neurons, epithelial cells, keratinocytes, and tenocytes have been described, often requiring EPCR. Only little is known about receptors or mechanistic steps for APC's effects on these cells, but EPCR is almost always required.[47,276,279,281,329–331] The remarkable effects of APC include the ability to promote wound healing, likely based on its effects on keratinocytes. Generally, it appears that APC is a homeostatic protease that stabilizes stressed or challenged cells of various types.

Apolipoprotein E Receptor 2

The observation that ApoER2 (gene symbol LRP8) (low-density lipoprotein receptor–related protein 8) binds APC with high affinity and that APC can mediate activation of signaling pathways via ApoER2 expanded the receptor repertoire for APC's cytoprotective effects on cells.[43,275] ApoER2 is found in platelets and endothelial cells, but it is best known for its central role in the "Reelin signaling pathway," which plays a crucial role in the correct positioning of neurons during embryonic brain development.[332–357] Reelin, a very large protein (>3,400 residues), initiates signaling via Dab1 by binding simultaneously to very low-density lipoprotein receptor and ApoER2.[358] Dab1-dependent activation of the Src family kinases ultimately results in the activation of PI3K-Akt signaling cassette, a well-known survival pathway, and a major mechanism for promoting cell survival. APC can activate a "Reelin-like signaling pathway" on monocytes via rapid ApoER2-dependent Dab1 phosphorylation at Tyr220 and phosphorylation of Akt at Ser473.[43] The *in vivo* significance of apoER2 as a physiologic or pharmacologic receptor for APC has not been assessed.

ENDOGENOUS CYTOPROTECTIVE PROTEIN C ACTIVITIES

While much evidence indicates that the cell-signaling activities of APC are primary for pharmacologic applications of APC's ability to reduce mortality, recent studies have established an important physiologic role for cell signaling by the endogenous protein C system in mice. Mice that are genetically engineered to be null for EPCR exhibit embryonic lethality, whereas mice with high levels of EPCR expression show resistance to lipopolysaccharide-induced death, showing there is a physiologically essential role for EPCR.[359–361] The cytoprotective activities of endogenous APC are required for protection in murine sepsis models and also appear to be necessary for survival of the initial shock injury in a different model of trauma/hemorrhagic shock.[362,363]

PHARMACOLOGIC PROTEIN C THERAPIES

Preclinical and clinical studies of APC and protein S have established these molecules as antithrombotic agents with anti-inflammatory activity. The additional *in vivo* effects of APC therapies include antiapoptotic activity and inhibition of vascular leakage. Studies that provided mechanistic insights are noted elsewhere in this chapter. Clinical studies and animal model systems in which APC therapy provided promising results are reviewed elsewhere.[6,9,13,274,364,365]

APC provides remarkable neuroprotective effects *in vivo* and increases survival in murine ischemic stroke studies.[276,366–368] Beneficial effects of daily dosing of APC have proven efficacious in animal models of amyotrophic lateral sclerosis and appear promising in animal models of multiple sclerosis and Alzheimer disease.[13,280,369] Thus, APC conveys disease-modifying effects in both acute neurologic injury (e.g., stroke and nerve crush injury) and chronic neurodegenerative disorders. These neuroprotective actions appear to be based on APC's cytoprotective properties.[13] In murine models of brain injury, APC's neuroprotection required PAR-1, EPCR, and PAR-3.[17,47,276,277,309,370] Whereas tissue plasminogen activator (tPA) is capable of directly causing damage to neurons, APC effectively counteracts tPA's neurotoxic effects.[368,370–373] Moreover, APC prevents tPA-induced hemorrhagic transformation during ischemic stroke therapy.[309] Thus, preclinical studies suggest that APC's cytoprotective activities are promising for providing neuroprotective therapies.

Purified plasma-derived protein C concentrates have been developed and approved for replacement therapy in patients with deficiency of plasma protein C. This protein C product is made using plasma fractionation methods and has been used both for standard replacement therapy and for clinical investigations of the value of protein C therapy.[89,374,375]

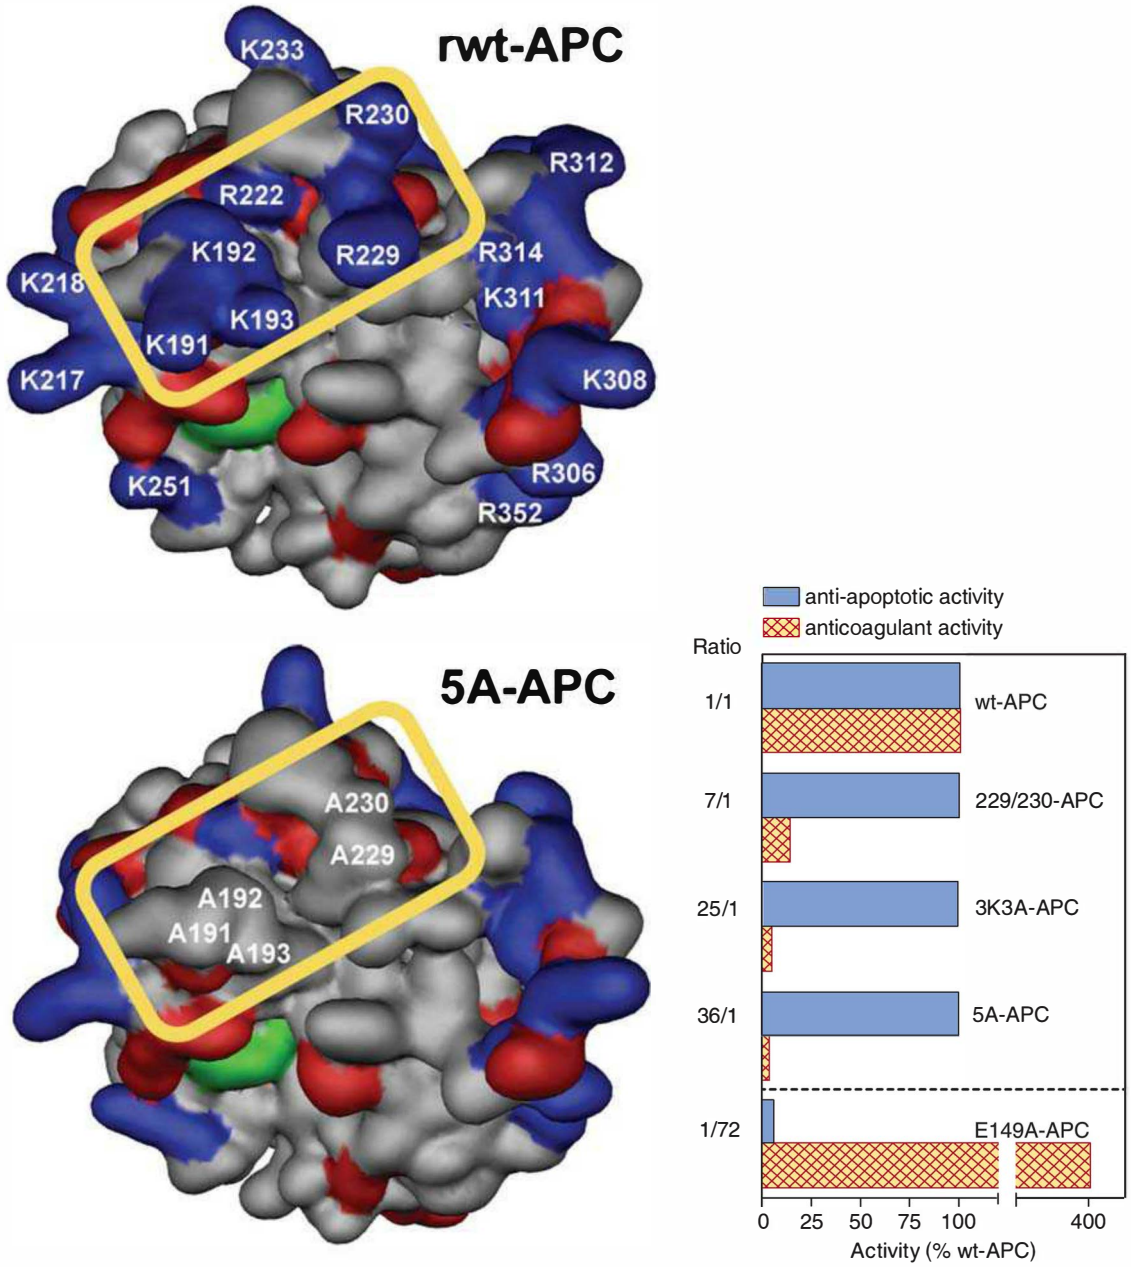

FIGURE 19.8 APC exosite residues on the protease surface that mediate APC anticoagulant activity but not antiapoptotic activity. Interactions of APC with its macromolecular substrates (factor Va, factor VIIIa, and PAR-1) are dictated by exosite interactions of APC protease domain surface loops. Residues in the 37-loop (Lys191, Lys192, and Lys193) and in the calcium-binding loop (Arg229 and Arg230) are required for normal cleavage of factor Va at Arg506 and thus for normal anticoagulant activity while they are not involved in proteolytic activation of PAR-1 that generates antiapoptotic activity. Based on this exosite specificity difference, the 3K3A-APC and 5A-APC variants may provide reduced risk of bleeding due to reduced anticoagulant activity but provide full cytoprotective activity.[381] The surface contours with positive (*blue*) and negative (*red*) side chains are shown for wildtype APC (wt-APC) and for the 5A-APC variant (containing five Ala substitutions at Lys191, Lys192, Lys193, Arg229, and Arg230). The neutral side chain of Ala at 191, 192, 193, 229, and 230 appears *gray*. Comparison of the protease domain for 5A-APC **(bottom left)** to that of wt-APC **(top left)** highlights the loss of five positively charged surface residues (*blue*) from an exosite that is required for normal recognition of FVa. The values for antiapoptotic activity (*gray bars*) and anticoagulant activity (*cross-hatched bar*) for wt-APC and each APC variant are shown where the reference values for wt-APC are defined as 100% **(right)**. The ratio of antiapoptotic to anticoagulant activity is shown, where 1/1 is the reference ratio for wt-APC. The 3K3A-APC and 5A-APC variants have greatly reduced anticoagulant activity relative to cytoprotective activity, while the converse is the E149A-APC variant. Protein S has beneficial antithrombotic and neuroprotective effects in several preclinical studies; however, few data are available to clarify the relative importance of antithrombotic actions versus cell-signaling actions induced by protein S.[46,376,377]

ENGINEERED APC MUTANTS

Engineering of APC mutants in the last century was driven by efforts to clarify why human mutations in protein C–deficient patients caused thrombosis and to explore structure–function relationships for APC's anticoagulant activity, and many APC mutants have been studied.[2,6,378,379] However, the success of the PROWESS sepsis trial, combined with the failure of other anticoagulants, AT, and TFPI in similar sepsis trials, helped to stimulate discoveries of APC's cytoprotective actions. It was also disturbing that bleeding was a serious side effect of APC in the PROWESS trial.[31,380] These considerations stimulated the authors to try to prepare APC variants with a reduced risk of bleeding due to reduced anticoagulant activity but with normal direct effects on cells.[381]

Efforts to engineer cytoprotective-selective APC mutants were based on the assumptions that (a) anticoagulant activity is based on APC exosite's recognition of factor Va; (b) antiapoptotic activity is representative of APC's cytoprotective effects *in vivo*; (c) APC's cytoprotective effects require APC-mediated PAR-1 activation; and (d) cleavage at Arg41 in the *N*-terminal tail of PAR-1 has different APC exosite requirements than cleavage at Arg506 in factor Va. This would mean that the factor Va exosites and the PAR-1 exosites on APC are, at least partially, nonoverlapping. Thus, we attempted to alter factor Va exosites in APC without affecting exosites that might recognize PAR-1.[6,381]

The interaction of APC with the Arg506 cleavage site in factor Va that is critical for APC's normal anticoagulant activity involves a positively charged surface of the protease domain that includes loop 37 (protein C residues 190 to 193, equivalent to chymotrypsin [CHT] residues 36 to 39), the Ca^{2+}-binding loop (residues 225 to 235, CHT residues 70 to 80), and the autolysis loop (residues 301 to 316, CHT residues 142 to 153) (see FIGURE 19.8).[40,200,202–205,382] To provide proof of concept, two APC variants were selected with Ala mutations in two exosites defined by two APC surface loops; these mutants involved Ala replacements of Arg229 and 230 and/or of Lys191, 192, and 193. When tested in assays of staurosporine-induced endothelial cell apoptosis, these two APC variants, 3K3A-APC and 5A-APC, had reduced anticoagulant activity but retained normal antiapoptotic activity that requires PAR-1 and EPCR and exhibited a normal ability to cleave a PAR-1 *N*-terminal peptide at Arg41.[381] When the anticoagulant and antiapoptotic activities of these APC variants were normalized to wildtype APC (wt-APC), the two APC variants exhibited 25 times and 33 -times greater antiapoptotic activity relative to anticoagulant activity when compared to wt-APC (FIGURE 19.8). Other APC mutants with altered activity profiles include the cytoselective mutants, L38D-APC, an engineered disulfide APC mutant, and anticoagulant-selective mutants with mutations at residues 330 or 333.[234,383–386]

When murine cytoprotective-selective, 3K3A-APC and 5A-APC mutants lacking most anticoagulant activity were compared *in vivo* to wt-APC for APC's ability to reduce mortality in sepsis or to provide neuroprotection in ischemic stroke models, these mutants were fully active and appeared indistinguishable from wt-APC.[42,47,79,387] In contrast, the murine anticoagulant-selective E149A-APC mutant lacking antiapoptotic activity failed to reduce mortality in mice. Moreover, murine 5A-APC also reduced death in murine pneumonia.[323] These data support the idea that APC's cytoprotective actions are primarily responsible for APC's *in vivo* benefits in sepsis and neuroprotection for stroke and they set the stage for efforts to develop APC mutants as second-generation biologics with greatly reduced risk of bleeding. Cytoprotective-selective APC mutants also should permit trials with altered dosing regimens, consistent with APC's ability to alter cell signaling rather than to provide constant, prolonged anticoagulant therapy with anticoagulant APC.

CHAPTER

20 Plasminogen Activation and Regulation of Fibrinolysis

NICOLA J. MUTCH AND NUALA A. BOOTH

Hemostasis requires mechanisms both to stop bleeding by formation of a hemostatic plug and to dissolve this plug following wound repair, thereby allowing normal blood flow through the vessel. The latter function relies on local activation of plasminogen (PLG) to plasmin, which dissolves fibrin. The system is finely tuned, to allow healing of a vascular lesion without compromising the early stability of the hemostatic plug and to limit fibrinolytic activity to the injured area. There is a dynamic equilibrium between coagulant and fibrinolytic activities and, within these systems, a further balance between proteolytic and inhibitory proteins. Excessive local or systemic fibrinolytic activity can result in bleeding, often occurring after a delay, as the weakened plug is dissolved. Conversely, an inadequate fibrinolytic response may retard lysis of a thrombus and contribute to its extension.

Plasmin is the central enzyme responsible for thrombus degradation. It is a trypsin-like serine protease generated by activation of the zymogen, PLG. The central players governing the system are plasminogen activators (PAs) and inhibitors of both the activation stage and plasmin activity. Additional players include fibrin and cell surfaces and further proteins that interact with the PLG activation system. This chapter first introduces the key components and then considers how they interact to regulate the activation of PLG and the degradation of fibrin.

PROTEASES AND SUBSTRATES

Fibrinolytic proteases include plasmin, the enzyme that degrades fibrin, and two major PAs that occur in the circulating blood, tissue-type plasminogen activator (tPA) and urinary-type plasminogen activator (uPA), also called urokinase (UK). Like the serine proteases of blood coagulation, they generally exist as a zymogen, a single-chain form of the molecule that is activated by cleavage of a single peptide bond. All the active serine proteases cleave arginine and/or lysine bonds and originated from a simple trypsin-like ancestor protease.[1,2] In the case of the fibrinolytic proteases, the products are all in a two-chain form held together by one or more disulfide bonds. An exception to this rule is tPA, which is an active protease in its single-chain form; tPA can be considered to be at one end of the scale of zymogenicity, with PLG as a totally inactive example at the other.[3]

The typical structure of these proteases (FIGURE 20.1) is that they have an *N*-terminal A chain containing several independently folded modules or domains, which have particular binding properties, and a *C*-terminal B chain, which contains the protease domain. The kringle domain—named after a Danish pastry—is approximately 80 residues long and is held together by three internal disulfide bonds. The finger domains are homologous to type I and type II fibronectin regions. Type I finger domains are approximately 50 residues long, contain two internal disulfide bonds, and may play a role in fibrin binding. The epidermal growth factor (EGF) domains, which are homologous with a module in the EGF precursor, contain 53 residues and three internal disulfide bonds. In several proteins, these domains bind to specific cell-surface receptors or binding proteins. The protease domain (about 250 residues, including four disulfide bonds) contains the catalytic triad, Ser195, His57, and Asp102 (chymotrypsin numbering). The protease domain is well conserved, with particularly high-sequence identity in the vicinity of the three active site residues and at the *N*-terminus.

The individual components of the fibrinolytic system are now discussed in more detail, beginning with the central enzyme, plasmin, and its action on fibrin.

PLASMIN DEGRADATION OF FIBRIN(OGEN)

Fibrin is the substrate most relevant to this chapter but many studies of cleavage sites used fibrinogen, a soluble protein that is more amenable to study (reviewed by[4]). Plasmin cuts primarily at lysyl and arginyl bonds. Plasmin initially cleaves the α chain of fibrinogen to release the αC fragments, thereby producing fragment X (~260 kDa; FIGURE 20.2). Further cleavage of fragment X in the α, β, and γ chains along one-coiled coil, connecting the central E and terminal D domains of fragment X, splits the molecule asymmetrically generating fragment Y (~160 kDa) and fragment D (~100 kDa).[5] Plasmin then cleaves fragment Y into two additional products, a second fragment D and fragment E (~60 kDa), which contains the amino-terminal portion of all six polypeptide chains. Fragment X can be subsequently clotted by thrombin while fragments Y and D have antipolymerizing effects.

Plasmin digestion of non–cross-linked fibrin is identical to that of fibrinogen, supporting the hypothesis that fibrinogen does not undergo major structural reorganization during polymerization.[6] Cross-linked fibrin is degraded more slowly by plasmin and produces different fibrin degradation products (FDPs). Initially a fragment, termed D-dimer, consisting of two fragment D moieties from adjacent fibrin monomers covalently bound between their γ-chain remnants is generated (FIGURE 20.2). Fragment E exists free and in a noncovalent complex with D-dimer (DD/E complex). A variety of large degradation products are released from cross-linked fibrin. These complexes represent a noncovalently bound two-stranded, half-staggered fibrin protofibril. The DD/E fragment is the smallest complex, with larger forms representing longitudinal strings of DD/E held together by uncleaved coiled coils.[5] These larger FDPs are able to associate, in a size-dependent manner, both with themselves and with the clot.[6]

PLASMIN(OGEN)

Human PLG is the zymogen form of plasmin (EC 3.4.21.7). PLG is a single-chain glycoprotein of 92 kDa, consisting of 791 amino acid residues and approximately 2% carbohydrate (Table 20.1). In the human adult, the plasma concentration of PLG is approximately 200 mg/L, or 2 μM (Table 20.1) and is generally rather stable, but there is an increase in the acute-phase response.[7] The circulating half-life ($t_{½}$) of native PLG, which has a glutamic acid residue at its *N*-terminus (Glu–PLG), is approximately 2.2 days; the partially cleaved Lys–PLG (see subsequent section, "Activation of Plasminogen") has a much shorter $t_{½}$ of 0.8 days.[8] The principal production site for PLG is the liver, but PLG is present in the extravascular space of most tissues. Some tissues, such as eosinophils, kidney, cornea, brain, and adrenal medulla, may be capable of synthesizing it.[9–12]

Expression and Structure

The PLG gene is 52.5 kb and is located on chromosome 6q26–q27,[13] close to two genes for apolipoprotein (a) and for the PLG-related genes A and B.[14,15] Two sequence elements of CTGGGA common to acute-phase reactant genes are at position 76 to 81 and −553 to −558.[16] Three interleukin-6–responsive elements are at positions −830, −518, and +117 in the 5′-flanking region.[17] Two main regions conferring liver specificity of expression to the PLG gene were found in the *cis*-acting element, AAAAATA, at −2,194 to −2,188 and +48 to +61.[18] Several other putative regulatory transcription elements are present in the 5′-flanking region (reviewed in Ref. 17). On the 3′-flanking region, the location of the consensus polyadenylation sequence AATAAA and of potential CAYTG sequence indicates the presence of three polyadenylation sites.[16]

PLG consists of an *N*-terminal activation peptide, five kringles, and the protease domain with the catalytic triad His603, Asp646, and Ser741[16] (FIGURE 20.3). The kringles are well conserved between species[19] and consist of some 80 residues, the structure being shaped by a characteristic 1–6, 2–4, 3–5 disulfide bond pattern using the conserved Cys residues in positions 1, 22, 51, 63, 75, and 80 (kringle 5 numbering). K2 and K3 are covalently linked by a further disulfide bond.[20] Functionally, the kringles give PLG the ability to bind to exposed lysyl residues in fibrin,[21,22] $\alpha_2$antiplasmin (α_2AP),[23] tetranectin,[24] histidine-rich glycoprotein (HRG),[25] collagen,[26] high molecular weight (HMW) and low molecular weight (LMW) kininogen,[27] thrombospondin,[28] and cell-surface receptors or binding proteins for PLG (discussed

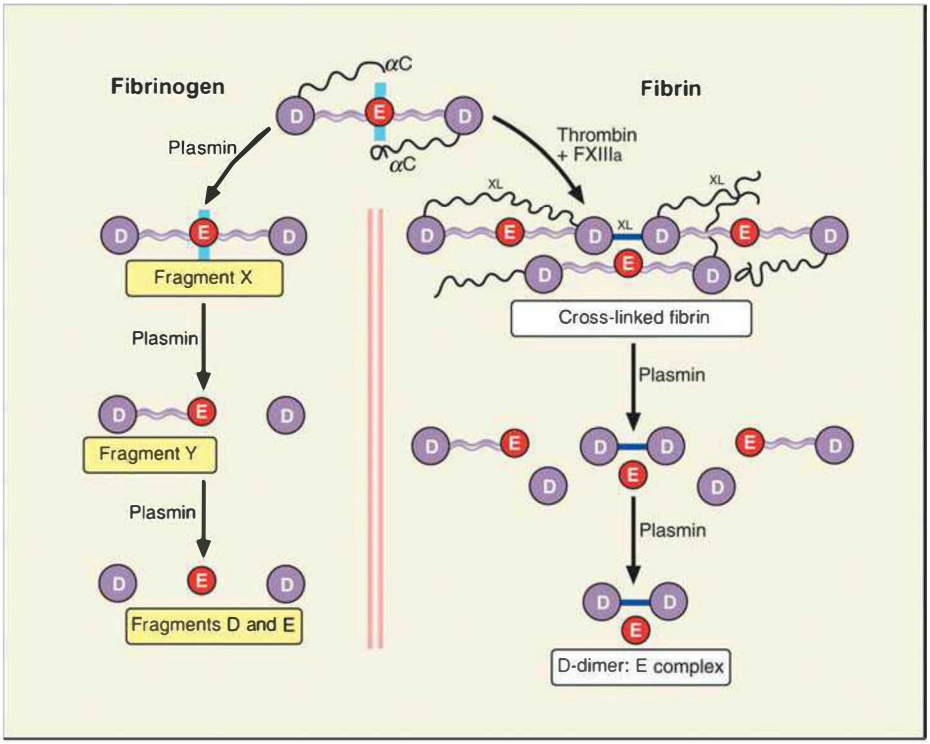

FIGURE 20.2 Degradation of fibrin(ogen) by plasmin. The principal structure of fibrinogen **(top)** is a three domain globular protein with extending αC domains. Through the action of plasmin the degradation fragments D, E, α-helical coiled coils that connect them, and the Aα chains that extend from the carboxy-terminus of the D-domains. Fibrinogen is degraded asymmetrically **(left panel)**. Intermediate degradation product, fragment X, consists of all three domains connected by coiled coils, but lacks the Aα chains and the Bβ1-42 sequence. Fragment Y is composed of the central E-domain connected by a coiled coil to the D-domain. Cross-linked fibrin **(right panel)**, occurs through the enzymatic actions of thrombin and activated factor XIII (FXIIIa). Thrombin cleaves fibrinopeptides A and B from the E-domain, and FXIIIa cross-links (XL) fibrin longitudinally between D-domains and within the α-chain extensions (see Chapter 16). Plasmic cleavage of the two-stranded protofibrils initially removes the cross-linked α chains, then the coiled coils to liberate a series of FDPs, the smallest of which is DD/E. Larger complexes, such as DY/YD, are also liberated from cross-linked fibrin, but these are subsequently degraded to the DD/E moiety.

in more detail below). The affinity of the kringles for lysine is exploited in affinity chromatography.[29] The kringles also bind to ω-aminocarboxylic acids, such as 6-aminohexanoic acid (εACA, 6-AHA), *p*-aminomethyl benzoic acid (*p*-AMBA), and *trans*-4-amino-methyl-cyclohexane-carboxylic acid (*trans*-AMCA, also known as tranexamic acid). These are used experimentally and clinically to inhibit the functional activity of plasmin by competing with the binding of plasmin(ogen) to fibrin and cell surfaces.

Human PLG kringles have different affinities and specificities for ω-amino acids, such as εACA. Kringle 1 exhibits the tightest binding (K_d 9 μM),[30,31] followed by kringle 4[30,32,33] and kringle 5,[32,33] with kringle 2 interacting only weakly and kringle 3 not at all.[34] Kringle structures have been solved both in solution and in crystals and show the general feature of a hydrophobic groove with acidic and basic residues that are ideally spaced for docking of zwitterions such as lysine or εACA, the opposite charges of which are approximately 7 Å apart. The lack of binding by kringle 3 is explained by the positive charge at position 57, which in the other kringles is negatively charged.[35]

Experimentally, kringle 4 can be isolated from PLG by digestion with elastase, typically yielding three major components: a fragment containing kringles 1 to 3, kringle 4, and kringle 5 attached to the protease domain.[20] The latter fragment, also called *mini-PLG*, can be activated to plasmin by PAs,[36–38] as can microplasmin, which has only the last 31 amino acid residues of the A chain and a complete B chain.[38] Kringle 1 can be obtained from kringles 1 to 3 by further digestion with other enzymes, such as *Staphylococcus aureus* V8 protease.[39] Other fragments of PLG have effects on tumor growth and metastasis; these fragments are known as angiostatins. Their activity depends crucially on their disulfide pattern.[40]

Activation of Plasminogen

All known PAs cleave the Arg561–Val562 bond in PLG (FIGURE 20.4), generating a two-chain plasmin molecule in which the A and B chains remain attached by two disulfide bonds. PLG exists in different conformations, affected by its *N*-terminus and also by the presence of lysine analogues. A particularly important consideration is whether PLG is free in solution or bound to a surface, either fibrin or cells, as discussed more fully in the section on "Balance of Plasminogen

Table 20.1

Properties of proteins of the fibrinolytic system

Factor	M_r (kDa)	Residues	Concentration (mg/L)	Molar Concentration	$t_{½}$	Function

[a] M_r of nonglycosylated form as listed in Swiss protein base ExPASy.
[b] Heavy chain of homotrimer.
[c] Many isoforms due to 13 up to 37 type 4 kringle motifs.
[d] Activated form.
[e] Heavy chain of heterotetramer (formed by two heavy and two 10-kDa light chains).
tPA, tissue-type plasminogen activator; uPA, urinary-type plasminogen activator; PAI-1, plasminogen activator inhibitor 1; PAI-2, plasminogen activator inhibitor 2; HMW, high molecular weight; C1-inhibitor, complement component 1 esterase inhibitor; TAFI, thrombin-activatable fibrinolysis inhibitor; uPAR, urinary-type plasminogen activator receptor; LRP, low-density lipoprotein receptor–related protein; MR, macroglobulin receptor.

Activation and Regulation of Fibrinolysis" At this stage of our discussion, it can be assumed that the binding is primarily dependent on exposed lysine residues, and that the binding to fibrin and to cell receptors for PLG are generally equivalent.

Cleavage of Glu–PLG generates trace amounts of plasmin cleaved at the *N*-terminus at one or several of the following bonds: Arg68–Met69, Lys77–Lys78, or Lys78–Val79.[41,42] The final product obtained is termed Lys–plasmin (FIGURE 20.4). These two conformations differ in several features, including efficiency of activation and binding to fibrin. Small-angle neutron scattering revealed that Glu–PLG has a more closed form than Lys–PLG,[43] making it less readily activated. In the closed form, the five kringle domains and the catalytic domain interact to produce an ellipsoid shape. The open form of Lys–PLG, in contrast, has increased flexibility, which facilitates the binding of PAs some 10-fold.[44–46] Binding of εACA to Glu–PLG elicits a similar, but probably not identical change in conformation.[43] Lys 50 of Glu–PLG binds to kringle lysine binding site (LBS),[47,48] making them less available for binding to *C*-terminal lysine in fibrin, PLG receptors, and other proteins, so that Lys–PLG binds with higher affinity to fibrin than does Glu–PLG. The susceptibility of Glu–PLG to activation is dependent on additional factors, such as the presence of anions, which in the human plasma are mainly chloride ions, and of the divalent cations Ca^{2+}, Mg^{2+}, and Mn^{2+}. These ions counteract the effect of εACA and stabilize PLG in the Glu-form.[46,49]

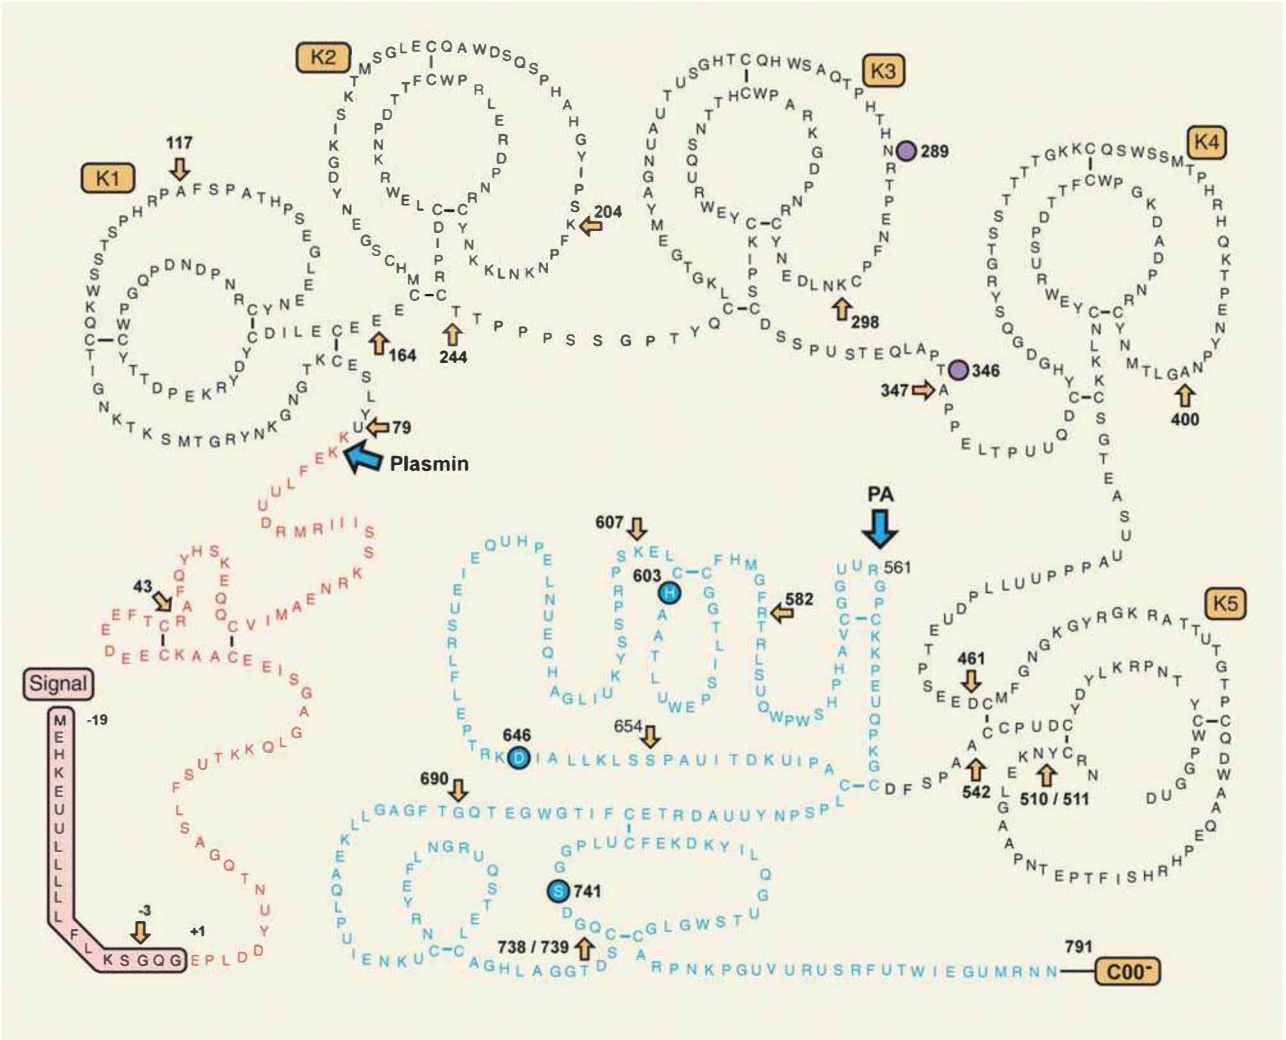

FIGURE 20.3 Sequence of the human PLG molecule. Positions of the 18 introns are indicated by *yellow arrows* at (for type 1 and 2 introns) and between (for type 0 introns) residues. The 19-residue signal peptide (shown in the *pink box* with negative numbers) is cleaved by the signal peptidase at the Gly–Glu peptide bond. Conversion of PLG to plasmin by PAs occurs after the peptide bond Arg561–Val562 (shown by a *blue arrow*). Plasmin cleaves primarily at Lys77–Lys78 bond (shown by a *blue arrow*) to release the activation peptide (*red lettering*) generating Lys–plasmin(ogen). K1–K5 kringles are located in the A chain (*black lettering*). The B chain remains attached to the A chain (*blue lettering*) after cleavage at 561–562 by PAs via the disulphide bonds Cys548–Cys666 and Cys558–Cys566. Carbohydrate attachment sites (Asn289 and Thr346) are shown as *purple circles*. The residues that comprise the classical serine protease Ser–His–Asp catalytic triad are *circled in blue*. (Redrawn based on Petersen TE, Martzen MR, Ichinose A, et al. Characterization of the gene for human plasminogen, a key proenzyme in the fibrinolytic system. *J Biol Chem* 1990;265:6104.)

Variants of Plasminogen

The PLG molecule is subject to considerable variation in the normal population. In addition to the limited proteolysis and activation processes already discussed, the two important sources of variation are glycosylation and genetic polymorphism.

Glycosylation

Human Glu–PLG occurs in two variants that differ in glycosylation. PLG variant 1 is diglycosylated, with *N*-linked carbohydrate moiety of the mannose type with 10 to 11 monosaccharide units on Asn289, and an *O*-linked moiety of three to four residues on Thr346 (FIGURE 20.3).[50] PLG 2, which accounts for a little more than half the circulating PLG, contains only the carbohydrate group at Thr346.[51] Both of these forms exhibit additional heterogeneity with respect to their sialic acid content, generating six additional isoforms with pIs between 6.1 and 6.6.[41,42,52,53] All 12 molecular forms are present in plasma from single donors.[8]

Activation of PLG 1 in solution is faster than PLG 2, but this difference is not evident on fibrin. PLG 1 switches more readily to the open conformation in the presence of fibrin or tranexamic acid than PLG 2.[54] PLG 2 is more rapidly cleared than PLG 1 and bound five times faster to a de-endothelialized

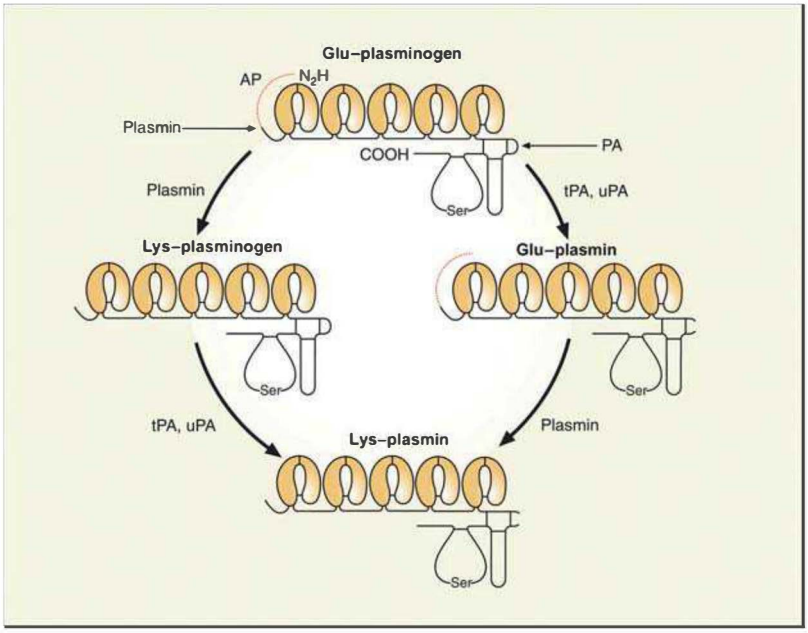

FIGURE 20.4 Activation of native Glu–PLG. PA cleaves at Arg561–Val562, separating the B (light, protease, or catalytic) and the A (heavy, kringle) chains. Glu–PLG and Glu–plasmin forms both contain the amino-terminal activation peptide from Gln1 to Lys76 (shown in *red*). Plasmin has the potential to cleave this activation peptide (*left side*), producing Lys–PLG, an intermediate form that interacts with fibrin more efficiently and is readily cleaved by the PAs (tPA and uPA). Plasmin can also cleave the activation peptide from Glu–plasmin, generating Lys–plasmin (*right side*). The five kringle structures of the A chain are involved in binding of PLG to both fibrin and cell receptors. The catalytic center contains the typical Ser–His–Asp residues and is the major site of interaction with $\alpha_2$antiplasmin.

vessel surface.[55–57] Additional glycosylation sites at Ser249[58] and Ser339[59] have been described; a further serine residue, Ser578, can be phosphorylated.[60]

Polymorphism and Deficiency

Isoelectric focusing of neuraminidase-treated plasma (which removes sialic acid) revealed several bands of activatable PLG, representing the genetic polymorphism of PLG alleles. The two most common variants found in all races are called *PLG A* (A for acidic pI) and *PLG B* (B for basic pI)[61] with Asp and Asn at position 453, respectively.[62] Variants with intermediate pI are designated as PLG M. Variants with more acidic pI than PLG A are assigned a numerical suffix that increases with decreasing pI. Similarly, variants with more basic pI than PLG B receive a numerical suffix that increases with increasing pI. Alleles are designated with an asterisk (e.g., PLG*A3), and silent (null) PLG alleles are designated PLG*Q0 (Q0 standing for quantitatively zero or nonexpressed). The frequency of the allele PLG*A in the Japanese population is considerably higher (95%) than in the Western population (70.1%).[63]

Recurrent thrombosis is associated with a deficiency of PLG antigen and activity (type I), or a normal level of antigen but reduced activity (type II, dysplasminogenemia). In most instances, a thromboembolic event or ligneous conjunctivitis prompt family studies. Cases in which the molecular defect has been identified are listed in Table 20.2[62–76]; updates can be found on the OMIM (Online Mendelian Inheritance in Man) Web site. The data do not prove conclusively that the heterozygous presence of one mutant PLG gene results in an increased incidence of thromboembolism.[77,78] Homozygous deficiencies, however, are clearly associated with ligneous conjunctivitis, caused primarily by Arg216 to His or Trp597 to stop mutations,[67] and replacement therapy with PLG is effective.[69] It is not clear why some mutations cause ligneous conjunctivitis and why very low functional PLG can be tolerated in some individuals, without thrombosis occurring.[67]

PLG-deficient mice also develop ligneous conjunctivitis.[79] These mice are predisposed to severe thrombosis and deposit intravascular and extravascular fibrin in many tissues.[80,81] PLG-deficient mice die prematurely and exhibit retarded growth and frequent rectal prolapse, but ovulation, embryonic development, and reproduction are normal.[82] Wound healing and tissue remodeling are impaired,[83,84] and response to an inflammatory stimulus is diminished.[85] After electric injury to the femoral artery, wound healing, removal of necrotic debris, leukocyte infiltration, smooth muscle cell immigration, and arterial neointima formation were greatly delayed in $Plg^{-/-}$ mice,[86] suggesting that PLG deficiency might reduce development of atherosclerosis. However, $Plg^{-/-}$ mice crossed with apolipoprotein E–deficient mice develop early atherosclerotic lesions.[87] $Plg^{-/-}$ mice crossed with $fibrinogen^{-/-}$ mice were restored to normality in many of these cases, demonstrating the causative role of intravascular and extravascular fibrin deposition.[88,89]

PLASMINOGEN ACTIVATORS

There are two physiologic PAs, tPA (tissue-type) and uPA (urinary-type, UK), named after the original sources of purified proteins. A further activation system, which is dependent on factor

XII (FXII), prekallikrein (PK), and high molecular weight kininogen (HK), is known as the contact PA pathway. There are also PAs from bacteria and the vampire bat, which are briefly included here. The two human proteases, tPA and uPA, are also implicated respectively in neurobiology (for review see Ref. 90) and tumor biology (for review see Refs. 91 and 92). These aspects are not considered further in this chapter, which focuses on PAs in hemostasis.

TISSUE-TYPE PLASMINOGEN ACTIVATOR

tPA, a serine protease of 68 kDa (EC 3.4.21.68), previously known as vascular PA or extrinsic activator, is a glycoprotein of 527 residues (FIGURE 20.1). It exerts its effect primarily in the vascular system, because it is produced and secreted by endothelial cells[93]; many other cells in culture also synthesize tPA. In normal plasma, the antigen concentration of tPA is approximately 5 μg/L, which corresponds to approximately 70 pM (Table 20.1),[94] but most is in complex with its primary inhibitor, plasminogen activator inhibitor 1 (PAI-1).[95,96]

Expression and Structure

The gene for tPA is located on bands p12–p11 on chromosome 8[97]; it contains four exons[98] and comprises 32.7 kb. The mature protein exists in two forms, the *N*-terminus being Gly or Ser in Bowes melanoma cell tPA,[99] but predominantly Ser in recombinant tPA,[100] and the numbering in this chapter is based on Ser at position one. tPA expression in cultured cells can be stimulated through multiple intracellular signaling pathways. Vasoactive substances, such as thrombin and histamine, increase tPA synthesis in human umbilical vein endothelial cell (HUVEC), acting through their G-coupled receptors and the protein kinase C pathway.[101–103] Steroid hormones[104,105] and retinoids can increase synthesis of tPA.[106,107] The expression of tPA has been reviewed[108] and will not be covered in detail here. It is important to note that not all endothelial cells synthesize tPA *in vivo* and that expression is restricted to small vessels.[109,110]

The structure of tPA (FIGURE 20.1) shows a finger and EGF domain, and two kringle domains in the A chain, whereas the protease domain resides in the B chain. The finger domain extends from residues 6 to 43. It contains a binding site for fibrin, as mutants lacking kringle domains are still capable of binding fibrin.[111] Consistent with this, a degraded form of tPA that had lost the *N*-terminal 12 kDa bound less well to fibrin than wild-type tPA.[112] The binding of the finger domain is independent of LBS, in that it cannot be blocked by εACA.[113] Structurally, the finger domain is very similar to the seventh type 1 repeat of human fibronectin.[114]

The EGF domain (residues 44 to 92) is structurally similar to other EGF structures, as shown by nuclear magnetic resonance (NMR).[115] There is some evidence from deletion mutagenesis that the EGF domain binds to the mannose receptor and is involved in tPA clearance.[116] Kringle 2 has affinity for lysine, ω-amino acids, and fibrin, whereas no function has yet been ascribed to kringle 1.[111] The affinity for the binding of εACA (a model for *C*-terminal lysine residues) and of *N*-acetyllysine methyl ester (a model for intrachain lysine residues) is approximately equal, suggesting that unlike PLG, tPA does not have a preference for *C*-terminal lysine residues binding.[113] Intact tPA and a variant consisting only of kringle 2 and the protease domains were found to bind to the cyanogen bromide (CNBr) fibrinogen fragment FCB-2, which also binds PLG and acts as a stimulator of tPA-catalyzed PLG activation.[111] In both cases, binding was completely inhibited by εACA, pointing to the involvement of LBS in this interaction.[111]

The structure–function relations among kringle 2 and ω-amino acids and lysine have been studied in detail, using NMR,[117] microcalorimetry,[118] crystallography,[119] and site-directed mutagenesis.[118,120,121] The crystal structure of kringle 2 resembles that of PLG kringle 4; there are, however, differences in the lysine-binding pocket. The core of kringle 2 is formed by a hydrophobic cluster of three tryptophan residues in positions 25, 63, and 74, surrounded by aromatic and hydrophobic side chains that form, at the surface of the kringle, a hydrophobic grove. Ligand binding appears to rely mostly on the integrity of Trp63 and Trp74, and an aromatic residue at position 76, which is normally Tyr.[122] Mutation of the critical amino acids Lys33, Asp55, Asp57, or Trp72 markedly diminished binding to lysine–Sepharose, εACA, or both.[123]

The protease domain of tPA has the typical catalytic triad His322, Asp371, and Ser478. The 2.3-Å crystal structure of the protease domain revealed strong structural similarity with other trypsin-like serine proteases, thrombin in particular.[124] The active site cleft is shaped and narrowed by four surface loops. The loop around Arg299 exhibits five additional residues, Arg298–Arg–Ser–Pro–Gly302, compared with chymotrypsin. It projects out of the molecular surface as a β-hairpin and is of fundamental importance for the interaction with PAI-1.[3] The 60-loop around Arg327 is similar to but shorter than the corresponding loop in thrombin. Further loops are found around Ser381 and Gly465. The fully solvent-exposed hydrophobic region, comprising amino acids 420 to 423 of tPA, which forms a surface loop near one edge of the active site of tPA, is an important secondary site for the interaction of tPA with PLG in the absence of fibrin.

tPA is secreted as a single-chain molecule (sctPA) that is converted to the two-chain form (tctPA) by plasmin by cleavage at Arg275–Ile276. Unlike most serine proteases the single-chain form is not a zymogen but a protease that, in the presence of fibrin, is nearly as active as the two-chain form.[125] Mutagenesis studies have revealed that tPA lacks a specific zymogen triad Asp194, His40, and Ser32 (chymotrypsin numbering).[3,126] The constructed double mutant Phe305His and Ala292Ser was more zymogenic.[126]

Release

The major source of tPA in the circulation under basal conditions is thought to be the endothelial cell, from which it is constitutively released.[127] A secondary pool of tPA is present in specialized storage vesicles and is released in response to specific extracellular stimuli.[128–131] High concentrations of tPA are contained within these storage vesicles that occur in various cells, such as endothelial, neuroendocrine, and adrenal chromaffin cells.[129,131] In rats, the tissue stores of tPA were calculated to be sufficient to maintain a steady-state plasma level of tPA for 2 days in the absence of protein synthesis.[132] Compounds that triggered release within a few minutes include bradykinin, histamine, eledoisin, acetylcholine, β-adrenergic agents, platelet-activating factor, endothelin, calcium ionophore A-23187, and acidosis.[133,134] These compounds induce calcium influx into the endothelial cell and activate G-protein–coupled receptors.[135] Some interventions that cause elevated tPA act through decreased clearance, including exercise and α-adrenergic agents.[136] In all situations in which epinephrine levels are increased, such as stress, anxiety, and exercise, tPA antigen levels increase.[96,137]

Acute release of tPA is established from early studies on venous occlusion.[138–140] Young patients with a history of recurrent venous thromboembolism exhibited an abnormal response to venous occlusion and this could be attributed either to subnormal tPA release or, more often, to elevated PAI-1.[95,139,140] In isolated cases with severe forms of von Willebrand disease, a complete lack of response to venous stasis and the infusion of 1-deamino-8-D-arginine vasopressin (DDAVP) was found.[141] These patients may have a functional or structural defect in their endothelial cells. It should be noted, however, that release of von Willebrand factor (vWF) and tPA occur by different mechanisms.[142] Lower PA activity is found in leg veins than in proximal veins and may be one etiologic factor for development of deep venous thrombosis. DDAVP was widely used in the 1980s to study the release potential for tPA in patients with idiopathic or recurrent thrombosis.[143–145] Comparison of the effects of DDAVP and sodium nitroprusside showed that nitroprusside produced a greater increase of forearm blood flow but no increase of tPA; however DDAVP stimulated tPA release from the vascular bed.[146] The increase of circulating tPA levels after intra-arterial infusion of acetylcholine and methacholine was shown to be mediated by muscarinic receptors.[146–148] Bradykinin and substance P both induced tPA release after being infused into the forearm of volunteers,[149,150] and the releasable pool of tPA, rather than the availability of PAI-1 to inhibit it, was the key factor.[151]

Enzymatic Properties of Tissue-Type Plasminogen Activator

tPA is unusually specific among the serine proteases. Its major substrate is PLG, in which it cleaves the Arg561–Val562 bond but is a relatively inefficient activator of PLG in the absence of its cofactor, fibrin.[152] Binding of sctPA and tPA to fibrin is roughly comparable.[153] The K_d for binding of tPA to fibrin clots in the absence of PLG ranges from 140 to 400 nM.[125,153,154] In the presence of PLG, the affinity of tPA to fibrin increases approximately 20-fold (K_d 20 nM).[155] These observations are explained by formation of a ternary complex between tPA, PLG, and fibrin or binding of tPA to PLG, which subsequently, upon binding to fibrin, takes on an open conformation. The isolated A chain of tPA has been shown to bind to Glu- and mini-PLG with a K_d of 100 nM.[156]

There is a wide range of kinetic parameters reported for the activation of PLG by tPA due to many potential experimental variables, such as different protein preparations, substrate

concentrations, and nature of the fibrin stimulator. In the absence of fibrin, K_M values for the activation of Glu–PLG by tPA range from 9 μM to slightly more than 100 μM.[125,157,158] In general, K_M is three to four times lower with tPA than with sctPA for the activation of Glu–PLG in the absence of fibrin. In the presence of fibrin, this difference is less apparent with K_M values typically two orders of magnitude smaller, with only moderate increases of k_{cat}. Values for K_M in the presence of fibrin range from 0.16 to 1.1 μM PLG, and k_{cat} values from 0.1 to 1.1 per second.[125,158] Several authors found nonlinear enzyme kinetics,[156,157,159] and there appear to be two phases in the activation of Glu–PLG by tPA in the presence of fibrin, with an initial K_M of 1.05 μM and k_{cat} of 0.15 per second. Later in the process, as new high-affinity binding sites for PLG and tPA are exposed in partially digested fibrin,[160–164] K_M decreases to 0.07 μM, whereas the k_{cat} is unchanged.[159] The key message is that PLG is not readily activated by tPA except in the presence of fibrin, because it is only in this situation that the K_M for the reaction is consistent with the circulating PLG concentration of 2 μM.

Distinct sites in the fibrin molecule have been identified as accelerating PLG activation; notably, they are not available for binding in fibrinogen but become exposed in fibrin.[165] The D-region of fibrin binds both PLG and tPA in a region that encompasses the residues Aα148–160. Both these associations are of low affinity and in the circulation the Aα148–160 site would bind only PLG, which is present in much higher concentrations than tPA. Another binding in the D-region encompasses γ311–336 and γ337–379, which are linked by a disulfide bond.[166] Antibodies have revealed that there is a tPA binding site that includes γ312–324.[167] Higher affinity sites for binding tPA and PLG are in the *C*-terminus of the α chain, within the region Aα392–610.[168] The conformational changes that occur on fibrinogen cleavage and fibrin assembly[169] reveal new sites for binding of tPA and PLG, and for enhancement of PLG activation.

Mutations have been engineered in tPA to change its characteristics, with the aim of making it an even more effective therapeutic agent. The most striking of these is the series of mutations to make tPA resistant to PAI-1. Madison et al.[170] identified the importance of interactions between the positively charged tPA sequence 298 to 302 and the negatively charged PAI-1 sequence 350 to 355. Mutagenesis of Arg298, 299, and 304 resulted in a mutant that was inhibited 120,000 times less rapidly by PAI-1 than wild-type tPA.[171] These observations led, in part, to the development of the new tPA mutant tenecteplase (TNK–tPA), in which the sequence 296 to 299 (Lys–His–Arg–Arg) is replaced by four alanines.[172] This variant also exhibits slower clearance, by virtue of its changed glycosylation, and its enhancement of PLG activation is more selective for fibrin over fibrinogen and the fibrin degradation product DD/E.[173]

URINARY-TYPE PLASMINOGEN ACTIVATOR

The urinary-type PA (EC 3.4.2.73; urokinase, uPA) is found in urine at 40 to 80 μg/L,[174] and is synthesized by several cell types, particularly cells with a fibroblast-like morphology, but also by epithelial cells[175] and monocytes and macrophages.[176,177] uPA activates PLG by the cleavage of Arg561–Val562, as does tPA, but importantly does not require fibrin as a cofactor. This characteristic has generated the view that tPA functions in fibrinolysis in the vasculature, whereas uPA's primary role is in processes such as degradation of extracellular matrix and cell migration, with consequences for wound healing, inflammation, embryogenesis, and invasion of tumor cells and metastasis.[178,179] These clear roles of the uPA system outside of fibrinolysis do not argue against its importance in fibrin degradation, as discussed in subsequent text.

Expression and Structure

The human uPA gene is located on chromosome 10q24 and is 6.4 kb in length.[180] It contains 11 exons, and the intron–exon organization of the uPA gene closely resembles the tPA gene. The regulation of its expression has been reviewed in detail elsewhere[108] and is not included here. uPA is produced as a 54-kDa, single-chain glycoprotein, 411 residues long (Table 20.1) and containing three domains: an EGF domain, a kringle, and a protease domain (FIGURE 20.1). The EGF domain interacts with urokinase plasminogen activator receptor (uPAR) found on many cells, as discussed in subsequent text. The kringle domain has no affinity for fibrin but has been reported to stabilize the interaction of uPA with uPAR.[181] The protease domain contains the catalytic triad, His204, Asp255, and Ser356, and has approximately 40% sequence identity with tPA.[98] uPA is normally glycosylated at Asn302, whereas a covalently attached single monosaccharide, fucose, to Thr18,[182] appears to affect the mitogenicity of uPA.[183] There are two phosphorylation sites on Ser138 and Ser303. The phosphorylated form diminishes uPA's interaction with cells and PAI-1.[184]

Activation of single-chain urinary plasminogen activator (scuPA, also called *proUK*) to the active enzyme, uPA (UK), is by cleavage of Lys158–Ile159.[185] Many enzymes can cleave this bond but the most important to hemostasis are plasmin,[186,187] factor XIIa, and kallikrein.[188] In PLG-deficient mice activation of scuPA is ascribed to kallikrein.[189] Cleavage close to the activation site (Lys158–Ile159) generates an inactive form of uPA. Thrombin cleaves Arg156–Phe157 in scuPA[188,190,191] and the inactive product can be subsequently activated through release of the *N*-terminal dipeptide of its B chain by cathepsin C or, albeit slowly, by plasmin.[185,192] Granulocyte elastase and cathepsin G cleave the Ile159–Ile160 peptide bond to yield an inactive product.[193] uPA has two active forms: HMW-UK and LMW-UK.[194] These are, respectively, full-length active uPA and a processed form, cleaved at Lys135–Lys136 to yield the amino-terminal fragment (ATF), which interacts with uPAR, leaving 21 residues of the A chain and an intact B chain.

Enzymatic Properties of Urinary-Type Plasminogen Activator

The question of whether scuPA is a true zymogen was debated for several years, a controversy that was fuelled by the problem of trace plasmin or uPA contamination, with reciprocal activation of scuPA and PLG.[195] The issue has been resolved by studies on mutant forms of the proteins and by examining scuPA in the absence of PLG. For instance, the Lys158Glu mutant of scuPA, which cannot be cleaved by plasmin into uPA, still converted PLG to plasmin.[196] The consensus is that scuPA has approximately 0.5% of the activity of uPA.[197,198,199,200] Therefore, scuPA lies on the spectrum between PLG, a true zymogen, and tPA, which is almost fully active in its single-chain form. Lys300 and Asp355 are key structural elements of scuPA's enzymatic

activity. Lys300, situated in the flexible loop region 297 to 313, forms a weak interaction with Asp355 and pulls the adjacent active site Ser356 into the position found in the fully active protease. Site-directed mutagenesis of Lys300 to Ala[201] or of Asp355 to Asn[202] resulted in a 40-fold and 270-fold reduction in activity, respectively, compared to wild-type scuPA. Altering the flexibility of the 297–313 loop changes the intrinsic catalytic activity of scuPA.[203]

Urinary-Type Plasminogen Activator Receptor

A cellular receptor for uPA (uPAR; CD87) was first isolated on human monocytes[204] but is expressed on several cell types. The gene for uPAR (gene code PLAUR) is on chromosome 19 and consists of seven exons and six introns extending over 23 kb.[205,206] Regulation of its expression has been reviewed[108] and is not included here. The 1.4-kb mRNA encodes a signal peptide of 22 and a protein of 313 residues, with a glycosylphosphatidyl inositol (GPI) anchor (FIGURE 20.5). The *N*-terminus of the receptor consists of three homologous domains; region 1 interacts with uPA and regions 2 and 3 enhance binding.[207]

scuPA and uPA bind to uPAR receptor via the ATF.[208] The binding is of high affinity (K_d 10^{-9} to 10^{-11}M) depending on the cell type.[209] uPAR does not play a catalytic role but serves to localize scuPA and PLG on cell surfaces,[210] thereby enhancing plasmin generation approximately 20-fold.[211] Binding of uPA to uPAR elicits a number of intracellular signaling responses, acting through the extracellular, regulated kinase/mitogen-activated protein kinase pathway.[212] uPAR is not a transmembrane protein and therefore other components are enlisted to transmit a signal to the intracellular compartment. Several proteins are known to bind uPAR, including vitronectin and integrins in complex with caveolin.[213] On some cells, the complex uPA/uPAR is associated with Endo 180, also known as uPAR-associated protein,[214] and is involved in collagen IV internalization.[215] Receptor-bound uPA is susceptible to inactivation by PAI-1, but inhibition is less efficient than in solution.[211] The uPA/PAI-1 enzyme/inhibitor complexes are internalized, and the uPAR is recycled to the surface. This process requires the cooperation of low-density lipoprotein receptor–related protein (LRP).[216,217] The structure of uPAR has been solved at high resolution, providing insights on the interaction with its ligand and informing drug design.[218–220]

Urinary-Type Plasminogen Activator in the Circulation

scuPA is found in plasma in relatively stable concentrations of 2 to 4 ng/mL.[221,222] In contrast with tPA and PAI-1, there is little circadian fluctuation in plasma uPA.[223] Venous occlusion did not increase uPA antigen once values were corrected for

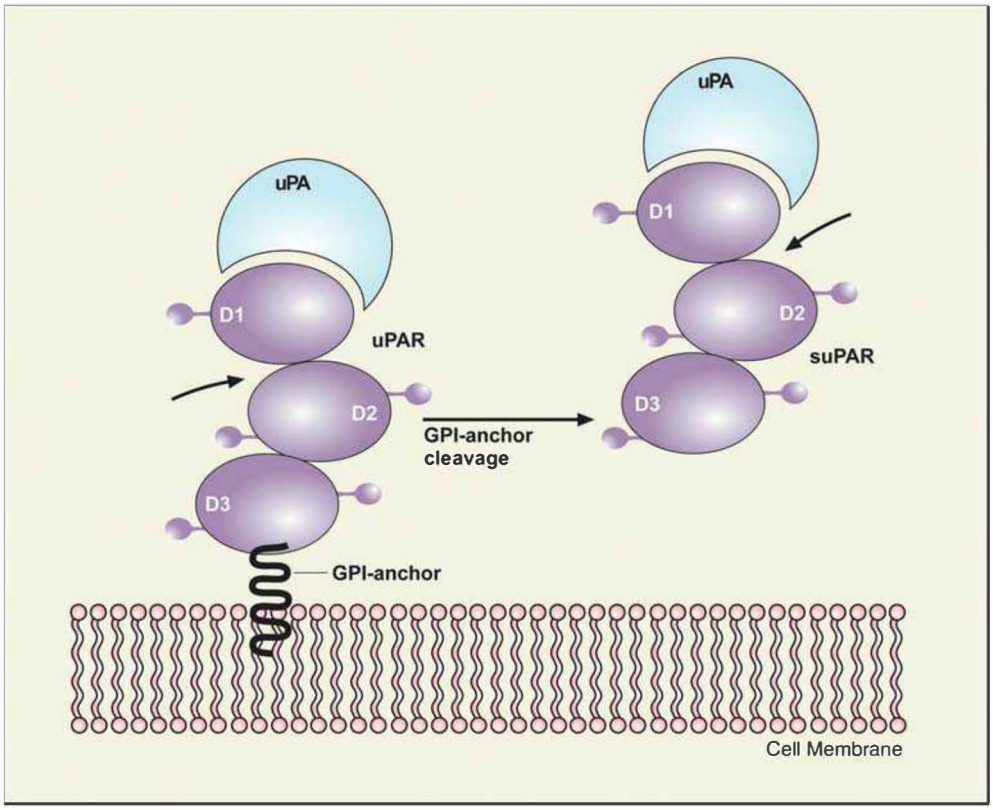

FIGURE 20.5 Domain structure of the uPAR. The *N*-terminal portion of uPAR is composed of three homologous domains with several potential glycosylation sites. uPA binds to domain 1 of uPAR but domains 2 and 3 enhance binding. The receptor is linked via a GPI anchor to the cell membrane. Shedding of uPAR from the cell surface forms the soluble form (suPAR). The region linking D1 and D2D3 can also be cleaved by proteases such as neutrophil elastase, plasmin, and uPA itself (*black arrow*).

the increase of hematocrit,[94] but there are reports of increases of uPA antigen after venous stasis,[222] DDAVP infusion,[224] and strenuous physical exercise.[225] Under normal circumstances, uPA activity is not detected in plasma, but both leukocyte-associated and free scuPA are elevated in leukemia[226] and other disorders, including liver disease.[227] If generated, uPA is cleared quickly from plasma, with a $t_{½}$ of approximately 7 minutes, in a manner that depends on hepatic blood flow.[228] The LRP system binds and internalizes scuPA and uPA–PAI-1 complexes.[216,229,230] The asialoglycoprotein receptor, located exclusively on parenchymal liver cells is also reported to remove uPA from the circulation.[228]

The activity of scuPA is markedly increased when it is bound to uPAR on the surface of monocytes.[231,232] This local activity is relevant to thrombus stability, into which monocytes migrate[233] and express fibrinolytic activity.[176]Indeed, monocyte-bound uPA has been shown to reduce thrombus size in a model of venous thrombosis.[234] In freshly formed model thrombi, there is considerable spontaneous generation of fibrinolytic activity, most of which can be inhibited by antibodies to uPA.[235] Polymorphonuclear cells, primarily neutrophils, generate this local uPA activity, apparently on uPAR[236]; plasma α_1-antitrypsin is crucial in protecting the activity from neutrophil elastase.[237] The integrin $\alpha_M\beta_2$ is important in the generation of such local activity.[238] When scuPA is present on uPAR, for instance on monocytes, it can associate with PAI-1 and other serpins, not in a classic covalent complex but in a reversible manner.[239] This has given rise to the idea that receptor-bound scuPA initiates proteolytic activity and that conversion to uPA is primarily a way of achieving inhibition by PAI-1 and other inhibitors, thereby regulating activity.[240]

scuPA does not bind to fibrin directly, but has some fibrin specificity, in that it degrades fibrin with less systemic degradation of fibrinogen and other plasma proteins than does uPA. It therefore is a more potent thrombolytic agent than uPA.[199,241] The explanations for this include the different but complementary mechanisms by which tPA and scuPA induce fibrinolysis.[242] tPA activates Glu–PLG, which is bound to an internal lysine, probably AαLys157, which is exposed in nondegraded fibrin. As soon as some fibrin is digested by plasmin, new *C*-terminal lysyl residues are generated, increasing the binding of Glu–PLG[160,162] to fibrin. scuPA binds with high affinity to PLG (K_d approximately 65 nM) and appears to selectively activate Glu–PLG, which is bound to *C*-terminal lysines on partially degraded fibrin.[243,244] The generation of small amounts of fibrin-bound plasmin also converts scuPA to uPA, explaining the typical lag phase observed for fibrinolysis by scuPA. A similar phenomenon has been observed with platelet-bound plasmin, where the localized PLG has a potent effect on scuPA activation.[187] Efficient scuPA-mediated lysis occurs after some fibrin has been degraded by tPA. Therefore, sequential administration of tPA followed by scuPA resulted in increased thrombolysis in a rabbit jugular vein thrombosis model; the reverse order was less effective.[245]

CONTACT SYSTEM

The contact pathway is composed of four proteins, FXII, PK, factor XI (FXI), and HK. Reciprocal proteolytic activation of FXII and PK to their active forms, FXIIa and kallikrein respectively, is stimulated by negatively charged surfaces. FXIIa subsequently cleaves downstream FXI to its activated form, FXIa, which feeds into the coagulation pathway. FXI and PK circulate in complex with the nonenzymatic cofactor HK, which assembles these proteases onto the activating surface. Zinc ions induce a conformational change in FXII[246–250] and HK,[251–253] enhancing surface interactions. Artificial anionic surfaces, such as kaolin, ellagic acid, sulphatides, and dextran sulphate, are known to stimulate FXII autoactivation and cleavage by kallikrein.[254–259] Recent work has identified natural surfaces, such as polyP,[260,261] RNA,[262] misfolded proteins,[263] and collagen,[264] that are also capable of triggering this pathway. PK activation can also take place independently of FXII when bound to HK on endothelial cells.[265]

FXII has traditionally been considered a coagulation factor but is structurally related to tPA, uPA, and PLG[266,267] (FIGURE 20.1), and is functionally implicated in fibrinolysis by different mechanisms. Firstly, FXIIa directly activates PLG (FIGURE 20.6) albeit relatively poorly compared to tPA and uPA.[268–270] The reaction can, however, be dramatically enhanced by the presence of dextran sulphate and zinc.[44] The relative plasma concentrations of FXII compared to tPA and uPA (that of FXII is four orders of magnitude higher) suggest it could be as effective as uPA as a PLG activator and may be potentially relevant *in vivo*.[271]

In a second mechanism, generation of kallikrein by FXII dependent[188,272] and independent[265] pathways triggers kinetically favorable activation of scuPA (FIGURE 20.6). Finally, indirect stimulation of fibrinolytic activity arises from kallikrein cleavage of HK. This generates the vasoactive peptide bradykinin, a potent stimulator of tPA release from endothelial cells.[273,274]

These three distinct mechanisms indicate the potential contribution of the contact pathway in regulating fibrinolysis, but further studies are required to define the relative contribution in response to various stimuli and in different local environments.

OTHER PLASMINOGEN ACTIVATORS

Streptokinase

Streptokinase (SK), an extracellular protein produced by streptococci, activates the human fibrinolytic system.[275] SK and other bacterial activators have evolved for the purpose of invasion of the mammalian host[276] and are a key pathogenicity factor in group A streptococcal infection.[277] SK rapidly forms a 1:1 complex with PLG, by inserting its *N*-terminal Ile[1] residue into the PLG amino-terminal binding cleft, activating the catalytic site nonproteolytically.[278–280] The activated SK–PLG′ complex binds a second molecule of PLG and cleaves it at Arg541–Val562 to form plasmin.[279–282] SK–PLG′ retains the ability to bind fibrin and is thereby relatively protected from inhibition by α_2AP.[283]

NMR and crystallographic studies show that SK (47 kDa) consists of three β-grasp tightly folded domains, α, β, γ joined by flexible segments.[284,285] The *C*-terminus of SK regulates the PLG binding and activation.[286] SK residues Arg253, Lys256, and Lys257 mediate plasmin substrate recognition via LBS-dependent interactions with kringle 5.[287] SK is highly antigenic. Most individuals have anti-SK antibodies as a result of previous infections with β-hemolytic streptococci, and anti-SK titers may rise several 100-fold after administration to humans.[288,289] After intravenous injection of SK into humans, dogs, or mice, SK is cleared from the circulation with a $t_{½}$ of 15 to 30 minutes.[290] Clearance mostly takes place in the liver, primarily by LRP.[229,290]

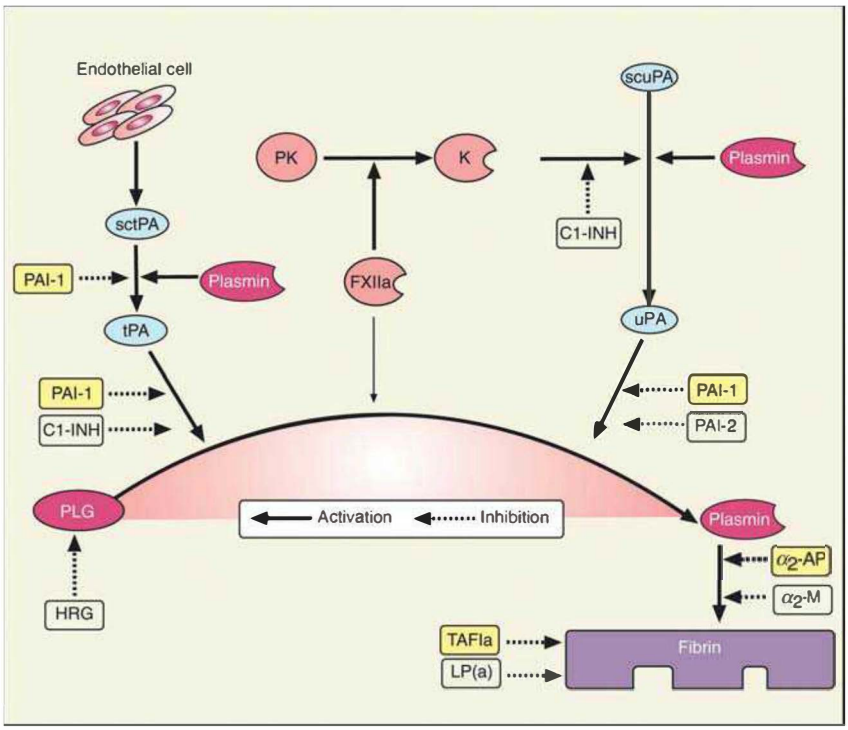

FIGURE 20.6 Activators and inhibitors of the fibrinolytic system. scuPA, single-chain urokinase plasminogen activator; sctPA, single-chain tissue plasminogen activator; α_2AP, $\alpha_2$antiplasmin; α_2M, $\alpha_2$macroglobulin; C1-INH, C1 inhibitor; HRG, histidine-rich glycoprotein; PAI-1, plasminogen activator inhibitor 1; PAI-2, plasminogen activator inhibitor 2; Lp(a), lipoprotein a; TAFI, thrombin activatable fibrinolysis inhibitor; PLG, plasminogen; PK, prekallikrein; K, kallikrein.

Staphylokinase

Staphylokinase (SAK), a protein with a M_r of 15,000, produced by *S. aureus*, has been known for more than 40 years to have thrombolytic properties.[291,292] Like SK, SAK is not an enzyme but forms a stable stoichiometric complex with PLG.[293] In the absence of fibrin, it does not activate PLG. Trace amounts of plasmin, such as may be found on the surface of a thrombus, cleave 10 residues from the amino terminus of SAK.[294,295] Removal of this ATF allows SAK to bind PLG, although it still has a relatively low affinity for circulating PLG and preferentially interacts with fibrin-bound PLG. Free plasmin then converts the SAK–PLG complex to SAK–plasmin complex that is a highly fibrin-specific PA. Unlike the SK–plasmin complex the SAK–plasmin complex is not protected from inactivation by α_2AP.[296–298] SAK is antigenic, and extensive mutagenesis has been undertaken to decrease this property.[299] Coupling of SAK mutants to polyethylene glycol of M_r 20,000 was shown to increase the $t_{½}$ of the complex several-fold, which would permit single bolus thrombolytic therapy in humans.[300] Several clinical studies with SAK have been reported. In peripheral arterial occlusions and in patients with myocardial infarction, SAK compared favorably with tPA.[301,302]

Vampire Bat Plasminogen Activator

Many hematophagous animals, such as leeches, hookworms, mosquitoes, and the vampire bat, produce substances that interfere with the clotting or fibrinolysis mechanisms. In the 1960s, a potent PA was found in the saliva of the common vampire *Desmodus rotundus*.[303] The bat lives exclusively on blood and uses the enzyme in its saliva to keep blood in a fluid state. The *D. rotundus* salivary plasminogen activator (DSPA) was cloned independently by two research groups and shows more than 70% identity with human tPA.[304,305] Three major forms were identified: DSPA-α, which contains a finger, EGF, kringle, and protease domain; DSPA-β, which lacks the finger domain; and DSPA-γ, which has just a kringle and a protease domain.

DSPA-α comprises 441 residues and, like SAK, has higher fibrin specificity than tPA.[306] In the absence of fibrin, hardly any PLG activation occurs.[307,308] PLG activation by DSPA is barely stimulated by D-dimer or the DDE complex, whereas these fibrin fragments strongly enhance tPA activity.[306] The crystal structure of the catalytic domain of DSPA-α_1 has been solved at 2.9 Å resolution[309] and shows strong similarity to sctPA. Experiments in animals revealed that the thrombolytic potential of DSPA was at least equal to, and the clearance rate approximately 10 times slower than, that of tPA.[310,311] The hope that high fibrin specificity would result in lesser bleeding at comparable thrombolytic potential was not fully realized,[310] but this agent has several promising features, long clearance time, and fibrin specificity, which permits bolus administration and may be useful in stroke as well as acute myocardial infarction.[312]

INHIBITORS OF THE FIBRINOLYTIC SYSTEM

Several inhibitors control and modulate the expression of fibrinolytic activity. These act at the PLG activation step or on plasmin (see FIGURE 20.6), and they prevent excessive systemic fibrinolytic

activity. The principal inhibitor of tPA and uPA is PAI-1, whereas α_2AP inhibits plasmin. Both are members of the serpin family, which also includes antithrombin and heparin cofactor (see Chapter 18). Serpins function by presenting the target protease a reactive center loop, the P1–P1′ of which mimics a substrate. A stable inactive 1:1 complex is formed between protease and serpin, lowering the effective protease concentration. Dissociation of the covalent complex, which occurs at different rates for different protease–serpin pairs, results in a cleaved form of the serpin, which lacks the short peptide from P1′ to the original *C*-terminus. The serpins have marked specificity for particular proteases, but the specificity is not absolute, so that other inhibitors present at high concentration provide a backup inhibitory system.

PLASMINOGEN ACTIVATOR INHIBITOR 1

The emphasis of this section is the role of PAI-1 in regulation of the PA system in the vasculature. In addition to its inhibition of tPA and uPA, PAI-1 has a role in regulating cell adhesion processes relevant to tissue remodeling, mediated by its binding to the adhesive glycoprotein vitronectin, rather than by proteinase inhibition.[313]

The 52-kDa glycoprotein consists of 379 residues. It is unusual among the serpins in its tendency to lose activity through spontaneous insertion of the reactive center loop into the body of the molecule, forming an extra strand of β-sheet A. This form was termed *latent* because, after denaturation and refolding, activity was regained[314]; there are no physiologic conditions under which this can occur. The noncovalent binding of vitronectin stabilizes the active form of PAI-1,[315] which is present in plasma at low concentrations, approximately 20 ng/mL.[316–318] It has a $t_{½}$ of <10 minutes and consequently its rate of synthesis is high. The variation between normal individuals is large, ranging from 1 to 40 ng/mL, corresponding to 1 to 40 U/mL, the unit being the activity that neutralizes 1 U of tPA in 10 minutes.

PAI-1 is produced by most cultured cells, and early publications identified it as a platelet protein,[319] a product of megakaryocytes,[320] endothelial cells,[321] hepatocytes,[322] and adipocytes.[323–325] The source of resting plasma PAI-1 is not certain. Studies showing that normal endothelium or hepatocytes do not express PAI-1[324] point to adipocytes as the normal source, whereas elevations in the acute phase are likely to result from hepatocytes.[326] Platelets constitute the major pool of circulating PAI-1. Although it is less active than plasma PAI-1, platelet PAI-1 accounts for about half the circulating PAI-1 activity, by virtue of the abundance of the protein in platelets.[317] Large amounts of platelet PAI-1 accumulate in thrombi,[327,328] and this directly correlates with their lysability.[328]

PAI-1 inhibits tPA (tc and sc) and uPA. It does not inhibit scuPA, which is largely inactive, but it does associate with scuPA noncovalently, as discussed in the section on uPA.[239] PAI-1 in plasma is in excess over tPA; therefore, most of the tPA is present in a complex with PAI-1. The second-order rate constants for the interaction with tPA and uPA are $>10^7$/M/s, a little lower for sctPA.

Hereditary deficiency of PAI-1 in humans is quite rare but leads to a lifelong bleeding disorder, presumably caused by premature lysis of hemostatic plugs at sites of vascular trauma, and consistent with this, bleeding occurs after a delay.[329–332] The oral administration of fibrinolytic inhibitors such as AMCA has been effective in normalizing hemostatic function.[331,332]

Mice with a disrupted *PAI-1* gene demonstrate normal development, fertility, and survival. The lack of inhibitor activity induces a mild hyperfibrinolytic state and confers a greater resistance to the prothrombotic effect of endotoxin injected into the footpad.[333] After arterial injury, wound healing in PAI-$1^{-/-}$ mice was accelerated with rapid migration of smooth muscle cells from the uninjured tissue.[334] In an arterial thrombosis model, time to development of an occlusive thrombus was approximately twice as long in PAI-$1^{-/-}$ than in PAI-$1^{+/+}$ mice.[335] In a model of carotid artery injury, partially or completely occlusive thrombi were found in 34% of PAI-$1^{-/-}$ mice and 65% of PAI-$1^{+/+}$ mice.[336]

In contrast to the lack of PAI-1, mice overexpressing human PAI-1 in the endothelium are subject to age-dependent development of arterial thrombosis.[337] In humans, high circulating PAI-1 is clearly associated with a variety of pathologies, including cardiovascular disease[338,339] and cancer.[340] Many studies have been conducted to investigate causal significance, and it appears that high PAI-1 does not independently predict disease, once other factors like obesity, diabetes, and elevated triglycerides are taken into account.[341] A guanine insertion/deletion polymorphism at position 675 in the PAI-1 promoter[342] is associated with differences in circulating PAI-l.[343] Despite promising early findings,[344] the current view is that the predictive power of studying this polymorphism is low.[341,345] Gram-negative septicemic patients have dramatically raised plasma PAI-1 concentrations, as much as 50-fold over normal, which is associated with high mortality.[346]

α_2 Antiplasmin

α_2Antiplasmin (α_2AP), also called *plasmin inhibitor*, is the principal fast-acting inhibitor of plasmin.[347] The gene (symbol PLI) is located on chromosome 17p13.[348] It gives rise to a single-chain protein of M_r of 70,000, comprising 452 residues, the additional mass accounted for by approximately 13% carbohydrates on four potential asparagine glycosylation sites (Table 20.1). The plasma concentration of α_2AP is 70 mg/L (i.e., 1 μM), approximately half the molar concentration of PLG. It is synthesized in the liver and consequently decreased in patients with advanced impairment of hepatic function. The $t_{½}$ of the native inhibitor is approximately 3 days, whereas the plasmin/α_2AP (PAP) complex is cleared with a $t_{½}$ of approximately 0.5 days.[349] The inhibitory activity of α_2AP resides in its reactive center loop, in which the P1–P1′ is Arg–Met; as with other serpins, mutation of Arg to Ala destroys inhibitory function.[350] The rate of interaction of wild-type α_2AP with plasmin is very fast, with a rate constant of 4×10^7/M/s.[351]

α_2AP exists in plasma in several forms, depending on limited proteolysis at *N*- and *C*-termini. This processing appears not to affect the inhibitory capacity of α_2AP, which resides in the core of the protein. The *N*-terminus of α_2AP was originally identified as Asn,[352] but it was later recognized that there is also a proform with an additional 12 residues at the *N*-terminus.[353] Plasma α_2AP was shown to have about equal amounts of the two forms,[354] whereas HepG2 cells produced the Met-form, which, after addition to plasma, was cleaved to the Asn form.[355] An enzyme that removes the 12 residue *N*-terminal fragment has been purified and characterized.[356] The importance of the *N*-terminal processing lies in the accessibility of Gln (at position two in the processed form); the proform terminus blocks access to the cross-linking site.[353] Gln2 in α_2AP is cross-linked by factor XIIIa to the Aα chain of fibrinogen or fibrin, at Lys303.[357,358] Fibrin with cross-linked α_2AP is markedly more resistant to

lysis, an observation that allowed the discovery of the first deficiency of α_2AP.[357] The cross-linking site can be saturated, as elegantly shown by studies with wild-type α_2AP and an active site Arg to Ala mutant.[350] Antibodies specific for cross-linked α_2AP greatly stimulated lysis of fibrin.[359]

The *C*-terminus of α_2AP is extended by approximately 50 residues, relative to other serpins.[352] Two forms are detectable in normal human plasma.[360] The native, full-length form binds PLG, whereas a processed form retains inhibitory capacity but cannot bind PLG.[361] The two forms were distinguished by two-dimensional immunoelectrophoresis, with PLG incorporated in the gel in the first dimension.[362] The ratio of the PLG binding to nonbinding form remains relatively constant in plasma samples, at approximately 65:35, even in patients with advanced liver cirrhosis.[227] The enzyme responsible for processing the *C*-terminal variant of α_2AP has yet to be identified. In addition to binding PLG the *C*-terminus contains an Arg–Gly–Asp sequence that mediates binding of α_2AP to endothelial cells.[363]

The ability of α_2AP to bind PLG interferes with the fibrin–PLG interaction, because both involve the same LBS (FIGURE 20.7). It is also crucial to the fate of plasmin formed on the fibrin surface, to which both tPA and PLG bind by virtue of their LBS. Plasmin formed on fibrin is therefore relatively protected from the action of α_2AP[364] (FIGURE 20.7). This concept arose from experiments using lysine analogues, where α_2AP was shown to be approximately 100 times less effective toward plasmin in the presence of lysine analogues.[351] The exact Lys residues responsible for binding the *C*-terminal region of α_2AP to LBS in PLG are not yet defined. Binding of recombinant *C*-terminal peptide (55 residues) to isolated kringles was most affected by mutation of Lys452, but other internal Lys residues appear to "tether" the kringles.[365] A different study, in which each Lys from position 429 to the *C*-terminal Lys452 was separately mutated, indicated that Lys436 had the greatest effect; their modeling suggested that Lys452 is too close to Phe448 for it to be able to interact with the LBS.[366]

The importance of α_2AP in stabilizing fibrin has been revealed in several *in vitro* systems, including clot lysis.[367,368] A mutant of tPA that is relatively resistant to α_2AP was very efficient in lysing both clots and model thrombi.[369] Deficiency of α_2AP results in delayed bleeding, but initial hemostasis is normal, and this is characteristic of fibrinolytic defects.[370] Inheritance was autosomal recessive in a well-characterized Japanese family.[371,372] An interesting defect in α_2AP Enschede was explained by the abnormal protein behaving as a substrate for plasmin rather than as an inhibitor,[373] as a result of the extended (by one Ala residue) reactive center loop.[374] Mice deficient in α_2AP were essentially normal in many respects, but they did show enhanced endogenous fibrinolytic activity without overt bleeding.[375] In experimental

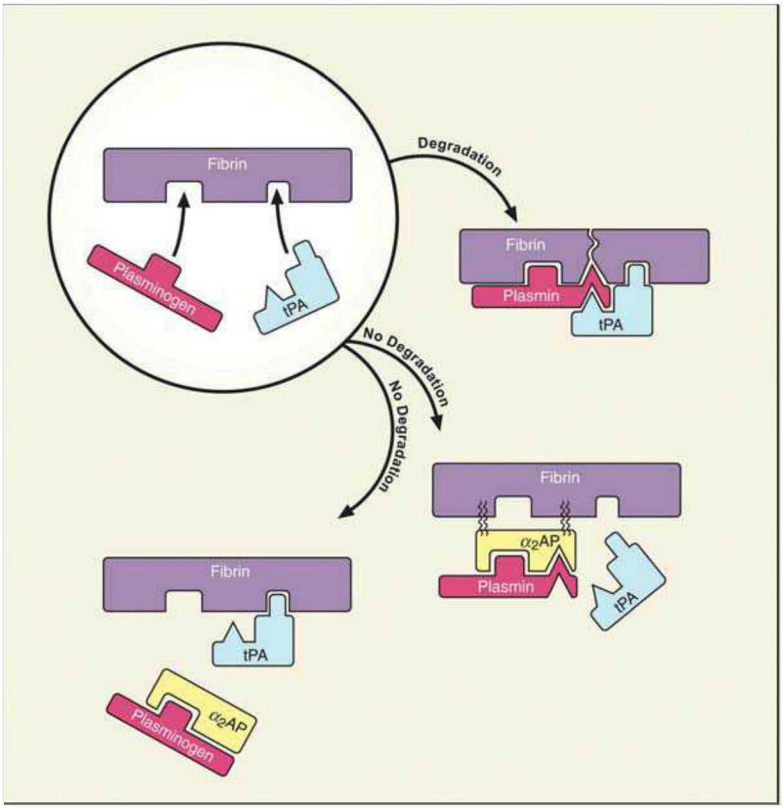

FIGURE 20.7 Interaction of plasmin(ogen), tPA, and fibrin; interference by $\alpha_2$antiplasmin (α_2AP). Plasmin(ogen) and tPA interact directly with fibrin, which acts as a cofactor in PLG activation stimulating fibrin degradation. In solution α_2AP can bind plasmin(ogen) thereby occluding binding to fibrin. α_2AP can also cross-link to fibrin that both prevents plasmin from binding to fibrin and neutralizes the activity of the enzyme. Both these events prevent PLG activation or plasmin activity and thereby inhibit fibrin degradation.

models, the lack of α_2AP had effects on liver regeneration,[376] platelet aggregation,[377] and pulmonary heart failure.[378]

THROMBIN-ACTIVATABLE FIBRINOLYSIS INHIBITOR

The generation of *C*-terminal lysyl residues is an important feedback mechanism for the binding of PLG to fibrin and the enhancement of fibrinolysis (discussed further in the section on "Balance of Plasminogen Activation and Regulation of Fibrinolysis"). These residues can be removed by activated thrombin-activatable fibrinolysis inhibitor (TAFIa) (EC 3.4.17.20; synonyms: carboxypeptidase B, U, or R), further regulating fibrinolysis.[379] The zymogen TAFI is activated by the thrombin/thrombomodulin complex[380] and by plasmin,[381] in a reaction that is enhanced by glycosaminoglycans. It is considered a molecular link between the fibrinolysis and coagulation pathways.[382]

TAFI is primarily produced by the liver and circulates at approximately 75 nM, but the normal variation is wide[379,383] and only a small proportion needs to be activated for full function.[380] There is no known endogenous inhibitor of TAFIa, but it displays a very short $t_{½}$ of approximately 10 minutes at 37°C.[384] The function of TAFIa was shown originally in clot lysis assays; potato tuber carboxypeptidase inhibitor relieves the inhibition.[382,385] The effect of TAFIa has also been shown in model thrombi made from whole blood,[386,387] and in animal studies, where TAFIa activity increased the time taken to restore blood flow in a canine coronary artery thrombosis model.[388] Inhibitors of TAFIa enhanced endogenous fibrinolysis and also thrombolysis by tPA.[389,390] Homozygous-deficient mice show enhanced plasma clot lysis but are comparable to wild-type mice in many thrombus models; mostly those in which time to occlusion rather than thrombus resolution is assessed.[391]

Elevated TAFI has been cited as a mild risk factor for thrombosis, and levels are known to increase in inflammation, correlating with other acute-phase markers.[392] A recent report has indicated that the venous thrombosis risk associated with plasma hypofibrinolysis is related to elevated levels of TAFI and PAI-1.[393] Conversely, it has been shown that deficiency of TAFI in mice increases the risk of intracerebral thrombosis and ischemic stroke.[394] Several polymorphisms in the TAFI gene have been reported. These seem to explain the wide normal range of concentrations but do not correlate strongly with disease.[395] Some methods show bias toward particular polymorphic variants of TAFI[396,397]; associations with disease therefore need to be interpreted with caution.

Increased fibrinolytic activity in hemophilia patients is explained by defective TAFI activation. Most thrombin is formed after clot formation, mainly via the intrinsic pathway by activation of FXI by thrombin. This leads to a positive feedback mechanism and optimal activation of pro-TAFI.[398] Clots composed of factor IX–deficient plasma lysed prematurely, but the defect could be reversed by the addition of factor IX or thrombomodulin to the plasma.[399] Similarly, addition of TAFI, thrombomodulin, or factor VIII to hemophilia A plasma restored normal fibrinolysis.[400] Consistent with this, incorporation of anti–factor XI antibodies or inhibition of TAFI in a rabbit model resulted in an almost two-fold increase in endogenous thrombolytic activity.[401]

OTHER INHIBITORS

Plasminogen Activator Inhibitor 2

PAI-2 was initially identified as a UK inhibitor in human placenta[402] and was purified from human placenta and the monocytoid cell line U-937.[403,404] PAI-2 is the predominant PA inhibitor of squamous epithelia in epidermis, esophagus, cornea, oral mucosa, tongue, and vagina.[405] It is incorporated into the cornified envelope during terminal differentiation of the keratinocyte via transglutaminase-catalyzed crosslinks.[406] Monocytes are an important source of PAI-2[407] and may increase fibrin stability on migration into thrombi, especially because the PAI-2 is cross-linked to fibrin.[408]

PAI-2 is an efficient inhibitor of two-chain uPA (tcuPA), with a second-order rate constant of 10^6/M/s; it reacts approximately five times more slowly with tctPA and quite poorly with sctPA.[404] In normal plasma, there are no measurable levels of PAI-2, but high levels are found in pregnancy, with a steady rise until around 33 weeks, to reach approximately 250 ng/mL.[409] Smaller increases in PAI-2 were observed during intrauterine growth retardation[410–412] suggesting it may be a marker for decreased placental function.[411,412]

PAI-2 is also found in the plasma of patients with acute myeloblastic leukemia of the M_4 and the M_5 type,[413] and in patients with sepsis, in whom PAI-1 is also increased.[414] Speculation remains on the real function of PAI-2. Mice with a disrupted PAI-2 gene do not present any phenotypic abnormalities.[415] The intracellular location of this serpin suggests roles other than inhibition of PA. Protection of cells from the cytopathic effects of alphavirus infection[416] and a role as a retinoblastoma (Rb)-binding protein[417] have been reported. The local activity of PAI-2 appears to be relevant to a number of cancers and this may provide clues to its physiologic function.[418,419]

α_2-Macroglobulin

α_2-Macroglobulin exhibits wide specificity and serves as the backup inhibitor of several proteases, including plasmin. It comes into play when the fibrinolytic system is fully activated and when the capacity of α_2AP is exhausted; it also forms complexes with tPA and uPA.[226] α_2-Macroglobulin is a glycoprotein of M_r 725,000 that consists of four identical chains of M_r 160,000 and contains approximately 8% carbohydrate (Table 20.1). It circulates at a relatively high concentration of 2.5 g/L (3 μM). The tetramer is arranged as a pair of dimers, each consisting of two monomers linked together via a disulfide bond. The complete sequence of this 1,451-residue molecule has been established and the gene locus (gene symbol A2M) attributed to chromosome 12p13.3–p12.3.[420,421] The inhibitor contains two reactive sites. The sequence Arg–Val–Gly–Phe–Tyr–Glu (681 to 686) acts as a bait region that contains sites for proteases of different specificities.[422] Cleavage results in a conformational change and activates the thioester site at positions 949 to 952. Electron microscopic studies showed that the catalytic domain of the rod-shaped plasmin molecule is entrapped inside the α_2-macroglobulin cavity, whereas its *N*-terminal kringle domains protrude outside one end between the two arm-like features of the transformed α_2-macroglobulin structure.[423] It is noteworthy that proteases inhibited by α_2-macroglobulin can still act on small peptide substrates, but their position in the inhibitor cavity makes them inaccessible to larger targets.

C1-Inhibitor

C1-inhibitor is a highly glycosylated 105-kDa serpin, consisting of 478 residues (Table 20.1). The 16 kb gene is located on chromosome 11q12–q13.1.[424–426] It inhibits the activated subcomponents, C1r and C1s, of complement C1, the contact proteases, FXIIa, FXIa, and plasma kallikrein, and the PA proteins plasmin, tPA, and uPA. It circulates in plasma at a relatively high concentration (1.7 μM). In situations in which tPA is present in excess over PAI-1, complex formation with C1-inhibitor is observed.[96,227,427] It has been shown to prevent nonspecific PLG activation induced by a uPA mutant while preserving the fibrin-specific fibrinolysis.[428,429] The role of C1-inhibitor in regulation of fibrinolysis is not extensively described in the literature but by virtue of its inhibitory effect on components of the contact system, it is likely to play a role in controlling contact phase–dependent fibrinolysis and the conversion of scuPA to uPA (FIGURE 20.6).

Lipoprotein (a)

Apolipoprotein (a), a component of lipoprotein (a) (Lp(a)), is linked by a disulfide bond to apolipoprotein B-100. Apo(a) has a wide size distribution, which depends on the number of kringle repeats; these are similar to kringle 4 of PLG.[430] The total mass of Lp(a) therefore varies between 800 and 1,300 kDa. There are also a wide range of plasma Lp(a) concentrations, from 10 to 1,000 mg/L, and a skewed distribution, median value 50 mg/L. The apo(a) gene is located in a cluster on chromosome 6q26–27 with PLG and two apo(a)-related genes.[15,431,432]

Lp(a) binds to fibrin, extracellular matrix, platelets, and cells.[433–436] Interaction with fibrin(ogen) has been shown to involve both Lys-dependent and independent mechanisms.[437] A proportion of the binding is via its kringles to *C*-terminal Lys residues and is inhibited by lysine and εACA. Lp(a) therefore competes with PLG and tPA for binding sites on fibrin exerting an antifibrinolytic effect.[433–435,437] PLG binding and activation on both platelet[436] and fibrin[438–441] surfaces is attenuated by Lp(a). Lp(a) has also been reported to interfere with the self-propagating phase of PLG activation by preventing the plasmin mediated conversion of Glu–PLG to Lys–PLG (FIGURE 20.4).[442] Transgenic mice expressing the human apo(a) gene resolved experimental thrombi poorly when treated with tPA,[443] consistent with the association of high Lp(a) with coronary artery disease.[444–446] Lp(a) size is a key factor with only the smaller forms binding fibrin with high affinity.[447–449] Individuals with the combination of high Lp(a) levels and predominance of the small isoform demonstrate reduced fibrinolytic activity.[449]

Histidine-Rich Glycoprotein

HRG is named for the region between residues 330 and 389, which are similar to the histidine-rich regions in human and bovine kininogen.[450] The 75-kDa protein has 507 residues and approximately 14% carbohydrate (Table 20.1). HRG is synthesized in the liver but can be taken up by platelets and megakaryocytes and released upon thrombin activation.[451] HRG competitively inhibits PLG associations by binding LBS-1 of PLG (K_d 1 μM). It is suggested, on the basis of their relative concentrations, that PLG (2 μM) and HRG (1.5 μM) would circulate predominantly in a 1:1 reversible complex,[25] which would decrease the PLG available for binding to fibrin. However, α_2AP had a greater effect than HRG on binding of PLG to fibrin.[452] HRG has been proposed to tether PLG to the cell surface, which would enhance the cells' migratory potential.[453] Only one family with congenital heterozygous HRG deficiency has been described. The proband, but none of the other five family members with low HRG levels, displayed thrombotic complications.[454] Mice deficient in HRG exhibit shorter plasma prothrombin times and bleeding times as well as faster clot lysis.[455] These results indicate that HRG has both anticoagulant and antifibrinolytic activity.

BALANCE OF PLASMINOGEN ACTIVATION AND REGULATION OF FIBRINOLYSIS

The primary function of the fibrinolytic system is to remove fibrin from the circulation in a controlled manner, thereby preventing excessive accumulation. It is a highly modulated enzyme system, and has evolved to be limited in its action in time and space but with appropriate feedback loops that enhance the fibrinolytic system on the local level. The system is represented schematically in FIGURE 20.8. Circulating PLG is not normally converted to plasmin, which would cause generalized fibrinogenolysis, proteolysis, and degradation of clotting factors, particularly factor V, factor VIII, vWF, and platelet glycoproteins. Instead, fibrin and cell surfaces act as a focus for the generation of plasmin activity, which is then shielded from inactivation by inhibitors. Activation of PLG on fibrin and cell surfaces by the PAs tPA, uPA, and scuPA will be discussed below but it is important to stress that most features of PLG activation on surfaces are unaffected by the activator used.

PLASMIN GENERATION ON FIBRIN

Many modulators increase or decrease the rate of PLG activation; the most important of these is fibrin, which has a dual function, acting both as a cofactor in PLG activation and as the target substrate for active plasmin. PLG binds to fibrin, directing the process of clot lysis to its target, binding that is competed by ω-amino carboxylic acids.[456] Identification of the binding sites was achieved by examining the products of elastase digestion of PLG. Kringles 1 to 3 and miniplasminogen bound to fibrin, but kringle 4 did not.[21,22,457,458] Partial degradation of fibrin by plasmin creates a positive feedback mechanism, whereby native Glu–PLG is bound to newly created *C*-terminal lysines on the fibrin molecules, particularly on the *C*-terminal portion of the α chain.[160–162,459,460] A few studies support the concept that PLG might bridge adjoining fibrin molecules and that probably both kringle 5 and kringle 1 bind to fibrin, albeit not at the same binding site.[16,458,461] There is little consensus on the values of the dissociation constants and number of binding sites for the binding of PLG, particularly of Glu–PLG to fibrin. Taking all reported figures together, it appears that an average K_d for the binding of Glu–PLG to native fibrin is approximately 5 μM and that of Lys–PLG, roughly one order of magnitude lower, representing 10-fold stronger binding. In the presence of partially digested fibrin, the K_d for the binding of Glu–PLG approaches that of Lys–PLG for native fibrin (0.5 μM).[162,460]

Two phases have been identified in tPA-mediated lysis of fibrin (reviewed by Thorsen [462]). During the initial slow phase, sctPA accumulates on fibrin protofibrils and activates the small amount of PLG bound to the fibrin surface. Newly generated plasmin partially degrades the fibrin surface generating *C*-terminal lysine residues that bind additional PLG and possibly tPA. This stimulates the second faster phase of tPA-mediated

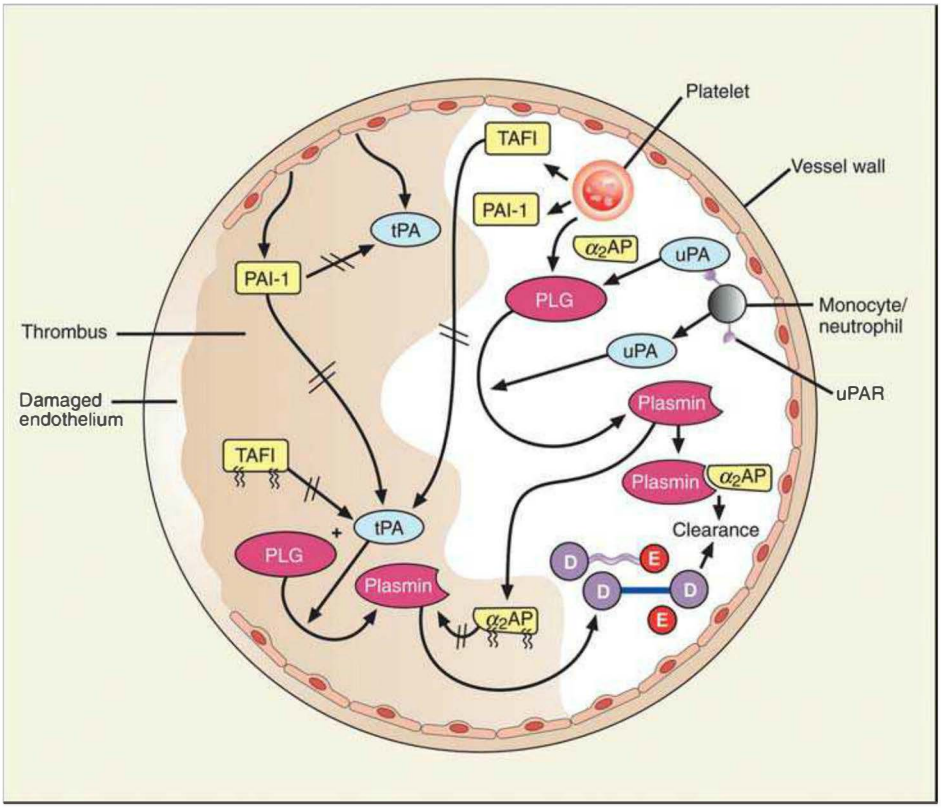

FIGURE 20.8 The balance of fibrinolysis. Schematic representation of the different paths of plasmin formation, inhibition, and clearance within a damaged vessel wall with a partially occluding thrombus. Solution, cell-surface, and fibrin phases of plasmin formation are represented. PLG is present at a relatively high plasma concentration (2 μM) and is readily incorporated into a thrombus as a result of its capacity to bind fibrin. In contrast tPA, which is mainly derived from the endothelium, circulates at low concentrations. tPA is a poor activator of PLG in solution, but it's activity is enhanced several fold when bound to fibrin. This localizes the majority of tPA-mediated PLG activation to the fibrin surface. uPA is found in the circulation and can be released from cells such as monocytes and neutrophils. uPA does not exhibit fibrin specificity and can activate PLG both in solution and while bound to its cell surface receptor, uPAR. Binding to uPAR colocalizes uPA and PLG, providing a focal point for plasmin generation. Plasmin degrades fibrin into FDPs, represented here as D-dimer and DD/E complexes. The system is under the control of several inhibitors; only the principal ones are shown here for simplicity. Complexes of active enzyme and inhibitor are rapidly cleared from the circulation. PAI-1, which is present at low concentrations in plasma, is released from damaged endothelium, but the major circulating active pool is contained within platelets. Once released, PAI-1 can inhibit tPA and uPA in solution. It can also inhibit PA activity in the presence of fibrin or cell surfaces, but this process is generally less efficient. $\alpha_2$antiplasmin (α_2AP) is in abundance in plasma and can be released from platelets. It can act on plasmin generated in solution but that formed on cell or fibrin surfaces is relatively protected from inhibition. α_2AP can be cross-linked onto fibrin localizing it at the site of plasmin formation. The carboxypeptidase inhibitor TAFI is found in plasma and platelets and can be cross-linked to fibrin. TAFI is activated by thrombin/thrombomodulin complex to generate TAFIa that attenuates PLG activation by removing the C-terminal lysines residues from fibrin that are important for binding of PLG and to a lesser extent tPA. This complex series of interactions and events serve to regulate fibrin accumulation in the body in a controlled manner. The many different feedback loops and surfaces involved localize the reactions and prevent excessive generation of plasmin activity.

fibrinolysis. The molecular interactions and specific binding sites involved have been extensively reviewed.[165] Low affinity binding sites (K_d 1 μM) for tPA (γ312–324) and PLG (Aα148–160) are located in the D-region of fibrinogen, only about 45 Å apart. The close proximity of these sites allows a cyclic ternary complex to form, facilitating activation of PLG by tPA. The αC domain of fibrin(ogen) is also reported to play a role in tPA-mediated PLG activation. A fragment corresponding to the αC domain (Aα221-612) binds tPA and PLG with high affinity (K_d 16 to 33 nM) and enhances plasmin generation. It is noteworthy that the binding sites for tPA and PLG in the D region and αC domain are cryptic in circulating fibrinogen and are exposed only during fibrin formation. Binding sites localized within the αC domains are probably uncovered during the switch from intramolecular interaction in fibrinogen to intermolecular interaction in fibrin. During fibrin assembly, conformational

changes in the D region, involving insertion of the B knob in the E region into the αC domain of the D region, are likely to expose tPA and PLG binding sites.

Exposure of *C*-terminal lysine residues in partially cleaved fibrin during the second phase of clot lysis dramatically accelerates the lysis rate.[463] Recent observations, using tPA variants, indicate that the finger domain of tPA plays a more dominant role in the interaction with fibrin than the kringle 2 interaction with *C*-terminal lysine residues.[464] This in turn indicates that the binding of PLG to partially degraded fibrin is the critical step in accelerating the second phase of fibrinolysis.

The structural characteristics of the fibrin network also influence the ability of fibrin to act as a cofactor in PLG activation.[465] Thin fibers are reported to lyse at a more rapid rate than coarse fibers, but yet fibrin networks composed of thin fibers lyze more slowly. These contrasting observations are most likely explained by the increased fiber density in clots composed of thin fibers, which regulates fibrinolytic speed and impairs movement of tPA and PLG into the dissolving clot.[466]

Unlike the single-chain form of tPA, scuPA has very low intrinsic catalytic activity (~0.5% of tcuPA). In the presence of fibrin scuPA, but not tcuPA, induces fibrin specific lysis.[199] The ability of scuPA to activate PLG bound to internal lysine residues is relatively low but partial digestion of fibrin by plasmin and exposure of *C*-terminal lysine residues dramatically increases the ability of scuPA to stimulate PLG activation. In the presence of a fibrin surface, activation of PLG by scuPA does not require conversion to the two-chain form of the activator, suggesting a conformational change in either PLG or scuPA that accelerates the interaction.[467] A further aspect of fibrin-specific lysis by scuPA is that the plasmin formed on the surface is relatively protected from inhibition, as discussed below.

PLASMIN GENERATION ON CELL SURFACES

The roles of fibrin and of cell surfaces in stimulating PLG activation can be viewed as broadly equivalent. PLG binding sites are broadly distributed on eukaryotic cells with most interactions being regulated by LBS within the kringle domains of PLG. Pretreatment of cells with carboxypeptidase B, an enzyme that removes *C*-terminal lysine residues, dramatically impairs the ability of cells to stimulate PLG activation.[468] Gangliosides and a class of glycolytic enzymes with *C*-terminal lysine residues, such as α-enolase, mediate binding of PLG to cell surfaces. Other PLG receptors include histone H2B,[469,470] TIP49a,[471] and p11[469] on monocytoid cells and integrin $\alpha_M\beta_2$ on neutrophils.[238] Annexin A2 on HUVECs binds both tPA (K_d 30 nM) and PLG (K_d 114 nM). Consistent with a role for this receptor in PLG activation, mice deficient in annexin A2 exhibit fibrin deposition in the microvasculature and incomplete clearance of injury-induced arterial thrombi.[472] Injection of recombinant annexin A2 increased the patency of vessels in a rat carotid artery model and enhanced activation of PLG in solution approximately 60-fold.[473]

A novel integral membrane receptor that is synthesized with a *C*-terminal lysine, Plg–R_{KT}, has recently been identified.[474] Plg–R_{KT} is broadly expressed in normal human tissues and is upregulated during differentiation. PLG binds with high affinity to the *C*-terminus of Plg–R_{KT} and regulates cell-surface activation of PLG. The *C*-terminus of Plg–R_{KT} also binds tPA in an overlapping binding site. However, the relative concentrations of PLG and tPA in the circulation should allow simultaneous binding of both ligands to the cell surface, with each tPA molecule bound within the vicinity of multiple PLG molecules. Interestingly, the receptor colocalizes with uPAR, suggesting that it can function to localize PLG with scuPA/uPA to promote cell-surface PLG activation.

