bond, is located in the carboxy terminus of the protein and is encoded by exon VI. The HBS of AT is located in the amino-terminal domain and consists of two regions encoded by exon II and exon IIIa (see Chapter 18).

One of the two alleles is not expressed in type I deficiency, leading to a 50% reduction in the circulating protein. The database lists 80 different point mutations, including microinsertions and deletions; partial or entire deletions have been found in 12 patients.[21]) The high proportion of Alu repeats plays an important role in the generation of large SERPINC1 deletions causing AT type I deficiency.

The type II_{RS} mutations result from amino acid substitutions in the reactive site loop, comprising amino acids 378 (P15) to 398 (P5′), protruding from the surface of the protein. Mutations located in the hinge domain, affecting Ala382 or Ala384 (P10–P12), transform AT into a substrate for thrombin.[24] The Ala384 Ser mutation is particularly frequent in the British population.[25,26] Mutations affecting Gly392, Arg393, and Ser394 (P2, P1, P1′) prevent AT recognition by its target protease.[25]

Most published mutations modifying AT affinity for heparin (type II_{HBS}) are located in the amino-terminal domain encoded by exon II or exon IIIa. Several patients have been found to

Table 81.2

Main features of hereditary thrombophilia

Protein Affected	Antithrombin	Protein C	Protein S	Factor V	Factor II
Gene location	1q23–25	2q13–14	3p11	1q21–22	11p11–q12
Type of mutation(s)		Loss of function Private mutations		Gain of function Arg506Gln	Gain of function G20210A
Frequency in the general population (%)	0.02[a]	0.2–0.4[a]	0.7–2.3[a]	2–10	2–4
Type of assay	Heparin cofactor activity against FXa	Clotting assay or amidolytic assay	Clotting assay or immunoassay for free PS	APCR (second-generation aPTT-based assay) or FV genotyping	FII genotyping
Functional effect	Thrombin and FXa inhibitor	Reduce thrombin generation by inactivation of FVa and FVIIIa		FV variant resistant to APC inactivation	Increases the circulating FII concentration
Risk of VTE	× 10	× 4–5	× 4–5	× 4–5	× 3–4

be homozygous for the Arg47Cys mutation or the Leu99Phe mutation.[21,22]

A cluster of mutations located on the carboxy-terminal side of the reactive loop, affecting residues 402, 404, 407, and 429, have a pleiotropic effect (type II_{PE}). The identification of an Asn187Asp mutation in a patient with recurrent thrombosis and apparently normal circulating AT is puzzling.[27] Indeed, this AT variant has a normal function in its native form, but tends to adopt an inactive conformation during storage *in vitro*, leading the authors to suspect that the thrombotic episodes were provoked by fever.

We identified a Phe229Leu mutation in a 13-month-old child with cerebral thrombosis. This mutation appears to generate an unstable variant that spontaneously polymerizes in the circulation.[23] This observation confirms that conformationally altered AT variants with reduced thermostability can be associated with severe thrombosis.[28]

More than 130 different mutations have been reported and are described online at gene database (http://www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/antithrombin/).

Protein C and Protein S Deficiencies

Biochemistry

PC is a vitamin K–dependent zymogen that is activated at the endothelial surface when thrombin binds to thrombomodulin. This reaction transforms thrombin from a procoagulant enzyme into an inhibitor, by activating PC to activated protein C (APC). PC binding to the endothelial protein C receptor (EPCR) augments its PC activation by the thrombin–thrombomodulin complex.[29] In the presence of its cofactor PS, APC degrades activated FV (FVa) and FVIIIa, thereby impeding further thrombin generation.[30] FV inactivation occurs in a biphasic reaction, with rapid cleavage at Arg506, followed by slower cleavage at Arg306. The first cleavage only partially affects FVa activity, whereas full inactivation occurs after the second cleavage at Arg306. PS markedly stimulates the second phase of the inactivation process, by a 20-fold enhancement of Arg306 hydrolysis.[31] The mechanism of FVIIIa inhibition by APC is also biphasic, with cleavage at Arg562 and then at Arg336. FVIIIa inactivation by APC is increased by PS and FV, which act synergistically as cofactors for the reaction.[32] The anticoagulant activity of PS has also been attributed to interaction with the prothrombinase complex, independent of APC.[33,34] Furthermore, PS enhances around 10-fold the inhibition of factor Xa by tissue factor pathway inhibitor-alpha (TFPI-alpha) in the presence of Ca^{2+} and phospholipids.[35] In addition to its anticoagulant function, APC also binds to EPCR in lipid rafts/caveolar compartments to activate protease-activated receptor 1, thereby eliciting anti-inflammatory and cytoprotective signaling responses in endothelial cells. These properties have led to FDA approval of recombinant APC as a therapeutic drug for severe sepsis (see Chapter 123).

PC is synthesized by hepatocytes and circulates at a concentration of approximately 70 nM, with a half-life of approximately 8 hours. APC forms inactive complexes with serine protease inhibitors, mainly protein C inhibitor, but also protease nexin 3, α_1 antitrypsin, and α_2 macroglobulin.[36]

Although PS is mainly produced by hepatocytes, it is also detected in endothelial cells and platelets. In the circulation, PS forms inactive complexes with C4b-binding protein (C4BP). Free PS represents approximately 40% of the total circulating level, and only this fraction has APC cofactor activity. C4BP is a multimeric protein composed of six or seven α chains, plus or minus a β chain. Only isoforms with a β chain (C4BP β+), which normally represent 80% of circulating C4BP, can bind PS. The interaction between PS and C4BP is reversible, but, in the presence of Ca^{2+}, the dissociation constant is $<10^{-9}$ mol/L. All circulating C4BP β+ molecules carry one molecule of PS, so free plasma PS results from a molar excess of PS over that of C4BP β+.[37] PS plasma levels are lower in women younger than 45 years and in those who are pregnant or are using oral contraceptives.[38] During acute-phase reactions, plasma C4BP concentrations increase after stimulation of the C4BP α, C4BP β, and *PROS1* genes by inflammatory cytokines. PS not only suppresses coagulation as an enhancing cofactor for the coagulation inhibitors APC and TFPI but is also a physiologic ligand for the Tyro/axl/Mer-family of receptor tyrosine kinases that mediate an anti-inflammatory regulatory loop of dendritic cell and monocyte inflammatory function.

Clinical Manifestations of Protein C and Protein S Deficiencies

PC and PS deficiencies are transmitted as autosomal dominant traits with incomplete penetrance, and heterozygous subjects belonging to families with the disorder are at risk of recurrent VTE during adulthood. Hereditary PC deficiency was first identified in subjects who had about half the normal PC concentration and a family history of thrombosis. At 45 years of age, 65% of affected members of the family described by Bovill et al.[39] and 50% of affected members of the 24 families described by Allaart et al.[40] were still free of thrombotic events. In prospectively studied asymptomatic members of thrombophilic families, the incidence of VTE was approximately 0.5% per patient-year in patients with PC deficiency and between 0.5% and 1.65% in patients with PS deficiency.[14–18]

The thrombotic risk associated with PC levels <67% was confirmed in a case–control study of unselected patients who developed DVT before 70 years of age, with a relative risk (RR) of approximately 3.[41] Homozygous patients with undetectable PC have a very severe clinical phenotype, including life-threatening thrombotic complications at birth, mainly neonatal purpura fulminans with large bruises that become necrotic and gangrenous. The parents and family members of these homozygous infants have about half the normal PC concentration and are asymptomatic.[42,43] This form of genetically determined PC deficiency was believed to be recessively transmitted.

Heterozygous subjects belonging to families with PS deficiencies are at risk of recurrent thromboembolic disease in adulthood (review in[44]). In heterozygous subjects, the probability of being free of thrombotic events at 45 years of age is approximately 50%.[45] We found that free PS and/or PS anticoagulant activity below the 10th percentile (ELISA < 75%) of control values was indeed associated with a risk of developing VTE.[46] Homozygous PS deficiency, such as homozygous PC deficiency, is a rare disease associated with severe thrombosis, including neonatal skin necrosis and purpura fulminans.[47,48]

Laboratory Diagnosis

Most clinical laboratories now use the snake venom protease Protac-based assay, allowing PC to be specifically and directly activated in plasma.[49] Such one-step assays evaluate the APC

generated after activation by Protac with synthetic substrates (amidolytic assays) or measure the prolongation of the activated partial thromboplastin time (aPTT) (anticoagulant assays). An immunoenzymatic assay measuring the protein concentration in plasma and functional assays measuring enzymatic or anticoagulant activity are used to distinguish several types of PC deficiency. In type I (quantitative) deficiency, which is caused by reduced synthesis of a normal protein, the plasma concentration is low in the three assays; this is the case in most PC deficiencies. Type II (qualitative) deficiency is characterized by normal synthesis of a nonfunctional protein that affects both the amidolytic and coagulation assays when the mutation disturbs the catalytic site but that affects only the coagulation assays when the mutation disturbs the interaction of PC with calcium, phospholipids, or macromolecular substrates (FV and FVIII). Therefore, it is recommended to use coagulation assays to screen patients for PC deficiency. It is difficult to establish normal ranges, as PC levels in subjects with PC gene abnormalities overlap with levels in healthy subjects[49] and vary with age. According to Miletich,[49] the increase in the PC concentration is approximately 4% per decade. Therefore, patients with PC concentrations <70% may have a hereditary deficiency, although values between 55% and 70% must be considered as borderline.

The diagnosis of PS deficiency is complicated by the presence in plasma of two molecular forms, that is, free PS and C4BP/PS complexes. Therefore, to measure the total circulating PS, immunoenzymatic assays have to be performed in conditions in which C4BP/PS complexes are dissociated, such as with highly diluted plasma in anti-PS–coated plates.[50] PS deficiency characterized by a low free PS concentration but a normal total PS concentration was identified by Comp.[50] A monoclonal antibody-based immunoenzymatic assay is available to measure free PS specifically.[51] APC cofactor activity can be evaluated in an aPTT assay after adding diluted plasma to PS-depleted plasma in the presence of purified APC and purified FVa.

According to the International Society on Thrombosis and Hemostasis (ISTH) standardization subcommittee, three types of PS deficiency have been defined on the basis of total PS levels, free PS levels, and APC cofactor activity. Type I deficiency is characterized by low total PS and free PS antigen levels; type II deficiency is characterized by normal free PS and low APC cofactor activity; and type III PS deficiency is characterized by low free PS levels and normal or near-normal total PS levels. Type I and type III deficiencies in fact appear to be two phenotypic expressions of the same genetic disease,[45] and free PS is used to diagnose PS deficiency in these cases. The lower normal limit of total and free PS levels is 65% of the level observed in a pool of normal plasmas. However, the reference range in women younger than 45 years is approximately 55% under the same conditions. It is recommended to use both the clotting assay and the monoclonal based immunoassay specific for free PS to screen patients for PS deficiency.

Molecular Bases of Protein C and Protein S Deficiencies

The human *PC* gene (PROC) maps to chromosome arm 2q13–q14, spans over 11 kb, and comprises a coding region (exons II to IX) and a 5′ untranslated region encompassing exon I.[52] The protein domains encoded by exons II to IX show considerable homology with other vitamin K–dependent coagulation proteins such as factors VII, IX, and X. Exon II codes for a signal peptide, whereas exon III codes for a propeptide and a 38–amino acid sequence containing nine Glu residues. Exons IV, V, and VI encode a short connecting sequence and two epidermal growth factor (EGF)-like domains, respectively. Exon VII encodes both a domain encompassing a 12–amino acid activation peptide that is released after activation of PC by thrombin and dipeptide 156 to 157, which, when cleaved, yields the mature two-chain form of the protein. Exons VIII and IX encode the serine protease domain, with His211, Asp257, and Ser360 forming the catalytic triad.

The database published on behalf of the ISTH coagulation inhibitor subcommittee[53] lists 160 different mutations. The proportion of missense mutations is very high and the spectrum very wide, making the molecular basis of PC deficiencies similar to that of FIX deficiency (hemophilia B). The large spectrum of mutations responsible for PC deficiency is probably caused by a high rate of *de novo* mutations.[54] Among 90 patients with point mutations, selected on the basis of PC levels <65% and with at least one episode of thrombosis, 76 bore a missense mutation. Interestingly, 4.4% of the patients with the missense mutation were homozygous or compound heterozygotes, of whom only one had purpura fulminans at birth.[55] Homozygosity and compound heterozygosity may account for concentrations ranging from <1% to 25%. Only patients with concentrations <5% are at risk of purpura fulminans.[55,56]

The amount of PC produced by the mutant allele (null or plus), as well as genetic status (heterozygous, homozygous, or compound heterozygous), partly accounts for the variable clinical expression. However, these factors do not explain why, in many families carrying a single *PC* gene mutation, more than 50% of the affected members remain asymptomatic. Other putative genetic factors may therefore favor thrombosis or protect against disease expression.

Two kinds of type II deficiency can be distinguished on the basis of plasma assays after PC activation by Protac. The substitution of different residues in the propeptide or the gamma carboxyglutamic acid (GLA) domain always resulted in low PC anticoagulant activity, whereas amidolytic activity was normal. It is not surprising that mutations giving rise to this biologic phenotype affect exon III because both the propeptide and the *N*-terminal region play a major role in the formation of the GLA domain, required for the anticoagulant activity of PC.

A few mutations in exon IX, which encodes the serine protease domain, also affected the coagulation assay but not the amidolytic assay, suggesting that, in addition to the catalytic pocket, this domain encompasses a region or regions required for PC anticoagulant activity. The other mutations in exon IX led to abnormal results in both the coagulation assay and the amidolytic assay.[57,58] The possible structural impact of natural substitutions has been examined by Greengard et al.[59] using three-dimensional molecular modeling.

Two homologous genes for PS map to chromosome 3p11.[52] The active gene, *PROS1*, spans over 80 kb and comprises 15 exons. Because *PROS2* has no open reading frame and shows multiple base changes, stop codons, and frameshifts, it is probably a pseudogene. The 5′ part of the *PROS1* gene shows strong homology with the other vitamin K–dependent proteins, particularly PC. Exon I encodes the signal peptide; exon II encodes the propeptide and the GLA domain; exon III encodes a domain with a high aromatic amino acid content; exon IV encodes a thrombin-sensitive loop; and exons V to VIII encode four EGF-like domains. The 3′ part of the *PROS1* gene

differs from that of all other known coagulation proteins: The last seven exons (IX to XV) encode a sex-hormone-binding-globulin-homologous domain.[56] On screening consecutive patients with unexplained thrombosis and low PS levels, we found mutations in 70% of cases.[60] Simmonds et al.[61] found a mutation in 41% of 34 patients with type I deficiency, selected using criteria similar to ours. The mutations observed in type I deficiency are distributed throughout the coding sequence. More than 200 different mutations are listed in the database.[44,48,62] Other mechanisms may explain why one allele is not expressed in patients with type I deficiency who have no detectable mutation. Because the screening strategy is based on selective amplification of the *PROS1* gene, recombination events between the *PROS2* and *PROS1* genes are not detected by polymerase chain reaction (PCR)-based techniques. However, only three *PS* gene abnormalities involving large deletions have been shown to be responsible for PS deficiencies.[63] No mutations in the promoter domain have been identified (unpublished data).

A single mutation transforming Ser460 to Pro (Heerlen polymorphism), first described by Bertina et al.[64] as a polymorphism, was found in 28 of our 118 patients referred with unexplained thrombosis and PS type III deficiency; however, approximately 50% of the patients also carried the FV Arg506Gln mutation or a *PC* gene defect, suggesting a cooperative effect on clinical expression.[60] The fact that the affected members of seven families carrying the Ser460Pro mutation were all asymptomatic[65] further suggests that this mutation is not itself a major cause of thrombosis. The type I and type III phenotypes were found to be associated with a similar thrombotic risk, and the two phenotypes coexisted in 14 families, leading the investigators to postulate that type I and type III are phenotypic variants of the same genotype.[45] Taken together, these results show that type III phenotypes have a heterogeneous molecular basis and a wide range of clinical consequences. Recently, it has been shown that the cutoff levels of free PS identifying type III individuals at risk for DVT might be far below the normal range in healthy volunteers. Indeed, individuals with free PS level less than the 5th percentile (<41 IU/dL) had 5.6 times increased risk of DVT compared with those in the upper quartile (>91 IU/dL).[66]

PS type II deficiency is fairly infrequent, and only a few mutations have been identified in patients with normal PS concentrations and low APC cofactor activity. Most mutations giving rise to a type II phenotype are located in the amino-terminal part of PS, which is homologous to that of other vitamin K–dependent proteins and encodes the domains interacting with APC.[60]

A database of mutations responsible for defective genes, including PROC and PROS1, is available online at http://www.hgmd.cf.ac.uk.

FACTOR V_{LEIDEN}

Biochemistry of Activated Protein C Resistance

In 1993, Dahlback described three families in whom APC did not yield the expected prolongation of the clotting time in an aPTT assay[67,68]; this defined a new phenotype called APCR. This was found in 15% to 25% of patients with DVT and in 2% to 10% of control subjects.[69,70] The study by Bertina et al.[71] showed that APCR cosegregated with the *FV* gene and with a single mutation (FV_{Leiden}, Arg506 Gln) affecting one of the APC cleavage sites. Most, but not all, cases of APCR are caused by FV_{Leiden}. In the Leiden Thrombophilia Study (LETS), after exclusion of patients with FV_{Leiden}, a relation was observed between APC sensitivity and the risk of thrombosis: the lower the normalized APC sensitivity ratio, the higher the associated risk. The adjusted (i.e., age, sex, and FVIII) odds ratio (OR) for the lowest quartile was 2.5 (95% confidence intervals [CI], 1.5 to 4.2) compared with the highest quartile.[72] In another study, phenotypic resistance to APC was associated with VTE, independently of FV_{Leiden} status; the age- and sex-adjusted OR for VTE was 1.7 (95% CI, 1.0 to 2.7) in participants who had a normalized APC sensitivity ratio of 0.50 to 0.84 compared with those who had a ratio of 0.85 to 1.3.[73] Clinical states with low APC sensitivity that are not caused by FV_{Leiden} may also be acquired, as is the case during pregnancy, with the use of oral contraceptives, or in patients with lupus anticoagulant or high levels of FVIII.

Molecular Basis of Activated Protein C Resistance

FV is a 330-kDa multidomain single-chain glycoprotein, with a plasma concentration of 20 nmol/L (0.007 g/L).[74,75] The FV gene (gene locus on chromosome arm 1q23) spans more than 80 kb and contains 25 exons. The complimentary DNA (cDNA) has a length of 6,672 bp and encodes a preprotein of 224 amino acids. Similar to FVIII, FV is organized into six domains (i.e., A1, A2, B, A3, C1, and C2). FV and FVIII share approximately 40% sequence identity in their A- and C-domains. Thrombin and FXa activate FV by a cleavage at peptide bonds at positions 709, 1,018, and 1,545, thereby releasing the B-domain, which connects the heavy chain (domains A1-A2) to the light chain (domains A3-C1-C2). Upon activation, FVa is formed by the heavy and light chains that are noncovalently associated by a Ca^{2+} ion. FVa is an essential FXa cofactor; its presence in the prothrombinase complex enhances the rate of prothrombin activation 10^3- to 10^5-fold. Downregulation of the procoagulant activity of FVa is accomplished through its inactivation by APC at positions Arg306, Arg506, and Arg679. Cleavage at Arg506 is essential for optimal exposure of cleavage sites Arg306 and Arg679 but results in partial inactivation of FVa (~40% of procoagulant activity remains). The slower Arg306 cleavage is required for complete inactivation of the protein, whereas the third cleavage site (Arg679) is less important. Therefore, any defect on one or more of these three cleavage sites (i.e., Arg506, Arg306, and Arg679) may potentially affect APC inactivation. FVa inactivation is enhanced by PS. The PS effect is highly phospholipid dependent and is mediated by a selective 20-fold stimulation of APC-catalyzed cleavage at Arg306. In addition to its major role in the procoagulant process when activated, FV also has an anticoagulant role as an APC cofactor (such as PS), downregulating FVIIIa activity after cleavage at position 506. Therefore, this dual pathway involving both inactivation of procoagulant FVa by APC and partial proteolysis of intact FV generating an anticoagulant protein is a complex and subtle regulatory system.

Bertina identified the genetic explanation for the APCR phenotype first in 1994, followed closely by three other groups.[71,76–78] A single base mutation, guanine to adenine at position 1,691 of the *FV* gene, is responsible for the Arg506Gln mutation known as FV_{Leiden}. This mutation results in a substantially reduced

anticoagulant response to APC, because FV_{Leiden} is inactivated about 10 times slower than normal FV. This impairment of FVa inactivation increases thrombin generation and explains more than 90% of clinical APCR phenotypes. However, other mechanisms may contribute to the hypercoagulable state, as suggested by similar inactivation of FVa and FVa_{Leiden} by APC in the presence of PS, FXa, and high concentrations of FVa.[68] The fact that FV_{Leiden} is a much less active cofactor of APC than wild-type FV for FVIIIa inactivation may also explain the thrombophilic state. Impaired FVa inactivation and loss of APC cofactor activity contribute equally to the APCR phenotype in subjects with FV_{Leiden}.[79] Interestingly, two other mutations in FV affect the Arg306 cleavage site. Arg306 is replaced by Gly in $FV_{Hong\ Kong}$, and by Thr in $FV_{Cambridge}$.[80,81] $FV_{Hong\ Kong}$ is prevalent (~5%) among the Chinese in Hong Kong, but neither of these latter mutations is associated with an increased risk of developing venous thrombosis.[82] The two FV mutations involving Arg306 yield identical mild APCR patterns. The associated APC resistance is due not only to incomplete FVa inactivation, but also to reduced APC cofactor activity in FVIIIa inactivation.[75] It strongly argues for the importance of the loss of the APC cofactor activity of FV when it is mutated; it is also strengthened by the demonstration that a recombinant FVa, in which the three known APC cleavage sites have been mutated, is still inactivated by APC, although much slower than the wild-type protein.[83] FV Ile359Thr (FVLiverpool) and FV Glu666Asp are two rare mutations also associated with thrombosis and APCR.[75]

Epidemiology

The prevalence of FV_{Leiden} is high in populations of white descent, but low in native populations of Asia, Africa, and Australia.[84] All FV_{Leiden} alleles are carried by the same haplotype, leading to the inference that the mutation occurred only once and spread by a founder effect. The estimated time of the mutation is approximately 30,000 years ago, implying that it took place after the out-of-Africa divergence that occurred approximately 100,000 years ago.[85] Its spread among whites and its high prevalence suggest that FV_{Leiden} is associated with a survival advantage, such as a decrease in severe bleeding after delivery.[86,87]

The frequency of FV_{Leiden} in white populations is between 2% and 15%.[69,70,88–93,94,95] FV_{Leiden} is very rare in China, Korea, Taiwan, and Japan.[96–98] In the United States, FV_{Leiden} is found in 2.21% of Hispanic Americans, in 1.23% of African Americans, in 0.45% of Asian Americans, and in 1.25% of American Indians.[99] The risk of DVT in heterozygous carriers is approximately fivefold higher than in control population (see Table 81.3). The association of FV_{Leiden} with pulmonary embolism is much weaker than with DVT, with a prevalence of FV_{Leiden} <10% versus 15% to 25%,[100] perhaps explained by the formation of a thrombus that is more stable and adherent and less prone to embolism.[101,102] Whatever be the reasons, this imbalance between the risk of DVT and pulmonary embolism, known as FV_{Leiden} paradox, is not caused by a bias in selection and is specific for FV_{Leiden}, as it has not been observed in carriers of the prothrombin G20210A mutation.[102] To date, there is no clear explanation to understand the FV_{Leiden} paradox.[103]

Familial and case–control studies show that FV_{Leiden} is clearly a milder thrombophilic state than heterozygous AT, PC, or PS deficiency.[16–18] The absolute risks of VTE events in subjects with AT, PC, and PS deficiency are between 0.5% and 1.5% per year, compared to only 0.1% to 0.3% per year in heterozygous carriers of FV_{Leiden}. On the basis of these data, it is estimated that the lifetime probability of developing thrombosis in heterozygous FV_{Leiden} carriers is between 5% and 10%.[73,104] A census-based screening study of 15,109 persons between 18 and 65 years of age suggested that the FV mutation could explain approximately 7% of all cases of VTE and could be responsible for at least 50 cases of VTE annually per million community-living adults.[73]

The prevalence of FV_{Leiden} homozygosity in the general population is approximately 1 in 2,500. The thrombotic complications are far less severe than in homozygous PC and PS deficiencies.[105,106] FV_{Leiden} homozygosity was found in 4.1% of 1,200 consecutive patients with juvenile VTE.[107] In a pooled analysis of eight case–control studies on behalf of the ISTH coagulation inhibitor subcommittee, we found FV_{Leiden} homozygosity in 1.3% of 2,310 cases and 0.13% of 3,204 controls.[94] In homozygotes, the risk of venous thrombosis is increased 30- to 140-fold; yet an additional environmental or genetic risk factor is often present at the first thrombotic event.[94,107] The risk of death among FV_{Leiden} carriers is identical to that among noncarriers.[108,109]

Table 81.3

Risk of a first venous thrombosis and of recurrence with FV_{Leiden} and FII G20210A mutation

	Heterozygous FV_{Leiden} Mutation OR (95% CI)	Heterozygous FII G20210A Mutation OR (95% CI)
OR for a first venous thrombosis (94)	4.9 (4.1–5.9)	3.8 (3.0–4.9)
OR for a recurrent event (after 112)		
Ho et al. (2006)	1.41 (1.14–1.75)	1.72 (1.27–2.31)
Marchiori et al. (2007)	1.39 (1.15–1.76)	1.20 (0.89–1.61)
Segal et al. (2009)	1.56 (1.14–2.12)	1.45 (0.96–2.21)

Factor V_{Leiden} and Recurrent Venous Thrombosis

Two studies showed an increased risk of recurrence in heterozygous carriers of FV_{Leiden},[110,111] but nine other studies did not.[93,112–118,119,120] In three systematic reviews (reviewed in[112]), the risk of heterozygous carriers was around 1.4 (Table 81.3). However, because the increased rate of recurrence remains low, long-term anticoagulant therapy is not mandatory after a first thrombotic event in heterozygous carriers of FV_{Leiden}. The risk of recurrence in FV_{Leiden} homozygotes appeared to be increased, mainly from retrospective studies.[22,93,106,107] Nevertheless, a recent and large case–control study in a cohort of families with thrombophilia did not demonstrate any high risk of recurrent venous thrombosis in individuals with homozygous FV_{Leiden} and/or homozygous prothrombin G20210A or double heterozygous carriers of FV_{Leiden} and prothrombin G20210A.[121]

Factor V_{Leiden} and Arterial Thrombosis

The possible link between FV_{Leiden} and arterial thrombosis is elusive.[122–126] Most studies have shown no association between FV_{Leiden} and myocardial infarction. Nevertheless, meta-analysis of 19 studies (17,500 individuals) suggests that FV_{Leiden} may be associated with a 20% increase in the risk of myocardial infarction.[122] In a case–control study of young women (18 to 44 years), the OR for myocardial infarction was 2.4 (95% CI, 1.0 to 5.9), the increased risk being largely confined to current smokers.[127] A meta-analysis of five studies on premature myocardial infarction determined an OR of 1.54 (95% CI, 1.07 to 2.22).[122] Another meta-analysis of six studies determined an OR of 1.34 (95% CI, 0.94 to 1.91) associated with the FV_{Leiden} and myocardial infarction before the age of 55 years.[126] Two studies suggest that the prevalence of FV_{Leiden} is higher in patients with myocardial infarction associated with nonsignificant stenosis or obstruction, as shown by coronary arteriography.[128,129] Any association between myocardial infarction and FV_{Leiden} would be weak and would not justify screening for the mutation in patients with coronary artery disease.