Cell bound PLG is activated approximately 10-fold faster than PLG in solution. There are two alternative explanations for this, activation of Glu–PLG to Glu–plasmin or plasmin-mediated conversion to Lys–PLG, which is then activated to Lys–plasmin (FIGURE 20.4). On cell surfaces, and in contrast to solution phase, local plasmin is generated and converts Glu–PLG to Lys–PLG.[475,476] This echoes what happens on fibrin, where small amounts of plasmin are formed, sufficient to convert Glu–PLG to Lys–PLG.[477]

Binding of scuPA to its cellular receptor uPAR accelerates plasmin generation, as a result of the effect on PLG activation and on feedback activation of scuPA to uPA by formed plasmin. Both these steps depend on the association of PLG with the cell surface. Cell-bound plasmin is protected from inhibition by α_2AP, although the (sc)uPA is still susceptible to inhibition by PAI-1 and PAI-2. Direct anchoring of a GPI-linked uPA variant to the cell surface stimulates PLG activation to a similar degree as uPAR.[478] This suggests that the principal function of uPAR is to localize uPA to the cell surface and not to enhance activity of the PA.

In addition to uPAR, other receptors for uPA may exist on different cell types. An example of this is $\alpha_M\beta_2$ on neutrophils that binds both PLG and uPA to stimulate plasmin generation.[238] Platelets also exhibit the ability to bind scuPA[479,480] and indeed tPA.[481,482] None of these receptors have been identified conclusively. Plasmin activity associated with platelet membranes is capable of activating added scuPA, the local plasmin being much more active than in solution.[187]

uPA on monocytes or endothelial derived microparticles specifically activates PLG bound to platelets, fibrin, or extra cellular matrix proteins (e.g., fibronectin, laminin).[483] This recent evidence suggests that components of the fibrinolytic system need not be assembled on the same surface to induce PLG activation. This cross-talk mechanism of plasmin generation fulfills the requirement for PLG to be bound to a biologic surface for efficient activation (i.e., fibrin or cell surface)[438] but differs in that uPA is expressed on an adjacent cell or microparticle. Interestingly, cells bearing tPA were not able to elicit a cross-talk response, indicating that this is a specific feature of uPA-mediated PLG activation.

Balance of Proteases and Inhibitors

The PA and their inhibitors are subject to large variation, suggesting that regulation of fibrinolytic activity occurs mainly via subtle changes in the balance of PA and their inhibitors. This view arises both from the relative concentrations of PA, many orders of magnitude lower than the PLG concentration, and the very short half-lives of PA compared to PLG, minutes rather than days (Table 20.1). In normal individuals, steady-state levels of PLG in plasma are rather stable. Plasma levels reflect synthesis, release, and also clearance, primarily by the LRP family of receptors.[229] Liver endothelial cells express a mannose receptor that specifically interacts with the mannose-type carbohydrate on kringle 1 of tPA. A calcium-dependent receptor on the surface of

liver parenchymal cells recognizes the finger and EGF domains of tPA[116] and most likely represents LRP, which is also important for clearing tPA–PAI-1 complexes from the circulation.[229]

The fibrinolytic system is normally quiescent as a result of two factors: the relative abundance of inhibitors over proteases and the requirement for fibrin or cell surfaces for initiation of activity. In healthy individuals, there is a molar excess of active PAI-1 in plasma over tPA (Table 20.1). Consequently, most of the tPA in plasma is in the form of an inactive complex with PAI-1.[484] Small amounts of free tPA occur in the circulation as a result of the high synthesis rate of both proteins and the finite time it takes for complex formation to occur. Despite the stabilization of plasma PAI-1 in an active conformation by vitronectin[485,486] it still loses activity. This increases the possibility that plasma tPA can, in some circumstances, overcome inhibition by its primary inhibitor. Normally, tPA activity is detectable at approximately 0.1 to 0.5 U/mL of plasma, even when blood is collected in an acidified anticoagulant to prevent complexing of any free tPA by PAI-1.[487] The maximum activity normally seen is equivalent to 1 μg/L; tPA has a specific activity of 500,000 to 700,000 U/mg.[488] This low tPA activity is generally close to the borderline for detection, which is why procedures like euglobulin preparation, which removes most plasma inhibitors, but notably only about half the PAI-1,[317] are used. The levels of free tPA increase several-fold, after strenuous exercise, venous occlusion, or intravenous injection of DDAVP to healthy volunteers, but despite this no circulating plasmin is generated because PLG activation does not occur within this physiologic range of tPA concentrations. This does not apply during therapy with recombinant tPA, during which circulating plasma concentrations of tPA are achieved that are up to 1,000-fold higher than those observed in normal plasma.

Changes in the balance of tPA and PAI-1 are a clear example of how fibrinolytic activity can be initiated. Indeed, these components of the system fluctuate remarkably during a 24-hour period.[489] tPA activity is lowest at night and in the early morning and then increases up to three-fold during the day. PAI-1 antigen and activity are highest in the early morning hours and then gradually decline during the day, reaching their lowest level in the early afternoon. Various factors may interfere with the normal circadian rhythm.[223] There is a large body of literature on the predictive value of tPA antigen and PAI-1 as risk factors for acute myocardial infarction, stroke, and peripheral vascular disease.[339,344,345,490] High tPA antigen is found to be associated with disease in a number of studies, and this probably reflects tPA/PAI-1 complex.[484,491]

It is generally assumed that PLG, present in plasma at approximately 2 μM, is not rate-limiting for fibrinolysis. Even though its concentration is so much higher than the activators (Table 20.1), it is indeed possible for it to become a limiting factor. The need to consider local PLG concentration, especially when the activators are used therapeutically, has been clearly shown.[463] Even *in vitro* in platelet-rich plasma, platelet-associated PLG was shown to have a marked effect on scuPA activation, despite the presence of plasma PLG, pointing to the importance of local pools.[187] The outcome of variations in available PLG is highlighted in studies on TAFIa.[492] The effect of TAFIa on tPA-initiated lysis is usually stressed, in line with tPA's known fibrin dependence, but TAFIa also modulates uPA and scuPA-induced lysis, pointing to its primary effect being on PLG binding.[386]

Fibrinolytic activity is modulated by serpins. tPA and uPA are efficiently inhibited by PAI-1. More than 90% of blood PAI-1 is located in platelets and is promptly released upon activation. Although platelet PAI-1 is less active than the plasma pool, there is still enough active PAI-1 in platelets to stabilize platelet-rich thrombi, as occur in the arterial circulation where blood pressure is high and premature lysis of a hemostatic plug is undesirable. Plasmin bound to fibrin is partly protected from inactivation by α_2AP. This assures that fibrinolysis proceeds on the surface of a clot. However, free plasmin that spills over into the general circulation is rapidly inactivated by α_2AP. After massive activation of the fibrinolytic system has taken place, such as in thrombolytic therapy, the amount of α_2AP does not suffice to inhibit all circulating plasmin, and α_2-macroglobulin acts as a scavenger protease inhibitor.

The activity of the fibrinolytic system can be viewed as being regulated by a number of different factors: the local generation of plasmin on fibrin or cell surfaces rather than free in the circulation, the relative abundance of protease zymogens and inhibitors, which in turn is dictated by synthesis, release, and clearance. There are several means to activation of the system, whether by tPA or (sc)uPA, or the direct use of plasmin. Similarly inhibition is multifaceted, with TAFIa modulating plasmin generation on fibrin or cell surfaces, PAI-1 directly inhibiting tPA and uPA, and α_2AP directly inhibiting plasmin. The relative potencies of the proteases and the inhibitors can appear different depending on the experimental system or the clinical situation, reflecting the subtle interplay of interactions. Thus, while the system is superficially much simpler than coagulation and boasts only a couple of steps, it should not be interpreted simplistically and its subtleties require further work to reveal all their secrets.

CHAPTER

21 Inhibitors of Fibrinolysis

BJÖRN WIMAN AND ANNA ÅGREN

The fibrinolytic system has many different functions *in vivo*. Within the blood vessels, its main function is to remove fibrin deposits and keep the blood vessels open after clots have been formed. But the fibrinolytic system also seems to play roles in other processes such as reproduction, tissue repair and remodeling, invasive growth, and metastasis.[1] When activated, the fibrinolytic system results in the formation of active plasmin, a very powerful proteolytic enzyme, with an action very similar to that of trypsin. Plasmin eventually has the capacity to degrade almost all of the plasma proteins *in vivo*. It is therefore of utmost importance that both its action and its formation are highly regulated.[2] This is achieved in two distinct ways. Firstly, activation of plasminogen to plasmin physiologically occurs preferentially at the surface of fibrin. Secondly, free plasmin becomes inactivated rapidly. In that way, the action of the fibrinolytic system in the blood vessels is localized to eventual deposits of fibrin. Fibrinolytic inhibitors play important regulatory roles in different stages of this process. The inhibitors are mainly antiplasmin and *PAI-1* (plasminogen activator inhibitor 1), two inhibitors belonging to the serine proteinase inhibitors or the serpin superfamily of proteins. In addition, other substances influence the process both in a positive and a negative way. They may also be of great physiologic significance. A schematic picture of the fibrinolytic process and its regulation is demonstrated in FIGURE 21.1. In this chapter, we mainly discuss the inhibitors involved in this regulation, such as those inhibiting plasmin, which are antiplasmin and α_2-macroglobulin, those inhibiting plasminogen activators, which are *PAI-1* and *PAI-2* (plasminogen activator inhibitor 2), and finally, other compounds influencing the process, such as fibrin and TAFI (thrombin-activatable fibrinolysis inhibitor).

From the pathophysiologic point of view, an increased function of the fibrinolytic system leads to an increased bleeding tendency. This is, for example, seen in patients with antiplasmin deficiency and may result in bleedings as severe as in patients with hemophilia. On the other hand, a decreased fibrinolytic function, as is found in patients with increased plasma levels of *PAI-1*, gives a thrombotic tendency both in the arteries and in the veins.

ANTIPLASMIN

Discovery and Basic Information

Antiplasmin is a serpin with a molecular weight of about 70,000. It was discovered in 1976 by three different groups.[3–5] It is produced in the liver,[6] and therefore its plasma concentration is decreased in severe liver diseases where protein biosynthesis is diminished.[7] The plasma concentration of antiplasmin is about 70 mg/L (1 μmol/L), which is approximately half the concentration of plasminogen in plasma on a molar basis. Therefore, under normal circumstances, when only little plasminogen is activated, the antiplasmin concentration is in far excess of the formed plasmin. However, during thrombolytic treatment, especially with non–fibrin-specific plasminogen activators, such as streptokinase or urokinase, large amounts of the plasminogen will become activated rapidly with the risk of all the antiplasmin becoming depleted. Under those circumstances, α_2-macroglobulin might become an important inhibitor of plasmin. The half-life in the circulation of native antiplasmin is approximately 3 days.[8]

Antiplasmin has several different functional properties. Its main physiologic activity is inhibition of plasmin by forming an irreversible enzymatically inactive complex with plasmin.[9,10] It inhibits plasmin extremely rapidly.[9] In addition, it inhibits the binding of plasminogen to fibrin, which is a very important regulatory phenomenon in the fibrinolytic process.[2,11] It may also become cross-linked to the α-chains of fibrin during clotting by the action of coagulation factor XIIIa.[12,13] Antiplasmin bound to fibrin in this way is believed to protect the formed fibrin from becoming prematurely degraded, keeping the fibrinolytic activity somewhat delayed until the healing processes get started.

Structure

The gene of antiplasmin has been localized to chromosome 17p13.[14] This inhibitor is a glycoprotein consisting of a single polypeptide, containing approximately 13% carbohydrate.[15] Holmes et al.[16] determined the primary structure of mature human α_2-antiplasmin by DNA sequencing of overlapping cDNA fragments prepared from human liver mRNA. It was found to contain 452 amino acids as deduced from the cDNA sequence, with Asn as NH_2-terminal amino acid. Later, it was found that native antiplasmin has an additional 12 amino acids at the NH_2-terminal end and is rather composed of 464 amino acids with an NH_2-terminal Met.[17,18] In plasma, Met-antiplasmin is converted to Asn-antiplasmin.[19] There are four potential asparagine-linked glycosylation sites in the molecule. Antiplasmin has not yet been possible to crystallize, so much of its structure had to be anticipated by homologies with other proteins. It belongs to the serpin superfamily of proteins. It seems to contain all the important structural elements of a serpin. Of these, the reactive center loop (RCL), which contains the scissile peptide bond (red string in FIGURE 21.2) and the A β-sheet (yellow part in FIGURE 21.2), is of special functional importance. RCL is the part catching the protease and thus the most important portion of a serpin. It might occasionally be inserted into the A β-sheet as a new central strand and then form an inactive,

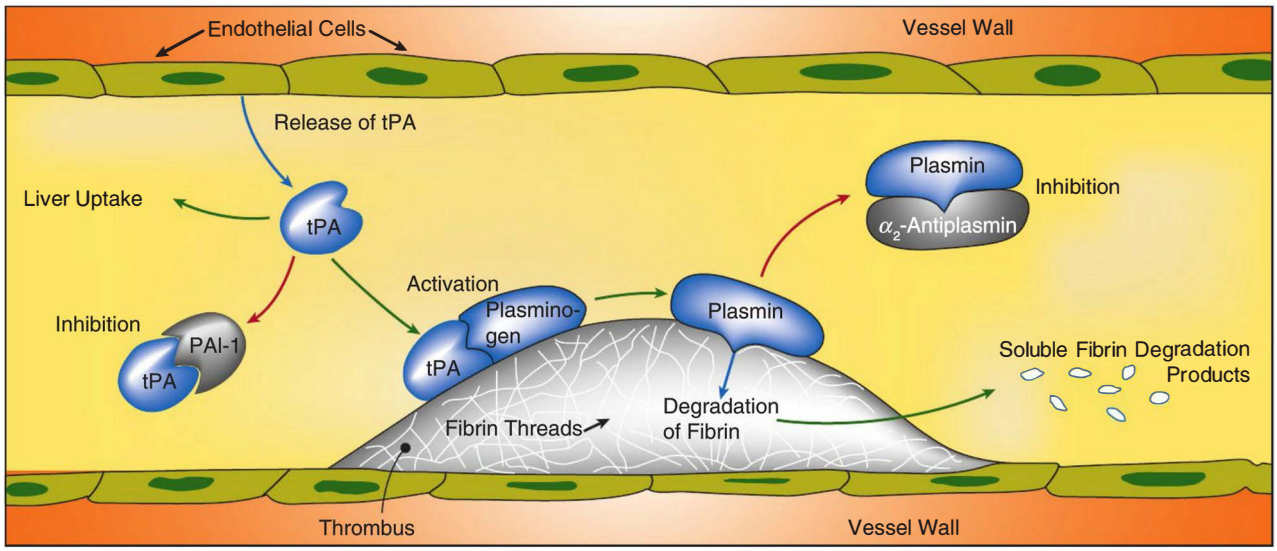

FIGURE 21.1 A schematic picture of the fibrinolytic system and its activation is demonstrated. Activation of plasminogen occurs preferably at the surface of fibrin, while plasmin becomes inhibited only after it has left the fibrin surface. (Adapted from Wiman, MFR informerar, 1987.)

latent form that may be reactivated, if treated with denaturing substances, followed by dialysis. Alternatively, the RCL might be inserted into the A β-sheet of another molecule resulting in a tendency of polymerization.

Reaction with Plasmin

Antiplasmin is capable of reacting with and forming stable enzymatically inactive complexes with plasmin. The reaction is very rapid, with a rate constant of about 2×10^7 $M^{-1}s^{-1}$, and occurs in several steps involving several different interacting sites.[9,10,11,20,21] The first step, which seems to be the rate limiting, takes place between one of the lysine-binding sites in the plasmin molecule and a complementary site in the very COOH-terminal (CT) portion of the antiplasmin molecule. The second is a noncovalent interaction between the substrate-binding pocket in the plasmin active site and the scissile peptide bond in the RCL of antiplasmin. Subsequently, peptide bond cleavage occurs.[22] After formation of an ester bond between plasmin and antiplasmin, major conformational changes occur both in the plasmin molecule and in the antiplasmin molecule.

The lysine-binding-site-mediated interaction has an important role in regulating the fibrinolytic system. The same site in the plasmin molecules are also involved in the interaction with fibrin. Therefore, fibrin-bound plasmin reacts much slower with antiplasmin than free plasmin, thereby keeping the fibrinolytic process localized.[2,9,11] It was initially believed that the CT lysine (Lys^{452}) in antiplasmin is responsible for the lysine-binding-site-mediated interactions with different proteins.[11,23–26,27,28–31] Current evidence indicates that K436, but not K452, is important in this reaction.[32] Using single-site mutants, the variant K436E reacted much more slowly than wild-type antiplasmin (wt-antiplasmin) or the other variants including K452E or K452T. In addition, in the presence of 6-aminohexanoic acids, the reaction rate decreased about 10-fold or more for wt-antiplasmin and most variants. The variant K436E was less affected by 6-aminohexanoic acids, again suggesting that this residue is involved in the lysine-binding-site-mediated interaction between plasmin and antiplasmin. The data were further supported by studies using surface plasmon resonance to examine the interaction of antiplasmin mutants to immobilized plasminogen or an elastase fragment from plasminogen constituting "kringles" 1–3. The only antiplasmin variant with decreased affinity was the K436E, again demonstrating that the lysine residue 436 is important in this interaction.[33] Thus, available data clearly demonstrate that Lys^{436} of antiplasmin is involved in the lysine-binding-site-mediated interaction with plasminogen and fibrin.

Stability

Many of the serpins seem to be metastable proteins, with quite interesting mechanisms regulating their stability. In contrast to some of the other serpins, human antiplasmin is quite stable at physiologic conditions, but that activity is rapidly lost at acidic conditions[34] or at neutral pH at elevated temperatures.[35] At temperatures above 45°C, the rapid inactivation was found to be a polymerization process. However, the inactivation occurring at low pH occurred mostly without any visible polymerization tendency. However, such material could gradually recover activity at neutral pH, and if treated with guanidinium chloride, followed by dialysis, antiplasmin activity was again recovered,[35] in a similar fashion as for *PAI-1* (see below).

Using site-directed mutagenesis, four single-site mutants, His197Thr, His341Thr, Glu353Ala, and Glu382His, were found to display significantly increased stability.[36] The mutant His341Thr was found to have the longest half-life at pH 4.9, about sevenfold increased stability as compared to wt-antiplasmin. One mutant, Glu346Thr, had a shorter half-life

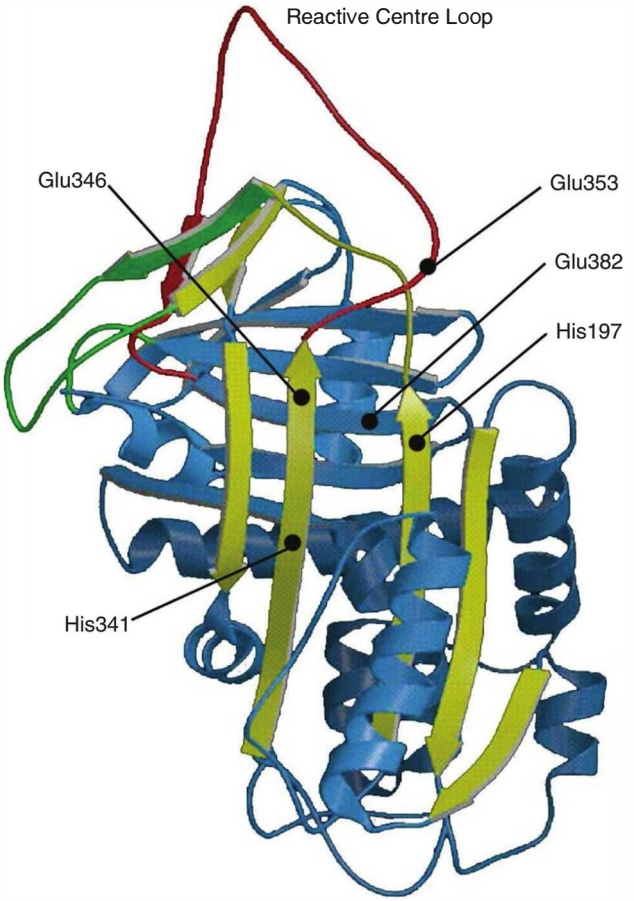

FIGURE 21.2 A schematic picture of active *PAI-1* (Adapted from Aertgeerts et al. 1994). The expected sites for some mutations if this was in antiplasmin are indicated. Antiplasmin has not yet been crystallized. Therefore, we show a model of *PAI-1* instead, since most serpins are expected to have a very similar basic structure. The RCL is labeled red and the A β-sheet yellow.

than wt-antiplasmin. All these residues are believed to be situated in the vicinity of the point where the RCL is inserted into the A β-sheet to get latent molecules (FIGURE 21.2). Unfortunately, so far it has not been possible to crystallize antiplasmin. However, the serpin superfamily of proteins all seem to be very similar in their overall structure. Therefore, in FIGURE 21.2, a schematic picture of *PAI-1* is shown as adapted from Aertgeerts et al.[37] 1994. The expected places for where the important mutations in antiplasmin, as discussed above, would be situated are indicated in this figure.

Incorporation into Fibrin

Antiplasmin is incorporated into the α-chains of fibrin during the clotting process through the action of activated coagulation factor XIII. This interaction involves the NH_2-terminal portion of antiplasmin, more specifically the Gln residue number 2. Only a fraction of the fibrin monomers will have an antiplasmin incorporated, but these molecules are believed to be very important from the physiologic point of view. They catch and inactivate the initial plasmin molecules formed upon activation of the fibrinolytic system. In that way, fibrin is initially protected and the fibrinolytic process becomes somewhat delayed.[38] This permits the repair processes to get started before the fibrinolytic process really gets accelerated.

Clinical Significance

A few individuals have been identified with congenital antiplasmin deficiency.[39] They suffer from a severe bleeding tendency, similar to individuals with classical hemophilia. However, when correctly diagnosed, these patients are very easily treated with antifibrinolytic drugs. Tranexamic acid or earlier 6-aminohexanoic acid is the most frequently used drug to achieve this. It interferes with the interaction between plasminogen and fibrin and prevents formation of the ternary complex between fibrin, plasminogen, and tPA (tissue plasminogen activator). This causes a dramatic decrease in the activation rate of plasminogen and thus, an antifibrinolytic effect is obtained. Aprotinin, a low molecular weight and very efficient inhibitor of trypsin and plasmin, has also been used. Decreased plasma concentrations of antiplasmin are seen in connection with severe liver disease.

PAI-1

Discovery and Basic Information

PAI-1 is a serpin with a molecular weight of about 50,000. It was initially discovered in endothelial cells [40] in human plasma [41,42,43] and in hepatocytes.[44] It is now known that *PAI-1* is produced by several types of cells, including vascular endothelial cells, adipocytes, platelets (or rather megakaryocytes), and placental cells.[1] *PAI-1* is also produced by smooth muscle cells in atherosclerotic arteries.[1]

The concentration of active *PAI-1* in human plasma is 0.6 nmol/L (about 30 μg/L), much lower than for the other serpins. Some individuals have 5 to 10-fold higher plasma concentrations. This is true for individuals with increased body weight, especially those with an increased waist/hip ratio, or those with an increased inflammation, but it is also true for pregnant women.

PAI-1 efficiently inhibits tPA and uPA (urinary plasminogen activator) by forming a 1:1 very stable complex that resists strong denaturing substances such as SDS.[45] The reaction between *PAI-1* and tPA/uPA is also extremely fast with second-order rate constants above 10^7 M^{-1} s^{-1}.[46,47] During complex formation, the scissile peptide bond Met^{346}-Arg^{347} in *PAI-1* becomes cleaved.[45,48]

The *PAI-1* Gene

The human *PAI-1* gene is located on chromosome 7 and is approximately 12.2 kbp long. The gene contains nine exons separated by eight introns. Several groups have sequenced and analyzed this gene.[49,50,51,52–55] Two different *PAI-1* mRNA species seem to exist in humans with lengths of 2.4 and 3.2 kb.[50] They both contain the entire coding region and just differ in the length in their 3′-untranslated region.[51,56] Both these messengers seem to function similarly, but they differ in stability, with the 2.4-kb form being more stable.[57] The different transcripts are the result of the presence of multiple polyadenylation splice sites.[58]

Several polymorphisms within the *PAI-1* gene have been described. The most frequently studied one is the 4G/5G polymorphism located 675 bp upstream of the transcriptional start site.[59,60] It is a polymorphism of functional importance since it correlates with the plasma *PAI-1* concentration (see below). Other reported polymorphisms are a *Hin*dIII polymorphism in the 3′-region,[56] a $(CA)_n$ repeat in intron 3,[60] a G/A substitution at −844 in the promoter [61,62] and at +1334[194], a T/G substitution at +11053,[62] a 9-nucleotide insertion/deletion between +11320 and 11345,[62] and a G/A substitution at position +9785 in intron 7.[62] None of these have yet been shown to be of any practical importance.

Structure

Human *PAI-1* is a single-chain glycoprotein with a molecular weight of about 50,000.[42] Recombinant *PAI-1* expressed in *Escherichia coli* has a molecular weight of approximately 43,000 due to the lack of glycosylation in the bacteria. After removal of a signal peptide of 23 amino acids, the mature protein consists of 379 amino acids. *PAI-1* lacks cysteine residues and contains three potential glycosylation sites.[50] It has the typical serpin structure (FIGURE 21.2).

The *PAI-1* molecule is fully active upon synthesis,[63] but under physiologic conditions it seems to be spontaneously transformed into an inactive form. This form can, however, again become active if treated with some denaturing (preferably hydrogen bond–cleaving) substances and allowed to refold.[40,63,64] This form has come to be called "latent" *PAI-1*. The crystal structure of latent *PAI-1* was solved in 1992[65] and revealed that in the latent conformation the RCL (red string in FIGURE 21.2) is fully inserted forming a new strand in the middle of the A β-sheet[37] (yellow portion in FIGURE 21.2). In the active conformation, the RCL is exposed on the surface of the molecule (see FIGURE 21.2).

The Reaction between *PAI-1* and Plasminogen Activators

As mentioned above, the reactions between *PAI-1* and the different plasminogen activators, tPA or uPA, are very rapid. This seems to depend on the presence of second-site interactions [46] in analogy with the reaction between plasmin and antiplasmin.[9,20] Besides the interaction between the active site in the activators and the scissile peptide bond Met[346]-Arg[347] in the RCL in *PAI-1*, an interaction between Glu350 in *PAI-1* with Arg[304] in tPA also seems to be of importance.[66,67]

The formation of the stable complex between a serpin and a serine proteinase occurs by the binding of the RCL to the active site of the proteinase, followed by cleavage of the reactive center peptide bond and formation of an ester bond between the carboxyl group of the P1 residue of the serpin and the hydroxyl group of the active-site serine of the proteinase (P1P1′).[22,48,68,69] The amino acid residues at positions P1–P16 are then inserted into the A β-sheet, and the serine proteinase is transported toward the opposite pole of the RCL in the serpin.[48,69–71]

The inhibition of plasminogen activators by *PAI-1* involves an interaction between the RCL of the inhibitor and the catalytic groove of the proteinase in question. The mobility of the RCL is required for the inhibitory function of *PAI-1* but not for the initial recognition of the plasminogen activators.[72] The basic residue at the P1 position within the RCL plays a crucial role for the uPA inhibitory activity.[73–75] However, the presence of a neutral or hydrophobic residue at this position does not affect the inhibitory activity toward tPA.[76]

Different Molecular Forms of *PAI-1* and Stability

The existence of latent *PAI-1* was described above. The transformation of active to latent inhibitor is a spontaneous process at physiologic conditions. The importance of some residues on β-strand 5A for the activity and latency transition of *PAI-1* has been investigated.[77] It was shown that the side chain of Gln[303] is important since substitution of this residue toward a His increased the latency transition fourfold. Binding of a murine monoclonal antibody produced against the human tPA-*PAI-1* complex induced a 4,000-fold decrease in the half-life of active *PAI-1*.[78] Binding of this antibody seems to cause a partial insertion of the RCL into the *PAI-1* A β-sheet. Different parts of helix F in the *PAI-1* molecule seem also to be involved in the conversion from active to the latent form. When substituting Asp[125] by Lys and Arg[133] by Asp, these variants were rapidly transformed into latent forms.[79] The residue Lys[325], situated at β-strand s5A and normally forming a hydrogen bond with Asn[150] (located on the s3A/hF loop), also seems to be important in regulating the latency transition.[80]

Several studies have been performed to increase the understanding and mechanisms regarding *PAI-1* stability, by generating and investigating the properties of mutants of the molecule. The importance of the positively charged residues (Arg[186], Arg[187], His[190], or Lys[191]) on the turn connecting s4C with s3C for the functional stability of *PAI-1* has been nicely demonstrated by generating double-site mutants.[81] It was earlier suggested that the mobility of loop 1 (His[185]-Pro[200], the turn connecting strand s4C with s3C) is required for transition to the latent form.[82] It has also been demonstrated that mutation of His[185] and His[190] significantly decreased the stability of *PAI-1* at pH 7.5 as well as the pH dependence of stability.[83] Using random mutagenesis,[84] a very stable mutant with a half-life of 145 hours was constructed. This variant had four residues mutated, and it was suggested that large increases in stability require contributions from several amino acid substitutions.

PAI-1 has a significantly increased stability at slightly acidic pH.[85] A decrease in pH is accompanied by protonation of imidazole groups, and it is therefore likely that histidine residues are involved in stabilizing the active form of *PAI-1*. It was speculated that His[143] in helix F, situated in the vicinity of the A β-sheet in the three-dimensional structure of *PAI-1*, could be involved.[86] However, the introduction of mutations at this position did not favor that hypothesis.[87] Instead, it was found that His[364] close to the CT end of the molecule was important for the pH-dependent stability.[83] Other structures may of course also be involved.

By molecular modeling of *PAI-1*, the normal inhibitory function of this molecule has been transformed into a substrate form as well.[88,89] After complex formation, the ester bond is in this case no longer stable, but becomes rapidly hydrolyzed. Substrate behavior has also been induced by insertion of synthetic peptides corresponding to the RCL[90] or by binding of certain monoclonal antibodies directed against the human tPA-*PAI-1* complex.[91]

Interaction with Vitronectin

Already at the discovery of *PAI-1* in plasma, it was found that its gel filtration behavior deviated from expected[42] and suggesting that it was bound in plasma to a specific binding protein.[92] It was subsequently demonstrated that this binding protein was vitronectin.[93,94] Vitronectin is a 75,000 Mr glycoprotein[93] present in plasma at a concentration of about 200 mg/L. When *PAI-1* is purified from human plasma, it copurifies with vitronectin.[94] Although the interaction between vitronectin and latent, or cleaved, forms of *PAI-1* or *PAI-1* in complex with plasminogen activators is weak, vitronectin binds active *PAI-1* with very high affinity.[95,96] The vitronectin-binding sites in *PAI-1* have been localized to the region from Gln^{55} to Lys^{145}.[97–99] In addition, the deletion of residues 127 to 158 decreased the binding of *PAI-1* to vitronectin by a factor of 3,000.[100] This suggests that the most important part for this interaction most probably resides in the portion residues 127 to 145. It has been proposed that, although vitronectin does not bind to the RCL, interactions with vitronectin induce conformational changes in the reactive center of *PAI-1*.[101] The corresponding site in vitronectin seems to be localized to the NH_2-terminal region[102,103] as studied by the binding of fragments from vitronectin to active *PAI-1*.

In plasma, active *PAI-1* is virtually completely bound to vitronectin. This stabilizes the active form of *PAI-1* and prolongs the half-life from 2 to 4 hours regarding the transition of active to the latent molecule.[93,94] Increasing the concentration of NaCl from 50 mM to 1 M dramatically increases the stability of *PAI-1*.[104] It was demonstrated that an anion-binding site is located between strand 5 of the central β-sheet and a small domain constituting the residues 128 to 161 in helix F and the loop connecting to s3A.[105] During the active to latent transformation, the domain containing these residues is directed away from the main body of the protein while RCL is inserted. Thus, a chloride ion in the anion-binding site stabilizes the active conformation.

Interaction with Heparin

Heparin is a cofactor for several serpins and stimulates the inhibition of uPA by *PAI-1*.[106] When *PAI-1* is bound to heparin, the inhibition of thrombin by *PAI-1* is greatly enhanced.[107–110] Based on site-directed mutagenesis studies, the positively charged residues Lys^{65}, Lys^{69}, Arg^{76}, Lys^{80}, Lys^{88}, [108] and Arg^{115} and Arg^{118} [79] in *PAI-1* were suggested to be involved in the *PAI-1* binding to heparin. In addition, it was reported that four residues His^{3}, His^{77}, His^{112}, and His^{229} could also be partly involved in this interaction.[83] The affinity between heparin and *PAI-1* has been used practically to purify *PAI-1* in a gentle and efficient way.[111] However, it is not known if this interaction really is of physiologic significance.

Regulation of *PAI-1*

There is a large diurnal variation of the *PAI-1* concentration in plasma.[112–114] The *PAI-1* concentration is highest in the early morning and then decreases quite rapidly, causing the tPA activity to be lowest in the early morning and instead increasing during the day. The reason for this is that the *PAI-1* gene transcription is regulated by clock genes.[115] *PAI-1* also acts as an acute-phase reactant, which increases during an inflammatory response. Lipopolysaccharide or certain cytokines increase the *PAI-1* expression in endothelial cells in culture.[116–118] The synthesis and secretion of *PAI-1* is, however, affected by many other factors. Insulin induces an increase in *PAI-1* secretion from hepatocytes in culture.[119,120] It was suggested that insulin is a major regulator of the plasma *PAI-1* concentration.[121] In fact, a very strong correlation has been found between plasma insulin antigen and *PAI-1* levels in a study of about 1,500 patients with angina pectoris.[122] On reducing plasma insulin levels and insulin resistance by exercise, by weight loss, or by medication with metformin, the plasma *PAI-1* activity becomes decreased.[123–125] The decreased fibrinolytic capacity frequently seen in type 2 diabetes is most likely due to increased *PAI-1* levels. In a rat model, it was found that hyperglycemia in diabetes mellitus is associated with increased *PAI-1* content in several different types of tissue.[126]

Plasma *PAI-1* correlates positively with the concentration of serum triglycerides.[127,128,129] *In vitro*, it has also been shown that very low density lipoprotein (VLDL) and oxidized low density lipoprotein (LDL) stimulate the production of *PAI-1* in cultured endothelial cells.[130–133]

The 4G/5G polymorphism located 675 bp upstream of the transcriptional start site [59,60] correlates to the plasma *PAI-1* concentration. Individuals who are homozygous for the 4G allele have higher concentrations of *PAI-1* in plasma. It has been proposed that both the 4G and the 5G alleles bind a common factor which may work as a transcriptional activator.[134] It was also proposed that a repressing nuclear protein binds to the 5G allele, which decreases the binding of the activator protein, thus reducing the transcription of *PAI-1*.[134] VLDL seems to induce transcription of *PAI-1* in endothelial cells through binding of a VLDL-inducible transcription factor to residues −672 to 657 in the *PAI-1* promoter.[135)]

Endothelial cell growth factor combined with heparin and agents increasing intracellular cAMP (e.g., forskolin) are among the few substances that down-regulate the *PAI-1* gene expression in endothelial cells in culture.[136,137] The most important factors influencing the plasma *PAI-1* concentrations are summarized in FIGURE 21.3.

Clinical Significance

Increased plasma levels of *PAI-1* have been reported to correlate with the development of thrombotic disease, both venous and arterial.[127,138,139–143] In contrast, a total *PAI-1* deficiency[144–149] has been found to be associated with increased bleeding problems. The genetic background has not been examined in most of the reports concerning individuals with increased bleeding and low or nonmeasurable plasma *PAI-1* concentration. However, a child with complete deficiency of *PAI-1* due to a frameshift mutation was reported.[148] This mutation was a dinucleotide insertion in exon 4 leading to a new stop codon in the *PAI-1* gene. In a later study, this mutation was found among 26 other individuals, 7 of which were homozygous and with a complete *PAI-1* deficiency. These individuals experienced increased bleeding problems after trauma and surgery.[149] The heterozygous individuals, however, did not have any clinical signs of increased bleeding tendency. In addition, individuals with very low or immeasurable *PAI-1* concentrations in plasma, but with a normal gene did not display any significantly increased bleeding tendency.[150,151]

As already mentioned, increased plasma concentrations of *PAI-1* are associated with the development of thrombotic events, such as deep vein thrombosis,[140–143,152] myocardial

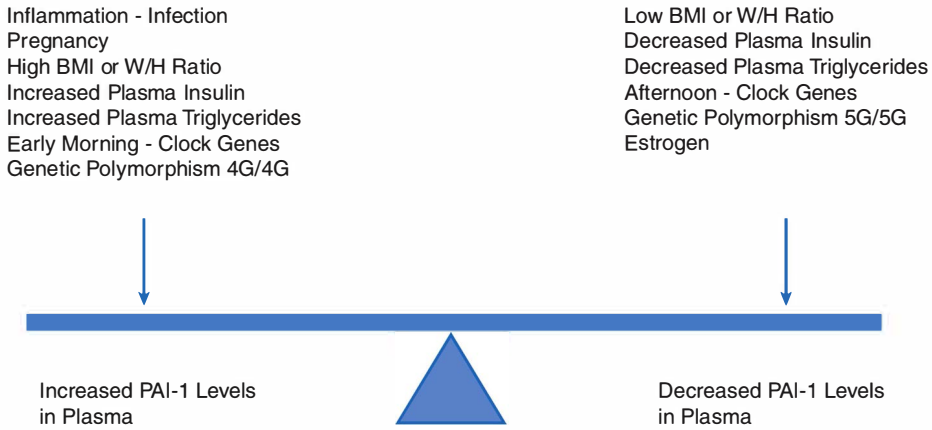

FIGURE 21.3 Factors that influence the plasma *PAI-1* concentration. BMI is body mass index; W/H ratio is waist-to-hip ratio.

infarction,[127,138,139,153] and stroke. *PAI-1* concentrations in plasma are not normally distributed in humans, but it correlates quite well with tPA/*PAI-1* complex that is normally distributed. This complex is also more stable in plasma. For this reason, it might be an advantage to measure this complex in plasma rather than *PAI-1* and use the complex as a risk indicator for myocardial infarction.[153] Further support that *PAI-1* is etiologically involved in the development of thrombosis comes from studies on transgenic mice overexpressing *PAI-1*.[154] The data regarding increased plasma *PAI-1* concentration in connection with myocardial infarction is getting impressive. Prospective data from the SHEEP study of reinfarction in patients with a previous infarction demonstrated that individuals with increased *PAI-1* levels or tPA/*PAI-1* complex in combination with smoking or type II diabetes had five- to eightfold increased risk of reinfarction.[155]

The *PAI-1* in plasma may have different origins. Thus, high plasma concentration in individuals with high waist-to-hip ratio mostly has its origin in the visceral fat, while that seen during an inflammatory process mostly have its origin in the liver. It has been demonstrated that *PAI-1* of different origin has different glycosylation patterns.[156] This can of course be used to determine the origin of plasma *PAI-1*. It is not known if *PAI-1* in plasma of different origin has deviating clinical significance.

PAI-1 is also present in platelets in quite high concentrations.[157,158] However, most of it seems to be latent, even if some individuals can have a large portion of active inhibitor.[159] The reason for this is not known with certainty, but it has been demonstrated that biosynthesis of *PAI-1* may occur within the platelets.[160] If the platelets contain much active *PAI-1*, it might play a role in stabilizing clots and slows down fibrinolysis *in vivo*.[161] The high concentration of mostly inactive *PAI-1* in platelets might cause problems in blood sampling for measurement of *PAI-1* in clinical studies. Under conditions where *PAI-1* leaks from the platelets, such as if the sodium citrate concentration is too low, the *PAI-1* antigen concentrations in plasma might be artifactually increased. The *PAI-1* antigen concentrations in serum are typically about 10 times higher than in plasma.

PAI-2

PAI-2 was first discovered in human placental extracts.[162] Later, it was found in macrophages and in several other different cell lines in culture.[163] In plasma from healthy nonpregnant individuals, it is typically not found in measurable concentrations. However, during pregnancy, *PAI-2* is produced by trophoblasts in the placenta and released into plasma. As a result, high concentrations are found also in plasma from pregnant women.[164,165] *PAI-2* has been purified from placenta and from plasma from pregnant women.[166] The plasma concentration of *PAI-2* increases steadily during pregnancy and reaches concentrations above 35 μg/L, but decreases sharply after delivery.[165,167] This suggests that *PAI-2* may have a hemostatic role during pregnancy and delivery. Also in patients with acute myeloblastic leukemia, plasma *PAI-2* could frequently be found in high concentrations.[168] In fact, *PAI-2* is mostly found as an intracellular protein, and as such, many other functions have been suggested for this serpin.[169]

PAI-2 is a single-chain protein, consisting of 425 amino acids.[170,171] The gene spans 16.5 kb and is located on chromosome 18q22.1.[170,172] *PAI-2* exists in two forms: a secreted glycosylated form with a molecular weight of about 70,000 and an intracellular nonglycosylated form with a molecular weight of about 46,000. *PAI-2* is an efficient inhibitor of uPA.[165] It also inhibits two-chain tPA, but it is a very poor inhibitor of single-chain tPA.[165] *PAI-2* may spontaneously and reversibly polymerize by insertion of the RCL from one *PAI-2* molecule into the A β-sheet in another *PAI-2* molecule.[173,174] The exact physiologic role of *PAI-2* is not known, but a decreased fibrinolytic activity could be important in late-state pregnancy and even more so during delivery. Pregnant women with placental insufficiency typically have low concentration of *PAI-2*.[175] Preeclampsia patients also seem to have lower concentrations of *PAI-2* and higher concentrations of *PAI-1* than women during a normal pregnancy.[176] For a recent review of *PAI-2*, see Croucher et al.[177]

α_2-MACROGLOBULIN

Human α_2-macroglobulin is a large plasma protein, with a molecular weight of about 720,000. It is composed of four identical subunits, each with a molecular weight of 180,000, held together by disulfide bridges and noncovalent interactions.[178] In the central portions of these subunits, a bait region is present, which is easily cleaved by a number of proteases of completely different classes. Cleavage results in a dramatic conformational change, resulting in entrapment of the responsible protease, frequently

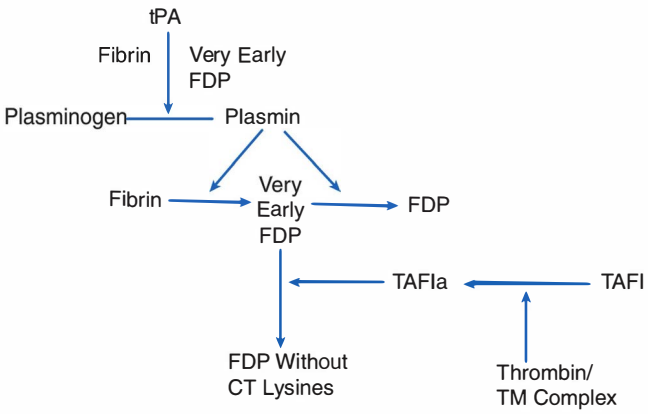

FIGURE 21.4 A schematic picture of the function of TAFI. Fibrin and early fibrin degradation products (FDPs) stimulate plasminogen activation by tPA. If the formed CT lysines are removed by activated TAFI, the FDP no longer stimulates plasminogen activation. TAFI is activated mainly by thrombin in complex with TM.

preserving the active site of this protease, especially toward low molecular weight substrates. α_2-Macroglobulin reacts with plasmin, forming a 1:1 complex. It can typically bind two molecules of low molecular weight proteases/molecule of α_2-macroglobulin, but only one mol/mol of a large protease such as plasmin. Its concentration in plasma is typically between 1.5 and 4 g/L, and its half-life in the circulation is about 6 days. However, α_2-macroglobulin in complex with proteases is rapidly cleared from the circulation by uptake to the reticuloendothelial system by binding to LDL receptor–related protein followed by internalization.[179] Under normal circumstances, α_2-macroglobulin is not a very good inhibitor of plasmin. The reaction rate is too slow to be of physiologic significance. However, during conditions where antiplasmin is severely depleted as is frequently seen in connection with thrombolytic treatment, especially with non–fibrin-specific plasminogen activators (streptokinase or urokinase), α_2-macroglobulin might be very important as a fibrinolytic inhibitor. In fact, under such conditions, when antiplasmin is depleted to a large extent, fibrinogenolysis is often seen and the risk of bleeding complications increases drastically. It is possible that a depletion of α_2-macroglobulin as well would rapidly lead to a deteriorated situation.

TAFI

TAFI is a glycoprotein with Mr 60,000, consisting of 417 amino acids, which is synthesized in the liver. Even if TAFI has the capacity to inhibit or slow down the fibrinolytic process, it is not an inhibitor by itself, but activated, it is a carboxypeptidase type B. As such it has the capacity to remove CT lysine residues, preferably from partially degraded fibrin.[180] Partially degraded fibrin is an important stimulator regarding plasminogen activation by tPA, because the presence of CT lysines increases the number of binding structures for plasminogen (via lysine-binding sites). This causes a rapid and localized activation of plasminogen. Removal of those CT lysine residues in fibrin will slow down the fibrinolytic process (FIGURE 21.4). TAFI therefore may act as an inhibitor of fibrinolytic activity. It is also known as procarboxypeptidase U or plasma procarboxypeptidase B, names that in fact are more accurate. It can be activated by thrombin, trypsin, kallikrein, or plasmin into the active enzyme TAFIa. The most efficient activator seems, however, to be the complex between thrombin and thrombomodulin (TM).[181,182] Activation occurs by releasing a 92-residue activation peptide, generating the active 35-kd enzyme. The physiologic or clinical importance of TAFI still remains to be settled. TAFI-deficient mice did not display any major clinical problems.[183] However, such mice had an easily measurable enhanced endogenous fibrinolytic activity, suggesting that it might play a pathophysiologic role.[184]

CHAPTER 22

Overview of Megakaryocyte and Platelet Biology

JOEL S. BENNETT

Platelets are circulating anucleate fragments of bone marrow megakaryocytes that provide primary hemostasis by forming hemostatic plugs at sites of vascular injury; likewise, platelet thrombi are predominantly responsible for the morbidity and mortality of arterial vascular disease. The discovery of platelets as formed elements of the blood, the identification of their central role in hemostasis and thrombosis, and the research that has led to our current understanding of the mechanism and regulation of platelet production and function have been outlined in excellent reviews by Coller[1] and Coller and Shattil.[2] The chapters in this section of the textbook provide detailed analyses of the current understanding of platelet production and function.

PLATELET PRODUCTION FROM MEGAKARYOCYTES

Megakaryocyte development and the subsequent production and release of platelets are unique phenomena that are discussed in Chapters 23 to 25. Megakaryocytes are relatively rare cells in the bone marrow, constituting <1% of marrow cells, but they are also the largest marrow cells with diameters of up to 40 to 50 μm. They are located in the extravascular compartment of the bone marrow along the albuminal face of the sinusoidal endothelium, frequently in clusters (FIGURE 22.1). Despite their apparent scarcity, sufficient numbers of megakaryocytes are present in the marrow to produce the 10^{11} platelets per day required to maintain the normal steady-state level of circulating platelets.[3] In order to meet this need, megakaryocytes have evolved a unique maturation process in which the diploid DNA of megakaryocyte precursors undergoes repeated cycles of duplication (endomitosis), reaching a modal DNA level of 16N or greater, but without cell division.[4] This results in a cell with a single polylobulated nucleus and with an expansive cytoplasm whose fragmentation is the source of circulating platelets. Although the mechanism responsible for endomitosis in megakaryocytes is not known, it is thought to be related to failure to develop and sustain a cleavage furrow during the late stage of mitosis with subsequent absence of cytokinesis. Recent evidence indicates that this is associated with the RUNX1-induced downregulation of the nonmuscle myosin IIB heavy chain,[5] a component of the contractile ring that generates the forces necessary for cytokinesis, and with downregulation of the RhoA-specific guanine-nucleotide exchange factors (GEFs) GEF-H1 and ECT2,[6] thereby preventing the RhoA signaling required for the formation of the contractile ring.

As discussed in Chapter 24, the conversion of megakaryocyte cytoplasm into platelets has been studied predominantly *in vitro* using cultured murine megakaryocytes. This process begins with the generation of large pseudopod-like structures from one pole of the megakaryocyte that elongate, in a microtubule-driven process, into long thin branching tubular projections termed proplatelets, which are themselves comprised of tandem arrays of platelet-sized swellings connected by thin cytoplasmic bridges.[7] When this process was observed *in vivo* in mouse skull bone marrow using multiphoton intravital microscopy, megakaryocytes were observed to extend cellular processes, either pseudopodia or immature proplatelets, into bone marrow sinusoids.[8] This implies that intravascular shear forces may help to separate proplatelets from the megakaryocytes and that proplatelet morphogenesis into platelets occurs in the peripheral blood.

The primary humoral regulator of megakaryocyte proliferation and differentiation is thrombopoietin (TPO), a 331-amino acid homologue of erythropoietin and a member of the four-helix bundle family of cytokines[3] (see Chapter 25). TPO is synthesized predominantly by the liver, but constitutive TPO mRNA expression can be detected in kidney, smooth muscle cells, and other tissues as well. Moreover, TPO mRNA transcription can be induced in bone marrow stromal cells by substantial degrees of thrombocytopenia, and transcription in the liver can be enhanced by the inflammatory response mediator IL-6, perhaps accounting for the reactive thrombocytosis that often accompanies inflammatory states. However, absence of TPO or its receptor (see below) does not preclude platelet production, and platelet counts remain approximately 10% of normal following their genetic elimination in mice. This suggests that other hematopoietic cytokines also support platelet production. Although IL-3, IL-6, and IL-11 stimulate megakaryocyte colony formation *in vitro*, crossing TPO-receptor null mice with mice null for signaling by these cytokines does not eliminate basal thrombopoiesis. On the other hand, the chemokine SDF-1 synergizes with TPO to support megakaryopoiesis, suggesting that it may support at least a portion of basal platelet production.

The receptor for TPO on megakaryocytes and platelets is c-Mpl, the protooncogene of the murine myeloproliferative leukemia virus and a member of the type 1 hematopoietic cytokine receptor family.[3,4] c-Mpl is also present on hematopoietic stem cells that require TPO stimulation for maintenance and expansion. The *c-Mpl* gene encodes a 610-amino acid protein that resides on cell surfaces as a constitutive homodimer. TPO binding to the homodimer extracellular domain is thought to induce a conformational change in the homodimer that enables autophosphorylation and activation of JAK family kinases (JAK2 and TYK2) associated with its cytoplasmic domains. In addition to phosphorylating the c-Mpl cytoplasmic domains

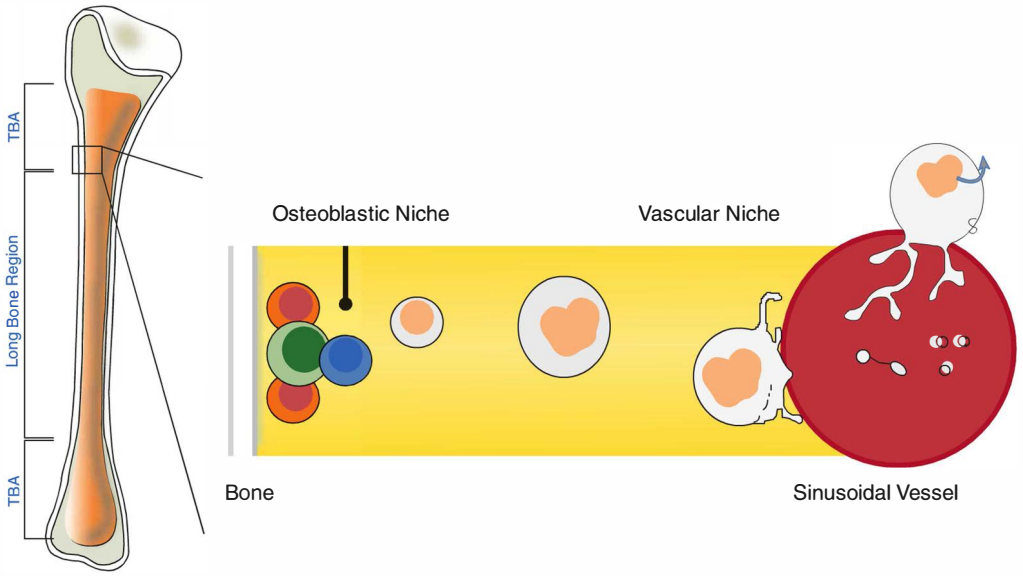

FIGURE 22.1 Diagrammatic representation of megakaryocyte production and platelet production. Hematopoietic stem cells located in the osteoblastic niche next to the endosteal bone surface migrate to the center of the marrow cavity where they undergo successive cycles of endomitosis to produce polyploidy megakaryocytes. Mature megakaryocytes then extend proplatelet elongations into marrow sinusoidal blood vessels where the proplatelets are released and ultimately release individual platelets. (Adapted from Thon JN, Italiano JE. Platelet formation. *Semin Hematol* 2010;47: 220–226, with permission.)

themselves, thereby providing binding sites for signaling molecules, activated JAK phosphorylates a number of signaling molecules that promote cell survival and proliferation, including members of the signal transducer and activator of transcription (STAT 1, 3, and 5), MAPK, and phosphotidylinositol-3 kinase pathways, as well as proteins that limit cell signaling including the phosphatases SHP1 and SHIP1 and members of the suppressors of cytokine signaling (SOCS) family. There are also a small of number of copies of c-Mpl expressed on the platelet surface (25 to 100 per platelet). Although TPO binding to platelet c-Mpl does not by itself result in platelet activation, it does prime platelets for activation by the classical platelet agonist, perhaps enhancing platelet reactivity in the presence of thrombocytopenia. On the other hand, TPO binding to c-Mpl on platelets and megakaryocytes is thought to play an important role in regulating the concentration of TPO in plasma. TPO adsorbed to the platelet surface is internalized and metabolized. Thus, in the presence of thrombocytopenia, the TPO concentration in plasma increases, stimulating megakaryocyte proliferation; conversely, the TPO concentrations decrease in the presence of thrombocytosis because of an increase in platelet-mediated clearance.[9] The low TPO concentrations observed in autoimmune thrombocytopenia has been attributed to increased TPO clearance by the hyperplastic megakaryocytes seen in this disorder.[10]

ELEMENTS OF PLATELET FUNCTION

Platelet Adhesion

Platelets circulate for 7 to 10 days in a nonreactive state in humans until they are needed for hemostasis. The nonreactive state of circulating platelets is maintained, at least in part, by the inhibitory effect of nitric oxide and prostacyclin secreted by endothelial cells, which increase the platelet content of cyclic AMP (cAMP) and cyclic GMP (cGMP), respectively,[11] by the ability of the endothelial cell ecto-ADPase CD39 to metabolize ambient plasma adenosine diphosphate (ADP),[12] through the inhibitory effect of platelet proteins such as PECAM-1,[13,14] and because the negative surface charge of circulating platelets inhibits their interaction with each other and with erythrocytes, leukocytes, and the vascular endothelium. Further, the intact endothelium presents a barrier separating platelets from adhesive substrates in the subendothelial connective tissue matrix. Disruption of the endothelial barrier by trauma, or by a disease such as atherosclerosis, allows platelets to come in contact with and adhere to the subendothelial matrix.

At the low shear rates present in the venous circulation, the integrins $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$ can mediate the binding of unactivated platelets to the subendothelial matrix components collagen, fibronectin, and laminin, respectively, at least *in vitro*.[15] However, as discussed in Chapters 28 and 29, at the higher shear rates present in arteries, arterioles, and the microcirculation, efficient platelet adhesion requires the additional presence of subendothelial von Willebrand factor (vWF).[16,17] vWF is an elongated multimeric glycoprotein synthesized by endothelial cells and megakaryocytes that binds to the GPIb-IX-V complex on unactivated platelets and to the integrin $\alpha_{IIb}\beta_3$ on activated platelets.[18] Although vWF is present in plasma, it is normally not present on the platelet surface. However, exposing vWF *in vitro* to the antibiotic ristocetin or to the snake venom protein botrocetin induces vWF binding to GPIb-IX-V.[19,20] As discussed in Chapter 26A, the factors that enable platelets to

adhere to vWF *in vivo* are likely shear stress-induced changes in the conformations of vWF, GPIb-IX-V, or both and/or changes in the conformation of vWF that occur when it is incorporated into the subendothelium.[21,22] Regardless, the bonds between vWF and GPIb-IX-V are characterized by rapid on and off rates so that platelets tend to translocate along, rather than firmly adhere to, vWF-coated surfaces.[23,24] This reduces platelet velocity, facilitating subsequent adhesion and activation events that would otherwise not occur under high-flow velocity conditions.

Collagen is not only a substrate for platelet adhesion, but it is a binding site for vWF in the subendothelium and an agonist for platelet aggregation and secretion, as discussed in Chapters 28 and 30. Although a number of platelet proteins have been found to interact with collagen, only two, the immunoglobulin superfamily member glycoprotein VI (GPVI)[25] and the integrin $\alpha_2\beta_1$ (also known as GPIa-IIa),[26] are physiologic platelet receptors for collagen. As currently understood, the relatively low affinity interaction of GPVI with collagen, mediated by the more distal of its two extracellular Ig-C2–like domains[27] and glycine-proline-hydroxyproline triplets in collagen,[28] initiates a signal transduction activation pathway via the Fc receptor γ chain noncovalently associated with GPVI.[29] This eventually results in the activation of phospholipase Cγ2 and the hydrolysis of the relatively scarce membrane phospholipid phosphatidylinositol 4,5-bisphosphate into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3) to activate protein kinase C (PKC) and increase the intracellular concentration of Ca^{2+}, respectively.[30] In turn, the latter increase the affinity of α2β1 for glycine-x-hydroxyproline-glycine-glutamic acid-arginine (GxOGER) motifs, enabling activated platelets to adhere firmly to collagen.[31,32]

Platelet Aggregation

Following adhesion, platelets aggregate to form hemostatic plugs or platelet-rich thrombi. In contrast to platelet adhesion, platelet aggregation is an active metabolic process in which agonist binding to specific membrane receptors initiates signaling pathways that enable the integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) to bind soluble macromolecular ligands such as fibrinogen or vWF.[33] The fibrinogen and/or vWF bound to $\alpha_{IIb}\beta_3$ then crosslinks platelets into a hemostatic plug or thrombus. The events responsible for platelet aggregation are summarized in Chapters 26B and 31.

$\alpha_{IIb}\beta_3$, the platelet structure directly responsible for platelet aggregation, is a calcium-dependent, noncovalent heterodimer composed of two type I transmembrane glycoproteins, α_{IIb} and β_3.[33] Each glycoprotein contains a large extracellular domain, a single transmembrane domain, and a short cytoplasmic domain that can interact with a variety of cytoskeletal and signaling proteins.[34] There are approximately 80,000 copies of $\alpha_{IIb}\beta_3$ per platelet, making it the most densely expressed platelet membrane protein.[35] Based on the estimated platelet surface area, $\alpha_{IIb}\beta_3$ molecules are spaced <200 Å apart. Rare congenital deficiency or dysfunction of $\alpha_{IIb}\beta_3$ produces the autosomal recessive bleeding disorder Glanzmann thrombasthenia (GT).[36] Patients with GT usually present in infancy with mucocutaneous bleeding that can be severe.

Crystal structures for the extracellular domains of $\alpha_{IIb}\beta_3$ and the related integrin $\alpha_v\beta_3$ indicated that these domains are bent over on themselves when the integrins are inactive; accompanying electron microscope images suggested that the molecules are extended when the integrins are active.[37–39] Ligand binding to $\alpha_{IIb}\beta_3$ requires that its extracellular domain shifts from a closed low-affinity to an open high-affinity conformation, the end result of a concerted "switchblade-like" rearrangement of the entire heterodimer that begins with separation of the cytoplasmic and transmembrane domains.[38] The resting conformation of $\alpha_{IIb}\beta_3$ appears to be maintained by an extended interface involving portions of its cytoplasmic, transmembrane, and extracellular stalk domains.[40] $\alpha_{IIb}\beta_3$ activation occurs when this interface is disrupted by binding of the cytoskeletal proteins talin and kindlin-3 to the β_3 cytoplasmic domain.[41] In turn, this causes transmembrane and stalk domain separation and the exposure of ligand-binding sites on the $\alpha_{IIb}\beta_3$ extracellular domain (FIGURE 22.2).

The major $\alpha_{IIb}\beta_3$ ligand is fibrinogen.[33] Fibrinogen is composed of pairs of Aα, Bβ, and γ chains folded into three nodular domains. Although peptides corresponding to the carboxyl terminal 10 to 15 amino acids of the γ chain or containing the arginine-glycine-aspartic acid (RGD) motif present at two places in the α chain can inhibit fibrinogen binding to $\alpha_{IIb}\beta_3$, fibrinogen binding is mediated by the γ chain sequences.[42,43] Nevertheless, clinical studies confirm that RGD-containing peptides inhibit $\alpha_{IIb}\beta_3$ function.[44] Based on the three-dimensional structure of fibrinogen, the ability of RGD-based peptides and peptidomimetics to inhibit $\alpha_{IIb}\beta_3$ function would seem paradoxical, but crystal structures of RGD and γ chain peptides bound to $\alpha_{IIb}\beta_3$ revealed that the RGD and γchain–binding sites on $\alpha_{IIb}\beta_3$ overlap.[45]

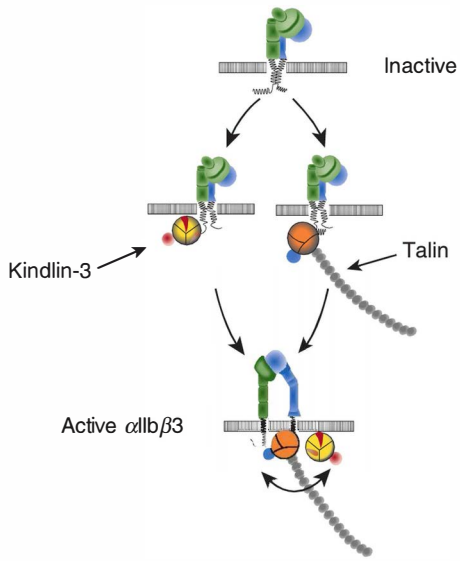

FIGURE 22.2 Activation of $\alpha_{IIb}\beta_3$ by talin and kindlin. Cartoon illustrating that both talin and kindlin-3 must bind to the β_3 cytosolic domain to cause $\alpha_{IIb}\beta_3$ activation by inside-out signaling. Whether there is a preferred sequence of protein binding to β_3 remains to be determined. (Adapted from Moser M, Legate KR, Zent R, et al. The tail of integrins, talin, and kindlins. *Science* 2009;324:895–899, with permission.)

Platelet Agonists

Agonist-stimulated platelet activation is required to enable binding of soluble ligands to $\alpha_{IIb}\beta_3$. As discussed in Chapter 33, the receptors responsible for platelet activation by the classical platelet agonists have all been identified. The serine protease thrombin is the most potent platelet agonist. Human platelets contain two signaling receptors for thrombin, PAR1, and PAR4.[46,47] Although PAR1 and PAR4 are members of the large family of GTP-binding protein (G-protein)–coupled seven transmembrane domain receptors, they are unique in that they are activated when thrombin cleaves their amino-termini to expose new termini that act as tethered intramolecular ligands.[48,49] Tethered ligand binding, in turn, activates the G-proteins G_q, $G_{12/13}$, and G_i to stimulate phospholipase Cβ2 activity, increase cytosolic calcium, induce platelet shape change, and inhibit platelet adenylyl cyclase. Since higher thrombin concentrations are required to cleave PAR4 than PAR1, it is likely that PAR1 is the predominant receptor for thrombin at the low thrombin concentrations needed to activate platelets, but once activated, PAR4 signaling is more prolonged than PAR1.[50,51]

ADP, the first platelet agonist to be identified, is secreted by stimulated platelets from storage sites in platelet-dense granules and may be released from damaged tissue and red cells. There are at least three platelet receptors for ADP.[52] The first, $P2X_1$, is an ATP-gated nonselective Ca^{2+} channel whose physiologic function in platelets is unclear, although $P2X_1$ stimulation by ATP *in vitro* can amplify the platelet response to low concentrations of other agonists.[53] The other two receptors are G-protein–coupled seven transmembrane domain proteins. ADP binding to $P2Y_1$ activates phospholipase Cβ via the G-protein G_q and induces platelet shape change, perhaps via the G-protein $G_{12/13}$.[52,54] ADP binding to $P2Y_{12}$ inhibits platelet adenylyl cyclase via the G-protein G_i.[52] $P2Y_{12}$ is the pharmacologic target for clopidogrel and other thienopyridines.[52] Simultaneous stimulation of both $P2Y_1$ and $P2Y_{12}$ is required to induce platelet aggregation.[54,55] Moreover, because antagonism of either the G_q- or G_i-coupled ADP receptor can be overcome by stimulating another platelet receptor coupled to G_q or G_i, respectively, it appears that signals emanating each G-protein are needed to activate $\alpha_{IIb}\beta_3$.[56]

Agonist-stimulated platelets synthesize prostaglandins from arachidonic acid released from membrane phospholipids by the enzyme phospholipase A_2[57] (see Chapter 34). The released arachidonic acid is then converted by the enzyme prostaglandin endoperoxide H synthase-1 (cyclooxygenase-1) to the prostaglandin endoperoxide intermediates PGG_2 and PGH_2 and subsequently to TXA_2 by the enzyme thromboxane synthase.[58] The endoperoxide intermediates and TXA_2 exit from the platelet and function as platelet agonists and vasoconstrictors by binding to the G_q-coupled thromboxane receptor TP.[59] Two TP isoforms (α and β) result from alternative splicing of the TP mRNA transcript, but only TPα protein has been detected in human platelets.[60] Inhibition of TXA_2-stimulated platelet aggregation by a $P2Y_{12}$ antagonist indicates that like thrombin and ADP, concurrent stimulation of a G_i-coupled receptor is required to complement TP-mediated activation of G_q in order to induce platelet aggregation.

Epinephrine stimulates platelets by binding to a_2A-adrenergic receptors that are coupled to the G-protein G_i and acts in synergy with agonists like thrombin and ADP to induce platelet aggregation.[61] Platelets also express G_q-coupled receptors for serotonin ($5\text{-}HT_{2A}$),[62] vasopressin (V_1),[63] and platelet-activating factor (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, PAF-acether).[64] The latter is a lipid synthesized by a variety of cells, including neutrophils, eosinophils, monocytes, platelets, endothelial cells, and mast cells, and activates platelets at nanomolar concentrations.

In contrast to the platelet stimulatory effect of hydrolyzing platelet membrane phosphatidylinositol 4,5 bisphosphate, increasing platelet concentration of cAMP and cGMP inhibits most aspects of platelet function.[65] cAMP is synthesized by a membrane-associated enzyme complex, adenylyl cyclase, which converts ATP to cAMP. cAMP increases result from stimulation of adenylyl cyclase by prostaglandins such as PGD_2, PGE_1, and PGI_2 (prostacyclin) or by low concentrations of adenosine, as well as by inhibition of the phosphodiesterases responsible for cAMP degradation.[66] cGMP synthesis results from stimulation of platelet guanylyl cyclase by nitric oxide.[67] Whereas stimulating adenylyl or guanylyl cyclase inhibits $\alpha_{IIb}\beta_3$ function, inhibiting these enzymes by stimulating agonist receptors coupled to G_i does not cause $\alpha_{IIb}\beta_3$ activation.[68] Nonetheless, stimulating these receptors does prevent the increased cAMP synthesis stimulated by PGD_2, PGE_1, and PGI_2.

There is limited understanding of the biochemical pathway coupling agonist stimulation to $\alpha_{IIb}\beta_3$ activation. It is known that increases in cytosolic free calcium, PKC activation, and the active form of the diacylglycerol-regulated guanine nucleotide exchange factor I (CalDAG-GEFI) activate the small GTPase Rap1.[69–71] By interacting with an effector scaffold, Rap1-GTP-interacting adaptor molecule or RIAM, activated Rap1 directs RIAM-bound talin to the plasma membrane where it can bind to β integrin cytoplasmic tails, causing integrin activation.[72–74] Whether this is the only, or even the predominant, pathway for $\alpha_{IIb}\beta_3$ activation in platelets is not known. Although the Rap1-RIAM-talin complex reconstitutes $\alpha_{IIb}\beta_3$ activation in transfected CHO cells, deletion of Rap1b from murine platelets attenuated, but did not eliminate, agonist-stimulated platelet aggregation and fibrinogen binding to $\alpha_{IIb}\beta_3$,[75] implying that other pathways are present to couple agonist stimulation to $\alpha_{IIb}\beta_3$ activation.

Platelet Secretion

The platelet cytoplasm contains four types of granules: three to eight dense (δ) granules containing ADP, ATP, calcium, serotonin, and polyphosphate; approximately 50 α-granules containing a variety of proteins, some derived from the plasma such as fibrinogen, vWF, factor V, albumin, and IgG and others synthesized by the megakaryocyte such as platelet factor 4, β-thromboglobulin, platelet-derived growth factor (PDGF), and thrombospondin; lysosomes containing acid hydrolases; and microperoxisomes containing a peroxidase activity. δ-Granule ADP is thought to be involved in propagating the primary platelet response, α-granule PDGF in wound repair, and α-granule factor V in thrombin generation. The function of other α and δ-granule substances is unclear, since many are already present at high concentration in plasma. Nevertheless, platelet secretion disorders are a frequent cause of a mild- to-moderate bleeding, implying that platelet secretion plays a role in supporting normal hemostasis.

The contents of these granules are extruded following platelet stimulation, a process known as platelet secretion. The α-granule membrane also contains many of the same proteins as the platelet plasma membrane ($\alpha_{IIb}\beta_3$ and GPIb-IX-V), as well as others specific for α-granules (P-selectin and osteonectin). Each α-granule membrane protein can be translocated to the platelet surface during secretion. Secretion stimulated by weak agonists such as ADP and epinephrine requires platelet aggregation, the synthesis of prostaglandin endoperoxides and thromboxane A_2, and is prevented by inhibiting prostaglandin synthesis.[76] On the other hand, secretion stimulated by strong agonists such as thrombin and collagen can bypass the aggregation and prostaglandin requirements.

Platelets contain components of the secretory machinery similar to those found in neurons where granule secretion is governed in part by matching a vesicle SNARE (v-SNARE) with a target membrane SNARE (t-SNARE).[77,78] As discussed in detail in Chapter 32, platelets contain four v-SNARES (VAMPs 2, 3, 7, and 8), and studies using platelets from knockout mice suggest that VAMP-3, and in particular VAMP-8, are important for platelet secretion. Platelets also contain members of two t-SNARE families (syntaxins 2, 4, 7, 11 and SNAP 23, 25, 29). SNAP-23 is phosphorylated on serine residues after platelet stimulation and may be a link between platelet activation and granule membrane fusion. Similarly, there are data suggesting roles for syntaxins 4 and 2 in α-granule and lysosome secretion and in α-granule, δ-granule, and lysosome secretion, respectively. It is noteworthy that syntaxin 11 is mutated in familial hemophagocytic lymphohistiocytosis type 4, and platelets from FLH4 patients have impaired platelet secretion.[79] Platelets also contain a number of SNARE regulators, including members of the Munc18, Rab, Munc13, synaptotagmin, and tomosyn families, whose apparent roles in platelet secretion are to enhance the efficiency of SNARE-mediated exocytosis, primarily by interacting with syntaxins or syntaxin-containing complexes. Thus, substantial progress has been made in identifying the components of the platelet secretory mechanism, but how these components assemble to couple platelet stimulation to fusion of platelet granule and plasma membranes is not yet understood.

Platelet Procoagulant Activity

The plasma membrane of activated platelets provides a procoagulant surface for the assembly of the "tenase" and "prothrombinase" complexes that activate coagulation factor X and prothrombin, respectively, a result of the calcium-induced exposure of anionic phospholipids on the platelet surface[80] (see Chapter 35). The phospholipid composition of the platelet plasma membrane bilayer is asymmetric with phosphatidylcholine and sphingomyelin localized predominantly in the outer membrane leaflet and phosphatidylserine and phosphatidylethanolamine concentrated in the inner leaflet.[81] This asymmetry is established by two enzymatic activities: a "flippase" directing the inward transport of lipids[82] and a "floppase" that directs the transport of choline- and amino-phospholipids to the outer leaflet.[80] Following an agonist-stimulated rise in intraplatelet Ca^{2+}, membrane asymmetry is lost with exposure of anionic phospholipids on the platelet surface, as well as on the surface of shed platelet membrane vesicles or microparticles[83] (see Chapter 36). The Ca^{2+}-induced movement of phospholipids between membrane leaflets in platelets and other cells appears to be mediated by a membrane-associated phospholipid scramblase activity, an essential component of which is the protein TMEM16F.[84] It is noteworthy that when TMEM16F expression is knocked down in Ba/F3 cells, Ca^{2+} ionophore-stimulated anionic phospholipid exposure is decreased. Moreover, TMEM16F mutations have been identified in two patients with isolated congenital deficiency of platelet procoagulant activity (Scott syndrome), further supporting its role as a component of scramblase.[84,85]

PLATELET FUNCTION UNRELATED TO HEMOSTASIS

Although the most important function of platelets is to provide primary hemostasis, it is also becoming clear that platelets contribute to a number of processes in addition to hemostasis such as inflammation,[86] tissue regeneration,[87] host defense,[88,89] angiogenesis,[90] lymphatic development,[91] and tumor metastasis.[92] A role for platelets outside of hemostasis has been the topic of a number of recent reviews.[86,93,94,95]

Activated platelets express on their surface and secrete a variety of bioactive molecules that participate in the processes listed above[93] (Table 22.1). Platelet α-granule contents contain growth factors that support processes such as wound repair and immunomodulation including platelet-derived growth factors A, B, and C (PDGF A, B, C); vascular endothelial growth factor (VEGF); fibroblast growth factor (FGF); epithelial growth factor (EGF); connective tissue growth factor; hepatocyte growth factor; transforming growth factor β (TGFβ); and insulin-like growth factor-1. For example, PDGF is instrumental in initiating and regulating tissue wound repair and platelet α-granules are the largest source of TGFβ in the blood where it functions as an antiproliferative and immunosuppressive factor. The α-granule membrane also contains CD40 ligand (CD40L, CD154) that is translocated to the platelet surface following platelet activation,[86,96] where it either remains membrane bound or is cleaved from the platelet surface, primarily by MMP-2, as soluble CD40L (sCD40L).[97] In either case, it transmits the effect of platelet activation to CD40 expressed by endothelial cells, leukocytes, macrophages, dendritic cells, smooth muscle cells, fibroblasts, and keratinocytes, affecting fundamental process such as atherogenesis and innate and adaptive immunity.[98]

Besides functioning as a neurotransmitter, serotonin is a mitogen and modulates tissue remodeling.[99] In a mouse model of liver regeneration following partial hepatectomy, thrombocytopenia and impaired platelet function were associated with decreased liver cell proliferation, effects that were reversed by a serotonin receptor agonist.[87] Because the vast majority of serotonin in the blood is present in platelet δ-granules, partial hepatectomy was performed in tryptophan-hydroxylase 1–deficient mice whose platelets lack serotonin, resulting in a decrease in all markers of hepatocyte proliferation. Restoration of platelet δ-granule serotonin by infusing 5-hydroxytrytophan also restored the markers of hepatocyte proliferation, consistent with a role for platelet-derived serotonin in the initiation of liver regeneration.[87]

Platelet activation leads to the release of more than a dozen cytokines and chemokines from platelet granules including platelet factor 4 (PF4, CXCL4), CXCL7, and IL-1.[94] PF4 binds with high affinity to glycosaminoglycans (hence its designation

Table 22.1

Platelet-associated molecules with immune function

Molecule	Location within Platelet and Mechanism of Release	Activation State	Functions	Cellular Targets
Histamine	Synthesized, location unknown; released during platelet activation	Preformed	Promotes allergic type hypersensitivities	Endothelial cells, monocytes, PMNs, NK cells, T cells, B cells, eosinophils
Serotonin (also known as 5-HT)	Dense granules; released during platelet activation	Preformed	Actions on central nervous system; promotes coagulation and T-cell activation	Monocytes, macrophages, platelets
Thromboxane A2	Plasma membrane	Synthesized	Promotes inflammation and coagulation	Platelets, macrophages, T cells
PAF	Plasma membrane	Synthesized	Promotes inflammation	Platelets, PMNs, monocytes, macrophages
PDGF	α-Granules; released during platelet activation	Preformed	Promotes wound healing	Monocytes, macrophages, T cells
TGFβ	α-Granules; released during platelet activation	Preformed	Growth inhibition; immunosuppression	Monocytes, macrophages, T cells, B cells
CXCL7 (also known as NAP2)	Not known	Cleavage product of performed precursor	Chemokine	PMNs
CXCL4 (also known as PF4)	α-Granules; released during platelet activation	Preformed	Chemokine	PMNs, platelets
CXCL1 (also known as GROα)	α-Granules; released during platelet activation	Preformed	Chemokine	PMNs
CXCL5 (also known as ENA78)	α-Granules; released during platelet activation	Preformed	Chemokine	PMNs
CCL5 (also known as RANTES)	α-Granules; released during platelet activation	Preformed	Chemokine	Monocytes, eosinophils, basophils, NK cells, T cells, dendritic cells (DCs), platelets
CCL3 (also known as MIP1α)	α-Granules; released during platelet activation	Preformed	Chemokine	Monocytes, eosinophils, basophils, NK cells, DCs
CCL7 (also known as MCP3)	Not known	Preformed	Chemokine	Monocytes, basophils, NK cells, DCs
IL-1β (and IL-1 precursor protein)	Not known	Synthesized	T-cell activation; multiple effects	Monocytes, macrophages, DCs, T cells
HMGB1	Not known	Preformed	Inflammatory gene regulation	Macrophages, PMNs, endothelial cells
Thrombocidins 1 and 2	α-Granules; released during platelet activation	Preformed	Antibacterial peptides	Bacterial cells
CD40	Plasma membrane	Preformed	Costimulation; endothelial interactions	T cells

Table 22.1

Platelet-associated molecules with immune function *(Continued)*

Molecule	Location within Platelet and Mechanism of Release	Activation State	Functions	Cellular Targets
CD154	α-Granules and plasma membrane; released and cleaved	Preformed	Costimulation; endothelial interactions	B cells, DCs, macrophages, monocytes, endothelial cells
TLR1, TLR2, TLR3, TLR5, TLR6, TLR7	Plasma membrane	Preformed	Pathogen detection	PMNs, DCs, macrophages, monocytes, platelets
TLR4	Plasma membrane	Preformed	Pathogen detection	PMNs, DCs, macrophages, monocytes
TLR9	Unknown internal site; upregulated on plasma membrane during platelet activation	Preformed	Pathogen detection	PMNs, DCs, macrophages, monocytes
TREM1 ligand	Plasma membrane; expression increased during platelet activation	Preformed	Pathogen detection	PMNs, DCs, macrophages, monocytes

as platelet antiheparin factor), as well as to a chemokine receptor CXCR3.[100,101] Although the physiologic function of PF4 is not known with certainty since it has both pro- and anti-inflammatory and both pro- and antiproliferation activities, it has been reported to be a negative autocrine regulator of megakaryopoiesis *in vivo*[102] and to impair T-cell proliferation and cytokine release and inhibit the angiogenic activity of endothelial cells in *in vitro* experiments. CXCL7 is derived from the proteolysis of pre-platelet basic protein into platelet basic protein, connective tissue–activating protein III, β-thromboglobulin, and CXCL7 (neutrophil-activating peptide 2).[94] By binding to CXCR1 and CXCR2, CXCL7 induces neutrophil adhesion and migration. IL-1 is noteworthy because platelet stimulation has been reported to induce splicing of IL-1β precursor mRNA present into platelets to IL-1β mRNA, which is then used as a template for IL-1β synthesis.[103] The synthesized IL-1β is then packaged into microparticles. Platelet microparticles have been detected in the joint fluid of patients with rheumatoid and other forms of inflammatory arthritis where the IL-1 they contain was thought to be proinflammatory, eliciting cytokine responses from synovial fibroblasts.[104]

Platelets have been found to express the pattern recognition Toll-like receptors 1 to 9 (TLRs), implying that platelets participate in innate immune responses.[93] TLR4 is a binding site for bacterial lipopolysaccharide (LPS), and LPS-induced thrombocytopenia has been attributed to LPS binding to TLR4.[105] Moreover, platelets contain all of the components of the LPS-signaling complex (TLR4, CD14, MD2, and MYD88), which may explain the ability of LPS to cause platelet activation.[106] In addition, LPS binding to TLR4 induces platelet binding to adherent neutrophils, neutrophil activation, and the release of intravascular webs of histone-containing DNA (neutrophil extracellular TRAPs, NETs) in liver sinusoids and pulmonary capillaries that have the capacity to trap circulating bacteria.[107] TLR2 is a natural ligand for lipoteichoic acid, a major constituent of the cell wall of gram-positive bacteria, but mixed and often contradictory effects of this interaction on platelet function have been reported.[89,108]

Thrombocytopenia has been associated with poorer outcomes in patients infected with malaria.[109] Because platelets bind to erythrocytes infected with malarial parasites via CD36,[110] it has been postulated that platelets can either positively or negatively affect the course of malaria. Platelets have been found to kill intraerythrocytic malarial parasites and have a favorable effect on survival after infection, an effect that appears to be reversed by aspirin treatment.[109, 111] Nonetheless, the effect of platelets is not straightforward since PF4 secreted by platelets has been reported to promote the development of experimental cerebral malaria by enhancing KLF4-dependent cytokine production by monocytes; in this case, the deleterious effects of platelets were reduced by platelet depletion or aspirin treatment.[112,113]

Besides directly supporting the integrity of the vasculature,[114] platelets participate in various aspects of vascular development. For example, platelets contribute to lymphatic vascular development by interacting with lymphatic endothelial cells through the C-type lectin-like receptor 2 (CLEC-2) and a platelet-signaling pathway that includes the Syk pathway–signaling component SLP-76.[91] Platelets have also been found to contribute to the postnatal occlusion of the ductus arteriosus, at least in newborn mice, by promoting its thrombotic occlusion and subsequent luminal remodeling.[115] New vessel development or angiogenesis can be either promoted (VEGF, bFGF, EGF, PDGF, and various matrix metalloproteinases [MMP]) or inhibited (endostatin, PF4, thrombospondin-1, α2-macroglobulin, PAI-1, and angiostatin) by factors present in platelet α-granules. Recent evidence suggests that pro- and antiangiogenic factors are segregated into separate α-granule populations that are also differentially secreted in response to platelet agonists.[116] Thus, proangiogenic

factors are secreted in response to platelet PAR1-selective agonists, whereas antiangiogenic factors are secreted in response to PAR4-selective agonists, suggesting a mechanism by which platelets can either stimulate or inhibit angiogenesis.

In addition to affecting the growth of tumors by either promoting or inhibiting tumor angiogenesis depending on microenvironmental circumstances, a number of mouse models suggest that platelets also play a role in tumor cell metastasis.[92] Thus, heteroaggregates of platelets and tumor cells or platelets, leukocytes, and tumor cells may protect circulating tumor cells from destruction by natural killer (NK) cells, may facilitate either transient or stable adhesion of tumor cells to vascular endothelium, and may modulate the extravasation of tumor cells out of the blood stream into target organs, either directly or by increasing vascular permeability. Despite the elegance of many of these models of tumor metastasis, they are by necessity contrived to greater and lesser extents. Thus, whether platelets play an important role in tumor metastasis in humans and whether intervention with antiplatelet therapy can be clinically beneficial will require continued investigation.

Platelet Production: Cellular and Molecular Regulation

ELISABETH CRAMER BORDÉ AND WILLIAM VAINCHENKER

Platelets are derived from the fragmentation of the cytoplasm of giant bone marrow cells, the megakaryocytes (MKs). MKs are the largest cells of the marrow, up to 50 μm in diameter, and are characterized by a single polylobulated nucleus. They constitute <0.05% of marrow cells. MKs arise and mature in the bone marrow, along with the precursors of other blood cells. Immature MKs are located near the osteoblastic niche and migrate to the subenthothelium of venous sinusoids during maturation (FIGURE 23.1). Given a normal platelet count (150 to 400 $\times$ 10^9/L) and platelet life time (8 to 10 days in humans), an average of 10^{11} platelets are produced every day to maintain the blood platelet level.

MKs are unique cells that display a single polyploid nucleus and grow by undergoing a unique phenomenon called endomitosis during which the nucleus increases its deoxyribonucleic acid (DNA) content without dividing. Following polyploidization, the cytoplasmic mass of MK increases roughly proportionally to the ploidy status. After achieving full maturation, the MK cytosol is filled with a network of membranes formed by invagination of the plasma membrane, is loaded with secretory granules, and is ready to deliver a myriad of newly formed platelets. Platelets detach from cytoplasmic MK protrusions called proplatelets that extend into the lumen of bone marrow sinusoids and are shed into the peripheral blood from the tips of the extensions. Study of MKs is difficult because of their low numbers in the bone marrow, but scientific advances and techniques such as intravital imaging have aided our understanding of MK maturation and platelet formation. The development of *in vitro* MK culture systems, allowing the preparation of pure MK populations and the identification of specific and early markers permitting the immunologic detection of MK and their precursors, have made the study of MK feasible. Finally, the identification, purification, and cloning of thrombopoietin (TPO), the major regulator of platelet production, and the availability of recombinant TPO for experimental purposes have facilitated the preparation of large enriched MK populations.

This chapter focuses on the cellular and molecular aspects of MK differentiation and its regulation in humans. Descriptions of relevant animal models are presented as well. TPO and its receptor MPL-R are discussed in detail in Chapter 25 and details of platelet maturation are provided in Chapter 24.

MEGAKARYOCYTE DIFFERENTIATION

The Megakaryocytic Cell

Platelet production ultimately results from the differentiation of a multipotent hematopoietic stem cell (HSC) into MK. HSCs are the only long-lived cells of the hematopoietic system and are capable of regenerating all the hematopoietic tissue by virtue of their self-renewal capability. When HSCs commit to MK differentiation, they lose self-renewal capability and multipotency. Committed cells are called hematopoietic progenitors. The loss of multipotency occurs through precise developmental stages. In a first step, the HSC gives rise to a common myeloid progenitor and a common lymphoid progenitor. The common myeloid progenitors subsequently commit toward specific lineages. The erythroid and MK lineages derive from a common progenitor called either MK/erythrocyte bipotent progenitor (MEP) or BFU-E/MK.[1] This bipotent progenitor has been characterized in mice and humans and gives rise to colonies containing mostly erythroblasts and a few MKs. The phenotype of this progenitor has been clearly assessed in the mouse,[2] whereas in human, its purification is more preliminary.

At a subsequent developmental stage, the MEP is only committed toward the MK lineage and its following differentiation stages can be divided into three developmental steps. The MK progenitor cell is capable of proliferation, giving rise *in vitro* to MK colonies. It further differentiates, through a variable number of mitosis, to a transitional cell (promegakaryoblast [PMKB]) that enters an endomitotic process with an average of three DNA cycles of duplication (modal ploidy of 16N). These cells correspond to MK that have begun to synthesize the main platelet proteins and are morphologically identifiable. Cytoplasmic maturation subsequently accelerates to yield a typical MK. Finally, the mature MK sheds platelets in the circulation outside the marrow itself.

Megakaryocytic Progenitors

In the hematopoietic hierarchy, MK progenitors derive from a common MEP, but the MK lineage begins with the appearance of committed MK progenitors. These were first defined by their proliferative capacities in several clonal assays, allowing the identification of three main types of MK progenitors according to colony size and the time required for colonies to develop.[3] More recently, immunologic phenotyping has been used for more precise delineation of MK progenitor compartments and better understanding of megakaryopoiesis, especially at the molecular level.

BFU-MK. These are the most primitive MK-committed progenitors, producing colonies composed of more than 50 cells organized into subcolonies. BFU-MK follow the same pattern as BFU-E–derived colonies. They mature in 12 days in mice[4] and in 21 days in humans.[5]

CFU-MK. These cells differ from the BFU-MK by a lower capacity for proliferation. They give rise to colonies containing 3 to 50 cells in 5 days in mice[6] and in 12 days in humans.[7] Unlike BFU-MK that are in the G0/G1 phase of the cell cycle, CFU-MK are in an active cell cycle.

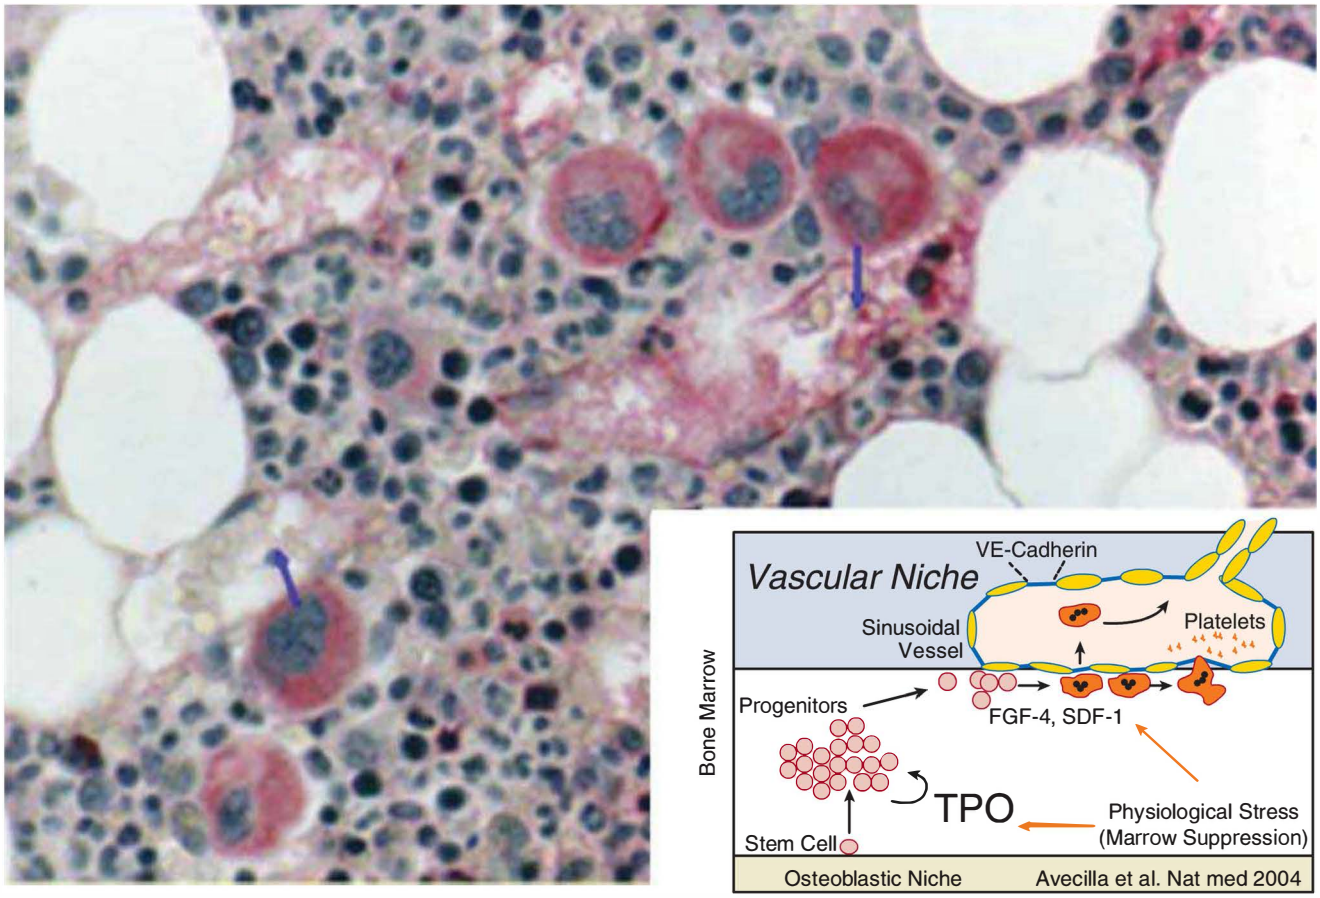

FIGURE 23.1 Normal human bone marrow biopsy immunostained for fibrinogen. Labeling detects blood vessels and MKs. MKs are frequently located along a vascular sinusoid (*V*) depicting the vascular niche. Fibrinogen displays a centrifugal staining pattern typical of an α-granule protein. The staining intensity is weak in the small immature MKs (*arrow*) and it is maximal in large, mature MKs (*arrowheads*). (Adapted from de Larouziere et al. Inverse immunostaining pattern for synthesized versus endocytosed alpha-granule proteins in human bone marrow megakaryocytes. *Br J Haematol* 1998;101:618–625, with permission.) **Inset:** Location of MK in vascular niche. (Adapted from Avecilla et al. Chemokine-mediated interaction of hematopoietic progenitors with the bone marrow vascular niche is required for thrombopoiesis. *Nat Med* 2004;10:64–71, with permission.)

Late progenitors. In the mouse, these are MK progenitors with a density of <1.050 mg/mL. In 2 to 3 days, they give rise to colonies composed of a few MK with high ploidy.[8] The developmental stage of these progenitors is extremely close to that of the transitional cell that has switched toward an endomitotic process.

Megakaryocyte Diploid Precursors

The size of diploid precursors is that of a small lymphocyte and they have no characteristic morphologic features. Thus, their identification depends on the presence of specific immunologic markers.[9] Electron microscopy is also a sensitive tool for the cytochemical detection of platelet peroxidase.[10]

Classification of megakaryocyte maturation stages. MK differentiation is a continuous process, but for the sake of clarity it has been classified into three distinct maturation stages (FIGURE 23.2).[11] Megakaryocytic differentiation becomes morphologically identifiable because cell size increases after nuclear ploidy becomes a multiple of 2N. On panoptic staining, the type I or immature MKs (FIGURE 23.2A) have a basophilic cytoplasm and can be distinguished by a large polyploid nucleus, frequent cytoplasm blebs, and relatively large cell volume (i.e., >14 μm in diameter). At this stage, no further cell division occurs and the cells only undergo endomitosis. The nuclear to cytoplasm ratio (N/C) is high, chromatin thin, and cytoplasm basophilic without azurophilic granules. Type II MKs of intermediate maturation (FIGURE 23.2B) are larger (i.e., 15 to 40 μm), with a polylobulated nucleus and a deep blue cytoplasm. The intense basophilia coincides with high RNA content, a large number of free ribosomes, and a well-developed rough endoplasmic reticulum (ER), indicative of active protein synthesis. In some, an azurophilic area is visible near the cell center where granule formation begins. As the cell matures, the N/C ratio decreases while the amount of cytoplasm dramatically increases and becomes azurophilic, the nuclear lobes become more distinct, and the chromatin condenses. The mature MK type III (FIGURE 23.2C) has a low N/C ratio. The nucleus is dark purple, with a dense chromatin texture and clearly distinct nuclear lobes. The cytoplasm is vast, uniformly granular, and azurophilic. At this stage, the MK is ready to fragment and liberate platelets. It has been estimated that each MK can produce 400 to 8,000 platelets.[12]

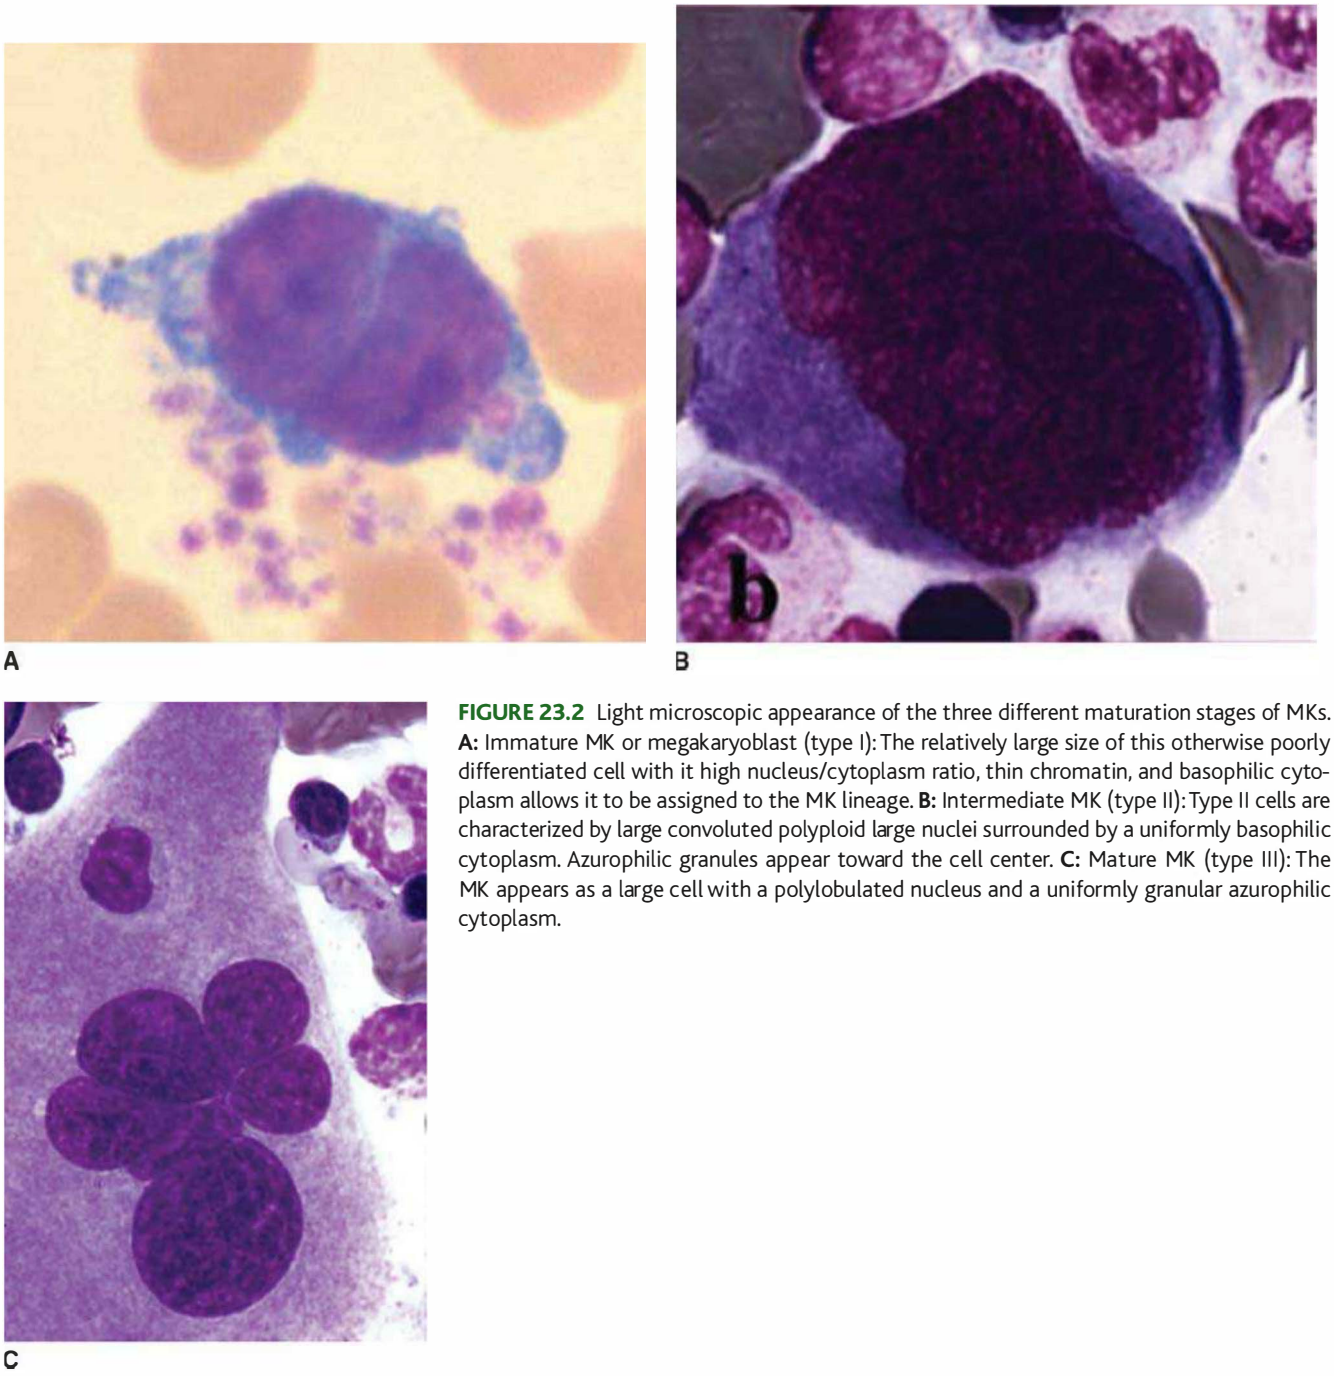

FIGURE 23.2 Light microscopic appearance of the three different maturation stages of MKs. **A:** Immature MK or megakaryoblast (type I): The relatively large size of this otherwise poorly differentiated cell with it high nucleus/cytoplasm ratio, thin chromatin, and basophilic cytoplasm allows it to be assigned to the MK lineage. **B:** Intermediate MK (type II): Type II cells are characterized by large convoluted polyploid large nuclei surrounded by a uniformly basophilic cytoplasm. Azurophilic granules appear toward the cell center. **C:** Mature MK (type III): The MK appears as a large cell with a polylobulated nucleus and a uniformly granular azurophilic cytoplasm.

ULTRASTRUCTURE OF MK DIFFERENTIATION

MK differentiation is characterized by structural changes that are easily observed under the electron microscope. Immunoelectron microscopy, in particular immunogold labeling, is a sensitive tool that has greatly contributed to the description of this process.

Demarcation membrane system. During the maturation process, the demarcation membrane system (DMS) develops as a network of smooth membrane channels located initially near the plasma membrane. These channels derive from multiple invaginations of the MK plasma membrane[13] (FIGURE 23.3). The demarcation membranes are always in contact with the extracellular medium, as demonstrated by the penetration of electron-dense extracellular tracers such as horseradish peroxidase. The DMS grows rapidly and becomes widespread within the whole cytoplasmic volume, expanding by more than 700% within 72 hours. Although some differences between the protein composition of the DMS and plasma membrane have been detected by freeze fracture studies,[14] the main platelet surface (glycoprotein [GP]) receptors are expressed equally on both.[15]

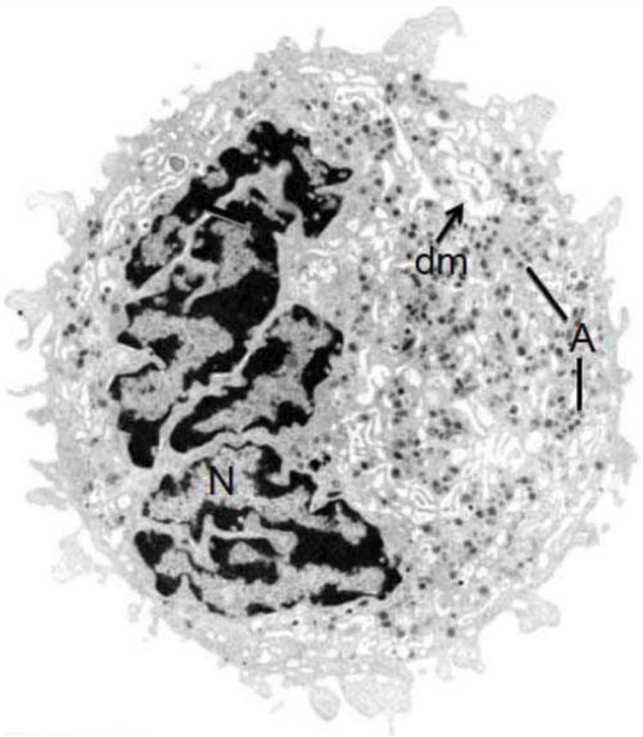

FIGURE 23.3 Electron micrograph of maturing MKs. Mature MKs are characterized by their large size and multilobed nucleus. The cells contain specific organelles (α-granules [*A*]) and a well-developed demarcation membrane system (*dm*) regularly scattered throughout the cytoplasm. (Magnification ×5,940.)

The DMS is the source of proplatelet membrane[16] and is the precursor of the membranes of future platelets (plasma membrane and surface connected canalicular system); the mechanism of platelet shedding is discussed in detail below.

Because mature MKs accumulate near marrow sinusoids and represent a potential physical barrier for other marrow cells migrating into the circulation, migrating cells are able to penetrate the open channels of the DMS and transmigrate across the MK volume. This natural phenomenon, termed "emperipolesis," is occasionally observed in normal bone marrow and is distinct from phagocytosis since the emigrating cell maintains its integrity.[17]

Golgi complexes and centrioles. Several Golgi complexes within a single MK follow the migration of several centrioles. The localization of centrioles within the cell is random, as are the Golgi complexes. The latter are found more frequently near the cell center in the perinuclear region. Their number appears to be roughly proportional to ploidy. Endogenously synthesized platelet granule proteins can be initially detected immunologically in the trans-Golgi network (TGN) where they undergo glycosylation, concentration, and precipitation. Granule proteins endocytosed from the extracellular medium are not detected in the TGN.[18] Membrane GPs also transit through the Golgi complex. It is noteworthy that immunolabeling of the GP Ib/IX/V complex is weak, whereas GPIIb/IIIa and P-selectin, major components of the α-granule membrane, are seen more prominently in the Golgi cisterns and arising vesicles.[19]

Endoplasmic reticulum. Rough ER and free ribosomes are abundant in immature MK. The smooth ER that derives from the rough ER after loss of ribosomes remains abundant until the end of the maturation process and is closely associated with the DMS. It contains a number of enzymes, including NADH–cytochrome *c* reductase, cyclooxygenase, thromboxane synthase, and Ca^{2+} Mg^{2+} adenosine triphosphatase. In humans, a peroxidase activity, the platelet peroxidase, is located in the ER and reflects the presence of cyclooxygenase, an early marker of the cell line. The ER gives rise to the platelet-dense tubular system containing the same cytochemical activity.[10] In rodents, acetylcholinesterase (AchE), a marker absent from mature human MK, is also specifically located in the ER.

Formation and packaging of cytosolic granules. Four different types of granules are formed during MK maturation: α-granules, dense granules, lysosomes, and peroxisomes. Their contents are detailed in Table 23.1; the following sections focus on their mechanism of formation.