The prevalence of APCR or the FV_{Leiden} mutation in patients who have had stroke has been examined in more than 30 studies, few of which showed a link with ischemic stroke.[130,131] In 100 patients younger than 45 years who survived an ischemic stroke without a cardiac embolic source, FV_{Leiden} was not overrepresented.[131] FV_{Leiden} is associated with cerebral vein thrombosis, with an OR of 3 to 4.[132–136]

Laboratory Diagnosis

Two types of tests can be used for diagnosing APCR: the functional APCR assay and the genetic FV_{Leiden} identification test. The functional test is based on aPTT prolongation after the addition of purified APC and is expressed as an APC sensitivity ratio: aPTT(+APC)/aPTT(–APC). A low APC sensitivity ratio defines APCR. Second-generation APCR tests, which use dilution of test plasma into FV-deficient plasma, have very good specificity and can even be used to test patients taking warfarin.[124,137] It is mandatory to confirm a positive APCR test by direct detection of FV_{Leiden}. The most commonly used genetic test for FV_{Leiden} is based on PCR amplification of the FV gene exon X. The presence or absence of the mutation can be determined with allele-specific probes or restriction enzymes. The advantage of genetic testing is that it avoids ambiguous results and determines heterozygous/homozygous status in patients with a low APC sensitivity ratio.

THE FII (PROTHROMBIN) G20210A MUTATION

Biochemistry

Prothrombin has procoagulant, anticoagulant, and antifibrinolytic activities after its activation into thrombin by the prothrombinase complex. Thrombin acts by activating factors XIII, XI and VIII, V, PC, and the thrombin-activatable fibrinolysis inhibitor (TAFI) and by cleaving fibrinogen to fibrin. Prothrombin is a 72-kDa multidomain single-chain vitamin K–dependent glycoprotein. Prothrombin activation is mediated by FXa, which cleaves prothrombin at Arg271–Thr272 and Arg320–Ile321 to release the catalytic domain from the carboxy-terminal domain. Prothrombin activation is accelerated approximately 300,000-fold in the presence of FVa, phospholipids, and Ca^{2+}. Human thrombin contains an A chain of 36 amino acids and a B chain of 259 amino acids. The prothrombin gene is 21 kb in length and is encoded by chromosome 11 (position 11p11–q12).[138] The gene comprises 14 exons separated by 13 introns, with the 5′ and 3′ untranslated regions that may play regulatory roles in gene expression.

Molecular Characteristics

By extensively screening the prothrombin genes of 28 families with unexplained venous thrombosis,[139] Poort et al. found one heterozygous nucleotide transition (G to A) at position 20210 in the 3′ untranslated region in five probands (18%). In 474 unselected patients with a first episode of venous thrombosis and 474 controls from the LETS, the frequency of the mutation was 6.2% and 2.3%, respectively. In this study, the OR for thrombosis associated with the FII 20210A allele was 2.8 (95% CI, 1.4 to 5.6). Interestingly, the FII 20210A allele was associated with significantly higher prothrombin levels in heterozygotes than in noncarriers (1.32 and 1.05 U/mL, respectively). The plasma prothrombin level was an independent risk factor for thrombosis. Together, these risk factors suggested that FII 20210A acts by increasing prothrombin levels, leading to increased thrombin generation.[140,141] Another possible explanation for the role of the FII level in thrombosis is that elevated prothrombin levels can inhibit APC-mediated inactivation of FVa.[142]

The mechanism by which the G20210A mutation influences prothrombin levels is controversial.[143–147] The increase in protein synthesis could result from more efficient 3′-end formation, increased messenger ribonucleic acid (mRNA) stability, increased translation efficiency, or a combination of these mechanisms. Mutations of the poly(A) signal sequence commonly cause loss of gene function. FII G20210A is the only example of mutation in the cleavage site required for mRNA polyadenylation that increases 3′ end processing. Another rare FII mutation (FII C20221T) was found in a child with arterial thrombosis after allogenic kidney transplantation and in a 28-year-old man with Budd-Chiari syndrome.[147–149] This paradoxical gain-of-function from mutations in the 3′ end of the *FII* gene was explained by unusual 3′ noncanonical sequence elements: The FII cleavage site for polyadenylation and uridine-rich elements in the 3′ flanking sequence seems less efficient than in other genes, thereby favoring gain-of-function mutations.[147] The same authors demonstrated that, compared to the wild-type FII (FII 20210G), the 20210C and 20210T mutations led to a 40% to 50% increase in mRNA expression, and the 20210A mutation led to a 215% increase.

It was reported that an intronic *FII* gene polymorphism, A19911G, influences splicing efficiency and modulates the effects of the FII G20210A mutation on mRNA and protein expression.[150] The 19911G allele is in linkage disequilibrium with the 20210A allele, and heterozygous carriers of the FII G20210A mutation who also have the 19911G mutation on the other allele (19911G homozygotes) have a higher risk of venous thrombosis.

Epidemiology

The prevalence of the FII mutation is high in populations of white descent but low or nil in Asians, American Indians, and African Americans.[151–153] As in the case of FV_{Leiden}, a founder effect explains the high prevalence of the factor II G20210A

mutation in whites.[153] Haplotyping suggests that the mutation arose 20,000 to 30,000 years ago, after the divergence of non-Africans from Africans and whites from Mongoloid subpopulations. A survival advantage based on a protective prenatal effect of the FII G20210A genotype, such as improved embryonic implantation, has been suggested.[154]

The estimated frequency of FII G20210A in white populations is between 1% and 6%.[94,138,155–161] This mutation is more common in southern than in northern Europe, a gradient opposite to that of FV_{Leiden}.[151] The risk of DVT is increased threefold to fourfold in heterozygous carriers of FII G20210A compared to noncarriers (Table 81.3). In two prospective studies, and in a large Italian cross-sectional survey, the risk of thrombosis was lower than in case–control studies.[155,156,160] In the rare FII G20210A homozygotes, the risk of thrombosis is only moderately increased,[141,162–164] often associated with other genetic or acquired risk factors.[164]

FII G20210A and Recurrent Venous Thrombosis

Two studies showed an increased risk of DVT recurrence among heterozygous carriers of FII G20210A,[109,165] but eight other studies did not.[93,114,116,117,119,120,166,167] Although systematic reviews showed an OR of around 1.4 for recurrence, consensus exists that in heterozygous FII G20210A carriers long-term anticoagulant therapy is not mandatory after a first thrombotic event.[112] The risk of recurrence in FII G20210A homozygotes is probably increased, as in double heterozygotes carrying both FV_{Leiden} and FII G20210A, in whom the risk of a primary VTE event is increased 20-fold.[94,115,116,165] As previously discussed for FV_{Leiden}, a recent and large case–control study did not demonstrate any high risk of recurrent venous thrombosis in homozygous FII G20210A carriers.[121]

FII G20210A and Arterial Thrombosis

Similar to FV_{Leiden}, any association of FII G20210A with arterial thrombosis would be very weak.[123–126,168] Most studies have shown no association between FII G20210A and myocardial infarction or stroke. Nevertheless, in populations at low risk of arterial thrombotic events, such as young women, the OR for myocardial infarction is increased fourfold in FII 20210A carriers.[127,169] A meta-analysis of three studies in patients with myocardial infarction before the age of 55 years found an OR associated with the FII G20210A mutation of 1.86 (95% CI, 0.99 to 3.51).[126]

More than a dozen studies have analyzed the association between the FII G20210A mutation and stroke, and none has shown a link with ischemic events.[130] One study, of 72 patients with ischemic stroke before the age of 50 years and no other risk factors, found a fourfold to fivefold increase in the risk of stroke in carriers of the FII G20210A mutation.[170] This increased risk of stroke in young patients was not found in another study.[135] The risk of cerebral venous thrombosis is increased in carriers of the FII G20210A mutation.[136]

Laboratory Diagnosis

Although FII G20210A heterozygotes have 30% higher prothrombin levels than noncarriers on an average, this phenotype cannot be used to identify carriers of the mutation because of a large overlap of prothrombin levels. The only way to reliably detect the mutation is genetic screening after PCR amplification of the 3′ untranslated region of the *FII* gene. Several techniques are based on detection using specific restriction endonucleases, gel electrophoresis, or fluorescent probing.[168] Multiplex PCR-based assay is valuable for concomitant detection of FV_{Leiden} and FII G20210A.[171]

OTHER GENETIC RISK FACTORS

The Protein C Gene Promoter Polymorphism

The 5′ untranslated region of the *PC* gene, which encompasses exon I, has polymorphic sites at positions –1,654 (C/T), –1,641 (A/G), and –1,476 (A/T). Three haplotypes are commonly observed (CGT, TAA, and CAA). In the LETS, individuals homozygous for CGT had a higher risk of venous thrombosis than individuals with the TAA genotype.[172] In the Paris Thrombosis Study (PATHROS), we found that both homozygotes and heterozygotes for the CG haplotype had lower PC concentrations than noncarriers. The CG allelic frequency was considerably higher in patients with VTE than in controls.[173]

The FXIII α Chain Gene Polymorphism

The replacement of Val34 by Leu in the α chain of FXIII modifies the activation process and results in faster activation by thrombin.[174] Unexpectedly, this polymorphism had a protective effect on myocardial infarction.[175,176] In VTE, several case–control studies failed to show any effect of the FXIII polymorphism; however, in a meta-analysis of four of these studies, we found a weak protective effect, with ORs of 0.86 (95% CI, 0.74 to 0.99) and 0.58 (95% CI, 0.41 to 0.82) in heterozygotes and homozygotes, respectively.[177]

Fibrinogen γ10034T

A C to T variant at position 10034 in the fibrinogen gamma chain (rs2066865) is associated with a 2.4 times increased risk of VTE.[178] Around 6% of individuals carry this variant which is associated with reduced $\gamma A/\gamma'$ fibrinogen ratio. Its association with VTE was confirmed in a Dutch population, in an Austrian population, and in a white population in the United States.[179]

Blood Group Non-0

It was known since 1969 that non-0 blood group is associated with an increased risk of VTE.[180,181] Blood group 0 is associated with decreased levels of factor VIII and von Willebrand factor (vWF), due to increased clearance of vWF.[180] A twofold increased risk for all non-00 genotypes, with a synergistic interaction with FV_{Leiden}, was confirmed in the LETS.[181] The attributable risk of VTE to the non-0 blood group is approximately 25% due to the magnitude of the frequency.[182]

X-Linked Thrombophilia (Factor IX Padua)

All genetic causes of thrombophilia reported to date are autosomal dominant, except for a recently described X-linked thrombophilia due to a Leu for Arg mutation in the factor IX gene. This mutation was found as a gain of function of factor IX, as

the male proband had a ratio of activity to antigen of 8 [183]. This mutation was only found in one family and does not play a role in the epidemiology of the disease. On the other hand, it is an excellent paradigm defining thrombophilia as the antithesis of hemophilia (see *Introduction*). Furthermore, it demonstrates that rare mutations in candidate genes could also play a role in unexplained familial thrombophilia.

GENOME-WIDE ASSOCIATION STUDIES

In the last 5 years, the genome-wide association study (GWAS) approach has been the most popular strategy to identify, with huge successes, new susceptibility loci for multifactorial diseases.[184–186] The first large-scale association analysis on VTE was a multistage strategy gathering 3,155 DVT patients and 5,087 controls and focusing on 19,682 single-nucleotide polymorphisms (SNPs) located in known genes.[187] Three new loci were revealed—the *F11*, the *GP6*, and SERPINC1 (encoding AT) genes. Given their role in coagulation and in platelet aggregation, these three genes are obvious candidates for DVT. The associations at the *F11* and *GP6* loci were further confirmed in a meta-analysis of three independent studies,[188] but the functional variant(s) remain to be identified. A second association study investigating 291,872 SNPs spanning the whole genome was carried out in a sample of 419 DVT patients with idiopathic VTE at a young age (<50 years) and 1,228 healthy controls.[188] In this work, the strongest associations were observed at two known loci, the *FV* and *AB0* genes; only one new locus on chromosome 6 (*HIVEP1* gene) was additionally detected, but its effect on VTE risk was modest when compared to those of *FV* and *AB0*.[189] *HIVEP1* belongs to the HIVEP gene family encoding very large sequence-specific DNA-binding proteins containing multiple zinc fingers, but the mechanisms relating *HIVEP1* to VTE risk remain to be elucidated.

To identify genetic factors that may influence the plasma levels of the three C4BP existing isoforms, $\alpha_7\beta_1$, $\alpha_6\beta_1$, $\alpha_7\beta_0$, a GWAS was conducted by analyzing 283,437 SNPs in the Genetic Analysis of Idiopathic Thrombophilia study.[190] Three SNPs at the *C4BPB/C4BPA* locus were found genome-wide significantly associated with $\alpha_7\beta_0$ levels. One of these SNPs was further found to explain approximately 11% of the variability of mRNA *C4BPA* expression in the Gutenberg Heart Study composed of 1,490 individuals, with no effect on *C4BPB* mRNA expression. The allele associated with increased $\alpha_7\beta_0$ plasma levels and increased *C4BPA* expression was further found associated with increased risk of VTE (OR = 1.24 [1.03 – 1.53]) in MARTHA and FARIVE, two French case–control studies gathering 1,706 cases and 1,379 controls. Interestingly, this SNP was not associated with free PS or total PS. This suggests that it acts on DVT through a PS-independent mechanism that remains to be elucidated.

Through a GWAS, seven SNPs were recently found associated with plasma levels of FVIII and vWF by the CHARGE consortium.[191] These SNPs were located in five genes that have not previously been suspected to be associated with these protein levels. The influence of these loci on thrombosis risk has been investigated in MARTHA and FARIVE. Among the five genes associated with FVIII and/or vWF levels, we observed strong arguments in favor of the *TC2N* gene (also referred to as *MTAC2D1*) as a new candidate gene for VTE, but the functional variants remain to be identified and biologic mechanisms relating it to DVT pathophysiology to be elucidated.[192]

Despite their indisputable successes to generate new candidate genes for VT, GWASs suffer from limitations. Moreover, the new genetic risk factors identified through this approach are not useful in the clinical setting given the very small risk they confer. Thus, other strategies are mandatory to identify the missing heritability of VTE. In a recent epidemiologic study, 30,179 siblings of 19,599 cases of VTE were identified. The siblings had an RR of 3.08 compared with the general population, with a similar increase among siblings of index cases with DVT as among those where the index cases had pulmonary embolism. This emphasized the still unknown genetic component of VTE.[193]

COMBINATIONS OF GENETIC RISK FACTORS AND ASSOCIATION OF GENETIC AND ACQUIRED RISK FACTORS

Combined Defects

There is an increased risk of VTE in patients carrying more than one genetic defect. Indeed, in two studies, 19% and 9.5% of symptomatic probands carrying a *PC* gene mutation also carried the FV_{Leiden} mutation.[194,195] Similar frequencies of combined defects were found in the probands of thrombophilic families carrying a *PS* gene mutation.[60,61] In family members with AT deficiency, coinheritance of FV_{Leiden} increased the risk of DVT.[196] A meta-analysis confirmed that the RR of thrombosis was much higher in carriers of both FV_{Leiden} and FII G20210A.[94] Patients heterozygous for a single genetic risk factor, with the possible exception for AT deficiency, have the lowest risk (RR 3 to 5). These patients may have DVT during adulthood, the risk increasing with age and, often, with acquired risk factors such as prolonged immobilization, surgery, pregnancy, and estrogen therapy. Combined genetic defects are associated with a stronger risk (RR 10 to 20) and may lead to thrombosis in early adulthood; this includes patients carrying two risk alleles, such as homozygotes for FV_{Leiden} and heterozygotes for FV_{Leiden} plus any of the other four genetic risk factors. Finally, homozygosity for PC, PS, or some types of AT deficiency is often associated with very severe early-onset thrombotic disease, and in some cases they could benefit from continuous or discontinuous preventive antithrombotic therapy. Because 10% to 30% of thrombophilic family probands have combined defects, the thrombotic phenotype may not be transmitted as a dominant trait.

Other unknown genes could possibly influence the thrombophilic phenotype. For example, noncarrier members of FV_{Leiden} families have a higher frequency of DVT than the general population does,[76,197] and the Vermont family study showed that other genes control the PC deficiency penetrance.[198,199]

Oral Contraception

The interaction between oral contraceptives and thrombophilia was first established in the LETS, by selecting 155 cases aged 15 to 49 years with a first episode of VTE and 169 matched controls. In this study, the use of oral contraceptives by women carrying FV_{Leiden} led to a 30-fold increase in the risk of VTE, which strongly suggested a synergistic effect.[200] In a meta-analysis of several case–control studies,[94] the risks of using oral contraceptives in FV_{Leiden} carriers were estimated in 517 women 15 to 49 years of age and in 518 controls. The OR (10.28) clearly

indicates a supra-additive effect of the association FV_{Leiden} and oral contraception. The risk of using oral contraceptives associated with FII G20210 was also evaluated in this meta-analysis (OR, 7.14). As already observed,[201] the latter mutation was found to interact synergistically with oral contraception.

The risk of thrombosis is also high in women with AT, PC, and PS deficiencies or homozygous for FV_{Leiden} who use oral contraceptives, particularly in case of AT deficiency, with an annual incidence of 3.4% per person (vs. 0.75% in nonusers).[202,203] Analysis of the LETS dataset led to the conclusion that women with inherited thrombophilia (FV_{Leiden}; FII G20210; and AT, PC, and PS deficiencies) develop VTE not only more often but also earlier than other women.[204] FVIII, FV, and FXI levels above the 90th percentile and FXII levels below the 10th percentile in patients whose first VTE episode occurred when they were taking oral contraceptives were associated with ORs of 10 to 12. However, the joint effect of these risk factors did not exceed the sum of separate effects (additive but not synergistic).[205]

These observations raise the question of whether asymptomatic young women should be tested for thrombophilic factors before the first use of oral contraceptives. Most authors agree that such tests in young women is not desirable because the absolute risk is very low in this population (to prevent one death by pulmonary embolism would require tests on ~500,000), although it might be justified in some cases.[206,207]

Hormone Replacement Therapy

Several observational studies have shown that women taking conjugated or natural estrogen therapy have an increased risk of VTE.[208,209] Few studies have been designed to evaluate the risk of such replacement therapies in thrombophilic postmenopausal women. In the Estrogen in Venous Thromboembolism Trial (EVTET) study,[210] 144 women younger than 70 years were randomly allocated to receive a dose of 2 mg per day of 17-β-oestradiol, norethisterone, or placebo in a double-blind study. Eight of the women receiving hormone replacement therapy (HRT) had recurrent VTE, compared to only one woman in the placebo group. In this study, which was interrupted for safety reasons, FV_{Leiden} carriers did not experience more frequent VTE than noncarriers, suggesting that this thrombophilic risk factor was not predictive of recurrence during HRT. In another study, 77 postmenopausal women who had had VTE were compared to 163 controls. The ORs (95% CI) were 3.9 (1.3 to 11.2), 3.2 (1.7 to 6.0), and 15.5 (3.1 to 76.7) in FV_{Leiden} carriers, in HRT users, and in FV_{Leiden} carriers taking HRT, respectively, suggesting a synergistic effect.[211]

There is no strong evidence that genetic thrombophilic factors can be used to identify a subpopulation at high risk of VTE. The risk of VTE is high in HRT users with prior VTE, whatever is the underlying mechanism.

Pregnancy

Pregnancy is an acquired risk factor for VTE, multiplying the risk fivefold. In families with inherited thrombophilia, asymptomatic carriers have an increased probability of VTE during pregnancy relative to noncarriers. Women carrying two risk alleles, such as homozygotes for FV_{Leiden} and double heterozygotes for FV_{Leiden} and FII G20210A, have a particularly high risk.[212]

In another approach, women with a history of VTE during pregnancy were compared with age-matched women with a prior pregnancy free of VTE. The results confirm that the probability of pregnancy-related thrombosis is high in women with homozygous FV_{Leiden} or with double FV_{Leiden} and FII G20210A mutations.[213,214] Unequivocal PC deficiency (<50%) and AT deficiency (<60%) were also associated with an increased risk of VTE during pregnancy.

Thrombophilia has also gained attention as a risk factor for pregnancy complications (see Chapter 117), as recently reviewed.[215,216] Despite this association, the conflicting results from literature preclude to give definite recommendations.[217]

THROMBOPHILIA SCREENING

There is no consensus on the subsets of subjects who qualify for thrombophilia screening, the types of laboratory test to use, or the clinical treatment of patients with thrombophilia. The most salient recommendations are summarized here.[19,218–222]

Thrombophilia is mainly associated with VTE rather than arterial thrombosis. Venous thrombosis most commonly occurs as DVT and/or pulmonary embolism, and a given case of thrombosis is not associated with a peculiar genetic thrombophilic state. Less common clinical forms such as upper limb, cerebral, and visceral vein thrombosis (i.e., portal, mesenteric, hepatic, and renal) should be screened because these forms are often associated with thrombophilia.[223,224]

The predictive value of a family history for identifying patients with a thrombophilic state is unreliable, and the absence of a family history does not preclude the need to screen for FV_{Leiden}, FII G20210A, and coagulation inhibitor deficiencies.[206,225–227] The multifactorial nature of VTE explains why thrombotic events in carriers of thrombophilic factors are triggered in half of the cases by acquired risk factors.[12,19] Therefore, VTE associated with an acquired risk factor does not preclude the need for screening. It makes sense to restrict screening after a first thrombotic event to young patients and to patients experiencing recurrences after withdrawal of oral anticoagulants.[228,229] Finally, testing for thrombophilia would be useful if we were able to identify patients who are particularly prone to recurrence, but the risk of recurrence is not markedly increased for FV_{Leiden} or FII G20210A.

CHAPTER

82

Epidemiology and Risk Factors for Venous Thromboembolism

JOHN A. HEIT

Thrombosis can affect virtually any venous circulation. This chapter focuses on the epidemiology of common deep vein thrombosis (DVT) of the leg, arm, or pelvis, and its complication, pulmonary embolism (PE). Venous thromboembolism (VTE) is a complex (multifactorial) disease, involving both environmental exposures (e.g., clinical risk factors) as well as genetic and environmental interactions. Most epidemiology studies of VTE addressed populations of primarily European origin, and the data discussed in this chapter mainly relate to these populations. Where available, data from populations originating from other continents are presented. This chapter focuses on population-based studies of VTE incidence, survival, recurrence, and risk factors.

INCIDENCE OF DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

The estimated average annual incidence rate of VTE among persons of European ancestry ranges from 104 to 183 per 100,000 person-years.[1–3,4,5,6] The incidence is similar or higher among African Americans[7,8] and lower among Asians,[9] and Asian[10] and Native Americans.[11] Unlike atherosclerotic arterial disease, the low incidence of VTE among Asians does not appear to increase after emigration and adoption of a western civilization diet and lifestyle, underscoring the probable role of heritability in the etiology of VTE. Using the age- and sex-specific incidence rates for the 5-year time period, 1991 to 1995, projected to the 2000 United States white population, at least 260,000 new cases of VTE occur among whites in the United States annually.[4] If incidence rates among African Americans are similar, then 27,000 additional incident cases occur among African Americans in the United States annually.