α-Granules. α-Granules appear early during MK maturation, concurrent with the development of the DMS.[20] They are the more numerous granule population in the mature MK (FIGURE 23.3). α-Granules arise from the TGN, where a dark nucleoid is rapidly

Table 23.1

α-Granule proteins

Matrix	Membrane

visible within budding vesicles. α-Granules are unique organelles in that they acquire their protein contents by two distinct mechanisms: (a) MK biosynthesis[21] and (b) plasma protein endocytosis, either receptor mediated or through a fluid phase.[22,23] Endocytosis may continue in platelets.[24,25] The cytoplasmic markers are initially detected in a diffuse staining pattern when located in the cisterns of synthesis and later in a granular pattern when packaged in granules. Two types of information have been provided by immunolabeling α-granules proteins. First, endocytosed proteins (e.g., fibrinogen and immunoglobulins) appear later in the MK than endogenously synthesized proteins (e.g., von Willebrand factor [vWF]),[18] and their distribution patterns within the maturing MK cytoplasm are distinct. Endocytosed proteins are centrifugal and maximal at the cell periphery, whereas synthesized proteins are centripetal and predominant in the juxtanuclear area.[26] vWF multimers are apparent in the form of 20-nm tubular structures, first appearing in the TGN and then in the α-granules.[27] Stored proteins may not be uniformly distributed among α-granules. For example, angiogenic proteins seem to be selectively located in distinct granule populations according to their function, pro- and antiangiogenic, leading to differential release from platelets.[28] The α-granule membrane contains numerous receptors that appear during MK maturation: P-selectin (CD62P), GPIIb/IIIa, CD36, CD9, and PECAM1.[19,29] Some are detectable in the Golgi apparatus and appear to be transported directly to α-granules, but others appear to transit *via* the plasma membrane and to be internalized. Evidence based on intracellular trafficking suggests that the GPIIb/IIIa present in the α-granule membrane originates directly from an internalized plasma membrane pool.[30] Finally, fully formed platelet α-granules appear as highly elaborated and compartmentalized structures, storing hemostatic and adhesive proteins and numerous growth factors (Table 23.1). Multivesicular bodies, present in MK and only occasionally in platelets, represent a sorting compartment, intermediately between the TGN and α- and dense granules.[31,32] In contrast to secretory cells such as endothelial cells, virtually no constitutive granule secretion occurs in MK; secretion follows the regulated pathway and secreted proteins are packaged within secretory granules.[33]

Dense granules. Dense granules are the final marker of the maturation of MK cytoplasm at the ultrastructural level.[34] Indeed, these granules acquire their dense appearance quite late, but their limiting membrane and intrinsic receptors are probably formed earlier.[35] They arise from TGN and their constituents are sorted from the α-granule components in multivesicular bodies.[32] They are lysosome-related organelles containing high concentrations of several low molecular weight molecules necessary for normal blood hemostasis. These include calcium, serotonin, adenine nucleotides, pyrophosphate, and polyphosphate. Their absence results in the hemorrhagic δ-storage pool deficiency disorders. In the Hermansky-Pudlak syndrome, δ-storage pool deficiency is associated with tyrosinase-positive albinism, revealing a relationship between platelet-dense granules and the melanosomes of melanocytes. There are similarities in the biogenesis and secretory code of both types of granules that are linked to the small G-protein rab27 deficient in the ashen strain of mice.[36] Murine models have also shown that a specific gene (*Slc35d3* gene) is involved in dense granule formation independent of lysosomes and melanosomes.[37]

Lysosomes and peroxisomes. These granules can be detected cytochemically within maturing MK because of their specific enzymatic content–acid hydrolases[38] and catalase, respectively.

The MK nucleus. The nucleus of MK displays several sparse rounded lobes with abundant euchromatin and conspicuous nucleoli (type I) (FIGURE 23.2A). Its maturation is characterized by a constant size increase and segmentation and by chromatin clumping (type II) (FIGURE 23.2B). Through the unique process endomitosis, nuclear lobulation and ploidy increase without division, with the DNA duplicating to levels of 4N to 64N (rarely 128N). A correlation between ploidy and the number of nuclear lobes has been found on squash preparations. Close to the final maturation stage of MK, the nucleus changes texture and aspect (type III) (FIGURE 23.2C). Electron microscopy shows that the nuclear lobes tend to elongate and gather, the chromatin becomes coarser, and long clefts of cytoplasm extend between each lobe. These structural changes herald the start of proplatelet formation and platelet shedding.

Megakaryocyte activation. MKs are able to react to agonists in a manner similar to platelets.[39] Thrombin induces dramatic morphologic changes as early as the megakaryoblastic stage, indicating the early expression of protease-activated receptors. In the presence of agonists, the MK plasma membrane becomes bristled and sends out numerous thin pseudopods, the nucleus becomes eccentric, cytosolic organelles centralize, and secretory granules fuse with DMS after which they discharge their contents. This phenomenon, which leads to inappropriate secretion of granule contents, including growth factors, may be implicated in pathologic states such as fibroblast activation and myelofibrosis.[40]

STAGE-SPECIFIC DIFFERENTIATION MARKERS

Megakaryocyte Progenitors

Monoclonal antibodies against platelet proteins such as GPIIb/IIIa (CD41b), the GPIb complex (GPIbα, GPIbβ, GPIX and GPV, or CD42a, b, c and d), CD9, and CD150 have been used to identify MK progenitors.

In mice, it has been possible to purify MK progenitors close to homogeneity based on the expression of several antigens: Lin^- c-$kit^+$$Sca\text{-}1^-$ $FcgR^{low}IL7R\alpha^-$ $Thy1.1^-$ $CD34^{low}$ $CD9^+CD41^+$ and more recently, Lin^- c-$kit^+$$Sca\text{-}1^-$ $CD41^+CD150^+$.[41,42]

In humans, MK progenitors were initially characterized by the expression of differentiation markers on their surface that are also present on other hematopoietic progenitors, such as CD34, CD31, and CD133. Based on the expression of HLA-DR, it is possible to distinguish between BFU-MK ($HLA\text{-}DR^{low}$) and CFU-MK ($HLA\text{-}DR^{high}$).[5] Late MK progenitors can also be isolated in the $CD34^+CD41^+$ population which is enriched in CFU-MK.[43]

Megakaryocyte Precursors

Markers have been identified for later stages of MK differentiation. In the mouse, AchE staining, easily detected with light microscopy, is a convenient marker for investigating murine megakaryopoiesis *in vitro*.[44] In humans, AchE predominates in the erythroid lineage and cannot be used to identify megakaryocytic cells.

Studies in the mouse have shown the presence in the marrow of small AchE-positive cells with 2N ploidy. These cells are the direct precursors of MK and differentiate into polyploid MK in a few days.[45] Most of the 2N cells have no proliferative capacity

and undergo cycles of endoreplication. Their number is greatly increased or reduced in induced thrombocytopenia or thrombocytosis, respectively.

Megakaryocytes

Recent studies have used monoclonal antibodies directed against platelet proteins, permitting a better understanding of MK differentiation. Most studies have focused on the main platelet GPs, GPIIb/IIIa ($\alpha_{IIb}\beta_3$ or CD41b) and the GPIb complex (GPIbα, GPIbβ, GPIX, and GPV, or CD42a, b, c, and d).

CD41b is composed of CD41a (GPIIb, αIIb) and CD61 (GPIIIa, β3). CD61 is not specific for MK because as the β subunit of the vitronectin receptor $\alpha_v\beta_3$, it can be detected on nonmegakaryocytic cells such as endothelial cells, activated macrophages, and osteoclasts. By contrast, CD41a appears more specific for the MK lineage, especially in adults. In the marrow, a minute cohort of small cells (0.8 to 2.5 × 10^4 marrow cells) expressing platelet proteins can be detected using an anti–GPIIb antibody.[46–48] During CFU-MK culture *in vitro*, a large number of these small cells are present just before the development of recognizable MK colonies (day 6).

CD41 can also be detected on $CD34^+$ cells. Most $CD34^+$ $CD41^+$ cells in the adult correspond to late MK progenitors capable of giving rise to clusters of MK in 5 days[43] and to typical CFU-MK. Other experiments in transgenic or knock-in mice, and using the thymidine kinase gene under control of the GPIIb promoter, have shown that after ganciclovir treatment, most hematopoietic progenitors, as well as some HSCs, were killed.[49,50]

Recently, it has been shown that CD41 is an ontogenic marker of murine hematopoiesis. It is the first marker of hematopoiesis in embryonic stem (ES) cells, as well as in the embryo.[51,52] During later development, CD41 becomes restricted to the megakaryocytic lineage, although it is also expressed during mast cell differentiation.[51,53] In human neonates, CD41 is not restricted to the megakaryocytic lineage, but it is detected on some hematopoietic progenitors, especially on the bipotent erythroid/MK progenitors, lymphoid progenitors, and some HSCs capable of reconstituting hematopoiesis in immunodeficient animals (SCID-RC).[54] It is noteworthy that the expression of Mpl, the TPO receptor, mimics the expression of CD41. It is expressed at a low level on HSCs and all types of hematopoietic progenitors. Its expression markedly increases after commitment toward the MK lineage.[55]

CD41 expression precedes the detection of other major platelet proteins. The CD42 antigen is detected slightly later on a cell that expresses the CD34 and CD41 antigens. These cells are capable of giving rise to a single MK or a cluster of less than four MKs. The proliferative capacity of these cells is quite similar to those of the human CFU-MK defined in the agar medium.[56] $CD41^+CD42^+$ cells have been called *transitional* cells because they can switch from a mitotic stage to an endomitotic stage. In contrast to the CD41, CD42 expression is restricted to the MK lineage, although some late erythroid progenitors may express this marker. To detect the CD42 antigen on the MK surface, the GP Iα (CD42b), GP Iβ (CD42c), and GP IX (CD42a) must be expressed together, whereas GP V (CD42d) is not required and may be synthesized later than the other proteins.[57]

CD42 expression corresponds to a later differentiation stage that is correlated with the appearance of CD36 (GPIV) and the detection of α-granule proteins such as platelet factor 4 (PF4) and vWF, as well as a marked increase in the expression of Mpl, GPVI, and the integrin $\alpha_2\beta_1$. CD34 disappears during the endomitotic process.

Finally, immature MKs express CD4, which may be relevant for the mechanisms of thrombocytopenia in HIV infection.[58–60] CD4 expression tends to decrease during MK maturation and is virtually absent from mature MKs and the platelet surface.

ENDOMITOSIS

At the end of the proliferative phase, *2N* MK precursors become polyploid. MK polyploidization is unique among mammalian cells in that a multiple of 2N chromosomes is enclosed in a single nucleus surrounded by a single nuclear membrane. To achieve polyploidization, MKs undergo several rounds of DNA duplication and the nucleus segments but without nuclear and cytoplasmic division.

MKs are the only cells that become polyploid during their normal differentiation, whereas other cells may become polyploid after a stress. Polyploidy is a way to increase platelet production because the MK cytoplasm volume increases in parallel with ploidy. An increase in MK ploidy is one of the first events to occur after the induction of acute severe thrombocytopenia in mice: within 24 hours, the modal MK ploidy increases from 16N to 32N. This increase is maximal at 48 hours and ploidy returns to basal values within 120 hours.

As a first maturation step, MKs increase their ploidy and stop DNA duplication at any point between 2N and 64N, rarely going up to 128N. In humans, as in most mammals, the modal ploidy is 16N. However, in some mouse species such as C3H mice, the modal MK ploidy is 32N.[61] In the fetus and embryo, MKs have a lower ploidy; most fetal MKs are only 2N or 4N in culture.[62] Nonetheless, low ploidy MKs, either on a physiologic basis or due to malignancy, are able to shed platelets *in vitro*.

MK endomitosis is a rare event that remains difficult to observe. Originally, the term endomitosis was given to the mechanism of polyploidization because it was suggested that the mitotic process was occurring without rupture of the nuclear envelope. However, ultrastructural studies have allowed a description of the endomitotic process. The first steps are identical to those of mitosis. They begin with chromosome condensation and disappearance of the nuclear membrane. Several mitotic spindles are subsequently formed with two centrosomes for a tetraploid nucleus. Each centrosome is active and participates in elongation of the mitotic spindle. At metaphase, chromosomes are aligned at the equator and have sizes similar to those of mitotic cells.

MK culture in the presence of TPO, in conjunction with immunolabeling of various components of the mitotic apparatus, has made it easier to precisely describe the endomitotic process. It was initially thought that endomitosis represented mitosis that had skipped anaphase B and cytokinesis.[63,64] In fact, the initiation of endomitosis is identical to a normal mitosis with duplication of the centrosomes, development of a mitotic spindle, chromosome condensation (prophase), rupture of the nuclear envelope, chromosomal alignment at the equatorial plate (metaphase), and separation of the sister chromatids (anaphase).[65] Initially, the late phases of endomitosis were not observed because of their rarity. However, with the use of time-lapse videomicroscopy, it has been observed that endomitotic

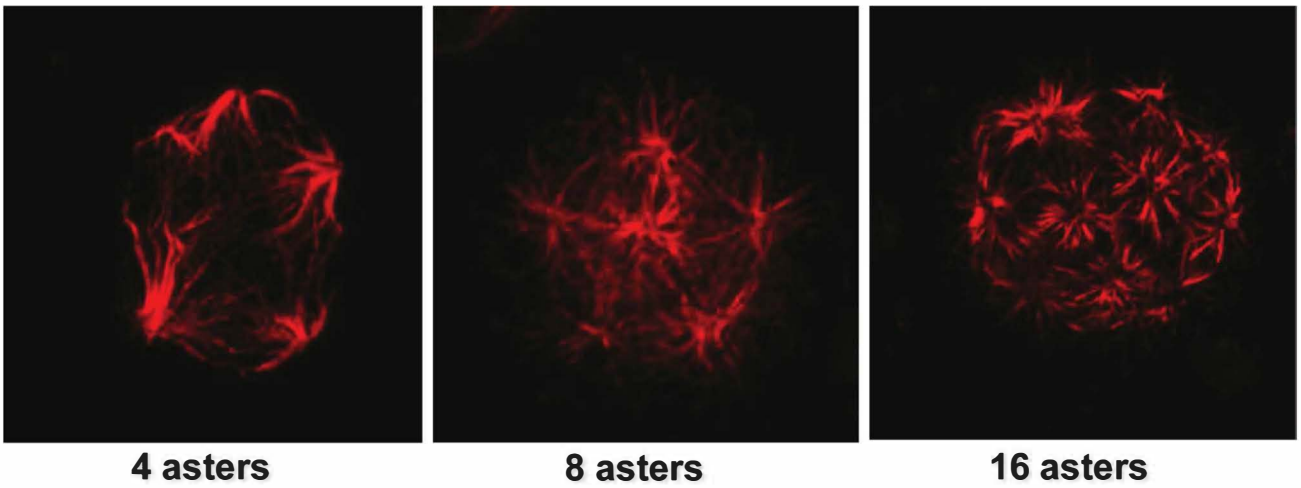

FIGURE 23.4 Immunofluorescent labeling of α and β tubulin in MKs undergoing endomitosis. These images of prometaphases of endomitosis from 4N to 8N, 8N to 16N, and 16N to 32N show the structure and asymmetry of the multipolar mitotic spindles.

MKs go through telophase and begin a cytokinesis that fails.[66,67] At the 2N and 4N transition, the two daughter cells that are nearly fully separated make a backward movement and fuse together. The structure of the central spindle has been a matter of debate, but it appears normal at the 2N and 4N transition. The main abnormality involves the cleavage furrow and its ingression which is incomplete. At higher ploidy, the abnormality is more pronounced with only incomplete cleavage furrow ingression.[66–69] When the MK is polyploid, its spindle is multipolar with the number of poles corresponding to the ploidy level; however, the number of chromosomes at each pole does not correspond to 2N because segregation of chromatids is asymmetrical during endomitosis[65] (FIGURE 23.4). It is surprising that a defect in cytokinesis leads to mononucleated cells because it usually induces multinucleated cells. This suggests that anomalies in chromatid separation may be also present during endomitosis. Preliminary evidence suggests that a large fraction of 4N MKs have two nuclei as a consequence of a pure defect in late cytokinesis. Because the abnormality is more pronounced in MK with higher ploidy, the chromatids are less separated, leading to a defect in karyokinesis and to a single nucleus. However, it has recently been shown that polyploid MKs are able to undergo a mitotic cycle with the generation of 2N cells.[70]

The cell cycle of a MK undergoing polyploidization is very similar to a mitotic process. There is clearly a succession of G1/S/G2/M phases, but the M phase is incomplete. After the M phase, the cell reenters G1 to undergo a subsequent cell cycle of DNA duplication. However, the molecular mechanisms responsible for the switch from a mitotic to an endomitotic cycle, as well as the mechanisms involved in stopping the process, are still incompletely understood.

REGULATION OF ENDOMITOSIS

The usual regulators of mitosis are active during the endomitotic process. Cyclin D3, cyclin E, and cyclin A are normally expressed during G, S, and G2/M phases, respectively.[71] The presence of cyclin B1 during endomitosis has been a subject of debate. There is now a large body of evidence indicating that cyclin B1 is expressed during the endomitotic cycle and is degraded in anaphase.[64,65] The presence of cyclin B1 is absolutely required for an entry in mitosis because the cdc2 (CDK1) kinase activity is indispensable for rupture of the nuclear envelope and chromatid condensation. Cyclin E may also play an important role in ploidization. Cyclin $E^{-/-}$ mice have a marked defect in MK ploidization,[72] but a proliferation defect was not observed in the other mitotic cells. In addition, cyclin E overexpression increases MK polyploidy.[73]

The anaphase-promoting complex is functional in MKs. This proteasome complex regulates the end of mitosis by degrading successive mitotic regulators such as the p55cdc20 subunit and cdh1. During the endomitotic process, cyclin B1, p55cdc20, and Aurora B are normally degraded.[65,74] On the other hand, CDK inhibitors such as p21 and p27 are expressed at high levels in polyploid MKs, but are not directly involved in endomitosis. These inhibitors do not seem to contribute to mitotic arrest as MK ploidy is normal in $p21^{-/-}$, $p27^{-/-}$ and double KO mice.[75] However, $p19^{Ink4d}$ appears to play a role in endomitotic arrest because $p19^{Ink4d}$ KO mice have MK with a 64N modal ploidy.[76] It is noteworthy that $p19^{Ink4d}$ is transcriptionally regulated by RUNX1 as well as several genes coding for platelet function. Thus, RUNX1 may be a link between the regulation of the end of endomitosis and terminal cytoplasmic differentiation.

There are also differences between endomitosis and mitosis. Levels of cyclin D3 and cyclin D1 are extremely high in MK,[71,77] and an increase in cyclin D increases MK ploidy. Cyclin D1 expression is regulated by GATA1 in MK.[77] In addition, it has been shown that STAT1, which is downstream of GATA1, also increases polyploidy and MK maturation.[78] Interferon γ, which induces STAT1 phosphorylation, induces MK polyploidization as well.

Whatever the molecular mechanisms involved, there are two main abnormalities in the cell cycle of the endomitotic MKs. One abnormality occurs at the end of mitosis and is responsible for the failure in cytokinesis. It has been suggested that this is related to a defect in Aurora B and survivin expression in polyploid MK,[79,80] but no major defect in the expression of these proteins and in their

localization in the central spindle has been found at the 2N to 4N transition.[74,81] Such abnormalities may be present in higher ploidy MKs.[80] Perhaps more germaine to the process, there is accumulation of myosin II at the contractile ring.[74] Myosin II normally plays a central role in cytokinesis by promoting the contractile ring forces required for cytokinesis. It is presently unknown if the defect in myosin II accumulation is primary or is secondary to low Rho/Rock pathway activation. The second cell-cycle abnormality occurs at the G1/S transition. A normal cell cannot become polyploid because an as yet unknown "sensor" detects the level of ploidy and blocks subsequent reentry into the S phase. This checkpoint is mainly regulated by p53.[82] However, a role for p53 in polyploidization remains controversial.[83]

Whether polyploidization is advantageous for platelet formation has been unclear. Theoretically, an endomitotic cycle could be shorter than a mitotic cycle because the late phases of the cell cycle are abrogated. However, the time for DNA duplication seems identical in both processes. During terminal differentiation, MK must synthesize large amounts of membrane to produce platelets. The endomitotic process could produce considerable economy of nuclear and plasma membrane synthesis which may aid in the efficiency of platelet production. Polyploidization may also be a way to markedly increase protein synthesis. In favor of this hypothesis, it has been shown that all 2N alleles of a gene remain functional during polyploidization; therefore, polyploidization represents true gene amplification.[84] Whether platelets arising from MK of different ploidy have similar or different sizes and function remains a matter of debate. In addition, polyploidy may induce resistance to mutations leading to haploinsufficiency as multiple gene copies are present. Whether polyploidization modifies protein synthesis and gene expression also remains to be determined. It has been reported that there is a linear correlation between mRNA or protein expression and ploidy. However, at high ploidy, expression may reach a plateau. Gene profiling during polyploidization has shown that the processes of polyploidization and terminal differentiation are partially intermingled because expression of genes involved in platelet function increases with ploidy.[85] Perhaps this is because terminal differentiation and polyploidization are regulated by the same transcription factors, for example, GATA1, FLI-1, or RUNX1.[76,77]

PLATELET FORMATION AND SHEDDING

Platelet formation has been described in vitro[86] and recently proplatelet formation was observed directly in mice in vivo through vital imaging.[87] In vitro, bone marrow MKs produce long extensions of cytoplasm called proplatelets (FIGURE 23.5) giving the MKs, in the process of shedding platelets, the morphologic appearance of an octopus.[88]

TPO-containing cultures have enabled the study of platelet formation and shedding in vitro using human[89] and murine precursors.[90] In addition, electron microscopy has enabled the identification of sequential subcellular events that lead to platelet production.[89,91] First, there is peripheral redistribution, alignment, and dilatation of demarcation membranes (Online FIGURE 23.5A,B). This is followed by extension of a proplatelet containing an axial bundle of microtubules and regular constriction zones (Online FIGURE 23.5C). Finally, there is breakage of a distal constriction rich in microtubules and liberation of a newly formed platelet (Online FIGURE 23.5D,E).

FIGURE 23.5 Photomicrograph of platelet formation by human MKs in culture. After reaching full maturation, the MK cytoplasm is remodeled into long processes termed proplatelets. The proplatelets develop constrictions along their length, giving them a beaded appearance. Finally, there is breakage of distal constrictions rich in microtubules and liberation of newly formed platelets. (See also Online FIGURE 23.5A-E).

Proplatelets bend, branch, and bend again, each elbow and tip being surrounded by a circular microtubule belt.[90] Future platelets detach from these cytoplasmic extensions. Alternatively, proplatelets may detach from the cell core and deliver platelets. The extension of proplatelets is accompanied by trafficking of organelles, mainly granules and mitochondria, in both directions, until they reach the tip of the proplatelet where they are immobilized. Videomicroscopy shows that proplatelets are dynamic and reversible structures and that future platelet organelles move freely along their long axes. It could be the circular microtubule at the proplatelet tip that prevents the organelles from going backward again.

In these models, the platelets that detach from the tip of the proplatelet contain a circular loop of microtubules. To explain the presence of this loop, it has been suggested that some newly formed platelets still bear a longitudinal bundle of microtubules in the circulation, then bend, curl, and form a loop with a central vacuole; both its extremities fuse together, then the vacuole shrinks, and the circumferential belt of microtubule is formed. Finally, blood platelets are still capable of protein synthesis.[92] It has been suggested that platelets can divide *in vivo*. However, it is unclear whether they are capable of duplicating the amount of proteins, such as actin or tubulin, which are fundamental for platelet function.

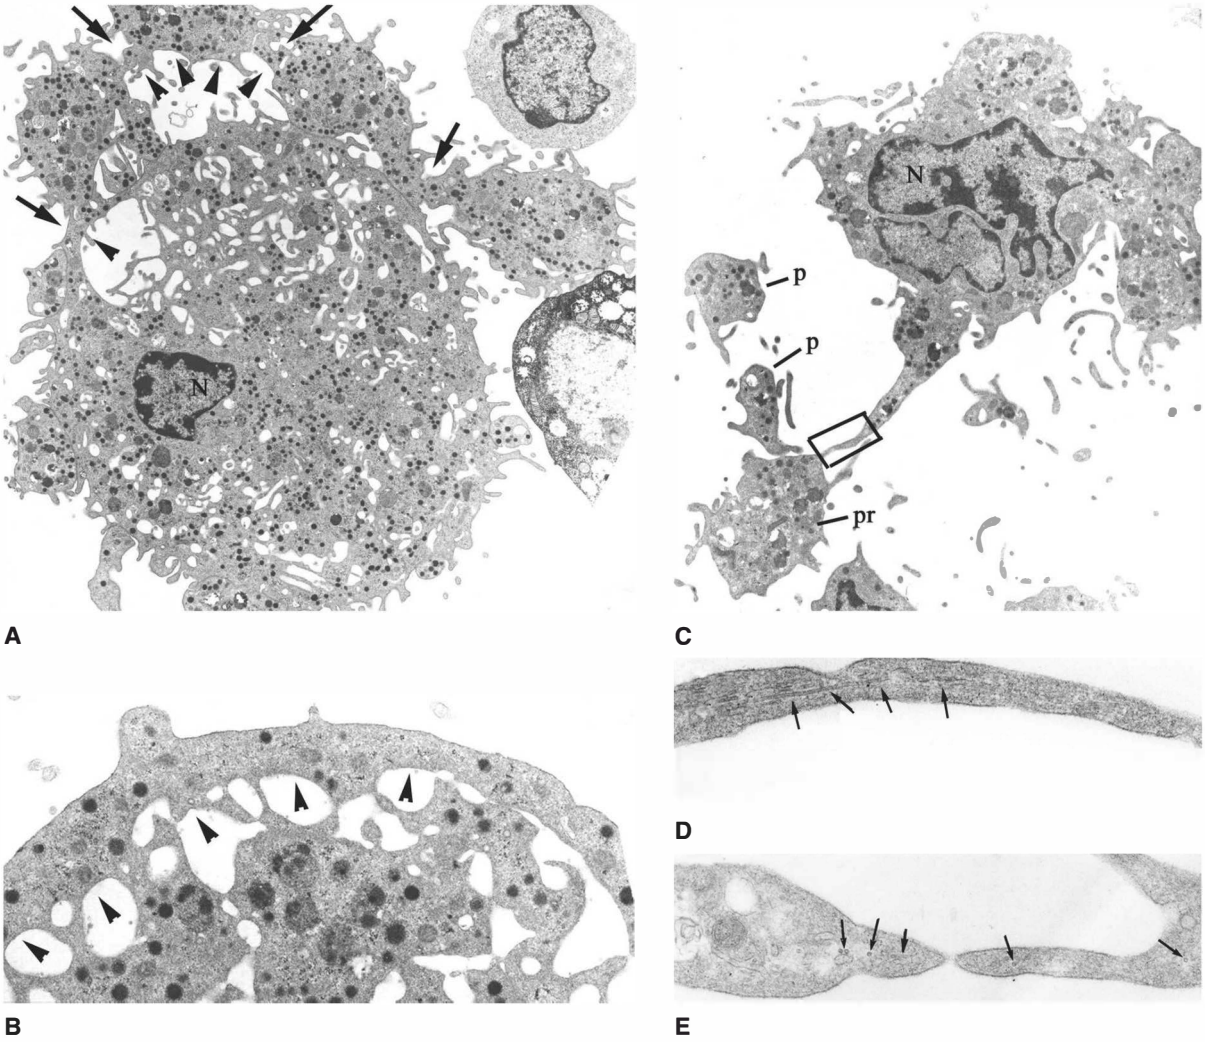

FIGURE 23.5. **A** and **B:** After reaching full maturation, megakaryocytes (MK) display the alignment and dilatation of some peripheral demarcation membranes (*arrowheads*), creating an outer ring of cytoplasm. The peripheral sheet of cytoplasm unfolds from the cell core, forming an elongated proplatelet process. Constriction zones are regularly disposed along this cytoplasmic extension (*arrows*), delimiting future platelet territories (*N*, nucleus) [magnification **(A)**, ×3,520; **(B)**, ×9,560]. **C:** Cytoplasm extends away (*box*) from the core of the mother cell, forming a proplatelet (*pr*). Some platelets (*p*) have detached from its tip (*N*, nucleus). **D:** A high magnification of the constriction zone shows some elongated parallel microtubules stretching along the long axis of the proplatelet (*arrow*) (magnification ×36,650). **E:** At places of constriction along the proplatelets, transverse microtubules appear (*arrows*) that might help increase local fragility, leading to breakage and liberation of a newly formed platelet (magnification ×35,650). Adapted from Cramer EM, Norol F, Guichard J, et al. Ultrastructure of platelet formation by human megakaryocytes cultured with the Mpl ligand. Blood 1997; 89:2336–2346.

The following platelet organelles play a key role in platelet formation:

Demarcation Membranes. Mature MKs evaginate demarcation membrane channels to their surface which elongate to form proplatelet extensions. Thus, demarcation membranes do not delineate platelet territories in MK cytoplasm, even though previous ultrastructural images of murine bone marrow MK had suggested that platelet territories could have been preformed in the maturing cell.[93] Finally, the number and size of platelets released by individual MK are directly dependent on their developmental stage.[86,94]

Microtubules. Pharmacologic inhibitors of microtubule formation prevent extension of proplatelets.[91,95,96] Microtubules are longitudinally oriented along these processes and constrictions occur that delineate the future platelets. It has been suggested that the microtubules in each proplatelet are derived from one centriole, implying a direct relationship between platelet shedding and ploidy.[86] Microtubules in each proplatelet extension appear to be oriented in opposite directions in each bundle and can slide back and forth along each other, facilitating changes in proplatelet length.[97,98] Microtubules play a central role in the redistribution of organelles in proplatelets as well.[99]

Actomyosin. Paradoxically, the process of proplatelet formation is enhanced by disruption of the actin cytoskeleton, indicating that this filamentous network is not a main component in proplatelet extension.[91] On the other hand, it is involved in the bending and branching of these extensions, thereby determining the size and number of shed platelets.[90] Globally, the actin cytoskeleton provides antiprotrusive forces that restrict proplatelet formation, and myosin II activity must decrease to permit proplatelet formation.[100] Actomyosin may also be involved in the scission process required for platelet shedding. Finally, the actin cytoskeleton is a major determinant of the MK migration required for the transit of MK from the osteoblastic to the vascular niche.[101] In support of the importance of the actin cytoskeleton in platelet formation, several inherited platelet disorders characterized by alterations in platelet size are related to mutations in components of actomyosin (MYH9)[102] or its regulators (WASP).[103].

Platelet size. Regulating the size of shed platelets is of importance since large platelets appear to be more functionally active than small platelets. The subcellular structures described above are involved in determining platelet volume. The main regulatory element appears to be the microfilament network. Indeed, the ability of proplatelet bending and kinking seems to be critical for platelet territory formation.[90] Actin filaments are linked to the plasma membrane by actin-binding protein (filamin) bound to the GPIb/V/IX complex, and abnormalities of GIbα, GPIbβ, and GPIX result in the macrothrombocytopenia that is characteristic of the Bernard-Soulier syndrome.[104] Other congenital macrothrombocytopenias, grouped together under the name MYH9-related disorders, are autosomal dominant syndromes that variably affect platelet formation and result from mutations in the human nonmuscle myosin-IIA heavy-chain gene, the only myosin heavy chain present in platelets.[102] It is unclear whether this disease results from haploinsufficiency of MYH9 or from an alteration in myosin heavy-chain function. MYH9 knockout mice develop macrothrombocytopenia that resembles the MYH9 syndrome in humans, but these abnormalities are only observed in MYH9$^{-/-}$ mice.[100] In contrast, knock-in mice for the mutations present in the MYH9 syndrome develop macrothrombocytopenia in the heterozygous state.

In autoimmune thrombocytopenia, platelet volume increases, and this can be compared to the effect of hemolysis on red blood cell volume where accelerated production increases cell size. Accelerated platelet production leads to a quasi-immediate increase in platelet size, and this can be attributed to repartition of the constriction zones, which when closer to the MK core along the proplatelet delimits larger territories.[86,89,97] Finally, pathologic states like myelodysplasia are often characterized by an increased mean platelet volume. Given that acquired mutations of the transcription factor GATA1 that accompany some preleukemic states also lead to macrothrombocytopenia, the increased platelet volume of myelodysplasia likely originates from a complex combination of cellular and molecular abnormalities.

Apoptosis and platelet production. Platelet production and MK death are intimately linked processes. Following platelet release, the nuclei of senescent MK undergo morphologic changes such as chromatin condensation that are characteristic of apoptotic cell death.[105] Recent observations suggest that biochemical processes characteristic of apoptosis, including caspase activation and cytochrome *c* delocalization from mitochondria, appear to precede proplatelet extension during the final step of MK maturation.[106] Evidence also suggests that caspase activation occurs in a localized manner rather than throughout the cytosol, explaining how the intrinsic apoptosis pathway might be activated without causing premature MK death. Furthermore, blocking the intrinsic apoptotic pathway either by caspase inhibition or by overexpression of the antiapoptotic protein Bcl-2 inhibits proplatelet formation. A role for caspases in proplatelet formation has also been shown in studies of the human MK cell line MEG-01 where proplatelet formation is enhanced by activation of the extrinsic apoptotic pathway, by activation of the Fas pathway by receptor ligation, or by overexpression of the downstream effector caspase-8.[107]

A case of familial thrombocytopenia has been reported which is linked to a gain in function mutation affecting cytochrome c.[108] Early platelet formation was observed *in vitro*, together with the presence of mature platelets released in the bone marrow, suggesting a major deregulation of both the timing and the location of proplatelet formation and platelet release.

Mild thrombocytopenia is seen in mice that overexpress Bcl-2 in the hematopoietic compartment[109] or that have lost expression of proapoptotic Bim.[110] However, mice that overexpress Bcl-XL in MK show no alterations in platelet counts, although cultured MKs show reduced proplatelet formation, and platelet recovery *in vivo* is delayed following experimentally induced immune thrombocytopenia.[111]

However, a recent report argues against a role for the classical intrinsic apoptosis pathway in proplatelet formation.[112] Deletion of Bax and Bak in MK, the key proapoptotic Bcl-2 family proteins that trigger loss in mitochondrial membrane integrity and subsequent cytochrome *c* release, had no effect on proplatelet formation, and the observed thrombocytopenia was related to increased platelet clearance. On the other hand, mice lacking MK Bcl-XL had decreased platelet counts and their MKs begin to form proplatelets in culture, but subsequently die. It is unknown whether this is related to species differences in platelet shedding or to the induction of a caspase activation, independent of apoptosis, during proplatelet formation.

Microenvironment and MK localization in the bone marrow. Normal megakaryopoiesis takes place in the bone marrow where HSCs proliferate and differentiate close to the osteoblastic niche. When MKs mature, they are often gathered into small groups, consisting of up to three cells of various size, ploidy, and maturation stage. During the maturation process, MKs tend to migrate from the osteoblastic niche, the favored localization of HSC, to the

vascular niche in proximity to a vascular sinusoid[113] (FIGURE 23.1). During the maturation process, MKs are in close contact with stromal cells, whereas fully mature MKs are closer to endothelial cells.[114] This is important because MKs and endothelial cells share many potential pathways. MKs express mitogenic factors for endothelial cells, like vascular endothelial growth factor (VEGF),[115] whereas endothelial cells express receptors and adhesion molecules that contribute to retaining MK in proximity to the bloodstream where platelets are shed.[116] In mice and rats, but not in humans, MKs are distributed equally in the bone marrow and the spleen, and to a lesser extent the liver.[93] In addition, MKs are occasionally observed in the pulmonary circulation of both human and animals. Mature bone marrow MKs are extremely deformable and not only can adhere to the sinusoidal wall, but can also transmigrate across the barrier to enter the circulation. The first capillary bed that MKs encounter when they exit the bone marrow is the pulmonary microcirculation where they can be easily trapped. Indeed, it has been pointed out that MKs are present in consistent numbers in the small vessels of the lung and are trapped in the pulmonary capillary beds where they release platelets.[117] This hypothesis has been recently supported by injection of mature MKs into the circulation of mice where they are trapped in the pulmonary circulation to produce platelets.[118] These observations suggest the lung as a possible site of platelet production.

MK chemotaxis. MKs express the chemokine receptor CXCR4, a G-protein–coupled seven transmembrane domain receptor. The CXCR4 ligand, stromal cell–derived factor-1 (SDF-1), contributes to retaining HSC in the marrow and to inducing MK chemotaxis *in vitro* in a modified Boyden chamber.[119] Under these conditions, mature MKs were observed to form a unilateral cytoplasmic pseudopod with the nuclear lobes gathered at the opposite pole, enabling MK migration through a transwell of bone marrow endothelial cells. Others also observed that CXCR4 expression increases with MK maturation, but mature MK, as well as platelets, do not respond to SDF-1. This suggests that SDF-1 signaling operates to retain immature MK in the marrow, whereas mature MKs can migrate into the blood.[101,120,121]

SDF-1 is also a chemoattractant for human CD34 hematopoietic progenitors. Thus, it is involved in homing of HSC to the bone marrow[122,123] and plays a major role in the retention of hematopoietic cells in the marrow.[124] Downregulation of CXCR4 by either proteolysis or endocytosis participates in the mobilization of hematopoietic progenitors in blood.[125] Lastly, CXCR4 is a coreceptor for HIV.[126]

MK localization. In normal individuals, platelet shedding does not occur in the marrow but directly into the circulation. In the marrow, MKs are located in the subendothelial region, in close contact with endothelial cells.[127] Long cytoplasm pseudopods appear to pass through the endothelial barrier and enter into the marrow sinusoids.[13,87,113,128] Alternatively, mature MKs can migrate through the endothelial cell barrier and can be detected in the circulating blood.[128] Platelet release occurs by breaking off long proplatelet extension at the level of constrictions, perhaps due to the mechanical force of flowing blood. Initially, proplatelets are released with a longitudinal orientation of the microtubules and their tips elongated (like a teardrop). Subsequently, rearrangement of microtubules occurs, giving rise to a marginal microtubule coil and discoid-shaped platelets. Others have proposed a model in which proplatelet curvature results in platelet formation.[90] However, recently reported intravital microscopy has shown that true proplatelets are released in the circulation, as well as entire MKs.[87] Finally, the demonstration of a role for physical force in platelet shedding from MK provides additional evidence that a substantial proportion of platelet formation occurs in the circulation.

Effect of shear stress on platelet formation and shedding. Because mature bone marrow MKs migrate toward the vascular niche, it is likely that proplatelets or entire MKs enter capillaries where they are exposed to the physical forces of blood flow. Indeed, when mature MKs are placed in a perfusion chamber with shear stresses ranging from 900 to 1,800 s^{-1},[96] they undergo the specific changes that accompany platelet formation. It is noteworthy that these changes occur much faster than under static conditions with the entire process, from a spherical MK to platelet release occurring in <30 minutes; under static conditions in culture, the process takes at least 10 hours.

There are also morphologic differences between platelet production under shear and under static conditions. When platelets are produced under shear, proplatelets extend from the cell core in a bipolar manner and are oriented parallel to the flow. Entire proplatelets detach, followed by the release of platelet subunits; alternatively, platelets may be shed directly from the tip of the proplatelets still attached to the MK core. This process is sustained by microtubules and is completely reversed by the microtubule inhibitor nocodazole. It is also GPIb dependent and is completely blocked by antibodies to GPIb.

Embryonic stem cells and platelet production. By differentiating murine ES cells in coculture with stromal cells, Fujimoto et al.[129] succeeded in producing functional platelets that were able to spread, aggregate, bind fibrinogen, and express P-selectin. There was evidence that these platelets were functional because they recirculated when injected in immunodeficient mice and participate in the formation of clots. This promises to be an extremely useful model because the differentiated ES cells closely mimic cultured MK, including proplatelet and platelet production (FIGURE 23.6). One possible limitation is that the platelets had embryonic/fetal features, and it is not presently known whether they function differently from their adult counterparts. Another approach is based on the induced pluripotent stem (iPS) cell model and the recent observation that fibroblasts expressing Oct4 can proliferate and generate multipotent progenitors in unlimited quantities which could then differentiate

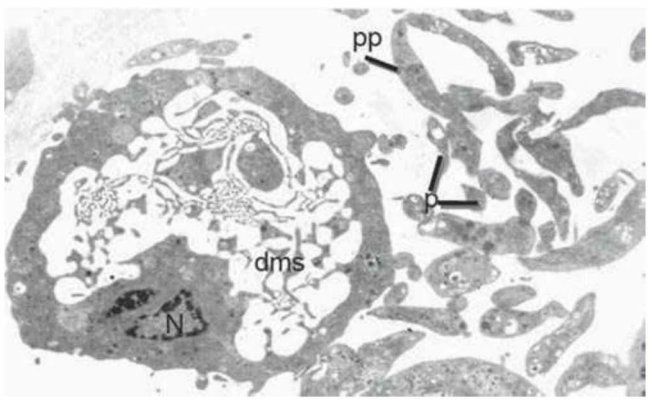

FIGURE 23.6 MK derived from an ES cell. The ultrastructure of this cell is very close to an MK in primary culture, exhibiting a lobated nucleus (*N*), prominent demarcation membrane system (*dms*), adjacent proplatelets (*pp*), and newly formed platelets (*p*).

into MK.[130] The advantage of the reprogramming technique is that it gives rise to adult MKs in contrast to ES cells. In addition, iPS cells could be used to recapitulate congenital platelet disorders.[131]

MOLECULAR REGULATION OF MEGAKARYOPOIESIS

There has been substantial progress in understanding normal MK differentiation, its relationship to erythroid differentiation and platelet shedding, and the basis for congenital and acquired MK abnormalities (FIGURE 23.7).

The GATA transcription factor family and its partners. Sequencing the promoters of MK-specific genes such as GPIIb, PF4, GPIba, β-thromboglobulin, GPIX, and GPV revealed the presence of consensus-binding sequences (WGATAR) for transcription factors of the GATA family previously observed in erythroid-specific genes.[132] MK-specific gene promoters also possess DNA consensus sequences for the Ets family of transcription family (GGA/T), some being in tandem with GATA motifs. Mutations impairing Ets binding reduce the activity of MK promoters by 60%. Therefore, GATA and Ets-binding sites appear equally important for the activity of MK gene promoters. Ets-binding sites are not found in erythroid-specific genes, whereas CGCC or CACC motifs are associated with GATA-binding sites.

Two GATA proteins are expressed during erythromegakaryocytic differentiation. GATA-1 was first described as a specific regulator of erythroid-specific genes but was later detected in MKs. Knockout of GATA-1 in mice is embryonic lethal due to anemia.[133] When GATA-1 was specifically knocked out in MK, the mice were viable but presented with profound macrothrombocytopenia and the presence of small immature MK in the marrow.[134] The latter exhibited increased proliferation capacity. In addition, synthesis of the major platelet GPs was markedly decreased.

GATA-2 is mainly involved in the proliferation of multipotent progenitors but is also required for normal MK development in GATA-1 mutant cells. GATA-2 prevents induction of a latent myeloid gene expression program. In the absence of GATA-1, GATA-2 contributes to cell-cycle progression and the maintenance of MK identity of GATA-1-deficient cells.[135]

The GATA-1 protein is associated with other transcription factors, the most important for MK differentiation include Friend of GATA-1 (FOG-1), TAL-1, RUNX-1, and FLI-1. The significance of GATA-1/FOG-1 association has been underscored in human X-linked congenital thrombocytopenia which is characterized by large platelets and moderate dyserythropoiesis. Four distinct *GATA-1* mutation types have been detected in X-linked disorders,[136,137] including mutations impairing FOG-1 binding, impairing binding to a GATC motif, affecting the N finger of GATA-1 but not disrupting FOG-1 or DNA binding, as well as mutations generating a truncated form of GATA-1 (GATA-1s).

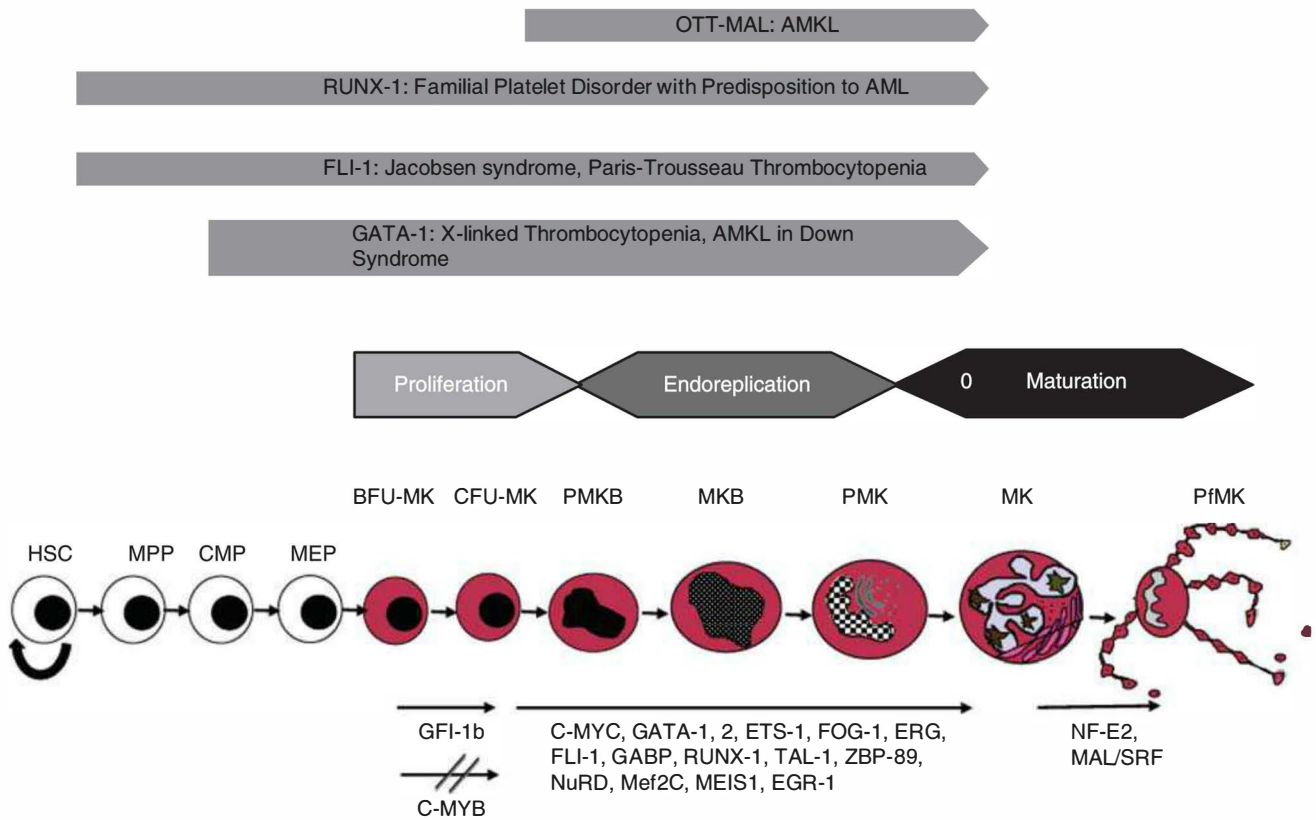

FIGURE 23.7 Molecular regulation of megakaryopoiesis and related disorders. FOG, friend of GATA; BFU, burst-forming unit; CFU, colony-forming unit; GP, glycoprotein; PMKB, promegakaryoblast; PF4, platelet factor 4; vWF, von Willebrand factor.

Acquired mutations in exon 2 of GATA-1 that generate a short GATA-1 variant (GATA-1s) lacking its *N*-terminus are responsible for the transient myeloproliferative disorder associated with Down syndrome which may lead to megakaryoblastic leukemia (AML-M7). It is noteworthy, however, that in a family with germline GATA1s, no myeloproliferative disorder or megakaryoblastic leukemia were described. In some patients with the Bernard-Soulier syndrome, a mutation of the GATA-binding site was detected in the *GPIb* promoter.[138]

FOG-1. FOG-1 was identified by a double hybrid approach. The knockout of FOG-1 gave a phenotype similar to that of GATA-1 in the erythroid lineage but with an additional profound absence of MK progenitors, suggesting that FOG-1 may have another partner in the early stage of the megakaryocytic lineage. GATA-2 appears to be a good candidate because simultaneous inactivation of critical FOG-binding regions of GATA-1 and GATA-2 leads to failure of the early and late stages of MK differentiation. The interaction between FOG-1 and GATA-1 is specifically required for late stages of MK maturation, but not early MK development, suggesting that GATA-1 and -2 are functionally interchangeable only at early stage in megakaryocytic development.[139]

ZBP-89 and NuRD were also identified as being components of multiprotein complexes involving GATA-1 and FOG-1. Studies in FOG-1- and GATA-1-deficient zebrafish and mice revealed a ZBP-89 requirement for megakaryopoiesis and definitive erythropoiesis but not for primitive erythropoiesis.[140] NuRD acts as a repressor or activator of select GATA-1/FOG-1 target genes, and the GATA/FOG1/NuRD axis not only promotes erythroid and MK maturation but is required for maintaining lineage fidelity by constraining lineage-inappropriate gene expression throughout MK-erythroid development.[141]

TAL-1. TAL-1 (also called SCL) is a bHLH transcription factor.[142] TAL-1/GATA-1 are present in a complex that also includes E2A, Ldb1, SSBP2, and LMO2 when regulating erythroid genes and in a complex that includes GFI1B, ZFP143, and the corepressor ETO2 when regulating MK genes.[143] TAL-1 knockout is embryonic lethal because of the absence of HSC.[144] Surprisingly, an inducible *Tal-1* knockout revealed that TAL-1 is not necessary for the stem cell properties of hematopoietic cells but is a master gene in the commitment of a mesenchymatous precursor cell toward hematopoiesis. In addition, TAL-1 is indispensable for the development of the erythroid, megakaryocytic, and mast cells.[52] It is also critical for platelet production during stress thrombopoiesis by directly regulating NF-E2 transcriptional activity.[145] Moreover, deletion of Mef2C, a direct TAL-1 target in MK cells, severely impairs *in vitro* megakaryopoisis and platelet quantity and functions *in vivo*.[146]

RUNX-1. A third transcription factor interacting with GATA-1 is RUNX-1 (AML-1).[147] RUNX-1 is the DNA-binding subunit of the core-binding factor (CBF) transcription complex. RUNX sites consisting of TGT/cGGT motifs have been found in several megakaryocytic promoters. Both RUNX-1 and CBFβ are highly expressed during megakaryocytic, but not erythroid, differentiation. Germ-line heterozygous missense, frame shift, and nonsense mutations, and a nucleotide deletion in a single allele of the *RUNX-1* gene have been detected in cases of familial thrombocytopenia with a predisposition to develop AML (FPD/AML).[148] The majority of these mutations are localized to the RUNT domain and impair DNA binding. By contrast, *C*-terminal domain mutations retain the ability to bind to DNA but lack transactivation properties. Two mechanisms for FPD/AML induction have been proposed based on the consequences of these mutations. One is linked to haploinsufficiency and the second to a negative dominant effect. In the former, mutated RUNX1 is unable to bind to DNA and to interact with CBFβ; in the second, the RUNX-1/CBFβ interaction is conserved, but the complex cannot bind DNA or cannot cause transactivation. The predisposition to develop AML seems to be related to the role of RUNX-1 in HSC homeostasis and may be increased when RUNX-1 mutants display a dominant negative function. Knockout mice indicate that RUNX-1 is essential for establishing definitive hematopoiesis and an inducible knockout of both RUNX-1 and CBFβ causes profound disruption of megakaryopoiesis.[149,150] Recently, several genes, including MYL9,[151] PF4,[152] ALOX12,[153] and MPL,[154] all implicated in megakaryopoiesis, proplatelet formation, and platelet function, were found to be directly regulated by RUNX1.

Ets family transcription factors. The Ets family of transcription factors consists of at least 13 different proteins. The products of two candidate genes, *ETS-1* and *FLI-1*, expressed in MK cell lines and MK, are able to transactivate MK-specific genes. *Ets-1* knockout mice have a marked defect in lymphoid lineages but normal megakaryopoiesis. However, ETS-1 expression increases during MK maturation and its overexpression promotes MK differentiation and enhances the upregulation of GATA-2 and MK-specific genes.[155] In contrast, the Fli-1 knockout is embryonic lethal due to defects in vascular development and megakaryopoiesis.[156] There is marked thrombocytopenia with an excess of small immature MK undergoing apoptosis. These abnormalities are related to those observed in the macrothrombocytopenia present in the Paris-Trousseau syndrome thrombocytopenia, a variant of the Jacobsen syndrome. These syndromes are associated with a deletion in human chromosome 11q23 involving both the *ETS-1* and *FLI*-1 genes. Overexpression of FLI-1 in $CD34^+$ cells partially restores the dysmegakaryopoiesis linked to this syndrome.[157] A direct role for FLI-1 in the late stages of megakaryopoiesis has been demonstrated in a mouse model in which there was an association between the loss of a carboxy-terminal regulatory domain and thrombocytopenia.[158] FLI-1 cooperates with GATA-1, FOG-1, and RUNX-1 to transcriptionally activate late MK genes such as GPIX, GPIbα, and PF4. The ETS transcription factor GABPα also regulates the expression of genes such as GPIIb or c-mpl expressed earlier during MK differentiation.[159] The transcription factor EKLF has been recently shown to act as an antagonist FLI-1 antagonist. While FLI-1 is involved in the commitment of a megakaryocyte–erythrocyte progenitor toward the MK lineage, EKLF plays the same role in the commitment to the erythroid lineage.[160] An inducible knockout of TEL-1, an ETS transcription factor, leads to a dramatic decrease in platelet counts.[161] Finally, the Ets-related gene ERG is also required for normal megakaryopoiesis. ERG is expressed in acute megakaryoblastic leukemia (AMKL) and strongly cooperates with GATA1s present in Down syndrome AMKL to immortalize MK progenitors, suggesting that the additional copy of ERG in trisomy 21 may have a role in Down syndrome AMKL.[162] Simultaneous alterations in FLI-1 and ERG lead to phenotypes more dramatic than single heterozygotes. These include a reduction in the number of committed hematopoietic progenitors, a significant decrease

in MK number, and an MK dysmorphogenesis leading to severe thrombocytopenia. These observations illustrate an indispensable requirement for both FLI-1 and ERG in normal HSC and MK homeostasis and suggest that these transcription factors may coregulate common target genes.[163]

p45$^{NF\text{-}E2}$. A hierarchical relationship between the GATA-1 and p45$^{NF\text{-}E2}$ transcription factors was demonstrated in MKs, showing that p45$^{NF\text{-}E2}$ acts downstream of GATA-1, although only 50% of p45$^{NF\text{-}E2}$ expression depends on GATA-1. p45$^{NF\text{-}E2}$ is a basic leucine zipper transcription factor that forms a heterodimer with proteins of the maf family to form an active NF-E2 transcription factor. p45$^{NF\text{-}E2}$ has also been identified in erythroid cells where it regulates genes involved in heme synthesis. Surprisingly, p45$^{NF\text{-}E2}$ knockout mice die at birth from severe thrombocytopenia with no defect in the erythroid lineage. In these p45$^{NF\text{-}E2-/-}$ mice, there was an increase in MK number with marked maturation defects, especially in the development of demarcation membranes and in the distribution of α-granules. p45$^{NF\text{-}E2-/-}$ MKs were unable to form proplatelets *in vitro*, correlating with acute thrombocytopenia.[164] The partner of p45NF-E2 in MK is predominantly MafG and, to a lesser extent, MafK. Double knockout mice, MafG$^{-/-}$ MafK$^{-/-}$, have thrombocytopenia similar to that of p45NF-E2$^{-/-}$ mice. Recently, it was demonstrated that the MafG C terminus is essential for proplatelet formation and platelet gene activation, but not for p45 binding to the Maf recognition element.[165]

Discovery of the p45$^{NF\text{-}E2}$ target genes has provided an opportunity to characterize genes involved in proplatelet formation. β1-Tubulin is restricted to the megakaryocytic lineage and is expressed at late stages of differentiation.[166] β1-Tubulin knockout mice are thrombocytopenic with abnormal-shaped platelets (i.e., absence of a discoid shape). However, overexpression of β1-Tubulin in p45$^{NF\text{-}E2-/-}$ MK does not restore proplatelet formation. It has also been shown that Rab27b, a small G protein involved in granule trafficking, is a target gene of p45$^{NF\text{-}E2}$ and may play a role in proplatelet formation,[167] whereas thromboxane synthase, also a p45$^{NF\text{-}E2}$ target, has no role in proplatelet formation.[168] The combination of NF-E2, GATA-1, and Ets-1 proteins plays a critical role in regulating expression of αn isoform of the human thromboxane A_2 receptor-α during megakaryocytic differentiation. Another NF-E2 target, Lims1/Pinch1, is implicated in cell migration, spreading, and platelet release.[169] The MK maturation process is closely related to the cellular response to oxidative stress in bone marrow. Thus, NF-E2 regulates not only platelet genes, but also cytoprotective genes that are common targets of p45 and Nrf2. The functional domination by p45 over Nrf2 favors reactive oxygen species (ROS) accumulation by limiting the expression level of cytoprotective genes. ROS accumulation promotes the full activation of platelet genes such as *Txas, Gp6, Selp,* and *Slamf1*.[170]

GFI-1b. GFI-1b, a transcription factor with a SNAG domain, is thought to be a transcriptional repressor. It is mainly expressed during erythroid and megakaryocytic differentiation and regulates the proliferation and differentiation of bipotent MEP.[171] GFI-1b knockout is embryonic lethal due to major abnormalities in erythroid and megakaryocytic differentiation with fatal anemia and thrombocytopenia.[172] Fetal liver progenitors from GFI-1b KO mice give rise to small MK colonies with a decreased level of GPIIb, c-mpl, and NF-E2 compared to wild-type cells. Although GFI-1b target genes responsible for this phenotype as well as its partners are unknown, GFI-1b controls erythropoiesis and megakaryopoiesis at least in part by regulating *TGFBR3* expression in MEP.[171]

Transcription factors linked to AML-M7. Study of AML-M7 has suggested that additional transcription factors are involved in MK development.

Neonatal AML-M7 is usually associated with a t (1;22) translocation leading to a fusion protein between two ubiquitous transcription factors MAL (MKL1) and OTT (RBM15).[173,174] MAL is an important transcription factor for MK development because it is a coactivator of the serum responsive factor (SRF) that is regulated by Rho signaling pathway.[175] MAL is associated with cytosolic G-actin in nonactivated cells. When the Rho pathway is activated, G-actin is sequestered and MAL is translocated to the nucleus. In combination with SRF, it activates target cytoskeletal genes such as *Tpm1, Actb, Flna, MMP9,* and *MYL9* that are required for MK migration and platelet biogenesis.[176] The role of SRF/MAL in polyploidization is controversial.[177]

The transcription factor c-MYB also plays an essential role in MK development. Suboptimal levels of c-MYB favor the differentiation of MKs and macrophages, while high levels are important for erythropoiesis and lymphopoiesis. At the stage of definitive MEP, c-MYB is an essential regulator of erythroid–megakaryocytic lineage bifurcation, while primitive erythropoiesis and megakaryopoiesis are c-MYB independent.[178] The expression level of c-MYB is downregulated in MEP by TPO through induction of miR-150.[179] Loss-of-function mutations are also associated with expansion of megakaryopoiesis and platelet production in mice.[180]

Additional transcription factors. MEIS1, a member of the TALE family of homeobox genes, is essential for MK development since MEIS1-deficient embryos lack MK/platelets and show extensive haemorrhage.[181] The transcription factors EGR-1 and FosB are involved in the megakaryocytic differentiation of the K562 cell line that is induced by phorbol ester.[182,183] EGR1 is also involved in the induction of p21 during MK differentiation leading to a senescent phenotype.[184] Absence of functional Foxp3, a key transcription factor for regulatory T cell development, also leads to defects in MKs and platelets.[185] MLLT3, originally identified as a fusion partner of MLL in acute myeloid leukemia, is a positive regulator of E/Meg differentiation decisions and acts in a regulatory circuit that includes GATA-1.[186] Among the different STATs, STAT1 seems to play a major role in MK differentiation. Finally, c-MYC plays a positive role in MK progenitor proliferation and was reported to be essential for the TPO–c-mpl axis in megakaryopoiesis. In contrast, studies using *c-Myc*–deficient mice showed that absence of the gene led to an increase in the platelet count,[187] while transient activation of *c-MYC* expression is critical for efficient platelet generation from human iPS.[188]

HUMORAL REGULATION OF MEGAKARYOPOIESIS INDEPENDENT OF THROMBOPOIETIN

Study of the cytokine regulation of megakaryopoiesis has largely been dominated by two concepts. First, humoral regulation by a late differentiation factor called TPO,[189–191] analogous to erythropoietin, but for the MK lineage. Second, sequential dual regulation corresponding to different developmental stages: one

regulator acting early in differentiation (*MK-CSF*) and a second acting late (differentiation potentiators or synergistic factors)[192] (FIGURE 23.8). Identification of TPO has verified these hypotheses since TPO acts on both early and late stages of megakaryopoiesis. However, in contrast to erythropoietin, TPO is not the only growth factor that acts on late stages of megakaryopoiesis. In particular, it does not regulate proplatelet formation. Indeed, the thrombocytopenia of c-mpl$^{-/-}$ and TPO$^{-/-}$ mice corresponds to about 10% of the normal platelet number, suggesting that other growth factors also regulate platelet production. Further, negative regulation by feedback may also influence platelet production.

Stimulatory Factors

Stem cell factor (kit ligand or steel factor). Stem cell factor (SCF), one of the most important cytokines, acts as a synergistic factor with most hematopoietic growth factors. It is synthesized by marrow stromal cells. Its predominant effect is in the early stages of hematopoiesis where it is a costimulator with erythropoietin on erythroid lineage. SCF also plays a role in megakaryopoiesis. Steel mice, deficient in SCF, exhibit a decrease in MK number, but also an increase in MK size, resulting in normal platelet count. It is noteworthy that Steel mice have no rebound thrombocytosis after 5-fluorouracil treatment.[193] However, when they are treated with SCF, they are able to undergo rebound thrombocytosis like their wild-type litter mates. *In vitro*, SCF greatly potentiates the effects of other cytokines including TPO on the growth of MK progenitors, increasing both the cloning efficiency and the size of MK colonies.[194–196] *In vivo*, injection of SCF accelerates platelet recovery after myelosuppression. In addition, SCF mobilizes hematopoietic progenitors in addition to MK progenitors. However, its use in clinical situations is limited by its toxicity.

Interleukin-3 (IL-3). IL-3 is a 14 to 22 kDa GP synthesized by T cells, but not by stromal cells, that acts directly on CFU-MK.[197,198] With the exception of TPO, IL-3 is the only cytokine that is able to induce MK colony formation alone. Its effect predominates in the early stages of megakaryopoiesis. It has even been suggested that IL-3 may impair MK terminal differentiation.

Erythropoietin. Epo is synthesized by the kidneys and regulates erythropoiesis. The Epo receptor is present on MK and platelets. There are strong indications that Epo is essentially a maturation cytokine.[199] Therefore, it acts more effectively as a costimulator with other cytokines and is able to favor terminal differentiation. Epo may also potentiate proplatelet formation by purified murine MKs.[200] However, its effect *in vivo* is controversial. It may increase platelet function, but also platelet production. In humans, chronic administration of Epo may slightly increase platelet production.[201,202]

Interleukin-6, Interleukin-11, leukemia inhibitory factor, oncostatin M and ciliary neurotrophic factor. These cytokines have pleiotropic effects on numerous cell types.[203] Their redundancy is explained by the molecular biology of their receptors. All utilize a common signal transducing chain (GP130). They are essentially mediators of the inflammatory response.

IL-6 was the first molecule of this family to be studied on megakaryopoiesis. It is a 21 to 26 kDa GP that is synthesized by a large number of cells including monocyte/macrophages, T cells, stromal cells, and MKs.[204,205] IL-6 has a minimal effect on MK colony formation, especially in humans, but acts in synergy with IL-3 and SCF.[206,207] IL-6$^{-/-}$ mice have no quantitative or qualitative defects of platelets, and IL-6 is not responsible for the basal platelet number in TPO$^{-/-}$ or *c-mpl*$^{-/-}$ mice.[208] IL-6 and IL-11 are probably responsible for the increase in platelet production in inflammatory diseases, although this effect might be indirect and related to increased synthesis of TPO.

In mice, leukemia inhibitory factor (LIF) potentiates the effects of IL-3 on MK colony formation[209]; its injection induces thrombocytosis.[210] However, in humans, its effect on *in vitro* megakaryopoiesis is less pronounced than IL-6.[196,211] LIF knockout mice have normal platelet count.[212] Oncostatin M has similar effects on thrombopoiesis as leukemia inhibitory factor.[213]

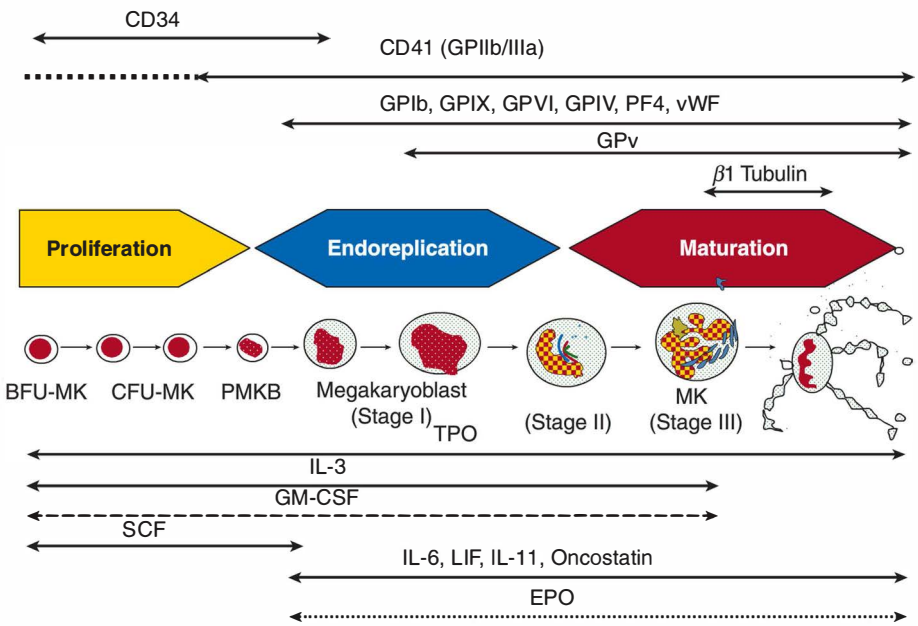

FIGURE 23.8 Regulation of MK development by cytokines. BFU, burst-forming unit; CFU, colony-forming unit; PMKB, promegakaryoblast; MKs, megakaryocytes; TPO, thrombopoietin; SCF, stem cell factor; EPO, erythropoietin.

IL-11 has marked effects on thrombocytopoiesis. *In vitro*, IL-11 has no MK-stimulating activity alone, but acts in synergy with IL-3 to stimulate murine and human colony formation.[214,215] IL-11 acts on the late differentiation by increasing MK size and ploidy in humans.[214] IL-11 has been used a therapeutic agent in human, but clinical trials have been discontinued due to secondary effect.

CXCL12 or stromal cell–derived factor-1 (SDF-1). SDF-1, also called *pre–B*-cell growth stimulating factor, is a CXC chemokine that binds to CXCR4 and is synthesized by stroma, bone marrow, endothelial, and dendritic cells. Disruption of the *CXCR4* and *SDF-1* genes in mice indicates that these molecules play an essential function in different tissues. Mice die at birth from numerous developmental abnormalities including cerebellar and cardiac abnormalities as well as abnormal blood vessel formation. CXCR4 and SDF-1 play major roles in B-cell development and in bone marrow colonization by HSC from fetal liver during ontogenesis. Thus, SDF-$1^{-/-}$ embryos have a marked defect in marrow myelopoiesis, whereas fetal liver myelopoiesis is normal.[216,217]

Besides its chemoattractive effect, SDF-1 is a growth factor for HSC.[218,219] MK progenitors and MK express CXCR4 which increases with maturation.[220] Despite increased expression, mature MKs respond poorly to SDF-1, at least in chemotactic assays.[120,121] SDF-1 has a synergistic effect with growth factors such as TPO on MK colony formation. It can directly affect MK polyploidization and maturation, increasing proplatelet formation.[221] High SDF-1 or fibroblast growth factor-4 expression can restore normal platelet production in $TPO^{-/-}$ and c-$mpl^{-/-}$ mice. This effect is not direct and is related to the chemoattraction of MK precursors toward a hematopoietic vascular niche that is permissive for MK maturation.[114] Therefore, TPO-independent platelet production may not be directly related to a specific cytokine, but rather to the interaction of megakaryocytic cells with the bone marrow environment and endothelial cells.

Bone morphogenic protein 4 (BMP4). BMP4 belongs to the TGF-β family that regulates cellular events such as differentiation, migration, adhesion, and apoptosis. BMP4 is able to regulate human MK differentiation by interfering with TPO signaling through the JAK/STAT and mTOR pathways. In the absence of TPO, BMP4 is able to induce $CD34^+$ progenitor differentiation into MK through all stages. TPO uses the BMP4 pathways to induce megakaryopoiesis. In addition, TPO upregulates the BMP4 autocrine loop by inducing BMP4 production by MK progenitors and upregulates BMP receptor expression.[222]

Inhibitory Factors

It became evident through MK colony assays that the MK lineage was different from the erythroid or granulocytic lineages because MK colony formation was partially inhibited by serum in a dose-dependent manner. However, serum derived from platelet-poor plasma had no effect,[223] implying that platelets store and secrete factors that inhibit megakaryopoiesis. It was subsequently found that these inhibitory proteins are present in platelet α-granules and consists of four different proteins: *TGF-β*, PF4-associated peptides, β-thromboglobulin, and connective tissue activating peptide (CTAP-III).[224,225]

The inhibitory effect of TGF-β on megakaryopoiesis is extremely potent,[224] but is not specific for megakaryopoiesis as all primitive hematopoietic progenitors, including HSCs, are inhibited.[226] Nonetheless, the effects of TGF-β on the MK lineage differ from those observed in other cell lines since TGF-β not only inhibits MK progenitor growth but also the endomitotic process and cytoplasmic maturation.[227,228] The inhibitory effect may be related to inhibition of TPO signaling.[229] Treatment of mice for 7 to 14 days with TGF-β1 induces a 95% reduction in the platelet count, as well as anemia and an increase in granulopoiesis.[230]

PF4, β-thromboglobulin, and CTAP-III belong to the chemokine family and are able to bind heparin. Their inhibitory effects may be related to a common dodecapeptide sequence, Asn–Gly–Arg–Lys–Ile–Cys–Leu–Asp–Leu–Glu–Ala–Pro.[224] Injection of PF4 into mice induces thrombocytopenia. *In vitro*, PF4 inhibits MK progenitor proliferation, MK polyploidization, and proplatelet formation. However, its effect on megakaryopoiesis is nonspecific. Similar to other members of this family, such as MIP-1α, PF4 acts on primitive hematopoietic cells and may also inhibit angiogenesis.[231] PF4 appears to exert its effect through low-density related protein-1, which is present on large, polyploidy MK and nearly absent from MEP and platelets.[232]

Thrombospondin 1 may inhibit MKs *in vitro* by binding to CD36.[233] Other cytokines such as interferons and TNF-α also inhibit megakaryopoiesis *in vitro*.[234,235] Finally, the Notch ligand, Delta4, also inhibits the terminal differentiation of human MKs,[236] whereas it may favor MK commitment at an early stage of megakaryopoiesis.[237]

The physiologic relevance of platelet inhibitory molecules on platelet production is currently unknown. These molecules could play a role in a feedback regulation process and could be involved in the mechanisms that render platelet production dependent on the platelet mass.

CONCLUSION

Megakaryopoiesis, the cellular process responsible for platelet production, is part of the general hematopoietic proliferation and differentiation process that takes place in the bone marrow. It takes an average of 1 week for an undifferentiated bone marrow stem cell to give birth to mature platelets. Megakaryopoiesis has a number of unique features when compared to the other hematopoietic cell lines. These include:

- Proximity to the erythroid lineage during the early steps of differentiation
- A switch during differentiation from DNA duplication followed by cytokinesis to DNA duplication without cytokinesis, leading to a polyploid cell with a single polylobulated nucleus. This process is quasi-obligatory during differentiation, in contrast to many other cell systems where polyploidization is a stress response
- A complex cellular process leading to platelet release into the blood

Platelets are born from the cytoplasmic fragmentation of MK via a regulated and dynamic process with intermediary proplatelet formation. The number of platelets formed is not the direct reflection of MK number but of MK mass. Nonetheless, the precise mechanism and site in the human body where platelets are released from mature MK still remain to be established.

CHAPTER

24

Megakaryocyte Structure and Platelet Biogenesis

JOSEPH E. ITALIANO, JR. AND JOHN H. HARTWIG

INTRODUCTION

The process of making platelets is both amazing and bewildering. In the humans, 10^8 megakaryocytes are born each day, as the same number of mature megakaryocytes move to the bone marrow sinusoids and undergo terminal differentiation to release 10^{11} platelets. The ability to culture megakaryocytes, primarily from mice, and follow their maturation and platelet production *in vitro*, is beginning to provide information on the sequence of events leading to platelets and the molecules that regulate and power this process. In general, proplatelet and platelet production are driven by microtubule assembly and sliding, while mature platelet-based hemostasis is an actin-controlled process. In this chapter, we summarize the current knowledge of how megakaryocytes subfragment into platelets.

HISTORY/THE PROPLATELET MODEL

The process by which platelets are generated has been studied for over 100 years. In 1869, Italian biologist Giulio Bizzozero described a "cellule gigantic" up to 45 μm in diameter. However, it was not until 1906 that James Homer Wright discovered that platelets derive from these large precursor cells called megakaryocytes.[1] Wright established that platelets did not emerge in embryos until megakaryocytes appeared and demonstrated platelets coming off the cortex of megakaryocytes in the human, dog, rabbit, guinea pig, pig, and opossum. Many different theories have been proposed to explain how megakaryocytes produce platelets. Early microscopists documented that maturing megakaryocytes became filled with membranes, called demarcation membranes, and hypothesized that this membrane system divided the cytoplasm into "platelet territories" in which individual platelets were formed.[2,3] Release was postulated to occur by the complete fragmentation of the megakaryocyte cytoplasm into thousands of platelets. Later, it was observed that megakaryocytes extend long processes called proplatelets whose shafts are decorated with platelet-sized beads.[4,5] The classical "proplatelet theory" of platelet production was introduced by Becker and De Bruyn who first proposed that megakaryocytes extend long, sinus processes that fragment into platelets.[6] Later, Radley and Haller developed the "flow model," postulating that platelets derived from bead-like structures connected by thin cytoplasmic bridges.[7,8] Proplatelets have been observed both *in vitro* and *in vivo* across species and the bulk of experimental evidence now supports the involvement of proplatelets in platelet production.[9,10,11–14,15] Although the basic idea that proplatelets give rise to platelets is correct, the precise mechanism of platelet release has only recently been established.

CYTOPLASMIC MATURATION

As megakaryocytes mature in the bone marrow, they customize their cytoplasm and membrane systems for platelet formation. Before a megakaryocyte has the capability to produce platelets, it expands significantly to diameters of 50 to 100 μm and fills its cytoplasm with high levels of ribosomes producing platelet-specific proteins. Multiple rounds of endomitosis, a process that amplifies the DNA content by as much as 64-fold, facilitate this rapid cytoplasmic expansion.[16–18] In addition to DNA expansion, megakaryocytes undergo considerable maturation as internal membrane systems, organelles, and granules are assembled during their development. In particular, their cytoplasm, except for the most cortical regions, becomes densely filled with an expansive and interconnected membranous network of flattened cisternae and tubules[19] (FIGURE 24.1) This unique internal membrane system was initially called the demarcation membrane system (DMS) and as mentioned above was thought to divide the megakaryocyte cytoplasm into fields where individual, preformed platelets would assemble and release. This theory of cytoplasmic fragmentation as a mechanism for platelet biogenesis has lost support and DMS membranes are now thought to function primarily as a reservoir that continuously provides membrane for the growth of proplatelets.[8,20,21]

OVERVIEW OF PROPLATELET PRODUCTION

The discovery of thrombopoietin (Tpo) in 1994 has permitted major advances in the study of thrombopoiesis.[22–25] Tpo has facilitated the development of methods to culture bone marrow cells committed to the megakaryocyte lineage and that have successfully reconstituted the transition of terminally differentiated megakaryocytes into functional platelets *in vitro*. Megakaryocytes cultured in the presence of Tpo extend numerous proplatelets, consistent with the flow model. These proplatelets are structurally similar to those seen *in vivo* extending into bone marrow sinusoids and within the bloodstream.[9,10,26] Platelets released from megakaryocytes grown *in vitro* are also structurally and functionally similar to those found *in vivo*. Culture-derived platelets are of 2 to 3 μm diameter, disc-shaped fragments containing a microtubule-based marginal band and are responsive to platelet agonists.

Video microscopy has revealed the spatial and temporal changes leading to the generation of proplatelets[26] (FIGURE 24.2A–C). The production of platelets from megakaryocytes involves an elaborate process that converts the megakaryocyte cytoplasm into long, branched proplatelets upon which platelets are assembled. The process begins at a single position

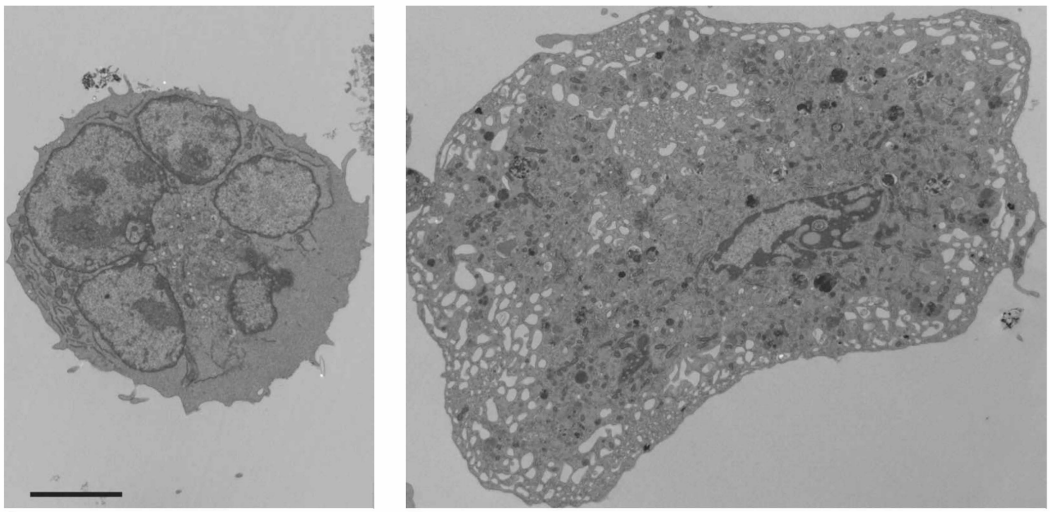

FIGURE 24.1 Maturation of the megakaryocyte DMS. **A:** Thin-section electron micrograph showing an immature mouse megakaryocyte that lacks a well developed internal membrane system. **B:** An extensive and interconnected system of internal membranes and channels that are connected to the plasma membrane characterizes the mature mouse megakaryocyte. The bar is 5 μm.

on the megakaryocyte plasma membrane. From this region, a large pseudopod forms, initially as a thickening of the plasma membrane. Over 4 to 8 hours, the pseudopod continues to extend and narrow into a tubule with an average diameter of 2 to 4 μm. Multiple bulges, termed swellings, each similar in size to a platelet, form along the length of the proplatelet, giving them the appearance of beads connected by thin bridges (FIGURE 24.2D). A teardrop-shaped tip develops at the proplatelet terminus and is believed to be the primary site of platelet maturation. Formation of additional proplatelets continues from the original erosion site and spreads in a wave-like manner throughout the remains of the cell until the megakaryocyte cytoplasm is entirely converted into an extensive and complex network of interconnected proplatelets. The multilobed "naked nucleus" remains in the megakaryocyte cell body as it is transformed into proplatelets. The events involved in platelet release from proplatelets are described below.

THE CYTOSKELETAL MECHANICS OF PLATELET PRODUCTION

The Cytoskeleton of the Resting Platelet

As discussed in Chapter 23, resting blood platelets have a well-defined microtubule cytoskeleton that functions to maintain the discoid shape of the resting platelet, as well as a robust filamentous (F)-actin cytoskeleton that both stabilizes the resting cells and is reorganized to generate the active shapes of spread platelets.[27–29] The microtubule skeleton is composed of an approximately 100 μm long microtubule and multiple dynamic short microtubules that shape the platelet into its discoid form by coiling around the edge of the cell.[30,31] In megakaryocytes, this microtubule cytoskeleton is the "engine" of platelet production (FIGURE 24.3). In the resting platelet, an actin-based membrane skeleton also plays a major role in stabilizing the discoid structure and in organizing the topology of surface receptors.[32,33] Hence, to understand the ultimate steps in platelet release, knowledge of the structure of the actin membrane skeleton in the resting platelet is essential.

Although the actin cytoskeleton of cells is complex, four proteins are critical in defining the architecture of the platelet membrane: spectrin, filamin, the von Willebrand factor receptor (vWfR), and F-actin. Spectrin forms a planar network linked together by the ends of F-actin to support the plasma membrane.[33,34,35] Disruption of spectrin tetramers (the functional unit of spectrin) prevents proplatelet elaboration and destabilizes released forms. Filamin links the GP1bα subunits of the vWfR to underlying F-actin.[32,36,37] The importance of the filamin–vWfR interaction has been established in both humans and mice where loss of expression of either molecule in platelets results in macrothrombocytopenia and bleeding.[38,39]

Two isoforms of filamin are expressed in platelets.[40–43] The most abundant isoform, filamin A (flnA), is expressed at a concentration of 5 μM (12,000 molecules per platelet). FlnA is in 20-fold molar excess over the second isoform filamin B.[44] Expression of FlnA increases dramatically in megakaryocytes in culture on days 2 to 4, particularly on day 4 when proplatelet formation begins. FlnA and FlnB are large elongated homodimers whose monomers are assemblies of an amino-terminus high-affinity actin-binding site followed by 24 Ig-like repeats, each composed of seven runs of β–structure.[45,46] Repeats 15 and 16 and repeats 23 and 24 are interrupted by hinge regions that are sites for calpain cleavage. Repeat 24 self-associates to dimerize the subunits.

In addition to binding and cross-linking F-actin, filamin molecules are scaffolds for the binding of additional proteins, including GP1bα, β–integrin tails, FilGAP, ralA, migfilin, and Syk.[47] The interaction of flnA with GP1bα is now understood at the atomic level. Binding occurs between a short run of

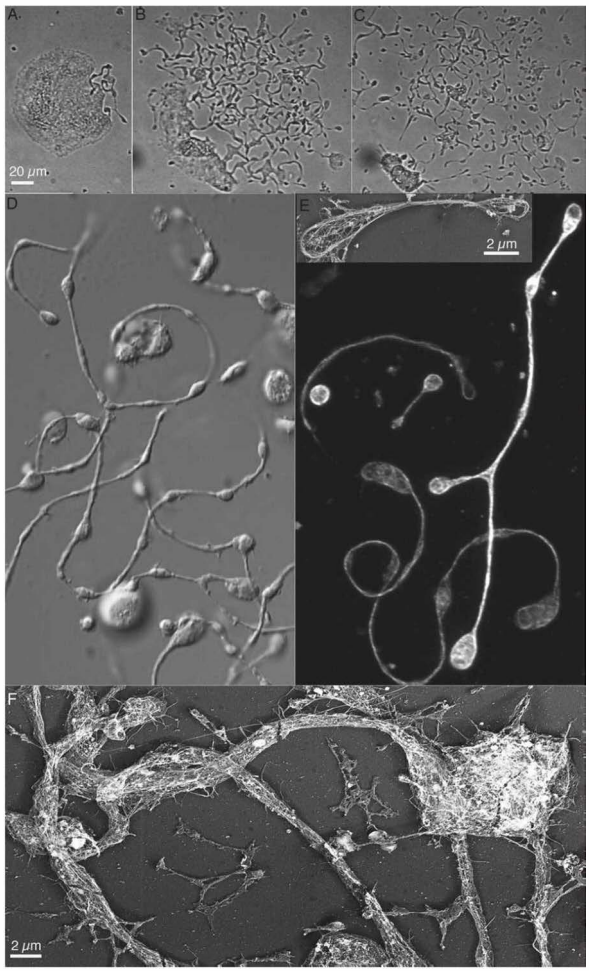

FIGURE 24.2 Visualization of production of platelets by megakaryocytes. **A:** Time-lapse sequence of a maturing megakaryocyte, showing the events that lead to the formation of proplatelet intermediates *in vitro*. Platelet formation initiates when the megakaryocyte begins unraveling at one pole. The bar is 25 μm. **B:** The bulk of the megakaryocyte cytoplasm has been transformed into multiple proplatelets. Proplatelets are highly dynamic and undergo extensive bending and branching. **C:** Proplatelets elongate and thin until the bulk of the megakaryocyte cytoplasm has been consumed. **D:** Differential interference contrast image of proplatelets elaborated by mouse megakaryocytes in culture. **E:** Proplatelets stained with antitubulin antibodies reveal the organization of its microtubules. Microtubules line the length of proplatelets and form coils only at the ends of the proplatelets. **Inset:** Low magnification electron micrograph showing the microtubule-based cytoskeleton of a representative released proplatelet. **F:** Undercoat structure of the proplatelet. The plasma membrane of the proplatelet tube is supported by a fibrous, spectrin-based membrane skeleton that is similar in structure to the membrane skeleton of resting platelets.

β–strand in the GP1bα cytoplasmic tail (amino acids 566 to 577) and two of the β–strands in flnA repeat 17; the GP1bα site binds in an antiparallel fashion between a groove formed between the C and D β–strands of FlnA.[36,37,48] FlnB shares the identical GP1bα binding site. Tight binding between these two proteins requires each GP1bα subunit in a vWfR to be bound to each repeat 17 in a filamin molecule. As there are 25,000 GP1bα chains expressed on the surface of a platelet, the stoichiometry for this interaction is ideal, and biochemical experiments have demonstrated that 90% to 95% of GP1bα is bound constitutively to flnA.[49] The stoichiometry of GP1bα binding to filamin is 1:1. Moreover, biochemical experiments indicate that 90% to 95% of GP1bα is bound constitutively to flnA.[49]

In turn, filamin is linked to underlying F-actin. This interaction organizes the topologic arrangement of the vWfR on the surface of mature platelets, and presumably on the surface of maturing proplatelets and preplatelets, as well. The final result is a linear alignment of vWfR on the platelet surface, a process that stabilizes and adheres the spectrin membrane skeleton to the plasma membrane.[50] The ends of actin filaments are bound on their sides at multiple points by flnA and on their ends by the spectrin tetramers where they cross-link the spectrin strands into a two dimensional lamina under the cytoplasmic surface of the plasma membrane. Curiously, platelets express both erythroid and nonerythroid spectrins.[33,34,35] This maybe due, in part, to the common stem cell origin of platelets and red blood cells or to the necessity of coping with membrane deflections during blood flow in similar fashion to erythrocytes; however, heterodimers of nonerythroid spectrin have lower affinity for one another compared to the nonerythroid molecules. This allows them to undergo dynamic association-dissociations *in situ*.

When and how the GP1bα and F-actin connections are established during platelet formation remains to be established. Failure to express either flnA or GP1bα results in platelets that are approximately three times larger than normal platelets and are extremely fragile, resulting in their rapid clearance from circulating blood.

Extension of Proplatelets is Powered by Microtubules

Proplatelet formation is dependent on microtubules because exposure of megakaryocytes to drugs that disassemble microtubules, such as vincristine and nocodazole, blocks proplatelet production.[8,11,15,51] Microtubules, polymers assembled from tubulin dimers, are the major structural component of the engine that powers proplatelet extension. Each microtubule is 25 nm in diameter and composed of a circular assembly of 13 protofilaments. Examination of the microtubule cytoskeletons of megakaryocytes in the act of producing proplatelets provides clues as to how microtubules power platelet development.[26,52] The microtubule cytoskeleton undergoes a dramatic remodeling during proplatelet formation. In immature megakaryocytes, microtubules emanate from the center of the cell to the cortex. During the initial stage of proplatelet formation, as blunt pseudopodia form, cortical microtubules consolidate into thick bundles positioned just beneath the plasma membrane. The pseudopodia then elongate at an average rate of 0.85 μ/min and microtubules form linear arrays that line the entire length of the proplatelet extensions. The microtubule bundles are thickest in the proplatelet near the cell body of the megakaryocyte, but thin to bundles of 5 to 10 near the proplatelet tips. The distal end of each proplatelet always contains a microtubule bundle that loops just beneath the plasma membrane and reenters the shaft to form a teardrop-shaped structure (FIGURE 24.2D,E).

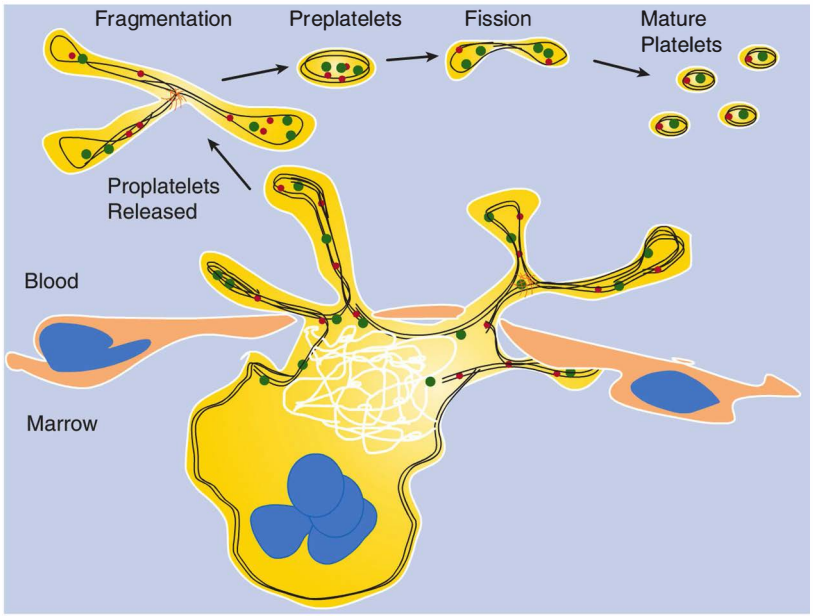

FIGURE 24.3 Proplatelet model of platelet production. Megakaryocytes mature in the bone marrow. In the final stage of development, megakaryocytes mature their cytoplasm, granules, and DMS and move near the marrow sinusoids. Proplatelets are elaborated, many of which, protrude through the sinusoids and release into the flowing blood. Proplatelet production begins with the generation of large pseudopodia that elongate and form thin proplatelet processes with bulbous ends. The proplatelet ends contain a peripheral bundle of microtubules that loops upon itself to form a teardrop-shaped structure. Sliding of overlapping microtubules powers proplatelet elongation as organelles are moved individually over microtubules into proplatelet tips. In the marrow, or in blood, proplatelets mature by fragmentation into smaller sized proplatelets until they reach sizes that can release 2 to 10 platelets, called preplatelets. Microtubule dynamics cause preplatelets to take on barbell shapes that ultimately undergo fission and release the mature platelets from their ends.

Megakaryocytes express different β–tubulin isoforms, but the divergent, hematopoietic b1 isoform is dominant (Table 24.1). β1-tubulin is expressed exclusively in megakaryocytes and platelets during the late stages of megakaryocyte development and several observations reveal it is essential for the generation of normal platelet numbers, as well as the disc shape of platelets.[53] First, β1 tubulin is a downstream effector of the megakaryocyte transcription factor NF-E2.[54] Second, genetic elimination of the β1-tubulin gene in mice causes thrombocytopenia and circulating platelets are spherical, not discoid.[55] Third, megakaryocytes derived from β1-tubulin knockout mice do not form proplatelets in culture and instead extend only a small number of short protrusions.[55]

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided insights into how microtubules orient to power proplatelet elongation.[52] End-binding protein 3 (EB3), a microtubule plus end-binding protein associated only with growing microtubules, when fused to GFP and retrovirally expressed in murine megakaryocytes, can be used as a marker to locate microtubule plus ends and follow plus-end dynamics (FIGURE 24.4). Immature megakaryocytes without proplatelets employ a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosome and grow outward into the cell cortex where they turn and run in parallel with the cell edges. However, just before proplatelet production begins, centrosomal assembly ends and microtubules release and consolidate into the cortex as bundles. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP revealed that as proplatelets elongate, microtubules assembled continuously throughout the entire proplatelet. The EB3-GFP studies also revealed that microtubules polymerize in both directions in proplatelets, for example, both toward the tips and cell body, demonstrating that microtubules composing the bundles have a mixed polarity.[52] How is this microtubule polymerization regulated? Ran binding protein (RanBP10) is a β1-tubulin binding factor that concentrates on proplatelet microtubules and may regulate microtubule assembly.[56] RanBP10 contains a guanine nucleotide exchange factor (GEF) activity for related nuclear protein (RAN). To nucleate microtubules, the GEF RCC1 loads Ran with GTP, leading to the activation of Tpx2, a factor that carries positional information for microtubule nucleation (FIGURE 24.4). Accordingly, RanBP10 depletion in megakaryocytes causes disruption of microtubules.[57]

Even though microtubules are continuously assembling at their plus ends in proplatelets, polymerization *per se* does not provide the force for proplatelet elongation. Proplatelets possess an inherent microtubule sliding mechanism. Cytoplasmic dynein, a minus end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding, since inhibition of dynein through disassembly of the dynactin complex prevents proplatelet formation.[52] Microtubule sliding can also be reactivated in detergent-permeabilized proplatelets. ATP, known to

Table 24.1

Specific molecules involved in thrombopoiesis

Polymer System	Protein	Function	MK KO Phenotype	PP KO Phenotype	Platelet KO Phenotype	Reference
Microtubules	B1-tubulin	Main MT component		Decreased in formation	Decreased platelets, spherical platelets	55
Microtubules	EB-1, EB-3	Promotes + end assembly				52
Microtubules	RanBP10	Ran GEF	MT disruption			57
F-actin	Filamin	Cross-link F-actin, scaffold signaling proteins, link GP1bα to actin	Altered DMS *in vitro*, *in vivo* 5–10× more megakaryocytes	Accelerated formation of large proplatelets	Fragile and large platelets, short circulation times	77
F-actin	GP1bα	vWf binding		Blockage of preplatelet maturation	Fragile and large platelets, short circulation times	39
F-actin	Myosin II	Clot retraction, actin contraction	Abnormal inclusions	Accelerated formation	Decreased formation	59
F-actin	Spectrin	Stabilize membranes	No KO but expression of dimerizing fragment disrupts DMS	Stops proplatelet elaboration		26
F-actin	Cofilin	F-actin turnover	Unknown	Unknown	Macrothrombocytopenia—platelets filled with F-actin	78
F-actin	ADF				Small platelets	78
F-actin	Rac/cdc42 CalDAG-GEF Kindlin Rab27b Dynamin 3	Regulate actin assembly RapGAP Integrin	 Over expression increases ploidy in megakaryocytes	 Dominant negative reduces PP formation *in vitro*	Mild thrombocytopenia Normal numbers, poor integrin inside- out activation Diminished integrin inside-out signaling	79, 80 Bergmeier 81 82 83

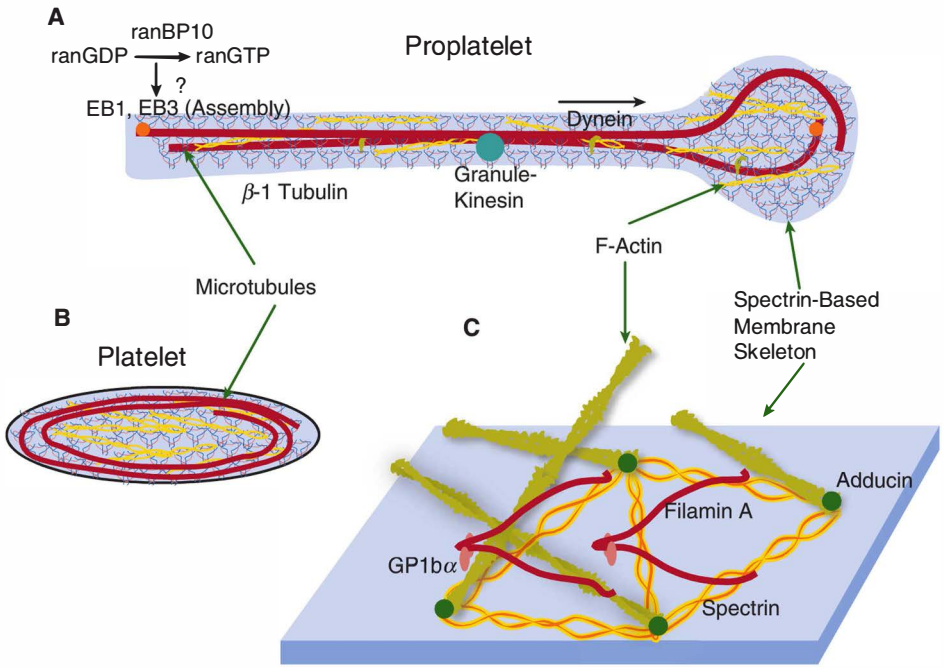

FIGURE 24.4 Cytoskeletal systems that form and stabilize proplatelets and platelets. **A:** Cytoskeleton of the proplatelet. Proplatelets are protruded from the megakaryocyte cell body by microtubule-based forces. Microtubules are assemblies of αβ-tubulin dimers. β1-tubulin is unique to the megakaryocyte lineage and is the major isoform expressed. In proplatelets, microtubules are organized into bundles that run from the cortex of the megakaryocyte into the shafts of proplatelet. These bundles are composed of multiple microtubules having mixed polarity. Individual microtubules are highly dynamic, continuously undergoing assembly-disassembly reactions. Assembly occurs at the plus end of microtubules and is promoted by end-binding proteins such as EB-1 and EB-3. The ends of proplatelets are enlarged and contain loops of microtubules. Elongation of proplatelets is driven primarily by cytoplasmic dynein, which attaches to one microtubule and slides a second past. Small GTPases such as Ran are upstream in these reactions. RanGDP is converted to RanGTP by the ranBP10 GEF. The microtubule bundles are also the tracks used by kinesin-coated granules that move up and down the proplatelet shafts. Proplatelets also have a spectrin-based membrane skeleton **(C)** that is required to stabilize the protruded forms. **B:** The mature platelet. Fission of preplatelets is mediated by the sliding apart of microtubules in the shafts of the preplatelet barbell forms and by their rolling into a coil to define the mature platelet and provide it with a discoid shape. **C:** The membrane skeleton of preplatelets and platelets. A two-dimensional lamina of spectrin tetramers coats the cytoplasmic surface of the plasma membrane. This network is interconnected by the barbed ends of actin filaments that are targeted to spectrin by bound adducin molecules. This network is tightly laminated to the plasma membrane by connections between the sides of actin filaments and the vWfR. These connections are made by fInA molecules that bind to both F-actin and the GP1bα chain of the vWfR.

support the enzymatic activity of microtubule-based molecular motors, activates elongation in permeabilized proplatelets that contain dynein and its regulatory complex, dynactin. Thus, dynein-facilitated microtubule sliding appears to be the key event in driving proplatelet elongation.

Transport and Packaging of Organelles/Granules is Microtubule-Dependent

Nascent platelets, maturing at the proplatelet tip, must ultimately be loaded with their allotment of granules and organelles prior to release. Central to the principle that proplatelets are the precursors of platelets is the requirement that granules/organelles have the ability to move sizable distances from the megakaryocyte cell body. In some cases, these granules/organelles must travel approximately 0.5 mm, a serious challenge to the distribution system. Organelles move individually and bidirectionally along the microtubules of proplatelets by two major mechanisms: (a) translocation of granules over microtubule tracks, and (b) attaching granules to and sliding them with microtubules.[58] However, measurements of the velocity of granule/organelle movement leads to apparent paradoxes because granule/organelle movement is extremely slow relative to the 4 to 8 hours needed to complete proplatelet and platelet formation and because granule/organelle movement changes directions frequently. Thus, although the transport mechanism effectively moves granules/organelles into proplatelets, it does not seem capable of producing rapid unidirectional delivery to proplatelet ends. One solution to this problem employed by the megakaryocyte is to detach the proplatelet and also use the fragmented end for platelet production. A second solution is to sequentially reduce the length of the proplatelet by inward trimming from the ends as platelets release, consequently shortening the distance that granules/organelles must travel. Once granules

arrive in the vicinity of the proplatelet ends, they are captured by the microtubule coil in the nascent platelets and concentrated at the tips.[58] It is also likely that megakaryocytes use some type of counting mechanism to ensure that each platelet receives its correct number of granules and essential organelles.

Amplification of Proplatelet Ends is Driven by Actin

Because platelet maturation is limited to proplatelet tips, efficient platelet production requires generation of large numbers of ends. Analysis of live action video microscopy of proplatelet formation from cultured megakaryocytes has revealed that ends of proplatelets are increased in a dynamic process that repeatedly bends and branches the shaft of the proplatelet.[26] End amplification begins when a proplatelet shaft is bent into a sharp kink, which then folds back on itself, forming a loop in the microtubule bundle. The new loop ultimately elongates, forming a new proplatelet shaft branching from the side of the original proplatelet. Loops lead the proplatelet tip, define the site where nascent platelets will assemble, and where organelles and granules are trafficked. Megakaryocytes treated with the actin inhibitors latrunculin or cytochalasin can only extend long, unbranched proplatelets that are decorated with few swellings along their length.[26] Despite extensive characterization of actin filament dynamics during platelet activation, how actin participates in this reaction and the cytoplasmic signals that regulate bending are not understood. Electron microscopy and phalloidin staining of megakaryocytes undergoing proplatelet formation indicate that actin filaments are distributed throughout the proplatelet and are particularly concentrated within swellings and at proplatelet branch points. One possibility is that proplatelet bending and branching is powered by the actin-based molecular motor myosin. Interestingly, a mutation in the nonmuscle myosin heavy chain-A gene in humans produces the May-Hegglin anomaly, a macrothrombocytopenic disorder.[59,60] Protein kinase Cα also associates with aggregated actin filaments in megakaryocytes undergoing proplatelet formation, and inhibition of protein kinase Cα or integrin signaling pathways prevent actin filament aggregation and proplatelet formation in megakaryocytes.[61] Nonetheless, the function of actin filament dynamics in platelet biogenesis remains to be clarified.

Expression, Assembly, and Importance of the Megakaryocyte Membrane Skeleton

The plasma and demarcation membranes of megakaryocytes are supported by an elaborate skeleton system. The major component of this system is a planar spectrin network. This plasma membrane undercoat structure is made up of spectrin strands crosslinked by actin filaments. Spectrin strands bind to the ends of actin filaments to assemble a continuous mesh-like structure beneath the plasma membrane (FIGURE 24.4C). Pores in this network have a triangular shape and are similar to those observed in the well-characterized erythrocyte membrane skeleton. However, the organization is somewhat different to that found in the red blood cell. The spectrin strands are bound to the ends of long actin filaments instead of short actin oligomers. Electron microscopy reveals that proplatelets, like circulating platelets, have a dense membrane skeleton whose main fibrous component is spectrin (FIGURE 24.2F), although unlike other cells, megakaryocytes and their progeny express both erythroid and nonerythroid spectrins. Assembly of spectrin into tetramers is required for DMS maturation and proplatelet extension, as expression of a spectrin tetramer–disrupting construct in megakaryocytes inhibits both processes. Incorporation of this spectrin-disrupting fragment into a novel octyl glucoside-permeabilized proplatelet system rapidly destabilizes proplatelets, causing blebbing and swelling. Spectrin tetramers also stabilize the "barbell-shapes" of the penultimate stage in platelet production (see section, *The Final Stage Of Platelet Production-Release*), since addition of the tetramer-disrupting construct converts these barbell-shapes to spheres.

THE INFLUENCE OF THE BONE MARROW NICHE ON THROMBOPOIESIS

Megakaryocytes cultured outside of the bone marrow can form highly developed proplatelets in suspension, demonstrating that direct interaction with the bone marrow niche is not a requirement for platelet production. Nonetheless, the efficiency of platelet generation *in vitro* appears to be reduced relative to that observed *in vivo* and the bone marrow environment composed of a complex adherent cell population may play a role in platelet production by direct cell contact or secretion of cytokines. Scanning electron micrographs of bone marrow megakaryocytes extending proplatelets through junctions in the endothelial lining into the sinusoidal lumen have been published, suggesting platelet production occurs in the bone marrow.[4,7,62–64] Bone marrow megakaryocytes are strategically located in the extravascular space on the abluminal side of sinus endothelial cells and appear to send beaded proplatelet projections into the lumen of sinusoids. Electron micrographs show that these cells are anchored to the endothelium by organelle-free projections extended by the megakaryoctes.[65] Several observations suggest that thrombopoiesis is dependent on the direct cellular interaction of megakaryocytes with bone marrow endothelial cell–specific adhesion molecules.[66] It has been shown that the translocation of megakaryocyte progenitors to the vicinity of bone marrow vascular sinusoids is sufficient to induce megakaryocyte maturation.[67] The chemokines stromal cell–derived factor 1 and fibroblast growth factor 4 (FGF-4), known to stimulate expression of adhesion molecules such as very late antigen-4 on megakaryocytes and vascular cell adhesion molecule 1 (VCAM-1) on bone marrow endothelial cells, have been implicated in this process.[68,69] Disruption of bone marrow endothelial cell VE-cadherin–mediated homotypic intercellular adhesion interactions results in a profound inability of the vascular niche to support megakaryocyte differentiation and to act as a means to the bloodstream.

THE FINAL STAGE OF PLATELET PRODUCTION-RELEASE

Although *in vitro* systems have provided insight into platelet generation, the exact mechanism of platelet release *in vivo* is still highly debated. Megakaryocytes are produced in the bone marrow and may undergo fragmentation into platelets at this location. Bone marrow megakaryocytes positioned on the abluminal side of sinus endothelial cells have been visualized extending proplatelets into the vessel lumen, where they have been hypothesized to release into the circulation and undergo

further fragmentation into individual platelets. In 1998, Behnke and Forer proposed a model suggesting that the final stages of platelet maturation occur exclusively in the circulation. In this model of thrombopoiesis, megakaryocyte fragments released into the blood become transformed into platelets while in the circulation. This theory is supported by several observations. First, the presence of beaded megakaryocyte processes in circulating blood has been thoroughly documented.[70,71,72,73,74] Megakaryocyte fragments can make up to 5% to 20% of the platelet mass in plasma. Second, megakaryocyte fragments, when isolated from platelet-rich plasma, have been reported to elongate, undergo curving and bending motions, and eventually fragment to form disk-shape structures resembling chains of platelets.[70] Third, because both cultured human and mouse megakaryocytes can form functional platelets *in vitro*, neither the bone marrow environment nor the pulmonary circulation is essential for platelet production and release.[9,10,26]

Visualization of thrombopoiesis within the bone marrow of living mice also supports a model in which proplatelet morphogenesis continues in the blood. Using intravital fluorescence microscopy to examine the opened cranial marrow cavity of mice, living megakaryocytes have been visualized in the act of elaborating proplatelet processes into the vascular lumen.[75] Multiphoton intravital microscopy of intact bone marrow visualized proplatelet extensions protruding into microvessels, where they appeared to be sheared from their transendothelial stems by blood flow. Most of the shed fragments of megakaryocytes exceeded the dimensions of platelets, suggesting that proplatelet development continues in the blood to produce individual platelets.[75]

The cytoskeletal mechanics of proplatelet maturation and platelet release have recently been established.[76] By isolating released proplatelets and analyzing their conversion into individual platelets *in vivo* and *in vitro*, a new intermediate stage in platelet production, the preplatelet was identified. Preplatelets are anucleate discoid particles 3 to 10 μm across that have the capacity to convert reversibly into elongated proplatelets. The preplatelet to barbell proplatelet transformation is powered by twisting microtubule-based forces. Preplatelets can mature into platelets both *in vivo* and *in vitro*. Platelet release from the ends of proplatelets occurs at an increasing rate during culture as larger proplatelets undergo successive fission.[76] Shear forces accelerate proplatelet fission and individual platelet release in culture.