VTE is predominantly a disease of older age.[1–3,4,5,6,12] In the absence of a central venous catheter[13] or thrombophilia,[14] VTE is rare prior to late adolescence.[1,15] Incidence rates increase markedly with age for both men and women (FIGURE 82.1) and for both DVT and PE (FIGURE 82.2).[1,5,6] The overall age-adjusted incidence rate is higher for men (130 per 100,000) than women (110 per 100,000; male:female sex ratio is 1.2:1).[1,6] Incidence rates are somewhat higher in women during the childbearing years, while incidence rates after the age of 45 years are generally higher in men. PE accounts for an increasing proportion of VTE with increasing age for both sexes.[1]

SURVIVAL AFTER DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

Overall, survival after VTE is worse than expected, and survival after PE is much worse than after DVT alone (Table 82.1).[16–19] The risk of early death among PE patients is 18-fold higher compared with DVT patients alone.[16] PE is an independent predictor of reduced survival for up to 3 months after onset. After 3 months, observed survival after PE is similar to expected survival.[6,16,17] For almost one-quarter of PE patients, the initial clinical presentation is sudden death. Independent predictors of reduced early survival after VTE include increasing age, male sex, lower body mass index, confinement to a hospital or nursing home at VTE onset, congestive heart failure, chronic lung disease, serious neurologic disease, and active malignancy.[16,17,20] Additional clinical predictors of poor early survival after PE include syncope and arterial hypotension.[20,21] Evidence of right heart failure based on clinical examination, plasma markers (e.g., cardiac troponin T, brain natriuretic peptide), or echocardiography predicts poor survival among normotensive PE patients.[20] Survival over time may be improving for those PE patients living sufficiently long to be diagnosed and treated.[16,22,23] The risk of a diagnosis of subsequent cancer is significantly increased within the first 6 to 12 months after an incident of DVT or PE.[24,25]

VENOUS THROMBOEMBOLISM RECURRENCE

VTE recurs frequently; about 30% of patients develop recurrence within the next 10 years.[26] The hazard of recurrence varies with the time since the incident event and is highest within the first 6 to 12 months but never falls to zero (FIGURE 82.3). The aim of acute anticoagulation treatment for acute VTE is to prevent DVT extension and embolization. The duration of acute treatment must be individualized but generally ranges from 3 to 6 months. After this period of time, the acute thrombus is either lysed or organized and unlikely to extend or embolize. From this time forward, any continued anticoagulation is to prevent recurrent VTE (i.e., secondary prophylaxis). The duration of acute treatment does not affect the risk of recurrence after anticoagulation is stopped,[27–33] suggesting that VTE is a chronic disease with episodic recurrence.[26,34–36] Independent predictors of recurrence include increasing patient age and body mass index,[26,37] neurologic disease with leg paresis,[26] and active cancer.[3,26,34,35,38,39] Among cancer patients, the hazard of VTE recurrence is significantly increased with lung, gastrointestinal, or genitourinary (uterus, kidney, ovary, testicle, bladder, prostate) cancer, and with extensive or moderately extensive cancer disease.[35] While men have been reported to have a higher risk of recurrence compared to women,[40–42] sex is not an independent predictor of recurrence after adjusting for sex-specific risk factors.[26,43] Additional predictors of VTE recurrence include "idiopathic" VTE,[29,30,44,45] a lupus anticoagulant or antiphospholipid antibody,[28,46] antithrombin, protein C or protein S deficiency,[47–49] hyperhomocysteinemia,[50] inflammatory bowel disease,[51] a persistently increased plasma

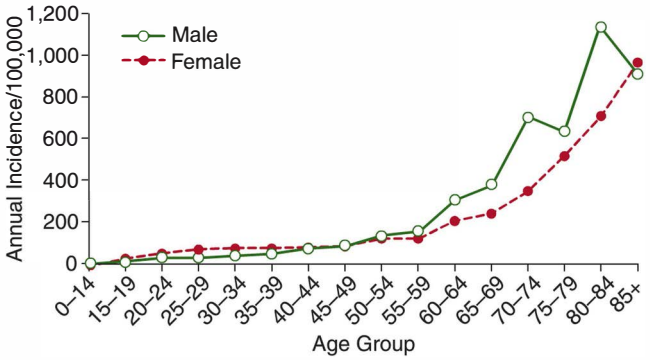

FIGURE 82.1 Annual incidence of VTE by age and sex. (From Silverstein M, Heit J, Mohr D, et al. Trends in the incidence of deep vein thrombosis and pulmonary embolism: a 25-year population-based, cohort study. *Arch Intern Med* 1998;158:585–593.)

Table 82.1

Survival (%) after DVT versus PE

Time	DVT Alone	PE
0 d	97.0	76.5
7 d	96.2	71.1
14 d	95.7	68.7
30 d	94.5	66.8
90 d	91.9	62.8
1 y	85.4	57.4
2 y	81.4	53.6
5 y	72.6	47.4
8 y	65.2	41.5

D-dimer among patients with idiopathic VTE,[52,53,54] and possibly persistent residual DVT.[55] Anticoagulant-based secondary prophylaxis should be considered for patients with these characteristics.

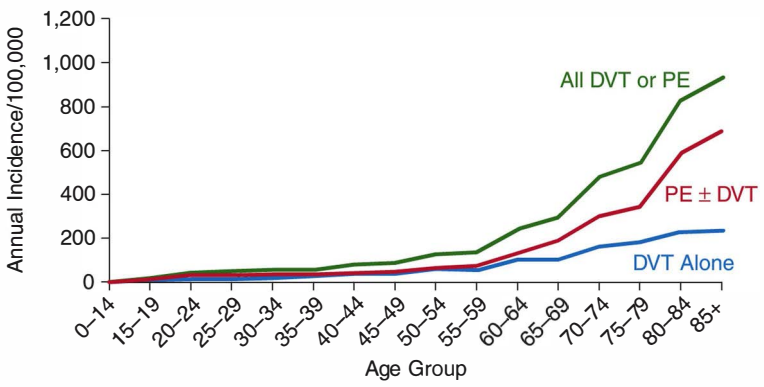
Equally important is the fact that several baseline characteristics predict either a reduced risk of recurrence or are not predictive of recurrence.[26,30,34,38,45,56] For women, pregnancy or the postpartum state,[26,57] oral contraceptive use,[26] hormone therapy,[58] and gynecologic surgery[26] are associated with a reduced risk of recurrence. Recent surgery and trauma/fracture either have no effect[26] or predict a reduced risk of recurrence.[38] Additional characteristics having no significant effect on recurrence risk include recent immobilization, tamoxifen therapy, and failed prophylaxis.[26] For these patients, and for patients with isolated calf vein thrombosis, a shorter duration of acute therapy likely is adequate.[30,44,59] While the reported risk of recurrence by incident event type (DVT alone vs. PE) varies with one report suggesting a higher recurrence risk associated with incident PE,[19,26,59] patients with recurrence are significantly more likely to experience recurrence of the same event type as the incident event type.[60] Because the 7-day case fatality rate is significantly higher for recurrent PE (34%) compared to recurrent DVT alone (4%),[61] secondary prophylaxis should be considered for patients with incident PE, especially those with chronic heart and/or lung disease causing reduced cardiopulmonary functional reserve; it is these patients who are most likely to die from recurrent PE.

Complications of VTE include venous stasis syndrome (post thrombotic syndrome) and chronic thromboembolic pulmonary hypertension, which are discussed in Chapter 85.

RISK FACTORS FOR VENOUS THROMBOEMBOLISM

In order to improve survival, avoid recurrence, prevent complications, and reduce health care costs, the occurrence of VTE must be reduced. However, the incidence of VTE has remained virtually unchanged since about 1981.[1,4,5,6,62] The main independent risk factors for VTE are shown in Table 82.2. Additional risk factors include central vein catheterization or transvenous pacemaker, prior superficial vein thrombosis, varicose veins, urinary tract infection, and family history of VTE; patients with chronic liver disease have a reduced risk.[63–67] Compared to residents in the community, hospitalized residents have over a 100-fold increased incidence of acute VTE.[62] Hospitalization and nursing home residence together account for almost 60% of incident VTE events occurring in the community.[68,69] Thus, hospital confinement provides an important opportunity to significantly reduce VTE incidence. Of note, hospitalization for medical illness and hospitalization for surgery account for

FIGURE 82.2 Annual incidence of all VTE, DVT alone, and pulmonary embolism with or without DVT (PE ± DVT) by age. (From Silverstein M, Heit J, Mohr D, et al. Trends in the incidence of deep vein thrombosis and pulmonary embolism: a 25-year population-based, cohort study. *Arch Intern Med* 1998;158:585–593).



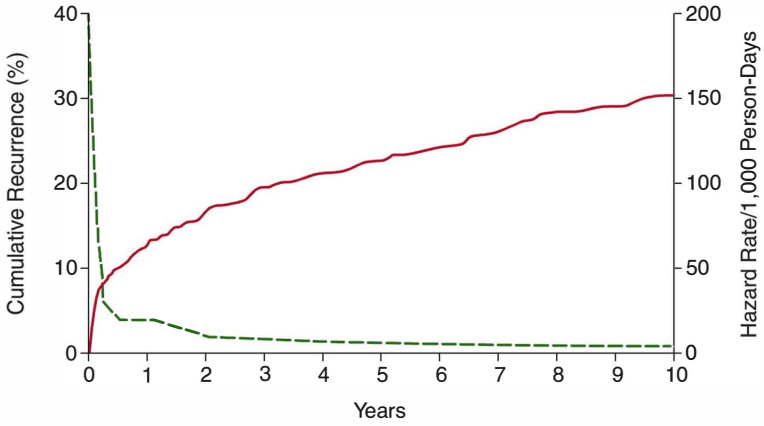


FIGURE 82.3 Cumulative incidence of first VTE recurrence (*solid line*), and the hazard of first recurrence per 1,000 person-days (*dashed line*). (From Heit J, Mohr D, Silverstein M, et al. Predictors of recurrence after deep vein thrombosis and pulmonary embolism: a population-based cohort study. *Arch Intern Med* 2000;160:761–768).

almost equal proportions of VTE (22% and 24%, respectively), emphasizing the need to provide prophylaxis to both of these risk groups. Nursing home residence independently accounts for over one-tenth of all VTE disease in the community.[68,69]

The risk among surgery patients can be further stratified based on patient age, type of surgery, and the presence of active cancer.[70,71] The incidence of postoperative VTE is higher for surgery patients who are 65 years of age or older.[72] High-risk surgical procedures include neurosurgery, major orthopedic surgery of the leg, thoracic, abdominal, or pelvic surgery for cancer, renal transplantation, and cardiovascular surgery.[65,72,73] Obesity[74–76] and poor American Society of Anesthesiology physical status[77] are risk factors for VTE after total hip arthroplasty.

Active cancer accounts for almost 20% of incident VTE events occurring in the community.[68,69] The risk appears to be higher for patients with malignant brain tumors and cancer of the pancreas, ovary, colon, stomach, lung, kidney, and bone,[78,79] and in patients with distant metastases.[79] Cancer patients receiving immunosuppressive or cytotoxic chemotherapy are at even higher risk for VTE,[63,79] including therapy with L-asparaginase,[80,81] thalidomide,[82] lenalidomide[83] bevacizumab,[84] or tamoxifen,[85] or epoetin or darbepoetin.[86,87] A routine examination for occult malignancy is warranted for patients presenting with idiopathic VTE, especially among patients with abdominal vein or bilateral leg vein thrombosis,[88,89] or in whom VTE recurs.[90] Among cancer patients, the risk of chemotherapy-associated VTE is higher in patients with pancreatic or gastric cancer, platelet count ≥350 × 10^9/L, hemoglobin <100 g/L or use of red cell growth factors, leukocyte count ≥11 × 10^9/L, or body mass index ≥35 kg/m^2;[91] biomarkers (plasma soluble P-selectin and D-dimer) add further predictive value.[92]

A central venous catheter or transvenous pacemaker accounts for 9% of incident VTE occurring in the community.[68] Central venous access via femoral vein catheters is associated

Table 82.2

Independent risk factors for DVT or PE

Baseline Characteristic	Odds Ratio	95% CI
Body mass index (kg/m^2)	1.08	1.05, 1.11
Major surgery	18.95	9.22, 38.97
Hospitalization for acute medical illness	5.07	3.12, 8.23
Nursing home confinement	4.63	2.77, 7.74
Trauma/fracture	4.56	2.46, 8.46
Active cancer	14.64	7.73, 27.73
Neurologic disease with leg paresis	6.10	1.97, 18.89
Pregnancy or postpartum	4.24	1.30, 13.84
Oral contraceptives	4.03	1.83, 8.89
Estrogen alone	1.81	1.06, 3.09
Noncontraceptive estrogen plus progestin	2.53	1.38, 4.63

CI, Confidence interval.
From Barsoum MK, Heit JA, Ashrani AA, et al. Is progestin an independent risk factor for incident venous thromboembolism? A population-based case-control study. *Thromb Res* 2010;126:373–378.

with a higher incidence of venous thrombosis compared to subclavian vein catheterization.[93] Prior superficial vein thrombosis is an independent risk factor for subsequent DVT or PE, remote from the episode of superficial thrombophlebitis.[63,94] The risk of DVT imparted by varicose veins is uncertain and appears to vary by patient age.[63,95,96]

Long haul (>4 to 6 hours) air travel is associated with a slightly increased risk for VTE (~1 per 4,656 flights)[97,98,99] that is preventable with elastic stockings.[100] Hypertriglyceridemia doubles the risk of VTE in postmenopausal women.[101] HMG-Coenzyme A reductase inhibitor (statin) therapy may provide a 20% to 50% risk reduction for VTE.[102–104] However, the risk associated with atherosclerosis, or other risk factors for atherosclerosis, remains uncertain.[105–108] Diabetes mellitus,[67] current or past tobacco smoking, high-density lipoprotein cholesterol, lipoprotein (a) and chronic obstructive pulmonary disease are not independent risk factors for VTE.[63,109,110] The risk associated with congestive heart failure, independent of hospitalization, is low.[63,70]

Among women, additional risk factors for VTE include oral contraceptive use,[67,70,111,112,113] hormone therapy,[67,114,115] pregnancy and the postpartum period,[70,112,116,117] and therapy with the selective estrogen receptor modulator, raloxifene.[118] First and third generation oral contraceptives convey higher risk than second generation oral contraceptives.[113] Oral contraceptives containing drospirenone convey two- to threefold increased risk for VTE compared to oral contraceptives containing levonorgestrel.[119,120] Injectable depot medroxyprogesterone acetate for contraception is associated with a threefold increased risk for VTE, while a levonorgestrel intrauterine device imparts no risk.[121] Hormone therapy is associated with a two- to fourfold increased risk of VTE,[67,114] but the risk may vary by type of estrogen.[122] The overall incidence of pregnancy-associated VTE is about 200 per 100,000 woman-years; compared to nonpregnant women of childbearing age, the relative risk is increased about fourfold.[117,123] The risk during the postpartum period is about fivefold higher than the risk during pregnancy.[117] Prior superficial vein thrombosis is an independent risk factor for venous thrombosis during pregnancy or postpartum.[124]

Other conditions associated with VTE include Bechet syndrome, celiac disease,[125] heparin-induced thrombocytopenia,[126] homocystinuria and hyperhomocysteinemia,[127,128] hyperthyroidism,[129] immune thrombocytopenia,[130] inflammatory bowel disease,[131] intravascular coagulation and fibrinolysis/disseminated intravascular coagulation, myeloproliferative disorders (especially polycythemia rubra vera and essential thrombocythemia),[132,133] chronic kidney disease with severely reduced glomerular filtration rate,[134] nephrotic syndrome,[135] paroxysmal nocturnal hemoglobinuria,[136] thromboangiitis obliterans (Buerger disease), thrombotic thrombocytopenic purpura, sickle cell disease,[137] systemic lupus erythematosus, and Wegener granulomatosis.[138]

Family-based studies indicate that VTE is highly heritable and follows a complex mode of inheritance involving environmental interaction.[139–141] Genetic risk factors for VTE are discussed in Chapter 81. While the clinical utility of diagnostic testing for an inherited or acquired thrombophilia remains controversial, such studies hold the potential for further stratifying individual patients into high and low risk for incident and recurrent VTE, targeting prophylaxis to those who would benefit most, and ultimately, reducing the occurrence of VTE.

CHAPTER

83

Clinical Manifestations and Diagnosis of Venous Thromboembolism

HENRI BOUNAMEAUX AND ARNAUD PERRIER

Pulmonary embolism (PE), the source of which is predominantly located in a thrombosis of the deep veins of the legs, is a major health concern. It is the third cause of mortality by cardiovascular disease after coronary artery disease and stroke. In Western countries, it remains a leading cause of death in the puerperium and the postoperative period. In addition, late consequences of deep vein thrombosis (DVT) may produce disabling leg symptoms including venous ulcers in a substantial proportion of patients, resulting in a considerable economic burden. Also, chronic pulmonary hypertension can develop in a small percentage of patients with PE within a few years and require pulmonary thrombendarterectomy, a difficult procedure performed in few dedicated surgical centers.

During the past two decades, the approach to diagnosing DVT and PE has changed in several major ways. First, it has been recognized that these two conditions are manifestations of a single entity, venous thromboembolism (VTE). Second, novel noninvasive diagnostic tools such as D-dimer (DD) measurement, venous compression ultrasonography (CUS), and multidetector computed tomography angiography (MDCTA) have become available. These tools have drastically reduced the need for invasive procedures such as phlebography and pulmonary angiography. Third, the clinical index of suspicion has progressively become lower, so the vast majority (80% or even more) of patients with suspected VTE do not have the disease. Fourth, efficient, mainly noninvasive strategies have been validated in large-scale outcome studies, and more attention has been paid to their cost implications.[1,2]

Finally, the appropriate approach to the diagnosis of VTE differs depending on the nature of the clinical setting: clinical suspicion of a first episode of DVT or PE, clinical suspicion of a recurrent episode of DVT or PE, or screening of asymptomatic DVT or PE in high-risk patients or in patients participating in clinical trials on prophylaxis or therapy of VTE.

CLINICAL MANIFESTATIONS

Clinical Classification of DVT and PE

DVT is defined as the presence of a thrombus in the deep vein system. Although it may occur in all veins (lower and upper limbs, renal, mesenteric, splenic, portal or cerebral veins), it mainly affects the deep veins of the lower limbs (FIGURE 83.1). It must be distinguished from superficial thrombophlebitis, a more benign condition[3] that usually does not require therapeutic anticoagulant therapy, except in selected patients.[4] In general, deep vein thrombi arise in the calf veins (peroneal and posterior tibial veins, almost never anterior tibial veins) and may progress proximally, the so-called *ascending thrombosis*. In some cases (pregnancy, Cockett or May-Thurner syndrome, tumor), DVT may develop proximally, for example, in the common or external iliac vein, and progress distally, the so-called *descending thrombosis*.

Lower limb DVT may be *proximal* (from and including the popliteal vein and upward) or *distal* (in the calf below the popliteal veins), an important distinction because the embolic potential of proximal vein thrombosis is definitely higher than that of distal vein thrombosis.[5] Calf muscle vein thrombi are considered as distal vein thrombosis though their clinical relevance is not well established.

DVT can be *symptomatic* or *asymptomatic*. Asymptomatic thromboses occur more frequently in bedridden patients, especially in the postoperative period, because symptoms (mainly pain and swelling) that are essentially due to venous stasis are usually more prominent in the upright position and thus in outpatients. Symptoms do not necessarily parallel clinical relevance: an asymptomatic iliac thrombosis in a bedridden patient carries a higher risk than a painful calf muscle vein thrombosis in an ambulant individual.

PE is defined as the presence of clots in the pulmonary arteries. The origin is from the lower limb deep veins in more than 90% of cases. Other sites of DVT can also result in PE, but this a rarer occurrence mainly because DVT is most often located in the lower limbs. Traditionally, PE was classified as *massive* or *nonmassive* but this classification is ambiguous because it is used alternatively to designate extensive PE on imaging (usually more than 50% amputation of the pulmonary vasculature), a finding only loosely correlated to clinical outcome, and PE accompanied by shock or at least systemic hypotension, which carries a high mortality and indicates thrombolytic treatment. Moreover, this classification does not account for those patients who have no systemic hypotension but present with right ventricular (RV) dysfunction secondary to PE, demonstrated on echocardiography. According to the ESC definitions, PE is now classified into the following categories (Table 83.1):[6]

- High-risk (previously *massive*) PE: PE provoking shock or cardiorespiratory arrest (5% of cases)
- Intermediate-risk (previously *submassive*) PE: PE provoking RV strain despite normal systemic blood pressure (30% of cases)
- Low-risk (previously *nonmassive*) PE: PE associated with normal systemic blood pressure and normal RV function (65% of cases).

Presentation of Deep Vein Thrombosis

Classic symptoms of DVT include swelling and pain in the involved limb, but those symptoms are neither specific nor sensitive.[7,8] Many nonthrombotic conditions can produce

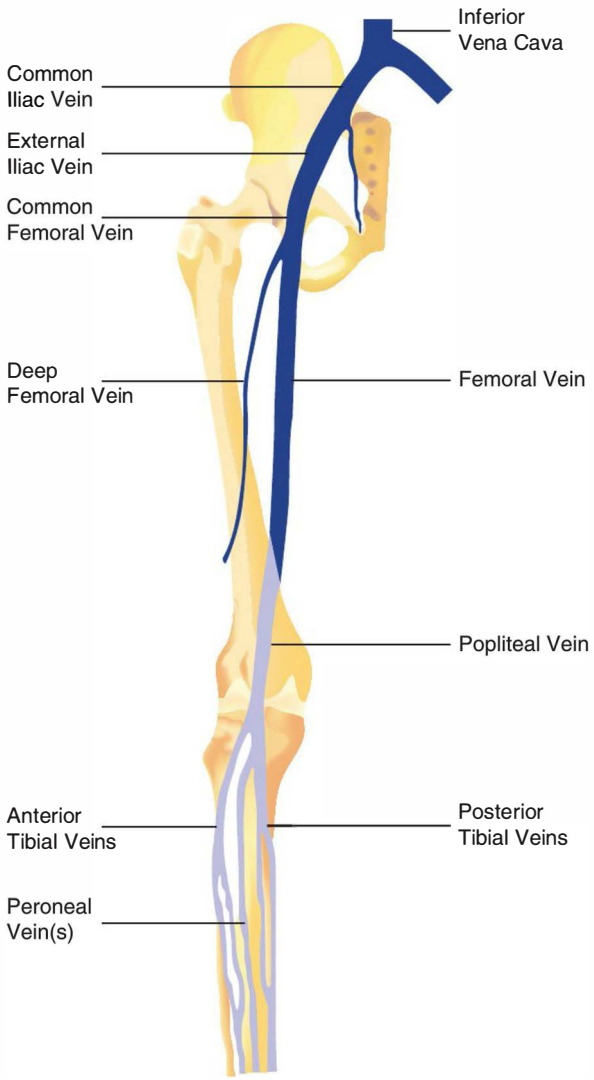

FIGURE 83.1 Anatomy of the deep veins of the lower limb. Note that the femoral vein was previously named "superficial femoral vein," a potentially dangerous misnomer because this vein belongs to the deep vein system.

symptoms similar to those encountered in DVT, such as muscle strain, direct twisting injury to the leg and hematoma, Baker popliteal cyst, cellulitis, and the postthrombotic syndrome. The presence of one or several traditional risk factors (history of immobilization or prolonged hospitalization/bed rest, recent surgery, prior episode of DVT or PE, cancer, trauma, hormonal treatment, pregnancy or postpartum) increases the probability that symptoms are due to DVT. The most informative findings on clinical examination are pain on palpation of the deep veins, significant unilateral edema or swelling, and superficial venous dilation. Warmth, tenderness, and erythema are inconstant and less useful. It is nevertheless possible to assess the clinical probability of DVT in two or three categories based on a limited number of risk factors and clinical signs (see further Section).[9] There is no correlation between clinical presentation and severity, as many thrombi are nonobstructive and are not associated with venous stasis or significant inflammation of the vessel wall or perivascular tissue. Severe forms of proximal vein thrombosis include the *phlegmasia alba dolens* that implies total occlusion of the deep venous system. The leg, then, must rely on the superficial venous system for drainage, which is not effective enough and results in edema, pain, and a white appearance of the leg. The next step in the disease progression is occlusion of the superficial venous system, thereby preventing all venous outflow from the extremity. At this stage it is called *phlegmasia cerulea dolens*. The leg becomes more swollen, cyanotic, and increasingly more painful. Additionally, the edema and loss of venous outflow leads to microcirculatory damage due to the very high venous pressure. Venous gangrene is the ultimate consequence. *Phlegmasia cerulea dolens* is frequently associated with cancer.

Presentation of Pulmonary Embolism

Clinical diagnosis of PE is not possible, due to the lack of sensitivity and specificity of clinical signs and symptoms.[10] Incidental finding of PE is increasingly frequent (2.6% of patients undergoing a CT in a recent meta-analysis[11]), particularly in hospitalized patients or in cancer patients. However, PE is most often symptomatic and usually presents as one of the following three clinical pictures: pleuritic pain associated or not with dyspnea (65% of cases), isolated dyspnea, usually acute but sometimes slowly progressive (20%), or syncope (<10%). These clinical presentations correspond to three syndromes of different pathology and variable severity:[12] (a) pulmonary infarction, (b) isolated dyspnea, and (c) shock, which defines high-risk PE (see next section).

A. Pleuritic pain is usually due to irritation of the visceral pleura by peripheral emboli. Hemoptysis may also be present, although more rarely. Although this syndrome is usually coined as "pulmonary infarction," the histopathologic correlate is in fact an alveolar hemorrhage probably provoked by the efflux of blood from the high-pressure bronchial circulation in the segment obstructed by the embolus.[13] The classic radiologic picture is a wedge-shaped pleural-based infiltrate that affects around 20% of patients.[14] Other common chest x-ray anomalies include plate-like atelectasis and pleural effusion. Tachycardia and dyspnea are less frequent in this clinical syndrome reflecting the peripheral character and lesser hemodynamic repercussions of such pulmonary emboli.[12]

B. In the isolated dyspnea syndrome, the absence of pleuritic pain is probably due to more proximal embolization of the pulmonary vasculature. Patients may complain of retrosternal chest pain oppressive in character evoking the differential diagnosis of angina. In fact, such pain probably reflects true myocardial ischemia due to increased RV wall tension and reduced right coronary artery flow. Tachycardia, although more frequent, is still present in only 45% of patients.[12] The electrocardiogram is rarely normal, but its anomalies are often nonspecific. Although dyspnea is usually of abrupt or rapid onset, in some patients it may progress over several days.

C. Systemic arterial hypotension and shock are the hallmark of high-risk PE causing acute severe pulmonary hypertension and RV failure. It is usually due to large central clots. Although suggestive of PE in patients with obvious risk factors such as recent surgery, syncope may be a misleading presentation.[15] Suspected high-risk PE with shock is a distinct situation requiring a specific diagnostic approach detailed in Section 5.2.2.

Table 83.1

Risk stratification of patients with PE

Risk Category	Mortality	Risk Markers			Clinical Decisions
		Shock or Hypotension	RV Dysfunction[a]	Elevated BNP or Troponin	
High	>15%	+	+	+	Thrombolysis or embolectomy
Nonhigh					
Intermediate	3%–10%	–	+	±	Hospital admission
Low	<1%	–	–	–	Early discharge or outpatient treatment

[a]Echocardiographic signs of RV dysfunction.
Adapted from Torbicki A, Perrier A, Konstantinides S, et al. Guidelines on the diagnosis and management of acute pulmonary embolism: the Task Force for the Diagnosis and Management of Acute Pulmonary Embolism of the European Society of Cardiology (ESC). *Eur Heart J* 2008;29:2276–2315.