CONCLUSION

Megakaryocytes are highly specialized precursor cells that function exclusively to generate and release platelets. After completing endomitosis, polyploid megakaryocytes undergo a rapid cytoplasmic expansion phase characterized by the formation of an extensive DMS and the accumulation of cytoplasmic proteins and granules critical for platelet function. During the final stages of development, the megakaryocyte cytoplasm undergoes a massive remodeling in cytoplasmic extensions termed proplatelets. Proplatelets function as the assembly lines of platelet production. Microtubules, actin filaments, and the spectrin membrane skeleton all contribute to the formation of proplatelets and production of individual platelets.

CHAPTER

25 Thrombopoietin

KENNETH KAUSHANSKY AND IAN HITCHCOCK

HISTORY

The term erythropoietin (EPO) was coined at the turn of the last century to describe the humoral substance responsible for red cell production. At that point in time, blood platelets were barely distinguishable in the best microscopes, prompting their dismissal as "the dust of the blood." However, the pioneering work of Carnot, Wright, and others in the early 20th century defined the critical role of blood platelets in coagulation and their origin from the marrow megakaryocyte, ultimately prompting the Hungarian physician Keleman to coin the term thrombopoietin (TPO) to describe the humoral substance responsible for the recovery of platelet levels following thrombocytopenia.[1]

In the mid-1960s, several groups set out to purify TPO from the plasma of thrombocytopenic animals. At the time, the only reliable assay on which to base a purification strategy was the ^{35}S uptake assay, in which radioactivity incorporated into blood platelets of injected mice or rats served as a measure of thrombopoietic activity. This *in vivo* assay proved very cumbersome; the assay was too insensitive, costly, and time-consuming to be practical, and little progress was made. With the availability of *in vitro* megakaryocyte differentiation assays in the 1980s, additional purifications were attempted; nevertheless, although the availability of what was thought to be partially purified TPO helped to define its expected biologic properties,[2–4] none of the initial purification efforts led to amino acid determination or cloning of the molecule.

Occasionally in science, a finding from one field, although important in itself, can have a profound, catalytic effect on a seemingly unrelated area of research. The discovery and characterization of the murine myeloproliferative leukemia virus had such an influence on the search for TPO. The virus causes an acute myeloproliferative syndrome in infected mice.[5] In 1990, the responsible oncogene was cloned, and the protooncogene obtained 2 years later.[6,7] Based on the predicted presence of four spatially conserved cysteine residues and a juxtamembrane pentapeptide sequence (Trp–Ser–Naa–Trp–Ser), it was immediately evident that the cellular gene was a member of the hematopoietic cytokine receptor family,[8] which includes the receptors for EPO, the granulopoietic factors interleukin-3 (IL-3), granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage colony-stimulating factor (GM-CSF), and multiple lymphokines. However, in 1992 its ligand was unknown; *c-mpl* encoded an orphan receptor. Based on the origin of the *c-Mpl* cDNA, the bipotent erythroid/MK cell line HEL,[9] and on antisense *c-mpl* knock-out experiments demonstrating a significant reduction in megakaryocytes,[10] many groups postulated that the Mpl ligand might be identical to TPO.

THE CLONING OF THROMBOPOIETIN

While progress in understanding megakaryocyte biology and in purifying TPO was being made using the c-Mpl receptor, others had developed improved bioassays for TPO and continued to make efforts using conventional purification strategies. Using a modified *in vivo* assay in which the polyploidy of marrow megakaryocytes from injected rats was examined, Kuter et al.[11] performed an 11-step purification of ovine TPO, although the publication of this work did not report the cloning of the corresponding cDNA. In contrast, using an *in vitro* megakaryocyte assay, the scientists at Kirin Pharmaceuticals in a 12-step conventional purification scheme obtained sufficient plasma TPO from thrombocytopenic rats to obtain amino acid sequence and cloned cDNA for rat and then multiple species of the protein, including the human hormone.[12]

Using the *c-Mpl* protooncogene product coupled to affinity matrices, scientists at Genetech and at AMGen obtained microgram quantities of porcine and canine TPO, respectively, allowing their amino acid sequencing and cDNA cloning.[13] In contrast to the biochemical purifications utilized by these four groups, an expression cloning strategy was used by Lok et al.[14] to obtain cDNA for murine and then human TPO. In this approach a hematopoietic cell line, BaF3, that requires IL-3 for survival and proliferation, was engineered to express the *c-Mpl* protooncogene. In this way, if the c-Mpl ligand was present in the culture, the cells should remain viable and potentially proliferate after withdrawal of IL-3. The BaF3/mpl cells were chemically mutated and autonomously growing sublines were obtained; although most such sublines were producing their own IL-3, others were producing the c-Mpl ligand. This subline was used as source for cDNA library construction and an additional functional cloning strategy. Remarkably, the cDNA obtained from the above four groups, three of them cloned nearly simultaneously, all encoded the same polypeptide (except for species differences). Initial *in vitro* experiments using the corresponding recombinant proteins demonstrated the effect of each of these substances on megakaryocyte maturation, and injections into normal mice resulted in massive increases in peripheral blood platelet counts and marrow megakaryopoiesis. With these efforts TPO was finally cloned.

STRUCTURE OF THROMBOPOIETIN

The cloned human TPO cDNA encodes a polypeptide of 353 amino acids including the 21–amino acid secretory leader sequence.[15] The mature protein can be conveniently divided into two domains: the amino-terminal 154 residues bear striking sequence homology with EPO and bind to the mpl receptor; the

carboxyl-terminal domain bears no resemblance to any known proteins, but contains multiple sites of both *N*- and *O*-linked carbohydrate. This latter feature accounts for the large discrepancy between the predicted and actual molecular weight of the protein; approximately half of the 70-kDa TPO molecule is carbohydrate.

Based on its amino acid sequence, and like its closest homologue EPO, TPO is predicted to fold into a four-helix bundle protein. This prediction was recently confirmed with solution of the tertiary structure of the receptor-binding domain of TPO in complex with an anti-TPO monoclonal antibody.[16] Comparisons of the two proteins reveal striking similarities, but also some critical differences, likely accounting for the failure of the two hormones to cross react with the receptors for the other hormone.[17]

As noted, TPO can be conveniently divided into two domains based on homology to EPO; expression of a truncated version that represents the domain most homologous to EPO revealed that this amino-terminal half of the molecule is responsible for binding to and stimulation of the Mpl receptor.[18] However, the circulatory half-life of the isolated amino-terminal fragment is substantially shorter than the full length molecule, unless it is modified with polyethylene glycol.[19] In contrast to the stimulatory activity of the amino-terminal domain, the carboxyl terminal domain of TPO acts to enhance secretory efficiency of the protein; the level at which the isolated amino-terminal fragment is expressed from cells that normally produce TPO is reduced about 5- to 10-fold compared to the secretory level of the full length molecule.[20–22] Whether this is due to enhanced folding of the polypeptide, protection from intracellular proteolysis, or other mechanisms is presently under study.

Several investigators have attempted to ascertain the sites on TPO responsible for binding to its receptor. Using site-directed alanine scanning mutagenesis to study the functional activities of 40 solvent-exposed residues of the protein, monoclonal antibody epitope mapping, and a phage display-binding assay system, Pearce et al.[23] determined that the residues vital for hormone binding to c-Mpl are located in the first and fourth predicted α-helices of the molecule and the segment connecting the first and second helices, locations previously shown to be important for functional interactions in several other cytokine/receptor systems.[24] Subsequently, Jagerschmidt produced 20 TPO mutants and compared the mutants' ability to induce the proliferation of a c-Mpl-expressing cell line, M-07e, with that of wild-type TPO. Among the mutations that substantially reduced biologic activity, three were found located in the A helix of the protein (Arg10, Lys14 and Arg17) and four in helix D (His133, Gln132, Lys138, and Phe141). Moreover, they found that Arg10 and Arg17 seem to be specific determinants for TPO/c-Mpl recognition, although Pearce et al. failed to find any reduction in binding affinity of an Arg10 to Ala mutation. As these residues in EPO are Arg and Leu, respectively, the latter residue could help to explain the failure of the two cytokines to cross-react in receptor binding assays.[17]

THE REGULATION OF THROMBOPOIETIN EXPRESSION

As would be expected for the physiologic regulator of platelet production, plasma concentrations of TPO vary inversely with the platelet count in patients with marrow failure.[25] Northern blot analyses of multiple organs reveal that TPO is widely expressed, mRNA being present at highest levels in the liver of normal animals, but the kidney, smooth muscles, and a number of other organs also express transcripts for the hormone.[13,14,18] Based on the capacity of platelets to adsorb the hormone from its surroundings, internalize, and destroy it, Kuter and Rosenberg[26] and other investigators[27] have proposed that the regulation of TPO levels in plasma is dependent entirely on platelet numbers; in the presence of thrombocytosis, the steady-state level of hormone production is overwhelmed by platelet-mediated TPO removal and levels are low, and in states of thrombocytopenia, little of the same amount of TPO production is adsorbed, allowing levels to rise in order to stimulate thrombopoiesis. Initial findings of relatively low TPO levels in patients with immune thrombocytopenia (ITP) were explained by further postulating that the megakaryocytic hyperplasia seen in such states then accounts for the increased TPO adsorption. Ancillary data for this assertion come from the *tpo* hemizygous mouse[28]; loss of one allele of *tpo* leads to a 40% reduction in platelet counts. If active regulation of TPO exists, then increased expression from the second, normal allele should have corrected the reduction in hormone levels and reestablished a normal platelet count, much like what occurs in the EPO system.

These arguments not withstanding, a growing body of evidence suggests that additional mechanisms operate to affect TPO expression. At baseline, it is very difficult to detect specific mRNA in marrow cells. However, transcript levels can be substantially induced in marrow stromal cells in response to thrombocytopenia,[29–32] albeit at platelet levels lower than the 60% found in the *tpo* hemizygous mice. In addition, a number of inflammatory states are associated with TPO levels above that expected for their platelet count[33–35] although this finding has not been universal.[36] It has been shown that IL-6, a well known inflammatory response mediator, increases TPO production both *in vitro* and *in vivo*,[37–39] potentially helping to explain the enhanced levels seen in inflammatory and possibly other pathologic states.

The mechanism by which TPO production is regulated is coming under increased investigation. Using platelet granule proteins, Sungaran et al.[40] determined that the platelet α granule proteins PDGF-BB and FGF2 stimulated, and that platelet factor four, thrombospondin, and transforming growth factor-β inhibited TPO production from cultures of marrow stromal cells; on balance, whole platelet extracts suppressed TPO production. More recently, platelet granule proteins were shown to transcriptionally repress TPO mRNA expression in a marrow stromal cell line as well as in primary bone marrow stromal cell cultures. Like TPO mRNA, secretion of TPO protein was also suppressed by serum. Reporter gene constructs indicate that DNA elements located in an approximately 1.9 kb region between 250 bp upstream of the transcriptional initiation site and the middle of the second intron are able to mediate this transcriptional repression.[41] Thus, accumulating evidence indicates that marrow stromal cells can be induced by exogenous stimuli to produce TPO and help explain the response to inflammatory stimuli.

The *TPO* gene displays an unusual 5' untranslated region structure. Unlike the majority of genes that initiate translation with the first ATG codon present in the mRNA, TPO translation initiates at the eighth ATG codon in the transcript, located

in the third exon of a full-length mRNA (there are two transcription initiation sites that differ because of alternate splicing of the first exon).[42] As the eighth ATG is out of frame but embedded in the short open reading frame (ORF) of the seventh ATG, translation initiation is quite inefficient.[43] Thus, under normal circumstances, little TPO protein is produced for any given amount of mRNA. Although it is not yet certain whether this molecular arrangement has physiologic consequences (i.e., it can be differentially regulated), it is now clear from patients with familial essential thrombocythemia (ET) that mutation of the *TPO* gene in noncoding sequences can lead to enhanced translation efficiency and thrombocytosis. Several cases of autosomal dominant familial thrombocytosis have been linked to mutations in the region surrounding the initiation codon. In two families, a single mutation in different nucleotides of the intron three splice donor sequence results in alternate splicing of the primary transcript, eliminating the seventh and eighth ATG codons and creating a new amino-terminus by fusing of the fifth ORF with the hormone coding sequence. This novel TPO mRNA is efficiently translated resulting in supraphysiologic levels of hormone production and nonclonal expansion of thrombopoiesis.[44,45] In another mutant *Tpo* allele deletion of a single nucleotide within the seventh ORF leads to its fusion with the TPO coding sequence and now enhanced translation of TPO from the seventh ATG codon.[46] Finally, another mutation within the seventh ORF leads to its premature termination, preventing its interference with translation initiation from the usual eighth initiation codon[47] again enhancing protein production. The molecular mechanisms of diseases of mRNA translation have been summarized.[48]

MEGAKARYOPOIETIC ACTIVITIES OF THROMBOPOIETIN *IN VITRO*

As initially defined, TPO was thought to be a potent megakaryocyte differentiation factor but was not thought to influence cellular proliferation. However, as soon as recombinant protein was available it was established that in contrast to the partially purified samples thought to contain the hormone, TPO clearly acts to induce proliferation of megakaryocytic progenitor cells,[49] and in synergy with other cytokines, to support the proliferation of multiple types of immature hematopoietic progenitor cells.[50–53] From the initial studies of its biologic properties, it has been clear that TPO is a potent megakaryocyte colony-stimulating factor. Approximately 75% of a maximal number of megakaryocyte colony-forming cells can be induced to grow using optimal levels of TPO alone.[49,54] A number of other cytokines and hormones, including IL-3, kit ligand, EPO, and IL-11 also act in synergy with lower levels of TPO to promote megakaryocyte colony formation.[55] However, the hormone appears to exert its proliferative effect primarily on progenitors of limited developmental potential. The number of megakaryocytes present in each colony is greater for those that form in the presence of IL-3 or kit ligand, either alone or together with TPO, than in the presence of TPO alone. However, in the absence of the hormone, IL-3- or kit ligand-induced megakaryocyte formation is aborted; the cells display low ploidy values and poor cytoplasmic maturation.[54]

Serum-free suspension culture systems have been most useful for demonstrating the differentiative effects of the hormone on megakaryocytes. Using the recombinant protein several groups have established that TPO increases megakaryocyte cell size, shifts the cells to much higher ploidy classes, and enhances the expression of the lineage specific markers glycoprotein (gp)Ib and gpIIb/IIIa.[49,56–58] When examined under the electron microscope, TPO-induced megakaryocytes display prominent membrane production and numerous platelet specific granules, and the cytoplasm demarcates into regions destined to fragment into mature platelets.[49,54,56] When cultured slightly longer, especially in the presence of plasma, the cells form "proplatelet processes," and fragment into platelets that appear to function normally upon exposure to classic platelet agonists.[59] Moreover, this final process appears to be independent of TPO, instead being more dependent on a substance in normal plasma. One report suggests that the activity in plasma responsible for platelet formation is a complex of thrombin and antithrombin III.[60] At present, this report remains unconfirmed, so that the nature of a (regulatable) stimulus (if there is one) for the final stage of platelet formation is presently unclear.

One relatively consistent property of hematopoietic growth factors has been that the cytokine or cytokines that stimulate the production of a given cell lineage also activate or "prime" the resulting mature blood cells for activation in response to other signals.[61–63] Like that for IL-3, GM-CSF and G-CSF *in vitro* studies indicate that although incubation in the hormone leads to the priming of platelets to respond to an otherwise subthreshold level of classical platelet agonists,[64,65,66] TPO does not lead to frank platelet activation.

THROMBOPOIETIN AND THE HEMATOPOIETIC STEM CELL

Analogous to the lineage specific characteristics of EPO, the biologic properties of TPO were initially thought to be restricted to cells of the megakaryocyte lineage. Nevertheless, early studies of the biologic activities of the hormone included the stimulation of sorted $CD34^+$ cells.[56] As this population of cells includes megakaryocytic progenitors, it remained formally possible that the hormone was lineage restricted until two groups demonstrated that sorted marrow cells highly enriched in hematopoietic stem cells (HSCs) also survived in the presence of TPO alone, and proliferated in synergy with IL-3 or kit ligand.[52,53] Shortly after these *in vitro* findings were reported, genetic elimination of *c-Mpl* was found to result in a significant reduction in the number of hematopoietic progenitors of all lineages[67] and then using competitive repopulation, Solar et al.[68] demonstrated that the number of HSCs were reduced seven to eightfold in *c-Mpl* null mice. As it became appreciated that the congenital form of amegakaryocytic thrombocytopenia are due to a homozygous or mixed heterozygous mutation in the c-Mpl receptor locus, the role of TPO on stem cells has been extended to humans, as nearly all such children develop aplastic anemia due to dwindling numbers of stem cells within the first 2 to 5 years of life.[69,70,71,72] Consistent with this notion, we demonstrated that the self-renewal/expansion of HSCs is also vitally dependent on TPO, as transplantation of normal stem cells into *Tpo* null mice results in a 15- to 20-fold reduced level of stem cell expansion.[73] Thus, it is now clear that TPO joins kit ligand as the only cytokine that plays a nonredundant role in stem cell survival, self-renewal, and proliferation.

IN VIVO ACTIVITIES OF THROMBOPOIETIN

The effects of exogenous TPO on the kinetics of platelet production have been studied extensively. As would be expected from its megakaryopoietic effects *in vitro*, when TPO is administered to animals or people, the platelet count begins to rise after 3 to 5 days, depending on the dose and the recipient species.[13,14,18,74–79] These results indicate that TPO does not cause the immediate release of platelets from megakaryocytes, consistent with its failure to accelerate fragmentation of proplatelet processes, the long exvaginations of megakaryocyte cytoplasm felt to represent the most immediate platelet precursor.[59] Instead, TPO stimulates the development and maturation of new megakaryocytes. Once the size and numbers of megakaryocytes increase, the platelet count begins to rise until a new steady-state level is reached, the height of which depends on a log-linear relationship with the administered dose.[19] Due to a prolonged biologic effect (the result of its slow plasma clearance and action on both primitive and mature hematopoietic cells), enhanced platelet production resulting from parenteral administration of TPO occurs 6 to 16 days after a steady state level of the hormone is achieved.[79,80]

Given the panhematopoietic effects of TPO *in vitro*, careful attention was paid to all of hematopoiesis in animals administered the recombinant hormone; the *in vivo* effects of TPO were found to correlate with its *in vitro* properties. Administration of the hormone to either normal or myelosuppressed animals increased the numbers of all types of hematopoietic progenitor cells,[81] and genetic elimination of *Tpo* or its receptor causes a 65% to 95% reduction in number of transplantable stem cells and hematopoietic precursors of multiple lineages.[67] Thus, TPO should be thought of as a lineage-dominant panhematopoietic cytokine that plays multiple roles in blood cell production.

As noted above, a large body of evidence indicates that cytokines that stimulate hematopoietic cell production also activate the corresponding mature cell type. If this were also true for TPO, platelet activation and thrombosis could result. *In vitro* studies have indicated that the hormone primes platelets to aggregate in the presence of classical agonists, but does not, by itself, lead to platelet activation.[65] Studies performed *in vivo* are consistent with this conclusion; the administration of TPO to nonhuman primates[19] or humans did not result in *de novo* platelet activation,[78] and an excess of thrombotic complications has not been seen in multiple clinical trials of two forms of the hormone (see below). Nevertheless, these clinical trials have all avoided enrolling individuals with any history of pathologic thrombosis, as has the administration of FDA approved small molecule thrombopoietic agonists.

Despite this increased understanding of the vital role of TPO on thrombopoiesis, a remaining major question is what is responsible for the approximately 10% residual platelet formation present in mice and humans in which *Tpo* or its receptor are genetically altered. Based on the megakaryopoietic activities of IL-3, IL-6, IL-11, GM-CSF, and leukemia inhibitory factor, both *in vitro* and *in vivo*, in an attempt to identify the cytokine(s) responsible for residual platelet production in $Mpl^{-/-}$ mice, mice genetically deficient in *IL-3*, *IL6-R*, *IL-11-R*, or the combined signaling subunit of the IL-3, GM-CSF, and IL-5 receptors (β_C) were crossed to *Mpl* null animals; none of these double to quadruple cytokine/cytokine receptor deficient mice displayed more severe thrombocytopenia than found in the $Mpl^{-/-}$ mouse.[82–85] Whether another known (or possibly unknown) cytokine is responsible for the residual platelet production in the absence of TPO function, or as was suggested, this combination of the chemokine SDF-1, which displays a synergistic action on megakaryocyte growth[86] and endothelial cells.[87]

THE Mpl RECEPTOR AND MOLECULAR MECHANISMS OF TPO ACTION

The initial step in hematopoietic growth factor action is binding to its specific, cell-surface receptor. Recent studies of the response of many of these receptors have begun to provide molecular insights into cytokine-induced signaling. It is clear that protein tyrosine phosphorylation of the receptor itself, and several substrates is an integral part of the cellular response to hematopoietic growth factor stimulation, as protein tyrosine kinase inhibitors block the growth induced by many hematopoietic cytokines, and phosphatase inhibitors have the opposite effect.[88,89] However, the TPO receptor does not display any enzymatic activity; rather, cytokine receptors recruit cytoplasmic kinases to activate signaling molecules. The EPO receptor was the first member of the hematopoietic cytokine receptor family shown to recruit and activate a member of the Janus family of cytoplasmic tyrosine kinases (JAKs). Subsequent work has shown that JAK kinases mediate much of the secondary protein tyrosine phosphorylation triggered by the binding of hematopoietic growth factors to their corresponding receptors.[90,91] The role of other cytoplasmic kinases, such as src and the src-related kinases, in growth factor-induced signaling is also under active investigation.[92,93] Although many of the signals involved in thrombopoietic cytokine action are rapidly being identified, major challenges lie ahead in deciphering the molecular basis of signal specificity. For example, the cellular response generated upon TPO binding is distinct from that originating at the IL-3 receptor, but many of the same molecules are activated by both receptors; a thorough analysis of the specific patterns of signaling intermediates activated by each of the cytokines that act directly on megakaryocytes will be required to more fully understand the role played by each during thrombopoiesis.

Progress has been rapid in deciphering the signaling pathways employed by TPO. Because of its homology with EPO, and between c-Mpl and the rest of the cytokine receptor family, initial studies of TPO signal transduction concentrated on the JAK and signal transducers and activators of transcription (STAT) families of proteins. The first reports focused on leukemic cell lines that naturally express the c-Mpl receptor, or ones engineered to do so. These studies identified JAK2 and TYK2 as the immediate kinases that bind to c-Mpl and become activated on exposure to TPO.[94–102] Other proteins reported in various megakaryocytic cell lines to be phosphorylated in response to TPO include STAT3 and STAT5,[94,95,100,103,104] the adapter proteins Grb2,[100,101] Cbl,[101] and son of sevenless (SOS),[101] Shc and its related phosphatase SHIP,[95,100,101,105] phosphoinositol-3-kinase (PI3K) and its downstream kinase Akt,[64,106,107] an inhibitory transcription factor downstream of Akt, FKHRL-1,[108] the Raf-1/MAP kinase,[100,109,110] and hematopoietic cytokine receptor-related phosphatases such as SHPTP-2.[108]

In addition to determining the intracellular signaling pathways activated by TPO, much work has been performed to identify the site of the c-Mpl receptor from which each signal originates (summarized in FIGURE 25.1). For example, Tyr625

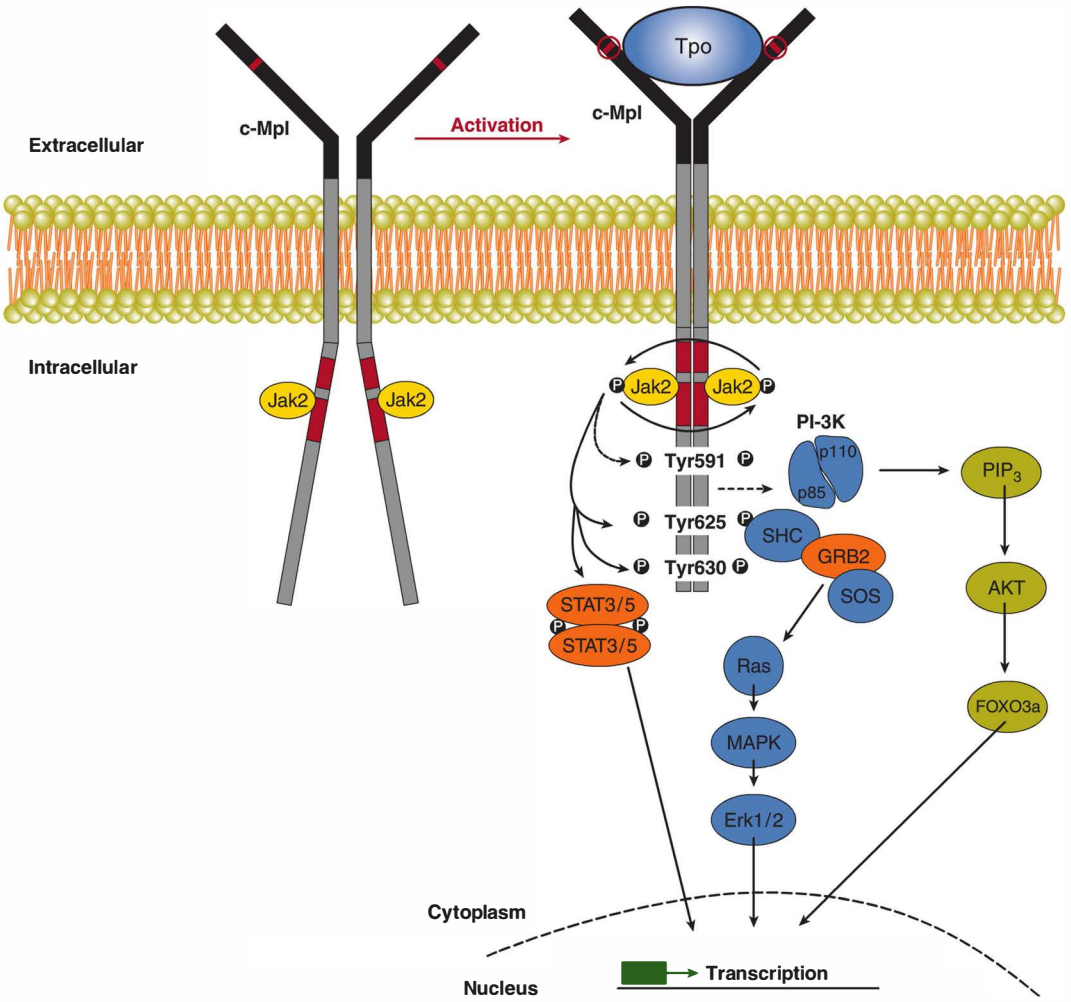

FIGURE 25.1 Schematic representation of c-Mpl signaling following TPO stimulation. TPO binding to its cognate receptor c-Mpl causes a conformation of the receptor homodimer, bringing associated Janus kinase (JAK) 2 proteins in closer juxtaposition, enabling their autophosphorylation. Activated JAK2 leads to phosphorylation and activation of signal transducers and activators of transcription (STAT) proteins and phosphorylation of c-homoogy domain-containing transforming protein (SHC)-1, which associates with growth factor receptor-bound protein (GRB) 2, and son of sevenless (SOS) to stimulate the mitogen-activated protein kinase (MAPK) signating pathway via the protooncogene Ras. In addition, TPO stimulation of c-Mpl activates AKT via phosphinositide-3-kinase (P1-3K) and phosphatidylinositol (3,4,5) triphosphate, upregulating the forkhead box 01 (FOX01) transcription factor.

in murine c-Mpl is phosphorylated in response to the hormone binding and serves to initiate both Shc and STAT3 activation.[96,111] Truncation of the c-Mpl receptor 69 residues from the transmembrane domain eliminated both Shc and STAT3 activation; however, it only reduced activation of STAT5, PI3K, and ERK1/2, leaving a receptor that was still capable of supporting cell growth, conclusions that were verified *in vivo* when a similarly truncated *c-mpl* cDNA was knocked in to the *c-mpl* locus in mice.[112] The resting platelet count of these mice was normal; however, platelet recovery following cytotoxic therapy-induced thrombocytopenia was significantly delayed, indicating that the proximal part of the Mpl receptor includes all signals required for baseline MK proliferation and maturation, but that either the additional signal intensity of STAT, ERK, and PI3K, and/or the distinct signals initiated from the distal part of the receptor are important for high level thrombopoiesis. Similar conclusions that STAT responses serve an amplification role in cytokine signaling are derived from studies of STAT5a/STAT5b double knockout mice.[95]

Given the number and variety of intracellular signaling pathways activated by TPO, stringent mechanisms are required for the negative regulation of c-Mpl to ensure the maintenance of normal cellular responses. Suppressors of cytokine signaling (SOCS) proteins have been shown to bind either directly to the transmembrane receptor or to JAK/STAT proteins, downregulating their activity (reviewed in[113]). Expression of SOCS-3 is significantly increased in response to TPO in c-Mpl-expressing cell lines, while IFN-α negatively regulates TPO-activated signaling pathways via upregulation of SOCS-1.[114] TPO-mediated activation of Lyn, a member of the Src-family kinases, also appears to negatively regulate TPO signaling. Suppressing Lyn activity using chemical inhibitors increased Erk1/2 phosphorylation

and also enhanced the proliferation of Mpl-bearing cell lines and promoted megakaryocyte differentiation of bone marrow cells.[115] Additionally, *Lyn*-deficient mice exhibit increased megakaryopoiesis and enhanced TPO-mediated signaling.[116] Lnk, an adaptor protein (AP) containing SH2-binding and pleckstrin homology domains, also negatively regulates TPO-mediated signaling[117] and has significant effects on HSC maintenance and quiescence.[118] Recent evidence shows that Lnk directly interacts with phosphorylated Y_{613} and Y_{813} on JAK2 following TPO stimulation. Furthermore, HSCs isolated from $Lnk^{-/-}$ mice exhibit a significantly increased JAK2 phosphorylation in response to TPO.[118]

In addition to increasing expression and activity of negative regulators, c-Mpl is rapidly internalized and degraded following TPO stimulation.[119] The intracellular motif Y_{591}RRL is critical for c-Mpl internalization, probably via interactions with AP-2, which drives clathrin-mediated endocytosis. Following its internalization, c-Mpl has three possible fates. It is either polyubiquitinated on both intracellular lysine residues (K_{553} and K_{573}) prior to proteasomal or lysosomal degradation,[120] or it is recycled back to the plasma membrane. However, the exact mechanisms behind c-Mpl endocytosis, degradation, and recycling remain unclear.

The nature of TPO signaling in mature platelets has also been explored[121–124] and reveals that the hormone stimulates the phosphorylation and activation of JAK2, STAT3, and STAT5. As the hormone has been shown to prime platelets for an enhanced response to classical platelet agonists, additional studies now focus on determining how these signaling intermediates might participate in platelet activation.

THE THERAPEUTIC POTENTIAL OF THROMBOPOIETIN

The toxicity and therapeutic efficacy of TPO have been tested in many animal species from mice to man. In all studies, administration of any form of the hormone was safe; there were no signs of hepatic, renal, or pulmonary toxicity, capillary leak, coagulopathy or hematopoietic toxicity, and no evidence of an acute phase response that is characteristic of other cytokines known to affect megakaryocyte development. When tested in animals treated with nonablative doses of either chemotherapy, radiation, or both, the administration of exogenous TPO resulted in higher nadir platelet counts and accelerated platelet recovery.[74,81,125–129] TPO administration also promoted improved recovery of the erythrocyte and granulocyte lineages in these animals, consistent with its *in vitro* stimulatory effects on cells of multiple hematopoietic lineages.[52,53,81] In one study using rhesus monkeys administration of TPO after sublethal irradiation resulted in functional iron deficiency, confirming its effect on erythropoiesis, and arguing for study of prophylactic administration of iron in patients receiving the recombinant protein.[129] Together, these results suggest that the therapeutic efficacy of the hormone might be greater than initially anticipated.

In contrast to the near universal success of the hormone in ameliorating the thrombocytopenia and in many studies the pancytopenia associated with myelosuppressive therapy, its effectiveness in accelerating platelet recovery after myeloablative therapy and stem cell transplantation has been less impressive. The administration of TPO to lethally irradiated mice receiving bone marrow cells accelerated platelet recovery by 2 to 4 days in two studies,[77,130] but did not augment hematopoietic recovery when fewer bone marrow cells were given.[131] In mice receiving peripheral blood stem cell transplants TPO accelerated platelet recovery by only 1 or 2 days as compared with mice receiving transplants but no exogenous hormone.[130] TPO also did not facilitate hematopoietic reconstitution in nonhuman primates undergoing autologous bone marrow transplant or peripheral blood stem cell transplantation.[132] For the most part, the preclinical studies of TPO have accurately predicted the response of patients administered the hormone for reasons of myelosuppression. The results of many clinical trials of TPO therapy given for up to 10 days have now been published.[80,78,133,134,135–139] In all studies, the administration of either recombinant human (rh) TPO or pegylated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF) to cancer patients was safe. Specifically, there were no significant changes in vital signs or weight, and the frequency of symptoms or signs of bone pain, organ dysfunction, superficial or deep venous thrombosis, or platelet activation was similar in the treatment and placebo groups. It must be noted, however, that patients with a history of cardiac, pulmonary, vascular, or thrombotic disease were excluded from all of the studies. Only a single patient in any of these clinical trials developed antibodies to TPO.[79] However, very few patients have been given more than a single course of treatment in the initial clinical trials, making any conclusions on the immunogenicity of the two products premature.

Due to the dramatic increase in our understanding of the structure and function of TPO in the 1990s, the first generation of thrombopoietic reagents for human use consisted of recombinant proteins aimed at mimicking the role of endogenous TPO. Two such compounds were extensively tested, rhTPO and PEG-rHuMGDF (reviewed in [140,141,142,143]). RhTPO is a glycosylated, full-length peptide identical to endogenous TPO and produced by CHO cells. When rhTPO was administered intravenously to cancer patients, a marked increase in platelet counts was observed after 5 days, which peaked 10 to 14 days later.[79,135] PEG-rHuMGDF, a pegylated product containing the amino-terminal 163 amino acids of human TPO, was produced in *Escherichia coli*. On subcutaneous administration to healthy volunteers, PEG-rHuMGDF caused a rise in platelet numbers in a time course similar to rhTPO.[144,145]

The efficacy of TPO in clinical trials of patients with thrombocytopenia has been mixed. Results from three studies using PEG-rHuMGDF or rhTPO in a total of 101 patients with cancer treated with carboplatinum-based chemotherapeutic regimens have been reported.[133,134,135] In all three studies, platelet counts returned to baseline significantly faster, and in two of the three studies nadir platelet counts were higher in the patients given TPO, as compared with either those given placebo or the same patients during their first cycle of chemotherapy. However, the chemotherapy regimens administered in these two trials induced only modest thrombocytopenia (mean nadir platelet counts in the placebo groups of 60,000/mm^3 to 111,000/mm^3); in neither study was hospital discharge delayed because of thrombocytopenia nor were significant numbers of platelet transfusions required. In the third study,[135] compared to a first cycle of carboplatin-based therapy without the hormone, nadir platelet values and the number of days with ≤20,000 platelets/mm^3 were both significantly improved by the administration of a single dose of TPO following the second cycle of chemotherapy ($P < 0.001$). Moreover, 59% of the patients enrolled in this study required platelet transfusions after their first cycle of

chemotherapy, but only 26% needed them following the cycle of chemotherapy augmented with TPO ($P = 0.02$).

Several additional indications for TPO therapy have been envisioned. TPO increases the number of megakaryocytic and other hematopoietic progenitors *in vitro* and *in vivo*,[52,53] and it mobilizes stem and progenitor cells from the marrow into the circulation,[79,130,136] properties that might benefit patients receiving stem-cell transplants. In 75 patients with breast cancer undergoing autologous bone marrow transplantation, administration of PEG-rHuMGDF led to a 5 to 6 day earlier rise in platelet count to 20,000/mm^3 and a halving of the use of platelet transfusions as compared with placebo.[137] However, when tested in 64 patients in a phase III trial, the drug failed to accelerate platelet recovery. Likewise, the recombinant hormone was administered to 38 patients with delayed platelet recovery after peripheral blood stem cell or bone marrow transplantation; the use of rhTPO lead to platelet transfusion independence in only two individuals.[139]

TPO has also been tested as an aid in mobilizing stem cells for subsequent autologous transplantation. Somlo et al. found that compared to a group of autologous transplantation patients in whom stem cells were mobilized with G-CSF alone, the addition of TPO to the mobilization phase lead to a reduction from a mean of three to a mean of one apheresis procedure necessary to collect the requisite number of CD34$^+$ cells, and upon infusion the patients who received cells mobilized with G-CSF and TPO demonstrated accelerated red cell and platelet recovery, and required a small but statistically significantly reduced number of platelet transfusions compared to patients who received G-CSF mobilized stem cells.[146]

Another potential indication for the hormone is in increasing platelet yields in normal individuals who donate platelets by apheresis. At present a 2 to 3 hour apheresis of normal donors yields approximately 3×10^{11} platelets, which when transfused into a single donor results in a 10–40 $\times$ 10^9/L increment in platelet levels. By increasing the platelet count in a donor, the number of platelets recovered should increase, potentially increasing the mean platelet increment when the cells are subsequently infused into a single recipient; alternately, such enhanced platelet collections could allow a single donor pheresis to be used for multiple recipients. Despite initially encouraging reports of this strategy,[147] clinical trials were halted following a large study with healthy volunteers given PEG-rHuMGDF. Of the 538 subjects receiving the drug, 13 developed thrombocytopenia as a result of an antigenic reaction against PEG-rHuMGDF, which produced antibodies that also recognized endogenous TPO.[148,149,150] All clinical trials involving first generation thrombopoietic agents were subsequently discontinued.

Prior to the withdrawal of recombinant TPO for the immunologic effects noted above, it was clear that the hormone could increase reduced platelet numbers in patients with ITP.[151] Although the typical bone marrow examination of a patient with classic ITP demonstrates impressive megakaryopoiesis, it remains possible that the levels of the hormone attainable physiologically are less than necessary for maximal megakaryopoiesis, and that levels attainable pharmacologically could further increase platelet levels in this disorder.

Following the failure of recombinant peptides in clinical trials, the focus shifted to the development of novel thrombopoietic agents that could be easily produced and administered without producing an antigenic response. By isolating hormone binding site peptides from phage display libraries, Cwirla et al.[152] identified a 14–amino acid peptide (Ile–Glu–Gly–Pro–Thr–Leu–Arg–Gln–Trp–Leu–Ala–Ala–Arg–Ala) with a high binding affinity for human c-Mpl, but no sequence homology with endogenous TPO.[152] To increase longevity and activity in circulation, the linear peptides were either PEGylated or fused to human Fab or Fc scaffolds. Romiplostim, (also known as AMG-531 and marketed as N-plate; Amgen) described as a "peptibody," was generated by the covalent fusion of four TPO peptide agonists to the Fc fragment of the human IgG1 heavy chain.[153,154] Romiplostim competed with rhTPO for binding to c-Mpl, and also activated downstream signaling pathways and promoted megakaryocyte differentiation in a similar manner to rhTPO.[155] When administered subcutaneously, romiplostim increased platelet counts in healthy volunteers and in 80% of patients with ITP, peaking at days 12 to 16. Longer-term studies show that romiplostim is well tolerated and no cases of anti-TPO neutralizing have been reported (clinical data reviewed in[142]). In 2008, the FDA approved the use of romiplostim for patients with chronic ITP who have not responded to traditional treatments.

Large-scale screening of nonpeptide, orally available TPO mimetic compounds in cell-based assays has also generated a number of potentially valuable reagents, including the leading nonpeptide TPO mimetic, eltrombopag (also known as SB497115 and marketed as Promacta/Revolade; GlaxoSmith Kline).[156–160] Unlike peptide mimetics such as romiplostim, which compete for binding to c-Mpl in the same region as endogenous TPO, eltrombopag binds to the transmembrane domain of c-Mpl,[161] resulting in a conformational change and its subsequent activation, in a manner similar to activating mutations of c-Mpl. Clinical trials of eltrombopag report significant increases in platelet counts, although these are several times lower than the increases reported following romiplostim.[162] In >80% of chronic ITP patients, platelet counts above 50 $\times$ 10^9/L were achieved, maintained over a longer-term trial, and accompanied by decreased bleeding symptoms (reviewed in[143]). The FDA has also approved the use of eltrombopag as a second-line treatment for patients with ITP.

Following the success of the second generation thrombopoietic agents in treating ITP, the number and variety of thrombopoietic agents in development is constantly increasing. Some concerns remain whether long-term use of these agonists may increase the risk of developing other conditions, namely increased platelet activation and/or increased bone marrow fibrosis, although neither condition has been reported. The approval of both romiplostim and eltrombopag by the FDA makes the thrombopoietic agents a gold standard in the development of other hematopoietic growth factor mimetics.

ROLE OF THROMBOPOIETIN AND ITS RECEPTOR IN PATHOLOGY

Other than the remarkable insights into the pathogenesis of chronic myelogenous leukemia afforded by the t(9;22) translocation, as of 5 years ago little had been known about the pathogenesis of the chronic myeloproliferative neoplasms (MPNs) polycythemia vera, ET, and primary myelofibrosis. Early evidence suggested that the cellular response to hematopoietic growth factors, dysregulation of the growth factors themselves, or of their signaling networks might contribute to the etiology of these disorders. The concept of autocrine secretion of peptide growth

factors by tumor cells dates to the work of Sporn and Todaro.[163] Later work suggested that hematopoietic growth factors and their receptors might play an important role in the malignant transformation of marrow cells in other clinical settings.

MPNs share a common origin in a pluripotent hematopoietic progenitor cell. Consequently, if growth factors, growth factor receptors, or their signaling networks play a role in these disorders, then that cytokine receptor must be expressed in HSCs. As illustrated above, Mpl is present on the repopulating HSC, and genetic elimination of *Tpo* or c-Mpl lead to the conclusion that it plays a critical, nonredundant role in these cells.

Several lines of evidence support the notion that TPO and/or its receptor play a role in MPNs. First, mutations of Mpl can lead to autonomous cell growth and leukemogenicity in mice. Perhaps the best example of this is the mutant form of *c-Mpl* that lead to its discovery, the *v-Mpl* oncogene.[6] Following upon the characterization of a constitutively active mutant of the EPO receptor, Alexander et al. engineered constitutively active receptor mutants of c-Mpl by substituting cysteine residues into the dimer interface domain of the receptor. Factor-dependent hematopoietic cells transduced with the mutant receptor displayed constitutive phosphorylation of both Mpl and the signal transduction molecules implicated in Mpl function, suggesting a potential for contributing to the tumorigenicity of the mutant cells.[164] Onishi et al. identified an activating mutation in the transmembrane domain of Mpl by using a combination of retrovirus-mediated gene transfer and polymerase chain reaction-driven random mutagenesis. This mutation resulted in the abrogation of factor dependency in all IL-3-dependent cell lines tested. One IL-3-dependent murine cell line that expressed only the mutated form of Mpl induced autocrine growth and leukemogenesis when transduced into syngeneic mice, apparently by constitutive activation of two distinct intracellular signaling pathways.[165] Finally, our group has demonstrated that truncation of the membrane-distal part of the extracellular domain of c-Mpl induces autocrine growth in factor-dependent cell lines.[166] These studies appear to confirm that certain mutations of the TPO receptor may contribute to the malignant transformation of some hematopoietic progenitors *in vivo*, at least in the mouse. Second, expression of normal c-Mpl in all marrow cells, or TPO in hematopoietic cells leads to MPNs. For example, Cocault et al.[167] demonstrated that a retrovirus containing natural murine Mpl cDNA is erythroleukemogenic *in vivo* when injected into adult mice. And several groups have observed that transgenic overexpression of *Tpo* in mice induces megakaryocyte proliferation in the spleen and massive marrow fibrosis, a disorder bearing strong resemblance to agnogenic myeloid metaplasia and myelofibrosis in humans.[168–170] Third, as noted above, one of the most characteristic findings in patients with myeloproliferative syndromes is "autonomous" colony growth, which in reality represents growth factor hyperresponsiveness. Hematopoietic progenitor cells taken from blood and bone marrow that normally die in culture without exogenous growth factors survive and proliferate in the presence of serum alone. Li et al.[171] have demonstrated, for example, that with the introduction of an antisense oligonucleotide to Mpl, there is a reduction in spontaneous colony formation in serum-free assays and in plasma clot assays. Similar conclusions were drawn by Taksin et al.[172] using an inhibitory, soluble form of the c-Mpl receptor. This outcome suggests that the TPO receptor may influence autonomous growth of these cells in culture. Fourth, TPO levels and c-Mpl expression is altered in patients with several of the MPNs. For example, Pitcher has observed that circulating TPO levels are unexpectedly high in patients with ET[173] although this has not been a universal finding.[174] Moreover, c-Mpl expression on megakaryocytes from patients with MPNs has been abnormal,[175,176] and a signaling defect has been observed in cells derived from patients with polycythemia vera.[177] In addition to being of potential diagnostic benefit, these findings again point to an abnormality in the TPO/c-Mpl system in patients with MPNs.

In 2006, two novel somatic mutations of c-Mpl ($MplW_{515}L$ and later $MplW_{515}K$) were identified in a small population of patients with IMF and ET.[178,179] $MplW_{515}L$ stimulates cytokine-independent growth in hematopoietic cells, activating JAK2-STAT signaling in the absence of TPO. $MplW_{515}K$ was identified in granulocytes of 1,182 MPN patients, and is also an activating mutation, although its exact effects on signaling remain unclear. In murine *in vivo* studies, transplantation of bone marrow transduced with Mpl carrying the $W_{515}L$ mutation resulted in the rapid development of myeloproliferative disease.[179] Further studies suggest that this mutation affects the amphipathic region of c-Mpl (KWQFP), located at the junction of the transmembrane and cytoplasmic domains.[180] It would appear that the normal $MplW_{515}$ residue acts to prevent the conformational change required for activation when TPO is not present. Consequently, the W to L/K mutation results in the constitutive activation of the receptor. Pharmacologic JAK2 inhibitors, a number of which are currently in clinical trials for treatment of $JAK2V_{617}F$-positive MPNs, have been shown to significantly reduce the extent of myeloproliferation in $MplW_{515}L$ mouse models[179] and could potentially be used to treat patients with Mpl activating mutations.

Homozygous, or compound heterozygous nonsense, or severe missense mutations of *c-Mpl* are responsible for the majority of cases of congenital amegakaryocytic thrombocytopenia (CAMT).[69,70,71,72,181] Infants with this disorder usually present with excessive bleeding in the perinatal period, although occasionally the diagnosis is delayed a short time. A diagnostic bone marrow aspiration and biopsy usually reveals normal cellularity, although only a few megakaryocytes are initially found, and those present are unusually small and hypolobated. With the availability of plasma TPO measurements nearly every such patient has been found to display very high levels of the hormone, which is biologically active and such children fail to express c-Mpl on their platelet surfaces, due to nonsense or severe missense codons in the extracellular domain of the receptor. Although children with CAMT usually present with isolated thrombocytopenia, they almost always develop pancytopenia within a few years of birth, presaged by declining numbers of marrow-derived hematopoietic progenitors of all types.[72] At this point, their marrow morphology resembles that seen in aplastic anemia, and stem cell transplantation is their only curative option. Also of great interest in this regard is the recent observation that the development of anti-TPO antibodies can lead to pancytopenia.[148] As noted earlier, TPO plays an important role in stem cell biology, perhaps helping to explain the stem cell failure that characterizes the latter stages of CAMT and the aplasia associated with accidentally neutralizing endogenous TPO in patients. However, this finding also raises an interesting research question; mice nullizygous for c-MPL or TPO display similarly low platelet counts, but do not develop pancytopenia. Further study into the cause of this discrepancy is likely to reveal much about stem cell kinetics in mouse and man.

Although the majority of patients with immune thrombocytopenic purpura display enhanced megakaryopoiesis secondary to peripheral immune destruction of platelets, usually due to an autoantibody to platelet gpIIb/IIIa or gpIb, careful platelet turnover studies reveal that not all patients have rapid platelet elimination.[182] In such patients it is possible that reduced production of platelets might be due to antibodies against TPO or its receptor; an additional study has borne out this possibility, in both *de novo* disease, and in response to administration of a genetically modified form of TPO.[150,183,184] In both of these situations, the clue to the unusual pathophysiology was reduced megakaryopoiesis in the marrow of the patients with presumed immune thrombocytopenic purpura.

Soon after the *c-Mpl* protooncogene was identified, it became clear that it was expressed on a sizable proportion of blast cells from patients with myeloid malignancies.[185] Although there is little evidence that disorders of *c-Mpl* are involved in the generation of acute leukemia, a sizable body of evidence suggests that its expression on the surface of leukemic cells adversely affects the response characteristics of the cells and the overall survival of the patients who develop such leukemias.[186,187] The same is true of patients with myelodysplastic syndromes; the presence of c-Mpl on the surface of the dysplastic cells predicted enhanced likelihood of evolution to acute leukemia.[188] In contrast, however, the adverse prognosis of expression of c-Mpl did not extend to chronic myelogenous leukemia.[189]

CHAPTER

26A

Major Platelet Glycoproteins: Platelet Glycoprotein Ib-IX-V

MICHAEL C. BERNDT AND ROBERT K. ANDREWS

In the past 5 years, understanding of the structure and function of the platelet glycoprotein (GP) Ib-IX-V complex[1,2] has advanced in a number of key areas that should facilitate future therapeutic targeting in thrombotic and other diseases. This chapter focuses on new experimental and clinical studies involving mechanisms regulating GPIb-IX-V expression, ligand binding and signaling, the role of GPIb-IX-V in hemostasis, and new nonhemostatic functions for this receptor. In hemostasis and thrombosis, engagement of GPIbα (the ligand-binding subunit of GPIb-IX-V) by von Willebrand factor (vWF) leads to platelet activation, secretion of platelet agonists such as ADP and thromboxane A_2, and initiation of intracellular signaling pathways resulting in activation of platelet integrins, mainly $\alpha_{IIb}\beta_3$ (GPIIb-IIIa), the receptor that binds fibrinogen or vWF and mediates platelet aggregation (thrombus formation) (see Chapter 15B). Critical to the structure and function of GPIb-IX-V are specific adaptations enabling interaction between GPIbα and vWF or other ligands at high physiologic or pathologic shear rates in the bloodstream. This underlies much of the current interest in GPIb-IX-V as a target for antiplatelet therapy in heart attack and stroke.

GPIb-IX-V STRUCTURE

The GPIb-IX-V complex is made up of the ligand-binding GPIbα subunit, disulfide bonded to GPIbβ and noncovalently associated with GPIX and GPV.[1,2] Key structural domains are illustrated in FIGURE 26A.1. The stoichiometry appears to involve each GPIbα linked to 1 or 2 GPIbβ subunits *via* adjacent Cys residues in the extracellular domain of GPIbα nearby the outer face of the plasma membrane.[2,3] There are equivalent levels of GPIX and GPIb expression and approximately half as many copies of GPV;[4] GPIbα, GPIbβ, and GPIX are required for stable surface expression.[2]

GPIb-IX-V EXPRESSION AND SHEDDING

Expression of GPIb-IX-V is regulated by ectodomain shedding (FIGURE 26A.1). ADAM17 is one of the sheddases involved in release of the GPIbα ectodomain (glycocalicin).[5,6] GPIbα is constitutively shed from circulating platelets, and glycocalicin levels in plasma are 1 to 3 μg/mL. Shedding is increased upon platelet activation or aging *in vivo* or *ex vivo*.[7] Thrombin, ADAM10, or ADAM17 cleave the ectodomain of GPV within the same region.[5,8] Deficiency of GPV in mice enhances the capacity of thrombin to stimulate platelets *via* GPIbα.[9]

GPIb-IX-V: EXTRACELLULAR BINDING PARTNERS

The primary GPIb-IX-V ligand is vWF, a multivalent multimeric adhesive protein secreted from platelets and endothelial cells. Each mature subunit of vWF (~275 kDa) is composed of conserved domains (in order, D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2). The vWF-A1 domain, encompassing an intramolecular Cys509–Cys595 disulfide bond, contains the binding site for GPIbα. The vWF-A3 domain binding contains a binding site for collagen and the vWF-C1 domain contains an Arg-Gly-Asp (RGD) sequence that mediates binding to the activated integrin, $\alpha_{IIb}\beta_3$. Binding of vWF-A1 to GPIb-IX-V has been investigated using proteolytic fragments of native vWF or GPIbα,[10,11] crystal structures of GPIbα/vWF-A1 interactive domain complexes,[12,13] mutagenesis studies examining this interaction under shear conditions,[14] and *in silico* modelling of individual receptor/ligand bonds.[15,16] Together, these studies have provided detailed insight into how vWF can support platelet adhesion under shear conditions, by conformational shear-dependent activation of catch-slip bonds,[16] which enhance or decrease individual bond strength to regulate platelet attachment or detachment, respectively. It has also been demonstrated by structural studies how small molecule inhibitors that bind GPIbα within the *N*-terminal leucine-rich repeat domain can allosterically block vWF binding.[17]

Other adhesive ligands for GPIb-IX-V are the counterreceptors P-selectin,[18] expressed on activated platelets and activated endothelial cells, and the integrin $\alpha_M\beta_2$ (Mac-1)[19] expressed on leukocytes. Binding of P-selectin involves the anionic sulfated tyrosine sequence of GPIbα, analogous to an *N*-terminal sulfated sequence within the counterreceptor for P-selectin on leukocytes, P-selectin glycoprotein ligand-1 (PSGL-1). The α_M I-domain (homologous to vWF-A domains) contains the binding site for GPIbα.[20] This interaction is involved in recruitment of leukocytes to adherent platelets at sites of injury or infection (P-selectin on activated platelets binding to PSGL-1 on leukocytes leads to activation of $\alpha_M\beta_2$) and could also be involved in platelet clearance. In this regard, clustered carbohydrate structures of GPIbα on platelets refrigerated *ex vivo* are recognized by $\alpha_M\beta_2$ on hepatic macrophages, and provides at least one mechanism for the cold storage lesion that results in rapid clearance of transfused cold-stored platelets.[21]

There is also evidence that collagen can bind GPV,[22] although the physiologic importance of this interaction is not yet established. GPV deficiency in mice does not result in a bleeding phenotype[23] and there is at most a limited effect on hemostatic

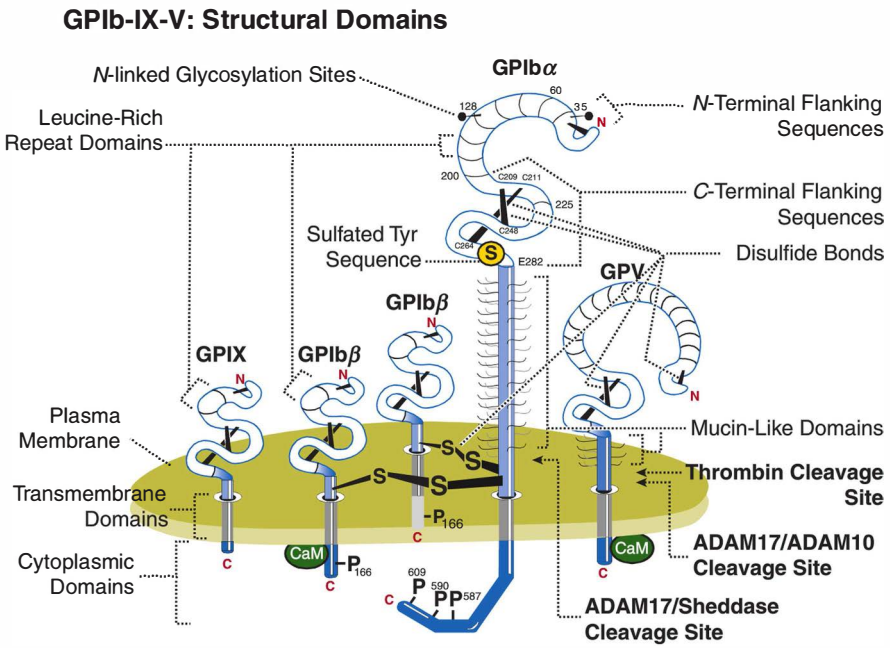

FIGURE 26A.1 GPIb-IX-V: Structural domains. Illustration of the GPIb-IX-V complex, consisting of GPIbα, GPIbβ, GPIX, and GPV subunits, showing leucine-rich repeats, disulfide-looped *N*- and *C*-terminal capping sequences, transmembrane domains, and cytoplasmic domains. GPIbα contains a mucin-like domain elevating the major ligand-binding domain (FIGURE 26A.2). The anionic sulfated tyrosine sequence (residues 269 to 282) contains three sulfated tyrosine residues (Tyr275, Tyr276 and Tyr278). ADAM17 or other sheddases cleave *N*-terminal to the disulfide bonds of GPIbα generating the soluble ectodomain (glycocalicin), and leaving a remnant membrane-associated fragment that remains disulfide linked to GPIbβ. Thrombin and ADAM10/ADAM17 cleaves the ectodomain of GPV at distinct sites, with loss of GPV enhancing the capacity of thrombin to stimulate platelets *via* GPIbα. The stoichiometry is not shown.

function.[24] Nevertheless, release of GPV by metalloproteinase-mediated ectodomain shedding in activated platelets or by thrombin (FIGURE 26A.1) has led to investigation of plasma GPV as a platelet-specific marker of platelet activation or coagulation *in vivo*.[25]

GPIbα also binds to coagulation factors from the intrinsic pathway (high molecular weight kininogen, FXII and FXI) and thrombin generated from activation of intrinsic or extrinsic coagulation pathways. Each of these factors bind to the *N*-terminal ligand-binding domain of GPIbα, whereas the extracellular mucin-like domain or other subunits may regulate the procoagulant activity of platelets by interacting with FVIIa and/or other factors.[26,27] Activation of platelets by engagement of GPIb-IX-V or other receptors can promote coagulation by inducing the expression of anionic phospholipids on the platelet surface, thereby leading to the activation of FX to FXa and secretion of polyphosphates or other factors that promote activation of FXII.[28]

In addition to these interactions, other extracellular or intracellular binding partners regulate GPIb-IX-V–dependent signaling. First, the ectodomain of GPIbα interacts with platelet collagen receptor, GPVI, of the immunoreceptor family. GPVI forms a noncovalent complex with Fc receptor γ chain that is required for GPVI surface expression and for downstream following of GPVI engagement.[29] GPIbα also associates with FcRγ in human platelets,[30] and acts with GPVI/FcRγas accessory signaling proteins that share common signaling pathways, as discussed below.[31] Second, the intracellular domain of GPIb-IX-V interacts with calmodulin that binds to membrane-proximal amphipathic/positively charged sequences of GPIbβ and GPV and with 14-3-3ζ that binds to phosphoserine-containing sequences at the *C*-terminal or upstream regions of GPIbα, or within GPIbβ (FIGURE 26A.2). Calmodulin dissociation regulates ectodomain shedding of GPIbα or GPV by ADAM17 or ADAM10/17, respectively.[5,32,33] The regulatory p85 subunit of phosphatidyl inositol 3-kinase (PI3-kinase) also binds to the *C*-terminal sequence of GPIbα, independent of phosphorylation status or 14-3-3ζ binding.[34,35]

GPIb-IX-V: INTRACELLULAR BINDING PARTNERS AND SIGNALING

Engagement of GPIb-IX-V triggers intracellular signals leading to activation of Src kinase (Lyn),[36] Syk, SLP-76, PI3-kinase (consisting of p85 regulatory and p110 catalytic subunits), Btk,[37] phospholipase Cγ, and protein kinase C. Activation results in elevation of cytosolic Ca^{2+}, secretion of α-granules and dense granules, and activation of integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) that binds vWF or fibrinogen to mediate platelet aggregation.[31] The calmodulin-binding sequence within the cytoplasmic domain of GPIbβ also binds TNF receptor-associated factor 4 (TRAF4) involved in assembly of the NADPH oxidase (Nox2) complex that generates ROS, enhancing platelet activation.[38,39]

GPIb-IX-V is also associated with the platelet cytoskeleton *via* an interaction between a sequence within the cytoplasmic tail of GPIbα and the actin-binding protein filamin-A.[40–43] Disruption of the filamin-binding sequence in transgenic

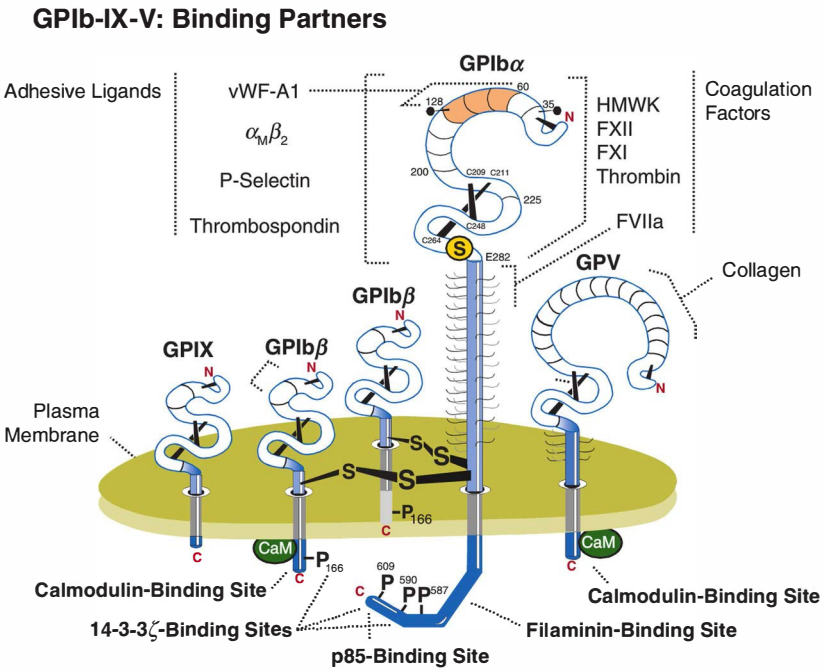

FIGURE 26A.2 GPIb-IX-V: Binding partners. Binding regions for adhesive or procoagulant ligands on GPIbα at the *N*-terminal globular domain (residues 1 to 282); collagen binds GPV. Binding of vWF under shear conditions depends on leucine-rich repeats (residues 60 to 128), and binding of P-selectin or thrombin is inhibited by antibodies against the sulfated sequence of GPIbα ("S"). The central region of the GPIbα cytoplasmic domain centered on Phe568/Trp570 binds the cytoskeletal protein filamin. Calmodulin binds membrane-proximal amphipathic, positively charged sequences of GPIbβ and GPV, and regulates surface expression/ectodomain shedding of GPIbα and GPV; this sequence in GPIbβ also binds TRAF4 of the Nox2 complex that generates ROS. Binding of 14-3-3ζ involves phosphorylated serine residues at the *C*-terminal penultimate residue (Ser609) and upstream residues at Ser587/Ser590 of GPIbα, and Ser166 of GPIbβ. Binding of p85 (regulatory subunit of PI3-kinase) also binds to the same *C*-terminal sequence of GPIbα, but is independent of phosphorylation/14-3-3ζ binding. See the text for details.

mouse models (wild-type human GPIbα or a mutant form of human GPIbα with Phe568Ala and Trp570Ala substitutions in the filamin-binding site) demonstrates that the link between platelet GPIbα and the cytoskeleton does not alter vWF binding or signaling by GPIbα, but results in unstable membrane tethers and defective platelet adhesion under high shear conditions.[44] This suggests that the GPIbα-filamin interaction regulates the membrane skeleton structure and mechanical stability of the plasma membrane under conditions of high shear.

HEMOSTATIC FUNCTIONS OF GPIb-IX-V

Platelet GPIb-IX-V plays a central role in hemostasis and thrombosis. First, in Bernard-Soulier syndrome, a rare human disease where there is a deficiency of functional GPIbα on platelets due to a variety of inherited mutations (see Chapter 65), patients have a mild to severe bleeding phenotype, typically associated with large platelets and low platelet count (macrothrombocytopenia).[45] The Bernard-Soulier syndrome supports a hemostatic role for GPIb-IX-V, but there may not be a precise correlation between the level of GPIbα expression and clinical bleeding due to other contributing factors.[46] The GPIbα-knockout mouse displays a comparable phenotype.[47]

In animal models, GPIbα is not only associated with arterial thrombosis or stroke,[48,49,50,51,52] but in recent studies, blocking GPIbα binding to vWF-A1 revealed that this interaction is involved in venous thromboembolism[53] and deep vein thrombosis.[54] Studies using mutant vWF expressed in vWF-deficient mice suggest that vWF binding to GPIbα and collagen, rather than to $\alpha_{IIb}\beta_3$, is critical in these thrombosis models.[55]

The role of GPIbα in arterial thrombosis may not be restricted to its interaction with vWF-A1,[48,51] and could also involve interactions with coagulation factors, interaction with activated leukocytes *via* $\alpha_M\beta_2$, and/or interaction with activated endothelium *via* P-selectin (FIGURE 26A.2). Therapeutic targeting of GPIbα in humans could potentially involve variations of fusion proteins consisting of GPIbα/vWF-A1 binding domains or humanized inhibitory antibodies used in experimental models.[49,52–54]

NONHEMOSTATIC FUNCTIONS OF GPIb-IX-V

In addition to the hemostatic roles described above, platelet GPIbα may also participate in some of the nonhemostatic functions of platelets.[56,57] In experiments involving injection of tumor cells into mice, depletion of GPIbα inhibited tumor metastasis and solid tumor formation.[58,59] Although the precise mechanism for these protective effects was not firmly established, they could be related to a role for adherent platelets in

regulating the angiogenesis required for solid tumor growth.[57] GPIb-IX-V is also critical in recruitment of leukocytes to sites of vascular injury through the interaction of GPIbα with $\alpha_M\beta_2$,[60] an important step in inflammation and wound healing, and potentially, in initiation of atherosclerosis depending on the model used or other variables.[61,62] Finally, platelet GPIb-IX-V also interacts with bacterial proteins and this can contribute to platelet activation during infection and/or promote the inflammatory response (reviewed in[63]).

CONCLUDING STATEMENT

Through interactions with adhesive proteins (vWF, thrombospondin), counterreceptors on other vascular cells (P-selectin, $\alpha_M\beta_2$), coagulation factors (kininogen, FXII, FXI, thrombin, FVIIa), and cancer cells or bacteria, platelet GPIb-IX-V plays a central role in initiating platelet dys/function in vascular biology. Downstream of GP-IX-V engagement, activation of platelets leads to secretion of bioactive molecules that can influence thrombus formation, inflammation, and other responses, and lead to activation of other platelet adhesion receptors such as $\alpha_{IIb}\beta_3$.

SUMMARY

The platelet GP Ib-IX-V complex of the leucine-rich repeat family is made up of GPIbα (the major ligand-binding subunit), GPIbβ, GPIX and GPV. In addition to its traditional role as a vWF receptor mediating platelet thrombus formation at arterial shear rates in hemostasis or thrombotic disease (heart attack or stroke), new evidence has shown that multiple extracellular ligands of GPIb-IX-V are involved in a plethora of new non-hemostatic functions for this unique receptor. New findings also show how intracellular interactions involving the cytoplasmic domain of GPIb-IX-V and binding partners such as filamin, 14-3-3ζ, p85 (regulatory subunit of phosphatidylinositol 3-kinase), and TRAF4 control activation of signaling pathways, cytoskeletal changes, and/or generation of reactive oxygen species (ROS) critical to platelet function.

Major Platelet Glycoproteins: INTEGRIN $\alpha_{IIb}\beta_3$ (GPIIb-IIIa)

FENG YE AND MARK H. GINSBERG

The first insight into the involvement of the integrin $\alpha_{IIb}\beta_3$ in hemostasis came from the observation that two major glycoprotein bands were either abnormal or completely missing from the platelets of some patients with Glanzmann thrombasthenia (GT),[1,2] a rare inherited bleeding disorder characterized by the absence of platelet aggregation. The two glycoproteins, named glycoproteins IIb (GPIIb) and IIIa (GPIIIa), were later found to form a cation-dependent complex.[3,4] The Phillips lab then successfully purified and reconstituted a functional complex containing these two glycoproteins, demonstrating biochemically that GPIIb and IIIa are subunits of the same protein.[3,5]

In the mid-1980s, a family of functionally and structurally related adhesion receptors, including GPIIb/IIIa,[6–8] emerged from research in a variety of biologic disciplines including immune biology and vascular biology and development. This family of proteins functionally integrates their extracellular ligands with the intracellular cytoskeleton and was formally named integrin in 1987. GPIIb/IIIa was renamed as integrin $\alpha_{IIb}\beta_3$.[9]

Further research demonstrated that the interaction between $\alpha_{IIb}\beta_3$ and its ligands was a critical event for platelet aggregation, hemostasis, and thrombosis.[10–12] Biochemical and structural details of the interaction between $\alpha_{IIb}\beta_3$ and its physiologic ligands facilitated the development of $\alpha_{IIb}\beta_3$ antagonists that are currently used in the treatment of acute arterial thrombosis by percutaneous coronary intervention (PCI).[13–16] Work over the past two decades underscored that integrins, including $\alpha_{IIb}\beta_3$, are not merely adhesion molecules but also signaling receptors.[17–19] Signals originating from inside the cell can modulate ligand binding to integrin extracellular domains (inside-out signaling). Inside-out signaling is tightly controlled, both temporally and spatially, to achieve hemostasis and prevent unwanted vessel occlusion. At the same time, signals initiated by ligand binding to the integrin extracellular domains (outside-in signaling) can trigger intracellular signals to regulate anchorage-dependent cellular responses. In the case of platelets, these include full aggregation and granule secretion as well as clot retraction. In this chapter, we will discuss integrin $\alpha_{IIb}\beta_3$ and its role in platelet function and bleeding disorders.

EXPRESSION AND STRUCTURE OF INTEGRIN $\alpha_{IIb}\beta_3$

$\alpha_{IIb}\beta_3$ expression is limited primarily to cells of the megakaryocytic lineage. However, the β_3 subunit is widely expressed as the beta subunit of the integrin $\alpha_v\beta_3$. Therefore, restriction of $\alpha_{IIb}\beta_3$ expression is limited by the promoter activity of α_{IIb} in cell types other than megakaryocytes.[20,21] Only a few exceptions have been reported. For example, $\alpha_{IIb}\beta_3$ is detected in certain cancer cells.[22] $\alpha_{IIb}\beta_3$ has also been detected on early hematopoietic progenitors and on mast cells where it plays a role in adhesion and in the response of the latter cells to chronic inflammation.[23,24] Efficient surface expression of the $\alpha_{IIb}\beta_3$ complex requires α_{IIb} and β_3 in a ratio of 1:1.[25–27] Excess expression of one results in the accumulation of the excess in the endoplasmic reticulum where association of nascent α_{IIb} and β_3 subunits occurs. Indeed, a subset of patients with GT results from mutations that alter the biosynthesis of only one subunit. In turn, this impairs the surface expression of the complete $\alpha_{IIb}\beta_3$ complex.[28,29]

$\alpha_{IIb}\beta_3$ is the most abundant protein on the platelet surface: there are approximately 80,000 copies on the surface of unactivated platelets.[30] An intracellular pool of $\alpha_{IIb}\beta_3$, located in the membrane of α-granules, can be translocated to the cell surface following platelet activation, increasing the amount of $\alpha_{IIb}\beta_3$ by 30% to 50%.[30–32] This high level of expression is important for efficient platelet function as platelets need to strongly adhere to multiple adhesive proteins to form a stable clot.

β_3 is expressed as a single polypeptide of 762 amino acid that folds into 10 distinct domains: a plexin-semaphorin-integrin (PSI) domain at the *N*-terminal, a βA domain that is inserted into the hybrid domain, followed by hybrid, EGF-1, EGF-2, EGF-3, EGF4, and βTD domains, a transmembrane domain (TMD) embedded in the lipid bilayer and a cytoplasmic domain[33,34] (FIGURE 26B.1). Folding is facilitated by 28 disulfide bonds formed from 56 cysteine residues. The β_3 βA domain has three divalent cation-binding sites: a metal ion–dependent adhesion site (MIDAS), a site adjacent to MIDAS, and a ligand-induced metal binding site, also referred to as the synergistic metal ion binding site. The β_3 A-domain assumes a nucleotide-binding (or Rossmann) fold in which a central six stranded β-sheet is surrounded by eight α-helices[33,34] (FIGURES 26B.1–26B.3).

α_{IIb} has 1,008 amino acid and folds into six domains: β-propeller, thigh, calf-1, calf-2, transmembrane, and cytoplasmic domains.[33,34] α_{IIb} is initially synthesized as a single polypeptide chain. During protein folding and maturation, it is proteolytically cleaved at a site in the calf-2 domain into heavy and light chains by a furin-like enzyme in the Golgi complex. However, the heavy and light chains remain covalently associated via a disulfide bond.[35] Thus, in nonreduced sodium dodecyl sulfate gels, α_{IIb} has an apparent molecular weight of 130 kDa. In reducing gels, however, it consists of a 115 kDa fragment containing most of its extracellular domains and a 25 kDa fragment that contains part of the calf-2 domain, as well as the transmembrane and the cytoplasmic domains. At its *N*-terminus, α_{IIb} consists of seven β sheets containing approximately 60 amino acids each that fold into a seven-bladed β-propeller (FIGURE 26B.2A). Four divalent cation binding sites are found at the base of the

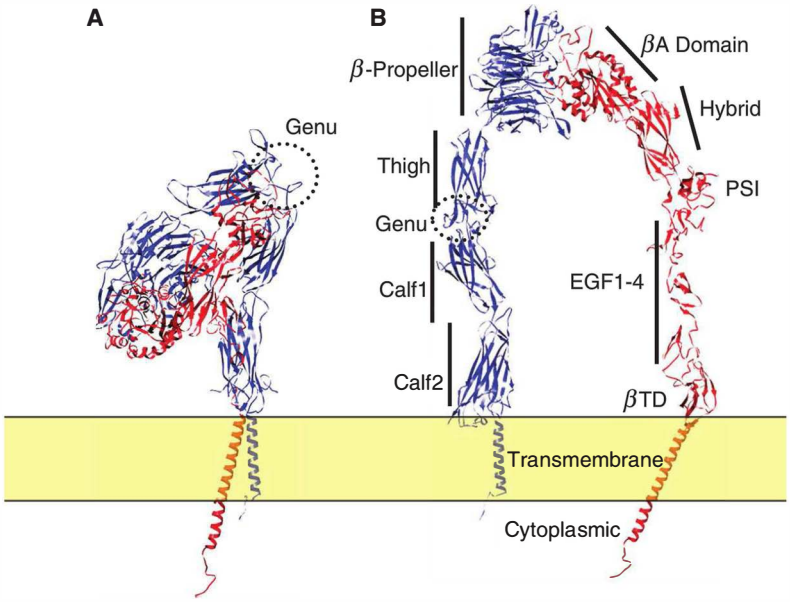

FIGURE 26B.1 Domain structures of $\alpha_{IIb}\beta_3$. **A:** Structures of $\alpha_{IIb}\beta_3$. The ribbon representation of $\alpha_{IIb}\beta_3$ was generated by combining a crystal structure of the $\alpha_{IIb}\beta_3$ extracellular domain (PDB file 3FCS), an NMR structure of $\alpha_{IIb}\beta_3$ TMD (PDB entry 2k9j), and an NMR structure of the β_3 cytoplasmic domain (PDB entry 2H7E). **B:** The $\alpha_{IIb}\beta_3$ molecule was arbitrarily extended to display individual domains as labeled in the figure. In both **(A)** and **(B)**, α_{IIb} was shown in *blue* and β_3 was shown in *red*.

propeller.[33,34] A flexible loop between the thigh and the calf-1 domain (often referred to as the "genu" region) then allows the molecule to undergo a functionally important global structural rearrangement[33,34,36,37] (FIGURE 26B.1).

α_{IIb} and β_3 associate to form a noncovalent heterodimer. Several interfaces hold the heterodimer together: a large interface between the β-propeller and βA domain that buries approximately 1,600 Å^2 of surface area and with Arg261 of the βA domain protruding off-center into the β-propeller's channel[33,34,38] (FIGURE 26B.2B); an interaction between the α_{IIb} and β_3 TMDs; and an interaction between the membrane proximal (MP) portions of each cytoplasmic domain.[39,40] Divalent cations are involved in this association because exposure to ethylenediaminetetraacetic acid causes the heterodimer to dissociate.[4,41]

Although no divalent cation is observed at the α and β interface, cations in the β-propeller and thigh–calf-1 interface might allosterically contribute to α and β interactions.[33] The Arg-Gly-Asp or RGD motif present in many integrin ligands inserts into a crevice between the βA and β propeller domains. The Arg side chain inserts into a narrow groove on the top of the β-propeller, and the side chain of Asp protrudes into a cleft in the βA domain. The Gly residue lies at the interface between the α and β subunits where it makes several hydrophobic contacts. Overall, 355 Å^2 of surface area or 45% of the total surface area of the peptide is buried, thereby contributing to a stable ligand–receptor interaction[42] (FIGURE 26B.3).

Structures of the $\alpha_{IIb}\beta_3$ TMD heterodimer, determined by nuclear magnetic resonance (NMR) spectroscopy, revealed that

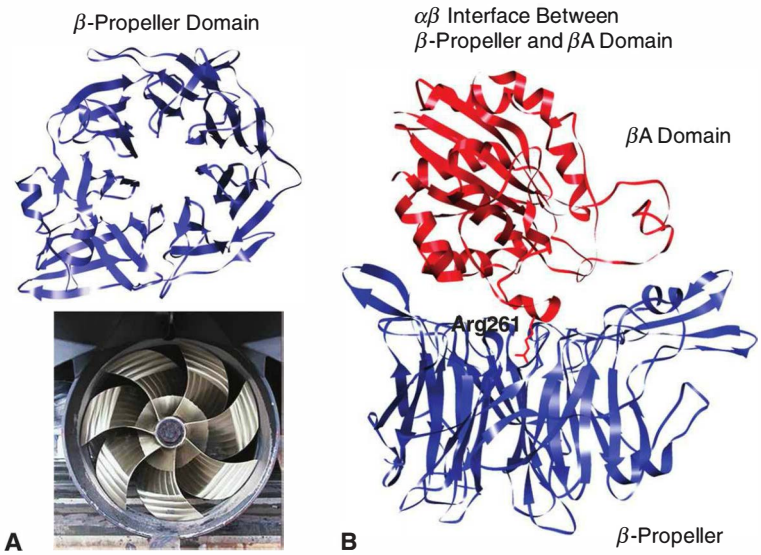

FIGURE 26B.2 The α_{IIb}-propeller domain and the interface between β-propeller and βA domain. **A:** The α_{IIb} β-propeller domain is formed by seven blades of β-sheet fold. **B:** At the interface, Arg261 of the βA domain protrudes off-center into the β-propeller's channel. From PDB entry 3FCS.

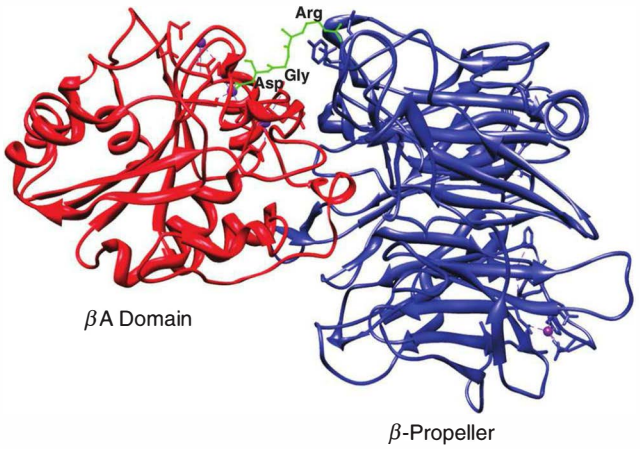

FIGURE 26B.3 Binding of the Arg-Gly-Asp (RGD) motif to the integrin $\alpha_v\beta_3$, a paralogue of $\alpha_{IIb}\beta_3$. The RGD peptide inserts into the interface between the β_3 βA and α_{IIb} β-propeller domains. The Arg points to the β-propeller whereas Asp make contacts with the βA domain. Gly lies at the interface. From PDB entry 3FCS.

the α_{IIb} and β_3 TMD pack together at two main interfaces with a vertical α_{IIb} TMD and tilted β_3 TMD.[39] At the outer membrane region, α_{IIb} and β_3 tightly pack against each other via a groove formed in the α_{IIb} $G^{972}XXXG^{976}$ motif and β_3 G^{708} (termed outer membrane clasp or OMC). The β_3 TMD forms a continuous helix that extends to the MP region of the cytoplasmic domain. A hydrophobic patch in the membrane-proximal region of β_3 is inserted into the membrane as a part of the TMD. Consequently, the β_3 TMD is long and crosses the lipid bilayer at an angle of 25 degrees. In contrast, the α_{IIb} TMD is a short and straight helix that ends at Gly991. Distal to Gly991, α_{IIb} makes a sharp turn toward β_3, enabling Phe992 and Phe993 to embed in the membrane and pack against β_3 residues Trp715 and Ile719. In addition, this places α_{IIb} Arg995 in close apposition to Asp723 of β_3, enabling an electrostatic interaction between them. The Phe packing interfaces and Arg995–Asp723 interaction completes the inner membrane interface (termed inner membrane clasp, or IMC)[39] (FIGURE 26B.4).

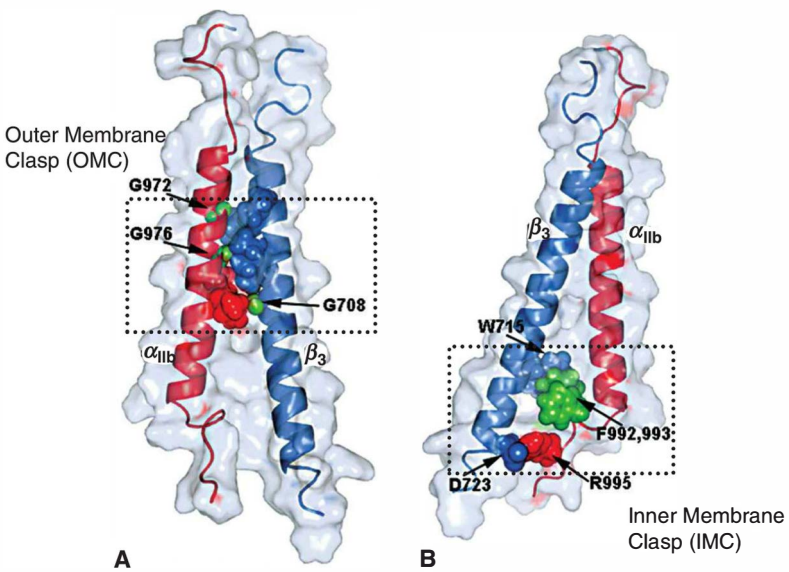
STRUCTURAL MECHANISMS OF INTEGRIN REGULATION

The combination of crystal and NMR structures and mutational studies has provided a detailed picture of integrin regulation. Integrin TMDs have two main interaction interfaces with three main contacts.[39,40] Mutations that disrupt these interactions favor the active form of the integrin. Charge reversal mutations of either α_{IIb} Arg995 or β_3 Asp723 disrupt the IMC and favor integrin activation, whereas combined charge reversals shift the equilibrium toward the inactive form.[43] Similarly, Phe to Ala mutations in the α_{IIb} MP region disrupt the IMC, inducing constitutive $\alpha_{IIb}\beta_3$ activity.[43]

Activating mutations are also found in the OMC. Most are substitutions of the Gly residues in both the α_{IIb} $G^{972}XXXG^{976}$ motif and β_3 Gly708 with residues containing bulky side chain, such as Leu, Ile, or Asn.[44–46] The side chains of these residues disrupt the tight packing interface between α_{IIb} $G^{972}XXXG^{976}$ motif and the β_3 TMD.[39,47] Furthermore, the 25-degree tilting angle of the β_3 helix is required to enable simultaneous interactions at the IMC and OMC.[39] Mutations that change the β_3 tilting angle, such as Lys716 to Ala, also result in disruption of the association of the β_3 TMD with α_{IIb}.[17] In short, integrins are kept in an inactive form by TM and cytoplasmic domain interactions. Following inside-out signaling, the α_{IIb} and β_3 TMD rearrange, causing integrin activation.

Integrin extracellular domains have multiple conformations, including those associated with inactive, active, and active ligand-occupied forms. The transition from one conformational state to another results in characteristic exposure of epitopes. A large inventory of conformation-specific $\alpha_{IIb}\beta_3$ antibodies has accumulated to study the relationship between $\alpha_{IIb}\beta_3$ conformation and function. How do the TMD and cytoplasmic domain rearrangements propagate to the integrin head

FIGURE 26B.4 Structure of the $\alpha_{IIb}\beta_3$ TMD heterodimer showing interactions at OMC and IMC. **A:** OMC interface. α_{IIb}(G972), α_{IIb}(G976), and β_3(G708) are shown as *green spheres*, with their β_3 and α_{IIb} packing residues shown in *blue* and *red*, respectively. **B:** IMC interactions. α–β TM complex stabilized by hydrophobic packing of α_{IIb}(F992, 993) (*green spheres*) against β_3(W715) (*blue sphere*) and α_{IIb}(R995) (*blue sphere*)–β_3(D723) (*red sphere*) electrostatic interaction. (From Lau TL, Kim C, Ginsberg MH, et al. The structure of the integrin alphaIIbbeta3 transmembrane complex explains integrin transmembrane signalling. *EMBO J* 2009;28:1351–1361.)



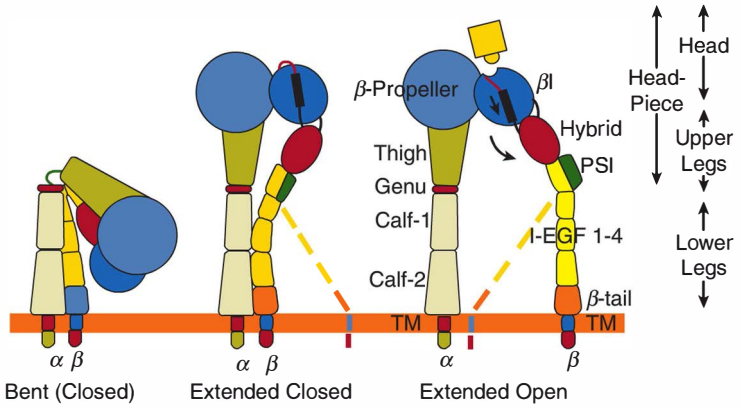


FIGURE 26B.5 Cartoon illustrating $\alpha_{IIb}\beta_3$ conformational changes. It has been proposed that $\alpha_{IIb}\beta_3$ has bent, extended closed, and extended open conformations that correspond to inactive, intermediate, and active state of the integrin molecule. (From Springer TA, Dustin ML. Integrin inside-out signaling and the immunological synapse. *CurrOpin Cell Biol* 2012;24:107–115).

piece to cause higher ligand binding affinities? One hypothesis proposes that a bent integrin conformation has a low affinity for ligand, while a more open and extended conformation is associated with high ligand affinity[37] (FIGURE 26B.5). It has also been proposed that TMD and cytoplasmic domain separation results in extension of integrin extracellular domain at the genu region and swing out of the β_3 hybrid domain.[48] The β_3 hybrid domain movement is coupled through the βA α7-helix to rearrange the ligand binding crevice at the interface between β-propeller and βA domains.[38] This global structural rearrangement increases the affinity of $\alpha_{IIb}\beta_3$ for its ligand[37] (FIGURE 26B.5). An alternative hypothesis posits that the bent conformation can be an active conformer, and that extension of the molecule is a post–ligand-binding event. This theory also has experimental support.[33,42,49,50] This is an area where there is likely to be continued debate.

INSIDE-OUT SIGNALING AND PLATELET AGGREGATION

At sites of vascular damage, platelets encounter agonists such as subendothelial collagen, ADP, or thrombin. Following agonist stimulation, signaling cascades are activated that eventually convert $\alpha_{IIb}\beta_3$ to its high affinity form. Activated $\alpha_{IIb}\beta_3$ binds tightly to multivalent ligands such as fibrinogen,[51,52,53] fibronectin,[54,55] and von Willebrand factor[56] each of which can contribute to platelet aggregation.

Among the earliest responses to agonist stimulation is activation of phospholipase Cβ (PLCβ) by Ca^{2+}. PLCβ then hydrolyzes the polar head group of phosphatidylinositol 4,5-bisphosphate to generate the secondary messengers diacylglycerol and inositol 1,4,5-triphosphate. This is followed by activation of protein kinase C (PKC), calcium- and diacyglycerol-regulated guanine nucleotide exchange factor I (CalDAG-GEFI), and phosphoinositide 3-kinase (PI3K). These signaling pathways can lead to Rap1B activation.[57,58,59–61] Rap1 activation is delayed in platelets lacking CalDAG-GEFI, and is completely abolished when both PKC and CalDAG-GEFI functions are absent.[62] Furthermore, knockout of Rap1B, the predominant Rap1 isoform in platelets, leads to reduced platelet aggregation, prolonged tail bleeding times, reduced $\alpha_{IIb}\beta_3$ activation, and defects in platelet spreading.[63] Thus, Rap1 has emerged as a possible common downstream effector for these signaling cascades. Rap1 interacts with a Rap effector, Rap1-GTP-interacting adaptor molecule (RIAM), which in turn binds to talin, forming a Rap1-RIAM–talin complex that targets talin to integrins[64,65,66] (FIGURE 26B.6). Talin, along with kindlin, forms the immediate $\alpha_{IIb}\beta_3$ activator.[67,68]

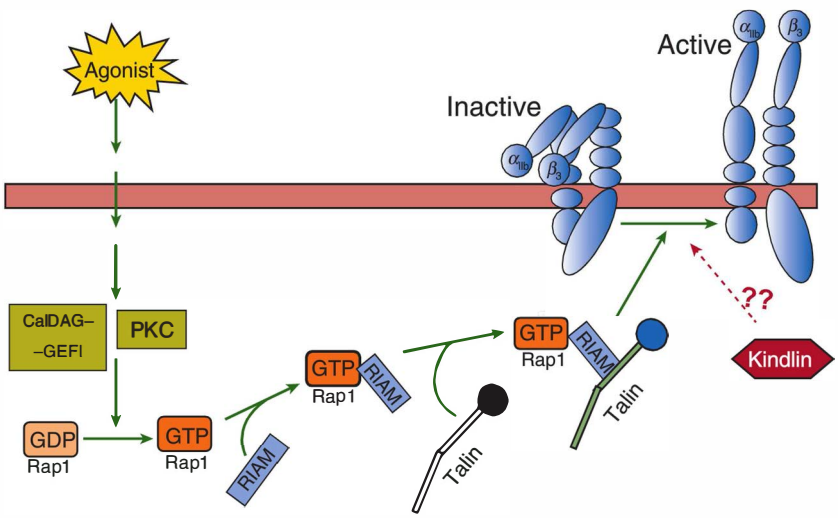

FIGURE 26B.6 Simplified representation of a signaling pathway from agonist stimulation to $\alpha_{IIb}\beta_3$ activation.

Talin, a 270 kDa cytoplasmic protein, can bind to integrin β tails through its 50 kDa head domain.[69,70] There are also multiple actin-binding sites in its 220 kDa rod domain.[71–73] Overexpression of the integrin-binding head domain in cells strongly activates $\alpha_{IIb}\beta_3$.[69] Tissue-specific deletion of talin in cells of the megakaryocyte lineage causes severe defects in platelet aggregation and agonist-stimulated $\alpha_{IIb}\beta_3$ activation. Consequently, mice that have lost talin in megakaryocytes and platelets have prolonged bleeding times and experience frequent pathologic bleeding.[74,75] The talin head domain binds to the β_3 cytoplasmic domain at two sites. First, it binds strongly to the β_3-W^{739}DTANNPLY^{747} sequence (membrane distal [MD] interaction) and then weakly to β_3 H^{722}DRKEFAKFEEER^{726} (membrane proximal [MP] interaction) that depends upon the presence of the first strong talin–integrin MD interaction.[76] In addition to the two integrin binding sites, the talin head domain has multiple positively charged residues on its surface that can interact with negatively charged phospholipids and to configure the talin–integrin interaction[77,78,79] (FIGURE 26B.7). The precise configuration of this integrin–talin-membrane interaction enables talin to alter the relationship between integrin α_{IIb} and β_3 subunits by both competitively disrupting α_{IIb} Arg995 and β_3 Asp723 electrostatic interaction pair and changing the tilting angle of the β_3 TMD.[77,79] As described above, the separation of α_{IIb} and β_3 results in integrin activation and higher affinity for ligands. *In vitro* reconstitution of inside-out $\alpha_{IIb}\beta_3$ activation using $\alpha_{IIb}\beta_3$-containing nanodiscs and liposomes demonstrated that all three interactions—distal and proximal talin binding to β_3 and talin interaction with the lipid bilayer—are necessary and sufficient for talin to activate $\alpha_{IIb}\beta_3$ *in vitro* and to favor an extended conformation.[80]

The kindlins, a second family of integrin β cytoplasmic domain-binding proteins, cooperates with talin to regulate $\alpha_{IIb}\beta_3$ activity.[67,68] There are three kindlin orthologues in mammals: kindlin-1, 2, and 3. Hematopoietic cells, including platelets, primarily express kindlin-3.[81] Loss of functional kindlin-3 in platelets results in severe bleeding, defective integrin activation, and defective platelet aggregation.[82] In model systems, coexpression of the talin head domain and kindlin-2 enhances talin-mediated integrin activation.[83,84] Thus kindlin and talin, together, regulate $\alpha_{IIb}\beta_3$ activation. The precise mechanism of kindlin function is a subject of intense investigation.

OUTSIDE-IN SIGNALING AND PLATELET FUNCTION

After $\alpha_{IIb}\beta_3$ engages ligands, intracellular signaling leads to events such as additional granule secretion, platelet spreading on extracellular matrices, stabilization of platelet adhesion and aggregation, and clot retraction that consolidates fibrin thrombi. Ligand engagement also induces further conformational changes in $\alpha_{IIb}\beta_3$ itself, as shown by exposure of new extracellular domain epitopes.[85] More importantly, multimeric macromolecular ligands, such as fibrinogen, fibrin, or fibronectin, induce $\alpha_{IIb}\beta_3$ clustering.[86–88] Conformational change and $\alpha_{IIb}\beta_3$ clustering together transmit the signals outside-in.

The earliest outside-in signaling event is activation of Src family kinases (SFK), particularly c-Src bound to the distal β_3 cytoplasmic domain.[89,90] Activated SFK rapidly phosphorylates ligand-occupied $\alpha_{IIb}\beta_3$ at β_3 residues Tyr747 and Tyr759. β_3 phosphorylation protects it from cleavage by proteases such as calpain,[91] and may enhance post ligand-binding events by generating docking sites for SH2-containing protein (Shc), an adapter in Ras signaling, and myosin, a motor protein involved in clot retraction and stabilization of platelet aggregates.[92] Mice in which both Tyr747 and Tyr759 have been mutated to Phe showed a tendency for rebleeding in tail bleeding time assays and impaired clot retraction.[93] Integrin clustering also brings

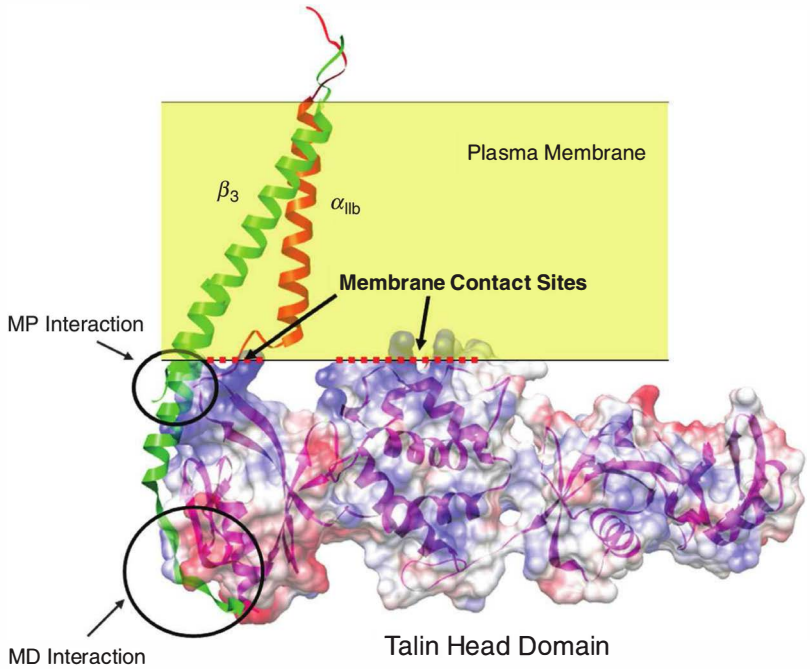

FIGURE 26B.7 Structural model of talin–integrin interaction at the plasma membrane. Talin binds to two sites in the integrin β_3 tail: the membrane distal (MD) interaction site centered on NPxY747 motif and a membrane proximal (MP) site. Talin also makes contact with the plasma membrane through the positively charged residues on its surface (*blue color* in the figure, *red dotted lines* indicate the membrane contact interfaces). Shown in *red* and *green* are the α_{IIb} and β_3 TMD from NMR structures (PDB entry 2k9j). The talin head domain (PDB entry 3IVF) is shown in surface representation. The ribbon diagram representation of β_3 was extended to the cytoplasmic domain by aligning the β_3 TM domain with the β1D cytoplasmic domain structure from a β1D-talin F2F3 (PDB entry 3G9W).

c-Src into clusters and result in dissociation of *C*-terminal Src kinase (CSK) from c-Src. Clustered c-Src is rapidly autophosphorylated at Tyr418 in the Src activation loop resulting in full activation of c-Src kinase activity[89,90] (FIGURE 26B.8). Activated Src phosphorylates immunoreceptor tyrosine-based activation motifs, which can then activate Syk.[94] Src and Syk together then phosphorylate and modulate the function of p190 Rho GTPase activating protein, SLP-76, Adhesion and Degranulation-Promoting Adapter Protein (ADAP), and Vav (a Rac exchange factor), all of which are implicated in further activation of platelets and contractile events that underlie clot retraction. For example, transient phosphorylation and activation of p190 Rho GTPase activating protein deactivate RhoA, which enables platelet to spread on $\alpha_{IIb}\beta_3$ ligands.[95,96] On the other hand, late and prolonged activation of mitogen-activated protein kinases and Rac-1 and myosin light chain phosphorylation result in platelet contraction and clot retraction.[97] Mutant mice in which the Src binding site in β_3 has been deleted manifest defective platelet spreading and reduced tyrosine phosphorylation of c-Src substrates. These mice are protected from carotid artery thrombosis after vessel injury with $FeCl_3$.[98]

$\alpha_{IIb}\beta_3$ AND BLEEDING DISORDERS

Given the important role of $\alpha_{IIb}\beta_3$ in platelet function and hemostasis, it is not surprising to find diseases resulting from mutations in $\alpha_{IIb}\beta_3$ and $\alpha_{IIb}\beta_3$ regulators. For example, loss of either α_{IIb} or β_3 expression due to nonsense mutations causes GT, a hereditary hemorrhagic disorder[1,2] (see Chapter 65). Another subset of GT patients carry mutations that disrupt folding, posttranslational processing, or intracellular transport of either α_{IIb} or β_3, resulting in reduced $\alpha_{IIb}\beta_3$ surface expression.[11] The most informative mutations have been those that cause GT without altering $\alpha_{IIb}\beta_3$ expression. These mutations perturb $\alpha_{IIb}\beta_3$ function and can be separated into three groups. One group of mutations is located in the extracellular portion of $\alpha_{IIb}\beta_3$ (e.g., β_3 Arg214 to Trp, β_3 Asp119 to Tyr) and perturbs the ligand binding pocket at the interface between α_{IIb} and β_3.[99,100] Another group is present in the $\alpha_{IIb}\beta_3$ cytoplasmic domains and disrupts the binding of $\alpha_{IIb}\beta_3$ regulators (e.g., β_3 Ser752 to Pro, β_3 Arg724 to Ter).[82,101,102] The third group locks $\alpha_{IIb}\beta_3$ in an activated conformation (e.g., β_3 Cys560 to Arg, β_3 Cys598 to Tyr).[103,104] In the latter group of mutants, patients exhibit GT-like symptoms because $\alpha_{IIb}\beta_3$ is constitutively occupied by ligand and may be internalized; thus it is not available to bridge $\alpha_{IIb}\beta_3$ from another platelet. An extensive list of $\alpha_{IIb}\beta_3$ mutations identified in GT patients has been compiled (available online at http://sinaicentral.mssm.edu/intranet/research/glanzmann/menu).

Patients with a variant of the leukocyte adhesion deficiency syndrome (LADIII) also display bleeding symptoms. These patients have mutations in kindlin-3,[105,106,107,108] the protein that together with talin regulates integrin activation. In platelets manifesting kindlin-3 mutations, $\alpha_{IIb}\beta_3$ activation in response to agonist stimulation is defective. Consequently, these platelets fail to aggregate or retract fibrin clots. A subset of kindlin-3–deficient LADIII patients were also reported to carry mutations in CalDAG-GEFI,[107,109] which might exacerbate the bleeding phenotype by impairing Rap1 activation.

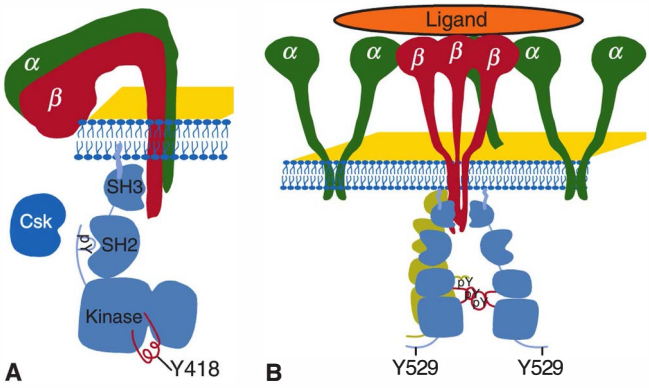

FIGURE 26B.8 Model for activation of β_3-associated Src. **A:** In platelets, a pool of c-Src (and several other SFK) is constitutively bound to the β_3 cytoplasmic tail through its SH3 domain. Because Tyr529 remains phosphorylated by Csk, Src is kept in a partially unclamped but not yet fully active state. **B:** Upon $\alpha_{IIb}\beta_3$ ligation and clustering, Src also becomes clustered and Csk dissociates from the integrin. This results in dephosphorylation of Tyr529, autophosphorylation of Tyr418 (Y418) in the Src activation loop, and full activation of Src kinase activity. (From Shattil SJ, Newman PJ. Integrins: dynamic scaffolds for adhesion and signaling in platelets. *Blood* 2004;104:1606–1615.)

$\alpha_{IIb}\beta_3$ ANTAGONISTS

The phenotype of patients with GT and of mice expressing $\alpha_{IIb}\beta_3$ mutants clearly shows that loss of $\alpha_{IIb}\beta_3$ function prevents platelet aggregation and protects against arterial thrombosis. Moreover, patients with GT rarely have spontaneous central nervous system bleeding despite suffering frequent mucocutaneous hemorrhages. These observations suggested that $\alpha_{IIb}\beta_3$ might be a therapeutic target for preventing arterial thrombosis. Three $\alpha_{IIb}\beta_3$ antagonists have been developed and approved for use in PCIs and as adjunctive therapy to prevent ischemic complications of coronary artery angioplasty in high-risk patients. The first clinically approved $\alpha_{IIb}\beta_3$ antagonist was abciximab, a humanized mouse monoclonal antibody 7E3 fab fragment containing murine variable regions and human IgG1 constant region.[110] In clinical trials, abciximab reduced all-cause mortality by approximately 20% during long-term follow-up after PCI.[111] This benefit outweighed the increase in absolute risk of major bleeding of approximately 7%. Furthermore, by reducing the dose of heparin used in combination with abciximab, the absolute increase in bleeding risk can be reduced to approximately 2% or less.[112]

Two low molecular weight $\alpha_{IIb}\beta_3$ antagonists, eptifibatide, a cyclic heptapeptide that selectively blocks $\alpha_{IIb}\beta_3$,[113] and tirofiban, a nonpeptide RGD-mimetic, were also approved for clinical use in patients with unstable angina and those undergoing PCI.[114,115] Eptifibatide and tirofiban confer a similar increase in risk of bleeding. Another complication common to all three $\alpha_{IIb}\beta_3$ antagonists is the occurrence of thrombocytopenia.[116,117] One possible cause of thrombocytopenia is the generation of antibodies against neoepitopes on $\alpha_{IIb}\beta_3$ exposed by the binding of the drugs to $\alpha_{IIb}\beta_3$. Use of abciximab resulted in even higher risk of thrombocytopenia probably due to the presence of alloantibodies against the murine components of the humanized antibody.

In contrast to the success of intravenous $\alpha_{IIb}\beta_3$ antagonists, chronic administration of oral $\alpha_{IIb}\beta_3$ antagonists to prevent recurrent thrombotic events has not been successful. Surprisingly, the oral $\alpha_{IIb}\beta_3$ antagonists were associated with increased mortality.[118,119] Several mechanisms have been proposed to explain this toxicity and the dissociation between benefits of intravenous and oral antagonists.[119,120,121] Compared with intravenous administration, fluctuation in plasma levels with oral dosing may provide suboptimal platelet inhibition for a portion of the treatment period. However, this explanation was undermined by the observation that higher-dose oral $\alpha_{IIb}\beta_3$ inhibition is associated with an even greater fatality risk.[118] It has also been speculated that the small molecule antagonists might act as ligand to trigger conformational change and outside-in integrin signaling, resulting in paradoxical thrombosis. In addition, the neoepitopes exposed by antagonists-triggered conformational change might be recognized by patient's antibodies, resulting in thrombocytopenia. Finally, these RGD-mimetic oral antagonists also have off-target effects on procaspase-3 activation in cardiomyocytes, resulting in increased cardiomyocyte apoptosis.[122] The exact mechanism of oral $\alpha_{IIb}\beta_3$ antagonist toxicity is still not known and may be a combination of these factors.

FUTURE OF $\alpha_{IIb}\beta_3$ RESEARCH AND MEDICAL APPLICATIONS

Research on the structure and function of $\alpha_{IIb}\beta_3$ has led to the development of the first generation intravenous $\alpha_{IIb}\beta_3$ antagonists. In the past 10 years, enormous progress has been made in understanding $\alpha_{IIb}\beta_3$ regulation. Novel therapeutic targets identified by these studies might offer superior clinical benefits with reduced risk of pathologic bleeding.[98,123] There is also an attempt underway to improve on the currently available drugs. For example, by designing drugs that inhibit $\alpha_{IIb}\beta_3$ without altering its conformation[124] or that only bind to and block active $\alpha_{IIb}\beta_3$,[125] both thrombocytopenia and antagonists-induced integrin outside-in signaling may be attenuated.

Platelet Glycoprotein Polymorphisms and Relationship to Function and Immunogenicity

THOMAS J. KUNICKI AND DIANE J. NUGENT

In order to place the effect of glycoprotein gene polymorphisms on platelet function and immunogenicity into proper perspective, a brief summary of key aspects of platelet function is helpful.

Following vascular damage, platelets interact with specific components of the extracellular matrix, particularly collagen, and a complex series of receptor–ligand interactions ensue that ultimately lead to the formation of a stable platelet plug or thrombus. This process is a continuum of at least three phases that can be described as *initiation*, *extension*, and *consolidation*, each requiring the orchestrated cooperation of a group of receptors.

In the *initiation* phase, plasma von Willebrand factor (vWF) binds to collagen via its A3 domain and becomes structurally altered, enabling its A1 domain to bind to the platelet membrane receptor complex glycoprotein Ib-IX-V (GPIb complex). It is GPIbα, the larger subunit of GPIb, that makes direct contact with vWF. This association is a requisite step in platelet adhesion to exposed thrombogenic surfaces at sites of vessel wall injury or in regions of atherosclerotic plaque rupture. This leads to the formation of a more stable platelet monolayer on the collagen surface, mediated predominantly by the platelet-specific receptor glycoprotein VI (GPVI) and the platelet integrin $\alpha_2\beta_1$.

The engagement of these receptors causes platelet activation leading to the *extension* phase, mediated largely by the conversion of prothrombin to thrombin on the activated platelet surface and the secretion of compounds from platelet granules (α-granules and δ-granules), which can further stimulate platelets. One of these compounds, adenosine diphosphate (ADP), augments platelet activation by binding to its cognate platelet receptors, the purinergic receptors $P2Y_1$ or $P2Y_{12}$. Activated platelets also produce and/or release additional agonists, including thromboxane A2 (TXA_2), which then binds to the platelet TXA_2 receptor. Most of the receptors involved in the events of the *extension* phase are members of the G-protein–coupled receptor family.

Other agonists that function during the extension phase include thrombin and epinephrine (EPI). Thrombin (also known as coagulation factor II) binds to a number of receptors, but of particular importance for this discussion is the protease-activated receptor 1 (PAR-1). EPI binds to the platelet α2A-adrenergic receptor (ADRA2A). EPI can contribute to the initiation phase and, in low doses, is thought to prime platelets for enhanced activation by other agonists. The ADRA2A is a G-protein–coupled receptor and activates heterotrimeric G proteins, including those containing the β3 subunit (GNB3).[1] Alternative splicing variants of GNB3 appear to enhance G-protein signal transduction[2,3] and could thus alter the effect of EPI on platelets. Thrombin contributes to the augmentation of platelet activation during the extension phase because the surface of activated platelets is a nidus for prothrombin conversion. Nonetheless, both thrombin and EPI, as well as ADP, are capable of binding to and activating the naïve platelet in an alternative initiation phase.

In the *consolidation* phase, platelet–platelet cohesion (aggregation), mediated by the binding of fibrinogen and/or vWF to the activated platelet integrin $\alpha_{IIb}\beta_3$ (also known as GPIIb-IIIa), together with the assembly of a fibrin network, results in the generation of platelet-rich aggregates or thrombi.

SINGLE NUCLEOTIDE POLYMORPHISMS AND GENE HAPLOTYPES

Receptor Glycoprotein Gene Haplotypes

This chapter is concerned with polymorphisms, defined as nucleotide sequence differences with a minor allele frequency (MAF) of ≥0.02 in any racial or ethnic group and that are detectable in unrelated normal subjects. Polymorphisms that are immunogenic and elicit a humoral response in normal subjects are defined as alloantigens and are designated by the prefix human platelet antigen (HPA-),[4] as shown in Table 27.1. Immunogenic polymorphisms that are unique to a single group of related subjects are considered familial or private antigens and are not discussed in this chapter. Single nucleotide polymorphisms (SNPs) in platelet glycoprotein receptor genes can give rise to differences in expression levels, activity, and/or immunogenicity. Genes harboring SNPs that create alloimmunogenic epitopes include the integrin α_2 subunit gene *ITGA2*,[5,6] the integrin αIIb subunit gene *ITGA2B*,[7,8] the integrin β_3 subunit gene *ITGB3*,[9,10,11–20] the GPIbα subunit gene *GP1BA*,[21,22] and the gene *CD109*.[23] In this chapter, protein and cDNA sequences are numbered from the ATG translation start codon, as recommended by the Human Genome Variation Society (http://www.hgvs.org/mutnomen/).

ITGA2. Polymorphisms in the *ITGA2* promoter and regulatory regions generate a fourfold range of $\alpha_2\beta_1$ expression on platelets and other cells. The six most common haplotypes are defined by three SNPs, C-52T (rs28095), C759T (rs1126643), and G1600A (rs1801106). The rs1801106 alleles result in the nonconservative amino acid substitution E534K, creating the clinically relevant HPA-5 alloantigen system, but these alleles do not affect $\alpha_2\beta_1$ binding to collagen.[5] G1600A is in linkage disequilibrium (LD) with C-52T that has a substantial effect on the rate of ITGA2 transcription. However, unlike C-52T, it is not associated

Table 27.1

with regulation of a2 expression. [24] However, selected gene association studies indicate that the minor allele of rs1801106 (1600A) is associated with recurrent stroke[25] and an increased risk for breast cancer in women.[26] Even though this SNP does not alter $\alpha_2\beta_1$ binding to collagen, it is possible that it modulates the binding of other physiologically relevant $\alpha_2\beta_1$-specific ligands, such as C1q, decorin, endorepellin, or perlecan.[27–30]

The *ITGA2* mutation T828M (rs79932422) produces the HPA-13bw alloantigen,[6] but has a MAF of 0.0025 and is not of clinical significance. Although T828M has no effect on platelet adhesion to collagen I, II, or IV, four individuals have been reported who are at least heterozygous 828M and whose platelets exhibit a diminished aggregation response to low-dose collagen (2.5 µg/mL) but a normal response to high-dose collagen (10 µg/mL).[6] Nonetheless, these reports must be interpreted with caution because platelet levels of $\alpha_2\beta_1$ in the affected individuals were not measured.

ITGA2B. Two major *ITGA2B* haplotypes are characterized by the SNP T2621G (rs5911) giving rise to the substitution I874S that defines the HPA-3 alloantigen system.[7] I874S is adjacent to the binding site of the murine monoclonal antibody PMI-1 that inhibits platelet adhesion and spreading on collagen,[31] suggesting that the region of α_{IIb} encompassing the HPA-3 and PMI-1 epitopes participate in aIIbb3-mediated platelet adhesion. The precise impact of the T2621G substitution on platelet function has not been determined, but homozygosity for the 2621G haplotype is associated with a fivefold increase in the risk of ischemic stroke among women with hypertension or diabetes.[32]

ITGB3. The β_3 SNP T176C (rs5918) results in an L59P substitution that defines the HPA-1 alloantigen system.[10] In whites, sensitization to HPA-1a is the leading cause of alloimmunization against platelets (discussed below). There has been considerable debate about the influence of *ITGB3* HPA-1b on platelet function and the risk of acute coronary disease or cerebrovascular disease. Several reports from one group of investigators indicated that HPA-1b confers either enhanced $\alpha_{IIb}\beta_3$ function or resistance to inhibitors of platelet function,[33–37] but not all studies have observed an increased biologic activity associated with the HPA-1b haplotype.[38,39] After considerable conflicting evidence from several gene association studies, most of which were seriously underpowered, subsequent meta-analyses failed to clarify the potential association of HPA-1b with risk for coronary artery disease: One meta-analysis[40] concluded that there is a weak but significant association of HPA-1b with overall cardiovascular disease in the general population and a stronger association in subgroups, such as younger cohorts or a restenosis subset with stents; the second meta-analysis[41] simply found that HPA-1b is not associated with an increased risk of developing myocardial infarction. As regards cerebrovascular disease, a recent meta-analysis found that HPA-1b does not represent a useful marker of increased risk[42].

GP1BA. The GPIb complex is a heptamer composed of four distinct gene products and consists of two molecules of GPIbα, two of GPIbβ, two of GP IX, and one of GP V. Each GPIbα molecule is disulfide-linked to a GPIbβ, whereas the interactions of GPIbα with GPIX and GPV are noncovalent. vWF binds directly to the *N*-terminal portion of GPIbα. Clinically relevant polymorphisms have been associated with the gene *GP1BA* encoding the GPIbα subunit, and two major haplotypes are distinguished by the SNP C482T (rs6065), giving rise to a T161M substitution within the GPIbα ligand-binding region that defines the HPA-2 alloantigen system.[21,43]

T161M is in LD with a variable number of tandem repeats (VNTRs) in the mucin-like macroglycopeptide region of GPIbα. The VNTR region results from duplication of a 13–amino acid sequence once (VNTR A), twice (VNTR B), thrice (VNTR C), or four times (VNTR D), leading to polypeptide lengths of 610, 623, 636, or 649 amino acids, respectively.[44,45] Because the repeats are rich in serine and threonine, they can be O-glycosylated, and each repeat adds 32 Å to the length of the GPIbα extracellular domain.[44] This progressively increases the distance of the vWF- and thrombin-binding sites on GPIbα from the plane of the platelet plasma membrane, increasing the accessibility of these binding sites and perhaps accounting for the reported increased risk for acute coronary artery disease associated with the GPIbα longer variants, VNTR C and VNTR D, which are in LD with M161.[46,47]

In addition, the SNP C-5T (rs2243093) at a position 5 nucleotides upstream from the GPIbα initiator codon ATG appears to enhance its translational efficiency.[48,49] Thus, the presence of the −5C allele increases the mean level of GPIbα on the platelet plasma membrane (roughly, a 50% increase in homozygous individuals and a 33% increase in heterozygous individuals).[48] The C–5T alleles and the M161T alleles are in complete LD.[50]

CD109. The *CD109* SNP C2108A (rs10455097) gives rise to the HPA-15 alloantigen system.[23,51] The resulting Y703S amino acid substitution is carried by the glycosylphosphatidylinositol-linked protein CD109, a negative regulator of the transforming growth factor (TGF)-β system in keratinocytes.[52,53] Currently there are no published data concerning the effect of anti-HPA-15 antibodies on platelet function.

PLATELET GLYCOPROTEIN IMMUNOGENETICS

Progress in understanding the biology of platelet membrane glycoproteins was stimulated by study of their immunogenicity because these glycoproteins figure prominently as alloantigens, autoantigens, and targets of drug-dependent antibodies. Platelet membrane glycolipids and phospholipids also represent autoantigenic components, but much less is known about the structure and immunogenicity of these platelet constituents. Thus, this review will highlight the immunogenetics of platelet glycoproteins.

Two clinically important syndromes, fetomaternal alloimmune thrombocytopenia (FMAIT), also known as neonatal alloimmune thrombocytopenia, and posttransfusion purpura (PTP), result from sensitization to platelet-specific alloantigens. The development of these alloantibodies is a major obstacle to platelet transfusion therapy in sensitized patients, such as those undergoing chemotherapy in conjunction with myelodysplastic syndromes or hematopoietic stem cell transplantation.

FMAIT is caused by maternal sensitization to paternal alloantigens on fetal platelets. The frequency of alloimmunization against each of the HPA varies according to race because of significant differences in frequencies of the minor alleles (Table 27.2).

In whites, sensitization to HPA-1a and -5b dominates. In one large study of 1,054 cases of clinically definable FMAIT, HPA-specific antibodies were detected in only 22% of cases,[54]

consistent with previous reports.[55–57] Among cases in which HPA-specific antibodies were detected, HPA-1a and -5b were the relevant target antigens in 95% of cases, while 5% of cases involve antibodies specific for antigens of the HPA-2, -3 or -15 systems. In another large study of 3,743 cases,[58] HPA-specific antibodies were detected in 31% of cases, with the distribution: 79% anti-HPA-1a; 9% anti-HPA-5b; 2% anti-HPA-3a; and 4% anti-HPA-1b. The HPA-4b allele is virtually nonexistent in white populations, and only two reports of FMAIT caused by HPA-4 incompatibility have been reported,[59,60] The remaining eleven HPA systems have been defined by at least one case of FMAIT but have been assigned the status "bw" since antibodies against the major allele have not yet been reported. These bw alleles are extremely rare, and antibodies specific for these were detected in only 8 of 1,054 cases in one comprehensive study of white women.[54]

In Asian populations, the HPA-1a frequency is so low as to be nonexistent (Table 27.2), and no cases of FMAIT associated with anti-HPA-1a have been reported.[61] On the other hand, the HPA-4b allele figures more prominently among Asians, and in a large study of pregnant Asian women (99% Japanese), the detected alloantibodies were most often specific for HPA-5b (75%) or HPA-4b (22%).[61]

The response to HPA-1a among individuals homozygous for HPA-1b is HLA restricted,[62–64] and responsive individuals are almost exclusively HLA DRB3*0101[63] or DQB1*02.[65,66] For DRB3*0101, the calculated risk factor is 141, a risk level equivalent to that of HLA B27 in ankylosing spondylitis.[65] On the other hand, the converse response of homozygous HPA-1a individuals to the more rare HPA-1b haplotype is not linked to HLA.[65,67] It is probable that T cells are responsible for the HLA restriction in this case, and Maslanka et al.[65] reported that in one case of FMAIT, T cells that share CDR3 motifs are stimulated by peptides that contain the same Leu59 substitution that is recognized by anti-HPA-1a alloantibodies.

PTP can result within 7 to 10 days after an immunogenic blood (platelet) transfusion and most often affects previously nontransfused, multiparous women. As with FMAIT, there is an increased risk to develop PTP among HLA-DR3–positive individuals, and HPA-1a is the antigen most often implicated in white populations.[62,68]

CANDIDATE GENE ASSOCIATION STUDIES

Prior to the genomic era, most attempts to identify genetic differences influencing platelet function in normal individuals relied upon a candidate gene approach. Target genes were rationally selected as candidates (Table 27.3) based on their established or logical involvement in any of the important molecular events that contribute to normal platelet function. Thus, studies focused on platelet surface receptors, for

Table 27.3

example, (a) fibrinogen-mediated platelet aggregation via integrin $\alpha_{IIb}\beta_3$ [37,69–72]; (b) collagen-induced platelet adhesion and signal transduction via integrin $\alpha_2\beta_1$[73,74] or GPVI[75,76]; (c) vWF-mediated platelet adhesion via GPIbα[21,44,45,48]; or (d) platelet signaling induced by various physiologic agonists.[77–81]

The success of any candidate gene association study depends on four key factors: (a) an accurate, reproducible, and vetted measure of the disease phenotype or of platelet function; (a) the inclusion of adequate cohort sizes; (c) a consideration of ethnic homogeneity of the cohorts; and (d) the appropriate SNP selection. Most gene association studies are compromised by small cohort sizes or a poor selection of SNPs. The most appropriate SNP choices, or tagSNPs, are those that take into consideration linkage and reflect haplotype definitions.[82] However, only a few of the foregoing studies used well-defined tagSNPs. Consequently, although the reported associations for *ITGA2* C807T (rs1126643),[74] *GP1BA* C-5T,[48,83] and the *GP6* haplotype b[75] have been replicated, others were not.[39,84] These studies and the details of the factors used to qualify their success have recently been reviewed.[85]

Functional Genomics Approach

Through the comparison of a relatively large number of SNPs ($n = 1{,}327$) in a selected group of several candidate genes ($n = 97$), Jones et al.[86] have recently identified 17 independently associated SNPs that account for 48% of the variation in platelet reactivity induced by either ADP or the GPVI agonist cross-linked collagen reactive peptide (CRP-XL). The success of this study reflects careful attention to study design and establishes a paradigm for future genomic studies. The study used the Platelet Function Cohort (PFC), a group of 500 healthy individuals with a similar Northern European ancestry.[87] Careful consideration was given to the selection of indices of platelet function. Consequently, platelet function was compared by measuring fibrinogen binding to activated $\alpha_{IIb}\beta_3$, the requisite step for aggregation, and the expression of P-selectin, a marker of platelet degranulation after stimulation with either ADP or CRP-XL. These agonists represent two distinct signaling pathways. GPVI signaling is an early event that acts via an Fc receptor-gamma chain/immunoreceptor tyrosine-based activation motif (FcRγ/ITAM) pathway, and ADP amplifies platelet activation in later stages through the G-protein–coupled receptors $P2Y_1$ and $P2Y_{12}$. Based on *a priori* knowledge of the protein components of each of the signaling cascades, 97 candidate genes were selected. The exons of these genes were resequenced in 48 reference DNA samples from the Center d'Etude du Polymorphism Humain European Cohort to maximize the database of sequence variation, leading to the identification of 1,327 SNPs that were then genotyped in the PFC samples.

This association study confirmed that *GP6* is a strong quantitative trait locus (QTL) for platelet response to CRP-XL. But the success of this study lay in the analysis of a large number of genes each exerting a small effect. Using a *P* value <0.005 as a cutoff, to overcome the errors inherent in multiple testing, 68 SNPs encompassed within 15 genes showed an association with the platelet response to CRP-XL, ADP, or both (Table 27.4).

Data from Jones CI, Bray S, Garner SF, et al. A functional genomics approach reveals novel quantitative trait loci associated with platelet signaling pathways. *Blood* 2009;114:1405–1416.

Variation in *GP6*, as anticipated, accounted for up to 40% of the variation in GPVI signaling.[87] This is consistent with our own *in vitro* results that the minor isoform of GPVI (GPVIb) is associated with decreased Fyn/Lyn binding and enhanced calmodulin binding to the cytoplasmic tail.[76]

For the remaining genes, 18 independent associations in 15 loci were identified. These included the cell surface receptor genes *CD36*, *GP6*, *ITGA2*, *PEAR1*, and *P2RY12*; adapter proteins *FCERG1* and *GNAZ*; kinases *JAK2*, *MA2K2*, *MAP2K4*, and *MAPK14*; and the intracellular signaling molecules *ITPR1* and *VAV3*.

Of note, an association was not found between *ITGB3* and any of the indices of platelet response. As noted above, there is conflicting evidence in the literature regarding the association of *ITGB3* rs5918 with variation in platelet function or risk for acute coronary artery or cerebrovascular disease.[37,39,40–42,69–71,84] One possible explanation is that the MAF is low (0.15), and the majority of studies were severely underpowered by small cohort sizes. In addition, the diversity of functional assays and platelet agonists employed in these studies certainly contributed to the discrepant findings.

Additional novel findings resulted from this study. Most notably, the platelet endothelial aggregation receptor 1, encoded by *PEAR1*, is now known to be a platelet receptor that undergoes phosphorylation upon platelet–platelet contact.[88] The promoter variant (rs2768759) is associated with increased platelet aggregation in PRP in response to EPI.[89] In this study, *PEAR1* was identified as a regulator of both CRP-XL and ADP signaling, with two distinct associations observed. One SNP, rs41299597, was associated with CRP-XL–induced pathways, while the more common SNP rs11264579 was associated with the ADP pathway.

GENOME-WIDE ASSOCIATION STUDY

The genomic era was ushered in by technological improvements that enabled massive genome-wide SNP association and deep sequencing studies. A genome-wide association study (GWAS) using a direct measure of platelet function was recently performed by Johnson et al.,[90] who tested the association of 2.5 million SNPs with platelet aggregation responses to three agonists (ADP, EPI, and collagen) in two cohorts of European ancestry (n = 2,753 in the Framingham Heart Study; n = 1,238 in the Genetic Study of Atherosclerosis Risk). Seven loci were associated with platelet aggregation (Table 27.5), the two most strongly associated lying near or within the platelet glycoprotein genes *GP6* ($P = 4.6 \times 10^{-13}$) and *PEAR1* ($P = 3.4 \times 10^{-12}$). The remaining five loci were near or within the genes *ADRA2A* ($P = 3.3 \times 10^{-11}$), *PIK3CG* ($P = 3.1 \times 10^{-9}$), *JMJD1C* ($P = 1.6 \times 10^{-8}$), *MRVI1* ($P = 2.0 \times 10^{-8}$), and *SHH* ($P = 4.5 \times 10^{-8}$). Six of these loci (save *PIK3CG*) replicated at $P < 0.05$ in an additional African American cohort (n = 840 in the Genetic Study of Atherosclerosis Risk).

Three loci were significant for ADP-induced aggregation: 1q23.1 (*PEAR1*, rs12566888, $P = 3.4 \times 10^{-12}$), 11p15.4 (*MRVI1*, rs7940646, $P = 2 \times 10^{-8}$), and 7q36.3 (sonic hedgehog homolog [SHH], rs2363910, $P = 4.5 \times 10^{-8}$). The *PEAR1* minor allele was associated with a decreased response, while the minor alleles of *MRVI1* and *SHH* were associated with increased responses. *PEAR1* was discussed above, and its presence here provides strong confirmation for the previous results of Jones et al.[86] *MRVI1* (a.k.a. *IRAG*) encodes a homolog of murine retrovirus integration site 1, which is a member of a signaling complex that influences smooth muscle relaxation through negative modulation of inositol triphosphate (IP_3)-induced calcium signaling.[91] In mice, MRVI1 is directly involved in the inhibition of platelet aggregation and thrombus formation in vivo.[92] Microvesicles containing SHH will induce differentiation along the megakaryocyte lineage, suggesting a relationship to platelet biology.[93]

Table 27.5

GWAS of platelet aggregation induced by ADP, EPI, or collagen

Locus	Nearest Gene	Effect of Minor Allele	dbSNP
1q23.1	*PEAR1*	↓ ADP, ↓ EPI	rs12566888 (G>T)
11p15.4	*MRVI1*	↑ ADP, ↑ EPI	rs7940646 (C>T)
7q36.3	*SHH*	↑ ADP	rs2363910 (G>T)
10q25.2	*ADRA2A*	↓ EPI	rs4311994 (C>T)
7q22.3	*PIK3CG*	↓ EPI	rs342286 (A>G)
10q21.2	*JMJD1C*	↑ EPI	rs10761741 (G>T)
19q13.42	*GP6*	↑ collagen lag	rs1671152 (G>T)

Data from Johnson AD et al. Genome-wide meta-analyses identifies seven loci associated with platelet aggregation in response to agonists *Nat Genet* 2010:42:608–615.

Four regions were strongly associated with EPI-induced aggregation: 10q25.2 (*ADRA2A*, rs4311994, $P = 3.3 \times 10^{-11}$), 1q23.1 (*PEAR1*, rs12566888, $P = 7.3 \times 10^{-10}$), 7q22.3 (*PIK3CG*, rs342286, $P = 3.1 \times 10^{-9}$), and 10q21.2 (*JMJD1C*, rs10761741, $P = 1.6 \times 10^{-8}$). In the case of *ADRA2A*, *PEAR1*, and *PIK3CG*, the minor alleles were associated with reduced EPI-induced aggregation, while the minor allele of the peak SNP nearest *JMJD1C* was associated with increased aggregation. *ADRA2A* encodes the major platelet α-adrenergic (EPI) receptor, and its association here is not surprising. *PIK3CG* (rs342293), which encodes a subunit of phosphoinositide-3-kinase, was recently shown to be associated with decreased mean platelet volume.[94] *JMJD1C* (jumonji domain containing 1C) is the only gene without a documented functional link to platelets, although it does exhibit enhanced expression in megakaryocytes relative to other hematopoietic cells.[95]

A single locus 19q13.42 including *GP6* (rs1671152) was significantly associated with lag time to collagen-induced aggregation response (European ancestry, $P = 4.6 \times 10^{-13}$; African ancestry, $P = 0.048$). This SNP creates a Y323K substitution in the longer isoform of GPVI but is alternatively H322N in the shorter GPVI isoform that we studied in an earlier report.[76] In either case, Johnson et al.[90] determined that the minor allele was associated with a decreased collagen response (increased lag time), while we showed that the minor allele attenuated binding of Fyn/Lyn to the GPVI cytoplasmic tail.[76] These observations provide a plausible explanation for the prolonged lag time to onset of aggregation, since the minor allele would attenuate downstream responses to collagen engagement. Our prior results thus provide a mechanistic explanation for the strong association of this SNP with platelet responsiveness to collagen in this GWAS.

The findings for the *GP6*, *PEAR1*, and *ADRA2A* regions provide robust validation of prior studies,[75,86,89,96–98] although with

a much larger sample size, while the associations with loci that include *MRV11*, *SHH*, *JMJD1C*, and *PIK3CG* are novel.

SUMMARY

Polymorphisms in platelet membrane glycoprotein genes have created a repertoire of human platelet alloantigens that can be clinically significant as causes of FMAIT and PTP. The six most commonly involved alloantigen systems are HPA-1 and HPA-4 on integrin subunit β_3; HPA-2 on platelet GPIb; HPA-3 on integrin subunit α_{IIb}; HPA-5 on integrin subunit α_2; and HPA-15 on CD109. Because of significant differences in allele frequencies between racial/ethnic populations, the relative importance of each differs. In white populations, HPA-1 and HPA-5 are implicated in the vast majority of cases of FMAIT; while in Asian populations, HPA-5 and HPA-4 figure most prominently.

SNPs in selected glycoprotein genes can have significant effects on receptor expression or function. Candidate gene associations studies have demonstrated that several SNPs are consistently associated with differences in platelet function between normal individuals. With respect to receptor genes, the most notable are *GP6*, *ADRA2A*, *P2RY12,* and *PEAR1*, but also *GP1BA* and *ITGA2*.

The importance of *ADRA2A*, *GP6*, and *PEAR1* has been validated in a genome-wide association study of differences in platelet responses to ADP, EPI, and collagen. Such studies have and will continue to provide new insight into regulators of platelet function that would otherwise remained unexplored. Platelet function QTL studies have already identified key regulators of signaling pathways. Further meta-analysis of platelet function in tens of thousands of subjects will increase the number of QTLs, and the completion of the ongoing one thousand genomes initiative (likely tens of thousands by 2014) will serve to identify rare coding and noncoding variants. Some of these may exert a large effect on platelet phenotypes.

Finally, it should be understood that knowledge of platelet QTLs for function should not be used in clinical practice to infer risk of thrombotic or bleeding events in individual subjects.

CHAPTER

28 The Basis for Platelet Adhesion

BRIAN SAVAGE AND ZAVERIO M. RUGGERI

PERSPECTIVE

Mammalian platelets are circulating fragments of bone marrow megakaryocytes[1,2] that function primarily to maintain the integrity of the vasculature by stopping hemorrhage after vascular injury and tissue trauma.[3] Although platelets lack genomic DNA, they contain megakaryocyte-derived messenger RNA and are capable of protein synthesis.[4,5] During their 10-day lifetime in the human circulation, most platelets never participate in irreversible adhesion, and are cleared from the circulation by macrophages in the spleen and liver. However, in response to alterations of endothelial cells lining the vessel wall or exposure of subendothelial matrix components following vascular injury, platelet adhesion, activation, and thrombus formation occur,[3] events that are crucial for maintaining primary hemostasis and preventing posttraumatic blood loss. On the other hand, thrombus formation in diseased vessels can impede blood flow to vital organs, for example, in heart coronary arteries and cerebral arteries, leading to myocardial infarction and stroke, respectively. In addition to their role in hemostasis and thrombosis, platelets are thought to contribute to other processes, such as atherogenesis[6–8] and inflammation,[9–12] by maintaining normal vascular permeability and directing other effector cells to sites where microbial and viral pathogens induce inflammatory responses.[13,14] Evidence also suggests a role for platelets in tumor angiogenesis[15] since tumor cells can activate platelets and induce release of angiogenic factors that directly affect the tumor endothelium.[16]

To ensure normal hemostasis without the undesired thrombus formation, the adhesive properties of platelets must be tightly regulated to respond to a precise set of stimuli. A comprehensive review of the signaling mechanisms that regulate platelet adhesion is not presented in detail here, but can be found elsewhere.[17–20] In this chapter, we focus on the principal substrates and receptors that mediate platelet adhesion, activation, and aggregation, and the role of blood flow in modulating platelet adhesive functions.

INDUCTION OF PLATELET ADHESION RESPONSES

Platelets circulating in close proximity to intact, unperturbed endothelial cells do not attach to them, at least in part because endothelial cells actively maintain an antiadhesive phenotype.[21–23] However, disruption of the endothelium by mechanical trauma or pathogenic stimuli resulting from endovascular or extravascular disease processes leads to platelet adhesion at the injured site. Initiation of platelet adhesion in posttraumatic hemostasis involves platelet interaction with exposed extracellular matrix components, consisting of a large number of adhesive macromolecules including various types of collagen,[24,25] von Willebrand factor (vWF),[26,27] fibronectin,[28] laminin,[29] fibulin,[30] and thrombospondin.[31] In addition, platelets can interact indirectly with extracellular matrix proteins that upon exposure to blood bind plasma-derived proteins such as fibrinogen/fibrin[32] vWF,[26] and vitronectin[33] that become immobilized onto subendothelial surfaces at sites of vascular damage. Depending on the prevailing rheologic conditions and the types of matrix proteins exposed to the flowing blood, platelet adhesion requires the synergistic function of distinct platelet receptors, ultimately leading to platelet activation and aggregation.[34] Following activation, the platelet membrane presents a negatively charged phospholipid surface required for the assembly of activated coagulation factor complexes, which in turn leads to thrombin generation and the formation of a fibrin network stabilizing the growing thrombus.[35]

PLATELET ADHESION TO vWF

The Essential Role of Immobilized vWF

vWF is a glycoprotein (GP) that circulates in plasma as large multimers ranging in size from 500 to 20,000 kDa[36,37] that contain binding sites for collagen, as well as the platelet receptors GPIbα and the integrin $\alpha_{IIb}\beta_3$(GPIIb/IIIa).[38] The monomeric subunit of mature vWF consists of 2,050 amino acids and is composed of four distinct repeating domains that are crucial for the function of the molecule.[39,40] Megakaryocytes and endothelial cells are the only cells that synthesize vWF. Megakaryocyte-derived vWF is stored in α-granules and is only released during agonist-induced platelet secretion. By contrast, endothelial cell vWF is either constituently secreted or directed to Weibel-Palade body storage granules for agonist-induced secretion.[36] Plasma vWF is almost exclusively derived from endothelial cells.[41] The multimers secreted from endothelial cell Weibel-Palade bodies are extremely large (ultra large vWF [ULvWF]) and their ability to bind to extracellular matrix proteins[42] and to the platelet receptor, GPIbα in the GPIb-IX-V complex is enhanced compared to the smaller vWF multimers present in plasma.[43] The metalloprotease, ADAMTS13, cleaves the secreted ULvWF to functionally less active, smaller multimers.[44,45]

Under conditions of elevated shear stress, typically present in arteries and small arterioles, vWF plays an essential role in initiating platelet adhesion and sustaining platelet aggregation.[26,32] It is present as a constitutive component of the extracellular matrix of endothelial cells[46] where it is associated with collagen type VI filaments,[47–49] and can directly support platelet adhesion.[50–54] In addition, circulating plasma vWF can interact with exposed extracellular matrix components, particularly collagen types I

and III in deeper layers of the vessel wall[55] and microfibrillar collagen type VI in the subendothelial matrix.[49,56–58] Other potential binding sites for plasma vWF include heparin, sulfatides, and fibrin.[3] The main site for vWF binding to collagen types I and III is located in the vWF A3 domain,[59] with a minor role, but possibly an essential one under high blood flow conditions, attributed to A1 domain binding to collagen type VI.[55,60] Additionally, plasma vWF can become immobilized by self-association; a process involving the reversible interaction of circulating vWF multimers with matrix bound and endogenous subendothelial vWF.[61] vWF self-association is modulated by multiple domains,[62] although none have been identified as essential, including A1 and A3[61] (FIGURE 28.1).

Platelet Capture by Immobilized vWF

When circulating platelets encounter immobilized vWF under arterial blood flow conditions, that is, wall shear rates exceeding 800/second (value for the human circulation; approximately double in the mouse circulation), they are captured and tethered by a mechanism involving the transient interaction of platelet GPIbα with the A1 domain of immobilized vWF.[32] Although this interaction is short-lived and insufficient by itself to mediate stable platelet adhesion, it maintains platelets in close contact with the blood vessel wall as they translocate in the direction of blood flow. This reduces their velocity and facilitates their subsequent adhesion and activation[32] (FIGURE 28.2). It is during the translocation phase that platelets establish contact with collagen in the extracellular matrix via platelet glycoprotein VI (GPVI) and integrin $\alpha_2\beta_1$, proteins that are unable to mediate platelet adhesion by themselves under high flow velocity conditions. Engagement of GPVI and $\alpha_2\beta_1$ with collagen triggers intracellular signals that activate platelets and shift platelet integrins to a high-affinity state, as well as the release of the agonists ADP and thromboxane A_2 (TXA_2) that contribute synergistically to induce full platelet activation. Following platelet activation, stable adhesion is reinforced by the β_1 integrins, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$, that bind to collagen, fibronectin, and laminin respectively, as well as by integrin $\alpha_{IIb}\beta_3$ that binds to fibronectin and collagen-bound vWF.

Role of Receptor GPIbα

There are two physiologically relevant platelet receptors for vWF[63,64]: GPIbα, a component of the GPIb-IX-V complex[65] that binds to the vWF A1 domain,[66,67] and the integrin $\alpha_{IIb}\beta_3$[68] that binds to the Arg–Gly–Asp motif located in vWF C1 domain.[69] A third receptor, the integrin $\alpha_v\beta_3$,[70] may participate in vWF-mediated platelet adhesion to endothelial cells.[71] GPIbα is a highly abundant, extensively glycosylated protein expressed exclusively on megakaryocytes and platelets. It is a component of the GPIb-IX-V complex composed of four gene products: GPIbα, GPIbβ, GPIX, and GPV.[72–75] Resting platelets express 25,000 copies of GPIb-IX and 12,000 copies of GPV. Human GPIbα has a 290-residue *N*-terminal domain containing 8 tandem leucine-rich repeats[73,76] that binds vWF[34] and α-thrombin.[77,78] GPIbα has also been reported to contain binding sites for coagulation factors XI and XII,[79] high molecular weight kininogen,[80] P-selectin,[81] and the leukocyte receptor Mac-1,[82,83] but the precise identity of these sites remains to be determined. The interaction between GPIbα and vWF under dynamic conditions of blood flow supports the activation-independent capture and tethering of platelets to immobilized vWF[32] and this occurs despite forces opposing platelet adhesion

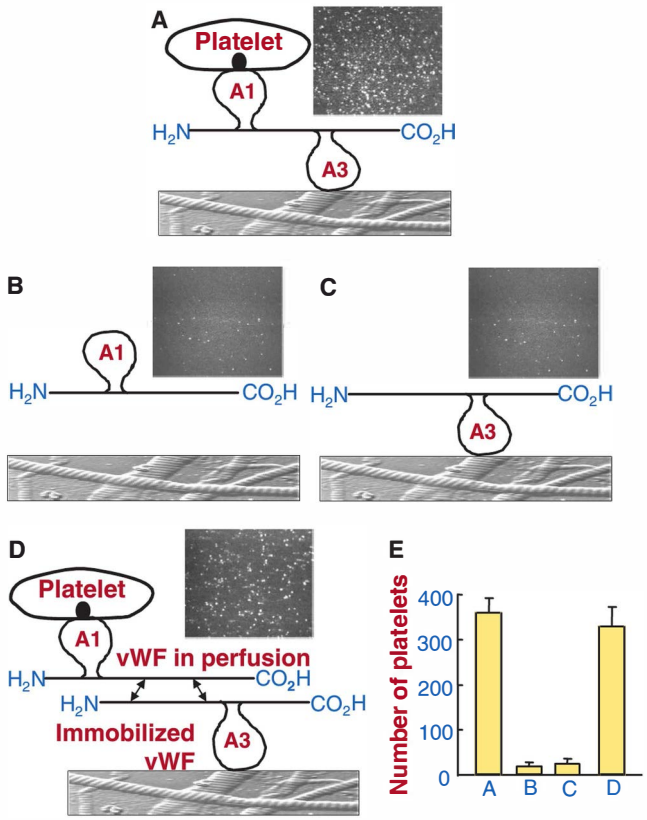

FIGURE 28.1 Functional self-association of vWF multimers. Suspensions of washed blood cells containing ethylenediaminetetraacetic acid (EDTA) to block integrin function and prostaglandin (PG) E_1 to block platelet activation were perfused over immobilized collagen type I fibrils at the wall shear rate of 1,500/s. **A**: Normal multimeric vWF was added to a cell suspension. Its A3 domain mediates vWF binding to collagen and the A1 domain interacts with platelet GPIbα. In the electron micrograph, tethered platelets are seen rolling on the collagen fibrils. **B**: vWF devoid of the A3 domain (ΔA3-vWF) which cannot bind to collagen or **(C)** vWF devoid of the A1 domain (ΔA1-vWF), which cannot interact with platelet GPIbα was added to the cell suspension. In neither case, were platelets tethered to the immobilized collagen. **D**: Collagen fibrils were precoated with ΔA1-vWF multimers and then exposed to the blood cell suspension containing ΔA3-vWF. Although the latter cannot bind directly to collagen, they can associate with the ΔA1-vWF multimers to support platelet tethering. The *two-sided arrows* between multimers indicate that the association is reversible. The images are single frames from a real time recording representing an area of 65,536 μm^2. The *bar graph* shows the number of platelets tethered to the surface under the different experimental conditions described above (mean ± SEM of two separate experiments). **E**: quantifies the results shown in **A–D**. (Modified from Savage B, Sixma JJ, Ruggeri ZM. Functional self-association of von Willebrand factor during platelet adhesion under flow. *Proc Natl Acad Sci U S A* 2002;99:425–430, and reprinted with permission. Copyright (2002) National Academy of Sciences, U.S.A.)

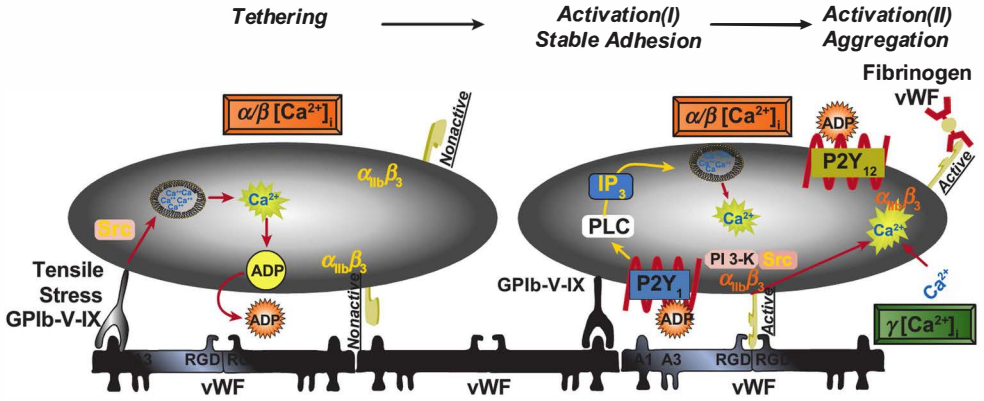

FIGURE 28.2 Schematic representation of the sequential signaling events induced by the interaction of platelets with immobilized vWF under high shear stress. On the left, a platelet is shown during the initial tethering to the A1 domain of immobilized vWF mediated by the GPIb-IX-V complex. An α/β $[Ca^{2+}]_i$ elevation is elicited as a consequence of this interaction and leads to ADP release from intracellular storage granules. Src family kinases may be involved at this stage and cAMP/cGMP levels modulate this and other downstream responses. Subsequent events are shown in the platelet on the right. Released ADP binds to the G_q-coupled $P2Y_1$ receptor, leading to PLC activation and enhanced Ca^{2+} release from internal stores during α/β oscillations. At this stage, there is a first level of localized $\alpha_{IIb}\beta_3$ activation that supports more prolonged platelet adhesion mediated by the RGD sequence in the vWF C1 domain. PI 3-K activation may enhance this response. Further PI 3-K activation, and possibly the involvement of Src family kinases, contribute to more generalized $\alpha_{IIb}\beta_3$ activation that permits soluble ligand binding and supports formation of platelet–platelet aggregates. This second level of $\alpha_{IIb}\beta_3$ activation is concurrent with or subsequent to a type $\gamma[Ca^{2+}]_i$ elevation dependent on a transmembrane ion flux. The second ADP receptor, $P2Y_{12}$, supports the formation of larger platelet aggregates through mechanisms that occur after the measured Ca^{2+} oscillations. The TXA_2 pathway inhibited by aspirin appears to have a very limited role in the successive stages of platelet adhesion, activation, and aggregation induced by the interaction with immobilized vWF. IP3, inositol-1,4,5-trisphosphate; Src, Src family tyrosine kinases; PLC, phospholipase C; PKC, protein kinase C; PI 3-K, phosphatidylinositol 3-kinase. (Adapted from Mazzucato M, Cozzi MR, Pradella P, et al. Distinct roles of ADP receptors in von Willebrand factor-mediated platelet signaling and activation under high flow. *Blood* 2004;104:3221–3227.)

at elevated flow rates.[32,84] GPIbα-mediated platelet adhesion to vWF is functionally similar to selectin-mediated leukocyte rolling on inflamed vascular surfaces,[85] and presumably shares similar biophysical characteristics, such as rapid on-rates[86–88] and rapid dissociation-rates.[84,86,88–90] In addition, both interactions support flow-enhanced adhesion[91] and are thought to involve "catch" bonds, rather than "slip" bonds.[92] Catch bonds are characterized by a lifetime that increases directly with applied shear force up to a maximum threshold value. As applied shear force increases above the threshold, the lifetime of the bond decreases, resulting in the transition to a more typical slip bond for which the lifetime decreases with increasing shear stress.[92] Recent studies have provided a better understanding of the biomechanical properties of vWF A1 domain binding to GPIbα.[93] A method that enables the repeated measurement of the binding and unbinding of interacting receptor and ligand domains engineered within a single molecule has revealed the existence of two states of the vWF A1 domain-GPIbα bond and has thus been named a flex-bond. One state is seen at low force, while the second state begins to engage at higher force (10 pN) with approximately 20-fold longer lifetime and greater force resistance.

Mutations in both vWF A1 domain and GPIbα can change the mechanical properties of the flex bond. A gain-of-function point mutation in GPIbα at Met239Val results in an approximately sixfold increase in affinity for the interaction with vWF A1 domain due to an increased on-rate.[94] By contrast, a gain-of-function point mutation in vWF A1 at Arg543Gln does not appear to form catch bonds with GPIbα, and has an increased affinity for GPIbα due mainly to a decreased off-rate, resulting from the formation of slip bonds even at low shear stresses.[95] Regulation of the GPIbα/vWF interaction appears to involve conformational changes in both the receptor and the ligand,[96] and phosphorylation of Ser166 of GPIbβ may negatively regulate vWF binding.[97]

GPIb-IX-V-Dependent Signaling

Until recently it was thought that the interaction of GPIbα with immobilized vWF only provides a mechanism for recruiting platelets to sites of vascular damage, thereby reducing their velocity to enable other platelet receptors to elicit intracellular activation signals. However, it is now clear that GPIb-IX-V, in addition to its role as an adhesion receptor, can mediate intracellular signals leading to activation of the integrins $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$, allowing platelets to firmly attach, spread, and aggregate.[26,98–101] Several intracellular signaling pathways are involved in GPIb-IX-V-mediated platelet activation, including the Syk/phospholipase C (PLC) pathway,[101,102] the phosphatidylinositol 3-kinase (PI 3-K)-Akt pathway,[103–105] the cGMP[106] and mitogen-activated protein kinase pathways,[107] and the TXA_2 and ADP pathways.[108,109] Members of the Src family kinases appear to

play an important role because Src inhibitors prevent GPIb-IX-V-induced $\alpha_{IIb}\beta_3$ activation,[110,111] Ca^{2+} mobilization,[112] PI 3-K activation,[113,114] and TXA_2 synthesis.[108] The Src family tyrosine kinase Lyn has been shown to be crucial in GPIb-IX-V-mediated activation of the cGMP pathway.[111]

Engagement of GPIb-IX-V with the vWF A1 domain also leads to the tyrosine phosphorylation of adhesion and degranulation promoting adaptor protein (ADAP),[110] a potential linker between cell activation events at the plasma membrane and intracellular events. ADAP is required for the modulation of $\alpha_{IIb}\beta_3$ affinity induced by GPIb-IX-V interaction with the vWF A1 domain.[115] Despite the many signaling pathways attributed to the interaction of GPIb-IX-V with vWF, the relative importance of this interaction *in vivo* compared to other receptor/ligand signaling pathways remains to be established. Indeed, platelet translocation on immobilized vWF *ex vivo* may last for several minutes before stable $\alpha_{IIb}\beta_3$-mediated attachment occurs,[32] indicating that the activating signal is relatively weak compared with those induced by more thrombogenic surfaces like collagen.

As recently demonstrated, platelet adhesion and aggregation can be initiated independently of platelet or integrin activation through a mechanism that involves the interaction with immobilized as well as soluble vWF under high shear stress conditions[116] (FIGURE 28.3). A key feature of this mechanism is that sustained platelet attachment and aggregation only occur above a threshold shear rate of 10,000/second, a pathologically relevant shear rate in arterial thrombosis.[116] These studies have been extended using experimental mouse models of vascular injury, demonstrating that thrombi initially develop through the progressive stabilization of discoid platelet aggregates.[117] These discoid platelets adhere preferentially in low-shear zones downstream of forming thrombi, indicating that disturbed blood flow, creating gradients of increasing and decreasing shear stress, may play an important role in initiating the process of thrombogenesis in arteries.

The Role of vWF in Venous Thrombosis

Although the participation of vWF in arterial thrombosis has been repeatedly demonstrated, its role in platelet recruitment during the initiation of venous thrombosis has only recently been documented.[118] Unlike arterial thrombosis, thrombosis in deep veins is not initiated by injury to the endothelial layer,[119] but rather by blood flow disturbances resulting in complete or partial flow restriction.[120] Although increased procoagulant states are known risk factors for deep vein thrombosis,[121–123] disturbed blood flow due to long-term immobilization can also provoke deep vein thrombosis in the absence of hypercoagulability.[124,125] Flow disturbance–induced venous thrombosis in mice due to prolonged flow restriction in the inferior vena cava was significantly reduced in mice genetically deficient in vWF.[118] Furthermore, infusion of a mutant GPIbα–IgG chimera that inhibits the interaction of vWF A1 domain with platelets prevented thrombosis in wild-type mice with normal vWF levels. Although circulating vWF is coupled to factor VIII, infusions of recombinant factor VIII did not rescue thrombosis in vWF-deficient mice. These observations suggest that vWF–platelet adhesive interactions may play a key pathogenic role in initiating venous thrombosis following flow restriction.

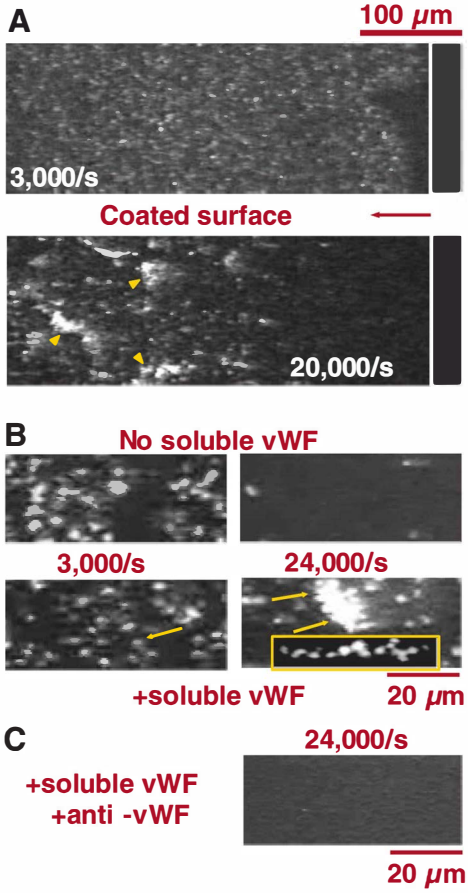

FIGURE 28.3 Activation-independent platelet adhesion and aggregation at the interface of immobilized and soluble vWF. **A**: Blood containing 93 μM D-phenylalanyl-L-prolyl-L-arginine chloromethyl ketone dihydrochloride to inhibit α-thrombin, the fluorescent dye mepacrine at 10 μM, 10 μM PG E_1, and 5 mM EDTA was perfused over immobilized vWF. The *white line* delimits vWF-coated (to the *left*) from uncoated glass. Single platelets adhere when the shear rate is 3,000/s **(top)**; rolling aggregates (some identified by *arrowheads*) form at 20,000/s **(bottom)**. **B**: Perfusion of washed blood cells suspended in buffer (20 mM Hepes, 150 mM NaCl, pH 7.4) over immobilized vWF. In the absence of soluble vWF, single platelets adhere when the shear rate is 3,000/s **(upper left)**, and fewer single platelets adhere at 24,000/s **(upper right)**. After adding 20 μg/mL soluble vWF, single platelets adhere at 3,000/s (**lower left**; an *arrow* points to a single platelet shown for reference), but aggregates form at 24,000/s (**lower right**; *arrows* point to a rolling aggregate and an *inset* highlights a stretched aggregate during stationary adhesion). **C**: Perfusion of washed blood cells with added soluble vWF and anti-vWF A1 domain monoclonal antibody (NMC-4, 20 μg/mL) over immobilized vWF. No platelet adhesion is detected. (From Ruggeri ZM, Orje JN, Habermann R, et al. Activation-independent platelet adhesion and aggregation under elevated shear stress. *Blood* 2006;108:1903–1910.)

PLATELET ADHESION TO COLLAGEN AND PLATELET COLLAGEN RECEPTORS

The vessel wall contains several different types of collagen, particularly the fibrillar collagens type I, III, and VI. The collagens can associate with each other and with other matrix proteins,

and play an active role in the initiation of platelet adhesion and aggregation in response to injury.[126] Experimental studies with collagens can be complicated by changes in collagen structure introduced during extraction of the protein from extracellular matrix. For example, acid-insoluble collagen type I fibers display a characteristic banded pattern due to the regular staggering of collagen monomers[126,127] and react with platelets bearing GPVI even when $\alpha_2\beta_1$ is inhibited. By contrast, pepsin-solubilized acid soluble collagen type I microfibrils lack the banded pattern and form spiral structures[127] and optimally interact with platelets bearing functional $\alpha_2\beta_1$, in addition to GPVI. As collagen is an insoluble matrix protein, preparations used in *ex vivo* experimental studies are often treated with proteases, such as pepsin, for solubilization resulting in functional behavior distinct from that of the native protein. Thus, the presence of spiral fibrils in pepsin-treated acid soluble collagen can lead to an overestimate of the role of $\alpha_2\beta_1$ in the interaction of collagen with platelets.

Collagen activates platelets primarily through the membrane proteins GPVI and $\alpha_2\beta_1$[55,128] (FIGURE 28.4); several other potential collagen "receptors" have been described, but none has been shown to convincingly play a role in platelet adhesion and aggregation. Even the relative contribution of GPVI and $\alpha_2\beta_1$ to these processes remains a topic for debate. Ambiguities introduced during the isolation of collagen from extracellular matrices, as discussed above, as well as poorly understood differences between human *ex vivo* and mouse *in vivo* experimental systems may explain the lingering uncertainties.[55,128] According to the prevalent current model, GPVI is essential for platelet activation and aggregation on collagen, whereas $\alpha_2\beta_1$ is required for firm platelet adhesion with only a relatively minor role in platelet activation.[128] More recent evidence, obtained studying platelet–collagen interactions under flow,[129,130] supports the existence of a functional synergy between $\alpha_2\beta_1$ and GPVI. Indeed, it was found that $\alpha_2\beta_1$ can signal independently of GPVI or $\alpha_{IIb}\beta_3$ (GPIIb–IIIa), and that GPVI function is facilitated by preceding intracellular Ca^{2+} elevations resulting from $\alpha_2\beta_1$ engagement. This does not exclude the possibility that the ligand-binding affinity of $\alpha_2\beta_1$ is enhanced following GPVI interaction with collagen and/or $\alpha_{IIb}\beta_3$ activation. Accordingly, the functional activities of $\alpha_2\beta_1$ and GPVI may be viewed as concurrent, or mutually reinforcing, rather than sequential, a concept supported by the finding that variations in the amount of $\alpha_2\beta_1$ on the platelet surface influences the extent of GPVI-dependent Ca^{2+} signaling.[129]

Glycoprotein VI

Approximately 10% of collagens I and III consist of a repeating GPO (glycine–proline–hydroxyproline) motif, also known as collagen-related peptide[131] that is the strongest platelet stimulus within the collagen molecule[132] and that reacts specifically with platelet GPVI.[133] The smallest collagen motif that recognizes and activates platelet GPVI consists of two GPO triplets.[134] On the platelet surface, GPVI is present in a noncovalent complex with the Fc receptor-γ chain, an interaction that is essential for both GPVI expression and function.[128,135] Functional GPVI is thought to be a dimer. Each GPVI monomer contains two extracellular Ig-C2-like domains, a mucin-like domain, a transmembrane region, and a short 51-residue cytoplasmic tail.[136,137] The cytoplasmic tail has distinct sites

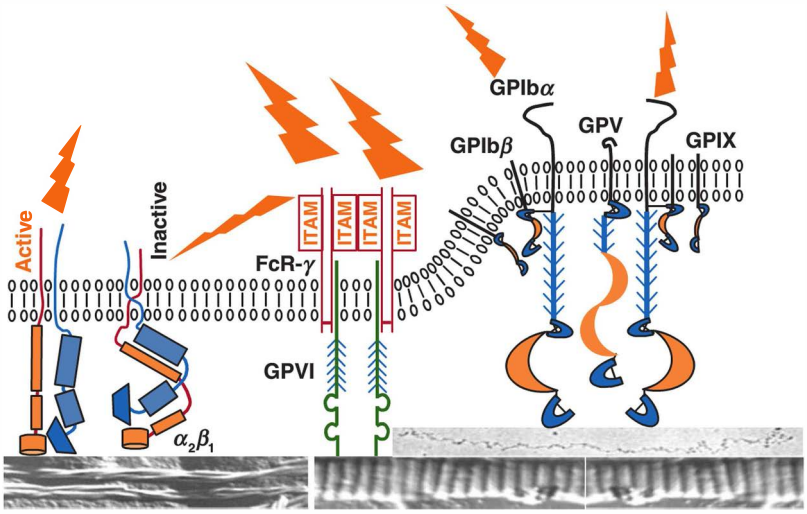

FIGURE 28.4 Schematic representation of the mechanisms of platelet adhesion to collagen. The collagen receptors, $\alpha_2\beta_1$ and GPVI, are depicted along with the GPIb-IX-V complex. Collagen and vWF are represented by electron micrographs (not in scale). Two forms of collagen type I are shown, "native" acid-insoluble fibers (on the **right**) and pepsin-treated acid-soluble "spiraled" fibrils (on the **left**), with a vWF multimer shown as if adhering to the native collagen fiber. On a surface in which collagen and vWF form a functional unit, initial platelet tethering is mediated primarily by GPIbα binding to vWF-A1 under high flow conditions, allowing subsequent GPVI binding to collagen, specifically to the prototypic repeating sequence Gly–Pro–Hyp (where Hyp is hydroxyproline), typical of the fibril-forming collagens. Both receptors can signal, but the role of GPVI is predominant in this regard. The integrin $\alpha_2\beta_1$ requires activation by an inside-out signal for high affinity binding to collagen; however, on partially degraded "spiraled" fibrils, it may be essential for the initial tethering through recognition of the sequence Gly–Phe–Hyp–Gly–Glu–Arg. The fact that GPVI is not sufficient for adhesion to this substrate attests to the conformational disruption of its recognition site in partially degraded collagen.

that interact with calmodulin to regulate Ca^{2+} signaling pathways and with the Src family tyrosine kinases Fyn and Lyn that signal independently of the Fc-receptor. GPVI can also signal in response to collagen or other ligands by an Fc-receptor-dependent pathway involving activation of the tyrosine kinase Syk.[99] Signaling through GPVI upregulates platelet integrins, including $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$, events essential for shear-resistant platelet attachment to collagen.

A mechanism for regulating GPVI function is based on the metalloproteinase-mediated shedding of the GPVI ectodomain. This process involves the calmodulin binding site in the GPVI tail and results in the disappearance of GPVI from the platelet surface and the release of a 55 kDa GPVI fragment.[138] Unlike $\alpha_2\beta_1$, GPVI is a platelet-specific protein that has a unique and indispensable function in platelet activation and thrombus formation.[139–141] Studies of mice lacking GPVI expression due to targeted Fc-receptor-γ gene deletion confirmed the essential role of GPVI for collagen-induced platelet activation and adhesion to the subendothelial matrix.[139,140,142]

Impaired thrombosis on injured carotid arteries in mice rendered GPVI deficient by specific antibody treatment implies that GPVI plays an essential role in thrombogenesis under arterial flow conditions *in vivo*.[143] Barring unknown effects of the antibody used, these results suggest that the adhesive defect of platelets lacking GPVI is the consequence of reduced activation. Indeed, in *ex vivo* perfusion experiments, mouse platelets congenitally-deficient in GPVI exhibit essentially normal initial platelet contact with insoluble type I collagen fibrils, but no activation-dependent spreading and a complete defect in platelet aggregation.[140] However, the extent of the defect caused by the absence of GPVI appears to depend on the nature of the surface to which platelets are exposed. In *ex vivo* experiments, thrombus formation is normal when the blood of $GPVI^{-/-}$ mice is perfused over the extracellular matrix deposited by mouse skin fibroblasts.[26] Such a finding indicates that the vessel wall contains substrates for thrombus formation independent of collagen. The results of *in vivo* studies have confirmed the influence of additional variables on the role of GPVI in hemostasis[144] and thrombosis.[26] By measuring the tail bleeding time and the occlusion of the carotid artery following a ferric chloride-induced injury, it was apparent that $GPVI^{-/-}$ mice present a dichotomous behavior, with one group showing normal results and another displaying marked prolongation of the bleeding time and absent arterial thrombosis (FIGURE 28.5). Of note, each phenotype was a hereditary trait. A possible explanation for these results is the existence of one or more modifier genes that, directly or indirectly, influence the thrombogenic potential of GPVI-deficient platelets. One candidate gene has been postulated to exist within the modifier of hemostasis locus on the mouse chromosome four, suggesting that conditions may exist at a site of vascular injury that indeed make the role of GPVI more or less relevant for platelet adhesion and aggregation.

It is noteworthy that inhibition of α-thrombin has been shown to have a more profound antithrombotic effect in mice deficient in GPVI/FcR-γ than in normal controls, indicating that thrombin contributes to overcoming the functional defect of platelets with an impaired collagen-induced activation response. These results suggest that the pathways of platelet adhesion/stimulation in injured arteries likely to influence the extent of thrombosis are determined by the nature of the vascular lesion and of the substrates exposed to blood, including those leading to α-thrombin generation.

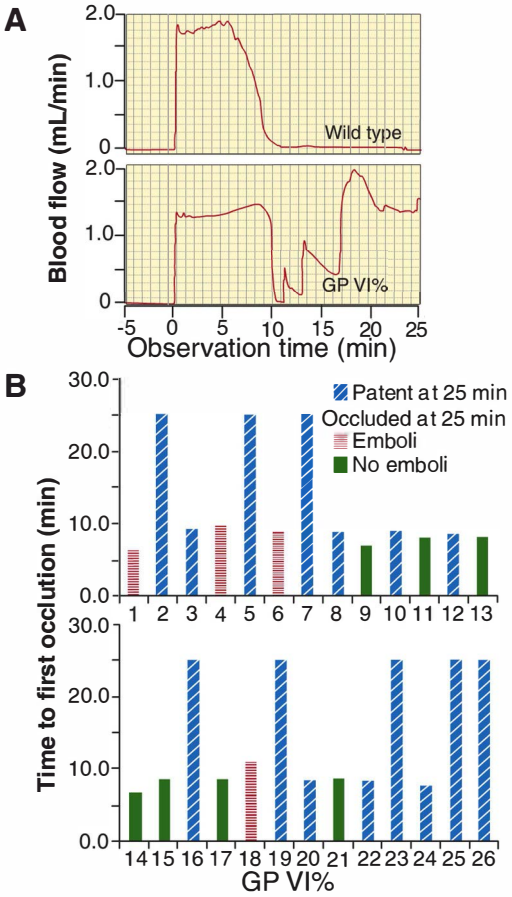

FIGURE 28.5 Ferric chloride-induced carotid artery thrombosis in GPVI deficient mice. **A**: Doppler tracings of blood flow in the carotid artery of wild type and $GPVI^{-/-}$ mice following $FeCl_3$ injury. In the wild type control shown, flow begins to decrease approximately 6 minutes after application of $FeCl_3$ to the artery and a complete occlusion occurs 3 minutes later with no resumption of flow. In the $GPVI^{-/-}$ mouse, flow reduction begins between 8 and 9 minutes after $FeCl_3$ application and complete obstruction develops over the next 1 to 2 minutes. However, blood flow resumes with alternating cycles of reocclusion and reopening of the vessel, indicating thrombus instability. Arterial flow is restored to normal at the end of the observation period in the $GPVI^{-/-}$ mouse. **B**: Bar graph representation of the time of first occlusion, occurrence of embolization, and presence or absence of occlusion at the end of the observation period in 26 $GPVI^{-/-}$ mice. (Modified from Konstantinides S, et al. *J Thromb Haemost* 2006;4:2014–2021).

$\alpha_2\beta_1$

The integrin $\alpha_2\beta_1$, also known as GPIaIIa, very-late-activation antigen-2, or CD49b/CD29, was the first collagen receptor to be identified and functions mainly as an adhesion receptor.[24,145–147] $\alpha_2\beta_1$ is composed of 150-kDa α_2 and 130-kDa β_1 subunits.[148] Its expression on normal platelets can vary up to 10-fold,[149] depending on a specific α_2 genotype. A polymorphism in the α_2 gene (C807T) was found to be a genetic marker of $\alpha_2\beta_1$ expression

levels, with platelets carrying the TT genotype expressing the highest levels, the TC genotype intermediate levels, and the CC genotype the lowest levels.[150] The amount of $\alpha_2\beta_1$ expressed on the platelet surface appears to correlate positively with the initial rate of platelet adhesion to collagen type I.[149,151] In addition to platelets, $\alpha_2\beta_1$ is expressed on fibroblasts where it functions as a collagen receptor and on epithelial and endothelial cells where it functions as both a collagen and laminin receptor.[152–154] The α_2 subunit contains an I-domain (amino acids 140 to 349) that serves as the primary ligand binding interface[155] when Mg^{2+} bound to the I domain interacts with a glutamate residue in the collagen molecule.[156] Recombinant α_2-I domain fusion proteins bind specifically to collagen in a divalent cation-dependent manner[157–160] and inhibit the interactions of platelets with collagen under flow.[157] Furthermore, antibodies that recognize epitopes in the I-domain inhibit $\alpha_2\beta_1$ binding to collagen.[161–163] Collagen-related peptides that contain the high affinity binding motif for $\alpha_2\beta_1$, Gly–Phe–Hyp–Gly–Glu–Arg,[164] have been used extensively in the study of platelet–collagen interactions.[24,156] In one study, $\alpha_2\beta_1$-mediated platelet adhesion to collagen-related peptides was enhanced by suboptimal stimulation of the thrombin receptor PAR4,[164] emphasizing the importance of multiple synergistic pathways in the adhesion process. Thus, while some receptors are constitutively active in a high affinity ligand binding state, others like platelet $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ require cellular activation and a conformational change to transition from a low to a high affinity binding state.[165,166]

The requirement that "inside-out" signaling precede high affinity $\alpha_2\beta_1$ binding to collagen has been confirmed using mouse platelets lacking GPVI.[128,139] Moreover, $\alpha_{IIb}\beta_3$ activation appears to be involved in platelet $\alpha_2\beta_1$ activation.[167] $\alpha_2\beta_1$ activation can also be induced by ligation of GPVI, as demonstrated by defective adhesion to matrix proteins of platelets lacking GPVI, or in the presence of GPVI inhibitors.[139,142,168] It should be noted that even in its low affinity state, $\alpha_2\beta_1$ might be capable of mediating platelet adhesion to collagen preceding GPVI-induced activation[24] in a manner akin to the binding of nonactivated $\alpha_{IIb}\beta_3$ to immobilized fibrinogen.[169] Indeed, evidence has been provided that $\alpha_2\beta_1$ can signal independently of GPVI and $\alpha_{IIb}\beta_3$.[129] The high affinity binding of $\alpha_2\beta_1$ to collagen induces a series of "outside-in" signaling events similar to those induced by GPVI, involving Src, Syk, SLP-76, and PLCγ_2.[128,170] Thus, despite their structural differences, the two main collagen receptors may share common signaling pathways to reinforce their interaction with collagen.[24,128,171] On the other hand, there are also differences in the signaling events following GPVI and $\alpha_2\beta_1$ ligation, as shown by the occurrence of distinctive intracytoplasmic Ca^{2+} transients following platelet adhesion to collagen/vWF.[129] It is now generally accepted that adhesion, activation, and aggregation are linked by an interplay of different receptors that integrate these functions according to the nature of the underlying vascular lesion.[26,172]

Deficits in the interaction of α_2-deficient murine platelets with collagen *ex vivo* have been detected, ranging from relatively mild decreases when platelet adhesion is measured under static conditions[173] to severely decreased adhesion when adhesion is measured under flow.[174] In the latter case, when blood is perfused over fibrillar collagen type I at shear rates between 400 and 1,300/second, isolated $\alpha_2\beta_1$ deficiency or the deficiency of the GPVI/Fc receptor γ-chain complex caused an equivalent but partial defect in platelet thrombus formation, whereas deficiency of collagen receptors caused complete inhibition.[174] These results suggest that although the two receptors can independently mediate platelet adhesion to collagen, they operate synergistically for optimal function. This contrasts with the alternate opinion that GPVI mediates all aspects of collagen-dependent platelet adhesion and activation, even in the absence of $\alpha_2\beta_1$.[128] Experimental conditions may tip the balance in favor of one view over the other, but it is likely that both receptors contribute to platelet thrombus formation depending on the nature of the vascular lesion and the presence of as yet unknown factors that can influence platelets and extracellular matrix components. It is noteworthy in this regard that congenital deficiency of either $\alpha_2\beta_1$[175,176] or GPVI[177] in humans results in a mild bleeding diathesis.

Conflicting results have been reported when $\alpha_2\beta_1$ function was studied *in vivo* using a variety of murine thrombosis models. Following mechanical injury to the mouse right common carotid artery, multiple integrin–ligand interactions appear to synergize to promote initial platelet adhesion, but there was no significant contribution by $\alpha_2\beta_1$. These results are consistent with previous *ex vivo* experiments using human blood and inhibitory antibodies[26] that indicated important roles for the integrins $\alpha_5\beta_1$ and $\alpha_6\beta_1$ as well as a contribution by $\alpha_{IIb}\beta_3$.[178] By contrast, when the right common carotid artery was injured photochemically, it was found that $\alpha_2\beta_1$ plays a role in subsequent thrombosis, although it was seemingly not involved in the intravascular thrombi and pulmonary emboli that occur after an intravenous injection of collagen.[179] These contradictory conclusions cannot be reconciled at present, but likely reflect differences in the nature of the vascular lesion, including severity of the endothelial damage and exposure of extracellular matrix components. Thus, similar to *ex vivo* studies, different thrombogenic surfaces, whether because of the composition or relative proportion of their constituents, seem to elicit distinct pathways of platelet adhesion and activation *in vivo*.

PLATELET ADHESION TO FIBRONECTIN

Fibronectin is a dimer composed of two covalently-linked 250 kDa subunits that is present as a soluble protein in plasma (at a concentration of 300 μg/mL), in platelets, and in other body fluids, as well as in insoluble form in the extracellular matrix of the vascular wall.[180,181] Each fibronectin subunit contains three types of homologous repeats, designated types I, II, and III,[182] and exists in multiple forms due to alternative splicing of a single pre-mRNA. This generates up to 20 variants, some with distinct functional properties.[183–185] A number of integrins interact with fibronectin including three present in platelets: $\alpha_5\beta_1$, $\alpha_v\beta_3$, and $\alpha_{IIb}\beta_3$.[186,187,188,189] Fibronectin binds to platelet $\alpha_{IIb}\beta_3$ in an activation-dependent manner,[190] but its interaction with $\alpha_5\beta_1$ is activation-independent.[191] Fibronectin contains distinct integrin binding motifs, the best known being the Arg–Gly–Asp (RGD) motif located in repeat III_{10}.[180] A second motif is present in repeat III_9 and has been designated a "synergy site" because it promotes $\alpha_5\beta_1$ binding by interacting with the α_5 subunit. The *N*-terminal region of fibronectin, containing repeats $I_{1–9}$ and $II_{1,2}$, also promotes $\alpha_5\beta_1$-mediated platelet adhesion.[180]

Fibronectin has other functional properties related to platelet adhesion, including binding to collagen/gelatin, heparin, and fibrin/fibrinogen.[192] Plasma fibronectin can bind to fibrin, fibrinogen, and self-associates through a mechanism that involves

cross-linking by activated factor XIII,[193,194] events that could be important for the incorporation of fibronectin into fibrin clots and for stabilizing platelet thrombi.[192] A role for fibronectin in thrombosis has been studied *in vivo* using intravital microscopy to measure thrombus formation in ferric chloride-injured arterioles of live mice.[195] In mice genetically deficient in plasma fibronectin, initial platelet adhesion was similar to that seen in control mice, but thrombus formation was delayed and thrombi were less stable. These results suggest plasma fibronectin plays a role in the formation of arterial thrombi. It is noteworthy in this regard that mice deficient in both vWF and fibrinogen display a normal bleeding time, and thrombi form at sites of vascular damage, although the platelet aggregates are unstable and embolize.[196] On the other hand, residual thrombus formation in mice deficient in vWF and fibrinogen is actually enhanced when plasma fibronectin is also deficient, implying that fibronectin is not essential for fibrinogen and vWF-independent thrombosis and that soluble fibronectin could function as an inhibitor of platelet aggregation.[197] Fibronectin isoforms containing the extra domain A are present in platelet α-granules, but absent in plasma fibronectin, and have been shown to have increased prothrombotic activity.[198] Further, soluble plasma fibronectin can assemble into fibrillar structures on the surface of fibroblasts and adherent platelets,[186,199,200] providing a potential substrate for the stable attachment of platelet aggregates.[201] Thus, although fibrinogen and vWF are the major ligands for platelet adhesion and aggregation, fibronectin may play a supplementary role and strategies that target fibronectin could have antithrombotic benefits.

PLATELET ADHESION TO THROMBOSPONDIN-1

Thrombospondins are a family of multidomain, multifunctional cell adhesive GPs[202] that is present in many cell types, including vascular endothelial cells,[203] smooth muscle cells,[204] and platelets[205] and is incorporated into the vessel wall matrix.[206] Thrombospondin-1 (TSP-1), released from platelet α-granules during activation-induced secretion,[205] can associate in a Ca^{2+}-dependent manner[207] with the platelet surface via specific thrombospondin receptors, and mediate platelet adhesion.[208–210] In general, TSP-1 is expressed in response to injury[211] and during growth and development[31] and has been found to be highly enriched in atherosclerotic plaques.[212,213] Although the physiologic function of TSP-1 is currently somewhat controversial, it can complex with many platelet adhesive proteins, including fibrinogen/fibrin, laminin, vWF, fibronectin, and collagen[214–217] and it may play a secondary role in platelet adhesion and thrombosis. TSP-1 has been reported to potentiate platelet activation and stabilize platelet aggregates *in vitro*,[218,219] although platelets from mice lacking TSP-1 aggregate normally.[220,221] TSP-1 has been identified as an alternative ligand to vWF for GPIb-dependent adhesion of activated platelets under high shear conditions *in vitro*[31] and has been reported to enhance thrombosis by protecting subendothelial vWF from cleavage by ADAMTS13.[221] It has also been reported to promote platelet aggregation by suppressing the production of the endogenous platelet inhibitor nitric oxide.[222,223] TSP-2, a constituent of extracellular matrices, but absent from platelets, has a high structural similarity to TSP-1, and interacts with a number of the same cellular receptors.[224,225] TSP-2 deficiency has been associated with impaired hemostasis in mice,[226] a finding that likely reflects the requirement for TSP-2 in normal megakaryocytopoiesis and the release of functionally competent platelets.[227]

PLATELET ADHESION TO LAMININ

Laminin, a major component of vascular basement membranes, interacts with collagen type IV and heparin sulfate proteoglycans to maintain the structural integrity of the basement membrane.[228] Purified laminin can mediate platelet adhesion and activation under static conditions by binding to the collagen receptor GPVI, an interaction that is facilitated by integrin $\alpha_6\beta_1$[229] in a manner analogous to the synergy between GPVI and $\alpha_2\beta_1$.[139,156,165,170] Under high shear flow conditions, laminin supports platelet adhesion by a mechanism that depends on the interaction of vWF with GPIbα,[230] reminiscent of the essential role of vWF and GPIbα for platelet adhesion to collagen at elevated shear rates.[26] Direct binding of soluble vWF to immobilized laminin has been detected by surface plasmon resonance spectroscopy, although the affinity of interaction was about 100-fold lower than that between collagen type I and vWF.[230] Studies to detect the direct binding of vWF to immobilized laminin using enzyme-linked immunosorbent assays were unsuccessful, possibly due to the low affinity or the reversibility of the interaction.[231] Although the relative contribution of subendothelial laminin to thrombosis remains to be established, the apparent redundant mechanism of platelet adhesion to laminin highlights a general paradigm for the interaction of platelets with the subendothelial matrices, involving GPVI, vWF, and GPIbα.

PLATELET ADHESION TO FIBRINOGEN AND FIBRIN

Whereas platelet $\alpha_{IIb}\beta_3$ cannot bind soluble fibrinogen unless platelets are activated, $\alpha_{IIb}\beta_3$ on nonactivated platelets can bind to surface-bound fibrinogen and to fibrin, thereby mediating platelet adhesion in a shear rate-limiting fashion.[32] Platelet adhesion to immobilized fibrinogen or fibrin in experimental flow systems becomes progressively less efficient with increasing wall shear rates, with relatively few platelet interactions at wall shear rates above 1,000/second.[32] Presumably the on-rate of bond formation is too low to permit platelet capture at high shear rates, or bonds may form, but their initial resistance to tensile stress may be insufficient to oppose the shear forces and maintain stable platelet attachment. However, most of the platelets that attach at low shear-rates do not detach when the flow rate is increased,[32] implying that the $\alpha_{IIb}\beta_3$-fibrinogen bond, once formed, may have a dissociation rate sufficiently low for sustaining stable attachment or that other factors such as $\alpha_{IIb}\beta_3$ receptor density and postadhesion platelet cytoskeletal rearrangements may influence the stability of platelet attachment. Platelets become activated and spread on immobilized fibrinogen and fibrin, but thrombus formation is noticeably absent unless other adhesive proteins are also present.[32] An explanation for this observation in not currently known, but it might reflect $\alpha_{IIb}\beta_3$ sequestration on the abluminal platelet

membrane surface resulting in a deficit in the amount of $\alpha_{IIb}\beta_3$ available to bind soluble ligands and support platelet–platelet cohesion.[232]

A ROLE FOR P-SELECTIN IN ARTERIAL THROMBOSIS

P-selectin, a GP present in the membranes of platelet α-granules and endothelial cell Weibel-Palade bodies, is rapidly translocated to the plasma membrane following cell activation. The P-selectin ligand, P-selectin glycoprotein ligand-1 (PSGL-1), is present on neutrophils and monocytes and provides a means of tethering these cells to activated platelets and endothelial cells.[233] By inducing tissue factor expression on circulating monocytes, P-selectin can promote fibrin formation since tissue factor is the major initiator of thrombin generation.[234] P-selectin also mediates the rolling interactions between leukocytes and the vessel wall that is required for leukocyte recruitment to sites of inflammation or infection.[235,236] Recent evidence indicates that P-selectin and PSGL-1 are involved in the process of thrombosis as well. Mice lacking either P-selectin or PSGL-1 exhibit reduced arterial thrombus formation, fibrin levels, and tissue factor accumulation following vascular injury.[237,238] Similar results were seen when wild type mice were treated with function-blocking P-selectin antibodies prior to the induction of arterial vessel damage.[239]

POSTADHESION EVENTS LEADING TO THROMBUS PROPAGATION

Whether platelet adhesion results in a monolayer of platelets or in thrombus formation depends on a number of factors, including the nature of the exposed substrate, the prevailing rheologic conditions, and the presence of functionally competent platelets. The initial adhesion and activation of platelets in response to changes in endothelial cells, or exposure to subendothelial matrices, promotes the binding of soluble adhesive proteins, mainly fibrinogen and vWF that form the immobilized substrate for platelet recruitment and thrombus propagation.[26,240] Since only the initial layer of adherent platelets are in contact with the subendothelial components, platelet accumulation into a growing thrombus depends on the formation of interplatelet bonds. However, platelet aggregation in this context should not be considered as a distinct process from platelet adhesion since it also involves the capture and arrest of free flowing platelets onto a reactive surface (the activated platelet membrane), and may even utilize common receptor/ligand interactions and signaling pathways leading to platelet activation. Because of these mechanistic similarities, both platelet adhesion and aggregation are subject to the same fluid dynamic influences generated by blood flow, a key modulator of thrombus formation and propagation.

Fibrinogen and vWF, present in circulating plasma or released from activated platelets, are the predominant adhesive molecules that link platelets to one another during thrombus development. On collagen type I fibrils, fibrinogen and vWF act cooperatively to support platelet aggregation since neither protein by itself can sustain the full development of a stable thrombi within the range of pathophysiologic flow conditions.[240,241] At high shear rates, vWF-mediated thrombi grow rapidly, but are unstable when fibrinogen is absent, whereas thrombi grow more slowly, but are more stable when both vWF and fibrinogen are present.[240] These observations are consistent with the clinical phenotype of patients with congenital deficiencies of either fibrinogen[242] or vWF.[243] However, studies with genetically modified mice have shown that sustainable thrombus formation can occur in damaged mesenteric arterioles, even when both vWF and fibrinogen are absent,[196] whereas both GPIbα and $\alpha_{IIb}\beta_3$ are absolutely required.[241,244] These studies suggest that other ligands for activated $\alpha_{IIb}\beta_3$ and GPIbα, such as fibronectin or TSP-1, might support the formation of stable platelet thrombi. During the thrombus propagation phase, the released secondary agonists ADP and TXA_2 reinforce the platelet activation by binding to the receptors $P2Y_1$, $P2Y_{12,}$ and the TpA receptors, evoking Ca^{2+} mobilization and the activation of intracellular signaling molecules such as protein kinase C and PI 3-K.

PERPETUATION OF ADHESION-INITIATED PLATELET ACTIVATION AND THROMBUS STABILIZATION

Platelet aggregation is a reversible process. Without stabilization, platelets disaggregate and embolization occurs under the shear forces produced by arterial blood flow. Although platelet agonists such as ADP, TXA_2, and thrombin initiate rapid integrin activation and platelet recruitment, signaling initiated in this manner is relatively limited in duration because their receptors become desensitized. Experiments indicate that sustained thrombus growth requires continuing function of ADP receptors, as well as PI 3-K-dependent activation pathways, and is accompanied by sustained cycles of intracytoplasmic Ca^{2+} transients across whole platelet aggregates.[245–248] Therefore, additional signaling mechanisms are necessary to perpetuate platelet activation and prevent dissolution of the platelet thrombus, at least until a fibrin meshwork can be established.

Activated $\alpha_{IIb}\beta_3$ plays a critical role in transmitting outside-in signals that lead to irreversible platelet aggregation and clot retraction.[249] Phosphorylation of tyrosine residues in the cytoplasmic domain of β_3 appears to be a critical step in this process.[250–252] Additional outside-in signaling may be initiated by Eph kinases and their ligands, the ephrins.[253] Human platelets have been reported to express at least one ephrin (EphinB1) and two Eph kinases (EphA4 and EphB1) and inhibiting Eph kinase binding to EphrinB1 appears to enhance the reversibility of platelet aggregation-induced low dose ADP, without affecting the exposure of fibrinogen binding sites on $\alpha_{IIb}\beta_3$.[253] Further, thrombi formed on collagen type I are significantly smaller.[254]

A number of adhesive molecules contained in platelet α-granules are absent on the surface of nonstimulated platelets but present after platelet activation. Some of these adhesive molecules have been reported to play an important role in the secondary reinforcement of thrombus growth and stability. Released CD40L[255] binds to $\alpha_{IIb}\beta_3$ and propagates platelet activation through $\alpha_{IIb}\beta_3$-dependent outside-in signaling, a process that is important for the stability of arterial thrombi in murine models of arterial thrombosis.[256,257] Growth arrest-specific 6 (GAS6), a ligand for the Axl/Sky family of receptor tyrosine kinases, is also involved in the stabilization of platelet thrombi.[258] Gas6 has been shown to enhance the formation of stable platelet aggregates in response to various agonists, and Gas6-deficient mice are protected against thrombosis without abnormal bleeding.[258]

On the other hand, the presence of Gas6 in human platelets has not been clearly established.[259] Likewise, the signaling lymphocyte activation molecule (SLAM) family of receptors may be important secondary mediators of platelet aggregation[260] since mice deficient in SLAM display delayed thrombus formation, but have normal tail bleeding times.[260] Platelet endothelial aggregation receptor 1 is another membrane protein identified on the surface of activated platelets that appears to signal secondary to $\alpha_{IIb}\beta_3$-mediated platelet–platelet contacts and may be involved in maintaining sustained platelet activation.[261] It has also been reported that semaphorin 4D (Sema4D) and its receptors are expressed on the platelet surface and that Sema4D$^{-/-}$ mice display a selective defect in collagen-induced platelet aggregation and an impaired vascular injury response.[262] It appears that $\alpha_{IIb}\beta_3$ and Sema4D jointly promote collagen responses through two interdependent but distinguishable processes leading to amplification of Syk activation and collagen-induced responses; one process is the binding of Sema4D to its receptors facilitated by integrin-mediated contacts and the other process is the enhancement of integrin outside-in signaling supported by Sema4D-receptor interactions.[263] Of note, loss of sema4D expression reduces the platelet hyperactivity otherwise found in dyslipidemia and confers protection against the development of atherosclerosis.[264]

Along with positive feedback, molecules that appear on the platelet surface after activation can also exert a negative regulatory function on thrombus formation. One example is endothelial cell specific adhesion molecule (ESAM), which localizes to interplatelet contact sites following activation and limits thrombus growth and stability, as shown by the finding that ESAM-deficient mice achieve more stable hemostasis than wild-type mice following tail transection and develop larger thrombi following arterial injury.[265] These effects may be explained by the enhanced response of ESAM-deficient, as compared to wild-type platelets, to lower concentrations of G protein-dependent agonists, and to greater resistance to disaggregation.[265]

CONCLUSIONS

There have been major advances in our understanding of the mechanisms involved in mediating platelet adhesion and the bidirectional coupling with platelet activation and aggregation. The application of genomic and proteomic approaches has greatly supported this progress, as has the use of an expanding collection of animal models with targeted gene deletions or mutations. The advent of improved drug development technologies is likely to permit the translation of this fundamental knowledge into more efficient therapeutic approaches. For example, preventing sustained integrin activation—as can be achieved by removing ADP, blocking ADP receptors, or inhibiting PI 3-K—may prove to be a relevant target for antithrombotic intervention and provide a means of restricting thrombus growth while avoiding major bleeding complications.

CHAPTER

29

Shear Effects on Platelets and the Vessel Wall in the Pathogenesis of Atherothrombosis

DAVID L. BARK, JR., WARWICK S. NESBITT, ANGUS K.T. WONG, AND SHAUN P. JACKSON

The hemodynamic effects of blood flow play a critical role in regulating the cardiovascular system from early prenatal development until death. Beginning with the first heartbeats, the embryonic primary vascular plexus responds to various hemodynamic forces that modulate plexus differentiation into arteries and veins. Blood flow is a critical requirement for ongoing vascular development, with wall shear stress (WSS) playing a significant role in developmental remodeling of the vascular endothelium. The plasticity of the vasculature in response to prevailing blood flow conditions allows it to rapidly adapt to hemodynamic perturbations, both physiologic and pathologic, with the purpose of maintaining vascular integrity throughout our lives.

Disturbances of blood flow perform an important role in the development of cardiovascular diseases, including atherothrombosis. Chronic disturbances in blood flow lead to vascular changes that promote atherosclerosis, whereas acute changes in blood flow at sites of atherosclerotic plaque disruption are important for the development of thrombosis. Therefore, temporal variations (seconds through to years) in flow are relevant to atherothrombosis. Early seminal work by the German physician, Rudolf Virchow (1856), identified an important role for blood flow disturbances in promoting venous thrombosis. However, an awareness of the central importance of hemodynamics in promoting atherothrombosis did not develop until the 1970s. Two major theories regarding the pathogenesis of atherothrombosis developed at this time: (a) that low and/or oscillatory WSS is important for atherogenesis and (b) that high WSS promotes arterial thrombosis. The purpose of this chapter is to expand on these concepts, highlighting the importance of disturbed "bulk" flow (macroscale flow disturbance) in regulating endothelial cell and platelet function. Furthermore, we focus on an emerging concept in the thrombosis field that localized microscale (1 to 10 μm) changes in blood flow may play a potentially important role in promoting thrombus formation.

ARTERIES RESPOND TO SPECIFIC HEMODYNAMIC FORCES

Blood flow in the arterial circulation is primarily driven by cardiac contractions that create a pressure gradient across the systemic and pulmonary vasculature. A pressure differential pushes blood from regions of high pressure to regions of low pressure, which is resisted by the frictional nature of the vascular wall (Box 29.1). As a result, blood flow creates three dominant stresses within the arterial wall: (a) circumferential stress, (b) axial stress, and (c) WSS, where stress is defined as the distribution of internal forces throughout a deformable body (force/area). Blood vessels are highly responsive to these stresses and modify their overall architecture and composition to maintain a near-constant stress environment that limits metabolic demand and preserves vascular integrity.

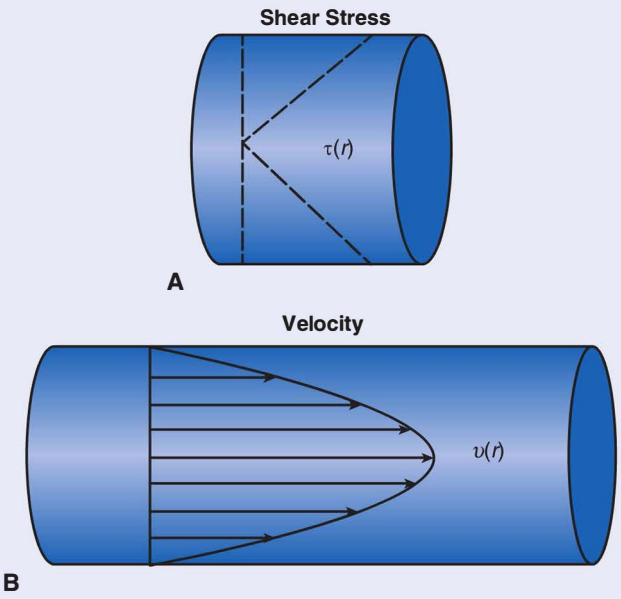
Circumferential Stress

Arterial pressure is a major source of stress in the vasculature. Pressure exerts an outward push on blood vessels, creating tension within the arterial wall. Tension results in circumferential stress, which is sensed by smooth muscle cells (SMCs) in the medial layer of arteries. These cells actively oppose this stress to prevent arterial expansion and bursting upon vessel pressurization. Furthermore, elastin and collagen provide additional passive structural support. Average circumferential stress remains at a near-constant value of 10^5 Pa in the arteries.[1] Hypertension creates chronic high pressure increasing circumferential stress and the vessel attempts to alleviate this stress by thickening the medial layer. Such changes to the vessel wall may promote atherosclerosis. The detailed effects of circumferential stress on vascular remodeling have been summarized previously[2,3] and will not be discussed further in this chapter.

Axial Stress

A stress that is indirectly linked to hemodynamics is the longitudinal (axial) stress, which exists because arteries are constantly stretched *in situ*. Axial stress remains near a value of 10^5 Pa, which is required to avoid vessel buckling (tortuosity) or tearing, and occurs through the modulation of the axial force.[3] Both endothelial cells and SMCs can sense axial stress and can signal for control of the vessel microstructure (collagen and elastin composition) in order to modify the internal axial force in response to changes in either the vessel radius or thickness.[2] It is interesting to speculate that microstructural changes from axial stress modulation may contribute to plaque formation or degradation, since axial stress is very sensitive to changes in wall thickness, which changes dramatically in the presence of plaque. However, little is known about the role of axial stress in atherothrombosis.

Box 29.1 Hagen-Poiseuille Flow

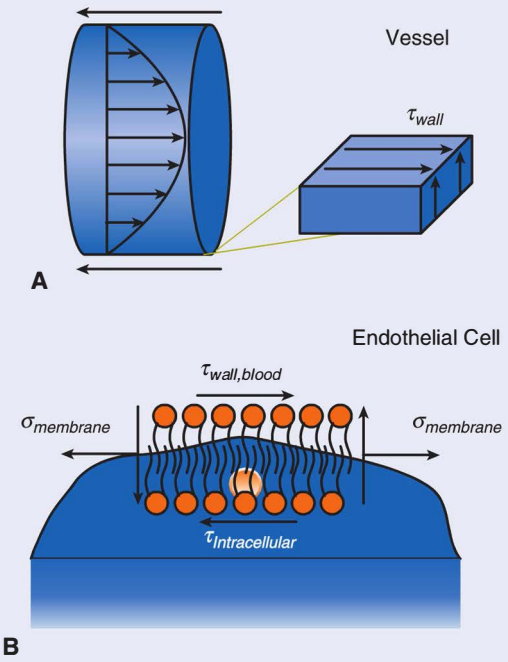


Blood flow is complex, but the general flow characteristics can be greatly simplified by some basic assumptions, leading to generalized Hagen-Poiseuille flow (see below). An important hemodynamic parameter to blood flow is the shear rate (velocity gradient), which is maximum at the vessel wall and linearly decreases to 0 at the central axis of the vessel for Hagen-Poiseuille flow. The shear stress, $\tau(r)$, is related to the shear rate by the dynamic viscosity (**A**). This flow exhibits a parabolic velocity profile, $v(r)$, and is driven by an axial pressure gradient, primarily generated by cardiac contractions (**B**).

Hagen-Poiseuille Assumptions:

- Newtonian fluid—valid for arteries with high shear and high flow—fluid where Newtonian constitutive equation can be applied
- Straight, circular pipe far from flow entrance (fully developed flow)
- Steady flow
- Laminar flow—valid, except in parts of the aorta
- There is no slip between fluid and the pipe wall.

Box 29.2 Wall Shear Stress



WSS, τ_{wall}, at the fluid–solid interface existing at the luminal side of the endothelium is equal between the shear stress in the blood, $\tau_{wall,blood}$, and shear stress on the endothelium (**A**). Therefore, the shear stress experienced by the endothelium can be defined by fluid properties, instead of the endothelial properties. Assuming a fluidic cytosolic interior for endothelial cells, the intracellular shear stress, $\tau_{intracellular}$, is negligible and the luminal shear stress is converted into a tension, $\sigma_{membrane}$, in the cell membrane and on the cytoskeleton (**B**). In addition to tension and luminal shear stress, there is also a vertical component to shear that resists cell rotation.

Wall Shear Stress

As blood flows through an artery, it creates a pulling force on the endothelial surface, similar to a frictional resistance. The force per unit area applied to and transmitted through the endothelium is equal to the hemodynamic shear stress at the surface (see Box 29.2). WSS is maintained at a near-constant arterial value of 15 to 20 dynes/cm^2 through alterations of the luminal radius.[1] The purpose, according to Murray's law, is to optimize the relationship between the flow rate and the arterial radius to reduce the metabolic work required from the body to maintain blood flow.[4] WSS is converted into a tensile force within the endothelial cell membrane[5] (Box 29.2) and cytoskeleton.

While the contributions of circumferential and longitudinal stresses to atherothrombosis remain poorly defined, the impact of WSS on the atherothrombotic process has been extensively investigated, as described below.

THE IMPACT OF WALL SHEAR STRESS ON ATHEROSCLEROSIS

It has long been recognized that certain areas of the vasculature, including the abdominal aorta, carotid bifurcation, coronary, renal, and femoral arteries, are prone to the development of atherosclerotic lesions. These vascular regions are more likely to exhibit chronic inflammatory changes that contribute to intimal thickening.[6–10,11] While systemic factors like hypertension, smoking, hyperlipidemia, obesity, and diabetes are associated with atherosclerosis propagation, a key factor determining plaque localization at specific arteries is the underlying regional hemodynamic environment, specifically the presence of low and/or oscillating WSS (FIGURE 29.1). Oscillating WSS refers to the temporal directional transition of WSS during the cardiac cycle, which occurs when near-wall blood flow reverses direction, a

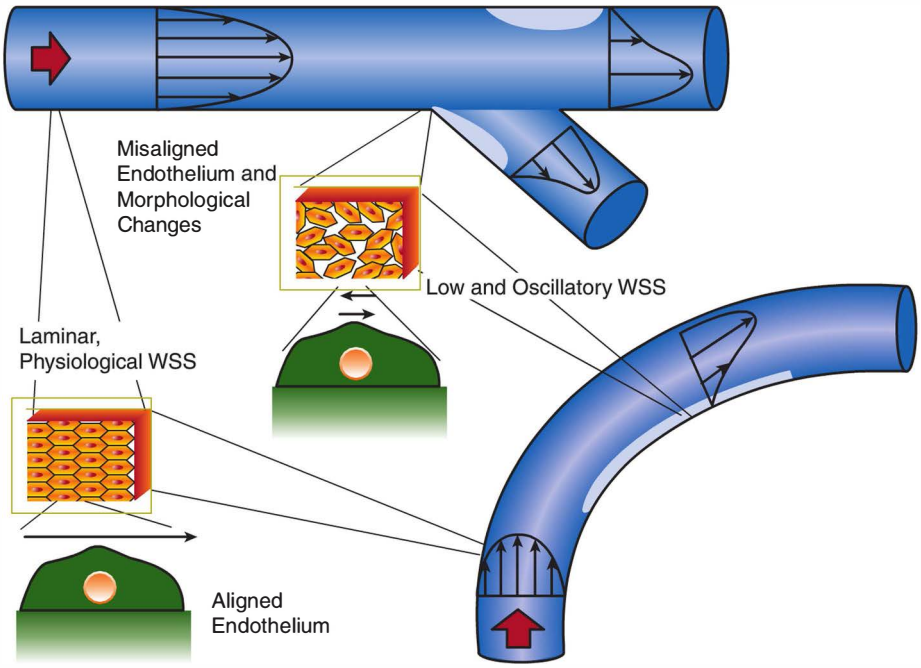


FIGURE 29.1 Regions prone to plaque formation include vessels with branches and sharp curvatures, corresponding to regions of altered velocity profiles. Areas of low and/or oscillating WSS can develop in these situations (*light gray regions*), which may promote atherogenesis. This process is promoted through numerous pathways, including endothelial cell morphologic and functional changes. One structural change is the altered shape and misalignment of neighboring ECs in regions of low and/or oscillating WSS (*arrows* representing WSS over ECs), resulting in increased endothelial permeability. Furthermore, these structural changes are associated with regions of chronic inflammation. Intimal thickening occurs most rapidly in regions of low and/or oscillating WSS, as determined by intravascular ultrasound.[11,12,13] Plaques found in these regions are commonly expansive, extending in the abluminal direction and preserving the luminal area. Expansive plaque generally has vulnerable characteristics, including a large lipid core, inflammatory infiltrate, and a thin fibrous cap.[14,15] Therefore, vessel geometries are closely tied in with atherosclerosis through the resulting effects on WSS distribution.

feature of proatherogenic arteries. Localized oscillating WSS promotes atherogenesis through multiple interrelated mechanisms including the tendency for foam cell formation and increased production and retention of proinflammatory mediators. These mechanisms promoting atherosclerosis have been most extensively associated with WSS-dependent altered endothelial structure and function (FIGURE 29.1).

Impact of Wall Shear Stress on Endothelial Cell Function

Endothelial cells play a key role in maintaining vascular integrity and in dynamically regulating vascular function. This occurs through several mechanisms including the regulation of vascular permeability, remodeling, synthesis, and secretion of vasoactive, prothrombotic, and antithrombotic molecules, as well as through the modulation of vascular tone through interactions with SMCs. The principle hemodynamic driver of endothelial cell function is the applied WSS. The response of endothelial cells to the WSS environment is complex and wide ranging, with changes in WSS triggering intracellular signaling pathways (FIGURE 29.2A) that modulate gene expression and cell morphology.[12]

Endothelial cells "sense" changes in blood flow, specifically oscillatory WSS (FIGURE 29.2A), and convert these mechanical signals into chemical signals (mechanotransduction) that modulate endothelial cell structure and function (FIGURE 29.2B). The luminal surface of the vascular endothelium contains several key membrane structures that are considered to be important for their mechanosensory function[13–15,16]:

1. **Caveolae**—these are small surface invaginations of the endothelial cell plasma membrane linked to the initiation and propagation of Ca^{2+} signaling in response to WSS. These functional lipid membrane compartments are important for shear dependent up-regulation of nitric oxide (NO) synthesis and represent a primary membrane component of the mechanosensory machinery.
2. **Primary cilia**—these are extensions of the endothelial cell plasma membrane that undergo mechanical deformation in response to blood flow. Bending of primary cilia is thought to lead to the opening of mechanically gated ion channels leading to Ca^{2+} influx and endothelial cell activation.
3. **The glycocalyx**—this is comprised of a network of glycosylated and sialylated transmembrane proteins protruding from the plasma membrane into the vessel lumen and has been found to directly respond to applied mechanical shear forces. Under low-flow conditions, this glycoprotein network exists in a tightly coiled state. With the application of blood flow, the glycocalyx uncoils in the direction of flow, leading to transmembrane conformational signaling. Significantly,

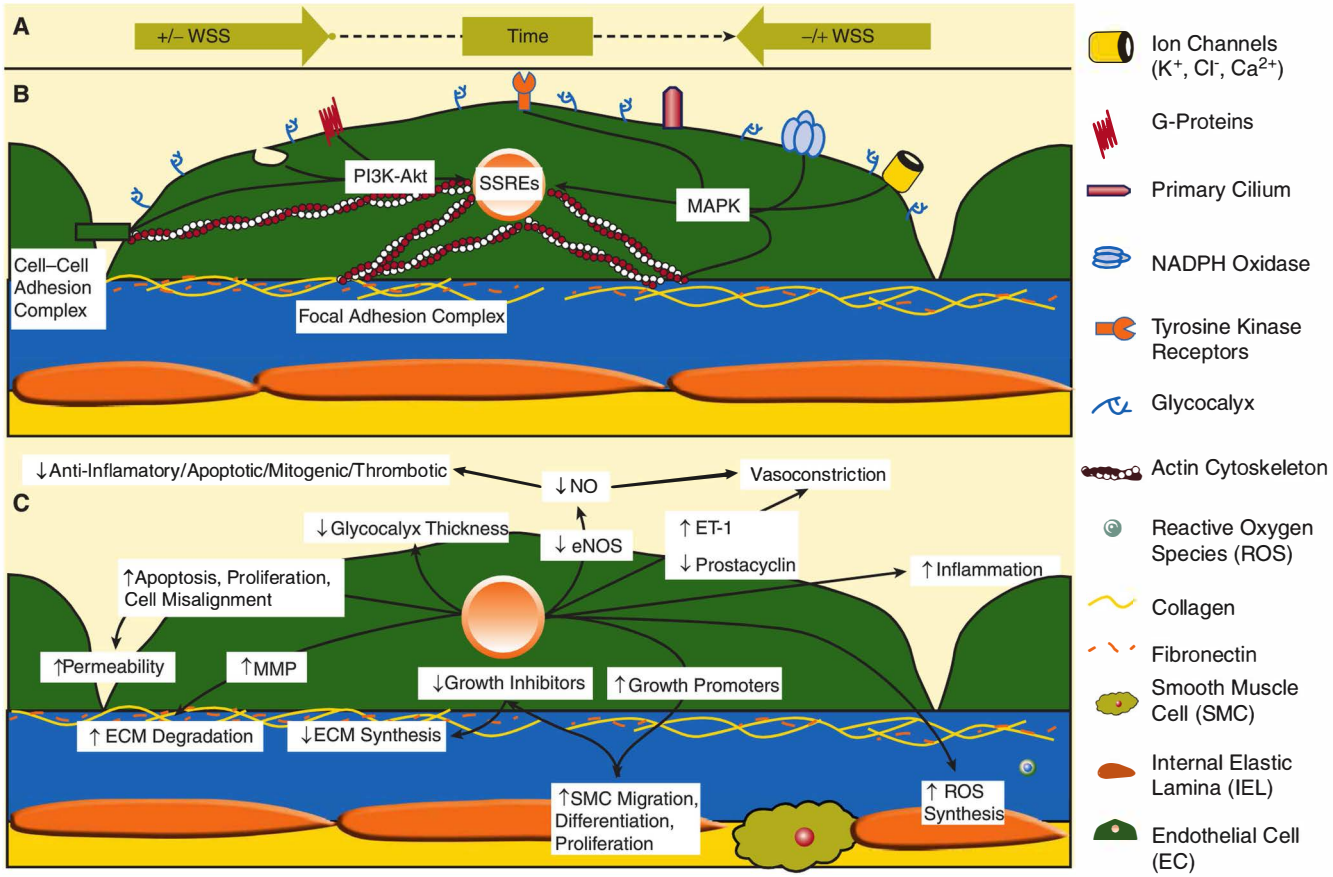

FIGURE 29.2 Endothelial cell responses at low and/or oscillatory WSS. **A:** Oscillatory WSS occurs in vascular regions where the near-wall flow changes direction during the cardiac cycle. These regions also typically correspond to regions of low WSS. When the near-wall flow changes directions, the overall WSS and drag force on the EC changes directions. Low/oscillatory WSS can occur even in regions where the bulk flow generally remains in monodirectional. These situations are possible in poststenotic regions and in the regions of a sinus, where the vessel expands abruptly. **B:** The luminal surface of the EC plasma membrane directly interfaces with blood flow and represents the sensing surface of the endothelium. On this surface are multiple mechanosensing elements, the caveolae, glycocalyx, and primary cilia. **C:** Multiple EC responses occur as a result of low/oscillatory WSS signaling, creating a proatherogenic environment. The extracellular matrix (ECM) is degraded by MMPs, while synthesis is down-regulated. SMC migration, differentiation, and proliferation are increased. The balance of vasomodulation is weighted toward vasoconstriction. Also, the overall EC morphology and alignment are disrupted, such that there are larger gaps between ECs. Figure is modified by permission from Chatzisisis et al.[23]

the glycocalyx serves to regulate vascular permeability, with increased permeability at oscillatory WSS resulting from an overall reduction in glycocalyx thickness.

In addition to mechanosensors on the luminal surface of endothelial cells, mechanical signals can also be transduced from the abluminal surface of endothelial cells, with integrin receptors on the basal plasma membrane playing a major role in transducing signals to the nucleus through the actin cytoskeleton (FIGURE 29.2B). The details underlying integrin mechanotransduction have been investigated in considerable detail and reviewed elsewhere[17] and will not be discussed further here.

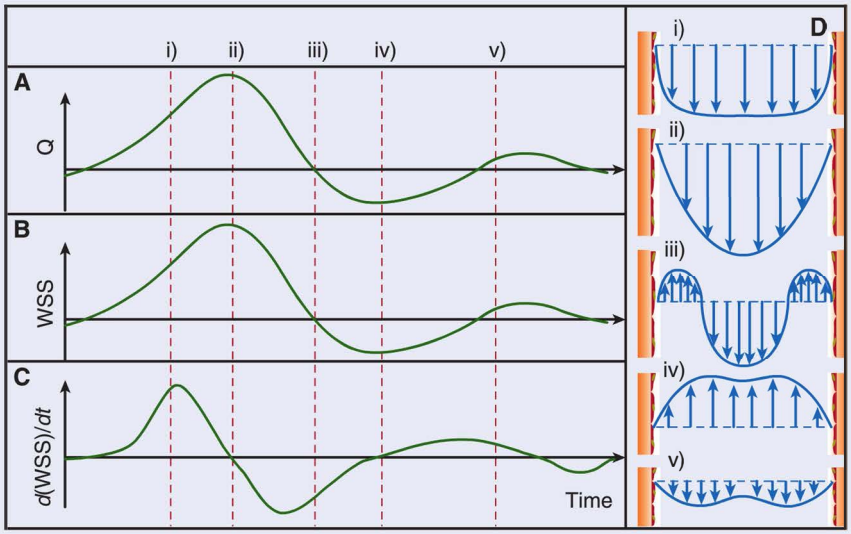
Atheroprotective Signals

Endothelial mechanosensors generally produce atheroprotective signals when the flow is unidirectional, laminar, and at a WSS that is >10 dynes/cm^2. A key antiatherogenic effect of endothelial cells is the up-regulated synthesis of NO and prostacyclin (PGI2), two major vasodilators that regulate local vascular tone and profoundly inhibit platelet activation and leukocyte adhesion.[18–20] Furthermore, such flow conditions also suppress endothelial cell proliferation and promote cell survival, through up-regulated expression of antiapoptotic genes.[21,22] In combination, these cumulative effects help reduce the proinflammatory and prothrombotic phenotype of endothelial cells, thereby inhibiting the development of atherosclerotic lesions.

Proatherogenic Signals

Atherosclerosis is promoted by localized disturbances in blood flow, specifically low oscillatory WSS (FIGURE 29.2A) and

Box 29.3 Temporal Wall Shear Stress Gradients



The cardiac cycle causes pulsatility in major arteries, including the coronary, carotid, femoral, and aortic arteries. Therefore, there is almost always a low temporal gradient in WSS for these arteries. Diseased arteries, specifically those with a stenosis, exhibit much larger oscillations in flow with respect to time, creating larger gradients in WSS.[39,40] In terms of cells in free flow (e.g., platelets) and cells at a vessel surface (e.g., ECs), both experience changes in WSS due to the pulsatility.

A) Flow rates through major atherosclerotic-prone arteries oscillate during the cardiac cycle. The waveform shown in this figure is an arbitrary waveform that has some characteristic features of flow through these arteries. Actual flow rate waveforms differ from artery to artery. During systole, flow rates accelerate (i) in most arteries, as pressure builds up in the aortic arch. Flow rates become the highest right before diastole (ii). During diastole (iii), the flow decelerates in most arteries. In the coronary arteries, the converse is true. During this cycle, flow can reverse direction (iv) in the coronary, femoral, and carotid arteries. Oscillatory WSS occurs when near wall blood reverses direction, such as the region consisting of sections (iii) and (iv).

B) WSS generally varies in a similar way as the flow rate, as illustrated by the proportionality between the two for Hagen-Poiseuille flow. However, it also depends on the velocity waveform, which changes throughout the cardiac cycle. The WSS presented here is an idealized case that is based solely on the flow rate and is independent of the velocity waveform, for the purpose of clarity.

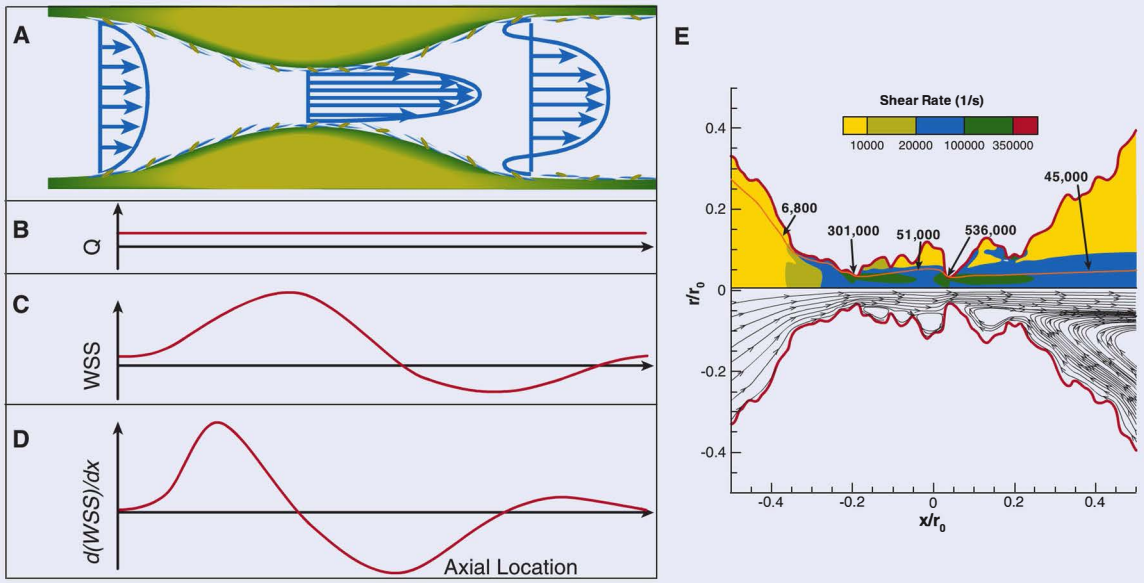
C) A temporal WSS gradient exists at a given location because of blood pulsatility. The gradient depends on local arterial conditions. It is maximum during flow acceleration and is minimum during flow deceleration. The temporal WSS gradient is the slope of the WSS versus time curve.