DIAGNOSTIC TOOLS

Diagnostic Criterion Standards for DVT and PE

Ascending phlebography is still considered the diagnostic standard for diagnosing DVT but it is invasive, costly, and not devoid of risk. It consists of injection of iodinated contrast dye in a superficial foot vein with sequential radiograms of the leg to follow the dynamic course of the contrast in the veins. Tourniquets can be used to force the dye into the deep veins but their use is controversial. The documentation is adequate when images are obtained in different views, and a filling defect surrounded by contrast is characteristic for a fresh thrombus (FIGURE 83.2, left). It is still used as the standard surrogate endpoint in thromboprophylactic trials for efficacy assessment of new drugs after orthopedic surgery. It can be used for quantification of the thrombotic burden, for example, by Marder score.[16] In clinically suspected individuals, however, it has been largely replaced by CUS. In a classic series by Hull et al.[17] of 160 patients clinically suspected of DVT and left untreated based on a normal phlebogram, the 3-month thromboembolic risk was 1.9% (95% confidence interval [CI] 0.4% to 5.4%), indicating the potential of even the gold standard for false negatives. That figure is the benchmark for comparing the safety of other diagnostic tests to rule out DVT.

Although it is considered the criterion standard for diagnosing PE, pulmonary angiography is difficult to interpret, frequent disagreement occurring even between expert readers,[18] more often on the absence (17% of angiograms) than on the presence of PE (8% of angiograms).[19] The 3-month thromboembolic risk in patients left untreated after an angiogram that was considered normal was 1.7% (95% CI 1.0 to 2.7) in a systematic review pooling the results of eight series totaling 1,050 patients.[20] The test is also costly, invasive, and not devoid of hazards. Moreover, the mortality due to pulmonary angiography was 0.2% (95% CI 0 to 0.3) in a pooled analysis of five series with a total of 5,696 patients.[21] However, the rare deaths attributable to pulmonary angiography occurred in very sick patients with hemodynamic compromise or acute respiratory failure. Nevertheless, pulmonary angiography provides excellent anatomic views of the arterial vasculature of the lungs (FIGURE 83.2, right) and allows quantification of the embolic burden quite precisely, for example, by the Miller et al.[22] index. Because of its invasive character, it should probably be restricted to patients for whom a clinically likely diagnosis could not be confirmed by other means or in those patients for whom endovascular treatment of PE is being considered.

In fact, phlebography and angiography are no longer used routinely in patients with a clinical suspicion of DVT or PE. Nevertheless, they still have a role in patients in whom the clinical likelihood of an acute thromboembolic event is high and in whom noninvasive tests have remained negative or inconclusive. Although valid, that change in clinical practice will probably result in decreasing expertise among radiologists performing these exams, which may decrease their accuracy in the future and further restrict their roles for routine use. Contemporary diagnostic standard equivalents are diagnostic criteria that have been proven safe in outcome studies with clinical 3-month follow-up. Admittedly, this standard is appropriate to ensure that a rule-out criterion has a high negative predictive value and safety, but does not inform on specificity and positive predictive value since positive tests in modern diagnostic strategies are no longer verified by the gold standard.

Obsolete Tests

While venous occlusion plethysmography and continuous wave Doppler flow examination are only used in anecdotal situations nowadays, electrocardiogram, arterial blood gases, and chest x-ray are still part of the so-called prior clinical probability assessment in patients with suspected PE although they no longer belong to the diagnostic tools. The same applies to the ^{125}I Fibrinogen uptake test in the lower legs in suspected DVT. This method has been utilized mainly for screening in clinical studies of thromboprophylactic regimens in the 70s and 80s.

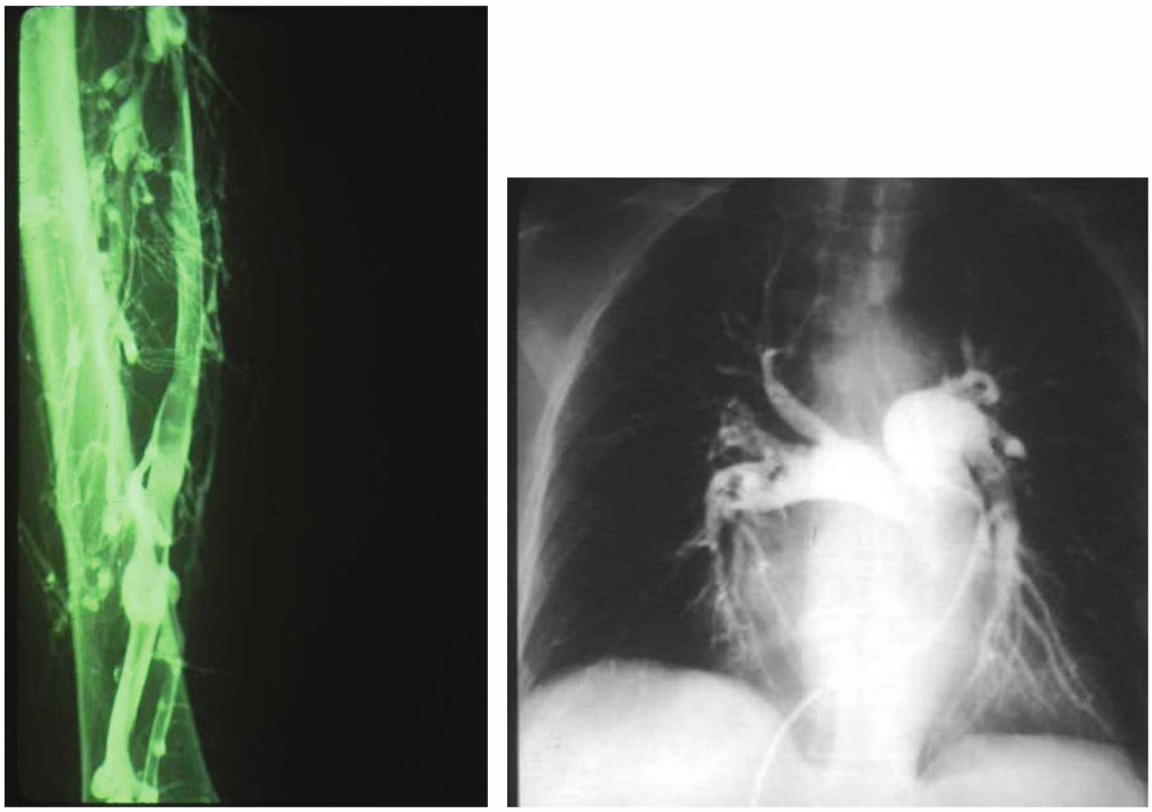

FIGURE 83.2 The historical diagnostic gold standards for DVT (phlebography, **left**) and PE (pulmonary angiography, **right**). The *arrows* point to filling defects surrounded by contrast dye (characteristic for a fresh thrombus) in the femoral vein (**left**), in the inferior lobar artery left, and in all lobar arteries right (**right**).

Clinical Probability Assessment

Sensitivity and specificity of clinical symptoms and signs, and abnormalities of blood gases, chest radiograph, and electrocardiogram in suspected DVT or PE are low when considered singly. The electrocardiogram is usually normal in small peripheral PE. Larger PE may induce modifications such as large P waves in leads II, III, and AVF, the S1Q3T3 pattern, or ST segment depression in leads V1 to V4. A right bundle branch block or right axis deviation is also possible.[23] Hypocapnia and hypoxemia are frequent in PE. However, approximately 20% of patients with proven PE have a normal arterial oxygen pressure and alveoloarterial oxygen gradient.[24] The most frequent anomalies of the chest radiograph are cardiomegaly, pleural effusion, plate-like atelectasis, and elevated hemidiaphragm.[14] Pulmonary artery enlargement and oligemia are rare and nonspecific. The typical infiltrate of so-called pulmonary infarction has already been discussed. Nevertheless, the chest radiograph remains extremely useful in a patient with suspected PE for differential diagnosis with conditions such as left ventricular failure, pneumonia, or pneumothorax.

Clinicians can combine these findings and other signs or symptoms very effectively either implicitly or by prediction rules in order to classify patients according to their probability of having the disease, the so-called prior clinical probability. As a practical tool for assessing prior clinical probability in suspected DVT, the Wells score[25] and its simplified version[26] have gained wide acceptance in spite of its partial subjectivity (Table 83.2). It is probably not more accurate than the simple implicit evaluation. However, it is easier to teach to junior physicians and allows discussing occasional disagreements among experienced clinicians on explicit grounds. Moreover, it has been shown that interobserver reliability was higher when using an explicit clinical model (kappa coefficient of agreement = 0.62 vs. 0.33 for implicit evaluation).[27] Nevertheless, both the implicit assessment and the explicit Wells score allow categorizing usefully patients in low, intermediate, or high clinical probability groups in which the prevalence of DVT is approximately 5%, 20%, and 80%, respectively.

Likewise, the initial step of any diagnostic workup in suspected PE consists of assessing the clinical probability of the patient having the disease. The aim of this step is to (a) identify the patients (probably those with a high or intermediate clinical probability) who require anticoagulant treatment while awaiting the results of diagnostic tests and (b) select the patients (those with a non–high clinical probability) in whom the diagnosis of PE can be excluded on the basis of a negative DD test result, also in relation with the type of DD assay (see also below) (FIGURE 83.3).

Two scores have been widely used (Table 83.3).[28,29] All these means of assessing clinical likelihood of PE allow a fairly accurate classification of patients into three categories corresponding to a prevalence of the disease of 5% to 10% (low clinical probability), 20% to 30% (intermediate clinical probability), and 60%

Table 83.2

Description of the Wells scores[9,26] for patients with clinically suspected DVT

Items, Original Score	Points	Items, Simplified Score	
Cancer	+1	Idem	+1
Paralysis or recent immobilization	+1	Idem	+1
Bedridden >3 d, or surgery/trauma <4 wk	+1	Idem	+1
Pain on palpation of the deep veins	+1	Idem	+1
Entire leg swollen	+1	Idem	+1
Calf swelling	+1	Idem	+1
Pitting edema (symptomatic side only)	+1	Idem	+1
Dilated superficial veins (symptomatic side only)	+1	Idem	+1
		Previously documented DVT	+1
Alternative diagnosis at least as likely as DVT	−2	Idem	−2
Clinical Probability		**Clinical Probability**	
Low	0	Unlikely	0–1
Intermediate	1–2	Likely	≥2
High	≧3		

to 80% (high clinical probability). Most patients with suspected PE have a low or intermediate clinical probability of having the disease. Those with a low or intermediate probability of PE can usually be investigated by entirely noninvasive algorithms. However, these rules also have limitations. The original Geneva score[30] required arterial blood gas values while breathing room air, a variable that was not available in 15% of the patients in the external validation sample. The Canadian score (Table 83.3) includes the clinician's judgment of whether an alternative diagnosis is more likely than that of PE.[29] This criterion has major

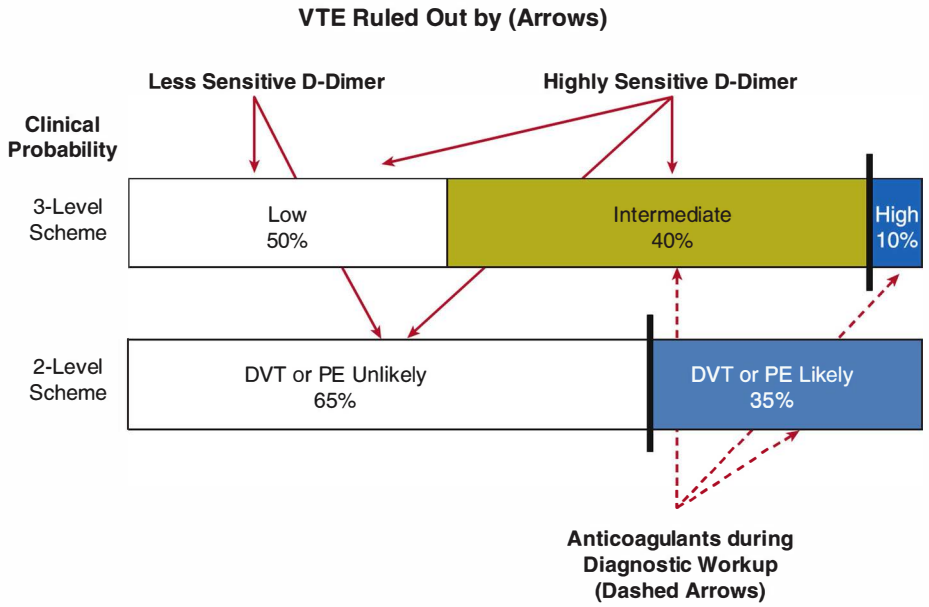

FIGURE 83.3 The objectives of clinical probability assessment. Clinical probability assessment can be expressed by means of 3-level or 2-level categories. It allows to rule out VTE by means of a negative DD test in patients with a low or unlikely assessment (less sensitive DD assays) or low and intermediate or unlikely assessment (highly sensitive DD assays). It also identifies patients who require anticoagulant treatment while awaiting results of diagnostic tests (patients with intermediate or high or likely assessment). The figures in the boxes represent the proportion of patients in the respective category.

weight in this score and can clearly not be standardized, thereby hampering its use by nonclinical health professionals.