D) The pulsatility of blood flow creates an unsteady flow field. Velocity profiles do not remain parabolic, but instead can be characterized by the Womersley solution.[10,41,42] Velocity profiles are a commonly used method to visualize fluid mechanics but can be conceptualized as the amount a fluid moves for a given time and how that varies across the diameter of the blood vessel. The fluid velocity can partially (iii -not shown in B) or completely (iv) change directions during the cardiac cycle, depending on the artery and geometrical conditions, corresponding to the roman numerals over the flow waveform plot in (**A**).

temporal shear gradients (Box 29.3).[23,24–26] Spatial WSS gradients (Box 29.4) may also promote atherogenesis, although the absolute importance of these flow changes to the atherosclerotic process remains unclear.[27–29] The effects of shear gradients on endothelial function and structure are complex and wide ranging. For example, temporal shear gradients and low oscillatory WSS have been demonstrated to activate the MAPK[23,25,30] and PI 3-kinase signaling pathways (FIGURE 29.2B) leading to activation of the nuclear shear-sensitive response elements and the induction of proatherogenic transcription factors.[23,25] As a consequence, there is increased expression of ICAM-1 and E-selectin on the surface of endothelial cells[23,26] and increased production of the chemokine MCP-1.[23,24] These changes enhance monocyte recruitment. Local disturbances in blood flow also promote the synthesis of growth factors, such as PDGF-A, which has proatherogenic and proangiogenic properties (FIGURE 29.2C).[24,31]

Temporal WSS gradients, as well as low/oscillatory WSS, lead to enhanced endothelial cell proliferation,[27] while spatial WSS gradients promote changes in endothelial morphology and enhance motility,[28,29,32] leading to changes in the permeability of the endothelium.[33] Misalignment of endothelial cells (FIGURE 29.1) as a result of endothelial morphologic changes,[65,71,72,73,74] enhanced cell turnover, and apoptosis[17–19] favors recruitment of monocytes into the intima and promotes

Box 29.4 Spatial Wall Shear Stress Gradients



A shear gradient exists at locations where vessel geometry changes in some way (e.g., stenosis, aneurysms, curvature, and branches). Cells in the bulk flow (e.g., platelets) experience changing shear stress and velocity as they travel through a stenosis. However, cells on the surface (e.g., ECs) only experience the local WSS. Only cell–cell communication and the local WSS gradient would provide any information to an EC that a stenosis can be found in its region.

A) Flow entering a stenosis accelerates and then decelerates downstream. Flow recirculation and reversal can occur in the downstream region (as depicted by the *light gray color* and the *arrows*).

B) The flow rate through a stenosis is constant along the axial direction because of the conservation of mass, neglecting blood pulsatility, despite the changes in average blood velocity.

C) High WSS exists at the stenosis peak and low WSS is found downstream of the stenosis apex. WSS becomes negative in the recirculation region with zero WSS at the flow separation and reattachment point (*gray region* downstream of stenosis).[40,43–45]

D) The gradient in spatial WSS maximizes upstream of the stenosis apex and is minimal just downstream of the stenosis apex. The gradient becomes zero far downstream of the stenosis, as the flow becomes fully developed.

E) Microscale shear gradients exist over rough surfaces that can be found on atherosclerotic plaque, developing thrombus, and intravascular devices (e.g., stents), as opposed to macroscale gradients. An example rough surface is superimposed on a stenosis, illustrating the changes in shear that can occur along a streamline (platelet path). (Reproduced from Bark DL Jr, Ku DN. Wall shear over high degree stenoses pertinent to atherothrombosis. *J Biomech* 2010;43(15):2970–2977, with permission.) WSS is capable of changing by an order of magnitude, despite very small changes in geometry.

foam cell formation.[22,23,24] Moreover, the glycocalyx on the surface of endothelial cells, which normally acts as a barrier between leukocytes and endothelial cells, becomes less dense under the influence of low/oscillatory WSS,[20,21] facilitating leukocyte–endothelial interactions. In addition, under the influence of low/oscillatory WSS, endothelial cells also increase production of matrix metalloproteinases (MMPs),[9,10,11] leading to increased matrix degradation and enhanced SMC migration (FIGURE 29.2C). Extracellular matrix degradation of collagen and elastin reduces the passive structural support for the vessel,[5] leading to pathologic remodeling of atherosclerotic arteries.

In an attempt to return WSS to arterial physiologic levels (i.e., increase WSS to >10 dynes/cm^2), endothelial cells stimulate vasoconstriction by down-regulating the production of the potent vasodilators, NO, and prostacyclin and up-regulating the generation of vasoconstrictors, such as endothelin-1. Since NO is involved in a broad range of biologic processes, including anti-inflammatory, antiapoptotic, antimitogenic, and antithrombotic actions, decreased NO production is an important pathogenic event in the development of atherosclerosis.[34]

COMPLEX HEMODYNAMICS OF ARTERIAL THROMBOSIS

As is the case for atherogenesis, arterial thrombosis is critically influenced by local hemodynamic conditions. In contrast to the low and/or oscillating WSS environment of atherogenesis,

arterial thrombi develop under conditions of high shear stress where blood experiences relatively rapid and high magnitude changes in flow velocity. Encroachment of a developing plaque into the vascular lumen can introduce significant spatial and temporal gradients in blood flow velocity (Box 29.3). As blood enters a stenosis, it accelerates as the vessel hydraulic area decreases. Maximum fluid WSS occurs near the peak of the stenosis,[35,36] reaching over 100,000 s^{-1} for moderate–severe (>70% by diameter) stenoses.[35,37] Blood decelerates, downstream of the stenosis apex leading to the generation of an adverse pressure gradient for moderate stenoses (20% to 98% for coronaries), which can produce flow separation and recirculation. Flow may eventually transition into turbulent flow, depending on both the flow rate and stenosis severity,[35,38,39] although it remains controversial whether turbulent flow actually occurs in coronary or carotid arteries.

Flow disturbances at sites of arterial thrombosis have been demonstrated to enhance platelet deposition and thrombus growth,[40,41] particularly at the apex,[41–43] but have also been found in recirculation regions[44,45] and near flow reattachment points.[46,47] This may in part be attributable to the trapping of platelets at recirculation sites,[45] as well as enhanced platelet transport at the reattachment point.[22]

In the remaining sections of this chapter, we focus on the mechanisms by which high shear stress promotes platelet deposition and thrombus growth at sites of atherosclerotic plaque disruption. In particular, we discuss emerging evidence that platelet tether formation, shear microgradients (SMGs), and von Willebrand Factor (vWF) elongation plays a potentially important role in promoting high shear-dependent thrombus formation.

Platelet Adhesion Under Shear Flow

The molecular mechanisms by which platelets adhere and form aggregates under high shear conditions have been extensively investigated and are discussed in detail in Chapter 28. They will only be briefly discussed here. The three factors having the greatest impact on the efficiency of platelet accumulation at sites of atherosclerotic plaque disruption include (a) the nature of the thrombogenic substrates, (b) thrombin generation, and (c) flow-directed transport of platelets.

Thrombogenic Substrates

The adhesive substrates mediating platelet adhesion under high shear at sites of atherosclerotic plaque disruption include collagen, vWF, fibronectin, laminin, thrombospondin, and potentially fibrinogen/fibrin and vitronectin. Of these substrates, type I and III fibrillar collagens are typically enriched in advanced atherosclerotic lesions and are the most reactive substrates toward platelets, playing a major role in promoting platelet activation and thrombus growth. Surface binding of vWF to exposed subendothelial collagen is fundamental to the initiation of platelet adhesion under high shear.[48] The vWF macromolecule consists of A1 domains that engage the GPIbα component of the GPIb-V-IX complex.[48,49,50] These bonds are characterized by rapid on/off rates and by "catch" or "flex bond" mechanisms.[21,51] Thus, they cannot mediate stabilized adhesive interactions but rather, support a "flip-flop" rolling or sliding form of platelet translocation. The dynamics of platelet–vWF interaction are influenced by multiple factors including the number, lifetime, and tensile force of vWF–GPIb bonds.[51,52] Collagen binding to platelet receptor GPVI and integrin $\alpha_2\beta_1$ is important for more stable platelet adhesion after a platelet decelerates through vWF–GPIb binding.[53] More stable adhesion occurs primarily through platelet activation *via* the GPVI pathway.[54–57]

Thrombin Generation

α-Thrombin is one of the most potent inducers of platelet activation and plays an important role in regulating the thrombogenicity of atherosclerotic plaques.[58,59] Disrupted plaques are particularly efficient at activating blood coagulation due to the presence of relatively large amounts of tissue factor (TF) in the plaque's necrotic core. TF is primarily derived from apoptotic macrophages and T cells and is expressed on the surface of procoagulant microparticles.[60,61] TF-stimulated thrombin generation, in combination with fibrillar collagen, subsequently promotes the platelet procoagulant response. This local generation of thrombin on the surface of platelets further enhances thrombus growth and stability by activating neighboring platelets and generating fibrin within the developing thrombus. Coagulation reactions typically occur in regions of low (stagnant) blood flow, such as within the confines of a developing thrombus or in downstream low shear pockets, leading to the formation of a "fibrin-tail."[62–65] Flow-dependent removal of activated coagulation factors is an important mechanism preventing excessive thrombin generation and thrombus propagation.[66] Efficient platelet activation at sites of vascular injury is also dependent on the localized generation and release of endogenous platelet agonists, including TxA_2 and ADP. Platelets respond rapidly to soluble agonists by undergoing shape change, calcium mobilization, granule secretion, and activation of one or more surface integrins, leading to the development of stable platelet aggregates that can resist the detaching effects of blood flow.[53,67] The efficiency of platelet activation is partially dependent on the rate and extent of soluble agonist generation, as well as the impact of blood flow on the clearance of agonists from the site of injury.

Flow-directed Platelet Transport

The rate of platelet thrombus growth is also influenced by the efficiency of the flow-directed accrual of platelets to the site of vascular injury. Two of the important effects of shear on platelet transport include (a) the influence of flow on the distribution and localization of blood cells within the vessel lumen and (b) the enhanced rate of platelet collision with the vessel wall (FIGURE 29.3). Blood flow selectively partitions erythrocytes to the center of flow, while platelets are displaced laterally, increasing their effective concentration (up to 15× average concentrations) at the vessel wall.[68,69–71] Supplementing margination under flow is enhanced lateral motion due to platelet collisions, fluid forces, and RBC rotation.[72,73,74] The rate of lateral platelet movement may be four orders of magnitude larger than that predicted for thermal motion alone (diffusion), based on platelet studies at wall shear rates (WSR) below 600 s^{-1} and extrapolations from other solutes (e.g., ferricyanide) for shear rates approaching 5,000 s^{-1}.[72] Significantly, reductions in platelet transport at relatively low WSR (<1,000 s^{-1}) can considerably limit the overall rate of thrombus growth.[75] In contrast, flow-based transport effects within a stenosis can considerably amplify platelet accumulation.

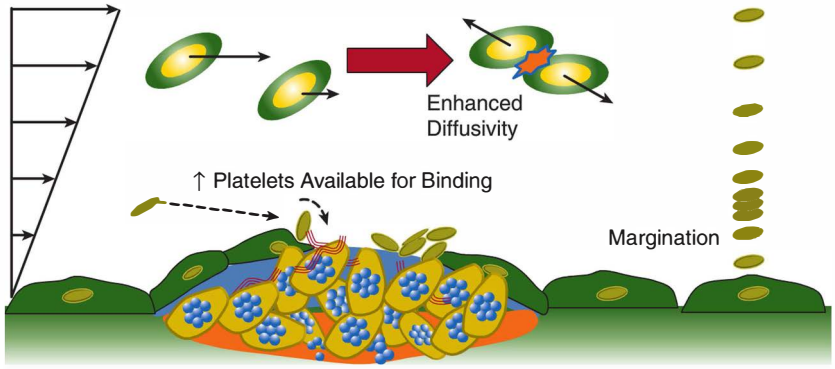


FIGURE 29.3 Platelet transport to a site of vascular injury is enhanced through the presence of red blood cells and shear. Hematocrit increases the number of cell–cell collisions because the number of cells in a given area is increased. Meanwhile, shear increases cell–cell collisions because the relative speed of cells in neighboring flow laminae is enhanced. Increased collisions contribute to enhanced lateral motion (*enhanced diffusivity*), which consequently supports the ability of blood to provide a consistent supply of platelets for hemostasis/thrombosis. Furthermore, platelets are also radially displaced to the vessel walls under flow by red blood cells. This phenomenon of platelet *margination* increases platelet concentration near the vessel wall, further supporting platelet collisions with the vessel wall, allowing platelets to reconnoiter the vessel for injury. (Maxwell MJ, Dopheide SM, Turner SJ, et al. Shear induces a unique series of morphological changes in translocating platelets: effects of morphology on translocation dynamics. *Arterioscler Thromb Vasc Biol* 2006;26(3):663–669.)

Localized Disturbances in Blood Flow and Discoid Platelet Aggregation: the Role of Shear Microgradients

In vivo studies have demonstrated that many of the platelets initially incorporated into the body of forming thrombi maintain their discoid morphology and[76,77] do not elicit a substantial cytosolic calcium response[76,78] or release their granule contents,[79] raising the possibility that platelet stimulation by soluble agonists is not essential for initial thrombus growth. Adhesive interactions between discoid platelets appear to be highly sensitive to local (microscale) changes in shear flow.[80] Thus, discoid platelets adhering to the surface of a growing thrombus experience an initial phase of shear acceleration, followed by a phase of shear deceleration (FIGURE 29.4) that facilitates the development of sustained discoid platelet adhesion contacts with the thrombus surface.[80] Notably, this SMG-dependent platelet aggregation mechanism is insensitive to the effects of ADP, TXA_2, and thrombin antagonists. SMGs are likely to develop on the surface of disrupted plaques and may contribute to the initial formation of platelet thrombi.[41,42,81]

Membrane Tethers Facilitate the Adhesion and Aggregation of Discoid Platelets

The mechanism by which discoid platelets adhere and aggregate under the influence of mechanical forces is primarily dependent on the development of membrane tethers. Investigations of *in vitro* and *in vivo* thrombosis models have demonstrated that discoid platelet capture at the surface of thrombogenic substrates and during platelet–platelet capture is mediated by the formation of specialized membrane adhesion structures that respond reactively to the local shear conditions.[53,82] These studies demonstrate that initial platelet impact with adhesive surfaces results in the pulling of thin filamentous membrane tubules or tethers that form the initial anchoring structure, denoted as a discrete adhesion point (DAP) by Reininger et al.[52] These thin membrane tethers can range in length from 0.91 to 47.90 mm.[52,83] A key observation from these studies has been the demonstration that platelet tether extraction becomes more prevalent with increasing levels of applied shear force.[82] While this may partially be due to the viscoelastic nature of the membrane, it may also suggest that tether generation conveys some

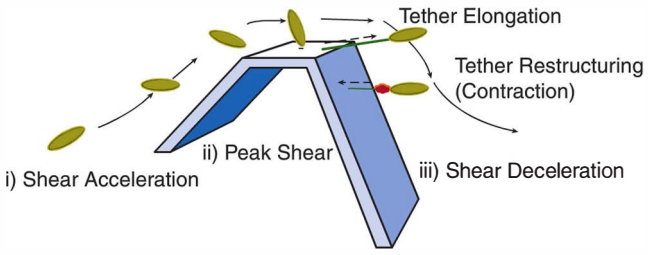

FIGURE 29.4 Platelets in free flow may experience microscale changes in the shear environment within stenoses that prime and subsequently trigger surface contact and subsequent tether formation. Microscale changes in shear following initial tether adhesion triggers localized restructuring of the membrane tether characterized by tether thickening and contractile shortening opposing blood flow leading to semistable platelet aggregate formation. Free-flowing platelets experience a rotational force directed perpendicular to their major axis forcing them toward the adhesive surface. Compressive force directed along the platelets' major axis leads to DAP contact formation forming the site of initial "touchdown" adhesion. Shear and elongational force due to blood flow leads to membrane–cytoskeletal failure initiating viscoelastic tether pulling. Elongation of the forming tether stabilizes the initial adhesive interaction.

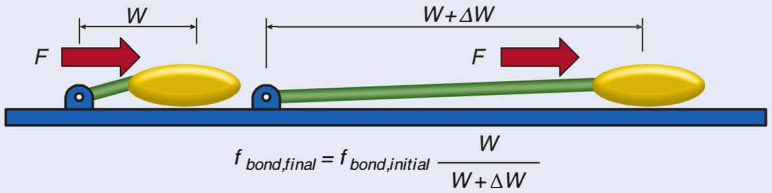
Box 29.5 Platelet Tethers Reduce the Required Bond Strength of an Adhered Platelet



Platelet tether formation can reduce the required surface binding force by elongating the tether.

- First, the viscoelastic nature of the tether avoids a high impulse force (sudden acceleration or deceleration of an object) by extending the collision time.
- Secondly, a tether reduces the required strength of adhesive bonds by reducing the vertical component of the tension/force experienced by the bond as the tether extends (**A,B**). The overall bond force, *f*, required to maintain adhesion for a given drag force, *F*, reduces proportionally, if the tether elongates, by the ratio of the initial tether length over the new tether length, based on a simple static analysis.

adhesive advantage as the blood flow environment begins to destabilize adhesion contacts. Indeed, tensile force experienced by adhesion receptor bonds under fluid flow can be reduced by effectively changing the length of the tether, minimizing the tensile force in the normal direction to the surface (Box 29.5).

Platelet Tethers are Reactive Shear Sensors

In general, the biophysical mechanisms underpinning platelet tether formation are not fully understood. Within the context of a generalized cell model (FIGURE 29.4), the extraction of a membrane tether by a sufficiently large pulling force has been proposed to occur *via* a two-phase process characterized by (a) the formation of an initial viscoelastic protrusion at relatively low pulling forces and (b) a secondary phase in which progressive increases in pulling force lead to extraction of a viscous tether at the end of the initial membrane protrusion.[53] Initial filamentous platelet tether formation may be a result of membrane to cytoskeleton association failure and represent a passive phase of viscoelastic membrane pulling. While the membrane properties of the initial extension phase are relatively well understood, the material properties of the secondary phase are poorly defined and complex, involving active cytoskeletal reorganization and receptor-based outside-in signaling, localized to the site of initial adhesion contacts. Significantly, recent studies examining the response of platelet membrane tethers to perturbations of blood flow velocity demonstrate that filamentous platelet tethers undergo dynamic contractile remodeling when the applied shear rate falls below 300 s^{-1}.[80] Thus, dynamic restructuring of tethers may represent an important mechanosensory element of platelet adhesion in response to microscale changes in the hemodynamic environment.

von Willebrand Factor as a Shear Sensitive Thrombogenic Substrate

An important emerging concept in the field is that not only do platelets respond to rapid changes in the shear environment but that immobilized ligands such as vWF also react dynamically to elevated shear stress and more complex shear environments. vWF exhibits a reversible globular transition to a stretched chain-like state at moderate-to-high shear rates (3,181 to 5,000 s^{-1} in solution phase or ~1,000 s^{-1} in whole blood), as determined by atomic force microscopy and epifluorescence microscopy.[84,85] Significantly, flow-based experiments suggest that this transition is reversible upon reduction of the applied shear stress, suggesting that temporally varying shear could result in vWF undergoing multiple rounds of globular-extended transitions. Such large transitions can exist along a rough stenotic surface.[35] Thus, vWF may act as a hemodynamically triggered biopolymer that may undergo conformational activation at sites of acutely elevated shear stress.

The shear-responsive nature of both platelets and vWF may operate in concert to facilitate thrombus formation under pathologic shear conditions. Under conditions where WSS exceeds 100 dynes/cm^2 (5,000 s^{-1}), such as at the apex of stenoses, vWF A1 domains become exposed on plasma vWF multimers that can bind to GPIbα to promote platelet recruitment.[52,84,85,86] Significantly, these high shear aggregates can form in the absence of soluble agonists. Aggregates formed in this way are unstable until the shear stress approaches 400 dynes/cm^2 (20,000 s^{-1}) at which point adherent platelets at the interface of surface-immobilized and membrane-bound vWF are stretched into elongated "beads on a string" -like structures.[48,52,86] These high-shear vWF–platelet aggregates may persist for minutes in the absence of platelet activation and may be a key determinant responsible for acute thrombotic occlusion in stenotic arteries. Thus, the shear-responsive nature of platelets and vWF has evolved to enable efficient thrombus formation under pathologic hemodynamic conditions.

CONCLUDING REMARKS

The impact of hemodynamic parameters on the atherothrombotic process is complex and wide ranging. In addition to the well-defined role of macroscale perturbations of flow in promoting the formation of atherosclerotic lesions, growing bodies of evidence suggest that microscale changes in flow may also play a major role in promoting disease progression and thrombus growth. Multidisciplinary approaches applied to the

atherosclerosis and thrombosis fields are starting to uncover some of the fundamental cellular mechanotransduction mechanisms translating microscale flow changes into single-cell adaptive responses. An increased focus on the interplay between the macro- and microscale effects of blood flow on cardiovascular pathology will be important for a more complete understanding of disease progression and may ultimately lead to the identification of new approaches to limit atherothrombotic complications.

CHAPTER

30 Platelet Collagen Receptors

STEPHEN P. WATSON, RICHARD W. FARNDALE, MASAAKI MOROI, AND STEPHANIE M. JUNG

Platelets, small anucleate circulating blood cells, are known to be activated by several physiologic substances, including ADP, thrombin, collagen, and adrenaline (epinephrine), as well as some nonphysiologic compounds. Collagen is thought to be one of the important physiologic activators because it powerfully induces platelet aggregation and is abundantly present in subendothelial tissue, which becomes exposed to the blood stream when blood vessels are damaged. Thus, exposed collagen fibers contribute to initial thrombus formation by interacting with circulating platelets. The mechanism of thrombus formation on collagen surfaces under blood flow has been studied by many investigators using *ex vivo* flow chamber systems designed to approximate the physiologic environment in blood vessels. This section provides a historical context for the platelet collagen receptors and subsequent sections provide details about our present knowledge of how these receptors initiate and facilitate the transmission of signals to result in thrombus formation.

After the high-affinity ligand–receptor interaction concept was established in the 1960s, such a stimulus-response reaction was also hypothesized for collagen–platelet interactions. Because platelets react specifically with collagen, a specific receptor for collagen was expected to be present on the platelet surface, but its identity remained elusive for many years because its ligand, collagen, a complex and insoluble macromolecule, is unlike classical ligands. This means that collagen may have numerous possible interactions, many of which would be of low affinity. Because of these obstacles, the collagen–platelet interaction was assessed only by collagen-induced platelet aggregation, not an ideal parameter since this response is influenced by numerous other platelet activating reactions, not only those directly related to platelet binding of collagen. Consequently, many proteins have been reported to be the candidates for platelet collagen receptors, even though they do not meet all the criteria for a physiologic receptor.

The first hypothesis, proposed by Jamieson et al.,[1] suggested that the collagen receptor was an enzyme, a collagen glucosyltransferase that works as a receptor through an enzyme–substrate interaction. This hypothesis was supported by reports showing that a glycopeptide fragment of chicken collagen induced platelet aggregation just like native collagen fibers. Later, Chiang et al. purified a protein that specifically interacted with the chicken collagen fragment and proposed that this was the collagen receptor, but subsequent investigators could not verify that this was the case. During this period, other proteins were suggested to be receptors including, fibronectin, GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$), thrombospondin, factor XIII, propolypeptide of von Willebrand Factor (vWF), and CD36 (GPIV). Although these proteins interact with collagen, to date, none have been confirmed to contribute significantly to the platelet–collagen interaction, particularly under physiologic conditions. The major platelet collagen receptors were subsequently found by a combination of biochemistry and, in the case of glycoprotein VI (GPVI), careful studies of patient platelets deficient in the receptor, as discussed below.

INTEGRIN $\alpha_2\beta_1$ (GPIa/IIa)

The integrins are heterodimers composed of an α and a β subunit selected from 18 α subunits and 8 β subunits, each a separate gene product, combining in 24 permitted pairings.[2] Key species are $\alpha_2\beta_1$, the only integrin collagen receptor expressed on the platelet; the fibronectin and laminin receptors, $\alpha_5\beta_1$ and $\alpha_6\beta_1$; and the fibrinogen receptor, $\alpha_{IIb}\beta_3$. $\alpha_2\beta_1$ also has laminin-binding activity. The integrin subunits each have a short, conserved cytoplasmic domain, a single transmembrane span, and a long glycosylated stem supporting the head group, where the two subunits interact strongly and where ligand-binding occurs. The α subunit head is a 7-bladed β-propeller.

Integrins fall into two categories, defined by the presence within the α subunit of an I domain, so named because it is inserted between blades 2 and 3 of the β-propeller. This 200 amino-acid domain has a similar structure to the A domains of vWF, and is sometimes called the vWF A-domain. In these integrins, which include $\alpha_2\beta_1$, the α subunit I domain contains the ligand-binding site,[3] comprising an electronegative DxSxS motif that forms part of the Mg^{2+}-binding metal ion-dependent adhesion site (MIDAS). This MIDAS Mg^{2+} ion is in turn coordinated by an amino-acid carboxylate anion in the ligand.

In the second category of integrins, those lacking an α subunit I domain, such as $\alpha_{IIb}\beta_3$ and $\alpha_5\beta_1$, the ligand-binding site is found in a very similar structure, namely the β subunit I domain. For $\alpha_{IIb}\beta_3$, the ligand carboxylate anion might be the aspartate found within the RGD motif of the α chain of fibrinogen or in the C1 domain of vWF. Cooperative binding of such extended, polymeric proteins may occur through secondary ligand, for example, KQAGDV in the γ chain of fibrinogen[4] binding to the α subunit β-propeller that forms the largest segment of the integrin head. Regulation involves the β subunit MIDAS, and two other cation-binding sites, the ADMIDAS (adjacent to MIDAS) and LIMBS (ligand-induced metal ion binding site).[5]

In 1985, Nieuwenhuis et al.[6] reported a patient who had defective collagen-induced platelet aggregation and a bleeding tendency in association with a marked decrease in GPIa.*

*The loss of collagen-reactivity in this patient was later shown to be due to a more generalized defect in adhesion molecules and was not specific to collagen.

Around the same time, Santoro[7] provided biochemical evidence suggesting that GPIa interacts with collagen. Later, GPIa on the platelet membrane was shown to be present as a complex with GPIIa, the GPIa/IIa complex.[8] Analyses of membrane proteins interacting with extracellular matrix proteins were performed for many different cells, leading to identification of very late activation antigens (VLA) of lymphocytes, cell adhesion receptors of leucocytes, and extracellular matrix receptors (ECMRs) of fibroblasts; the proteins interacting with collagen in these systems, VLA-2 and ECMR-II, were thus identified. It was subsequently discovered that GPIa/IIa, VLA-2, and ECMR-II were all the same protein, which was then designated as integrin $\alpha_2\beta_1$, establishing that integrin $\alpha_2\beta_1$ was a collagen receptor present in many cell types. The structural details of $\alpha_2\beta_1$ are shown in FIGURE 30.1 and are described below, although one defining characteristic of $\alpha_2\beta_1$, as related to its ability to interact with its ligand collagen, should be noted here. Since collagen is insoluble, the interaction of collagen and platelet $\alpha_2\beta_1$ is usually analysed by adhesion assay, a condition in which platelet activation and interaction of $\alpha_2\beta_1$ with collagen occur concomitantly and thus integrin activation cannot be differentiated from collagen adhesion. However, Stephanie Jung and Masaaki Moroi[9] at Kurume University succeeded in separating these reactions by kinetic analyses with soluble collagen III monomers and demonstrated that $\alpha_2\beta_1$ must be activated to exhibit high-affinity binding to collagen III, the resting state showing almost no binding activity toward this ligand.

GLYCOPROTEIN VI

Although $\alpha_2\beta_1$ was established as a collagen receptor on platelets, there was a report suggesting the presence of an approximately 60-kDa collagen-reactive platelet protein on platelets based on patient studies. In 1987, Sugiyama et al.[10] reported a patient

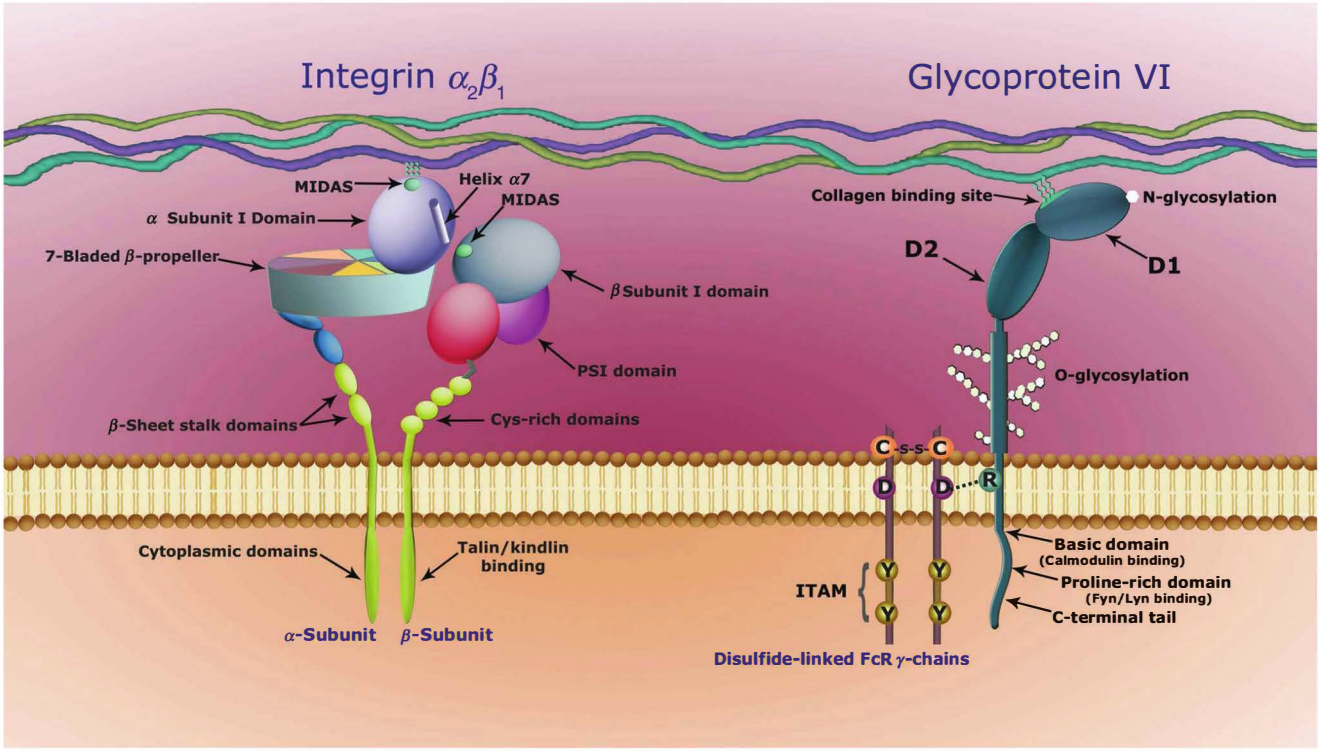

FIGURE 30.1 Structures of platelet collagen receptors. (Left) Integrin $\alpha_2\beta_1$: the extracellular domain of the α_2 subunit contains the I domain and its collagen-binding site. The I domain is located between blades 2 and 3 of the α subunit β-propeller. Helix 7, within the I domain, links the collagen-binding MIDAS with its counterpart in the β subunit I domain. The head of the β subunit also contains a hybrid domain (red), comprising polypeptide that is proximal to the I domain and a distal segment that leads into the plexin–semaphorin–integrin (PSI) domain, where the *N*-terminus is located. The β subunit stem contains cysteine-rich EGF domains. The cytoplasmic domains contain binding sites for numerous signalings, and adapter and cytoskeletal components, similar to focal adhesion components, and talin and kindlin binding regulate the activation of the integrin. (**Right**) Glycoprotein VI: The extracellular domain of GPVI contains two Ig-like domains (D1 and D2), and between the Ig-like domains and the transmembranes lies a mucin-like Ser/Thr-rich domain (O-glycosylation). A putative binding site for collagen is formed by interaction of two D1 domains when GPVI forms a dimer. The D1 domain may contain a glycosylation site (Asn72) for an *N*-linked carbohydrate chain. The presence of a charged residue (Arg252) in the transmembrane–membrane domain enables GPVI to associate with an FcR chain, which contains a negatively charged Asp residue. The cytoplasmic portion of GPVI consists of four regions: juxtamembrane portion; basic region, which contains a calmodulin binding site; proline-rich domain, to which Fyn and Lyn bind to through their SH3 domains; and the *C*-terminal region. Mouse GPVI is truncated, lacking the latter domain.

with idiopathic thrombocytopenic purpura (ITP) whose platelets were defective in collagen-induced aggregation. Her serum contained an antibody to a platelet protein of approximately 60 kDa, although her own platelets did not contain this antigen and lacked reactivity to collagen. These results suggested that the antigen, designated P62, may be a receptor for collagen or a protein involved in a collagen–platelet interaction. This was supported by studies of another patient whose platelets were deficient in GPVI. No one had studied the characteristics of this protein at that time, but it was named according to its mobility in nonreduced–reduced two-dimensional SDS gel electrophoresis according to the convention of Phillips and Agin.[11] The second patient's platelets also lacked collagen-induced aggregation, while showing no abnormalities in aggregation induced by other platelet agonists. The antibody from the serum of the first patient[10] did not react with platelets from the GPVI-deficient patient, indicating that P62 and GPVI were the same proteins. These results strongly suggested that GPVI was a newly defined platelet collagen receptor.

There were essentially no studies on GPVI for some years after its discovery because of the lack of tools to analyze this protein except for the patient autoantibody. While searching for platelet-reactive sites of collagen, Michael Barnes and Richard Farndale at Cambridge found that a collagen-mimetic peptide that was called collagen-related peptide (CRP), containing 10 repeats of the sequence Gly-Pro-Hyp (GPO), induced platelet aggregation and this reaction was independent of $\alpha_2\beta_1$.[12] Finally, the era of intense investigations on GPVI as platelet collagen receptor was initiated. Steve Watson's group in Oxford identified the Fc receptor γ chain as a critical component in collagen signaling in platelets that shortly thereafter was shown to associate with GPVI and to be essential for platelet activation.[13–15] CRP reacted specifically with GPVI[16] and could stimulate tyrosine phosphorylation in platelets in a manner similar to collagen.[17] A snake venom protein, convulxin, first identified in the late 1970s, was subsequently found to induce a pattern of tyrosine phosphorylation similar to that induced by collagen, including phosphorylation of the FcR γ chain. The identification of materials that specifically reacted with GPVI and activated platelets facilitated the purification and cloning of GPVI[18] and also the analysis of its function.

Human GPVI is a member of the immunoglobulin superfamily and is encoded in the leucocyte receptor complex on chromosome 19; the FcR γ chain is encoded on chromosome 1. GPVI possesses an *N*-terminal and a *C*-terminal extracellular Ig domain, designated D1 and D2, linked by a single peptide strand that allows some flexibility in the head of the receptor (FIGURE 30.1). A glycosylated stem connects D2 to the transmembrane domain and thence to the relatively short (50 amino acids) cytoplasmic domain that can bind calmodulin close to the plasma membrane, and the Src family kinases Fyn and Lyn through a proline-rich domain closer to the *C*-terminal cytoplasmic tail (see below). The transmembrane domain contains an arginine residue that forms a salt bridge with an aspartate residue in the equivalent location of FcR γ chain and supports the association between the two.[18] Coexpression of FcRγ with GPVI is required for cell-surface expression of the latter in platelets.

In 2006, the crystal structure of GPVI was described by Andrew Herr et al.[19] revealing interactions between two copies of the receptor that might form the basis for physiologic dimerization.[20] A collagen binding site, located largely within D1, was modeled onto the receptor, consistent with the effect of site-directed mutagenesis on ligand binding.[21] Whether this model properly reflects the interaction of GPVI with insoluble collagen has yet to be resolved. More recently, a crystal structure and binding study of LAIR1, a single Ig domain receptor that shares substantial homology with D1 of GPVI, led to the suggestion of a nearby but discrete ligand-binding site in GPVI.[22] These differing proposals will be fruitful areas for research.

GPVI has also been suggested to bind laminin, which is a major component of the basement membrane.[23] The interaction with laminin is dependent on integrin $\alpha_6\beta_1$ and leads to platelet spreading, but laminin is unable to induce aggregation of platelets in suspension, possibly because it has a 10-fold lower affinity for GPVI than collagen. Laminin is the major platelet-reactive component in the basal lamina, and, like collagen IV, is unable to activate platelets (see below). The physiologic significance of the interaction of platelets with laminin may be to mediate sealing and repair of small areas of damage to the vessel in the absence of thrombus formation.

Thus, platelets have two collagen receptors: $\alpha_2\beta_1$ that has higher affinity for collagen, but requires activation for its affinity to be fully expressed, and GPVI that activates platelets. Kinetic studies using recombinant GPVI indicated that the immunoglobulin receptor had a weaker affinity for collagen than $\alpha_2\beta_1$.[24] Under physiologic conditions, these two receptors would work synergistically, with $\alpha_2\beta_1$ supporting adhesion and GPVI supporting activation, and thus each contributing to effective thrombus formation. The use of GPVI- and $\alpha_2\beta_1$-specific peptides as surface coatings for *in vitro* flow studies reveals the need for both receptors along with vWF for full platelet aggregation to take place.[25]

There is also evidence in the literature that platelets may express one or more further receptors for collagen that may support adhesion and possibly activation. For the most part, this evidence is linked to a single study or a handful of studies that have implicated certain proteins, such as GPV, or have demonstrated signaling events that cannot be attributed to activation of GPVI and integrin $\alpha_2\beta_1$.[26] The overall significance of these putative receptors in platelet activation by collagen is uncertain and has been reviewed elsewhere.[27]

THE CLASSIC TWO-STEP, TWO-SITE MODEL AND THE CURRENT MODEL FOR PLATELET ADHESION

Any model proposed for how the platelet collagen receptors induce platelet activation must take into account the differential roles of $\alpha_2\beta_1$ and GPVI. In 1989, Michael Barnes reported that platelets could adhere to several specific cyanogen bromide (CB) peptides of collagen I and III, but only a subset of these peptides exhibited aggregatory activity.[28] This suggested that the collagen molecule may contain sites specific for platelet adhesion that are different from those that stimulate aggregation. Around this time, Samuel Santoro proposed the two-step, two-site model, based on chemical modification of collagen,[29] in which collagen has a higher-affinity binding site for $\alpha_2\beta_1$, for the adhesion reaction, and a lower-affinity binding site for a second receptor, presumably the one responsible for platelet activation. The development of peptide libraries (Toolkits)[30] based on the primary sequence of collagen type III by Richard Farndale's

group at Cambridge further advanced our understanding of the initial binding interaction between platelets and collagen. The various $\alpha_2\beta_1$-binding sites were defined,[31,32] and the activating site within CB4 of collagen III was identified as binding GPVI.[33] After GPVI was found to be a collagen receptor on platelets, this two-step, two-site model was applied to GPVI and integrin $\alpha_2\beta_1$ to explain their separate roles in the platelet–collagen interaction: $\alpha_2\beta_1$ would bind first, assisting the other collagen receptor GPVI to bind and initiate the activation of platelets. However, the finding that integrin $\alpha_2\beta_1$ exists in a resting state that exhibits low affinity for collagen III and an activated high-affinity state induced by platelet agonists mandated a reappraisal of this model: it is now thought that platelets first interact with collagen through GPVI, activate $\alpha_2\beta_1$, and the activated $\alpha_2\beta_1$ binds strongly to collagen, resulting in initiation of a cascade of reactions to activate platelets. However, it should be noted that the traditional two-step, two-site model and the currently accepted model are not mutually exclusive, since it may be possible that both types of receptor–collagen interactions may occur under physiologic conditions. Even in nominally "resting" platelets, the presence of a low level of the active, high-affinity form of $\alpha_2\beta_1$ may contribute to platelet adhesion to collagen and it is also possible that the resting receptor may be able to interact with the higher-affinity binding sequences in collagen type I (see below).

THE ROLE OF COLLAGEN IN THROMBUS FORMATION

The molecular events underlying thrombus formation in the high flow rates in arteries and arterioles are depicted in FIGURE 30.2. Platelets marginate along the vessel walls because of the large mass of red blood cells that flows in the centre of the vessels. Platelets are kept in a quiescent state by the continuous release of nitric oxide and prostacyclin from the vascular endothelial cells and by removal of low levels of ADP and ATP that have been released from damaged cells by apyrase-like activity of endothelial CD39. Damage to the endothelial surface exposes collagen fibers that capture vWF from the flowing blood through its collagen-binding A3 domain.

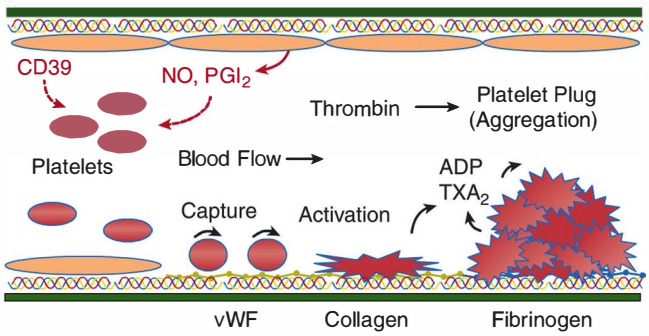

FIGURE 30.2 Role of collagen in platelet activation. Damage to the endothelial cell wall exposes subendothelial collagen fibers that bind to von Willebrand factor (vWF) in the bloodstream. Platelets are captured (or tethered) through the interaction of vWF and GPIb-IX-V complex on the platelet surface. This enables binding of collagen to GPVI, which stimulates activation of integrins $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$. In turn, the integrins bind to vWF and collagen, respectively, resulting in a stable adhesion. GPVI also promotes platelet spreading and secretion of the feedback agonists ADP and TxA_2 that activate circulating platelets. Cross-linking of platelets by fibrinogen mediates platelet aggregation.

vWF mediates platelet tethering through a very fast on-rate of association to the GPIb-IX-V complex on the platelet surface. The GPIb-IX-V complex is a unique receptor in the genome and mutations in GPIbα, GPIβ, or GPIX subunits give rise to the severe bleeding disorder Bernard Soulier syndrome due to loss of the capacity for platelet tethering, as well as variable thrombocytopenia. The interaction between GPIbα and the A1 domain of vWF, however, does not lead to rapid, stable adhesion because of a fast off-rate of dissociation. This can be illustrated experimentally by the rolling of platelets under flow conditions on an immobilized vWF surface.

In the subendothelial wall, platelet tethering facilitates the interaction of fibrillar collagen with the low-affinity GPVI receptor complex, stimulating powerful activation of the integrins $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$. These two integrins mediate stable adhesion through binding to collagen and vWF, respectively. Additionally, GPVI stimulates platelet spreading, thereby strengthening the interaction with the subendothelial matrix. The action of GPVI is supported by much weaker signals from the GPIb-IX-V complex and integrins $\alpha_2\beta_1$ and $\alpha_{IIb}\beta3$. The relative contribution of each receptor to platelet activation is unclear as all four receptors signal through overlapping pathways with critical roles for Src and Syk tyrosine kinases, and phospholipase Cγ2 (PLCγ2).

Platelet activation by GPVI causes ADP release from platelet dense granules and *de novo* synthesis of TxA_2 from arachidonic acid. These secondary mediators interact synergistically to mediate activation of platelets that have become newly tethered to $\alpha_{IIb}\beta_3$-bound vWF. In turn, plasma fibrinogen, which is present in molar excess over other adhesion proteins, mediates platelet aggregation by cross-linking the integrin $\alpha_{IIb}\beta_3$. Thus, aggregate formation is critically dependent on the secondary mediators ADP and TxA_2 that signal through the $P2Y_1$ and $P2Y_{12}$ receptors and the TP thromboxane receptors, respectively. $P2Y_1$ and TP receptors signal through activation of PLCγisoforms downstream of the heterotrimeric G protein, Gq. The $P2Y_{12}$ receptor signals through the Gi family of heterotrimeric G proteins and undergoes a powerful synergy with signals from both Gq and tyrosine kinase-linked receptors.

Activated platelets provide a procoagulant surface that leads to formation of thrombin through the coagulation cascade. Thrombin reinforces platelet activation through the protease activated receptors (PARs), PAR-1 and PAR-4, which are also coupled to Gq. In addition, thrombin cleaves fibrinogen to fibrin, thereby further strengthening the growing thrombus, and this is further cemented by clot retraction mediated through actin–myosin contraction mediated downstream of integrin $\alpha_{IIb}\beta_3$. Together these interactions generate a robust thrombus that is able to withstand the high shear forces found within the arteriolar circulation.

In situations of mild injury, the roles of GPVI and integrin $\alpha_2\beta_1$ are redundant with those of other signaling receptors and adhesive integrins, respectively. The level of expression of $\alpha_2\beta_1$ on the platelet surface is approximately 1% to 2% of that of integrin $\alpha_{IIb}\beta_3$, which therefore dwarfs its role in supporting adhesion. This is illustrated by the absence of patients

with platelet-bleeding disorders that can be attributed solely to a reduction in functional $\alpha_2\beta_1$, whereas there are several hundreds of patients with function disrupting mutations in integrin $\alpha_{IIb}\beta_3$, a condition known as Glanzmann thrombasthenia. Very few patients have also been reported with functional defects in GPVI associated with a bleeding diathesis. Furthermore, in the majority of these cases, the loss of GPVI is mediated by an immune thrombocytopenia and is associated with a marked reduction in platelet count. There are currently just two patients with a bleeding diathesis in which the only known platelet defect is the loss of functional GPVI as a result of inheritance of function-disrupting mutations in the glycoprotein receptor. This very low number of patients can be explained by redundancy with other platelet signaling receptors such as those for thrombin, which is generated by exposure of tissue factor on the surface of subendothelial smooth muscle and other cells, and therefore also plays a role in the initial events that trigger activation.

Mice deficient in GPVI and/or the integrin α_2 subunit are viable and can be used to investigate the relative contributions of the two collagen receptors in platelet activation. The majority of results are in line with those in patients and confirm that neither GPVI nor integrin $\alpha_2\beta_1$ is essential for aggregate formation, with deficiency of either receptor giving rise to a mild bleeding diathesis or no apparent loss of clotting ability, dependent on the nature of the test.

Thus, neither collagen receptor is essential for platelet activation although both clearly make important contributions following severe injury where limiting the loss of blood as rapidly and effectively as possible is paramount. However, it should be emphasized that the mild nature of the bleeding diathesis in the absence of GPVI or $\alpha_{IIb}\beta_3$ should not be construed as evidence against a significant physiologic role of these proteins in response to major injury. Indeed, a similar situation applies to the receptors for TxA_2 and ADP, in that defects in either receptor gives rise to a mild bleeding diathesis with only a handful of patients identified world wide. The apparent paucity of patients with defects in these receptors and their mild bleeding symptoms can be attributed to the redundancy between receptors in regulating platelet activation.

COLLAGEN STRUCTURE AND COLLAGEN MIMETICS

In the healthy vessel wall, collagens are concealed beneath the vascular endothelium and are only exposed to circulating platelets in disease or upon injury. The endothelium rests on a basal lamina composed of a collagen IV network, with laminins, entactin, and perlecan as important co-constituents. Deeper in the vessel wall, in the tunica media, the fibrillar collagens I and III are the major forms of collagen expressed by vascular smooth muscle, along with several others, including the minor fibrillar collagen V and the nonfibrillar collagens VI, VIII, and XVI. A key feature of the fibrillar collagens is their ability to assemble as an organized, rope-like structure. The fundamental tropocollagen unit is a triple-helical (COL) domain of approximately 1,000 amino acids with short nonhelical *N*- and *C*-terminal telopeptide extensions. The COL domain has four complete D-periods of 234 amino acids, and a fifth, partial D-period. Tropocollagen monomers align side-by-side and end-to-end within a fibril, with a fixed, one D-period offset

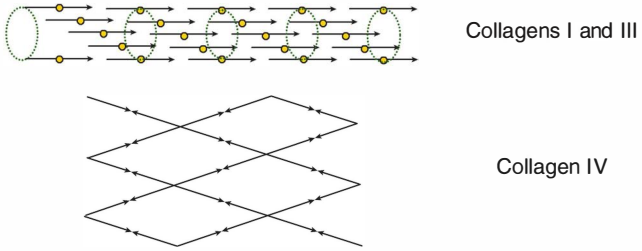

FIGURE 30.3 Structure of major blood vessel wall collagens. Each triple-helical collagen monomer is represented by an *arrow*, with the head at the *C*-terminus. In collagen fibers (I and III), monomers are aligned end-to-end with a gap between them, and each monomer is approximately 300 nm long. Cylindrical packing leads to a lateral separation between monomers of approximately 3 nm. Binding sites (*blue dot*) are aligned (*dashed circles*), and must appear on the fiber surface at least on every fifth monomer and perhaps more frequently. (Herr AB, Farndale RW. Structural insights into the interactions between platelet receptors and fibrillar collagen. *J Biol Chem* 2009;284:19781–19785). In collagen IV, monomers are arranged head-to-head and tail-to-tail forming a square-mesh network. Lateral separation between any binding motifs in collagen IV is approximately 800 nm. (Diagram after Ricard-Blum S. The collagen family. *Cold Spring Harb Perspect Biol* 2011;3(1):a004978.)

between adjacent molecules, indicating that a gap between the ends of tropocollagen molecules is needed to complete the partial fifth D-period (FIGURE 30.3). This periodic structure gives rise to the regular striations observed in transmission electron micrographs of tendon and other collagen preparations.[34] Fiber diffraction studies indicate that the next level of organization is the microfibril, comprising five tropocollagen strands, each offset longitudinally by one D-period and each stepping across to an adjacent axial position at each, less tightly packed, gap region.[35] Thus, each microfibril adopts a twisting structure. The collagen fiber is assembled as concentric layers of microfibrils within a fiber, giving rise, in cross section, to ordered quasihexagonally packed sectors with disordered liquid crystalline regions between them.[36,37] A consequence of this ordered fiber structure is that binding sites for platelet receptors and other relevant molecules such as vWF are not uniformly distributed on the fiber surface, but may be presented as coherent bands around the circumference of the fiber, allowing platelet receptors to be recruited in closely packed clusters that may be required to induce signaling.[38]

Receptor clustering is not readily achievable by collagen IV or other nonfibrillar collagens where triple-helical collagen monomers are not in close juxtaposition. Although the primary sequence of such collagens may contain motifs that can bind to platelet receptors, for example, GPO-rich regions in collagen IV that might in principle bind GPVI, these may be too far separated to support receptor clustering and signaling. Whilst recognition sequences in adjacent collagen monomers in a fiber lie <10 nm apart, in native collagen IV, they will be separated by approximately 800 nm, the effective mesh size of the collagen IV network. These considerations are depicted in FIGURES 30.3 and 30.4.

It is not yet clear which regions of the collagen monomer are available on a fiber surface. Some recognition motifs may

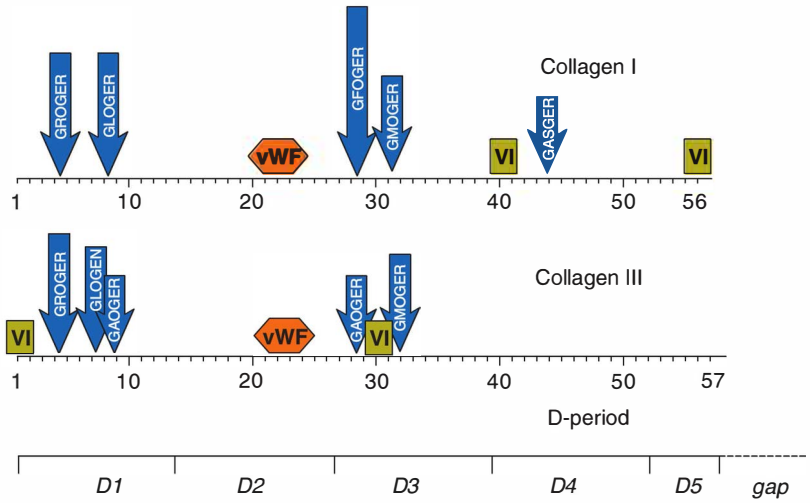

FIGURE 30.4 Receptor binding sites within collagens I and III. Peptide Toolkits allowed binding sites for GPVI (*squares*) and vWF (*hexagons*) to be mapped onto collagen monomers. Sites for $\alpha_2\beta_1$ are shown as *arrows*, where the length increases with intrinsic affinity of the site, and the motif is provided within the *arrow*. Numbers indicate the Toolkit peptide number. (Farndale RW, Lisman T, Bihan D, et al. Cell-collagen interactions: the use of peptide Toolkits to investigate collagen-receptor interactions. *Biochem Soc Trans* 2008;36:241–250.) Sites for collagen I are deduced from the highly-conserved collagen III Toolkit. Alignment of sites with D-period is indicated below.

be systematically concealed within the fiber by its precise architecture,[37] although this is debated.[38] However, a consequence might be that increased cell reactivity will result as fibers begin to disassemble, which might occur through limited proteolytic cleavage during inflammation or other disease.

Synthetic collagen-mimetic peptides, notably CRP,[39] are useful laboratory reagents because they contain receptor-binding motifs. GPO-rich peptides with more than 8 or 10 triplets will spontaneously adopt a triple-helical conformation, essential for interaction with the collagen receptors. If they contain suitable terminal residues, for example, Cys or Lys,[12] they can be chemically cross-linked to introduce polymeric structure that can support signaling through GPVI. In this cross-linked form, the peptide is known as CRP-XL, but without cross-linking, the peptide serves as an antagonist or partial agonist at GPVI.[12,40] The peptide can be made more potent by increasing its length,[41] though such materials remain to be developed for routine use.

The identification of motifs that bind $\alpha_2\beta_1$, typically GxOGER motifs,[42,43] has allowed the construction of triple-helical ligands of differing affinities for $\alpha_2\beta_1$. The most widely used and highest-affinity motif is GFOGER, derived from the α_1 chain of collagen I, but also found elsewhere including the α_1 and α_5 chains of collagen IV. This motif binds resting platelet $\alpha_2\beta_1$, but lower-affinity motifs, widespread in the collagens, such as GLOGER, GMOGER, and GAOGER, show increased binding upon platelet activation.[31] These motifs may be synthesized within GPO triplets that confer GPVI-binding activity on the peptide,[44] or within GPP triplets, that have sufficient propensity to form stable triple-helices but with little or no ability to bind GPVI. These peptide reagents are useful as surface coatings for research or diagnostic use, and have helped to establish the role of $\alpha_2\beta_1$ as necessary but not sufficient for thrombus deposition *in vitro* at low-to-moderate shear, and as contributing to the adhesion process at higher, vWF-dependent arterial shear rates.[25] It is noteworthy that collagens IV and V, although as replete with potential GPVI-binding sites (GPO triplets) as collagens I and III, are relatively poorly endowed with GxOGER motifs that bind $\alpha_2\beta_1$. Their lack of ability in native form to activate platelets no doubt results from a combination of inappropriate quaternary assembly of triple-helical monomers and scarcity of integrin-binding sites.

ANTIBODIES

Antibodies are important tools for basic research and may potentially have clinical applicability. An autoantibody from the blood of a patient with ITP was the first documented anti-GPVI antibody. Since IgG is bivalent, the patient's antibody induced platelet activation by cross-linking two GPVI molecules, but its monovalent Fab fragment inhibited platelet activation.[10] Most of the anti-GPVI antibodies developed subsequently also have these characteristics. A number of mAbs against GPVI were produced by hybridoma technology, including JAQ-1, 204-11, 9O12.2, and HY101, although OM4 was produced using knockout mice. Success has also been achieved using phage display that screens clones of Fab or scFv recognizing a specific epitope of GPVI. Examples of antibodies obtained in this way are 10B12, A10, and m-Fab-F, an antibody that recognizes GPVI dimer present on the platelet surface but does not bind to GPVI monomer and therefore is a powerful tool for detecting receptor dimerization (and activation—see below).

Many monoclonal antibodies against integrin $\alpha_2\beta_1$ have been developed, and unlike the GPVI antibodies, many are available commercially. These include activating antibodies such as TS2/16 that convert the inactive integrin to the active form.[45] Several sites on the β_1 chain have been identified as epitopes of the activating antibodies. Integrin $\alpha_2\beta_1$–specific inhibitory antibodies have also been reported. One of these antibodies, 6F1, developed by Coller et al.,[46] was reported to inhibit or delay platelet aggregation to collagen dependent on the conditions of the assay.

SNAKE VENOM AND OTHER TOXINS

Several toxins from venomous snakes have been found to activate platelets through GPVI. The best known is the C-type lectin convulxin from the South American rattlesnake *Crotalus terrificus*. Convulxin was proposed as a collagen mimetic in the late 1970s, but it was only after the identification of the GPVI-FcR γ chain complex that it was recognized to induce platelet activation through this glycoprotein receptor. Since then several other snake C-type lectin receptors, and also the metalloproteinase-disintegrin alborhagin, have been shown to activate platelets

through GPVI. GPVI-activating toxins have also been described in scorpion venom. In all cases, the toxin is believed to induce marked clustering of GPVI generating a powerful signal that leads to platelet activation.

The toxins are nonfibrillar and do not contain a collagenous GPO motif; thus they do not mimic collagen activation of GPVI. Several of the toxins may also bind to other platelet glycoproteins, thereby limiting their utility as GPVI-specific reagents. This includes convulxin that binds weakly to GPIb, although it is unclear if this influences its ability to induce platelet activation. The majority of the toxins, including the snake C-type lectins, are multimers of heterodimers, and cannot be readily expressed. They are available only as purified components, which brings the risk of contamination with other platelet-reactive agents.

GPVI SIGNALING

GPVI is the major signaling receptor for collagen on the platelet surface with the key functional motif being an immunoreceptor tyrosine-based activation motif (ITAM) in the associated FcR γ chain. ITAMs constitute the major signaling arm of many Fc and antigen receptors, including the low-affinity immune receptor, FcγRIIA, which is also expressed on platelets, and T- and B-cell antigen receptors. ITAMs are characterized by the sequence, $YxxLx_{6\text{-}12}YxxL$ with the two conserved tyrosines being critical for cell activation.

A related motif, known as a hemITAM and characterized by a single YxxL sequence downstream of a triacidic amino acid sequence, has recently been shown to signal in a similar manner to ITAM receptors. One of the founder members of the hemITAM family is expressed on platelets, namely the C-type lectin receptor, CLEC-2 (for review see[47]). The ligand for CLEC-2 is the transmembrane protein podoplanin, which is widely expressed with high levels on lymphatic endothelial cells, type 1 lung alveolar cells and kidney podocytes, but it is noticeably absent from vascular endothelial cells. The interaction between podoplanin on lymphatic endothelial cells and CLEC-2 on platelets plays a critical role in the separation of the lymphatic system from the cardinal vein.

The GPVI cytosolic tail contains a proline-rich region that confers binding to the Src kinases Fyn and Lyn through their SH3 domains.[48] This interaction places the two Src kinases in a "ready-to-go" position to mediate phosphorylation of the FcR γ chain ITAM, although deletion of this proline-rich region impairs but does not abrogate signaling by GPVI demonstrating the presence of an additional pathway of activation.[49] Clustering of GPVI leads to Src kinase–dependent phosphorylation of the two conserved tyrosines in the ITAM and subsequent binding and activation of the tandem SH2 domain-containing Syk tyrosine kinase. This leads to activation of Syk through autophosphorylation and phosphorylation by Src family kinases.

Syk initiates a downstream signaling cascade leading to formation of a signalosome that consists of a series of adapter and effector proteins (for review see[47]). Adapters are proteins with no enzymatic activity, but they serve as scaffolds for other proteins. The transmembrane protein, the linker for activation of T cells (LAT), plays a key role in GPVI signaling by localizing the signalosome to specialized cholesterol-rich regions in the membrane known as lipid rafts that are enriched in signaling proteins, including Src kinases with the exception of Src itself. LAT contains several conserved tyrosines that are phosphorylated by Syk, enabling binding to SH2 domains in the adapter proteins Grb2 and Gads, and also to PLCγ2. Gads is constitutively associated with the adapter SLP-76 and both proteins are recruited to the signalosome by phosphorylation of LAT. Several other effector proteins assemble into the signalosome including the tyrosine kinases Btk and Tec, the GTP exchange factors Vav1 and Vav3, the small GTPase Rac, and the PI 3-kinase α, β, and γ isoforms. Studies of mutant mice have shown that these proteins play varying roles in supporting activation of PLCγ2, which can range from relatively insignificant to being critical for activation of the phospholipase.[47]

At present, only two proteins have been found to be essential for activation of PLCγ2 by GPVI, namely Syk and SLP-76. LAT plays an important role in mediating activation, but its absence is overcome in response to high concentrations of GPVI ligands, including collagen. One explanation for the partial role of many of these signaling proteins is that of redundancy with other proteins in the same family. For example, while the absence of the GTP exchange factors, Vav1 or Vav3, has a minimal effect on the response to GPVI, mice deficient in both factors show a dramatic inhibition in response.[50] A related example is that of mice deficient in the tyrosine kinase Btk that have a marked reduction in platelet aggregation, whereas in mice lacking the related Tec family kinase, namely, Tec itself, aggregation is normal. On the other hand, the combined absence of Btk and Tec leads to abrogation of aggregation to GPVI ligands, including collagen.[51] Platelets from patients with the immunodeficiency disorder, X-linked agammaglobulinemia, which is caused by mutations in Btk, also exhibit a reduced response to collagen, but do not have a bleeding diathesis, presumably because of the redundancy with Tec.

PLCγ2 generates the two second messengers, inositol 1,4,5-trisphosphate (IP^3) and 1,2-diacylglycerol (DG) that release intracellular Ca^{2+} and activate protein kinase C respectively. The activation of PI 3-kinases generates a third second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP_3). These three second messengers synergize to mediate the majority of the responses associated with platelet activation including secretion, aggregation, procoagulant activity, and actin polymerization. Activation of platelets through GPVI undergoes a marked synergy with the platelet $P2Y_{12}$ receptor consistent with the feedback role of the Gi-coupled receptor in regulating activation.

Several other proteins play critical roles in GPVI signaling. In the absence of other agonists, the threshold for activation of the pathway is set by the membrane tyrosine phosphatase CD148.[52] Src family kinases are regulated through phosphorylation on stimulatory and inhibitory tyrosines. The phosphorylated inhibitory tyrosine residue (Tyr529 in Src and Tyr507 in Lyn) mediates intramolecular binding to the SH2 domain in Src kinases. Dephosphorylation of this residue is critical for activation of Src kinases and activation is further enhanced by phosphorylation of the stimulatory tyrosine. The tyrosine phosphatase CD148 is the major phosphatase that mediates dephosphorylation of Src kinases, thereby setting the threshold for platelet activation.

A second family of regulatory proteins belong to the immunoreceptor tyrosine-based inhibition motif (ITIM) family. This includes the immunoglobulin-gene family members PECAM-1 and G6b-B. In platelets, the ITIM in PECAM-1 is inducibly phosphorylated, while that in G6b is constitutively phosphorylated. Both proteins bind to the tandem SH2 domain-containing

tyrosine phosphatases, SHP-1 and SHP-2. It has been proposed that the recruitment of the two tyrosine phosphatases to PECAM-1 reduces signaling in platelets by GPVI and, to varying degrees, by other surface receptors, although the overall magnitude of this effect is small. By contrast, constitutively phosphorylated G6b-B has been proposed to play a critical role in inhibiting signals from GPVI and other platelet glycoprotein receptors in the absence of ligand engagement, thus preventing uncontrolled platelet activation.[53]

Platelet activation by GPVI is also regulated by other inhibitory proteins, including the SH2 domain-containing phosphatidylinositol 3,4,5-triphosphatase (SHIP), which removes the second messenger lipid PIP_3. It is noteworthy that signaling through GPVI is relatively insensitive to elevation of the cyclic nucleotides cAMP and cGMP, whereas they inhibit the action of the two G protein-coupled receptor feedback agonists, TxA_2 and ADP.

MODE OF ACTIVATION OF GPVI—DIMERIZATION

GPVI is expressed as a complex with the FcR γ chain that has a dual tyrosine phosphorylation site in its ITAM. The Src tyrosine kinases Lyn and Fyn are constitutively associated with GPVI. Thus, the clustering of GPVI by antibodies, snake toxins, or collagen induces colocalization of Lyn and Fyn with the FcR γ chain ITAM, allowing the ITAM to be phosphorylated.

Crystallographic studies using recombinant proteins indicated that GPVI has the potential dimerize, raising the possibility that this is required for formation of a collagen-binding site. This is supported by the observation that recombinant GPVI dimer can engage collagen under conditions where monomer cannot.[24] This suggests that dimerization or oligomerization of GPVI is an important event in platelet activation. At least some of the GPVI on resting platelets may be dimeric,[54,55] and an antibody against the GPVI dimer (GPVI-fc_2), m-Fab-F, has been developed that only recognizes the dimeric protein.[54] A model for the involvement of GPVI dimers in platelet activation is proposed in FIGURE 30.5: one GPVI molecule associates with the disulphide FcR γ chain as shown for other receptors in this class.[56] In this model, quiescent platelets have both GPVI dimers and monomers (upper left), which may exist in some type of equilibrium or with the number of dimers regulated. Upon vessel injury, the exposed endothelial collagen can bind to the pre-existing GPVI dimers, which may exist in small numbers but show high affinity for collagen. Upon collagen engagement, signaling is initiated and stabilization of dimers and/or

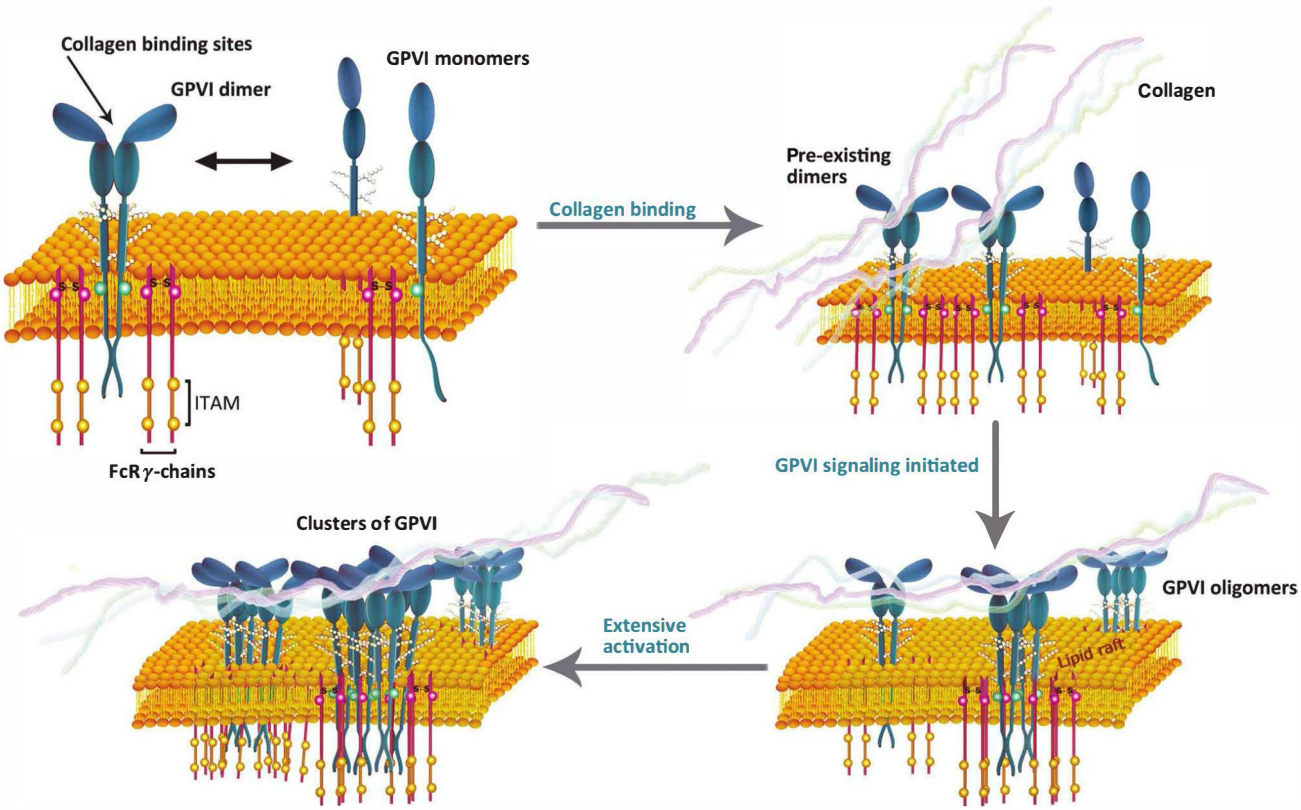

FIGURE 30.5 Mechanism of activation of GPVI by dimerization. **Upper left**: There is an equilibrium between the monomeric and dimeric forms of GPVI in resting platelets. A small amount of GPVI dimer is sufficient to bind to collagen, thus initiating the GPVI–signaling cascade (**upper right**). Collagen binding initiates signaling and stable dimers and/or oligomers of dimers form. This formation of stable dimers or oligomers of dimers may be mediated by translocation of GPVI molecules to lipid rafts and may involve reorganization of the cytoskeletal proteins (**lower right**). Activation results in further clustering of GPVI molecules, facilitating signaling reactions by juxtaposing the components of the GPVI signalosome at high local density (**lower left**).

oligomerization of dimers occurs (lower right). Because GPVI is present in lipid rafts in platelets,[57] newly formed GPVI oligomers would colocalize with the constitutive raft protein LAT, facilitating formation of the GPVI signalosome and platelet activation. Upon extensive activation, clusters of GPVI are formed, further increasing activation (lower left).

GPVI SHEDDING AND INTERNALIZATION

Programmed autologous cleavage of platelet receptors has emerged in recent years as an important mechanism for preventing the adhesive-signaling function of platelets, potentially acting to limit thrombus formation and thrombus stability (for review see[58]). Proteolytic activity can be mediated through metalloproteinase-induced removal of ligand-binding domains or by cleavage of cytoplasmic tails by intracellular proteases such as calpain. The former releases soluble ligand-binding domains, or ectodomains, and is a potential biomarker of platelet activation. Receptor shedding is mediated in platelets by two widely expressed members of the ADAM family of metalloproteinases, ADAM10 and ADAM17 (also termed TACE). These metalloproteinases are expressed on the cell surface in inactive forms but can be activated by a variety of stimuli including receptor activation.

GPVI is rapidly shed from the platelet surface *in vitro* following platelet activation by a variety of GPVI–specific ligands, including convulxin, collagen, and specific antibodies, releasing the 55 kDa ectodomain into the supernatant and retaining the 10 kDa membrane stalk. Shedding of GPVI can also be induced by activation of the low-affinity immune receptor, FcγRIIA, which also signals through an ITAM-dependent pathway, and by *N*-ethylmaleimide or mitochondrial damage (which activate ADAMs). By contrast, minimal shedding of GPVI is seen following stimulation by G protein–coupled receptor agonists.

GPVI shedding *in vitro* in response to GPVI ligation is mediated by ADAM10 and is believed to involve dissociation of calmodulin from a positively charged, amphipathic, juxtamembrane sequence in the cytoplasmic tail of the collagen receptor. Calmodulin dissociation can also be induced by W-7 in association with shedding of GPVI. By contrast, mitochondrial damage induces shedding of GPVI *in vitro* through ADAM17. Shedding of GPVI in response to GPVI ligands is not associated with loss of GPIbα, although shedding of the vWF receptor can be induced by W-7 through activation of ADAM17. Thus, the nature of the receptors that are shed and the protease responsible varies according to the mechanism of activation.

Bernard Nieswandt's group was the first to report that shedding, internalization, and transient thrombocytopenia can be induced *in vivo* in mice by antibodies to GPVI.[59] GPVI shedding can also be induced in human platelets that have been injected into a NOD/SCID mouse and treated with antihuman GPVI antibodies. Remarkably, shedding of GPVI *in vivo* in response to antibody challenge is independent of ADAM10 and ADAM17 and appears to be regulated by the intracellular level of cAMP.[60]

$\alpha_2\beta_1$ SIGNALING

There are approximately 1,500 to 2,500 copies of $\alpha_2\beta_1$ on platelets. In contrast, there are approximately 80,000 copies of the major platelet integrin $\alpha_{IIb}\beta_3$ on the resting platelet surface and another 40,000 copies on the δ-granule membrane that become exposed following platelet secretion. Integrin $\alpha_{IIb}\beta_3$ was the first glycoprotein receptor shown to stimulate tyrosine phosphorylation in platelets and has served as a major model for our understanding of integrin signaling in platelets and in many other cell types. It has also served as a model for our understanding of other platelet integrins, including integrin $\alpha_2\beta_1$ (for review see[61]).

$\alpha_{IIb}\beta_3$ signals through sequential activation of Src family kinases, notably Src and Fyn, and Syk kinase, independent of an ITAM. In turn, Syk initiates a downstream signaling cascade that culminates in activation of PLCγ2. Many of the proteins in this cascade are similar to those used by GPVI, including the adapter protein SLP-76, Vav and Tec family kinases, and PI 3-kinase α and β isoforms. On the other hand, the $\alpha_{IIb}\beta_3$ signaling cascade is independent of LAT as the integrin is excluded from lipid rafts where LAT is localized. The absence of an ITAM and a role for LAT in $\alpha_{IIb}\beta_3$ signaling may explain why it induces a much weaker signal than that of GPVI, despite having at least a 10-time higher level of expression.

$\alpha_2\beta_1$ generates a weak intracellular signal through Src and Syk family kinases and PLCγ2,[62] with the key events being similar to those of $\alpha_{IIb}\beta_3$. Relatively few studies have focused on $\alpha_2\beta_1$ signaling because of the powerful response initiated by GPVI relative to that of $\alpha_2\beta_1$-specific ligands, including antibodies and $\alpha_2\beta_1$-specific peptides. For example, mouse platelets only undergo partial spreading on an $\alpha_2\beta_1$-specific peptide, but undergo full spreading on immobilized CRP or in the presence of a G protein–coupled receptor agonist such as thrombin. Similarly, $\alpha_2\beta_1$-specific peptides do not induce aggregation even in the presence of threshold concentrations of G protein–coupled receptor agonists that induce integrin activation. Accordingly, signaling through integrin $\alpha_2\beta_1$ induces weak platelet activation.

It is unclear whether the weak signal from integrin $\alpha_2\beta_1$ is of functional relevance given the much more powerful signal elicited by GPVI. Its role may be restricted to supporting platelet adhesion and collagen binding to GPVI, thereby indirectly potentiating platelet activation as outlined above. The full significance of integrin $\alpha_2\beta_1$ signaling in hemostasis however is unclear because of the similarity in its signaling pathway to those of GPIb-IX-V and GPVI.

OUTSIDE-IN AND INSIDE-OUT SIGNALING THROUGH INTEGRIN $\alpha_2\beta_1$

The binding of collagen to $\alpha_2\beta_1$ and the conformational changes that mediate inside-out and outside-in signaling are now understood in some detail.[63] The α subunit MIDAS binds the glutamate of collagen GxOGER motifs described below. At its base, the α subunit I domain contacts and obscures the β subunit MIDAS, preventing direct ligand-binding activity of the β subunit.[2] Helix α_7 within the I domain moves up and down to regulate the binding affinity of the integrin for collagen, and the lower end of this helix contains a glutamate residue that engages the β subunit I domain. Thus, there is co-ordinated ligation of both integrin subunits by collagen, first, directly through the α subunit MIDAS, and then through the β subunit MIDAS by the Helix α_7 glutamate residue.[5,64] This molecular machinery is believed to mediate inside-out signaling, where cytoplasmic signals regulate the binding of species such as talin and kindlin to the β subunit tail.[65] This is proposed to separate the integrin

subunit stems, causing conformational change that culminates in the β subunit MIDAS pulling down on Helix α_7, opening up the α subunit MIDAS to allow collagen binding.[63] The binding of collagen then mediates outside-in signaling, with conformational changes upon ligation being transmitted through the β subunit stem to the cytoplasm.

The model integrin-binding motif within collagen is GxOGER. The highest-affinity motif found to date, occurring in the vessel wall collagens I and IV, is GFOGER.[32] Its phenylalanine residue binds snugly into a hydrophobic pocket on the α_2 I domain,[63] and GFOGER binds well to resting platelets, a capacity that does not increase upon platelet activation.[31] Other less-favorable sequences with hydrophobic residues in the x position occur elsewhere in collagen I and in collagen III.[31,41] For such sequences, there is a marked increase in binding upon platelet activation.

Thus, we envisage a situation where initial platelet binding to collagen, subsequent under high shear conditions to interaction of immobilized vWF with platelet GPIb/V/IX, will occur preferentially through high-affinity interaction with GFOGER, but after activation by collagen interaction with GPVI, other lower-affinity sequences become more important. Thus, an activated platelet will find a greater number of integrin binding sites within collagen, and so the tightness of the interaction will increase, facilitating weaker interactions with GPVI.

CONCLUDING REMARKS

Collagen is the most thrombogenic component in the vessel wall matrix and induces platelet adhesion through integrin $\alpha_2\beta_1$ and platelet activation through GPVI. The two receptors interact synergistically, with signals from GPVI activating the integrin and adhesion to the integrin increasing the binding of collagen to GPVI. Both receptors also work in combination with other platelet receptors to rapidly induce powerful platelet activation at sites of damage to the vasculature. Significantly, neither receptor appears to be essential for platelet regulation, as mice deficient in either GPVI or the integrin subunit α_2 present with mild defects in hemostasis and the two known patients with GPVI deficiency have a mild bleeding diathesis. There are no patients who are known to lack integrin $\alpha_2\beta_1$. These observations should not be taken as evidence against a significant physiologic role for the two collagen receptors in hemostasis as both almost certainly play vital roles in helping to prevent life-threatening bleeds following severe injury.

There has been considerable speculation as to whether GPVI and integrin $\alpha_2\beta_1$ are clinically relevant targets for development of novel antiplatelet agents that will have only minor effects on bleeding. Arterial thrombosis is frequently associated with rupture of atherosclerotic plaques in the vessel wall that leads to exposure of fibrillar collagen and powerful platelet activation. Several studies have shown effective platelet inhibition by targeting of GPVI in mouse thrombosis models using either a specific antibody to deplete GPVI from the platelet surface or recombinant dimeric GPVI to prevent binding of platelets to collagen. Antibody-induced depletion of GPVI, as pioneered by the Nieswandt group, is a particularly attractive form of prophylaxis as a single injection induces a sustained loss of the surface glycoprotein receptor with only a transient drop in platelet count.

It is becoming increasingly clear that platelets play additional roles beyond their established role in hemostasis including development of the lymphatic system and in angiogenesis. Collagen has a ubiquitous distribution in the body and platelets constantly come into contact with collagen at sites of damage to the vasculature and possibly via migration of platelet-leucocyte aggregates through the vessel wall. As we begin to learn more about the role of platelets beyond hemostasis in both health (e.g., lymphatic development[47]) and in disease (tumour metastasis[66] and rheumatoid arthritis[67]), it seems inevitable that we will identify new and further exciting roles for the interaction of collagens with platelet GPVI and integrin $\alpha_2\beta_1$.

CHAPTER

31 Integrin $\alpha_{IIb}\beta_3$ and Platelet Aggregation

ANA KASIRER-FRIEDE, KAMILA BLEDZKA, JUN QIN, EDWARD F. PLOW, AND SANFORD J. SHATTIL

PERSPECTIVE

In 1977, Phillips and Agin[1] provided important insight into the hemostatic function of platelets by demonstrating that two major glycoproteins, subsequently named IIb (GP IIb) and β_3 (GP IIIa), were missing from platelets of patients with Glanzmann thrombasthenia, a rare inherited bleeding disorder characterized by the absence of platelet aggregation. Earlier, Nurden and Caen[2] had observed an abnormal gel pattern of membrane proteins of thrombasthenic platelets. Subsequently, it was found that α_{IIb} and β_3 are subunits of a noncovalent complex, $\alpha_{IIb}\beta_3$.[3,4] A second inherited disorder, afibrinogenemia, provided additional insight into the mechanisms of platelet aggregation. Platelets from patients with afibrinogenemia[5] or washed normal platelets suspended in defibrinated plasma[6] fail to aggregate; readdition of fibrinogen to the samples restored their aggregation response. In the late 1970s and 1980s, the connection between these observations was established when fibrinogen was found to associate with ADP-stimulated platelets,[7] bind specifically to $\alpha_{IIb}\beta_3$,[8–10] and mediate platelet aggregation.[10,11] In the mid-1980s, another series of observations impacted on our understanding of the biology of $\alpha_{IIb}\beta_3$ when it was discovered that $\alpha_{IIb}\beta_3$ is a member of a widely distributed family of structurally, immunologically, and functionally related adhesion receptors,[12,13,14] the integrins, so called because they *integrated* their extracellular ligands with the intracellular cytoskeleton.[15] Thus, discoveries from studies of one integrin apply broadly to other family members.

These seminal observations have provided the underpinnings for investigations in many laboratories into the structure of $\alpha_{IIb}\beta_3$ and its function in platelet adhesion, aggregation, and hemostasis. Molecular details of how fibrinogen and other ligands interact with $\alpha_{IIb}\beta_3$ to effect platelet aggregation and adhesion have been defined. This work ultimately led to the development of parenteral $\alpha_{IIb}\beta_3$ antagonists for use in the prevention and treatment of arterial thrombosis in specific clinical settings.[16] More recently, it has become apparent that integrins, including $\alpha_{IIb}\beta_3$, function not only as adhesion receptors but also as conduits for *inside-out* signals to regulate ligand binding to their extracellular domains and *outside-in* signals to regulate anchorage-dependent cellular responses, which in platelets include full aggregation and granule secretion as well as clot retraction. This chapter focuses on $\alpha_{IIb}\beta_3$ and its role in platelet aggregation and signaling.

EXPRESSION AND BIOSYNTHESIS OF $\alpha_{IIb}\beta_3$

$\alpha_{IIb}\beta_3$ synthesis is restricted primarily to megakaryocytes and consequently protein expression is limited to these cells and to platelets. However, α_{IIb} expression has also been detected on early hematopoietic progenitors and on mast cells where in the latter it plays a role in adhesion and in the response of these cells to chronic inflammation.[17,18] Restricted $\alpha_{IIb}\beta_3$ expression is imposed by the α_{IIb}-subunit because its promoter limits the expression to these hematopoietic cells.[19,20] This is not the case for β_3 since the integrin $\alpha_V\beta_3$ is expressed by many cell types, including platelets, endothelial cells, and smooth muscle cells. The genes for α_{IIb} and β_3 reside in close physical proximity on chromosome 17.[21] α_{IIb} and β_3 must associate in a 1:1 noncovalent complex for efficient cell-surface expression,[22] and naturally occurring mutations that alter the biosynthesis of one subunit affect surface expression of the other (e.g.,[23–25]). The association of nascent α_{IIb} and β_3 occurs in the endoplasmic reticulum.[24,26] Although α_{IIb} is synthesized as a single polypeptide chain, it is proteolytically cleaved into heavy and light chains by a furin-like enzyme in the Golgi complex. However, proteolytic cleavage is not required for $\alpha_{IIb}\beta_3$ expression on the cell surface nor is it required for $\alpha_{IIb}\beta_3$ function.[27] $\alpha_{IIb}\beta_3$ is the most abundant cell-surface glycoprotein on platelets, present at approximately 80,000 copies per cell.[28,29] In addition, an intracellular pool of $\alpha_{IIb}\beta_3$ is present in the membranes of α-granules and can become surface expressed upon granule secretion, increasing the number of functional $\alpha_{IIb}\beta_3$ receptors by approximately 30% to 50%.[28,30,31] Rapid shuttling of $\alpha_{IIb}\beta_3$ between the cell surface and intracellular pools has been observed[32] and may be involved in the import of fibrinogen into platelet α-granules.[33]

STRUCTURE OF $\alpha_{IIb}\beta_3$

α_{IIb} and β_3 consist of 1,008 and 762 amino acids, respectively.[34,35] The extracellular domains of both subunits are glycosylated.[36] As assessed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis under nonreducing conditions, the apparent molecular weights of the α_{IIb}- and β_3-subunits are approximately 130 kDa and 95 kDa, respectively.[22] Upon reduction, the α_{IIb}-subunit separates into heavy and light chains with molecular weights of 115 and 25 kDa, respectively. The α_{IIb} light chain contains a 20–amino acid cytoplasmic tail (CT), a transmembrane (TM) region, and an extracellular segment that is disulfide linked to the heavy chain. The β_3-subunit is a single polypeptide chain and contains 56 cysteine residues that form an extensive array of intrachain disulfide bonds.[4] A schematic model depicting the domain organization of $\alpha_{IIb}\beta_3$ is shown in FIGURE 31.1. There are 16 domains in $\alpha_{IIb}\beta_3$: 6 in α_{IIb} and 10 in β_3, including their TM and CT domains.

Structure of α_{IIb}

The *N*-terminus of α_{IIb} consists of seven approximately 60–amino acid repeats that fold to form a seven-bladed β-propeller. At the base of the β-propeller are four divalent cation-binding

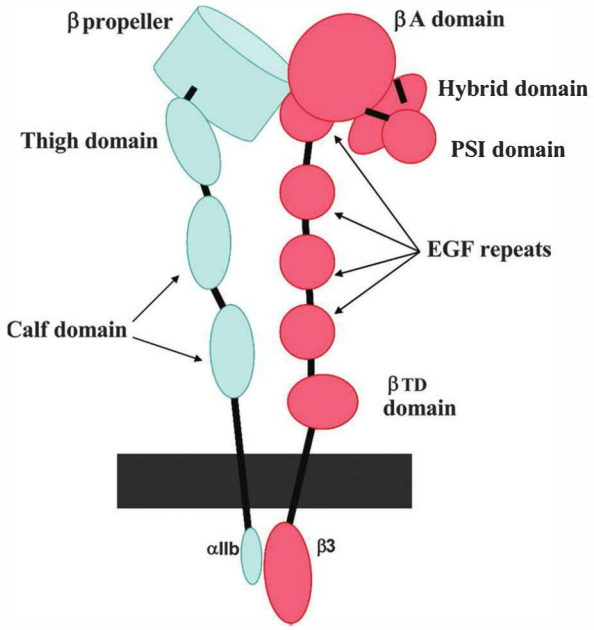

FIGURE 31.1 Schematic model showing the organization and structural domains of $\alpha_{IIb}\beta_3$. The α-subunit is in blue and the β-subunit is in red. PSI, plexin–semaphorin–integrin; EGF, epidermal growth factor, β-TD.

motifs in which oxygenated residues within short hairpin loops coordinate divalent cations. The remainder of the α_{IIb} extracellular region consists of a "thigh" and two "calf" domains. Between the thigh and the first calf domain is a "genu," a flexible segment that allows the molecule to bend and compact. The α_{IIb} TM domain is primarily helical.[37,38] Two available nuclear magnetic resonance (NMR) structures of the TM domain differ in the vicinity of the inner-membrane leaflet[37,38]: one indicates that the helix is followed by an inverse turn, the other indicates a continuous helix. These differences will be important to resolve since several regulators of $\alpha_{IIb}\beta_3$ function are purported to bind to this region of α_{IIb}.[39] Similarly, there are at least two different NMR structures for the α_{IIb} CT. In one structure, the membrane proximal region of the CT is composed of a short helix which terminates in a turn midway in the α_{IIb} CT and an acidic *C*-terminus.[40,41] A cation-binding site is present in this acidic *C*-terminal region, and occupancy of this site stabilizes the folding of the α_{IIb} CT.[40,42] In a second structure, the region following the membrane proximal helix is intrinsically disordered, consistent with a lack of hydrophobic residues to facilitate folding.[43]

Structure of β_3

The *N*-terminus of β_3 consists of two tandem nested domains. The first is the βA-domain whose fold is homologous to the I-domains present in the α-subunits of β_2-containing integrins, as well as the α-subunits α_1, α_2, α_{10}, α_{11}, and α_E (see FIGURE 31.1).[44] The βA-domain is inserted in the "hybrid" domain whose fold is similar to I-set Ig domain. The hybrid domain is itself inserted in the PSI (*p*lexin–*s*emaphorin–*i*ntegrin) domain that contains the *N*-terminus of β_3. The *C*-terminus of the PSI domain is contiguous with a protease-resistant region composed of a series of disulfide repeats arranged into four EGF-like domains. The final structural motif in the β_3 ectodomain is the βTD which extends to the outer leaflet of the plasma membrane.

The β_3A-domain contains three divalent cation-binding sites: a metal ion–dependent adhesion site (MIDAS) motif that is involved in ligand binding, a site adjacent to MIDAS termed ADMIDAS that when occupied by Ca^{2+} inhibits ligand binding, and a ligand-induced metal-binding site, also known as the synergistic metal ion–binding site or SyMBS.[45] The β_3A-domain is folded into an α-β-α sandwich in which six central β-sheets are surrounded by seven α-helices. A loop on its upper surface termed the "specificity-determining loop" or SDL, in conjunction with a "cap" composed of four loops on the upper surface of α_{IIb} β-propeller, forms a surface for ligand binding. The *C*-terminus of the PSI domain is contiguous with a protease-resistant region composed of a series of disulfide repeats arranged into four EGF-like domains. The final structural motif in the β_3 ectodomain is the βTD which extends to the outer leaflet of the plasma membrane.

The β_3 TM domain is a typical α-helix that extends into the CT. The helix is followed by a loop containing a kink,[38,46,47] a turn, and then by another short helix.[46] Noteworthy features of the β_3 CT are two NXXY motifs, NPLY747 and NITY759. In general, NXXY motifs bind proteins containing phosphotyrosine binding (PTB) domains and this is also true of the two motifs in $\alpha_{IIb}\beta_3$.[48,49] The interaction of these NXXY motifs with the PTB domains of binding partners has been implicated in regulating $\alpha_{IIb}\beta_3$ activation. The significance of the distal helix is demonstrated by the effects of the naturally occurring S752P mutation invariant Glanzmann thrombasthenia which disrupts the *C*-terminal helix, prevents binding of the kindlin-3 FERM domain to the β_3 CT, and impairs $\alpha_{IIb}\beta_3$ activation.[50,51]

Interdomain and Intersubunit Interactions of $\alpha_{IIb}\beta_3$

Each of the major regions of α_{IIb} and β_3, that is, the ectodomains, the TM helices, and the CTs, interact with each other to establish an inactive heterodimeric structure. While there are no disulfide bonds between the integrin α- and β-subunits, intra- and interdomain disulfide bonds play a significant role in maintaining the overall conformation of the integrin.[45,52,53]

The binding sites for fibrinogen and other adhesive ligands are located within a globular head formed by the interaction of the β-propeller in α_{IIb} with the β_3 A-domain.[54] Chemical cross-linking,[55,56] synthetic peptides,[57–59] and site-directed antibodies[60] have identified specific sequences as ligand-binding sites within $\alpha_{IIb}\beta_3$. Recent crystal structures of the $\alpha_V\beta_3$[53,61] and the $\alpha_{IIb}\beta_3$ extracellular domains complexed with peptides and small-molecule ligands[54] have further refined the location of the binding sites. Thus, fibrinogen binds at the interface between the α_{IIb} β-propeller and the β_3A-domain with β_3 contacts that include not only the MIDAS, but also a water-mediated interaction with the ADMIDAS, and with α_{IIb} contacts in a groove between loops that connect the 2nd and 3rd and 3rd and 4th blades of the propeller. It is noteworthy that some of the drugs that inhibit ligand binding to $\alpha_{IIb}\beta_3$ do so through allosteric mechanisms, that is, they change the conformation of the receptor, rather than binding directly at the site that engages macromolecular ligands.[54]

Two smaller discontinuous interactions between α- and β-subunits in the stalk and between the head and the stalk further stabilize the heterodimeric structure of the inactive ectodomain.[54,62] The α- and β-subunit TM helices also interact with each

other through multiple residues and cross at a 25- to 30-degree angle.[37,38] The membrane-proximal portions of CTs of the two subunits also interact weakly through electrostatic and hydrophobic bonds.[41,50] On the basis of mutagenesis experiments, it has been proposed that a salt bridge formed between α_{IIb} residue R995 and β_3 residue D723 is critical for maintaining $\alpha_{IIb}\beta_3$ in an inactive state,[63] but a structure of sufficiently high resolution to directly visual the salt bridge is lacking. Nonetheless, based on mutational analyses,[37,38] it is clear that changes in the interactions between the α_{IIb} and β_3 TM and CT domains regulate the ability of $\alpha_{IIb}\beta_3$ to bind extracellular matrix ligands.

PLATELET AGGREGATION IS MEDIATED BY $\alpha_{IIb}\beta_3$

The primary function of $\alpha_{IIb}\beta_3$ is to serve as a receptor for macromolecular ligands[22,64] including fibrinogen, fibrin, von Willebrand factor (vWF), fibronectin, vitronectin, and thrombospondin (reviewed in [65]). All of these ligands are constituents of extracellular matrices where their interactions with $\alpha_{IIb}\beta_3$ can support platelet adhesion under a variety of conditions.[66–68] Each ligand can also interact with at least one additional receptor on platelets. For example, fibrinogen can bind to $\alpha_V\beta_3$,[69] and $\alpha_5\beta_1$,[70] vWF to GPIb/IX/V,[71] fibronectin to $\alpha_5\beta_1$,[72] vitronectin to $\alpha_V\beta_3$,[73] and thrombospondin to GPIV (CD36).[74,75] Platelet aggregation requires engagement of $\alpha_{IIb}\beta_3$ by soluble fibrinogen[8,10,11] and/or vWF.[68] At high shear rates, such as those attained in stenosed arteries, vWF binding to $\alpha_{IIb}\beta_3$ is necessary for productive platelet aggregation.[68,76–78]

Ligand Recognition Specificity of $\alpha_{IIb}\beta_3$

Fibrinogen binding to activated $\alpha_{IIb}\beta_3$ is divalent cation dependent, rapid, and initially reversible, with a dissociation constant (K_d) of approximately 300 nM.[9,79,80,108] Stabilization then occurs, and the bound fibrinogen becomes essentially nondissociable.[9,79,80,81–83] This transition stabilizes platelet aggregates and presumably depends upon the formation of additional contacts between fibrinogen and $\alpha_{IIb}\beta_3$.[81,84] Stabilization may be promoted by multiple factors, including ligand-induced structural changes in the receptor,[82,85] receptor clustering, cytoskeletal reinforcements,[86] fibrinogen self-association, association of fibrinogen with other adhesive proteins, such as thrombospondin,[87,88] and receptor internalization.[89] Although the dimeric structure of fibrinogen and the multimeric structure of vWF may permit these ligands to bridge between receptors on adjacent platelets and thereby mediate aggregation,[90] such cross-bridging may not be the only mechanism that determines the size of platelet aggregates.[91,92] Postreceptor occupancy events occur upon binding of fibrinogen to $\alpha_{IIb}\beta_3$,[93] and are important for maximal aggregation. One direct manifestation of receptor occupancy is the induction of ligand-induced binding sites, which serve as epitopes for monoclonal antibodies that react with the occupied, but not with the resting or the activated but unoccupied conformers of $\alpha_{IIb}\beta_3$.[94–96] Occupancy of $\alpha_{IIb}\beta_3$ also leads to a series of intracellular responses, referred to as *outside-in signaling* (see section on Regulation of Platelet Function by $\alpha_{IIb}\beta_3$).[97,98,99]

Two synthetic peptides of four to six amino acids define the recognition specificity of fibrinogen for $\alpha_{IIb}\beta_3$.[100] The first of these peptides corresponds to the extreme *C*-terminus of the fibrinogen γ chain.[101] The *C*-terminal six amino acids of the γ chain are KQAGDV, and peptides corresponding to this sequence, or variants thereof, collectively referred to as the γ chain peptides, interact with $\alpha_{IIb}\beta_3$.[102] This sequence is present in fibrinogen but not in other $\alpha_{IIb}\beta_3$ ligands. Nevertheless, the γ chain peptide does inhibit the binding of other adhesive proteins to $\alpha_{IIb}\beta_3$.[91,103] A naturally occurring minor fibrinogen variant (the γ' variant) that results from alternative splicing of the γ chain mRNA alters the *C*-terminal sequence of the γ chain and neither binds to $\alpha_{IIb}\beta_3$ nor supports platelet aggregation.[104,105] Further, mutational studies conducted *in vitro*[106] and *in vivo*[107] confirm that the native γ chain sequence is essential for the productive interaction of fibrinogen with $\alpha_{IIb}\beta_3$.

The second peptide, referred to as the RGD peptide, has Arg-Gly-Asp-X (where X includes most amino acids) as its minimal sequence. Two RGD sequences are present in the Aα chain of human fibrinogen, and RGD-containing peptides inhibit fibrinogen binding to $\alpha_{IIb}\beta_3$ and platelet aggregation.[108,109] Indeed, several of the $\alpha_{IIb}\beta_3$ therapeutic antagonists were designed from the RGD sequence.[16,110] However, mutation of either RGD motif in the fibrinogen α chain does not alter fibrinogen recognition by the receptor.[106] However, the RGD motifs that are present in several other $\alpha_{IIb}\beta_3$ ligands mediate their interaction with $\alpha_{IIb}\beta_3$. The RGD motifs that are present in vWF[111] and vitronectin[112] are required to enable these proteins to interact with $\alpha_{IIb}\beta_3$. Fibronectin contains an RGD sequence as well as several alternative sequences that interact with $\alpha_{IIb}\beta_3$.[113,114] RGD functions as a major recognition sequence for several other integrins, including $\alpha_V\beta_3$.[115] Secondary roles for the RGD or other sequences in stabilizing $\alpha_{IIb}\beta_3$ interactions with its ligands have not been excluded. Roles for still other sequences, unrelated to the RGD and γ chain peptides, in the $\alpha_{IIb}\beta_3$-dependent retraction of fibrin clots by platelets have also been demonstrated.[116,117]

In contrast to $\alpha_{IIb}\beta_3$, there are only a few hundred molecules of $\alpha_V\beta_3$ per platelet,[118] and its physiologic significance is unclear. $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$ share the same β-subunit, and their α-subunits are approximately 40% identical. Glanzmann thrombasthenia can arise from mutations in either the α_{IIb} or β_3 genes. Thus, β_3 mutations produce $\alpha_V\beta_3$ as well as $\alpha_{IIb}\beta_3$ deficiency.[23] However, phenotypic differences have not been reported between individuals lacking one or both β_3 integrins. $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$ bind many of the same ligands, including the two ligands that can mediate platelet aggregation, fibrinogen, and vWF,[119] but ligands that bind to one receptor and not the other have also been identified; for example, osteopontin[120] and adenovirus penton base[121] bind to $\alpha_V\beta_3$ but not to $\alpha_{IIb}\beta_3$, whereas the snake venom barbourin binds to $\alpha_{IIb}\beta_3$ but not to $\alpha_V\beta_3$.[122] This pattern is recapitulated at the level of the fine recognition specificities of the two integrins; RGD peptides bind with much higher affinity to $\alpha_V\beta_3$ than to $\alpha_{IIb}\beta_3$, and γ chain peptides bind with much higher affinity to $\alpha_{IIb}\beta_3$ than to $\alpha_V\beta_3$.[123] Like $\alpha_{IIb}\beta_3$, $\alpha_V\beta_3$ can undergo activation,[124–126] even in platelets.[127] The breadth of functions ascribed to $\alpha_V\beta_3$ in cells other than platelets, including endothelial cells, has stimulated the development of specific $\alpha_V\beta_3$ antagonists, primarily for use as antiangiogenic drugs which would be useful in inhibiting tumor growth and metastasis,[128] as well as for other diseases in which angiogenesis plays a prominent role.

$\alpha_{IIb}\beta_3$ Antagonists

Platelet adhesion is mediated by many receptors and platelet aggregation can be induced by many agonists, but aggregation itself is absolutely dependent upon $\alpha_{IIb}\beta_3$. This funneling of function onto $\alpha_{IIb}\beta_3$ provided a firm rationale for blockade

of its ligand-binding activity as an antithrombotic strategy and stimulated an intensive effort to develop specific and potent $\alpha_{IIb}\beta_3$ antagonists throughout the 1990s. In some respects, this effort was successful, but the hope that these drugs would provide both short-term and long-term protection against cardiovascular disease proved to be overly optimistic.[129] Three $\alpha_{IIb}\beta_3$ antagonists, abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat), were approved by the US Food and Drug Administration as intravenously administered antithrombotics for specific indications. These drugs continue to be utilized to prevent acute coronary events in association with percutaneous coronary interventions (PCIs).[130] Abciximab, the first $\alpha_{IIb}\beta_3$ antagonist approved for human use, is an Fab fragment of a humanized mouse monoclonal antibody to $\alpha_{IIb}\beta_3$.[110,131,132] Abciximab also reacts with $\alpha_V\beta_3$ and $\alpha_M\beta_2$, and some of the positive effects of the drug may be attributable to this cross-reactivity.[133] Integrilin contains a K(Lys)GD within a structure rigidified within a disulfide loop.[122] The RGD peptide was the starting point for tirofiban, but ultimately peptide bonds were designed out of its structure.[134] Following on the early successes of these drugs in the setting of PCI, it was anticipated that they would also be efficacious in reducing acute coronary syndromes in general. However, clinical trials demonstrated only modest or no benefits, and ultimately they did not measure up well against other platelet antagonists, such as clopidogrel, in terms of cost and efficacy. Despite the anticipation that orally active $\alpha_{IIb}\beta_3$ antagonists would provide a long-term benefit to reduce the risk of thrombotic events,[135] in clinical trials, these drugs were found at best to have little clinical benefit and, at worst, to be detrimental.[136] As a result, the development of oral $\alpha_{IIb}\beta_3$ antagonists was abandoned. Thus, although the principle that $\alpha_{IIb}\beta_3$ blockade should prevent thrombus formation is mechanistically sound, the therapeutic window is narrow, meaning that underdosing would be ineffective and overdosing could cause bleeding. At this juncture, parenteral $\alpha_{IIb}\beta_3$ antagonists are only used for limited indications.[129] The development of inhibitors that directly target $\alpha_{IIb}\beta_3$ continues to be explored. Antagonists that block ligand binding without engaging the β_3 MIDAS metal ion or disrupt interactions of the β_3 CT with its activating binding partners may be the targets of future antithrombotic drugs.[98,137]

REGULATION OF $\alpha_{IIb}\beta_3$ ACTIVATION (INSIDE-OUT SIGNALING)

Key to the ability of $\alpha_{IIb}\beta_3$ to bind fibrinogen and vWF and support platelet aggregation is its ability to undergo a transformation from a *resting* low-affinity state to an *activated* high-affinity state as depicted in FIGURE 31.2. The overall shape of $\alpha_{IIb}\beta_3$ depicted in this figure is based on cryogenic electron micrographic images of the isolated receptor,[138] crystal structures of the homologous $\alpha_V\beta_3$ extracellular domain (Protein Data Bank: 1JV2, 1M1X)[53,61] and the $\alpha_{IIb}\beta_3$ extracellular domain (Protein Data Bank 3FCS),[45] as well as NMR analyses of the TM and CT (Protein Data Bank 1M8O)[41,46] (Protein Data Bank 2K9J).[37,38,139] In this model, the globular head of resting, unactivated $\alpha_{IIb}\beta_3$ rests on two stalks. By bending at the genu of the α_{IIb} and β_3 ectodomains, the head approaches the cell membrane[140,141] (see FIGURE 31.2). When $\alpha_{IIb}\beta_3$ is activated, its height increases as its legs separate and straighten.[142] In association with leg separation, one of the helices in the β_3A-domain and the hybrid domain swings away to render the ligand-binding site formed between the β-propeller in the α_{IIb}-subunit and the β_3A-domain accessible to macromolecular ligands.[142–144] While these

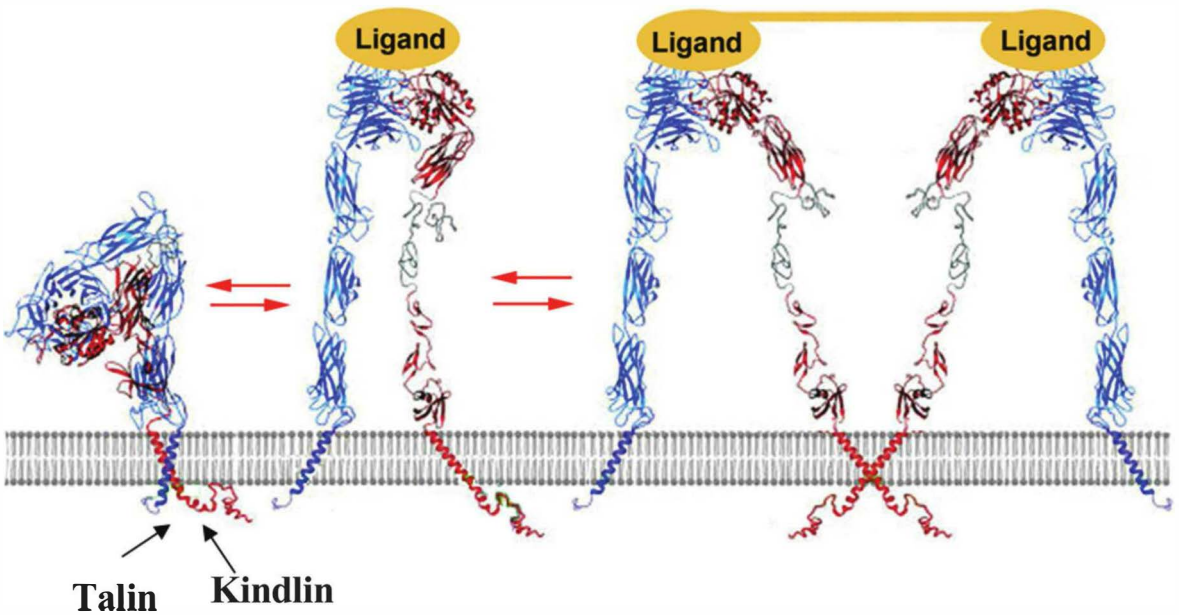

FIGURE 31.2 Model of a pathway for activation of $\alpha_{IIb}\beta_3$. Talin and kindlin binding to the CT of the β_3-subunit can lead to unclasping of integrin subunit tails and a membrane-associated structural change of the cytoplasmic face. This change may entail a transition from a bent conformation in its resting state to an extended conformation in which it becomes competent to bind soluble ligands. The α-subunit is in blue and the β-subunit is in red. (Reproduced from Qin J, Vinogradova O, Plow EF. Integrin bidirectional signaling: a molecular view. *PLoS Biol* 2004;2:e169, with permission.)

changes reflect the behavior of the ectodomains of the majority of $\alpha_{IIb}\beta_3$ molecules on the platelet surface during activation, it appears that some $\alpha_{IIb}\beta_3$ molecules are capable of binding ligands while still in a bent or partially unfolded conformation,[145] implying that extension of the ectodomain may also occur as a postactivation event.[146] The inside-out signals that induce these activation events may also promote clustering of $\alpha_{IIb}\beta_3$ heterodimers into heterooligomers[147]; clustering would be expected to increase $\alpha_{IIb}\beta_3$ avidity or valency.[148] However, conformational change and affinity modulation appear to be the dominant mechanism by which the ligand-binding activity of $\alpha_{IIb}\beta_3$ (and $\alpha_V\beta_3$) is regulated.[125,149]

Substantial progress has been made in understanding how integrin activation and the consequent movements of the ectodomain are triggered. In platelets, agonist signaling (inside-out signaling) eventuates in protein binding to and alterations in the interactions of the resting $\alpha_{IIb}\beta_3$ CT domain complex. A PTB domain located in the 270 kDa cytoskeletal protein talin binds to the β_3 CT domain and disrupts the hydrophobic and electrostatic bonds that maintain it in complex with the α_{IIb} CT domain. In turn, dissociation of this CT clasp affects insertion of the β_3 CT domain into the platelet plasma membrane and disrupts the association between the α_{IIb} and β_3 TM helices. Disengagement of the TM helices then provides the force needed to trigger the activating events in the $\alpha_{IIb}\beta_3$ ectodomain.[37,38,41,139,140,150–152] Once the CT and TM domains have dissociated, the propensity of the subunits to homooligomerize may also increase to influence the activation process.[147] With the ready availability of $\alpha_{IIb}\beta_3$ ligands in plasma, tight control of $\alpha_{IIb}\beta_3$ activation is essential. This regulation is achieved through the binding of cytosolic proteins to the α- and β-subunit CT domains. For integrin β CT, approximately 40 binding partners have been identified.[153] Among these, talin, filamin, kindlin, and integrin-linked kinase (ILK) are known to influence $\alpha_{IIb}\beta_3$ activation. Exactly how each does so remains unclear in many cases. Some of the proteins appear to induce or enhance integrin activation while others act as negative regulators.[37,154,155,156]

Proximal Regulation of $\alpha_{IIb}\beta_3$ Activation

A schematic identifying some of the intermediates in $\alpha_{IIb}\beta_3$ activation is shown in FIGURE 31.3. Talin binds directly to the CT of $\alpha_{IIb}\beta_3$ and is essential for integrin activation.[157] Talin is composed of an approximately 50 kDa head domain (talin-H) and a approximately 220 kDa rod domain (talin-R). The talin-H resembles a FERM (4.1 ezrin radixin moesin) domain and contains F1-, F2-, and F3-PTB subdomains.[158] In the resting platelet, talin exists in an autoinhibited conformation in which the talin-H interacts with talin-R.[159,160] The β_3 CT-binding site in talin-H can be exposed by calpain cleavage,[161] RIAM (Rap 1 interacting adaptor molecule) association,[162] or phosphoinositide binding.[163] Once unfolded, talin can interact with the $\alpha_{IIb}\beta_3$ CT.[155,164] The talin-H binds to two sites in the β_3 CT: the membrane-proximal NPLY747 motif with high affinity[165] and a membrane proximal region near the plasma membrane[41,166] with lower affinity. It is the second interaction that disrupts the clasp between the β_3 CT and the α_{IIb} CT, triggering the activation process. Talin-R also contains an integrin-binding site.[167]

Although it is clear that talin is necessary, and in model cell systems sufficient, to induce at least partial integrin activation,[155,168,169] in mice[170,171] and humans,[172,173] at least one additional molecule is essential for robust integrin activation. In platelets and other hematopoietic cells, this molecule is kindlin-3, and in other cells, the other two kindlin family members, kindlin-1 and kindlin-2, cooperate with talin to fulfill this *coactivator* role.[174,175,176,177,178] The coactivator role was originally demonstrated for kindlin-2, where the combination of kindlin-2 with talin-H–induced robust activation of integrins compared to talin-H alone.[168,179] The three mammalian kindlins have molecular weights of approximately 75 kDa. Like talin-H, kindlins also have a FERM domain. In kindlins, the F2 subdomain is interrupted by a pleckstrin homology (PH) domain. Four kindlin-binding partners have been identified: ILK,[179–181]

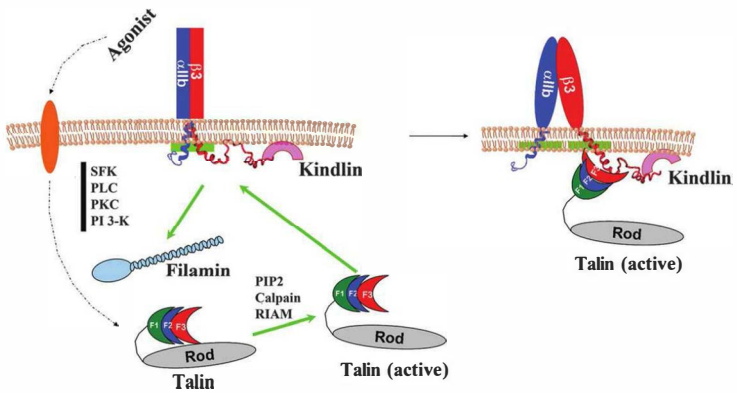

FIGURE 31.3 Model of a pathway for inside-out signaling to integrin $\alpha_{IIb}\beta_3$ in platelets. $\alpha_{IIb}\beta_3$ equilibrates between resting and activated states, the resting state predominating in unstimulated platelets and the activated state in stimulated platelets. Agonists induce activation of signaling intermediates, which leads to cytoskeletal changes, filamin dissociation, talin activation, affinity modulation of integrin $\alpha_{IIb}\beta_3$, and soluble ligand binding. The model depicted is incomplete and represents only some of the many molecules involved in this very complex process. Readers are referred to the text for a limited discussion. SFK, Src family kinase; PLC, phospholipase C; PKC, protein kinase C; PI-3K, phosphatidylinositide 3OH-kinase; PIP-2, phosphatidylinositol-4′5′-biphosphate; PIP-Kγ, phosphatidyl–inositol–phosphate kinase, gamma isoform.

migfilin,[181,182] and β_1-integrin and β_3-integrin CT.[179,183,184] Like talin, kindlins bind to β CT through their F3-PTB, but unlike talin, they bind to the membrane distal NXXY759 motif (NITY in β_3).[168,185] Phosphorylation of the Y in this sequence dissociates kindlin from the β_3 CT.[186] Kindlin-3 deficiency in humans gives rise to the leukocyte adhesion deficiency-III syndrome, LAD-III, also referred to as integrin activation deficiency disease[173] that is characterized by episodic bleeding of variable severity, increased susceptibility to infections, and sometimes osteopetrosis[172,173] and results from an inability to activate both β_2- and β_3-containing integrins. ILK, a 59 kDa cytoplasmic protein, can interact with the cytoplasmic domain of β_1, β_2, and β_3 integrin subunits.[187] Deficiency in mice or knockdown of ILK leads to defective platelet function,[188,189] although not as severe as that associated with kindlin-3 deficiency.

Filamin is a large cytoskeletal protein that binds to and stabilizes actin filaments.[190,191] Filamin contains an *N*-terminal actin-binding domain and a long rod-like domain of 24 immunoglobulin-like repeats. Filamin binds to a site in between the two NXXY motifs in integrin β-subunit CTs and overlaps sufficiently with the talin-binding site to dampen the talin–integrin interaction.[156,190,192] The cytoplasmic protein migfilin binds to filamin at the same site as integrin β CT. It is possible that by virtue of this competition, migfilin enhances integrin activation by blocking the inhibitory effect of filamin binding.[192]

REGULATION OF $\alpha_{IIb}\beta_3$ AND PLATELET ACTIVATION

Recent studies using novel inhibitors, proteomics, and gene-targeted mice harboring mutated and deleted proteins are leading to a new understanding of how signaling intermediates regulate, assemble, and relocalize molecules to drive $\alpha_{IIb}\beta_3$ activation in particular, and platelet activation in general. Platelets are transformed from a resting to an activated state when agonist stimulation of TM receptors induces intracellular signal transduction pathways. In addition to $\alpha_{IIb}\beta_3$ affinity modulation, platelet activation entails changes in platelet morphology, as well as centralization and exocytosis of storage granule. Inside-out $\alpha_{IIb}\beta_3$ activation can be triggered when any of a diverse array of agonists binds to their cognate receptors in the platelet plasma membrane (see Chapter 33). There are two principal receptor classes, based on their molecular associations with signal transducers: either G-protein–coupled or tyrosine kinase–coupled receptors.

G-proteins are heterotrimeric proteins consisting of α-, β-, and γ-subunits. They function as molecular switches that exchange GDP for GTP when they sense a conformational change in their associated receptor, resulting in dissociation of the α- from the β- and γ-subunits. The platelet-stimulating activity of thrombin is mediated by the protease-activated receptors PAR1 and PAR4 in humans and PAR3 and PAR4 in mice that are associated with Gαq, Gαi, and Gα12/13, whereas the thromboxane prostanoid receptor is associated with Gαq and Gα12/13. Full signaling by ADP requires that it bind to two purinergic receptors, the Gαq-associated P2Y1 and the Gαi-associated P2Y12. Epinephrine binds the β2 adrenergic receptor and signals through Gαz which couples to pathways similar to those coupled to Gαi.[193] Because ADP is released from platelet-dense granules during platelet secretion, ADP signaling constitutes a significant component of the total platelet stimulus initiated through multiple other receptors.[194,195] Deletion of receptors for each of these four major agonists results in abnormal thrombus formation in mouse models,[196] confirming their roles in platelet activation *in vivo*. The various G-proteins are associated with unique functions to promote platelet activation and aggregation: (a) Gαi inhibits adenylyl cyclase, the enzyme that catalyzes the formation of cAMP to maintain platelets in a resting state[197], and promotes phosphoinositide 3-kinase (PI-3K)–dependent Rap1 activation;[198] (b) Gαq stimulates release of membrane-bound phospholipase Cβ (PLCβ) to increase intracellular calcium levels and activate protein kinase C family members[199]; (c) Both Gα12 and Gα13 are present in platelets, although Gα13 is the primary mediator of thrombin-induced RhoA activation, shape change, and platelet aggregation.[200–202]

Tyrosine kinase–coupled adhesion receptors may signal independently or in conjunction with immunoreceptor tyrosine activation motif-containing receptors for optimal platelet activation. These adhesion receptors include GPVI which binds collagen and whose expression is regulated by the associated FcRγ,[203] GPIb-IX-V which binds vWF and signals alone[204] or together with FcRγchain in human and mouse platelets or with FcγRIIA in human platelets,[205,206] and $\alpha_{IIb}\beta_3$, a pool of which may associate with FcγRIIA.[207] Ligation of these adhesion receptors initiates a signaling cascade involving Src family kinases, activation of PLCγ2 for regulation of intracellular calcium levels,[208] and $\alpha_{IIb}\beta_3$ activation. Pathologically high shear stress stimulates signaling pathways activated by vWF binding to GPIb-IX-V.[209]

Platelet Phospholipases and Calcium Regulation

Platelets contain at least five isoforms of phospholipase C (PLC), including PLCβ and PLCγ2.[210] All PLC isoforms are activated by Ca^{2+} *in vitro*, while PLCγ2 may also be regulated by interactions of its PH domain with phosphoinositides.[211,212] These phospholipases hydrolyze the polar head group of phosphatidylinositol 4,5-bisphosphate (PIP2) to produce diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3). The latter binds to the IP3 receptor to effect release of calcium from platelet-dense tubules.[213] DAG can in turn activate classic and non-classical members of the protein kinase C family. Both PLCβ and PLCγ are essential for normal intracellular calcium oscillations, whether in response to ADP and thrombin (PLCβ)[213] or collagen (PLCγ2).[214,215] The PLC-mediated increase in intracellular calcium is detected by stromal interaction molecule 1 (STIM1),[216] a stimulator of store-operated calcium entry, which can promote opening of membrane calcium channel, Orai1,[217] allowing influx of extracellular calcium. Micromolar concentrations of calcium permit activation of a wide range of calcium-dependent proteins, including proteases, cytoskeletal proteins, protein kinase Cs (PKCs), and CALDAG-GEFI (also termed RasGRP2). CALDAG-GEFI functions as a GTP exchange factor (GEF) in platelets for Rap1b, a small Ras-like GTPase important for $\alpha_{IIb}\beta_3$ activation and platelet function.[218] Rap1b is activated in response to platelet agonists and by platelet adhesion to fibrinogen.[219] Both CALDAG-GEFI- and Rap1b-deficient mice show signaling defects in response to G-protein– and tyrosine kinase–coupled agonist receptors[220,221] and manifest partial loss of aggregation *in vitro*, as well as bleeding defects and reduced thrombus formation *in vivo*.[222] Other phospholipases, such as

PLD,[223] may be activated by platelet agonists and contribute to arterial occlusion and cerebral ischemia.[215]

Protein Kinase C Family

Members of the protein kinase C family are serine/threonine kinases that positively and negatively regulate $\alpha_{IIb}\beta_3$ and platelet activation in an isoform- and agonist-dependent manner.[204,224–226] Platelets contain conventional (α, βI/II and γ), novel (δ, ε, {in megakaryocytes}, η), and atypical (ζ and ι/λ) PKC isoforms that are classified according to the structure of their regulatory domains.[227] Phosphorylation of PKC on tyrosine residues induced by thrombin and collagen may affect its activity, localization,[228,229] and/or coupling to receptors for activated C-kinase (RACK) proteins.[230] The latter bind selectively to PKC isozymes,[231] for which they are themselves substrates.[232] The best studied of the PKCs, PKCα, has repeatedly been shown to be essential for platelet and dense granule secretion,[233,234] and platelet stimulation by the phorbol ester PMA or thrombin causes the phosphorylation of substrates that regulate the exocytotic process, including SNAPS and SNARES,[235,236] pleckstrin,[237] and myristoylated alanine-rich C kinase substrate.[238,239] In addition to its role in secretion, PKCα may positively regulate $\alpha_{IIb}\beta_3$ affinity by promoting Rap association and activation of talin,[240,241] or by phosphorylation and deactivation of a constitutively associated phosphatase, SHP-1, to prevent dephosphorylation of SHP-1 substrates such as Vav1.[242,243] Both *in vitro* models examining platelet adhesion and aggregation on collagen and *in vivo* mouse arterial injury studies reinforce the importance of PKCα in thrombus growth.[226,244] The PKCδ isoform, in contrast, is thought to be a negative regulator of GPVI-induced secretion, $\alpha_{IIb}\beta_3$ activation, and platelet aggregation,[245] although recent reports have suggested that PKCδ is needed for PAR-induced dense granule secretion.[245] The PKCθ isoform has been shown to participate in feedback loops, where PKCθ phosphorylation of Bruton tyrosine kinase (Btk; a member of the Tec family of kinases) on serine residues in GPIb-IX-V–stimulated platelets promotes Btk phosphorylation of tyrosines on PKCθ.[246] PKCβ and PKCθ appear to significantly modulate outside-in signaling and are discussed further below. PKCη may also become phosphorylated in platelets following ADP stimulation.[247]

Phosphoinositide 3OH-Kinase

PI-3K phosphorylate the 3′-OH group of the inositol ring of specific phosphoinositols (PI) including PI(4)P and PI(4,5)P2. Their products, PI(3,4)P2 and PI(3,4,5)P3, transduce signals in part by binding to specific PH and Src homology-2 (SH2) domains in relevant signaling proteins such as Akt (Protein kinase B) and PDK1,[248] thereby recruiting them to their locus of action at the membrane. At least four PI-3K isoforms are expressed in platelets that are classified based on the p110 catalytic subunit and mechanism of regulation, including the two best characterized isoforms, class Ia member p85/p110 PI-3Kβ and Class Ib member p110 PI-3Kγ.[249,250] Interestingly, 3-phosphorylated phosphoinositides can activate certain atypical and novel isoforms of PKC,[251] suggesting one possible link between PI-3K, PKC, and affinity modulation of $\alpha_{IIb}\beta_3$. General PI-3K inhibitors indicate a prominent role for PI-3K in platelet activation: (a) ligation of GPIb-IX-V induces dissociation of PI-3K from an α-actinin/PI(3,4)P2 complex,[252] PI-3K association with Src, an early upstream effector in the GPIb-IX-V signaling pathway,[253] and $\alpha_{IIb}\beta_3$ activation[204]; (b) PI-3K may amplify platelet secretion through an ADP-dependent feedback loop[254]; and (c) mice deficient in Akt1 and Akt2, downstream effectors of PI-3K, have impaired thrombin-induced fibrinogen binding to $\alpha_{IIb}\beta_3$ and impaired *in vivo* thrombus formation.[255] Recent studies using gene targeting in mice and isoform-specific PI-3K inhibitors have identified both overlapping and discrete roles for the PI-3K isoforms β and γ: ADP P2Y12 receptor–driven Akt phosphorylation, Rap1b activation,[256] and thromboxane generation[257,258] are mediated primarily by PI-3Kβ, but full $\alpha_{IIb}\beta_3$ activation and platelet aggregation also require PI-3Kγ.[259,260] In contrast, activation through GPVI appears to be entirely PI-3Kβ mediated.[261,262] Interestingly, the consequences of deleting the p85α regulatory subunit are restricted to the GPVI pathway and the defects mirror those seen with PI-3Kβ.[263] While chemical induced thrombosis is compromised in these mice, there is no bleeding defect.

Ras and MAPK Family of Proteins

Platelets contain members of the Ras (H-Ras, R-Ras, Rap1 and Rap2, Raf, RalA, and Rab)[264] and Rho (cdc42, Rac1, and RhoA) families of small GTPases,[265] and the guanine nucleotide exchange factors, guanine nucleotide dissociation inhibitors, and GTPase-activating proteins[266,267] that regulate their GDP/GTP content. Ras family members are known primarily for their mitogenic effects and activation of mitogen-activated protein kinase (MAPK) cascades in nucleated cells.[268] However, Ras and ERK may be activated independently of each other in platelets,[269] and activation of similar cascades has not been conclusively confirmed. The MAPK family of serine/threonine kinases is composed of three main subgroups: p38 MAPK, ERK 1/2, and c-Jun terminal kinases (JNK), and several isoforms of each are found within platelets. MAPK members are known to be phosphorylated by physiological platelet agonists, acting through either G-protein– or tyrosine kinase–coupled receptors,[270,271] ADP P2Y receptors,[272] or thrombin where ERK activation may be PKC dependent,[266,273] and to positively regulate $\alpha_{IIb}\beta_3$ activation.[274] JNK is often referred to as a stress response sensor,[275] and this appears to hold true in platelets: inhibition of JNK1 *in vitro* decreases thrombus growth on collagen and vWF at arterial shear rates *in vitro*,[276] and mice lacking JNK1 show hemostatic defects including increased tail bleeding times and delayed chemical induced venous and arterial thrombosis in a mouse model.[277]

Adapter Proteins as Platelet Signaling Intermediates

Adapter molecules are often regulated by platelet agonists and serve to scaffold interaction partners to enable signal transduction and $\alpha_{IIb}\beta_3$ activation. Adapters have modular domains through which large, combinatorially diverse complexes may be formed. In many cases, they are crucial for relocalizing proteins to their sites of action. For example, two adapters in platelets that enhance $\alpha_{IIb}\beta_3$activation and contribute to *in vivo* thrombus formation are SLP-76[278] and the adhesion and degranulation promoting adapter protein (ADAP; Fyb, SLAP130).[279–282] GPVI/FcRγ stimulation results in phosphorylation of three important tyrosine residues on SLP-76 that induce recruitment of PLCγ and additional adapters including ADAP, NCK,

and LAT[281,283–285] to promote increases in intracellular calcium. ADAP interactions may be mediated by a constitutive interaction with the Src family kinase member Fyn[204] or by inducible interactions with Src.[286] Other adapters have been implicated in thrombus formation *in vitro* and *in vivo*, such as Cbl, which negatively regulates platelet function.[287] Further studies are needed to reconstruct the interaction networks induced by diverse platelet agonist signaling pathways.

REGULATION OF PLATELET FUNCTION BY $\alpha_{IIb}\beta_3$ (OUTSIDE-IN SIGNALING)

Several platelet responses are dependent, in part, on initial binding of fibrinogen or vWF to $\alpha_{IIb}\beta_3$. These include (a) firm adhesion under high shear conditions[68,288,289]; (b) spreading on extracellular matrices containing fibrinogen or vWF[290]; (c) secretion from platelet α and dense granules in response to "weak" agonists, such as ADP or epinephrine; (d) conversion of small platelet aggregates into larger, more hemostatically effective ones; (e) fibrin clot retraction[291]; and (f) microparticle formation.[292,293] Some of these responses may be dependent on ligand binding to $\alpha_{IIb}\beta_3$ and others on platelet aggregation, thereby establishing a temporal–spatial hierarchy to outside-in signaling.[98] Graded degrees of cytoskeletal rearrangement occur from filopodial extension to actin organization into clusters,[294] lamellipodia formation, and full spreading, which depend on the matrix encountered, the degree of hydrodynamic stress,[295] and the presence of amplifying costimulatory agonists such as ADP and thromboxane A2.[296,297] Platelet outside-in responses are propagated by constitutively—or inducibly—associated $\alpha_{IIb}\beta_3$ CT-binding proteins.[39,298,299] These may serve to initiate signaling cascades for actin polymerization, cytoskeletal reorganization, and platelet spreading or serve to anchor platelets to substrata by direct or proximal coupling to actin[300–302,303,304] (FIGURE 31.4).

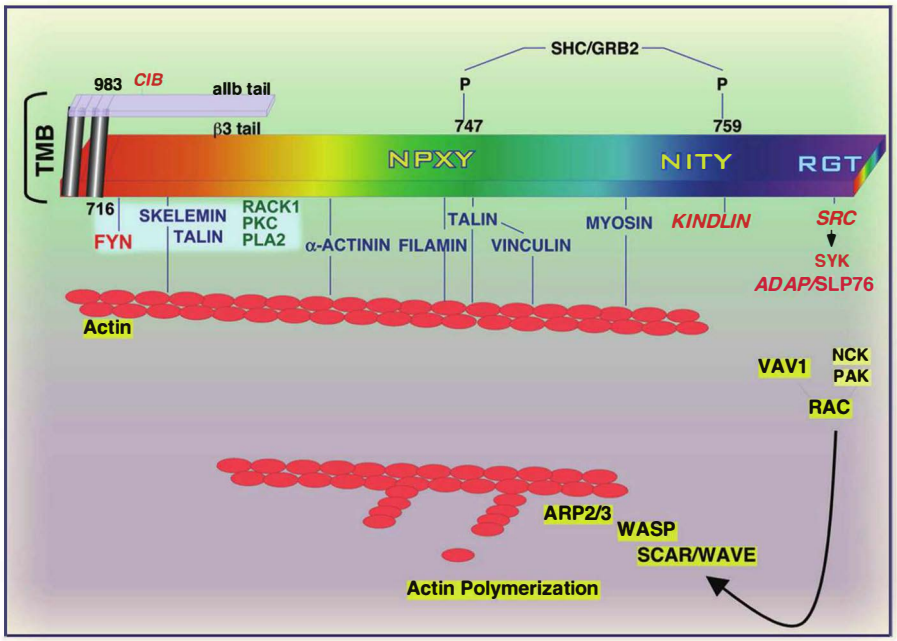

FIGURE 31.4 Model of integrin $\alpha_{IIb}\beta_3$ outside-in signaling mediators. Integrin $\alpha_{IIb}\beta_3$ is a type I TM heterodimeric protein composed of an α- and a β-subunit. Shown here is the intracellular platelet environment and highlights the α and β CTs (not drawn to scale) and several of the proteins that bind the tail subunits constitutively or inducibly upon ligand engagement. These proteins may function to anchor platelets to the substrate by direct or secondary linkage to actin, for example, talin-vinculin (labeled in *blue*), and/or may function to stimulate de novo actin polymerization, cytoskeletal reorganization, platelet spreading, or other outside-in signaling events by initiation and propagation of signaling cascades (labeled in *red*). Relevant sites proximal to the TM domains are, on α_{IIb} chain: CIB (amino acids (AA) 984--996), and on β3 chain: Fyn (AA 721–725), Skelemin (AA 716–730), a secondary talin-binding site, and an α-actinin-binding site. The region on the β3 chain between tyrosines 747 and 759 constitutes an important regulatory region: the talin-binding site spans AA739–752 and includes one of the two tyrosine-containing motifs, NPXY, and this site is partially overlapped and competed for by the actin-binding protein filamin. Kindlins recognize a region that includes the second tyrosine-containing motif, NITY. Phosphorylation of tyrosines 747 and 759 regulates binding of adapter proteins Shc and Grb2, and the cytoskeletal protein, myosin. The tyrosine kinase, c-Src, which is constitutively associated with the β3 chain three carboxy-terminal RGT residues, becomes activated upon integrin ligation and is critical for outside-in signaling. Src activation initiates a cascade of events including activation and recruitment of Syk, and other adapters such as SLP-76, ADAP, and NCK, which engage regulators of actin polymerization and reorganization (*yellow*). RACK1/protein kinase C family members may further promote significant integrin-proximal outside-in signaling (*green*).

Deletion of many of these proteins in mice decreases platelet spreading *in vitro* and thrombus stability *in vivo*.[196,305,306]

Talin was one of the first intracellular proteins found to provide a direct linkage between actin and integrins.[307,308,164] Cells lacking talin are unable to link integrins to the cytoskeleton[309] but are able to bind to the extracellular matrix.[310,311] Integrin binding to two other actin-binding proteins, α-actinin and filamin, has also been demonstrated.[312] Members of the kindlin family may play an important role as adaptor molecules linking the actin cytoskeleton to cell–extracellular matrix adhesion sites via a migfilin/filamin intermediary complex.[177] For example, cells that are defective in kindlin-2 expression have a severe spreading defect.[179] Kindlin-2 is also required to direct ILK to focal adhesions.[299] ILK deficiency disorganizes the actin cytoskeleton.[299] Many of these molecules are also implicated in integrin activation, and the distinction between their roles in inside-out and outside-in signaling becomes blurred as the processes are interconnected and cooperative.

Specific domains in $\alpha_{IIb}\beta_3$ serve to transduce signals subsequent to ligand binding. Phosphorylation of the β_3 tyrosines 747 and 759,[313] located in the NPLY- and NITY-binding motifs for talin and kindlin, respectively, promotes the association of β_3 with the Triton X-100-insoluble platelet cytoskeletal fraction, as well as binding of myosin and the MAPK cascade protein SHC (SH2 containing adapter protein) to the β_3 CT.[314,315] Phosphorylation of β_3 may also be induced by CD40 ligand[316] and necessitates mu-calpain.[317] Mutation of these tyrosines to phenylalanine in mice, peptides against this region, or truncation at β_3 at residue 724 affects outside-in signaling, as manifested by rebleeding after tail transection, a reduction in clot retraction, reduced $\alpha_{IIb}\beta_3$-dependent tyrosine phosphorylation of FAK, reduced platelet spreading on fibrinogen, and reduced $\alpha_V\beta_3$-dependent FAK and paxillin phosphorylation.[318–321] Interestingly, β_3 tail phosphorylation may advance downregulation of $\alpha_{IIb}\beta_3$ activation since tyrosine phosphorylation decreases the binding of two important $\alpha_{IIb}\beta_3$ affinity modulators, talin and kindlin.[186,322] Further, phosphorylation of β_3 serine 752 reduces platelet spreading.[323,324] In addition, structural changes in $\alpha_{IIb}\beta_3$ TM and extracellular domains induced by ligand binding may expose new CT epitopes for protein binding to promote spreading and clot retraction.[325,326]

$\alpha_{IIb}\beta_3$-mediated outside-in signaling initiates a cascade of events that result in cytoskeletal reorganization and are thought to begin with $\alpha_{IIb}\beta_3$ oligomerization.[125,327] $\alpha_{IIb}\beta_3$ oligomerization following fibrinogen binding was directly demonstrated in model cell systems using protein interaction-dependent fluorescence assays.[328,329] $\alpha_{IIb}\beta_3$ oligomerization (clustering) was found to promote cell adhesion to fibrinogen or vWF[125] and was followed by dynamic trafficking of intracellular kinases and adapters.[98] Oligomerization results in the activation of the c-Src that is constitutively associated with the RGT sequence located at the extreme *C*-terminus of the β_3 tail of resting platelets.[330–332] Src activation involves the dephosphorylation of Src residue Y529 by PTP-IB to relieve autoinhibition,[333,334] followed by autophosphorylation of Src at Y416.[334] Activated Src promotes the recruitment of the tyrosine kinase Syk to the Src-β_3 complex where Syk is activated.[335,329,330] The tyrosine kinase function of Src and Syk, as well as that of another Src family kinase Fyn, is required for full platelet spreading.[336] The Src–Syk complex can be seen in early membrane ruffles and lamellipodia where it is colocalized with cortactin.[329] Kinase activation promotes a molecular pathway of cytoskeletal rearrangement by activation of adapters including SLP-76, ADAP, Dok, Nck, Lnk, and the Cdc42/Rac GEF Vav1.[337,338,339] A small αIIβ-binding protein, CIB, associates with FAK to support focal adhesion and lamellipodia formation.[340] Overall, $\alpha_{IIb}\beta_3$-mediated outside-in signaling cascades promote actin polymerization. Consequently, branching actin polymerization may be effected by Rac-GTP activation of Scar/WAVE[341,342] to trigger WASP association and stimulate actin assembly[343] via the ARP2/3 complex.[344] In fully spread platelets, larger adhesive complexes are formed with PKC-dependent phosphorylation of α-actinin[345] and Src-dependent activation of vinculin.[346] Mutation or deletion of many of the above proteins in mice perturbs platelet spreading,[281,284,347,348] but regulation of the proteins, their intracellular localization, and how they are modulated by shear stress[295,349] are not fully understood.

Several studies have suggested that there are similarities between nonintegrin agonist-induced signaling pathways and $\alpha_{IIb}\beta_3$-mediated outside-in signaling. Thus, a pool of $\alpha_{IIb}\beta_3$ has been found to associate with Gα13 and modulate platelet contractility and shape change[200,350] as well as Src Y416 phosphorylation and platelet spreading.[351] Another pool has been identified that associates with FcγRIIA to control Syk- and PLCγ-mediated spreading.[207] These observations are supported by the participation of common signaling pathway intermediates. First, disruption of PLCβ or PLCγ2 and intracellular calcium elevations result in decreased platelet spreading and adhesion stability,[213,352,353] while a PLCγ gain-of-function mutation increases spreading and clot retraction.[215] Second, PI-3K can serve to stabilize platelet spreading,[262] clot retraction,[257] and adhesion stability under flow.[349,354,260] Third, certain PKC family members appear to selectively mediate outside-in signaling in platelets by partnering with isoform-specific RACKs and other signaling molecules. PKCβ can promote spreading through RACK1,[298] PKCδ attenuates filopodia formation through a constitutive interaction with VASP,[355] and PKC associated with $\alpha_{IIb}\beta_3$ promotes platelet spreading on fibrinogen through inducible interactions with Syk and Btk[356] but attenuates thrombus formation on collagen.[226] Therefore, it is possible that PKC/RACK and Src operate together, or may reflect distinct $\alpha_{IIb}\beta_3$-associated signaling pathways that converge on actin regulatory proteins to effect platelet outside-in responses. In support of this possibility, Dok1 and Dok3 undergo both Src-dependent and Src-independent phosphorylation following $\alpha_{IIb}\beta_3$ ligation[338] and mice lacking Group IVA cytosolic phospholipase A2, which releases arachidonic acid from membranes, have reduced PKCβ/RACK1 recruitment to β_3 and platelet spreading.[357]

CHAPTER

32 Molecular Basis for Platelet Secretion

SHAOJING YE AND SIDNEY W. WHITEHEART

INTRODUCTION

Platelets are small, anucleate, discoid cell fragments produced by bone marrow megakaryocytes. Structurally, platelets are simple, containing plasma membrane with a specialized region known as the open canalicular system (OCS), microtubules, mitochondria, and three types of granules: dense granules, α-granules, and lysosomes. Upon encountering a vascular lesion, platelets become activated and initiate thrombosis. Engaging cell surface receptors initiates a number of intracellular signaling cascades leading to increased intracellular Ca^{2+} and inducing dramatic alterations in platelet shape mediated by actin cytoskeletal rearrangements. Platelet activation also leads to the release of their granular stores, and the resulting releasate affects the microenvironment at the site of damage. Released molecules attract and activate more platelets to propagate thrombosis and initiate *sequelae* of thrombosis such as wound healing and leukocyte recruitment. Thus, platelet secretion is not only important for hemostasis, but is also associated with many other vascular processes, both normal and potentially pathologic. Further, understanding the mechanism of platelet secretion has the potential to identify new targets for the development of novel antithrombotic therapeutics to control thrombosis and to affect pathophysiologic aspects of platelet function that participate in atherosclerosis, tumor angiogenesis, and inflammation.

At sites of vascular injury, platelets release cargo from three granular stores: dense granules contain small, bioactive molecules,[1–3] α-granules contain bioactive peptides and proteinaceous components,[4,5] and secretory lysosomes contain hydrolytic enzymes.[6] Release of dense granule cargo is clearly important to hemostasis, given the bleeding diatheses associated with genetic defects in dense granule biogenesis (i.e., Hermansky-Pudlak syndrome [HPS][7]). Released adenosine diphosphate (ADP) plays a key role in enhancing the responsiveness to other agonists generated at the site of vascular damage.[8] Release of α-granule cargo has a more heterogeneous impact. Patients who lack α-granules (i.e., gray platelet syndrome [GPS]) generally have more diverse bleeding phenotypes, ranging from mild to severe.[9,10] The role that lysosome release plays is unclear; it is plausible that the released hydrolytic enzymes could be important for thrombus remodeling. Nonetheless, while the physiologic importance of platelet secretion is clear, the nature of the machinery that controls and mediates platelet granule exocytosis is not. This chapter discusses our present state of knowledge of the molecular mechanisms of platelet secretion.

PLATELET GRANULES AND THEIR CARGO

As with other regulated secretory systems, for example, neurons, release of cellular stores occurs in response to external stimuli. The resulting signaling steps mobilize the secretory machinery that then mediates the fusion of cargo-containing granules with the plasma membrane to facilitate cargo release into the extracellular environment. Each of the classes of platelet granules is released upon stimulation, but to differing degrees, depending on the levels of platelet activation.

Dense Granules

Platelets contain approximately three to eight electron-dense organelles, 20 to 30 nm in diameter.[3,11] The electron density of dense granules, when viewed in unstained whole mounts, is due to the relative insolubility of calcium salts of the various compounds stored in dense granules (i.e., $CaPO_4$). Dense granules contain high concentrations of serotonin, which is taken up from plasma by a plasma membrane transporter and then concentrated in the granules.[3] ADP and adenosine triphosphate (ATP) are also highly concentrated in dense granules. There is more ADP than ATP in the dense granules, which is the reverse of their relative cytosolic concentrations.[12] Calcium, polyphosphates, sphingosine-1-phosphate, and epinephrine are also found in dense granules.[12–14] The concentration of serotonin, and perhaps other dense granule cargo, is the result of the lower pH (~6.1) maintained in dense granules due to the action of a H^+ pumping ATPase on the granule membrane.[3]

α-Granules

α-Granules are the most abundant granule type in platelets, numbering approximately 50 to 80 per platelet.[15,16] They are approximately 200 nm in diameter and show variations in electron density; often, they contain a central electron-dense area termed a nucleoid.[17] The more electron-lucent areas often contain tubular elements in which von Willebrand factor (vWF), multimerin, and factor V are preferentially localized.[18] Platelets may contain distinct subpopulations of α-granules that undergo differential release of α-granule cargo during activation. For example, some α-granules appear to contain proangiogenic proteins, such as vascular endothelial growth factor (VEGF), whereas others contain antiangiogenic factors, such as endostatin.[19] Alternatively, these factors may be distributed in distinct regions within the same membrane-bound granule.[20,21] This is yet to be resolved.

α-Granules acquire their cargo through both biosynthesis (predominantly at the megakaryocyte level) and endocytosis (at both the megakaryocyte and circulating platelet levels). Small amounts of many plasma proteins are found in α-granules; thus, the plasma concentrations of these proteins determine the amount present in platelets.[22,23] For example, the α-granule pool of immunoglobulins contains most of the platelet immunoglobulin;

therefore, total platelet immunoglobulin is more affected by changes in plasma immunoglobulin levels than by changes in surface immunoglobulin. Other proteins, such as VEGF, factor V, and fibrinogen appear to be specifically endocytosed and trafficked to α-granules for subsequent release. Consistently, clathrin-coated pits have been observed budding from the specialized region of the plasma membrane, the OCS.[24] $P2Y_1$ and $P2Y_{12}$ receptor desensitization and resensitization are also thought to occur through an endocytosis, re-expression pathway.[25] Though it clearly occurs *in vivo*, the mechanism, the extent, and the biologic importance of platelet endocytosis are largely unknown and understudied.

The pathways that regulate α-granule assembly are also not fully understood, but several studies suggest that multivesicular bodies (MVBs) play a crucial intermediary role in α-granule biogenesis.[26] These membranous compartments, containing numerous small vesicles, develop from budding vesicles in the Golgi complex within megakaryocytes and can interact with endocytic vesicles. They are abundant in immature megakaryocytes and decrease in numbers with cellular maturation, suggesting that they are the precursors of α-granules and/or dense bodies. MVBs may also function as a sorting hub to route proteins into distinct classes of α-granules.

Lysosomes

Lysosomes are a key component of the endosomal membrane system. Platelet lysosomes contain acid hydrolases (e.g., β-glucuronidase, cathepsins, aryl sulfatase, β-hexosaminidase, β-galactosidase, endoglucosidase [heparitinase], β-glycerophosphatase, elastase, and collagenase).[2] Similar to other hematopoietic cells, platelets secrete lysosomes upon activation, but lysosomal release is slower and less complete than that of α- and dense granules.[6] Thus, stronger agonists are required to induce lysosomal enzyme release. The elastase and collagenase activities released from platelet lysosomes may contribute to vascular damage at sites of platelet thrombus formation.[27] The heparitinase may be able to cleave heparin-like molecules from the surface of endothelial cells, and the resulting soluble molecules appear to inhibit growth of smooth muscle cells.[28]

Platelet Secretome

Present estimates suggest that fully activated platelets can secrete hundreds of different molecules.[4,5,29] While dense granules predominantly contain only small molecules, α-granules contain a myriad cargo that comprises the bulk of the platelet "secretome." Some of these proteins are produced at the megakaryocyte stage and are packaged into granules during their biosynthesis.[26] It is generally thought that patients with GPS have a defect in this process. Other α-granule cargo (e.g., fibrinogen and factor V) are not made by megakaryocytes, but are thought to be endocytosed by circulating platelets.[30] Once internalized, these cargo molecules are transported to α-granules.[26,31]

This "secretome" can be classified by granular source or proposed function.[32] Dense granules mainly contain nonpeptide, small molecules: for example, ADP, serotonin, and calcium, which are critical for platelet activation and vasoconstriction. As discussed below, failure to release these components leads to defects in thrombosis. α-Granules contain proteinaceous components which have a wide array of functions.

Functionally, the "secretome" can be divided into even more categories (reviewed in Ref.[33]). The most obvious class of proteins is the adhesive proteins such as fibrinogen, fibronectin, vitronectin, and thrombospondin that are released from α-granules and function in platelet–platelet cohesion and subsequent thrombus formation. Other proteins, such as P-selectin, are present on the α-granule membrane and are exteriorized to the surface upon granule–plasma membrane fusion. Platelets also release fibrinolytic agents such as PAI-1 and TAFI which are important for clot remodeling. Perhaps the most diverse category is the mitogens such as IGF-1, VEGF, and FGFβbFGF. These proteins are thought to promote wound healing and angiogenesis by stimulating chemotaxis, cell proliferation, and maturation of the cells surrounding the wound site. Finally, platelets release a number of chemokines and cytokines such as RANTES, IL-8, and MIP1α that promote activation of passing leukocytes and lead to a range of immune responses. This releasate catalog suggests that platelet secretion is pivotal in establishing the microenvironment at the wound site. Therefore, controlling release from the granule stores, either specifically or globally, may prove to be an effective strategy to manipulate this microenvironment.

Granule Heterogeneity

It is becoming increasingly clear that our old views of platelet granules may be overly simplistic. Recent studies have suggested that α-granules are heterogeneous in content and that heterogeneity may result in differential release of granule cargo. Italiano and colleagues have shown that α-granules can be distinguished based on the pro- or antiangiogenic factors that they contain.[19] Antiangiogenic factors, such as endostatin, reside in different granules than do proangiogenic factors such as VEGF. A similar degree of granule heterogeneity was initially reported by Storrie and colleagues who examined the localization of fibrinogen and vWF.[20,21] Functionally relevant granule heterogeneity is seen in other hematopoietic cells such as mast cells and neutrophils. In these cells, differential release in response to distinct agonists appears to be mediated by different SNARE proteins.[34,35]

The diversity of the platelet releasate suggests that platelet secretion could be pivotal in establishing the microenvironment at an injury site. However, it is unclear whether platelet secretion is a controlled, thematic process or a random event. Several studies found that some angiogenesis regulators are packaged into distinct α-granule populations. Immunofluorescence and immunoelectron microscopy show distinct localizations for pro- and antiangiogenic factors.[19] Other studies have also shown that stimulating platelets with different agonists (i.e., PAR1 and PAR4 agonists) causes differential release of certain cargo molecules.[19,36,37] This led to the proposal that platelet secretion is contextually thematic, that is, capable of releasing specific sets of cargo (e.g., pro- vs. antiangiogenic factors) in response to specific agonists. Other data suggest that cargo is spatially segregated into subregions of the same membrane-bound granules and that there is no "thematic" colocalization of factors with like functions.[20,21] Though these data are intriguing, it is yet difficult to ascertain the extent to which platelet secretion is heterogeneous. If there is heterogeneity in cargo packing and/or secretion, regulating the release of specific α-granule subpopulations may allow

specific manipulation of the microenvironment at an injury site without disturbing hemostasis.

PLATELET SECRETORY MACHINERY

SNARE Overview

Platelet granule–plasma membrane fusion is analogous to exocytosis in neurons where detailed studies have shown the importance of a core set of integral membrane proteins called soluble N-ethylmaleimide Sensitive Factor (NSF) attachment protein receptors (SNAREs)[38,39] (FIGURE 32.1). Since the original description of SNAREs in neurons,[40] there have been significant advances to our understanding of how SNAREs function. Recent models of SNARE function posit that vesicle/granule-target membrane fusion is governed, in part, by the matching of a vesicle SNARE (v-SNARE), with a heterodimeric or trimeric, protein complex in the target membrane (t-SNAREs). This transmembrane complex is the minimal element required for membrane fusion.[41] v-SNAREs are type II integral membrane proteins of generally low molecular weight (15 to 25 kDa) that contain a characteristic 60 to 70 amino acid SNARE motif.[38] At present, approximately 20 different v-SNARE isoforms have been identified in humans. t-SNAREs are of two types: the synaptosomal-associated protein 23/25 (SNAP-23/25) type (SNAP-23, SNAP-25, SNAP-29, Sec9p), and the syntaxin type (syntaxin 1-19, etc.). The SNAP-23-like proteins have two SNARE motifs, lack transmembrane domains (TMDs), and are generally anchored to the membrane through thioester-linked acyl groups attached to a central cysteine-rich domain. The type II membrane protein syntaxins contain the characteristic SNARE motif, an *N*-terminal regulatory domain, and generally, a *C*-terminal TMD.[42] SNAREs employ the SNARE motifs to form a four-helix bundle arranged as a parallel coiled-coil.[43] This structure is stabilized by core hydrophobic interactions running the length of the bundle. Based on this inherent stability, the temporal and spatial control of SNARE complex formation and disassembly represent important tasks for the secretory machinery. Three groups have contributed to our present knowledge of the function of platelet SNAREs (for reviews see Refs.[44,45]). To date, four vesicle-associated membrane proteins (VAMPs -2, -3, -7, -8), four syntaxins (-2, -4, -7, -11), and SNAP-23, SNAP-25, and SNAP-29 have been detected in platelets.[46–48,49,50,51,52,53,54]

Platelet v-SNAREs

In human and mouse platelets, the v-SNAREs are VAMP-2/synaptobrevin, VAMP-3/cellubrevin, VAMP-7/TI-VAMP, and VAMP-8/endobrevin, with the latter being most abundant[46,52,53,54] (FIGURE 32.1). Assigning roles for these v-SNAREs was initially ambiguous, perhaps because in the *in vitro* exocytosis assays used, the v-SNARE-effecting agents were being added to permeabilized platelets. Flaumenhaft et al.[49] found that P-selectin exposure (a metric of α-granule release) was inhibited by pretreatment of permeabilized platelets with Tetanus neurotoxin, a heterodimeric, zinc-dependent, endopeptidase specific for VAMP-1, -2, and -3.[55] Subsequently, Feng et al.[56] showed that an antipeptide antibody to the divergent, *N*-terminus of VAMP-3 could inhibit α-granule release, suggesting a role for VAMP-3. However, secretion by platelets from VAMP-3$^{-/-}$ mice was normal.[54] In fact, secretion for these platelets seemed faster.[53] Polgar et al.[52] showed that the cytoplasmic domains of VAMP-3 or VAMP-8, containing the SNARE motif, could inhibit release from dense and α-granules. Since the isolated cytoplasmic domains are promiscuous in their associations *in vitro*,[57,58] it was uncertain whether the inhibitory effects were illustrative of a v-SNARE role or of t-SNARE heterodimer binding preferences.

Ren et al.[53] showed that VAMP-8/endobrevin is the primary v-SNARE in mouse platelets. VAMP-8$^{-/-}$ platelets had a clear secretion defect, which was not seen in VAMP-3$^{-/-}$, VAMP-2$^{+/-}$, VAMP-2$^{+/-}$/VAMP-3$^{-/-}$ platelets or from either permeabilized human or VAMP-3$^{-/-}$ platelets that had been treated with the catalytic Tetanus toxin light chain. However, the secretion defect in VAMP-8$^{-/-}$ platelets was not complete. α-granule and lysosome release were significantly affected even at high agonist doses and upon extended incubation, but dense granule release was only attenuated and eventually approached wild-type levels. The VAMP-8–independent release could be eliminated by treatment of permeabilized VAMP-8$^{-/-}$ platelets with Tetanus toxin, suggesting

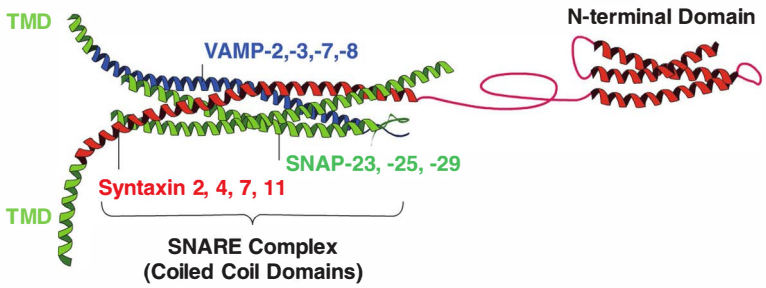

FIGURE 32.1 Platelet SNARES. SNARE proteins are membrane proteins that form a complex which bridges between the granule and plasma membrane. This complex is sufficient to mediate membrane fusion between the granule and plasma membrane to promote granule cargo release. SNAREs from the granules are known as v-SNAREs (vesicle SNAREs). They are small (~20 kDa) membrane proteins with a TMD and a cytoplasmically oriented SNARE motif. Platelets contain VAMP-2, -3, -7-, and -8. SNAREs from the plasma membrane (target or-t-SNAREs) come in two forms: the syntaxins (~35 kDa) are membrane proteins that generally contain a TMD, a SNARE motif, and an *N*-terminal regulatory domain. Platelets contain syntaxin 2, 4, 7, and 11. The syntaxins form a complex with the SNAP-23 family of t-SNAREs. The SNAP-23s (~30 kDa) lack TMDs and are anchored by thioester-linked acyl groups. They have two SNARE motifs. Platelets contain SNAP-23, -25, and -29.

that the secondary mechanism employed either VAMP-2 or -3. Experiments using permeabilized human platelets treated with Fab fragments prepared from VAMP-8-specific immunoglobulins showed that the role of VAMP-8 in mouse and human platelets is similar (Ren Q and Whiteheart SW, unpublished data, 2008).

The redundancy in v-SNARE usage is analogous to that seen in chromaffin cells[59] where there is a primary v-SNARE (VAMP-2) required for rapid and efficient, agonist-induced release, and a secondary v-SNARE (VAMP-3) which functions, albeit less efficiently, in the absence of the primary v-SNARE. Full ablation of release from chromaffin cells requires deletion of both VAMP-2 and VAMP-3. The redundancy in VAMP usage observed in *ex vivo* platelet secretion assays is consistent with the *in vivo* thrombosis phenotype of the VAMP-8$^{-/-}$ mice. Upon laser injury, VAMP-8$^{-/-}$ mice have a delay in thrombus formation and an increase in embolization, although the overall extent of platelet accumulation is not statistically different from wild type.[8]

In light of the role of VAMP-8 in platelets, it is noteworthy that a SNP (single nucleotide polymorphism) in the human VAMP-8 gene strongly correlates with early onset myocardial infarction (MI).[60,61] The authors of these studies suggest that this SNP might affect VAMP-8 expression levels, given its location in the 3'-untranslated region of the gene. It is conceivable that increased amounts of VAMP-8 could increase the likelihood that a platelet could release its granule cargo and thus be hyperthrombotic. Consistent with this possibility, expression of a microRNA controlling VAMP-8 expression correlated with platelet hyperactivity.[62] Normal donors, whose platelets were hyperresponsive to epinephrine, showed increased expression of the micro-RNA. Transfection studies suggested that increased VAMP-8 might make platelet hypersecretory, thereby explaining their hyperresponsiveness. Further analysis will be required to determine if VAMP-8 levels are a thrombotic risk factor.

Platelet t-SNAREs

There are two classes of t-SNAREs: the SNAP-23/25/29 type and the syntaxin type (FIGURE 32.1). Human and murine platelets contain syntaxins-2, -4, -7, and -11[49,50,63] as well as SNAP-23, -25, and -29.[49,50,64] All three SNAP-23/25-like t-SNAREs have been detected in platelets, although SNAP-25 and SNAP-29 levels appear to be low. Experiments introducing specific antibodies, Fab fragments, and inhibitory peptides have demonstrated that SNAP-23 is required for all three granule secretion events.[47,48,49,50,52,64,65] SNAP-23 is phosphorylated upon activation[64,66] and preliminary data from Karim et al. (*manuscript in preparation*, 2012) suggest that SNAP-23 might be an important link between platelet activation and membrane fusion. Polgar et al.,[64] using ion trap mass spectrometry, showed that human platelet SNAP-23 could be phosphorylated at Ser23/Thr24 and Ser61 after activation by thrombin. In murine mast cells and platelets, SNAP-23 phosphorylation sites are at Ser95 and Ser120.[66] SNAP-23 is important for full assembly of fusigenic SNARE complexes and, in mast cells, phosphorylation appears to contribute to that role.[66]

SNARE complexes may also be affected by calpain cleavage of SNAP-23. Calpains are calcium-dependent, nonlysosomal, neutral, cysteine proteases present in most mammalian tissues. Several inhibitors, such as calpeptin, calpastatin, and E64d, inhibit calpain activity and these inhibitors block SNAP-23 cleavage in activated platelets.[67,68] It is not clear if SNAP-23 cleavage plays a role in platelet exocytosis since the conflicting effects of the calpain inhibitors may reflect the assays used to monitor secretion.[68,69] Clearly, these data establish a role for SNAP-23 in platelet exocytosis and suggest that it may be regulated by several different mechanisms. Studies in knockout mice and/or humans with SNAP-23 mutations will be required to confirm this conclusion. Global deletion of SNAP-23 is embryonic lethal (at E3.5) and attempts to make conditional deletions have been unsuccessful thus far.[70]

Syntaxins-2 and -4 have been detected in platelets, but syntaxins-1, -3, and -5 have not.[49,50,65] Both syntaxins-2 and -4 had been shown to be involved in other secretion events at the plasma membrane.[71–74] Flaumenhaft et al.[49] first demonstrated a role for syntaxin-4 in platelet α-granule release using a permeabilized platelet assay system. Monoclonal antibodies against syntaxin-4 inhibited lysosome release but not dense granule release.[48] Chen et al.[47] demonstrated that an antisyntaxin-2 antibody could inhibit release of all three platelet granule stores.[48,51] Syntaxin-7 is localized to an intracellular compartment instead of the plasma membrane in nucleated cells[71] and was not considered a likely candidate to mediate platelet exocytosis. This was confirmed when specific syntaxin-7 antibodies were introduced into permeabilized platelets and had no effect on any of the three granule secretion events.[47,48,51] These early data suggested that syntaxins-2 and -4 are important for platelet secretion. As with the studies of the VAMPs, using antibodies as inhibitors can lead to ambiguous results. Recent studies have shown that deletion of both syntaxins from murine platelets causes no secretion defect despite a subtle effect on clot retraction (Ye et al., 2012, *Blood*, in press).

Proteomics studies were the first to show that syntaxin-11 is present in platelets.[63] Syntaxin-11 is a unique member of the syntaxin family, having an *N*-terminal, Habc, regulatory domain and SNARE motif, but lacking a classical TMD. Syntaxin-11 appears to be anchored to membranes by a, as yet to be identified, modification of its *C*-terminal cysteine residues.[75,76] Syntaxin-11 is associated with late endosomes and the *trans*-Golgi network in Hela cells.[76] Interestingly syntaxin-11 mutations are associated with Familial Hemophagocytic Lymphohistiocytosis type 4 (FHL4). FHL4 is a rare autosomal recessive disorder of immune dysregulation associated with uncontrolled T cell and macrophage activation (discussed below). Syntaxin-11–deficient NK-cells exhibit a defect in cytotoxic granules degranulation, indicating that syntaxin-11 could be involved in fusion with the plasma membrane. Analysis of platelets from an FHL4 patient suggests a role for syntaxin 11 (Ye et al., 2012, *Blood*, in press). Thus, loss of syntaxin 11 had no effect on syntaxin 2 or 4 levels, but significantly affected secretion of all three granule populations. Syntaxin 11 was also shown to form complexes with VAMP-8 and SNAP-23, further supporting its role in platelet exocytosis. Future studies should clarify how the various syntaxin proteins in platelets are used for secretion.

SNARE REGULATORS

Regulated platelet secretion only occurs in response to external signals, but how these signals are coupled to the SNARE machinery is unclear. Very few VAMP and SNAP-23/25 regulators have been identified. Based on the number of binding partners identified, it is thought that most SNARE regulation is mediated by syntaxins or syntaxin-containing complexes. Posttranslational modifications, such as phosphorylation of SNAREs or SNARE regulators could provide links from signaling to secretion.

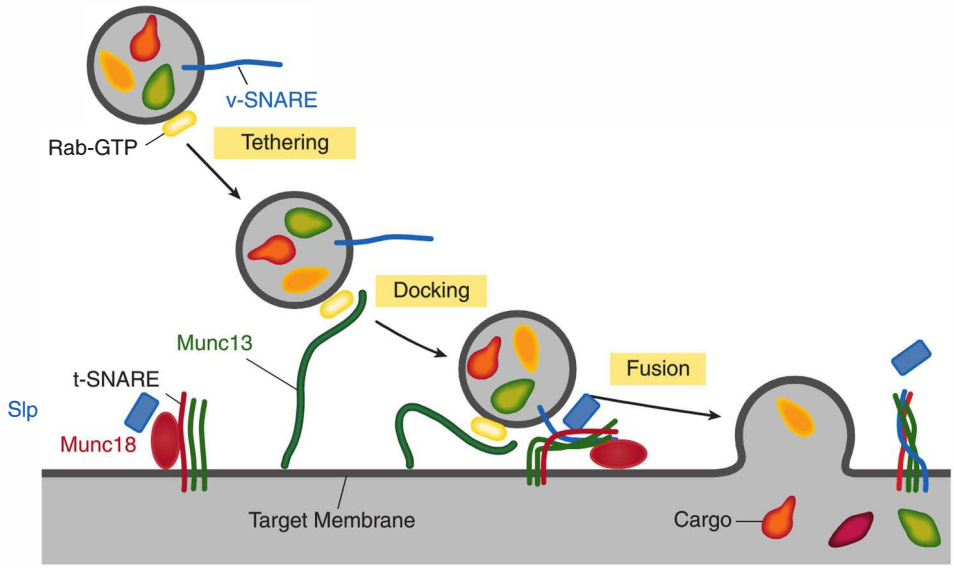

FIGURE 32.2 Platelet secretion pathway. The elements discussed in the text are arranged in a pathway of potential steps that could lead to cargo release. The SNARE proteins are proposed to mediate membrane fusion. The Munc18 proteins chaperone the t-SNAREs and perhaps participate in SNARE complex formation. The Munc13 and Rab proteins promote granule–plasma membrane tethering and docking. Docking facilitates the formation of the SNARE complexes. The role of the Slp proteins is less certain, though they do interact with Rabs and Munc18/syntaxin complexes. Tomosyn, not shown, somehow affects the t-SNARE complex before v-SNARE binding.

Several potential SNARE regulators have been identified in platelets and most are associated with t-SNARE heterodimers or t-SNARE–containing complexes. These include Munc18s, Rabs, Munc13s, Slps, and tomosyn (FIGURE 32.2).

While the SNARE proteins are sufficient for membrane fusion, they do so inefficiently and thus require accessory proteins to control where and when they interact. Many of these regulators appear to be sensitive to second messengers such as diacylglycerol (DAG) and Ca^{2+}, while others are potential kinase substrates. The Munc18 family (a, b, and c) control syntaxins and have been shown to be critical for platelet secretion.[65,77] Tomosyn may regulate t-SNARE heterodimers.[78] Munc13s bind to lipids and to SNAREs.[79] They have Ca^{2+} and DAG-binding sites and may be regulated when these secondary messengers are generated during platelet activation. Other potential SNARE regulators such as DOC2 and Slps have calcium-binding sites and thus could serve as calcium sensors.[80] The function of many of these proteins in platelets has yet to be studied.

Munc18s

Munc18s belong to the evolutionally conserved Sec1/Munc18 (SM) family, critical components of the secretory machinery[81] (FIGURE 32.2). There are three mammalian Munc18 isoforms (Munc18a, b, and c) and all have been detected in human and murine platelets by immunoblotting and/or polymerase chain reaction.[65,77,82] It has been thought that different SM family members are required for specific secretion steps through their interactions with specific syntaxins. Munc18a is almost exclusively expressed in neurons where it binds to syntaxin 1; Munc18c is expressed ubiquitously and appears to interact with syntaxin 4.[83] In platelets, Munc18a was shown to interact with syntaxin 2, Munc18c with syntaxin 4, and Munc18b was found associated with SNARE complexes[77] and with syntaxin 11 (Al Hawas et al., 2012, *Blood*, in press). Early studies suggested that Munc18c phosphorylation and Munc18c/syntaxin-4 complex formation could be important for platelet secretion.[65,82] Monoclonal antibodies that disrupted Munc18c/syntaxin-4 complexes had a positive effect on granule release from permeabilized platelets.[65] Introduction of peptides based on a conserved regulatory domain of Munc18s into permeabilized platelets inhibited Ca^{2+}-stimulated release from all three granule types.[77] Although these *in vitro* studies suggested that Munc18s are important for platelet secretion, platelets from Munc18c heterozygous mice exhibited normal release.[84] Double deletion of Munc18c is embryonic lethal.[85] Interestingly, the syntaxin-4 level is reduced approximately 50% in Munc18c heterozygous mouse platelets, which is consistent with Munc18c being the chaperone specific for syntaxin-4. The association between Munc18c and syntaxin-4 is required for the stability of both proteins.[77,84] Although *in vitro* studies suggest Munc18c plays a role in platelet secretion, the lack of secretion defect in Munc18c$^{+/-}$ platelets could be attributed to functional compensation by other Munc18s. Munc18a levels are low in human and murine platelets and although it is phosphorylated and binds syntaxin-2,[77] it is not clear if it plays any role in exocytosis. The most promising candidate for a functional Munc18 in platelets is Munc18b. Munc18b is the most abundant isoform and it was found to interact with syntaxin-11. Munc18b was also detected in pull-down experiments using SNARE complexes and t-SNARE heterodimers. Most importantly, Sandrock et al.[86] and Al Hawas et al. (2012, *Blood*, in press) showed that Munc18b-deficient platelets from FHL5 patients have a robust secretion defect, suggesting that Munc18b is required for platelet secretion. The fact that heterozygous patients have a partial

secretion defect might suggest that Munc18b is a limiting factor in the secretion process; this remains to be tested. Syntaxin-11 levels were affected in these patients.

Rabs

A pathway of protein–protein interactions has been proposed for platelet secretion in which granules are tethered and dock to the inner leaflet of the plasma membrane after which fusion of the two opposing lipid bilayers mediates cargo release.[87,88] Docking and tethering are thought to be, in part, mediated by small guanosine triphosphate (GTP)-binding proteins of the Rab family (FIGURE 32.2). The Rab subfamily of small Ras-like GTPase includes over 60 members in mammals and is thought to regulate most intracellular membrane traffic.[87,88] Platelets have been reported to contain at least 11 Rabs, although few have been shown to be functionally relevant. It is generally thought that different Rabs regulate different secretion routes through association with specific effectors. Rab6 and Rab8 are preferentially targeted to the plasma membrane and α-granules.[89] α-granule–associated Rab6 is phosphorylated upon thrombin stimulation in a protein kinase C (PKC)-dependent manner, and phosphorylation seems to increase its GTP loading.[90] Studies using a recombinant, dominant-negative mutant suggested that Rab4 regulates α-granule, but not dense granule secretion.[91] Biochemical studies have shown that the majority of Rab27 is associated with dense granules, while a small portion is located on the plasma membrane.[91] Rab27a/b is involved in both dense granule biogenesis in megakaryocytes and in platelet secretion. Deficiency of Rab27a in *ashen* mice causes "ghost" dense granules (a normal number but without contents),[92] while loss of Rab27b results in 50% reduction in both dense granule number and serotonin content[93] with normal α-granule contents and secretion. These data suggest that the Rab27 family is critical for dense granule biogenesis, but not for α-granule and lysosome biogenesis. Further, platelets from Rab27 double-knockout mice display more severe defect in serotonin secretion than knockout of Rab27b alone, suggesting that Rab27a can partially compensate Rab27b loss.[93] However, the exact role of Rab27 in dense granule secretion remains unclear. Presumably the distinct functions of Rab27 require different effectors. The fact that one of Rab27b effectors, Munc13-4, is required for platelet secretion[94,95] could explain why Rab27b plays a role in exocytosis. Further exploration of the mechanisms for Rab function in platelet secretion will clarify whether different granule secretion requires specific sets of Rab proteins, effectors, or even secretory machinery components in platelets.

Munc13s

The Munc13 family has four members: Munc13 1 to 3 are expressed in neuronal tissue; Munc13-4 is ubiquitously expressed.[96–99] Munc13s are widely believed to be vesicle priming factors (FIGURE 32.2). The strongest evidence for this comes from genetic ablation of both Munc13-1 and Munc13-2 in neurons. This abrogates synaptic vesicle priming and release.[100,101] Munc13-4 was first identified in platelets as a Rab27a-binding partner[95] and is essential for platelet secretion.[94] Mice lacking Munc13-4 have a severe bleeding diathesis, and release from dense granules is totally abolished, whereas release from α-granules and lysosomes is severely impaired. This implies that Munc13-4 mediates at least one step that is uniquely required for rapid, dense granule release, a step that is also critical for hemostasis *in vivo*. The residual secretion from α-granules and lysosomes could be due to compensation by another Munc13 family member since both Munc13-1 and Munc13-4 may be able interact with Munc18a/syntaxin-2 complex in platelets. Compared to other Munc13s, Munc13-4 does not contain a DAG-binding C1 domain, but does have two calcium/phosphatidylserine-binding C2 domains (C2A and C2B) and 2 Munc Homology Domains (MHD). Mutations in the MHD domain or deletion of C2B result in FHL3 in humans.[97] Recombinant Munc13-4 lacking C2B is a potent inhibitor of platelet secretion from permeabilized cells[94] and suggests that both the MHD domain and C2B domains are important for Munc13-4 function. It is possible that the MHD domain is required for interactions with important secretory machinery components, while C2B is important for anchoring to the plasma membrane or for regulating membrane fusion in response to Ca^{2+} signaling.

Munc13-4 is an essential component in dense granule secretion pathway. Identification of key Munc13-4 interacting partners will be an important step in understanding SNARE complex formation and membrane fusion upon stimulation. Clearly, Rab27 is a possible candidate, as are other Rab27 effectors such as members of the Slp family (see below). Another possible candidate effector is DOC2α because it has been shown to interact with other Munc13 isoforms.[102]

Synaptotagmin-Like Proteins (Slp)

Slps possess a *C*-terminal synaptotagmin-like domain with *C*-terminal tandem C2 domains (putative Ca^{2+}-dependent phospholipid binding sites) and an *N*-terminal Rab27-binding domain. There are five Slp isoforms (Slp1 to 5) in mammals.[103] Slp1 and Slp4 (or granuphilin) are present in platelets (Ye et al., *in preparation*, 2012 and Ref.[104]). Studies by Neumuller et al.[104] demonstrated that purified Slp1 can partially inhibit dense granule secretion from permeabilized platelets. Endogenous Slp1 forms a trimetric complex with Rap1GAP2 and Rab27 suggesting Slp1 is a Rab27 effector that regulates dense granule secretion (FIGURE 32.2).

Although little is known about the function of Slp4/granuphilin in platelets, it has been well studied in other secretory cells. Slp4/Granuphilin is abundantly expressed in beta cells and is considered to be essential for the stable attachment of insulin granules to the plasma membrane. There, it acts by linking Rab27a on the granule membrane with the syntaxin-1a/Munc18a complex on the plasma membrane,[105] and loss of Slp4/granuphilin causes a decrease in docked granules.[106] Slp4/Granuphilin can bind to both syntaxin-1a and Munc18a.[107–109] The enhanced insulin secretion from Slp4/granuphilin-deficient beta cells,[110] despite the docking defect, argues for it being a negative regulator. Granuphilin could have a negative effect on a step just prior to the final fusion event. It is possible that a local signal, such as increased intraplatelet calcium after stimulation, could cause dissociation of Slp4/granuphilin from the Munc18a/syntaxin-1a complex and allow SNARE assembly. Further analysis will be needed to determine what role this family plays in platelet secretion.

Tomosyn

Tomosyn-1 belongs to a family of WD-40 repeat–containing proteins associated with exocytosis, including Sro7/Sro77

in yeast, Tom1 in *Caenorhabditis elegans*, amisyn and lethal giant larvae (lgl) in mammals.[78,111–114] Two genes, tomosyn-1 and tomosyn-2, are present in mammals, but alternative splicing can produce a total of seven isoforms.[115,116] Little is known about the exact role of tomosyn-2 in secretion.[115] Tomosyn-1 is well studied in neuron and endocrine cell exocytosis. Tomosyn-1 has three isoforms (b-, m-, s-) and has several predicted phosphorylation sites. m-Tomosyn-1 was originally identified as a syntaxin-1 binding partner in rat brain tissue cell.[117] The s-tomosyn-1 and m-tomosyn-1 isoforms are enriched in synapse-specific domains while b-tomosyn-1 is ubiquitously expressed.[118] Structurally, mammalian tomosyn-1 contains an *N*-terminal WD-40 repeat, a small highly variable linker region, and a *C*-terminal v-SNARE motif.[116] Both the v-SNARE motif and *N*-terminal WD-40 repeat have been shown to inhibit secretion from PC12 cells[114] and neurons.[119] Thus, tomosyn-1 has been thought as a negative regulator for neurotransmitter release events. Consistently, deletion of tomosyn-1 enhances secretion.[119] Overexpression of tomosyn-1, in PC12 cells, reduces the ready-release pool and the resident time of secretory vesicles.[120] This observation is consistent with the hypothesis that tomosyn-1 functions by controlling vesicle priming.

It has also been suggested that the *N*-terminal WD-40 domain may catalyze the formation of nonfunctional SNARE complexes[121] or, through its loop region, by interacting with unknown factors.[122] Alternatively, the *C*-terminal v-SNARE domain could block v-SNARE binding to t-SNAREs, thus inhibiting membrane fusion and exocytosis. Posttranslational modifications, such as phosphorylation, have been suggested to regulate this process.[123] Despite these data, the exact mechanism by which tomosyn-1 functions as negative regulator remains unclear. Although data support a negative role for tomosyn, tomosyn also has been shown to have a permissive role. Overexpression of tomosyn in neurons enhances secretion,[123] and in chromaffin cells, it enhances the sustained component of exocytosis.[114,120] Moreover, depletion of both Sro7/Sro77 (yeast tomosyn) inhibits secretion, and knockdown of tomosyn in β-cell results in a secretion defect.[124] This suggests that tomosyn could function as place holder for v-SNAREs and positively regulate *trans*-SNARE complex formation.

The role of tomosyn in platelets has yet to be clarified. Tomosyn-1 was first identified in platelets by mass spectrometry as a specific binding partner of purified t-SNARE complexes (Ye et al., *in preparation*, 2012). The most abundant isoform of tomosyn in platelets is m-tomosyn, which is similar to that in β-cells.[124] Whether other isoforms of tomosyn-1 or tomosyn-2 are present in platelet is unknown. Platelets from tomosyn-1–deficient mice have a normal aggregation phenotype, but a partial secretion defect when compared to platelets from normal littermates. It is noteworthy that tomosyn-deficient mice manifest a robust bleeding phenotype in two *in vivo* thrombosis models, further suggesting that tomosyn plays an essential role for hemostasis (Ye et al., *in preparation*, 2012).

IMPORTANCE OF PLATELET SECRETION

In humans, defective platelet granule release presents as a mild to moderate bleeding diatheses. While generally not life threatening, this does increase the bleeding risks following traumatic and iatrogenic vascular damage. The two major class of storage pool deficiencies (SPD), Hermansky-Pudlak syndrome (HPS, δSPD)[7,125–127] and gray platelet syndrome (GPS, αSPD),[10,128,129] are characterized by the loss of cargo from dense granules and α-granules, respectively. There are 15 HPS-like mouse strains that have similar defects. Cloning of the defective genes and the subsequent analysis of their products has shown that the phenotypes are related to dysfunctional sorting of dense granule proteins during biogenesis.[126,127] Most of the HPS genes encode proteins that participate in the sorting of cargo from and through endosomal compartments. GPS patients present with more heterogeneous bleeding defects but generally have normal pigmentation. Less is known about the underlying molecular defects that cause GPS, though one knockout mouse strain (transcription factor Hzf$^{-/-}$) does display a loss of α-granule cargo.[130] In this strain, initial bleeding times are normal, but the incidence of rebleeding is increased. Mutations in the NBEAL2 gene have been identified as being associated with GPS.[131–133] This gene encodes a BEACH (beige-Chediak-Higashi)-domain-containing protein which is a member of a family that has been linked to other membrane trafficking events. Its function is unclear at present. One striking feature of GPS patients is that all have myelofibrosis.[10] This is perhaps due to the inability of the megakaryocytes to retain synthesized growth factors. Consistently, plasma levels of platelet factor IV (PF4) and β-thromboglobulin (both are α-granule cargoes) are elevated in GPS patients. Little is known about the consequences of the inappropriate distribution of α-granule cargo. Patients with loss of both types of granules are rare and do have bleeding defects.[134,135]

Platelet Secretion in Therapy and Diagnosis

The goal of antithrombotic therapies is to devise a regimen that dampens thrombosis without inducing excessive bleeding. The secretory machinery might prove an effective target to accomplish this goal. *In vivo* analysis of the VAMP-8$^{-/-}$ mice shows a clear defect in laser-induced arteriole thrombosis, but one not as complete as in an HPS mouse.[8] Thrombi in VAMP-8$^{-/-}$ mice display a significant delay in initiation as well as a lack of stability. However, thrombi do form, and there is no significant difference in tail-bleeding times in these animals. These data suggest that targeting the platelet's primary secretory machinery might be an effective way to manage thrombosis *in vivo* and thus limit clot formation without inducing excessive bleeding. Future analysis of other mouse strains with secretion-deficient platelets is ongoing to validate this concept and to probe the additional roles that platelet exocytosis might play in the vasculature.

FHL is a rare immune disorder characterized by proliferation of cells of the mononuclear phagocyte system (histiocytes) and hyperinflammation.[136–138] Typical clinical features include fever, hepatosplenomegaly, lymphadenopathy, jaundice, rash, and laboratory findings of lymphocytosis, histiocytosis, and hemophagocytosis. Five genes have been associated with FHL. FHL1 is associated with a potential gene locus (9q21.3-q22) but the specifically involved gene has not been identified.[139] The perforin gene (PFR1) mutations at 10q21-22 locus were described as the causative gene for FHL2.[140] Perforin is a toxin in cytotoxic granules that is essential for natural killer (NK) and cytotoxic T lymphocyte (CTL) cell-mediated killing. This pore-former plays a critical role in maintaining immune homeostasis.[141] Mutations in the genes encoding *Munc13-4* (FHL3), *Syntaxin-11* (FHL4), and *Munc18b* (FHL5) have been

shown to be involved in cytotoxic granule exocytosis from CTL and NK cells.[97,142,143] Detection of perforin, Munc13-4, syntaxin-11, and Munc18b expression in NK cells by fluorescence activated cell sorting (FACS) or immunoblotting analysis is a reliable method to screen for FHL2-5. However, these analyses may not be readily available to all patients. Although a consensus set of criteria for diagnosis of FHL was established in 2004 by the Histiocyte Society and was revised in 2007,[136] diagnosis is still difficult since most criteria are not specific. In reality, patients may be missed because some initial symptoms are rather nondescript,[137] may be disguised as a normal infection, or may overlap with some immune-deficient disorders. Thus, it is critical to find reliable methods for early screening in order to initiate therapy. Based on the studies of Munc13-4 (FHL3), syntaxin-11 (FHL4), and Munc18b (FHL5), it seems that analysis of platelet secretion might prove to be a valuable tool for diagnosing FHL.

Dysfunction of Munc13-4 (FHL3), syntaxin-11 (FHL4), and Munc18b (FHL5) all lead to a secretion defect that could be detected with simple platelet assays. Lumi-aggregometry to measure ATP release from dense granules or FACS analysis to measure P-selectin or LAMP-1 exposure from α-granules or lysosomes, respectively, are relatively simple and readily available assays that could be performed on small blood samples. A defect in secretion from platelets would suggest further tests and perhaps accelerate the diagnosis of FHL. Future analysis will be required to validate this approach. However, it should be noted that Murata et al.[144] have shown that FACS analysis of intraplatelet Munc13-4 protein is a sensitive and reliable method to screen for FHL3.

SUMMARY

Platelet secretion is clearly important for hemostasis and definitely contributes to the microenvironment at the site of vascular damage as well. Release of platelet granule cargo is mediated by SNARE proteins and regulated by proteins that control how SNAREs interact. In turn, these SNARE regulators integrate signals from the signaling cascades initiated by the numerous cell surface receptor proteins. Understanding how these signals control the secretory machinery has increased substantially over the last decade, and potentially relevant therapeutic targets are beginning to be uncovered, suggesting that directly modulating platelet secretion maybe a potentially useful way to affect thrombosis.

CHAPTER

33 Platelet Signal Transduction

CHARLES S. ABRAMS AND LAWRENCE F. BRASS

Platelets become activated when agonists such as collagen or thrombin bind to receptors on the platelet surface, initiating intracellular signaling events that eventually lead to reorganization of the platelet cytoskeleton, platelet aggregation, and platelet granule secretion. This process can only occur when local barriers to platelet activation are exceeded or overwhelmed. Platelets are normally shielded from the connective tissue matrix within the vascular wall by a continuous barrier of endothelial cells which physically separates platelets from platelet activators in the vessel wall. When vascular injury occurs, platelets adhere to exposed collagen fibrils, forming a discontinuous carpet. *In vitro*, adhesion to collagen can occur without the help of accessory molecules, but *in vivo*, the shear forces and turbulence caused by flowing blood would strip platelets away from collagen were it not for the stabilizing effects of von Willebrand factor (vWF). The metalloprotease ADAMTS13 cleaves vWF to prevent the accumulation in plasma of ultrahigh molecular weight multimers that would otherwise cause spontaneous platelet clumping and arterial thrombosis.[1,2,3,4] vWF binding to collagen *via* its A3 domain exposes binding sites on the vWF A1 and C1 domains for the platelet adhesion receptors, GP Ib-IX-V and $\alpha_{IIb}\beta_3$ (GP IIb-IIIa), respectively.[5,6] Combined with the activating signals produced when collagen binds directly to the $\alpha_2\beta_1$ integrin and to glycoprotein VI on the platelet surface, platelets that have adhered to collagen change their shape, spreading along the collagen fibrils, and releasing into the circulation thromboxane A_2 (TxA_2) and adenosine diphosphate (ADP) (FIGURE 33.1).

Released TxA_2 and ADP recruit additional platelets, causing them to stick to each other and to the platelets directly adherent to collagen. The growing mound of activated platelets is eventually stabilized by a crosslinked fibrin clot, but the critical contact between adjacent platelets depends on the binding of fibrinogen or fibrin to $\alpha_{IIb}\beta_3$ on the platelet surface, and this occurs only after platelets have been activated. Since fibrinogen is a symmetrical molecule, it can bind to two platelets at the same time, as can fibrin. Repeated as many as 80,000 times per platelet, this allows platelets to stick to each other, a process that can be made to occur when platelets are in suspension, but should normally occur only at a site of vascular injury. Like collagen, soluble platelet agonists cause platelets to change their shape, losing the discoid appearance characteristic of resting platelets, and transform them into an irregular sphere with pseudopodia. Underlying this shape change is rapid reorganization of the platelet cytoskeleton as actin filaments are uncapped, severed, and rebuilt in response to intracellular signals that include a rise in the cytosolic Ca^{2+} concentration and the sequential activation of low molecular weight GTP-binding proteins such as Rac and Rho.

Collagen, ADP, and TxA_2 are not alone in their ability to activate platelets. Vascular injury and inflammation expose tissue factor as well as collagen, and formation of the tissue factor/factor VIIa complex leads to the local generation of thrombin from prothrombin. Thrombin is a potent agonist, activating platelets at concentrations in the pM range by interacting with receptors on the platelet surface. Activated platelets facilitate this process by providing procoagulant phospholipids that accelerate thrombin generation. As a result, platelet activation and fibrin deposition are intimately linked, maximizing the growth and strength of the hemostatic plug. Human platelets express two G-protein–coupled receptors (GPCRs) that can be activated by thrombin. Cleavage of these receptors accounts for the long-established observation that only proteolytically active thrombin can activate platelets.

The process of transforming $\alpha_{IIb}\beta_3$ on the platelet surface into a competent receptor for fibrinogen is one of the most fascinating aspects of platelet biology.[7] It is also the final common pathway in platelet responses to most agonists, making it a frequent target for drug development. Stated succinctly, the central issue is this: although circulating platelets are surrounded by plasma proteins, they normally do not bind fibrinogen to their surface and stick to each other unless they have been activated. The reasons for this are multiple, but are ultimately due to the inability of fibrinogen or fibrin to bind to the resting conformation of $\alpha_{IIb}\beta_3$. Platelet activation alters the conformation of $\alpha_{IIb}\beta_3$ and exposes the fibrinogen-binding site. Normally, this should occur only at sites of vascular injury. However, even in the absence of substantial vascular injury, it is likely that the buffeting that platelets withstand as they move through the circulation, perhaps encountering low concentrations of thrombin or fractured atherosclerotic plaques, pushes them toward inappropriate activation.

Working against this tendency are a number of internal and external controls that dampen intracellular signals that would otherwise promote platelet activation. In addition to providing a physical barrier and a source of vWF, endothelial cells release PGI_2 and NO, two molecules that globally depress intracellular signaling in platelets by raising cyclic AMP (cAMP) and cGMP levels.[8–14] The ability of cyclic nucleotides to inhibit platelet activation has been exploited in the development of antiplatelet agents such as dipyridamole (Persantine), which raises cAMP levels inside platelets by inhibiting cAMP phosphodiesterase.[15] Cyclic GMP also inhibits cAMP phosphodiesterase in platelets, contributing to the rise of cAMP levels. In turn, cAMP activates protein kinase A, which phosphorylates multiple platelet proteins including the β chain of GP Ib,[16,17] actin-binding protein (filamin),[18] myosin light chain,[19,20] vasodilator-stimulated phosphoprotein (VASP),[21,22] and Rap1B.[23] The net effect is a generalized inhibition of platelet activation. The importance of PGI_2

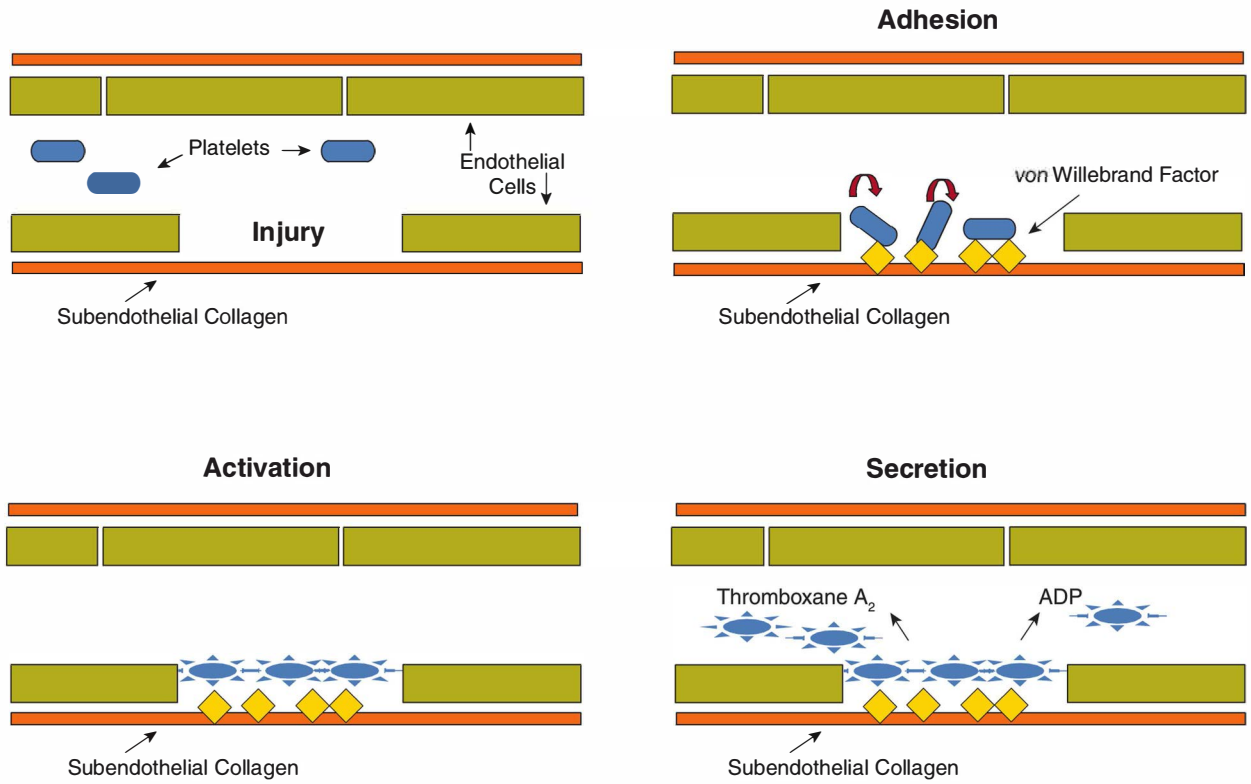

FIGURE 33.1 Stages in platelet plug formation. Prior to vascular injury, platelets are restrained from activation by the inability of plasma vWF to bind spontaneously to the platelet surface. The development of the platelet plug can be initiated by the exposure of collagen in the vessel wall or by the local generation of thrombin (or both). Rolling platelets adhere and spread on the collagen/vWF matrix, forming a monolayer of activated platelets that acts as a surface for subsequent recruitment of platelets by thrombin, ADP, and TxA_2.

and NO as barriers to platelet activation is indicated not only by the effectiveness of molecules that mimic PGI_2 as antiplatelet agents, but also by the prothrombotic effects in mice of deleting the gene encoding the platelet PGI_2 receptor (IP)[24] and by the decrease in basal cAMP levels found in $IP^{-/-}$ platelets.[25] In addition to releasing PGI_2 and NO, some endothelial cells express the *ecto*-ADPase CD39 on their luminal surface. CD39 can hydrolyze the small quantities of ADP released from damaged red cells and activated platelets, preventing the ADP from activating additional platelets.[26,27] Other barriers to unwarranted platelet activation include the diluting effects of continued blood flow, the presence of natural anticoagulants that limit thrombin formation, the short half-life of the platelet-derived agonist, TxA_2, and a variety of mechanisms that limit the duration of signaling by G proteins and GPCRs. This includes receptor desensitization, receptor internalization, and regulators of G-protein signaling (RGS) proteins. Collectively, these provide a threshold that helps to prevent platelet activation at inappropriate times and places.

THREE STAGES OF PLATELET PLUG FORMATION

One might consider the platelet surface as being crowded with receptors that support one or more of the phases of platelet plug formation. In fact, approximately half of the platelet's surface is occupied by $\alpha_{IIb}\beta_3$. Receptors that are directly involved in binding to adhesive proteins such as collagen, vWF, and fibrinogen are present in the greatest numbers. After recruitment of additional pools of receptors that are initially within the surface-connecting membrane system or in the membranes of α granules, there are approximately 80,000 copies of $\alpha_{IIb}\beta_3$ and 15,000 copies of GP Ib on the surface of human platelets (these receptors are also discussed in Chapters 26A, 26B, and 31). In contrast, receptors that primarily serve as signaling response elements for platelet agonists typically range from a few hundred to a few thousand per platelet (Table 33.1). Although these numbers are not large in absolute terms, when placed in the context of the relatively small size of human platelets, the density of these receptors is high. In cells other than platelets, it has been shown that some signaling molecules tend to be concentrated within or near cholesterol-enriched microdomains within the plasma membrane.[28] There is growing evidence that this occurs in platelets as well, increasing the efficiency of platelet activation.[29–31]

The platelet monolayer that forms following the exposure of collagen and vWF initiates platelet plug formation but is insufficient to prevent bleeding. The extension or recruitment phase of platelet plug formation occurs when additional activated platelets accumulate on top of the monolayer.[32,33] Recruitment is mediated by the local accumulation of molecules that are released from platelets, such as ADP and TxA_2. Contacts between platelets are maintained by a variety of molecular interactions, of which

Table 33.1

GPCRs expressed on human platelets

Agonist	Receptor	Approximate Number of Copies per Platelet	G-Protein Families	Reference
ADP	$P2Y_1$	150	G_q	109,110
	$P2Y_{12}$	600	G_i	65
Thrombin	PAR1	2,000	G_q, G_{12}	73,88,89,213,214
	PAR4	Unknown	G_q, G_{12}	215
TxA_2	TPα and TPβ	1,000	G_q, G_{12}	129–131,216–218
Epinephrine	α_{2A}-adrenergic	300	G_i (particularly G_z)	121,122,219
PGI_2	IP	Unknown	G_s	220

the best described, and most critical, is binding of fibrinogen and vWF to activated $\alpha_{IIb}\beta_3$. Thrombin continues to participate in this phase of platelet activation and, in turn, activated platelets provide a procoagulant surface on which more thrombin can be generated *via* assembly of the tenase and prothrombinase coagulation complexes. Circulating or locally secreted epinephrine causes vasoconstriction, but also potentiates the effects of other platelet agonists. In contrast to platelet activation by collagen, platelet activation by most of the agonists involved in extension of the platelet plug is very rapid, with some responses occurring within a fraction of a second. Teleologically, this makes sense since circulating platelets would not be expected to linger at a wound site long enough for a slower process to occur. Videos of thrombus formation at sites of focal vascular injury show that initially most platelets move by the site of injury at speeds too rapid for activation to occur.[32] Tethering to vWF-decorated collagen or to previously deposited platelets allows new platelets to remain in place long enough to become activated.

Formation of the platelet plug following vascular injury can be thought of as involving three stages: adhesion, activation, and secretion (FIGURE 33.1). Adhesion begins with the rolling, arrest, and activation of moving platelets by the collagen/vWF complex to form a platelet monolayer. Activation refers to the recruitment of additional platelets through the stimulation by fast-acting agonists such as thrombin, ADP, and TxA_2, all three of which activate platelets *via* GPCRs on the platelet surface. Secretion of additional agonists and adhesive ligands perpetuates these events by recruiting additional platelets to participate in the formation of the platelet plug. These definitions are arbitrary, since the adhesion of platelets to collagen and vWF also initiates some of the early stages of activation. In addition to these functionally defined stages in platelet plug formation, stable contacts between platelets make possible an additional wave of intracellular signaling that reinforces platelet activation. This "contact dependent" signaling is mediated in part by adhesion molecules such as $\alpha_{IIb}\beta_3$ and in part by platelet surface ligands such as ephrinB1 and sema4D that bind to receptors on the surface of adjacent platelets.[34]

PLATELET ADHESION

The arrest and eventual activation of moving platelets by collagen is accomplished by receptors on the platelet surface that either bind directly to collagen (GP VI and the integrin $\alpha_2\beta_1$) or bind indirectly to collagen *via* vWF (the GP Ib/IX/V complex and the integrin $\alpha_{IIb}\beta_3$). The integrins require prior activation *via* intracellular "inside-out" signaling to engage collagen and vWF, after which they can contribute further platelet activation by generating outside-in signals. The presence of collagen and vWF-binding sites on GP VI and GP Ibα allows platelets to slow down long enough to become activated and fully adherent. Platelet activation by collagen is summarized in FIGURE 33.2. Intracellular signaling in response to collagen is mediated by at least three receptors: GP VI, GP Ib, and, after integrin activation has occurred, $\alpha_2\beta_1$. The structure of GP VI places it in the immunoglobulin domain superfamily. Its ability to generate signals rests primarily on its constitutive association with a second molecule, the Fc receptor γ-chain.[35] Platelets from mice that lack the γ-chain[36] have impaired responses to collagen. So do platelets from humans,[37,38] but possibly not mice,[39] with reduced expression of $\alpha_2\beta_1$. Using blocking antibodies or a depletion strategy, Nieswandt et al.[39] concluded that GP VI is required for platelet responses to collagen.

Signaling through GP VI can be studied in isolation with the snake venom protein, convulxin, or with synthetic "collagen-related" peptides. According to current models, collagen causes clustering of GP VI and its associated Fc receptor γ-chain. This promotes phosphorylation of the γ-chain by nonreceptor tyrosine kinases in the Src family, creating an immunoreceptor tyrosine-based activation motif recognized by the tandem SH2 domains of Syk. Association of Syk with the GP VI/γ-chain complex activates Syk and leads to the phosphorylation and activation of phospholipase C (PLC) γ_2. Loss of Syk impairs collagen responses.[36] PLCγ PLCg2 hydrolyzes membrane PI-4,5-P_2 to form the second messengers 1,4,5-IP_3 and 1,2-diacylglycerol (DAG). IP_3 opens Ca^{2+} channels in the platelet-dense tubular system (DTS), raising the cytosolic Ca^{2+} concentration and triggering Ca^{2+} influx across the platelet plasma membrane that is initiated when depletion of the DTS Ca^{2+} pool triggers a conformational change in the DTS membrane protein, STIM1, allowing it to bind to Orai1 in the plasma membrane.[40] DAG and Ca^{2+} activate the more common protein kinase C (PKC) isoforms that are expressed in platelets, making possible the regulatory serine/threonine phosphorylation events that are needed for platelet activation. At least one of those phosphorylation events regulates the exposure of fibrinogen-binding sites on $\alpha_{IIb}\beta_3$, but the full mechanism for activating $\alpha_{IIb}\beta_3$ remains obscure. Events

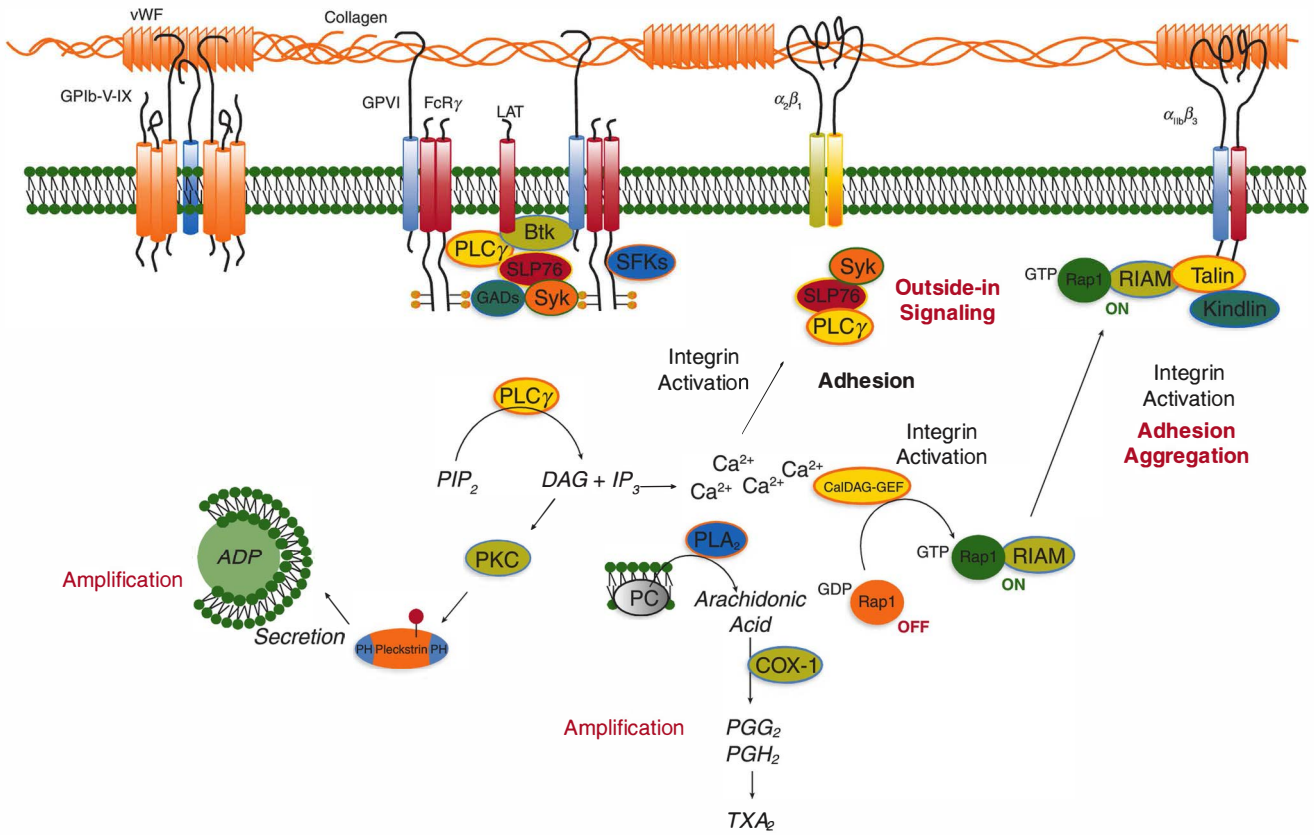

FIGURE 33.2 Platelet activation by collagen. Platelets use several different molecular complexes to support platelet activation by collagen. These include (a) vWF-mediated binding of collagen to the GPIb-IX-V complex and integrin $\alpha_{IIb}\beta_3$, (b) a direct interaction between collagen and both the integrin $\alpha_2\beta_1$ and the GPVI/FcRγ-chain complex. Clustering of GPVI results in the phosphorylation of tyrosine residues in the FcRγ cytoplasmic domain, followed by the binding and activation of the tyrosine kinase, Syk. One consequence of Syk activation is the phosphorylation and activation of PLCγ, leading to phosphoinositide hydrolysis, secretion of ADP, and the production and release of TXA_2. COX-1, cyclooxygenase 1; DAG, diacylglycerol; GP, glycoprotein; PG, prostaglandin; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLA_2, phospholipase A_2; PLCγ, phospholipase Cγ; TXA_2, thromboxane A_2; vWF, von Willebrand factor.

triggered by GP VI lead to activation of $\alpha_2\beta_1$ as well as $\alpha_{IIb}\beta_3$. Engagement of the two integrins with their respective ligands initiates a further round of signaling that features some of the same molecules that are downstream of GP VI: Syk, SLP-76, and PLCγ_2.[41] This is a theme that repeats itself during platelet activation: different agonists with disparate receptors trigger signaling events that involve a common set of intermediates. Outside-in signaling is discussed at greater length in the last section of this chapter.

Finally, GP Ib serves both as an anchor point for the platelet cytoskeleton and as the focus for assembling signaling complexes in platelets that have become bound to vWF. The cytoplasmic domain of GP Ibα can bind to filamin and to the scaffolding protein, 14-3-3ζ. Src becomes associated with GP Ib following vWF binding. The p85 subunit of PI3-kinase appears to mediate this association. In turn, Syk is activated. Thus, signaling through GP Ib takes advantage of some of the same signaling molecules that are involved in GP VI- and integrin-dependent responses to collagen, with the same potential for causing protein tyrosine phosphorylation, PI-4,5-P2 hydrolysis, and recruitment of cytosolic proteins whose Pleckstrin homology (PH) domains can support associations with 3-phosphorylated phosphoinositides.[42–49]

PLATELET ACTIVATION BY SOLUBLE AGONISTS

The agonists involved in extension of the platelet plug typically cause platelet activation *via* GPCRs on the platelet surface. GPCRs are well suited for this task in a number of respects. First, most of these receptors bind ligands with high affinity. Second, GPCRs comprise a single subunit that does not require oligomerization (although recent studies have shown that some GPCRs exist as homo- or heterodimers even in the absence of their ligands).[50–52] Third, GPCRs are constitutively associated with G proteins, eliminating the time that would otherwise be required to recruit them into complexes.[50] Fourth, because they act as guanine nucleotide exchange factors, each occupied receptor can activate multiple G proteins and, in some cases, more than one class of G proteins. This allows amplification of a signal that might begin with a relatively small number of receptors. It also enables some receptors to signal *via* more than one

effector pathway. Finally, because several generic mechanisms exist that can limit the activation of GPCRs, platelet activation can be limited, a property that may be useful when platelet activation is inappropriate and needs to be contained.[34]

GPCRs comprise a single polypeptide chain with seven transmembrane domains, an extracellular *N*-terminus, and an intracellular *C*-terminus. Binding sites for agonists can involve the *N*-terminus, the extracellular loops, or a pocket formed by the transmembrane domains.[50] The G proteins that act as mediators for these receptors are heterotrimers comprised of α, β, and γ subunits. Within this complex, the β subunit forms a propeller-like structure that is tightly associated with the much smaller γ subunit. The α subunit contains a guanine nucleotide-binding site that is normally occupied by GDP. Receptor activation causes the exchange of GTP for GDP, altering the conformation of the α subunit and exposing sites on both G_α and $G_{\beta\gamma}$ for interactions with downstream effectors.[53–55] Hydrolysis of the GTP by the intrinsic GTPase activity of the α subunit restores the resting conformation of the heterotrimer, preparing it to undergo another round of activation and signaling.[56] A family of GTPase activating proteins known as RGS proteins help to accelerate the hydrolysis of GTP by G_α.[57] Prenylation of the γ chain and acylation of the α subunit helps to anchor the complete heterotrimer to the plasma membrane and continues to anchor G_α-GTP and $G_{\beta\gamma}$ to the membrane when they dissociate from each other to expose effector binding sites. Platelets express 10 forms of G_α (Table 33.2). Although there is little information about which types of G_β and G_γ are expressed in platelets, the forms of G_α identified have included at least one $G_{s\alpha}$ family member, four $G_{i\alpha}$ family members, three $G_{q\alpha}$ family members, and two $G_{12\alpha}$ family members. The roles of each have been defined through knockout studies in mice.[58] Based on the available evidence, the abundance of G-protein types in platelets appears to be necessary to support the actions of multiple dissimilar platelet agonists.[25]

GPCRs and Platelets

The GPCRs that respond to platelet agonists differ in their potency and their preferences for intracellular effector pathways. Some, such as the receptors for thrombin (PAR1 and PAR4), TxA_2 (TP), and ADP ($P2Y_1$), cause phosphoinositide hydrolysis and raise the cytosolic Ca^{2+} concentration by activating G_q (FIGURE 33.3).[59] Others, such as the $P2Y_{12}$ receptor for ADP and the α_{2A}-adrenergic receptor for epinephrine, are coupled by G_{i2} and G_z, respectively, to the inhibition of adenylyl cyclase and the activation of PI3-kinase and Rap1B.[25,60–62] Optimal platelet activation *via* GPCRs is thought to require activation of both a G_q-coupled receptor and a G_i-coupled receptor.[63] The ability of the four G_i family members that are expressed in platelets to inhibit adenylyl cyclase, thereby decreasing cAMP formation, is most relevant when PGI_2 secreted by endothelial cells has inhibited platelet activation by raising platelet cAMP levels.[25] Otherwise, it is likely that other G_i effectors account for the required G_i-coupled receptor activation during platelet activation. The biological relevance of the G_{i2}-coupled $P2Y_{12}$ receptor for ADP is supported by the phenotypes of G_{i2} and $P2Y_{12}$ knockout mice and by the efficacy of $P2Y_{12}$ antagonists such as clopidogrel and prasugrel as antiplatelet agents.[25,62,64,65,66] Thrombin and TxA_2 receptors can also cause the rearrangement of the actin cytoskeleton that underlies platelet shape change by coupling to guanine nucleotide exchange factors for Rho *via* G_{12} and G_{13}.[67] In cells other than platelets, the link from G_{12} family members to Rho activation is provided by proteins with RGS

Table 33.2

G-proteins in platelets

Family	G-Protein	Effectors	Function	Reference
G_q	$G_{q\alpha}$ (the G_q predominant isoform)	PLC	↑ IP_3/DAG	221,222
	$G_{11\alpha}$	PLC	↑ IP_3/DAG	221,222
	$G_{16\alpha}G_{15\alpha}$ in mice	PLC	↑ IP_3/DAG	223–226
G_{12}	$G_{12\alpha}$, $G_{13\alpha}$	p115-RhoGEF?	Actin cytoskeleton	67,132,222,227
G_i	$G_{i2\alpha}$>$G_{i3\alpha}$>>$G_{i1\alpha}$	Adenylyl cyclase, other effectors?	↓ cAMP	228
	$G_{z\alpha}$	Adenylyl cyclase, other effectors?	↓ cAMP	229–231
	$G_{\beta\gamma}$ from G_i family members	PLCβ	↑ IP_3/DAG	
		PI3K(γ)	↑ 3-PPIs	
G_s	$G_{s\alpha}$	Adenylyl cyclase	↑ cAMP	223

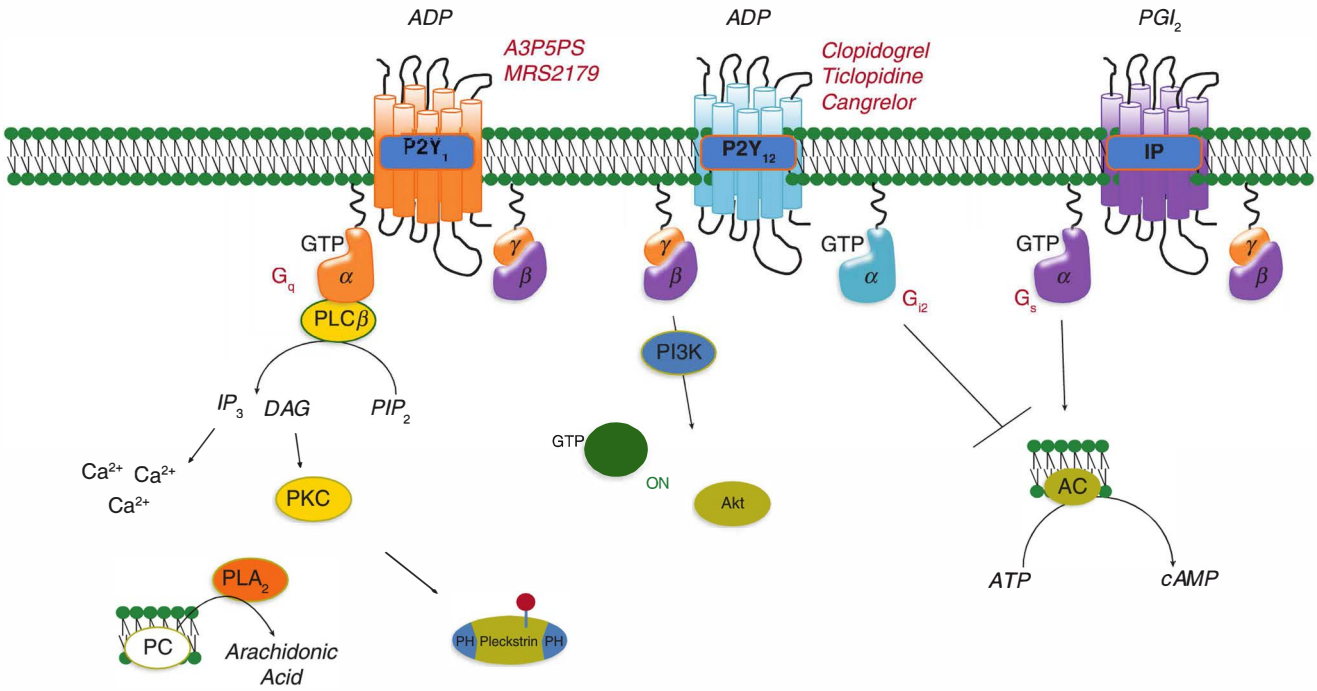

FIGURE 33.3 Platelet activation by ADP. Two receptors that can be activated by ADP have been identified in platelets. $P2Y_1$ and $P2Y_{12}$, which are coupled to different G proteins and therefore mediate different responses. G_q couples $P2Y_1$ receptors to the activation of PLCβ. The G_i family member, G_{i2}, couples $P2Y_{12}$ to the inhibition of cAMP formation (*via* $G_{i2\alpha}$) and to effector pathways that include PI3K and Rap1B (*via* $G_{\beta\gamma}$).

domains (for binding to G_α) and DBL-PH domains (for causing guanine nucleotide exchange on Rho family members)—proteins such as p115 RhoGEF, LARG, and PDZ-RhoGEF.[68] Which, if any, of these proteins plays a role in platelets remains to be determined.

Platelet responses to agonists such as thrombin, ADP, TxA_2, and epinephrine can be mediated by a single class of receptors coupled to different families of G proteins, by multiple classes of receptors each coupled to a single family of G proteins, or by the cumulative effect of two or more agonists, each of which evokes only a subset of the necessary G-protein–mediated responses.[69,70] The next section illustrates how this is thought to occur for several essential agonists, beginning with thrombin.

Platelet Activation by Thrombin

Thrombin activates platelets at concentrations as low as 0.1 nM (~ 0.01U/mL). Within seconds, the cytosolic Ca^{2+} concentration increases 10-fold to approximately 1 μM, triggering downstream Ca^{2+}-dependent events, including the activation of phospholipase A_2. Of these responses, platelet aggregation, phosphoinositide hydrolysis, and the increase in cytosolic Ca^{2+}, but not platelet shape change, are absent in platelets from mice lacking $G_{q\alpha}$.[59] Thrombin also activates Rac and Rho in platelets, leading to rearrangement of the actin cytoskeleton and shape change—presumably mediated by a combination of effector pathways coupled to G_{12} and G_q activation. Finally, thrombin is able to inhibit adenylyl cyclase activity in human platelets, either directly *via* a G_i family member coupled to a thrombin receptor[71] or indirectly *via* released ADP.[72]

Thrombin activates platelets *via* GPCRs of the protease-activated receptor (PAR) family, the first member of which, PAR1, was identified in the Coughlin[73] and Pouysségur[74] laboratories (reviewed at greater length in reference).[75] Prior work had shown that platelet responses to thrombin require the enzyme's proteolytic activity and are mediated by G proteins. Binding studies had identified high-affinity interactions with several sites on the platelet surface, including GP Ibα, but efforts to establish any of these as a receptor in the signaling sense were not entirely successful. Substrates for thrombin were identified on the platelet surface, including GP V. However, cleavage of GP V did not appear to be required for platelet activation by thrombin.

Four PAR family members have been identified, three of which (PAR1, PAR3, and PAR4) are thrombin receptors. Studies on PAR1 established a paradigm that applies to some of the other family members as well (FIGURE 33.4). PAR1 is normally activated when thrombin binds to the receptor *N*-terminus, cleaves it, and exposes a new *N*-terminus that serves as a tethered ligand. Given sufficient substrate recognition, proteases other than thrombin can also activate PAR1 or, by cleaving in the "wrong" place, render the receptor unresponsive to a subsequent addition of thrombin.[76] The contact sites for the newly exposed tethered ligand have been localized to the membrane-proximal region of the *N*-terminus and parts of the second extracellular loop.[77–79] Because the ligand is not free to diffuse away from the receptor, it is thought to effectively present a high local concentration at the receptor and perhaps maintain signaling longer than would otherwise occur. Peptides corresponding to the tethered ligand domain (SFLLRN) can also

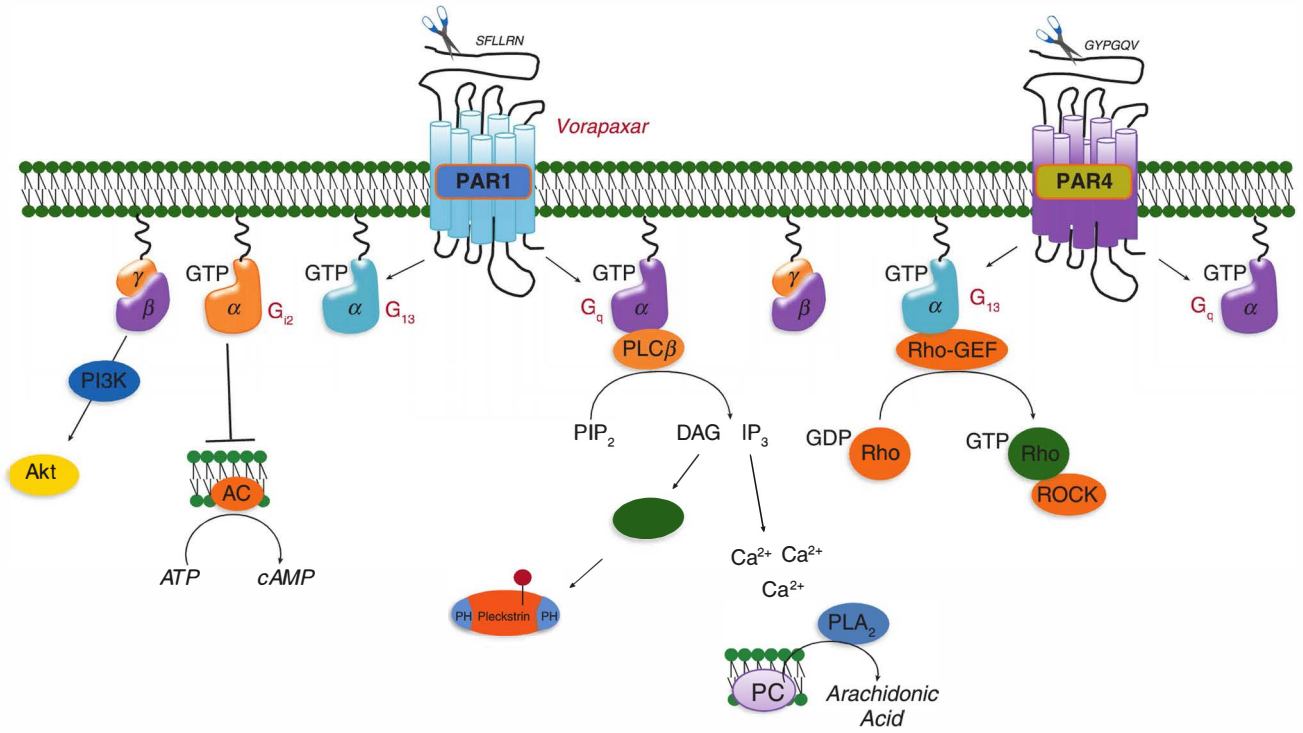

FIGURE 33.4 Platelet activation by thrombin. Platelet responses to thrombin are mediated by members of the PAR family. Human platelets express PAR1 and PAR4, which collectively are coupled to G_q- and G_{13}-mediated effector pathways. PAR1 can also couple to G_{i2}, but G_i-dependent signaling initiated by thrombin gets an additional boost from secreted ADP through $P2Y_{12}$ receptors. PAR1 (and presumably PAR4) are also subject to cleavage by proteases other than thrombin. Cleavage in the *N*-terminus by these proteases can activate PAR1 by exposing the tethered ligand domain or disable it by cleaving it elsewhere in the *N*-terminus that does not expose a competent tethered ligand.

activate PAR1, mimicking the effect of thrombin.[73,80] The same is true for PAR2 and PAR4, but not PAR3.

PAR1 was identified by expression cloning. The second PAR family member to be identified, PAR2, was cloned serendipitously. PAR2, expressed by endothelial cells, but not by platelets, can be cleaved and activated by trypsin, tryptase, TF/VIIa, and by factor Xa,[81,82] but not by thrombin.[83,84] The third family member, PAR3, was identified after gene ablation studies showed that platelets from mice lacking PAR1 were still responsive to thrombin.[85] PAR3 is a major regulator of thrombin responses in mouse platelets, but appears to do so solely by facilitating cleavage of PAR4.[86,87] PAR4 is expressed on human and mouse platelets and accounts for the ability of platelets from PAR3 knockout mice to respond to thrombin.[88,89] Simultaneous inhibition of human PAR1 and PAR4 with blocking antibodies or small-molecule antagonists completely abolishes platelet responses to thrombin,[90] as does deletion of the gene encoding PAR4 in mice.[91] Thus, the four PAR family members have some features in common, but there are differences among them as well. PAR1 and PAR3 have similar thrombin dose/response curves, while PAR4 requires 10- to 100-fold higher concentrations of thrombin, apparently because it lacks the hirudin-like sequences that interact with thrombin's anion-binding exosite and facilitate receptor cleavage.[87–89,92] Loss of PAR3 expression on mouse platelets shifts the thrombin dose/response curve to the right,[88] whereas loss of PAR4 abolishes thrombin responsiveness.[91]

Together, current evidence suggests that thrombin activates human platelets by cleaving and activating PAR1 and PAR4 (FIGURE 33.4). In turn, these receptors promote guanine nucleotide exchange on G_q, G_{12}, and G_i family members, leading to the activation of PLCβ, PI3-kinase, and the monomeric G proteins, Rho, Rac, and Rap1 and also cause an increase in the cytosolic Ca^{2+} concentration and inhibit cAMP formation. This process is supported, particularly at suboptimal thrombin concentrations, by released ADP and TxA_2. Since cleavage of human PAR4 requires a higher concentration of thrombin than does cleavage of PAR1, it is likely that PAR1 is the predominant signaling receptor at low thrombin concentrations. Once activated, PAR4 signals longer than PAR1.[93,94] By contrast, mouse platelets express PAR3 and PAR4, but signaling appears to be mediated entirely by PAR4, with PAR3 serving solely to facilitate the cleavage of PAR4 at low thrombin concentrations.[87,91]

One unresolved issue is the contribution of other thrombin receptors on platelets, particularly GP Ib (as discussed in Chapter 26A). GP Ib is a heterodimer comprised of α and β subunits that are disulfide linked.[95] There is a high-affinity binding site for thrombin at residues 268 to 287 on GP Ibα.[96] Deletion of the extracellular domain of GP Ibα or blockade of the thrombin-binding site decreases platelet responses to thrombin.[97–100] In theory, the binding of thrombin to GP Ibα could facilitate the cleavage of a PAR family member on human platelets, much as the binding of thrombin to PAR3 is thought to facilitate cleavage of PAR4 on mouse platelets.[100]

Platelet Activation by ADP

ADP is stored in platelet-dense granules and is released upon platelet activation. It is also released from damaged red cells at sites of vascular injury. When added to platelets *in vitro*, ADP causes TxA_2 formation, protein phosphorylation, an increase in cytosolic Ca^{2+}, shape change, platelet aggregation, and granule secretion. It also inhibits cAMP formation. These responses are half-maximal at approximately 1 μM ADP. However, ADP by itself is a weak activator of PLC in human platelets.[101,102] According to current models, human platelets express two distinct GPCRs for ADP: $P2Y_1$ and $P2Y_{12}$. Both are members of the purinergic class of GPCRs (Table 33.1 and FIGURE 33.3).[64,69,70,103,104] Optimal activation of platelets by ADP requires both receptors. A third "ADP" receptor, $P2X_1$, is an ATP-gated ion channel that allows a transient influx of Ca^{2+} before becoming desensitized.[105–108] All three proteins have now been cloned and the genes for each have been deleted in mice (Table 33.3).[65,109–111] In addition, $P2X_1$ has been overexpressed in mouse platelets by the introduction of a transgene driven by the α_{IIb} promoter.[112] The phenotype of the transgenic mouse includes increased responsiveness to agonists and increased susceptibility to lethal thromboembolism following the injection with collagen plus epinephrine.

In the absence of $P2Y_1$, ADP is still able to inhibit cAMP formation in mouse platelets, but its ability to cause an increase in cytosolic Ca^{2+}, platelet shape change, and platelet aggregation is greatly impaired, as was previously shown to be the case in platelets from mice that lack $G_{q\alpha}$.[59] The bleeding time in $P2Y_1^{-/-}$ mice is minimally increased and the mice are relatively resistant to disseminated thromboembolism following injection of ADP, but they show no predisposition to spontaneous hemorrhage. Primary responses to platelet agonists other than ADP are unaffected and when combined with serotonin, which is a weak stimulus for PLC in platelets, ADP causes the $P2Y_1^{-/-}$ platelets to aggregate. These results are consistent with earlier studies using receptor antagonists.[63,69] Taken together with observations made on $G_{q\alpha}^{-/-}$ mice, they indicate that platelet $P2Y_1$ receptors are coupled to G_q and responsible for activation of PLC. In view of the absence of ADP-induced shape change in $G_{q\alpha}$ knockout mouse platelets,[59] it is thought that ADP receptors do not couple to G_{12} family members in platelets.

The second platelet ADP receptor, $P2Y_{12}$, is also a member of the large family of purinergic GPCRs.[64,104] As predicted by inhibitor studies and by the phenotypes of individuals lacking functional $P2Y_{12}$,[113,114] platelets from $P2Y_{12}^{-/-}$ mice do not aggregate normally in response to ADP.[114] They retain $P2Y_1$-associated responses, including shape change and PLC activation, but lack the ability to inhibit cAMP formation. The G_i family member associated with $P2Y_{12}$ responses appears to be primarily G_{i2}, since platelets from $G_{i2\alpha}^{-/-}$ mice have an impaired ability to aggregate, inhibit cAMP formation, and activate Rap1B in response to ADP, while those lacking $G_{i3\alpha}$ or $G_{z\alpha}$ respond normally.[25,60–62]

The identification of the receptors that mediate platelet responses to ADP, the development of antagonists that target each of the known receptors, and the phenotypes observed in mice lacking the genes encoding $P2Y_1$, $P2Y_{12}$, $G_{q\alpha}$, or $G_{i2\alpha}$ have led to an increased appreciation of the contribution of ADP to platelet plug formation *in vivo*, as have studies performed *in vivo* with $P2Y_{12}^{-/-}$ mice in vascular injury and disseminated thrombosis models. The absence of $P2Y_{12}$ produces a hemorrhagic phenotype in humans, albeit a relatively mild one[64,113,115] (Table 33.3). Deletion of either $P2Y_1$ or $P2Y_{12}$ prolongs the bleeding time and impairs platelet responses not only to ADP, but also to thrombin and TxA_2, particularly at low concentrations.[65,110,116] Since platelet TxA_2 receptors do not couple directly to G_i family members, platelet aggregation induced by TxA_2 requires the secretion of ADP to inhibit adenylyl cyclase.[117] The identification of $P2Y_1$ and $P2Y_{12}$ has also made it possible to use the isolated receptors for the development of drugs to treat patients with cardiovascular and cerebrovascular disease. Metabolites of the thienopyridine compounds ticlopidine and clopidogrel irreversibly block $P2Y_{12}$. Other drugs, such as Cangrelor, are reversible $P2Y_{12}$ antagonists.

Table 33.3

Platelet phenotypes of GPCR knockout mice

Agonist	Receptor	Phenotype	Reference
ADP	$P2Y_1$	Impaired response to ADP. Absent increase in cytosolic Ca^{2+} and shape change in response to ADP. Normal inhibition of cAMP formation by ADP	109,110
	$P2Y_{12}$	Greatly diminished aggregation in response to ADP. Absent inhibition of adenylyl cyclase by ADP. Increased bleeding time	65
Thrombin	PAR1	None (not expressed on mouse platelets)	85,232
	PAR3	Higher concentrations of thrombin required to elicit responses, presumably because of the loss of the normal contribution of PAR3 to PAR4 activation	88
	PAR4	Complete loss of thrombin responsiveness	91
TxA_2	TPα and TPβ	Prolonged bleeding time, absent aggregation in response to TxA_2 agonists, and delayed aggregation with collagen	136
PGI_2	IP	Increased aggregation in response to ADP. Increased thrombosis following vascular injury	24

Platelet Activation by Epinephrine

In contrast to ADP and thrombin, epinephrine is a weak activator of human platelets and appears to serve primarily as a potentiator of platelet responses to other agonists. Nonetheless, there are reports of human families in which a mild bleeding diathesis is associated with impaired epinephrine-induced aggregation and reduced numbers of α_2-adrenergic receptors.[118,119] Platelet responses to epinephrine are mediated by α_{2A}-adrenergic receptors and are notoriously labile (Table 33.1).[120–122] The combination of epinephrine with a suboptimal concentration of ADP, thrombin, or a TxA_2 analog is a stronger stimulus for platelet aggregation than any of these agonists alone. Potentiation has traditionally been attributed to the ability of epinephrine to inhibit cAMP formation, but it is now clear that other effector pathways are involved as well, including pathways that lead to Rap1 activation.[61] Epinephrine has no detectable direct effect on PLC in platelets and does not cause shape change.[123] Taken together, these results suggest that platelet α_{2A}-adrenergic receptors are coupled to G_i family members, but not to G_q or G_{12} family members. Knockout studies show that the preferred partner is G_z.[60]

Of the four $G_{i\alpha}$ family members in platelets, $G_{z\alpha}$ is most distinct. Whereas $G_{i1\alpha}$, $G_{i2\alpha}$, and $G_{i3\alpha}$ are >90% identical to each other and ubiquitously expressed, $G_{z\alpha}$ is only 60% related to the others at the sequence level and has a restricted pattern of expression that includes some neurons and platelets. $G_{z\alpha}$ is also notable for having a relatively slow intrinsic rate of GTP hydrolysis[124] and for being a substrate for PKC [125] and p21-activated kinase (PAK).[126] One place where the $G_{z\alpha}$ sequence diverges from the other $G_{i\alpha}$ family members is at the *C*-terminus, a domain critical for receptor interactions. In particular, $G_{z\alpha}$ lacks a cysteine residue near the *N*-terminus that is the normal site for ADP-ribosylation by pertussis toxin. In reconstitution systems, overexpressed G_z will interact with a variety of receptors,[71,127] but studies using platelets from $G_{z\alpha}^{-/-}$ mice suggest that it normally couples only to α_{2A}-adrenergic receptors.[60] Aggregation in response to epinephrine, but not to ADP or a PAR4 agonist peptide, is reduced in the knockout at any concentration likely to be encountered *in vivo*. The diminished aggregation response is accompanied by a loss of epinephrine's normal ability to inhibit PGI_2-stimulated cAMP formation and by increased resistance to fatal thromboembolism following injection of epinephrine plus collagen, but not ADP plus collagen.[60] Taken together, these results suggest that epinephrine potentiates platelet activation by providing the type of G_i-dependent signaling that can also be seen with ADP, but does so *via* α_{2A}-adrenergic receptors coupled to G_z, rather than by $P2Y_{12}$ receptors coupled to G_{i2}.

Platelet Activation by Thromboxane A_2

TxA_2 is produced from arachidonate in platelets by the aspirin-sensitive cyclooxygenase pathway (see below). Once formed, TxA_2 can diffuse across the plasma membrane and activate other platelets (FIGURE 33.1).[128] Like ADP, this amplifies the initial stimulus for platelet activation and helps to recruit additional platelets. This process is effective locally, but is limited by the brief (≈30 seconds) half-life of TxA_2 in aqueous solution, helping to confine the spread of platelet activation to the original area of injury.

Only one gene encoding a TxA_2 receptor has been identified, but there are two splice variants (TPα and TPβ) that differ in their cytoplasmic tails (Table 33.1).[129] Human platelets express both forms of the receptor. Biochemical studies have shown that platelet TxA_2 receptors can physically associate with $G_{q\alpha}$[130] and $G_{13\alpha}$[131] and are able to activate G_{12} family members,[67] consistent with the observed ability of TxA_2 analogs to cause phosphoinositide hydrolysis and shape change in platelets. Loss of $G_{q\alpha}$ abolishes IP_3 formation and changes in cytosolic Ca^{2+} in response to the stable TxA_2 mimetic, U46619, but does not prevent platelet shape change.[59] U46619 continues to cause guanine nucleotide exchange on $G_{12\alpha}/G_{13\alpha}$ in platelets from $G_{q\alpha}^{-/-}$ mice.[132] Mice lacking $G_{13\alpha}$ have a defect in shape change, aggregation, and thrombosis, while mice lacking $G_{12\alpha}$ have no overt platelet phenotype.[133] In cells other than platelets, TP has been shown to couple to pertussis toxin-sensitive G_i family members.[134] However, in platelets, the inhibitory effect of U46619 on cAMP formation appears to be mediated by secreted ADP and is not seen when U46619 is added to platelet membranes.[135] Why this cell-specific difference occurs is unclear, but it suggests that platelet TP receptors are coupled to G_q and G_{12}, but not to G_i, family members. Platelets from mice lacking the gene encoding TP have a prolonged bleeding time and are unable to aggregate in response to TxA_2 mimetics (Table 33.3). They also exhibit delayed aggregation in response to collagen, presumably reflecting the role of TxA_2 in platelet responses to collagen.[136] A cohort of Japanese patients with impaired platelet responses to TxA_2 analogs, but normal ligand binding, were found to be either homozygous or heterozygous for a missense mutation replacing Arg60 with Leu in the first cytoplasmic loop of TP,[137] which presumably affects coupling, but not activation of the receptor.

Regulation of G-Protein Signaling in Platelets

RGS proteins in cells other than platelets have been shown to limit signaling intensity and duration by accelerating the intrinsic hydrolysis of GTP by activated G-protein α subunits.[138] The RGS family in mammals consists of at least 37 members, as defined by a conserved RGS domain.[139] As many as 10 have been identified in platelets at the RNA level, but only two, RGS10 and RGS18, have been confirmed at the protein level.[140–145] The evidence that RGS proteins are biologically relevant in platelets comes from studies on mice in which glycine 184 in the α subunit of G_{i2} was replaced with serine, rendering it unable to interact with RGS proteins, but without impairing its ability to interact with either receptors or downstream effectors. As would be predicted, this substitution produced a gain-of-function phenotype *in vitro* and *in vivo*, even in the heterozygous state.[146]

SECRETION

The platelet secretory response results in the release of the contents of intracellular storage granules. Granule constituents include substances that can stimulate circulating platelets and cause them to acquire new adhesive properties. Most of the substances that are actively and selectively secreted from platelets are packaged in preformed storage granules or are synthesized *de novo* from membrane phospholipids. Platelets contain three types of granules: (a) dense granules that contain small molecules such as ADP, serotonin, and Ca^{2+} which serve to amplify platelet activation and promote local vasoconstriction, (b) α-granules that contain numerous proteins that enhance the adhesive process and help regulate angiogenesis and wound

healing among other process, and (c) lysosomal granules that contain glycosidases and proteases which have unclear functions in platelet biology. Platelet secretion is triggered by a variety of strong agonists such as thrombin. Factor V, fibrinogen, thrombospondin, and other proteins secreted from the α-granules may be retained on the platelet surface by a transglutamination reaction.[147] This process is speculated to enhance the procoagulant activity of activated platelets.[148] Induction of secretion by weak agonists like ADP occurs when the cells are brought into close contact such as occurs during aggregation.[149,150] The latter secretory mechanism is clearly dependent on TxA_2 generated as a consequence of arachidonic acid release.

Granule Exocytosis

As noted previously, the two morphologically prominent platelet storage granules, α-granules and dense granules, contain a variety of substances important in platelet function. Since these granules have a limiting membrane, it would seem likely that the final secretory event involves exocytosis (i.e., the fusion of the secretory granule membrane with the plasma membrane).[151] This has been observed for dense body secretion.[152,153] Several families of proteins have been shown to be required for exocytosis in yeast and neuroendocrine cells. These include Rab GTPases and members of the SNARE-SNAP complex[154–157] (see Chapter 32 for a detailed discussion of the mechanism of platelet secretion).

Rab GTPases appear to be essential for both platelet α-granule and dense granule release. The SNARE-SNAP complex has also been shown to be critical for platelet secretion. SNARE proteins are docking proteins that are present on the inner face of the cell membrane, as well as on the outer face of vesicular membranes. The fusion of the vesicular membrane with the cell membrane requires the formation of a core complex created by the binding of SNARE proteins on the opposing membranes. Soluble NSF-attachment proteins (SNAPs) facilitate this process. Platelets have been shown to contain numerous members of these families, and blocking antibodies directed against several SNAREs and SNAPs impair granule secretion in permeabilized platelets.[154,157,158] PKC and its substrate pleckstrin are also essential components of the signaling cascade involved in platelet secretion. This will be discussed in the PKC section later in this chapter.

Eicosanoids and Arachidonate

In addition to the exocytosis of platelet granules, the passive release of TxA_2 from platelets is another mechanism that amplifies platelet activation. Eicosanoids are formed from the arachidonate released from membrane phospholipids by phospholipase A_2 during platelet activation.[159–161] Since the availability of arachidonate is the rate-limiting step in this process, phospholipase A_2 is tightly controlled. Platelet phospholipase A_2 activation is stimulated in part by the increase in the cytosolic Ca_{2+} that accompanies platelet activation. There is also evidence that MAPK pathway signaling activates phospholipase A_2, although not necessarily by direct phosphorylation of phospholipase A_2.[162,163] See Chapter 34 for a detailed discussion of platelet prostanoid metabolism.

Once released from membrane phospholipids, arachidonate can be metabolized to TxA_2 by cyclooxygenase–1 (COX-1).[164] Aspirin acetylates COX-1 causing it to be irreversibly inactivated.[165,166] Since platelets lack the ability to synthesize significant amounts of protein, inactivation of COX-1 by aspirin blocks TxA_2 synthesis until new platelets are released. Hence, aspirin is the most commonly used drug for antiplatelet therapy. However, there may be a subset of patients who are "aspirin resistant," although the molecular basis for this remains undetermined.[167,168] Nonsteroidal anti-inflammatory agents also inactivate COX-1, but without covalently modifying the enzyme.[169]

Once formed, TxA_2 can diffuse across the plasma membrane and activate other platelets through signaling pathways. Like ADP, TxA_2 amplifies the initial stimulus for platelet activation and recruits additional platelets. This process is effective locally, but is limited by the short half-life of aqueous TxA_2 in solution, confining the spread of platelet activation to the original area of injury.

INTRACELLULAR SIGNALING EVENTS

After platelet activation by an agonist, intracellular signaling is needed for cytoskeletal reorganization, fibrinogen receptor exposure, and granule secretion. Two pathways that are central to platelet activation are the phosphoinositide hydrolysis pathway and the eicosanoid synthesis pathway. The phosphoinositide hydrolysis pathway begins when PLC cleaves membrane phosphatidylinositol 4,5-bisphosphate (PIP_2) to form inositol 1,4,5-trisphosphate (IP_3) and DAG, both of which serve as second messengers. The eicosanoid pathway begins when phospholipase A_2 releases arachidonate from membrane phospholipids to form TxA_2. As mentioned above, most of the agonists that activate platelets do so *via* GPCRs, and it is the activation of G proteins that is the first step in the intracellular signaling pathway leading to platelet second messenger formation.

Inositol Signaling-Phospholipase C and PI3-kinases

One of the earliest responses of platelets to most agonists is the activation of PLC. Platelets contain β and γ forms of this enzyme. The β forms are activated by G proteins, while the γ forms (predominantly PLCγ_2) are regulated by tyrosine phosphorylation.[170,171] PLCβ is thought to be primarily responsible for the rapid burst of phosphoinositide hydrolysis that occurs during platelet activation by agonists such as thrombin and TxA_2.

In general, PLCβ_1 and PLCβ_3 respond best to G_α, particularly members of the $G_{q\alpha}$ family, while PLCβ_2 responds best to $G_{\beta\gamma}$. Coupling of specific heterotrimeric proteins to PLC was discussed earlier in this chapter. Once activated, PLC hydrolyzes PI-4,5-P_2 to DAG plus IP_3.[172,173] DAG activates PKC and contributes to protein phosphorylation, and IP_3 binds to receptors in the DTS and releases sequestered Ca^{2+}[174,175] (see below).

Phosphatidylinositol 3-kinases (PI3K) are a group of enzymes that phosphorylate the D-3 position of the inositol ring of phosphatidylinositol to produce phosphatidylinositol 3-phosphate (PI3-P), phosphatidylinositol 3,4-bisphosphates (PI3,4-P_2), and phosphatidylinositol 3,4,5-triphosphates (PI3,4,5-P_2 or PIP_3).[176] Four isoforms of PI3K that phosphorylate PI, PI4-P, and PIP_2 have been described in humans and are

classified according to their catalytic subunit: p110α, p110β, p110γ, and p110δ.

Using pharmacologic inhibitors, and platelets obtained from genetically modified mice, it has been possible to dissect the roles of different PI3K isoforms in platelets. Mice lacking the p110γ catalytic subunit of PI3K have a defect in ADP-mediated platelet aggregation,[177,178] whereas mice lacking the p85α regulatory subunit have a defect in signaling events initiated by the platelet collagen receptor, GPVI. No defect in platelet activation has been observed following stimulation by other platelet agonists such as ADP or thrombin.[179] Loss of PI3Kβ impairs Rap1B activation and thrombus formation *in vivo*, similar to PI3Kβ-selective inhibitors.[180] Most of the Akt expressed in platelets appears to be the Akt2 isoform, but Akt1 and Akt3[181] are present as well. All three appear to contribute to platelet activation, at least in mice. Deletion of the gene encoding Akt2 results in impaired thrombus formation and stability and inhibits platelet secretion.[182] Loss of Akt1 inhibits platelet aggregation[183] and affects vascular integrity.[184] Loss of Akt3 impairs aggregation and secretion.[181] Taken together, these results suggest that PI3K is involved in both the initial activation of $\alpha_{IIb}\beta_3$ and the subsequent stabilization of the $\alpha_{IIb}\beta_3$/fibrinogen interaction that leads to irreversible platelet aggregation. This may be due to irreversible effects of PI3K on the platelet's actin cytoskeleton.

Cytosolic Calcium Ions

Ca^{2+} ions serve as intracellular second messengers, and like protein kinases, affect enzyme activity and protein–protein interactions. Based on studies with intracellular probes such as Fura-2, the cytosolic free Ca^{2+} concentration in resting platelets has been found to be approximately 0.1 μM. Strong agonists, such as thrombin or collagen, cause an increase to >1.0 μM. Weaker agonists, particularly epinephrine, may have little or no effect on cytosolic Ca^{2+}.

The rise in cytosolic Ca^{2+} that accompanies platelet activation occurs in two steps, reflecting two sources of the Ca.$^{2+}$ The first surge in Ca^{2+} is due to the IP_3-mediated release of Ca^{2+} from the platelet DTS. The second surge occurs when depletion of the DTS Ca^{2+} pool triggers a conformational change in STIM1, a protein in the DTS membrane. This promotes the binding of STIM1 to Orai1 in the plasma membrane, triggering an influx of plasma Ca^{2+} driven by the steep Ca^{2+} gradient that normally exists across the plasma membrane.[40] These events can be separated by chelating extracellular Ca^{2+}, thereby precluding Ca^{2+} influx. The rise in $[Ca^{2+}]_i$ activates the GTP-binding protein, Rap1, which can then bind to and cause the translocation of RIAM and talin to the cytoplasmic domain of $\alpha_{IIb}\beta_3$ (FIGURE 33.2). Talin and kindlin binding to $\alpha_{IIb}\beta_3$ trigger a conformational change in the integrin extracellular domain, exposing a binding site for fibrinogen (discussed in Chapters 26B and 31).[7]

Protein Kinase C

PKC isoforms are a family of serine/threonine kinases that play an essential role in the signal transduction mechanism downstream of agonist receptor activation. PKC has been identified as the cellular receptor for the lipid second messenger DAG, and it is a key enzyme in the signaling events that follow activation of receptors coupled to PLC. PKC isoforms phosphorylate multiple cellular proteins on serine and threonine residues. Although some discrepancies between different studies on PKC isozyme expression exist, platelets probably express PKC α, β, δ, ε, η, θ, and perhaps ζ and λ.[185]

Because of the limitations of platelets as a system for genetic studies, studies on PKC in platelets have depended heavily on the use of pharmacologic activators (such as phorbol 12-myristate 13-acetate or PMA) and inhibitors. Those studies suggest that PKC isoforms control a variety of platelet functions, including aggregation, secretion, mobilization of intracellular Ca^{2+}, and regulation of cell shape. The δ and θ isoforms may be particularly important for these functions.[186,187] PKC isoforms also play an important role in megakaryocyte differentiation.

Recent evidence using genetically engineered mice has shown that the cytosolic protein pleckstrin is an essential component of PKC-mediated platelet secretion.[188] Pleckstrin constitutes approximately 1% of total cellular protein in platelets and contains two prototypic PH domains. PH domains are thought to mediate the association of proteins with phosphoinositides. Following platelet activation, pleckstrin is rapidly phosphorylated by PKC, inducing it to bind to membrane phospholipids such as phosphatidylinositol 4,5 bisphosphate. Although granules in platelets from mice lacking pleckstrin are able to move to the plasma membrane, the granule and plasma membranes fail to fuse so that the granules are unable to secrete their content into the extracellular environment.

Other Protein Kinases

In addition to other serine/threonine kinases such as p38 MAPK, platelets contain a large number of tyrosine kinases, some of which become active during platelet activation. These include receptors for extracellular ligands, such as growth factor receptors and ephA4, as well as a large number of nonreceptor (cytoplasmic) tyrosine kinases, including Src, Fyn, Lyn, Hck, and Syk. Broadly specific inhibitors of tyrosine kinases, such as genistein and the tyrphostins, can inhibit platelet activation.

Inhibitors of phosphotyrosine phosphatases, such as vanadate, promote platelet activation. In general, tyrosine phosphorylation serves two roles. It can have a regulatory effect on the phosphorylated protein, perhaps by causing a conformational change, or it can provide a binding site for modular domains located in other proteins, such as SH2 domains. Although studies of knockout mice have identified a role for some of these proteins in signaling pathways downstream of the GP VI collagen receptor, the function of most tyrosine kinases in platelets is still incompletely understood, as is the role of protein tyrosine phosphatases such as SHP-1 and SHP-2.

Cyclic AMP

Agents that raise the cAMP concentration in platelets inhibit platelet activation. In general, this effect is thought to be mediated by cAMP-dependent protein kinase A.[15] Platelet substrates for this enzyme include the 24 kDa β chain of glycoprotein Ib, actin-binding protein, and myosin light chain, VASP and Rap1B. Raising cAMP levels cause a number of specific changes in platelet function, including impaired phosphoinositide hydrolysis, attenuation of the increase in cytosolic free Ca^{2+} in response to agonists, and an accelerated uptake of Ca^{2+} into the DTS.

PGI_2 released from activated endothelial cells increases platelet cAMP levels by stimulating receptors on the platelet surface that are coupled to adenylyl cyclase *via* the G-protein G_s. This results in inhibition of platelet activation. Consequently, mice lacking the PGI_2 receptor manifest an increased thrombotic risk.[24] As described above, platelet agonists suppress cAMP formation by inhibiting adenylyl cyclase *via* one or more members of the $G_{i\alpha}$ family.

The drug dipyridamole (Persantine) exerts antiplatelet effects by inhibiting cAMP phosphodiesterase and increasing platelet cAMP.[15] However, the clinical efficacy of dipyridamole has been debated. Sildenafil has phosphodiesterase activity and decreases platelet cAMP levels. This has been speculated to contribute to the cardiovascular toxicity of this drug.[189]

Signals to and from $\alpha_{IIb}\beta_3$

A longstanding question in platelet biology is the mechanism by which inside-out signaling pathways produce integrin activation. Activation of $\alpha_{IIb}\beta_3$ is required for fibrinogen to bind to the platelet surface and for aggregation to occur (this is discussed in detail in Chapter 31). Human and mouse platelets lacking $\alpha_{IIb}\beta_3$ cannot aggregate. Normal platelets incubated with $\alpha_{IIb}\beta_3$ antagonists also show reduced or absent aggregation. The early (receptor-proximal) events have been identified. In general terms, the early events include the activation of one or more PLC isoforms yielding a rise in the cytosolic Ca^{2+} concentration and the activation of PKC. This leads to integrin activation *via* an intracellular pathway that includes a Ca^{2+}-dependent exchange factor (CalDAG-GEF), a switch (Rap1), an adaptor (RIAM), and proteins that interact directly with the $\alpha_{IIb}\beta_3$ cytosolic domains (kindlin and talin).[7] Multiple lines of evidence suggest that this is mediated by disruption of the interactions between the transmembrane regions of α_{IIb} and β_3.[190,191] This opening up of the transmembrane heterodimer induces a conformational change in the $\alpha_{IIb}\beta_3$ extracellular domain that exposes the fibrinogen binding site (FIGURE 33.2). The CalDAG-GEF/Rap1-dependent pathway accounts for the ability of Ca^{2+} ionophores to trigger platelet aggregation. Its biological relevance is reflected by the reduction of aggregation in platelets from Rap1 and CalDAG-GEF knockout mice.[192,193] That the CalDAG-GEF/Rap1 pathway is not the only way to accomplish integrin activation is reflected by the incomplete reduction of aggregation in $Rap1^{-/-}$ platelets and by the ability of PKC activators such as phorbol myristate acetate (PMA) to cause aggregation without causing an increase in cytosolic Ca^{2+}.[194] PKC isoforms phosphorylate multiple cellular proteins on serine and threonine residues. Activation of PKC by PMA is sufficient to cause integrin activation, granule secretion, and platelet aggregation in the absence of an increase in cytosolic Ca^{2+}. However, just as the ability of Ca^{2+} ionophores to activate platelets on their own does not fully account for platelet activation *in vivo*, neither does the response to PMA.

In addition to the inside-out signaling events that lead to activation of $\alpha_{IIb}\beta_3$, there are also outside-in signaling events that occur downstream of activated $\alpha_{IIb}\beta_3$ once fibrinogen binding has occurred.[195–197] Fibrinogen binding to and clustering of $\alpha_{IIb}\beta_3$ stimulates rapid increases in the activities of integrin-associated Src family and Syk tyrosine kinases. Studies of platelets from mice lacking these kinases suggest that these events are required for the initiation of outside-in signaling and for full platelet spreading, irreversible aggregation, and clot retraction.[198–201] Platelet aggregation results in the formation of large signaling complexes that include $\alpha_{IIb}\beta_3$. One of the proteins in these complexes is the kinase, FAK, which, when phosphorylated, can provide a binding site for, among other proteins, Src and the p85 subunit of PI3-kinase.[202,203,204] Proteins capable of binding directly to the cytoplasmic domains of $\alpha_{IIb}\beta_3$ include β_3-endonexin,[205] CIB,[206,207] talin,[208] Syk,[209,210] myosin[211] and Shc.[212] Shc binding requires phosphorylation of Y759 in the β_3 cytoplasmic domain.[212] Myosin binding requires phosphorylation of both Y747 and Y759.[211] The binding of talin, β_3-endonexin, and CIB is thought to be independent of β_3 tyrosine phosphorylation. Some of the protein:protein interactions that involve the cytoplasmic domains of $\alpha_{IIb}\beta_3$ (including talin) help to regulate integrin activation, others participate in outside-in signaling and clot retraction. Tyrosine phosphorylation of β_3 is thought to be integral to the later two events.

Tyrosine residues 747 and 759 of β_3 become phosphorylated following the onset of platelet aggregation.[211] Phosphorylation requires both activation of the integrin and its engagement with an adhesive protein. Inhibition of aggregation with an RGD-containing peptide or a peptidomimetic inhibits phosphorylation of β_3.[211] According to one model,[199,200] platelet activation and aggregation leads to the activation of an Src family member and the subsequent phosphorylation of β_3. Consistent with this hypothesis, phosphorylation is diminished in $Fyn^{-/-}$ mouse platelets.[200] Mutation of both Y747 and Y759 to phenylalanine produces mice whose platelets tend to disaggregate and manifest reduced clot retraction and a tendency to rebleed from tail bleeding time sites.[203] Clot retraction refers to the decreased volume of a clot that occurs when embedded platelets pull on fibrin strands. Loss of clot retraction is a hallmark of $\alpha_{IIb}\beta_3$-deficient platelets from patients with Glanzmann thrombasthenia, reflecting the dependence of clot retraction on the interaction of $\alpha_{IIb}\beta_3$ with extracellular fibrin and with intracellular actin/myosin filaments. The diminished clot retraction in the Y747F/Y759F mice is consistent with a reduction in the binding of myosin to β_3. Failure to phosphorylate β_3 in the Y747F/Y759F mice would also prevent the binding of the adaptor protein Shc,[212] abolishing any signaling pathways that lie downstream from that point.

CHAPTER

34 Platelet Prostanoid Metabolism

TILO GROSSER AND GARRET A. FITZGERALD

The prostanoids, which include prostaglandins (PGs) and thromboxane (TX) A_2, are a series of lipid hormones that act on specific G-protein–coupled receptors expressed at, or close to, their site of formation. They are formed by the sequential action of the PGG/H synthases, commonly known as cyclooxygenases (COXs), and specific prostanoid synthases (FIGURE 34.1).[1] TXA_2 is synthesized by COX-1 in activated platelets and released as a local signal that amplifies activation and recruits additional platelets to the site of clot formation.[2,3] It is also a potent vasoconstrictor and stimulates mitogenesis and the proliferative response to vascular injury.[4–7] Patients deficient in TXA_2 formation or signaling have a mild bleeding disorder.[8–13] Suppression of TXA_2 formation by low-dose aspirin, which inhibits platelet COX, is sufficient to explain the reduction of the incidence of myocardial infarction and stroke by about 25% in patients who have had a previous arterial thrombotic event.[14,15,16,17] Conversely, the defect in platelet function caused by aspirin can also lead to bleeding complications—primarily gastrointestinal and less frequently intracranial hemorrhage.

The development of nonsteroidal anti-inflammatory drugs (NSAIDs) targeted specifically at inhibition of COX-2 has emphasized the importance of PGs in the physiologic restraint of thrombotic processes. All COX-2 selective NSAIDs approved by the U.S. Food and Drug Administration were shown in placebo controlled trials to cause thrombotic complications—myocardial infarction, stroke, and venous thrombosis. The underlying molecular mechanism—inhibition of COX-2–dependent formation of prostacyclin (PGI_2) and other PGs in the vasculature, the heart, and the kidney—has been elucidated in more detail than that of any other adverse drug effect.[18]

PGI_2 is the major platelet inhibitory prostanoid. It also elicits vasodilation close to the site of formation and has antimitogenic and antiatherogenic properties.[19] Augmented PGI_2 biosynthesis in syndromes of platelet activation serves to constrain the effects of stimuli to platelet activation and vasoconstrictors.[7] The increased incidence of myocardial infarction and stroke in patients receiving COX-2 selective NSAIDs, which is explained by inhibition of COX-2–dependent PGI_2 formation, supports this concept.[18,20]

The role in platelet function of other prostanoids is less established. PGD_2 produced cooperatively by platelet COX and plasma PGD synthase may afford a mechanism of feedback inhibition of aggregation.[21–23] High concentrations of PGE_2 may inhibit platelet function,[24] while lower concentrations activate platelets *in vitro*.[25] Deletion of the enzyme primarily mediating inflammatory PGE_2 formation did not affect thrombogenesis in mice.[26]

PROSTANOID SYNTHESIS

Arachidonic acid, the precursor of a complex array of more than 20 carbon lipid mediators including the prostanoids, is metabolized by three major groups of enzymes, the COXs, lipoxygenases, and epoxygenases, to form the prostanoids, the leukotrienes, and the epoxyeicosatrienoic acids, respectively.[27] A fourth group of arachidonic acid–derived molecules, the isoeicosanoids, is formed by nonenzymatic peroxidation. Arachidonic acid itself is released from membrane stores by the enzymatic activity of phospholipase (PL) A_2. Several PLA_2 enzymes that hydrolyze arachidonic acid from the sn-2 position of membrane glycerophospholipids have been identified in vertebrates.[28] Free arachidonic acid is either available for metabolism into one of the 20 carbon lipid mediators, or it can be reacylated in the so-called Lands cycle, in which it is converted to arachidonoyl-CoA by arachidonoyl-CoA synthetases and reincorporated into phospholipids by CoA-dependent acyltransferases.[29]

Many platelet agonists initiate TXA_2 generation by activating Group (G) IVA PLA_2, the main isoform expressed in the platelet cytosol, with a calcium signal.[30] GIVA PLA_2 possesses a regulative C2 domain that is thought to mediate its translocation to the phospholipid membrane in response to increments in intracellular calcium concentrations.[31] Other activation pathways, including von Willebrand factor–initiated adhesion of platelets through the GPIb-V-IX complex, are thought to involve mitogen-activated protein kinase-mediated phosphorylation of GIVA PLA_2 serine-505.[32–35] Vascular wall cells express multiple PLA_2 isoforms to release arachidonic acid for prostanoid formation, including calcium-dependent and calcium-independent mechanisms, and in inflammatory scenarios, such as atherosclerotic lesions, also secretory PLA_2s.[36,37]

COX-dependent metabolism of arachidonic acid results in the formation of the prostanoids. Two evolutionary conserved[38] COX isoforms, COX-1 and COX-2,[39] convert arachidonic acid to PGH_2. COX-1 expression is relatively constant in most cells. It is the only isoform expressed in mature platelets.[40] Megakaryocytes, and immature platelets released in clinical conditions of accelerated platelet turnover, also express COX-2,[41,42] although its role in platelet development and function has yet to be elucidated.[43]

COX-2, a member of the inducible immediate-early gene family, is highly regulated in various contexts such as inflammation, pain signaling, fever, renal salt handling, and cell proliferation and differentiation. Its promoter contains several transcriptional regulatory elements including cyclic AMP response elements, nuclear factor kappa B sites, AP-2 sites, an E-box, a TATA box, an SP1 site, and a CAAT enhancer binding protein site.[44] COX-2 expression is also regulated at the

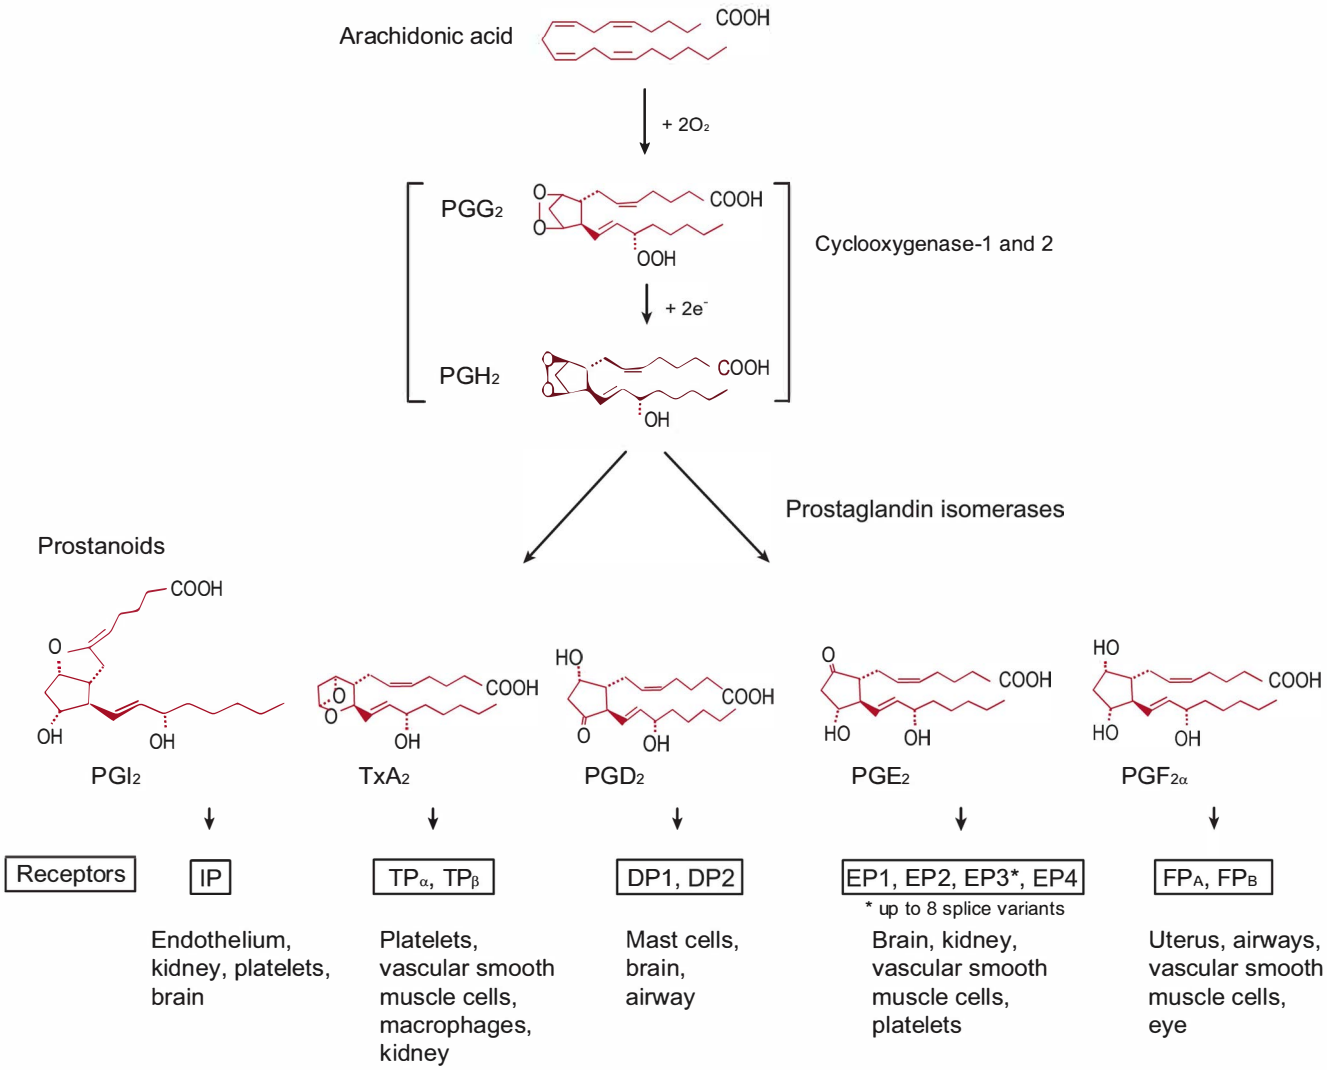

FIGURE 34.1 The cyclooxygenase pathway

posttranscriptional level by RNA-binding proteins and miRNAs forming RNA regulons.[45,46] While these influences on RNA stabilization, transport, and translation result in highly tunable gene expression, COX-2 is not only important during pathologic processes. It is developmentally expressed and has key functions in uninflamed tissues including the vasculature, kidney, gastric epithelium, spinal cord, and brain.[38]

The cyclooxygenase enzymes function as membrane-anchored dimers.[47] The two monomers act synergistically; inactivation of one monomer is sufficient to inhibit enzyme function.[47,48] Enzymatic PG synthesis involves both a COX and a peroxidase reaction. The COX activity incorporates oxygen into arachidonic acid that results in the formation of a labile intermediate peroxide, PGG_2. The peroxidase activity reduces PGG_2 to the endoperoxide product PGH_2.[39] This unstable compound is subject to further metabolism by at least nine terminal prostanoid synthases to form TX and the D, E, F, and I series PGs.[24,49]

While most human cells or tissues have the capacity to form an array of active prostanoids through tissue-specific expression of prostanoid synthases, the TX biosynthetic pathway predominates in platelets. The membrane-bound hemoprotein, thromboxane synthase (TXAS) that catalyzes the isomerization reaction of PGH_2 to TXA_2, also converts PGH_2 to 12-L-hydroxy-5,8,10-heptadecatrienoic acid (HHT) and malondialdehyde (MDA).[50] However, the importance of HHT and MDA in the regulation of human platelet function is still poorly understood.

Despite its short half-life, PGH_2 released from platelets can be also metabolized by PG synthases expressed outside of platelets in the plasma or in vascular cells. For example, platelets can contribute to the production of PGI_2 in endothelial cells or in inflamed synovial cells *in vitro* through a transcellular shunt of PGH_2.[51,52] Platelet-derived PGH_2 is also the substrate for PGD_2 formation by plasma PGD synthase.[21]

PROSTANOID SIGNALING

Because of their short half-life, prostanoids do not circulate.[53] They modulate cell function close to the site of their formation acting via specific G-protein–coupled receptors (GPCRs) on the membranes of their target cells (Table 34.1).[24,49,54,55] A single gene

Table 34.1
G proteins associated with prostanoid receptors

Receptor	Primary Activated G protein
TP, IP, EP_2, EP_4, DP_1	G_s
TP, EP_1, FP	G_q
TP, EP_3, DP_2	G_i
TP, EP_3	G_{12}
TP	G_{16}

product receptor has been identified for TXA_2 (the T prostanoid receptor or TP), prostacyclin (the IP), and $PGF_{2\alpha}$ (the FP), while four distinct PGE_2 receptors (the EP_{1-4}) and two PGD_2 (the DP_1 and the DP_2) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP_3 (A–D) are generated through differential splicing.

The sequences of the TP_α and TP_β carboxy terminal splice variants diverge distal to the seventh transmembrane domain. Their expression is differentially regulated by two distinct promoters within the single human TP gene.[56] Differences in signal transduction pathways have been noted,[57] as have differential rates of agonist-induced desensitization.[58] While both transcripts are present in human platelets, only the TP_α protein has been detected.[59] The TP couples to multiple G proteins to stimulate small G protein signaling pathways and may activate or inhibit adenylyl cyclase via G_s (TP_α) or G_i (TP_β), respectively. In platelets, the TP interacts predominantly with G_q and $G_{12}/_{13}$. G_q activates protein kinase C-dependent pathways, which facilitate platelet aggregation, whereas G_{12}/G_{13}-mediated regulation of myosin light chain phosphorylation participates in receptor-induced platelet shape change. TXA_2-induced platelet activation beyond the site of vascular injury is thought to be restrained by its short half-life (about 30 seconds) and by rapid TP desensitization. Heterodimerization with other GPCRs, such as the IP, may afford another mechanism to modulate downstream signaling.[60] Additionally, endogenous inhibitors of platelet function, including PGI_2 and nitric oxide, serve to limit platelet activation.[20]

Both PGI_2 and PGE_2 acting via the IP, or theoretically, via the DP_1, the EP_2, and/or the EP_4 (all coupled via Gs to adenylate cyclase activation), may inhibit platelet function,[24] while lower concentrations of PGE_2 activate platelets via the EP_3 *in vitro*.[25] EP_3 isoforms can couple via G_i or G_{12} to elevation of intracellular calcium, inhibition of cAMP generation, and activation of the small G protein Rho.

PROSTANOID DEGRADATION AND ELIMINATION

Thromboxane

TXA_2 is rapidly hydrolyzed ($T_{1/2}$ ~30 seconds) to the stable and biologically inactive compound TXB_2 in biologic fluids. Quantitation of TXB_2 in serum or platelet-rich plasma permits assessment of the capacity of platelets to form TXA_2 *ex vivo*.[61–64] Typically, TXB_2 formation is detected in serum derived from whole blood allowed to clot under standardized conditions or in platelet-rich plasma after induced platelet activation.[63] These approaches have been used, for example, to validate the use of low doses of aspirin in cardiovascular prophylaxis[65] or to reveal drug–drug interactions between low-dose aspirin and NSAIDs.[66,67]

Attempts to use TXB_2 as an index of platelet activation *in vivo*, however, have proved unsuccessful. Platelets have the capacity to form TXA_2 in concentrations of approximately 300 to 400 ng/mL blood,[68] while maximal endogenous concentrations have been estimated to be three orders of magnitude lower, in the range of 1 to 2 pg/mL.[69] This divergence between the capacity to generate TXA_2 and the actual production rate *in vivo* is a feature of the feed forward, activation amplification role of TXA_2 in the propagation of platelet-mediated clotting.[70] Thus, the inevitable platelet activation that occurs during blood sampling, even under standardized conditions, results in TXB_2 bursts that exceed circulating levels and render the measurement highly variable and essentially meaningless.[71]

The quantitation of urinary TXB_2 metabolites, themselves not formed in whole blood, avoids this problem because TXB_2 is rapidly cleared from the circulation.[53,69] The first of two major pathways of TXB_2 metabolism results in the formation of the β-oxidation products, 2,3-dinor TXB_2, and 2,3,4,5-tetranor TXB_2.[72] The second involves the formation of molecules with a δ-lactone ring structure, of which 11-dehydro TXB_2 is the major urinary product and the most abundant TXB_2 metabolite in humans (2,3-dinor TXB_2 is the most abundant metabolite in mice).[72] Both, 2,3-dinor TXB_2 and 11-dehydro TXB_2 have been qualified as indices of TXA_2 biosynthesis *in vivo*.[69,71,73,74] Because neither metabolite is formed in the kidney, their detection in urine affords a noninvasive measure of systemic TXA_2. 11-dehydro TXB_2 itself undergoes extensive degradation, but its half-life in the circulation (~60 minutes) exceeds that of 2,3-dinor TXB_2 (15 to 17 minutes) and it is more abundant in urine.[75,76] Thus, this metabolite is thought to be the more robust index of TXA_2 formation *in vivo*.[76]

Experiments with low-dose aspirin revealed that roughly 80% of the systemic TX biomarker in urine derives from platelets under physiologic conditions.[77] Excretion of urinary TX metabolites is augmented in clinical syndromes of platelet activation, including unstable angina and myocardial infarction,[78] reperfusion following therapeutic thrombolysis,[79] severe peripheral vascular disease,[80] preeclampsia,[81] pulmonary hypertension,[82] sickle cell anemia,[83] systemic lupus erythematosus,[84] scleroderma,[85] and stroke.[86] Conversely, high levels of a urinary 11-dehydro TXB_2, in patients on low-dose aspirin therapy have been linked to elevated cardiovascular risk.[87]

Prostacyclin

PGI_2 undergoes a metabolic fate similar to that of TXB_2. It is degraded hydrolytically to 6-keto-$PGF_{1\alpha}$ and then enzymatically to 2,3-dinor-6-keto-$PGF_{1\alpha}$ (6.8% of infused PGI_2) and 15-keto-13,14-dihydro-2,3-dinor-6-keto-$PGF_{1\alpha}$.[53] While quantitation of 6-keto-$PGF_{1\alpha}$ allows for monitoring the formation of PGI_2 *in vitro*, urinary excretion of 2,3-dinor-6-keto-$PGF_{1\alpha}$ has been qualified as an index of PGI_2 formation *in vivo*.[53] Quantitation of this metabolite revealed that the endogenous production of PGI_2 under physiologic conditions is very low.[53] The observation that its formation was markedly enhanced in clinical settings in which platelet–vascular interactions are increased, such

as unstable angina or myocardial infarction, suggested that PGI_2 may act as an endogenous platelet-inhibitory agent, perhaps to restrain the propagation of a thrombotic response beyond the site of injury.[88] Thus, concern was raised when clinical studies in healthy volunteers revealed unexpectedly that COX-2 selective NSAIDs depressed endogenous PGI_2.[89,90] These studies showed that COX-2 was the major source of PGI_2 biosynthesis in humans, suggesting—before the first compound within this class was granted marketing approval—that COX-2 inhibition might elevate cardiovascular risk.[18]

Other Prostaglandin Metabolites

While PGE_2 and PGD_2 are relatively stable in aqueous solutions, they are rapidly cleared from the circulation. PGE_2 is biotransformed by dehydrogenation, reduction, β-oxidation, and ω-oxidation, yielding the major urinary metabolite, 11α-hydroxy-9,15-dioxo-2,3,4,5-tetranor-prostane-1,20-dioic acid (PGE-M). PGD_2 is transformed to 1β-$PGF_{2\alpha}$, 2,3-dinor-11β-$PGF_{2\alpha}$, and 11,15-dioxo-9α-hydroxy-2,3,4,5-tetranor-prostan-1,20-dioic acid (tetranor PGD-M).[91] Urinary PG metabolites of both PGE_2 and PGD_2 have been used to monitor COX activity during NSAID administration.

PROSTANOIDS IN THROMBOSIS AND HEMOSTASIS

Thromboxane

The primary role of TXA_2 signaling during thrombosis is the amplification of platelet activation and recruitment of additional platelets to the site of clotting. Thus, inhibition or disruption of TXA_2 signaling *in vivo* substantially limits the aggregation response, but it does not completely prevent clot formation. Consistent with the function of TXA_2 to provide rapid feed-forward activation, the relationship between the capacity of platelets to form TXA_2 and platelet function is nonlinear.[70] A residual capacity to generate 10% TXA_2 is sufficient to fully sustain TXA_2-dependent platelet aggregation.[92] Thus, only compounds that afford permanent inhibition of more than 95% to 98% of the capacity of platelets to generate TX would be expected to be effective antiplatelet drugs.[93] Currently, aspirin is the only compound in this category, as it inactivates platelet COX-1 irreversibly. Traditional NSAIDs, with the possible exception of naproxen in some individuals, which inhibit the enzyme reversibly, achieve a level of inhibition of TXA_2 synthesis that translates into inhibition of platelet function only transiently during the dosing interval.[66] Previous attempts to develop TXAS inhibitors failed in part because persistent and complete platelet inhibition was not achieved with the compounds that were selected for clinical development.

As mentioned previously, mutations in the human TXA_2 synthesis/response pathway may result in mild bleeding disorders, such as minor mucosal bleeding and easy bruising. Patients typically have prolonged bleeding times and defective aggregation responses to arachidonic acid/TXA_2 pathway agonists.[8–10,12,13,94–101] Genetic defects in this pathway can be modeled in mice. TXAS or TP deficient mice have reduced responses to thrombotic stimuli and prolonged bleeding times.[43,102] They also show altered hemodynamic responses to hypertensive stimuli,[102,103] consistent with the role of TXA_2 in renal function and vasoconstriction.[103,104] TXA_2 derived from both platelet and nonplatelet sources[105,106] may also accelerate remodeling of the blood vessel wall in response to vascular injury[7] and lesion development during initiation of atherogenesis.[107,108,109]

Prostacyclin

PGI_2, a dominant product of the vasculature,[110,111] is largely derived from COX-2 under physiologic conditions in humans.[89,90,112–114] Hemodynamic forces are thought to regulate vascular expression of COX-2 *in vivo*.[115] PGI_2 acts as a general restraint on stimuli that activate platelets such as collagen, thrombin, or TXA_2 by raising the cAMP concentration in the platelet through activation of its IP receptor. As mentioned above, local production of PGI_2 is thought to be a component of the mechanism that prevents thrombus formation beyond the site of injury and its close vicinity.

Following activation of the IP-G_s-adenylyl cyclase pathway, cAMP activates protein kinase A (PKA), which, amongst a number of target proteins, deactivates myosin light chain kinase leading to reduced myosin phosphorylation and decreases platelet aggregation. PKA also phosphorylates the vasodilator stimulated protein, which regulates fibrinogen binding by modulating the inside-out signaling of the integrin $\alpha_{IIb}\beta_3$, the major fibrinogen receptor in platelets. PGI_2 may also affect the hemostatic system by regulating the expression of thrombin receptors and thrombomodulin.[116]

Disrupting PGI_2 signaling in mice by deleting its specific receptor, the IP, predisposes to thrombosis *in vivo*[7,117] and various models have been used to demonstrate that perturbation of PGI_2 function augments the thrombotic response. Thus, IP deletion accelerated the thrombotic occlusion of large arteries in response to injury in a gene dose–dependent fashion.[26] Administration of a selective COX-2 inhibitor at doses that reduced PGI_2 formation also resulted in a shortened vascular occlusion time.[26] Similarly, genetic disruption of COX-2 or partial genetic disruption, which would be expected to mimic pharmacologic inhibition more faithfully than complete knockout, reduced PGI_2 formation and accelerated thrombosis.[26,118–120] COX-2–derived PGI_2 formation was mapped to the vasculature using tissue-specific deletion of COX-2 in endothelial cells and vascular smooth muscle cells. Indeed, tissue-specific deletion of COX-2 in vessel wall cells was sufficient to reduce PGI_2 biosynthesis and augment the thrombotic response in a microvascular laser injury model.[111] Finally, selective inhibition of COX-2 also depressed PGI_2 biosynthesis in rats and predisposed rats and hamsters to platelet activation and arterial thrombosis.[121,122] These observations are consistent with findings in studies of human genetics. Thus, polymorphisms in COX-2, PGI_2 synthase, and the IP have variously been associated with adverse cardiovascular outcome after angioplasty and hypertension.[123,124,125]

Other Prostanoids

The role of PGE_2 in platelet function *in vivo* remains less clear. *In vitro*, high PGE_2 concentrations (>10 μM), acting via the IP or, theoretically, the EP_2 or EP_4, inhibit platelet function.[25] Low concentrations of PGE_2, acting via the EP_3, augment submaximal platelet stimulation by other agonists. Consistent with the latter observation, mice lacking the EP_3 have an increased bleeding tendency and decreased susceptibility to thromboembolism.[126]

Deletion of the enzyme primarily mediating inflammatory PGE_2 formation, the microsomal PGE synthase-1 (mPGES-1), did not affect thrombogenesis *in vivo,* probably due to substrate rediversion and augmented formation of PGI_2.[26]

INHIBITION OF PROSTAGLANDIN FORMATION

Platelet Inhibition with Aspirin

The COX isozymes are configured such that the active site is accessed by the arachidonic acid substrate via a hydrophobic channel. Aspirin acetylates serine 529 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of arachidonic acid to the active site of the enzyme and thus impairs the ability of the enzyme to make PGs. Although covalent modification of COX-2 by aspirin (serine 516) also blocks the cyclooxygenase activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(*R*)-hydroxyeicosatetraenoic acid [15(*R*)-HETE]. This may be metabolized, at least *in vitro*, by 5-lipoxygenase to yield 15-epilipoxin A_4, which has anti-inflammatory properties.

As anucleate platelets have limited capacity to synthesize proteins, new platelets need to be released into the circulation to recover clotting function following aspirin exposure. Inhibition of platelet COX-1–dependent TXA_2 formation therefore is cumulative with repeated doses of aspirin as low as 30 mg/d. The unique sensitivity of platelets to inhibition by such low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver.[127] In contrast to aspirin, salicylic acid is a weak, reversible competitive inhibitor of cyclooxygenase. Full recovery from COX-1 inhibition takes platelets roughly 8 to 12 days—the platelet turnover time—once therapy has been stopped. However, even a partially recovered platelet pool—just a few days after the last aspirin dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed. However, partial platelet function may also predispose to thrombotic events in noncompliant patients.

Irreversible, complete, and permanent inhibition of platelet COX-1 is thought sufficient to explain cardioprotection by aspirin.[14] Traditional NSAIDs, with the possible exception of naproxen in some individuals, which inhibit the enzyme reversibly, achieve a level of inhibition of TXA_2 synthesis that translates into inhibition of platelet function only transiently during the dosing interval.[66] Aspirin reduces the incidence of fatal and nonfatal serious vascular events in patients, who already had a vascular occlusive event (i.e., secondary prevention), by roughly 25%.[16,17,128] The absolute incidence of serious vascular events in this population is typically reduced yearly by 10 to 20 per 1,000 patients.[16,17,128] Most of the clinical trials demonstrating cardioprotection from low-dose aspirin have used doses in the range of 75 to 81 mg/d. Regular use of aspirin, including aspirin at low doses, can cause serious gastrointestinal and intracranial bleeds. For example, aspirin for secondary cardioprevention increases the incidence of gastrointestinal bleeds approximately 2.7-fold.[17] The yearly increase in the absolute incidence of bleeding, however, is about an order of magnitude smaller (1 to 2 per 1,000 patients) than the reduction in serious cardiovascular events, so that the overall benefit outweighs the risk in secondary prevention.[17] Although aspirin has also been shown to reduce the risk of CV events when used in populations at lower baseline cardiovascular risk,[14] its use for primary prevention is controversial, because the absolute reduction of cardiovascular events is an order of magnitude smaller than for secondary prevention, while the gastrointestinal risk remains roughly constant.[17] Thus, only in adults with a cardiovascular risk >1% per year would the number of cardiovascular events prevented be similar to or greater than the number of episodes of serious bleeding evoked by aspirin.[129]

Aspirin Resistance

Given the potential redundancy in the process of platelet activation and aggregation, low-dose aspirin is remarkably effective in the secondary prevention of important vascular events; it is unsurprising that some patients should suffer thrombotic events while being treated with aspirin. While no precise definition has been widely accepted, the term "aspirin resistance" has been variably used for three observations: (a) treatment failure in patients on low-dose aspirin who have clinical thrombotic events; (b) failed inhibition of platelet function; and (c) biochemical evidence of failed inhibition of COX activity. The prevalence of "aspirin resistance" was reported to be up to 60% depending on the definition used,[130] although most studies have observed rates of 5% to 20%.[131–135] These estimates derive mostly from small patient populations (small in comparisons to the sizes of the studies that were necessary to demonstrate the therapeutic benefit of aspirin)[15,16,17] who were classified as responders and nonresponders based on the failure to meet arbitrarily selected response criteria in various platelet function tests. These criteria include adenosine diphosphate–, collagen-, or arachidonic acid–induced platelet aggregation, cartridge-based bedside whole-blood clotting assays, measurement of platelet TXB_2 formation *ex vivo*, and quantitation of urinary 11-dehydro TXB_2, alone or in combination.

Given the wide use of aspirin for cardioprotection, there is great interest in the discovery of reproducible sources of nonresponsiveness, and in the development of specific tests that would allow for the identification of individuals who would more likely benefit from prophylaxis with higher doses of aspirin or other platelet inhibitors. Many factors may result in an insufficient response to aspirin—and indeed to any medication. For example, the physicochemical properties of aspirin render it particularly susceptible to factors affecting its bioavailability, which is only roughly 40%. The bioavailability may be further reduced in enteric coated aspirin formulations by as much as twofold[136,137] that can translate into attenuated antiplatelet activity.[138,139,140] Given the redundancy in the pathways that result in platelet activation, situations are conceivable in which inhibition of the COX pathway has an insufficient effect on platelet function. For example, environmental factors, such as surgical stress,[141] may activate sympathoadrenal mechanisms of platelet activation resistant to inhibition by aspirin[142] and transcellular mechanisms of platelet activation involving interactions with red blood cells[143] or neutrophils[144] may also proceed, at least *in vitro*, unimpeded by therapy with aspirin. However, these are situations that would not be expected to be specific to aspirin, but might also affect purinergic receptor blockers (e.g., clopidogrel, prasugrel). "True" pharmacologic resistance to aspirin would result from failure of aspirin to inhibit platelet COX-1 either because of failure of aspirin to reach its molecular target,

by failure of aspirin to acetylate COX-1 despite sufficient concentrations in the platelet, or by failure of COX-1 acetylation to suppress TX formation.

Variation in the genes in the TXA_2 biosynthetic/response pathway may account for treatment failure in some individuals,[145,146] but these seem to be uncommon. However, several studies suggest that nongenetic causes are likely to play a prominent role in fluctuation in the response to aspirin.[138,147,148–154,155] Thus, "aspirin resistance" detected in clinical trials appears to be primarily an acquired phenotype. It may be caused by (a) failure to consume aspirin regularly;[147,148,156] (b) insufficient bioavailability; [138] (c) accelerated recovery from irreversible inhibition in situations of enhanced platelet turnover; [157] (d) reduced COX acetylation in the presence of elevated oxidant tone or cholesterol;[149–151] or (e) drug–drug interactions with reversible COX inhibitors and aspirin.[152–154,158,159] Traditional NSAIDs, which bind to both platelet COX-1 and COX-2—ibuprofen,[152] naproxen,[158] and indomethacin[159]—may interfere with the capacity of aspirin to inhibit platelet COX-1 irreversibly, most likely by impeding access of aspirin to its active site.[152] This mechanism may not be restricted to the compounds that have been studied so far and it would be expected to translate into clinical nonresponsiveness to aspirin—a lack of reduction of myocardial infarction and stroke.[160–162]

Cardiovascular Risk of COX-2 Inhibition

The importance of the prostanoids in hemostasis and thrombosis is also highlighted by the clinical experience with inhibitors of COX-2. Enthusiasm for COX-2 selective NSAIDs was initially high as they promised to reduce the likelihood of gastrointestinal complications, although this was actually established to be the case only for a subset of the "coxibs" in clinical trials after they had been introduced to the market. All FDA approved COX-2 selective NSAIDs, however, were shown in placebo controlled trials to cause cardiovascular complications—myocardial infarction, stroke, heart failure, and venous thrombosis—affecting approximately 10 to 20 per 1,000 patients in randomized controlled trials per year,[18,20] which led to the withdrawal of rofecoxib and valdecoxib.[163] It has been estimated that rofecoxib and celecoxib caused over 70,000 acute myocardial infarctions and strokes and 26,000 deaths in the first 5 years of their release on the US market.[164] The underlying molecular mechanism—depression of COX-2–dependent PGI_2 formation in the heart, kidney, and vasculature—has been elucidated in more detail than that of any other adverse drug effect-integrating evidence from cell biology, animal models, and human pharmacology.[18,20] It is likely that the response to COX-2 inhibition in the vasculature, the kidney, and the heart all contribute to the development of cardiovascular complications, either acutely or over time. Aspirin, which suppresses just a component of prothrombotic mechanisms, may be expected to reduce the risk, but not eliminate it.

Mechanistic studies in mice and humans do not support the notion that all NSAIDs would carry the same cardiovascular risk. They suggest that the toxicity profiles of compounds with respect to the major relevant organ systems are as diverse as their gastrointestinal toxicity profiles. NSAIDs are a chemically heterogeneous group of compounds, thus, it is unsurprising that individual compounds are distinguished by multiple characteristics with potential to impact on their risk/benefit profile, such as their half-lives, potency, and selectivity for COX-2. Indeed, it was suggested that the combination of all factors that determine drug exposure—including half-life, drug potency, selectivity, and dose—with baseline cardiovascular risk integrate to determine the likelihood of cardiovascular complications in a patient.[20]

CHAPTER

35 The Role of Platelets in Blood Coagulation

PETER N. WALSH

The hemostatic response to vascular injury consists of a series of proteolytic reactions that occur on the surface of activated platelets and other intravascular cells including monocytes and neutrophils.[1–3] This localizes coagulation complex assembly to the hemostatic thrombus and protects coagulation enzymes from inactivation by plasma and cellular inhibitors of serine proteases.[1–3,4–6,7,8] The initial hypotheses explaining the normal coagulation mechanism, referred to as the *cascade*[9] and *waterfall*[10] *theories*, were proposed more than 45 years ago and have since been extensively revised.[11,12,13] The goal of this chapter is to describe our current understanding of the normal hemostatic mechanism. The contributions of leukocytes and monocytes to coagulation complex assembly and the role of cell membrane receptors in the assembly of the anticoagulant complexes involving activated protein C (APC), protein S, and thrombomodulin are discussed in Chapter 19. The interactions of thrombin with platelets and other cells is considered in Chapter 33.

SEQUENTIAL COAGULATION COMPLEX FORMATION

The cascade[9] and waterfall[10] theories of blood coagulation originally postulated a mechanism by which a minute initial stimulus was sequentially amplified through a series of enzymatic reactions to result in the local explosive generation of thrombin. These hypotheses postulated two alternative pathways for the initiation of coagulation, each leading to the activation of factor X (FX). One was termed the *intrinsic pathway* in which the "contact factors," FXII, prekallikrein (PK), high molecular weight kininogen (HK), and FXI, are assembled on negatively-charged surfaces,[14] and the other was termed the *extrinsic pathway*, initiated by FVIIa and by the exposure of tissue factor (TF).[13] It was subsequently shown that platelets make major contributions to each pathway, including an alternative, platelet-dependent pathway for the activation of FXI.[1,15–19] However, these hypotheses required revision because patients with deficiencies of FXII, PK, and HK do not experience abnormal bleeding,[14] whereas patients with deficiencies of factors VIII and IX (hemophilia A and B, respectively) experience severe, life-threatening, spontaneous, and posttraumatic bleeding,[20,21] and patients with FXI deficiency[22–29] and FVII deficiency[30] may bleed excessively after surgery or trauma. Nonetheless, because FIX activation can be catalyzed not only by FXIa[31–40] but also by FVIIa-TF,[37] it has been suggested that the TF pathway can initiate the intrinsic pathway directly and independently of the contact factor pathway. However, this does not account for the hemostatic defect observed in FXI deficiency,[22–29] and in 1991 an alternative mechanism for proteolytic activation of FXI by thrombin[11,12] was demonstrated. Thus, the initial event in hemostasis is likely the exposure of TF on cell membranes, resulting in the activation of FX by FVIIa-TF,[30] and leading to the generation of trace concentrations of thrombin because the TF pathway is rapidly shut down by tissue factor pathway inhibitor (TFPI).[41–46] The initial trace amounts of thrombin formed are sufficient to activate platelets, FXI, FVIII, and FV, permitting the intrinsic (or consolidation) pathway of coagulation to generate sufficient quantities of thrombin to promote hemostasis.[11,12] The intrinsic pathway is thought to occur on the surface membranes of activated platelets, where there are binding sites for FXI,[47–52] FXIa,[53–56] FIX,[57–60] FIXa,[57–73] FVIII,[74–78] FVIIIa,[74–78] FX,[75,79,80] FXa,[81–93] FV,[81–93] FVa,[81–93] prothrombin,[79,80] and thrombin.[2,94] These binding sites promote the assembly of coagulation enzyme–cofactor–substrate complexes that compared with solution-phase reactions, accelerate the kinetics of FXI activation by FXIIa,[95] of FX activation by FIXa,[57,58,62,64–66] and of prothrombin activation by FXa.[81–90] The assembly of these complexes is presented in schematic form in FIGURE 35.1, providing a point of reference for understanding the role of platelets and other cells in the initiation and consolidation pathways of blood coagulation.

INITIATION PATHWAYS

Assembly and Regulation of the Tissue Factor Pathway

As discussed in Chapter 11, the contact phase proteins can initiate intrinsic coagulation when foreign surfaces are introduced into the blood stream,[14] the initiating event in hemostasis is the expression of the transmembrane protein TF on cell membranes.[30] A number of cell types, including monocytes and leukocytes and those underlying the endothelium, can synthesize and expose TF to plasma proteins, but the specific cell type and mechanism of TF presentation has not been definitively identified.[30,96] Unactivated platelets do not constitutively express TF. However, TF-bearing microparticles,[97–103] derived from specialized membrane microdomains (i.e., lipid rafts) in monocytes, can fuse with platelet membranes, perhaps utilizing adhesive receptors such as P-selectin on activated platelets and PSGL-1 on microparticles to transfer TF to platelets by membrane fusion.

Platelets and the Contact Activation Pathway

The reciprocal proteolytic activation of FXII and PK on negatively charged surfaces in the presence of high molecular weight kininogen (HK) can lead to the limited proteolytic activation of FXI[14,104–112] and activation of the intrinsic coagulation pathway. However, the physiologic role of these reactions is uncertain

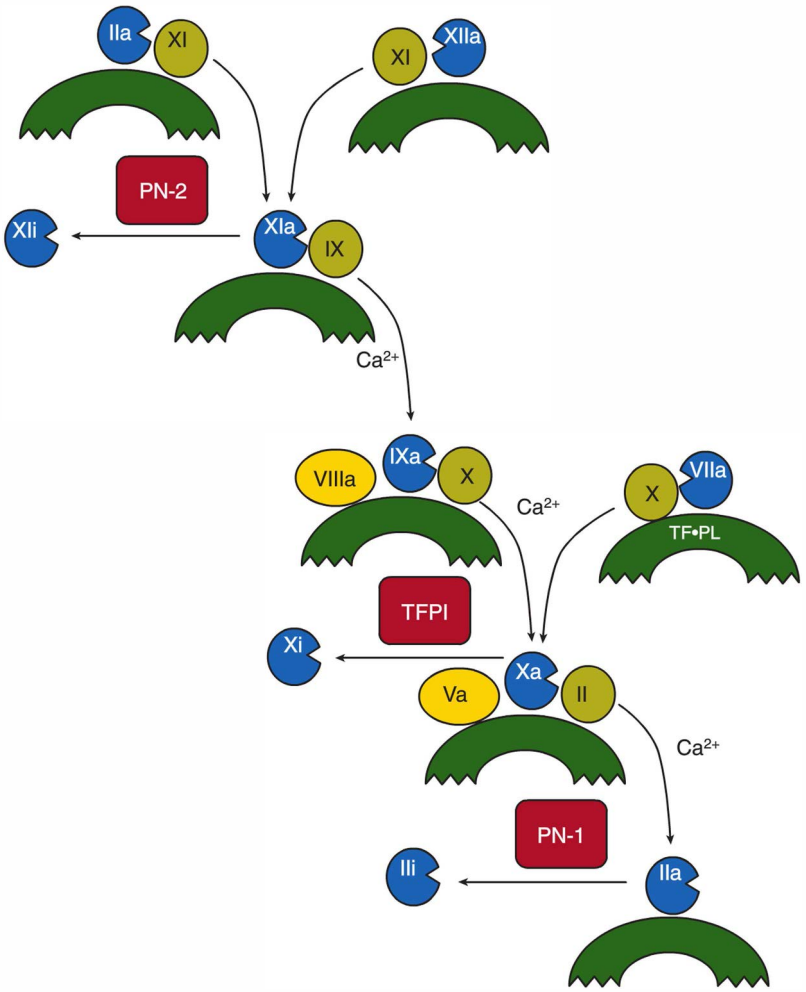

FIGURE 35.1 Schematic diagram representing a current hypothesis of the contribution of platelets to blood coagulation, and the postulated sequence of coagulation reactions that comprises the normal hemostatic mechanism. The crescentic forms represent the activated platelet membrane, except in the case of the form labeled **TF•PL**, which represents tissue factor expressed on a phospholipid membrane surface. The roman numerals represent the coagulation proteins including zymogens or substrates (*in circles*), cofactors (*in ellipses*), and enzymes (*in circles with segmental excisions*). TF, tissue factor; TFPI, tissue factor pathway inhibitor; PN2, protease nexin-2; PN1, protease nexin-1. The curved arrows represent conversions from zymogens (e.g., prothrombin, shown as II) to active enzymes (e.g., thrombin, shown as IIa), whereas the leftward pointing arrows represent the inhibition of these active enzymes (e.g., FXa, shown as Xa) to their inactivated forms (e.g., inactivated FXa, shown as Xi). Shown in boxes are the Kunitz-type inhibitors, PN-2 and TFPI, and the serpin, PN-1. The coagulation mechanism is initiated as the consequence of the assembly of the FVIIa/FX/TF/PL complex and is regulated by TFPI, whereas the consolidation phase of coagulation, regulated by PN-2 and PN-1, is activated by the resulting generation of low concentrations of thrombin sufficient to activate platelets, FXI, FVIII, and FV to produce thrombin in sufficient quantities to form a fibrin clot. (From Walsh PN. Platelets: yin and yang. *Blood* 2010;115:1–2, with permission.)

since patients deficient in contact activation pathway proteins do not bleed.[4,7,8,22–29,94,113,114] In fact, HK may downregulate platelet activation by impairing thrombin binding to the platelet glycoprotein (GP) Ib/IX/V.[115] Nonetheless, the contact activation pathway may contribute to the formation of pathologic thrombi, especially in patients with intravascular prosthetic devices.[14]

Activated platelets can participate in the activation of both FXII and FXI.[1,15–19] Thus, ADP- or collagen-stimulated platelets can promote the proteolytic activation of FXII by kallikrein and the subsequent proteolytic activation of FXI by FXIIa[95] by exposing high-affinity FXI binding sites that require the presence of either HK and zinc ions or prothrombin and calcium ions (Table 35.1).[47–55] Since there is evidence that activation of FXI on the platelet surface by thrombin can occur in the absence of FXII,[116] it is possible that under certain physiologic or pathologic conditions, assembly of contact pathway proteins on activated platelets can trigger intrinsic coagulation. For example, polyphosphates secreted from platelet dense granules[117–119] and RNA released from damaged vessels[120] can activate FXII. A recent systems biology approach, examining the kinetics of thrombin generation in blood treated with corn trypsin inhibitor (CTI) to inhibit contact activation, suggests that activated platelets support the initiation of coagulation via the combined activity of FXIIa and FXIa in the absence of any evidence for kinetically significant blood-borne TF.[121]

CONSOLIDATION PATHWAY

Interactions of Activated Platelets with FXI

FXI is a unique, homodimeric coagulation protein that circulates in plasma in a complex with HK. Although FXI can be activated by FXIIa, the physiologic relevance of this reaction is uncertain. On the other hand, thrombin has been implicated in feedback activation of FXI on negatively charged surfaces, either in the presence of HK and zinc ions or prothrombin and calcium ions.[11,12] Moreover, platelet activation appears to result in FXI binding to GPIb/IX/V, thereby colocalizing FXI with GPIb/IX/V bound in membrane microdomains or lipid rafts.[122,123] Although it was originally reported that platelet stimulation by thrombin promotes FXI activation,[124,125] these observations could not be confirmed.[126] On the other hand, activated platelets can enhance FXI activation when thrombin is generated by low concentrations of TF-FVIIa[116] and thrombin propagates further thrombin generation in CTI-treated plasma when FXI and platelets are present.[127] Nonetheless, the role of thrombin in FXI activation remains controversial. Although Pedicord et al.[128]

Table 35.1

Binding of coagulation zymogens, enzymes, and cofactors to activated platelets

Ligand	Conditions	K_D (nM)	# Sites/Plat	Function	References
FXI	HK + Zn^{2+} or FII + Ca^{2+}	10	1,500	FXI activation	47–52
FXIa	Zn^{2+}	1.7	250	FIX activation	53–56
FIX	Ca^{2+}	2.5	250	FIX activation	57–60
FIXa	Ca^{2+} FVIIIa + FX + Ca^{2+}	2.5 0.5	500 500	FX activation (k_{cat}/K_m ⇑ >10^8-fold)	57–73
FVIII		3.0	450	Unknown	74–78,157
FVIIIa	FIXa + FX	1.7 0.8	1,000 1,200	FX activation (k_{cat}/K_m ⇑ >10^8-fold)	74–78
FX	Ca^{2+} Ca^{2+} + FVIIIa	320 5.0	16,000 1,000	Shared with FII FX activation (k_{cat}/K_m ⇑ >10^8-fold)	75,79,80
FXa	Ca^{2+} + FVa	0.03	250	FII activation (rate ⇑ >10^5-fold)	81–93
FV		1.0	800	Unknown	81–93
FVa		1.0 0.1	4,000 800	FII activation (rate ⇑ >10^5-fold)	81–93
FII	Ca^{2+}	320	16,000	Unknown (shared with FX)	79,80

found no evidence that FXI activation by thrombin occurs in plasma or on the surface of activated platelets, others found that FXI activation by low concentrations of thrombin makes major contributions to the sustained generation of thrombin in plasma in the absence of FXII.[116,127,129–132] The latter observations are supported by evidence that activated platelets, but not endothelial cells, participate in the intrinsic pathway of blood coagulation by promoting the activation of FXI by thrombin and generating FXIa to promote the activation of FIX.[53,133]

Interactions of FXIa with Activated Platelets, FIX, and Protease Nexin-2

The zymogen FXI binds to approximately 1,500 sites on activated platelets via its A3 domain when HK and zinc ions are present, whereas FXIa binds to approximately 250 distinct sites via its catalytic domain in the absence of HK[56] (Table 35.1). Nonetheless, although both FXIa and FIX bind to activated platelets, the rate of FIX activation by FXIa is unaffected by the presence of activated platelets.[53,134,135] On the other hand, platelet-bound FXIa is protected from inactivation by plasma proteinase inhibitors including α_1-protease inhibitor.[135]

Protease nexin-2 (PN2), a truncated form of the Alzheimer β-amyloid protein precursor, contains a Kunitz-type protease inhibitor domain and is a potent inhibitor of FXIa whose activity is enhanced by heparin.[136–140] There is very little PN2 in normal human plasma, but the protein is present in sufficient amounts in platelet α-granules to achieve a plasma concentration of 2 to 5 nM, and possibly even as high as approximately 30 nM,[136,138,139] following platelet secretion. These concentrations, well above the K_i for FXIa inhibition, rapidly and completely inhibit FXIa in solution, whereas FXIa bound to activated platelets is completely protected from inactivation by PN2.[53,139] By contrast, FXIa bound to endothelial cells is not protected,[53] suggesting that platelets, by secreting PN2 and protecting FXIa from inhibition, provide a nidus for localizing coagulation reactions to the hemostatic thrombus.[1,53,133,141]

Interactions of Activated Platelets with FIXa, FVIIIa, and FX

In the early 1970s, it was found that human platelets, activated with collagen but not ADP, provided a membrane surface for the proteolytic cleavage of FX by FIXa in the presence of FVIII.[15,19,142] Subsequently, it was shown that activation of platelets by a variety of physiologic and nonphysiologic agonists, as well as activation of FVIII by thrombin, were required for optimal rates of FX activation by the FIXa–FVIIIa complex.[142–146] At a minimum, aminophospholipids exposed on the outer leaflet of activated platelets participate in the assembly of the FX-activating complex.[147,148] A variety of experimental results suggest that specific classes of platelet receptors exposed by platelet activation also participate in the assembly of the FX-activating complex,[57–69,74–76,79,80,149–151] but such receptors remain to be definitively identified.

FIXa Binding to Activated Platelets

The initial evidence that platelets play a specific role in FX activation was the observation that FIXa binds to approximately 500 high-affinity specific sites on activated platelets, half of which can also recognize the zymogen FIX when calcium ions are present (Table 35.1).[57] The presence of the cofactor FVIIIa and the substrate FX increases the affinity of FIXa binding approximately fivefold, but has no effect on FIX binding.[57] The conclusion that the FIXa binding sites are functionally relevant[58]

is supported by studies demonstrating that thrombin-activated platelets decrease the K_m for FXa activation >200-fold and permit FVIIIa to increase the V_{max} by >50,000-fold, resulting in an increase in catalytic efficiency >2 × 10^8-fold.[66] The effects of platelets on catalytic efficiency are almost identical to those of phosphatidylcholine (PC)/phosphatidylserine (PS) vesicles,[66,152] but are absolutely dependent on platelet activation by thrombin or the thrombin receptor activation peptide (SFLLRN)[57,58,79,80]; ADP has no capacity to expose FIXa receptors on platelets.[57,58,79,80]

The observations that FIXa binds to twice as many sites as FIX and displaces all bound FIX, whereas FIX displaces only 50% of bound FIXa[57] raise questions about the structural relation of the FIX and FIXa binding sites. FIX binding to activated platelets is mediated by residues G4–Q11 in the Ω loop of the FIX Gla domain, whereas FIXa binding is mediated by the Gla domain Ω loop, as well as residues C88–C109 of the EGF-2 domain.[59,61,63,65,67–69,151] Because FIX displaces FIXa from its Gla-mediated binding site, it was surprising to find that FIX potentiates FIXa-catalyzed FX activation by increasing the affinity of FIXa for the intrinsic FX-activating complex.[60] It is possible that by displacing FIXa from their shared binding site, FIX facilitates higher-affinity EGF-2 domain-mediated FIXa binding within the FX-activating complex (Table 35.1).

The active site of FIXa is not involved in its high-affinity, FVIIIa-dependent binding to activated platelets,[58] although this binding requires the presence of D47.[65] Moreover, FIX cleavage at R145–A146 is essential for its specific, high-affinity interaction with FIXa binding sites, as evidenced by studies of the variant $FIXa_{Chapel\ Hill}$ (D145 → H substitution).[65] Further, the EGF-1 domain of FIXa has no role in these interactions,[64] whereas both the Ω loop (residues G4–Q11) within the Gla domain and residues C88–C109 within the EGF-2 domain are essential.[59,61,63,67–69,151] Residues G4, K5, L6, F9, V10, and Q11 within the Ω loop (i.e., residues G4–Q11) of the Gla domain have been implicated for FIXa binding, for the assembly of the FX-activating complex[63] and in binding to phospholipid membranes.[153–156] Although conformationally constrained synthetic peptides comprising residues G4–Q11 of the FIX Gla domain displaced FIXa from 50% and FIX from 100% of their respective binding sites, these peptides were relatively ineffective (K_i ~165 μM) in inhibiting platelet receptor–mediated activation of FX by FIXa. Thus, although residues G4–Q11 mediate FIX/IXa binding to their shared platelet receptor, additional FIXa binding sites are functionally important in platelet-mediated FX activation.[59] Additional studies have implicated two disulfide-constrained loop structures, comprising residues C88–C109 within the EGF-2 domain in the high-affinity binding site of FIXa, but FIX, to approximately 250 sites per platelet.[58,68,69,71,72,151] When either residues G4–Q11 or residues C88–C109 in FIXa are mutated, decreased binding is observed; when both motifs are replaced or mutated, FIXa fails to bind to platelets or to promote FX activation on the platelet surface. This suggests that residues G4–Q11 comprise the shared FIX/FIXa platelet-binding site, whereas FIXa also binds via residues C88–C109 for efficient assembly of the FX-activating complex.

FVIIIa Binding to Activated Platelets

Nesheim et al.[157] reported that the procofactor FVIII interacts with approximately 450 high-affinity sites on thrombin-activated platelets (Table 35.1). The active cofactor FVIIIa binds to an additional 300 to 500 sites per platelet with an enhanced affinity; in the presence of active-site–inhibited FIXa and FX, FVIIIa binds to a total of approximately 1,200 sites per platelet with a K_d of approximately 0.8 nM.[74] Although FVa and FVIIIa are homologous, FVa does not compete with FVIIIa for platelet binding. On the other hand, the phospholipid binding protein annexin V is a potent inhibitor of FVIIIa binding to activated platelets,[74] whereas vWF inhibits FVIII, but not FVIIIa, binding. FVIIIa binding to thrombin-activated platelets is closely coupled to the rate of FX activation by FIXa.[74]

FVIII binds to platelets via its C2 domain[78,158–160] and is facilitated by the presence of the A2 and A1 domains.[74] The importance of FVIIIa binding to activated platelets is underscored by the severe hemorrhagic diathesis observed in a patient with the platelet defect known as Scott syndrome that is associated with impaired binding of both FVIIIa and FVa and with a deficiency in cell-surface exposure of PS.[62,85,161]

FX Binding to Activated Platelets

Equilibrium binding studies have revealed the presence of approximately 16,000 FX binding sites with a K_d approximately 320 nM on platelets activated with thrombin or the thrombin receptor (PAR-1) activation peptide (SFLLRN) but not with ADP[79,80] (Table 35.1). The FX binding site is shared with prothrombin. Detailed kinetic studies of FIXa-catalyzed FX activation in the presence of activated platelets demonstrated that FX bound to the activated platelets is preferentially cleaved by platelet-bound FIXa.[80] In addition, FVIIIa binding to the surface of activated platelets resulted in the generation of approximately 1,000 higher-affinity sites (K_d ~5 nM) that do not recognize prothrombin and whose occupancy was closely coupled to the rate of FX activation and to the >10^8-fold increase in catalytic efficiency compared to solution-phase catalysis.[72,74,75] Little is known about the motifs that mediate the interaction of FX with the latter site, but FX and prothrombin binding to the low-affinity, high-capacity binding site is mediated by their Gla domains interacting with aminophospholipids exposed on the surface of activated platelets.[79]

CONTRIBUTION OF PLATELETS TO PROTHROMBIN ACTIVATION

Interactions of Activated Platelets with FXa, FVa, and Prothrombin

Negatively-charged aminophospholipids, exposed on activated platelets, provide a surface for the assembly of the prothrombinase complex[162] that accelerates the activation of prothrombin by approximately 300,000-fold compared with FXa-mediated prothrombin activation in solution.[163–185,186–194,195] Kinetic and equilibrium binding measurements of the interaction of FV, FVa, and FXa in both human[82–86,93,196] and bovine[81,88,90–92] systems show that human[83,84] and bovine[81] platelets bind FXa, and that platelet activation is required. Reduced FXa binding to platelets from patients deficient in FV,[86] platelets studied in the presence of FV alloantibodies,[84] and platelets treated with APC,[197,198] demonstrate that FVa is the receptor for FXa. FVa is downregulated by APC during prothrombin activation, but both FXa and prothrombin protect FVa in a multiplicative manner, either in the presence or absence of protein S.[199]

On unactivated bovine platelets, FVa binds to approximately 800 high-affinity (K_d ~0.1 nM) and approximately 4,000 lower-affinity (K_d ~1 nM) sites per platelet, whereas FV binds to approximately 800 low-affinity (K_d ~1 nM) sites.[90] FVa can displace all bound FV, but FV displaces only FVa bound to low-affinity sites. Since Factor V is present in bovine plasma at a concentration of approximately 10^{-7} M, FV is always present on the platelet surface.[90] Further, although there are approximately 2,500 platelet bound FVa–FXa complexes, only approximately 900 (K_d ~0.2 nM) function in thrombin generation.[88,90]

Coordinate FXa–FVa binding studies have not been carried out using human platelets in part because human platelet α-granules contain 4,000 to 14,000 FV molecules per platelet,[200] complicating measurement of FVa binding. Nevertheless, FVa binding to human platelets does not require platelet activation, is stimulated by the presence of FXa and prothrombin, and is nonsaturable with as many as approximately 3,000 binding sites per platelet,[82,196] although only approximately 250 of these sites represent the functional FXa binding sites important for prothrombin activation.[83,84] On the other hand, kinetic measurements of prothrombin activation indicate that FVa and FXa colocalize on approximately 3,000 sites on thrombin-activated platelets with a stoichiometry of 1:1, an apparent K_d of approximately 0.1 nM, and a k_{cat} of approximately 30 per second.[87,89]

Exposure of anionic phospholipids such as PS on the outer leaflet of the activated platelet membrane has been correlated with the expression of prothrombinase complex formation.[186,201–207] Because thrombin concentrations >20 nM, as well as other "strong platelet agonists" such as the calcium ionophore A23187, mixtures of collagen and thrombin, or the complement protein lytic complex, C5b-9 are required to generate maximal FXa binding, functional prothrombinase complex assembly, and aminophospholipid exposure; it has been suggested that the physiologic site for prothrombinase assembly consists of aminophospholipids, exposed either on the outer leaflet of the platelet membrane or on platelet microparticles (see below).

In human platelets, FV is stored in massive, disulfide-linked complexes with the protein, multimerin,[208–211] is secreted from platelets in a partially activated form that can be further activated by FXa or thrombin, and accounts for 20% to 25% of the total FV in normal blood.[180,212–215] Platelet FV appears to be physiologically unique because FXa activates platelet FV 50- to 100-fold more effectively than thrombin,[212] whereas both proteins exhibit equivalent activity toward plasma FV.[216] Further, platelet FV, but not plasma FV, is phosphorylated by a casein kinase II–like enzyme[217–219] and when platelet FV is bound to platelet membranes, it is more resistant to inactivation by APC.[220,221] Platelet FV appears to play a significant role in hemostasis because patients with FV_{quebec} with nearly absent platelet FV and near-normal levels of plasma FV, have a severe bleeding diathesis,[222–224] whereas substantially less bleeding was observed in a patient with normal platelet FV, but markedly reduced plasma FV because of an anti–FV autoantibody.[214] The recent demonstration that residual platelet FV is sufficient to support adequate thrombin generation and to protect against major bleeding in patients with severe plasma FV deficiency[225,226] emphasizes its unique role, as does the substantially greater effectiveness of platelet transfusion over plasma in the management of hemorrhage associated with congenital FV deficiency.[227,228]

The serpin protease nexin-1 (PN-1) is stored in platelet α-granules. When it is secreted into plasma, it rebinds to the platelet membrane where it inhibits thrombin and reduces thrombin generation by TF. Platelets from PN-1–deficient mice demonstrate increased sensitivity to thrombin and enhanced thrombus formation in a ferric chloride-induced injury model, suggesting that platelet PN-1 has important antithrombotic properties.[229,230]

PLATELET RECEPTORS FOR FX AND PROTHROMBIN ACTIVATION

In addition to aminophospholipids, it is possible that platelet components, such as yet unidentified membrane proteins, participate in the assembly of the FX and prothrombin-activating complexes. Evidence supporting this possibility includes the observations that the affinity of FIXa for activated platelets is approximately 30-fold greater than for phospholipid vesicles, annexin V displays different kinetics for inhibiting FX activation on activated platelets compared to phospholipid vesicles, the kinetics of FX activation in the presence of phospholipid vesicles is more sensitive to variations in salt concentration than are the kinetics of FX activation in the presence of activated platelets,[149,150] and the order of bond cleavage that activates prothrombin is different on platelets compared to phospholipid vesicles. In the latter case, prothrombin is initially cleaved on the surface of activated platelets at Arg271 to generate prethrombin-2, which is subsequently cleaved at Arg320 to generate α-thrombin. By contrast, the order of bond cleavage is different on the surface of phospholipid vesicles with meizothrombin being initially formed by cleavage at Arg320, followed by subsequent cleavage at Arg 271 to generate α-thrombin and fragment 1.2.[231]

Circulating human platelets are heterogeneous with respect to age, density, volume, metabolic characteristics, and lipid peroxidation potential.[232,233] Moreover, although all platelets respond to thrombin, collagen, and other agonists by undergoing morphologic shape changes, aggregation, and secretion, perhaps only approximately 10% respond to thrombin and PAR-1 stimulation by exposing binding sites for FIXa, FVIIIa, and FX and assembling the FX-activating complex.[70] In addition, it has been reported that only approximately 10% of platelets display a sustained increase in calcium transients following platelet stimulation by thrombin and collagen, and only this subpopulation has the capacity to bind FIXa and other components of the FX-activating complex in support of FXa generation.[70,73]

Platelet stimulation with low concentrations of thrombin and collagen or convulxin may also produce a subpopulation of platelets that bind FIXa, FVIIIa, FX, and FVa, thereby assembling the FX-activating complex, so-called COAT platelets.[234,235] It has been suggested that COAT platelets arise when serotonin, secreted from platelet- dense granules, cross-links platelet-derived FVa and other platelet proteins to their receptors via platelet-derived FXIIIa.[236,237] It has also been reported that thrombin and collagen act synergistically to promote platelet procoagulant activity by inducing a sustained elevation in cytosolic calcium in a subpopulation of platelets and that the synergistic effect of thrombin on collagen-induced platelet procoagulant activity is mediated through PAR-1.[238] Recent studies utilizing flow cytometry have demonstrated that at concentrations of thrombin eliciting maximal platelet activation, only a subpopulation of platelets were positive for FVa and FXa binding and for prothrombinase assembly and function.[239] Taken together, these observations support the

surprising conclusion that although all platelets can undergo shape change, aggregation, and secretion, only a small fraction have the capacity to respond to physiologic agonists by undergoing pronounced and sustained increases in cytoplasmic calcium and participating in blood coagulation reactions by exposing binding sites and/or receptors for the assembly of the FX-activating complex.

ORGANIZATION OF PHOSPHOLIPIDS IN PLATELET MEMBRANES

Approximately 57% of the phospholipids in platelets are located in the platelet plasma membrane[242,243] and consist of 38% PC, 27% phosphatidylethanolamine (PE), 17% sphingomyelin (SM), 10% PS, and 5% phosphatidylinositol (PI).[240,241] Studies utilizing phospholipases and the nonpenetrating membrane probe trinitrobenzene sulfonic acid indicate that PC and SM are primarily located on the extracellular face of the resting platelet, whereas the acidic phospholipids, PE, PS, and PI, are located in the inner membrane leaflet.[142,187,193,203,240,242–249] The asymmetric distribution of phospholipids has been confirmed by studies using spin-labeled aminophospholipids and annexin V, a protein that binds with high affinity to aminophospholipids.[244,250] Annexin V binding to activated platelets inhibits the binding of FIXa and the assembly of the FX-activating complex, implying that the components of the FX-activating complex utilize acidic phospholipids to interact with platelets.[149]

Functional Aspects of Lipid Asymmetry

The asymmetric distribution of phospholipids in platelet membranes has major implications for blood coagulation since resting platelets, whose aminophospholipids are sequestered on the inner membrane leaflet, are virtually inert in assembling active coagulation complexes on the platelet membrane. Following platelet stimulation by a variety of physiologic and nonphysiologic agonists, the membrane undergoes major alterations, resulting in the exposure of PS and PE on the extrafacial membrane surface. Activation of platelets with thrombin alone increases the exposure of PE, but not PS, on the platelet surface[193] without altering the fatty acid composition of PE.[251] However, platelet activation with combinations of collagen and thrombin induces significant hydrolysis of both PE and PS.[242] Thus the extent of PS exposure depends on the activator, the most effective activator being the Ca^{2+} ionophore, A23187, followed by the complement membrane attack complex (C5b-9), collagen plus thrombin, collagen, and thrombin.[145,189,252]

The conclusion that externalization of aminophospholipids on activated platelets is physiologically important is supported by a correlation of the extent of PS exposure with the development of platelet procoagulant activity. The exposure of PS on the platelet surface provides binding sites for the components of the FX- and prothrombin-activating complexes.[70,149,253] The discovery that Scott syndrome,[254] characterized by an isolated defect in platelet coagulant activity, is associated with a decrease in PS exposure on the platelet surface,[62,85,161,245] provides further evidence of a role for PS in the development of platelet procoagulant activity, as does the observation that incubating platelets with phospholipase A2, which hydrolyzes PS, inhibits platelet coagulant activities, whereas phospholipases that spare PS do not.[189]

Platelet activation with strong agonists such as the calcium ionophore A23187, thrombin plus collagen, or complement proteins C5b-9 is accompanied by the shedding from the platelet surface of microparticles that contain plasma membrane GPs, P-selectin, and cytoskeletal proteins, as discussed in Chapter 36.[252,255–257] It has also been demonstrated that cytoskeletal preparations obtained from activated platelets contain all the components of the prothrombinase complex including procoagulant acidic phospholipids.[258,259] This suggests that the association of the platelet cytoskeleton with the plasma membrane prevents the shedding of procoagulant microvesicles from unstimulated platelets and that disruption of actin–membrane interactions by calpain may lead to the shedding of platelet microparticles.[260] On the other hand, calpain inhibition by MDL28170 fails to prevent the formation of microparticles that are enriched in acidic phospholipids.[202,244] Formation of platelet microparticles may be important for the assembly of the prothrombin-activating complex[245,252,255,256] since microparticle formation is defective in platelets from a patient with Scott syndrome.[252]

Regulation of Lipid Asymmetry

Three related enzyme-mediated mechanisms have been implicated in the regulation of the asymmetric distribution of phospholipids in platelet membranes, based on experiments utilizing fluorescent and spin-labeled lipid analogs, including nucleotide-binding domain-PS (NBD-PS) and NBD-PC.[246] The three enzymes consist of an inward-directed aminophospholipid translocase, an outward-directed flippase, and a bidirectional lipid scramblase.

An adenosine triphosphate (ATP)–dependent aminophospholipid translocase is postulated to rapidly transport PS and PE from the outer to the inner leaflet of the plasma membranes of platelets and other cells.[202,246,261–264] An ATP-dependent flippase, with properties similar to an ATP-dependent translocase in red blood cells,[265] is postulated to slowly transport all phospholipids from the inner to the outer surface membrane,[266] whereas the predominance of PC in the outer leaflet of plasma membranes is probably a consequence of passive translayer movement that compensates for the active transfer of aminophospholipids in the inner leaflet.[246] A lipid scramblase[267] is postulated to induce rapid, random, bidirectional movement of all phospholipids in surface membranes resulting in the exposure of aminophospholipids on the platelet surface membrane,[247] a rapid loss of phospholipid asymmetry, and the generation of platelet coagulant activity. Deficiencies of lipid scramblase[268,269] and flippase activities[266] have been reported in platelets from patients with Scott syndrome as the basis for their defects in platelet procoagulant activity. Recently a transmembrane protein (TMEM16F) has been identified and characterized as an essential component for Ca^{2+}-dependent exposure of PS on the cell surface, and the defect in PS exposure due to phospholipid scrambling activity in the platelets of a patient with Scott Syndrome has been demonstrated to arise from a mutation at a splice-acceptor site of the gene encoding TMEM16F, causing the premature termination of the protein.[270]

CONCLUSIONS

The schematic diagram presented in FIGURE 35.1 summarizes a current view of the postulated sequence of biochemical events

that comprise the normal hemostatic mechanism, emphasizing the intimate connections between the events of platelet activation, aggregation, and secretion on the one hand and blood coagulation on the other hand. Information summarized in this chapter indicates that the assembly of virtually all the coagulation enzyme–cofactor–substrate complexes that comprise the coagulation mechanism normally occurs on the activated platelet surface.[1] The platelet membrane comprises a surface for receptor-mediated catalytic complex assembly associated with major rate enhancements at each step in the reaction pathway.[1,9,10] The activated platelet surface also provides a protective nidus where binding of coagulation proteases protects them from inactivation by protease inhibitors.[1,271] Recent revisions in the theory of blood coagulation[11,12] replace the view that the intrinsic and extrinsic mechanisms, initiated by contact activation and TF exposure, respectively, are separate and alternative pathways converging on the common pathway for FX and prothrombin activation, with the revised hypothesis shown in FIGURE 35.1. Therefore, although blood coagulation can be triggered by exposure of the "contact factors" (FXII, HK, and PK) to negatively charged surfaces, the predominant mechanism for effecting normal hemostasis is initiated by TF exposure at sites of vascular injury resulting in the generation of minute quantities of thrombin, insufficient to convert fibrinogen to fibrin but sufficient to initiate the consolidation pathway by activating platelets, FXI, FVIII, and FV, leading to FIX activation, FX activation, and prothrombin activation, with enormous amplification at each reaction step, to produce sufficient thrombin to form a consolidated platelet–fibrin thrombus. Also emphasized in the figure are the contributions of the Kunitz-type inhibitors, PN-2 and TFPI, and the serpin, PN-1, all secreted from activated platelets that regulate the assembly of the FVIIa/FX/TF/PL complex (TFPI), whereas the consolidation phase of coagulation is regulated by PN-2 and the common pathway is regulated by PN-1.[271]