The more recent "revised" Geneva score is entirely based on readily available clinical variables and is independent of physicians' implicit judgment (Table 83.3).[28]

In two recent outcome studies, the Wells score for PE has been used with a single cutoff of 4 points instead of two cutoffs.[31,32] This resulted in a classification of patients into two clinical probability categories (PE unlikely or likely) instead of the traditional three levels of probability (low, intermediate or high), which would theoretically allow the use of a less sensitive DD assay in a higher proportion of patients than when using the three-level probability scheme but is further from implicit clinical judgment. Further simplifications of both the Wells rule and the revised Geneva score, in which all items carry the same weight, have also been proposed and have undergone external validation.[33,34]

In a systematic review and meta-analysis of the performance of all available clinical prediction rules for suspected PE,[35] it was concluded that the various prediction rules have a similar accuracy in suspected PE. However, they are not identical and the choice between the various prediction rules and classification schemes must be guided by the local prevalence of PE, the type of patients considered (outpatients or inpatients) and the type of DD assay used. When using a highly sensitive DD assay, a three-level classification scheme is preferred because it mimics more closely clinicians' empirical reasoning and potentially rules out VTE in a higher proportion of patients. Less-sensitive DD assays should be used in combination with the Wells score with two levels of probability (VTE likely or unlikely) as these assays are not able to exclude VTE in 40% of the patients in the intermediate clinical probability category, and the VTE unlikely category includes a higher proportion of patients than the low probability class. The performance of the Wells score for PE is sensitive to the overall prevalence of PE in the population of patients with suspected disease: in a series in which the prevalence of PE was higher than 20%, the prevalence of PE in the low and intermediate probability categories was significantly higher (16%, pooled average) than in series with a lower prevalence of the disease (3.4%). This is not a problem when using a highly sensitive DD assay, but might be with less-sensitive assays. We therefore advise using the revised Geneva score in populations with a prevalence of PE above 20% as that rule has been derived and validated in such settings. Finally, the Wells score for PE (two—or three-level) is the only validated score in inpatients.

Table 83.3

Description of the two most widely used scores for clinical probability assessment in patients with clinically suspected PE

Revised Geneva Prediction Score for PE[28]		**Wells Clinical Prediction Score for PE[29]**	
	Points		**Points**
Age > 65 y	+1	Previous PE or DVT	+1.5
Previous DVT or PE	+3	Heart rate > 100/min	+1.5
Surgery (under general anesthesia) or fracture (of the lower limbs) within 1 mo	+2	Recent surgery or immobilization	+1.5
Active malignancy (solid or hematologic malignancy, currently active or considered as cured since <1 y)	+2	Clinical signs of DVT	+3
Unilateral lower limb pain	+3	Alternative diagnosis less likely than PE	+3
Hemoptysis	+2	Hemoptysis	+1
Heart rate 75–94 bpm	+3	Cancer	+1
Heart rate ≥95 bpm	+5		
Pain on lower limb deep vein palpation and unilateral edema	+4

Low	0–3	*Initial rule*	
Intermediate	4–10	Low	0–1
High	≥11	Intermediate	2–6
		High	≥7
		Dichotomized rule	
		Unlikely	≤4
		Likely	>4

Fibrin D-Dimer Measurement

DD is a degradation product of cross-linked fibrin and its blood concentration is increased in patients with acute VTE. It has been used as an adjunct in the diagnostic workup of DVT and PE for 20 years.[36] When assayed using a quantitative enzyme-linked immunosorbent assay (ELISA) or an automated turbidimetric assay, the DD level has been shown to be highly sensitive (more than 95%) in acute DVT or PE, usually with a cutoff value of 500 μg/L. Hence, a DD level below this value reasonably excludes acute VTE, at least in patients with a low or intermediate clinical probability. Their 3-month thromboembolic risk is <1%, as shown in a meta-analysis on the use of the highly sensitive VIDAS D-dimer Exclusion test.[37] According to these data, PE could be ruled out in about one third of clinically suspected outpatients. This proportion, however, varies according to patient categories (Table 83.4).[38–47] The Tinaquant test, an immunoturbimetric assay, has also been largely validated.[32] The result was negative ruling out PE in 41% of patients who had either a low clinical probability of PE or were classified as "PE unlikely" according to the dichotomized Wells rule. The 3-month thromboembolic risk was also <1%. Finally, the SimpliRed assay, a whole blood less-sensitive bedside test has also been well validated[45] but interobserver variability may be a problem, and exclusion of the disease is only possible in patients with low or "unlikely" clinical probability. Conversely, patients with a high clinical probability should not be tested for DD because a concentration below the diagnostic cutoff is rare in this category of patients,[39] and above all because the upper limit of the 95% CI for the 3-month occurrence of PE remains above 3% despite a negative result.

In order to increase the exclusion rate of DD in elderly patients, a European group devised an age-dependent DD exclusion cutoff for PE that was based on 5,132 patients aged 50 or above from four previous prospective cohort studies.[48] The individualized DD cutoff value was defined as patient's age × 10 μg/L in patients aged above 50. In 1,331 patients in the derivation set with an "unlikely" score from clinical probability assessment, PE could be excluded in 42% with the new cutoff value versus 36% with the old cutoff value (<500 μg/L). In the two validation sets, the absolute increase in the proportion of patients with a DD below the new cutoff value compared with the old value was 5% and 6%, respectively. This increase was largest among patients aged above 70 years, ranging from 13% to 16% in the three datasets. The failure rates (all ages) were 0.2% (95% CI, 0 to 1.0) in the derivation set and 0.6% (95% CI, 0.3 to 1.3) and 0.3% (95% CI, 0.1 to 1.1) in the two validation sets, respectively. Thus, it appears that an age-adjusted DD cutoff point, combined with clinical probability, greatly increases

Table 83.4

Diagnostic yield of DD for ruling out PE in specific patient populations

Author	Clinical Conditions	NNT to Rule Out One PE
High-sensitivity, Low-specificity DD tests		
Perrier et al.[38]	Outpatients with suspected PE	3.3
Righini et al.[39]	High clinical probability Nonhigh clinical probability	9.1 2.2
Righini et al.[40]	Cancer No cancer	9.1 3.1
Le Gal et al.[41]	Previous VTE No previous VTE	6.3 3.1

Righini et al.[43]	Elderly outpatients of more than 80 y	20
Miron et al.[44]	Inpatients (nonsurgical patients) Inpatients (surgical patients)	30 Infinite[a]
Low-sensitivity, High-specificity DD tests		
Wells et al.[45]	Outpatients with suspected PE	2.1
de Groot et al.[46]	In and outpatients with suspected PE	3.7
Kearon et al.[47]	In and outpatients with suspected PE	3.1

The number needed to test (NNT) reflects the number of patients in whom DD measurement has to be performed to rule out one PE.
[a]No patient with negative DD result in this cohort

the proportion of older patients in whom PE could be safely excluded; this is presently being externally further validated in a prospective clinical outcome study. It is clear that this rule will be valid only for the two tests that were used in the original studies, the VIDAS and the Tinaquant DD tests. A similar approach has been proposed for pregnant women clinically suspected of DVT[49] but the proposed increased cutoffs clearly require validation in prospective management studies.

Although DD is very specific for fibrin, the specificity of fibrin for VTE is poor. Indeed, fibrin is produced in a wide variety of conditions such as cancer, inflammation, infection, and necrosis. Hence, a DD concentration above 500 μg/L (the diagnostic cutoff for many assays) has a poor positive predictive value for VTE, and cannot reliably rule in the disease. Nevertheless, based on the results of a retrospective analysis of a large patient sample, Bosson et al.[50] suggested that a DD level above 2,000 μg/L was predictive of the presence of PE, independently of the clinical score with an odds ratio of 6.9. They noted, however, that this result requires clinical validation in a prospective study, particularly because the PE prevalence in their series was high: 27%, 58%, and 85% in the low, intermediate and high clinical probability categories, respectively. The Geneva group had previously reported that patients with an intermediate or high clinical suspicion of PE and a DD level above 4,000 μg/L had a positive likelihood ratio of five of having the disease, but few clinicians would accept the diagnosis just on this basis.[51] Recent quantitative point-of-care (POC) tests have shown a promising sensitivity of 96% but only in patients suspected of DVT and in a relatively small sample size.[52]

In summary, negative highly sensitive DD assays rule out DVT and PE in outpatients with a low or intermediate clinical probability of PE, while whole-blood agglutination tests only rule out the disease in patients with a low clinical probability. Finally, DD is unlikely to be useful in very elderly patients or in hospitalized patients with suspected VTE, unless specific cutoff levels are well established in these subgroups.

Venous Compression Ultrasonography

In studies using phlebography as the gold standard, lower limb venous CUS, an entirely noninvasive test, has a sensitivity of 97% (95% CI 96% to 98%) and a specificity of 98% for symptomatic proximal DVT.[53] It has become the cornerstone of DVT diagnosis in clinically suspected individuals. The single well validated diagnostic criterion for DVT on CUS is absence of full compressibility of the deep vein when applying pressure through the ultrasound probe (FIGURE 83.4). Intraluminal venous ultrasonography has been reported to have variable accuracy, and neither changes in venous diameter during Valsalva maneuver nor assessment of Doppler flow have been found to improve diagnostic accuracy for DVT. The extensiveness of the exam (particularly the inclusion or noninclusion of calf veins in the diagnostic procedure) is heavily debated among experts and will be discussed in paragraph 5.1. In a patient with clinically suspected PE, finding a DVT (at least a proximal one) by CUS is sufficient evidence to warrant anticoagulant treatment without further lung imaging. CUS shows a DVT in approximately 30% to 50% of patients with proven PE.[53,54]

The observation of a low 3-month thromboembolic risk in patients with a negative CUS of the proximal veins (around 1% in management studies) questions the need for diagnosing the so-called distal DVT, at least in non–high clinical probability patients.[55] Indeed, in such patients, detecting clots in the posterior tibial or peroneal veins or even in calf muscle veins may be double-edged: on one hand, the potential of reducing the 3-month thromboembolic risk is limited (because it is already quite low), and, on the other hand, the risk of false-positive findings and subsequent unnecessary anticoagulant treatment in patients who could be left untreated, is quite high. Nevertheless, several large series suggest that complete examination of the leg deep vein system without any other exam is safe and effective in managing patients with clinically suspected DVT, as evidenced from a meta-analysis.[56] This finding, however, does not solve the problem of

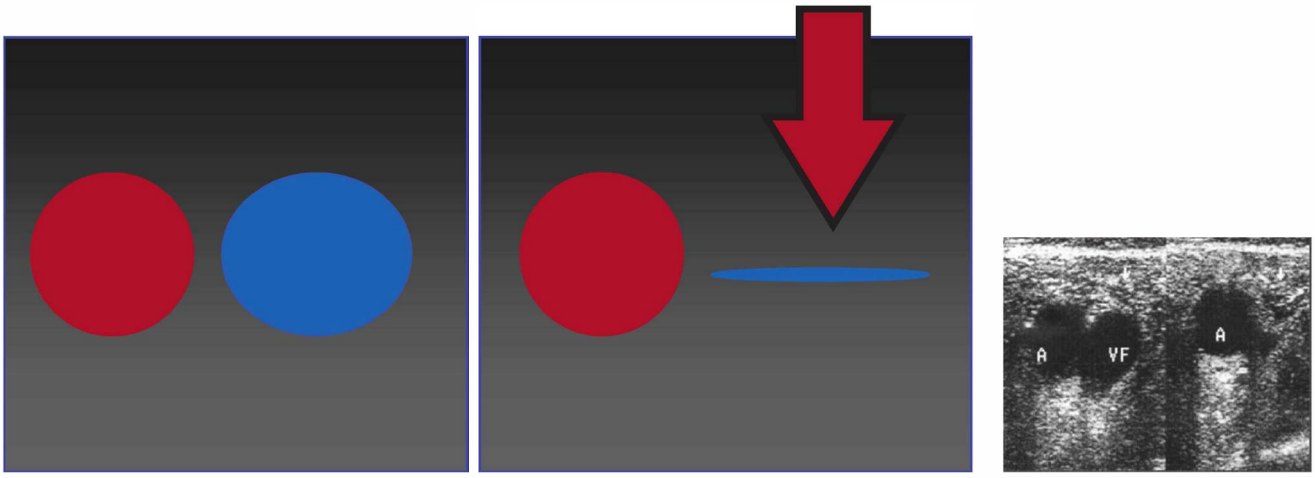

FIGURE 83.4 Ultrasonogram showing from the left to the right, the adjacent femoral artery (A) and vein (VF), the full compressibility of the vein by the transducer, characteristic of the absence of thrombosis (from **left** to **right**) schematic representation (without and with compression) and ultrasonographic representation (without and with compression), and (last image on the **right**) the incompressibility of the vein by the transducer, characteristic for the presence of a totally or partially occluding thrombus. This procedure is referred to as CUS.

the increased population put at risk of anticoagulation-induced bleeding. The ongoing randomized, double-blind CACTUS (NCT00421538) study comparing anticoagulant therapy with placebo should help clarifying this issue in the future.

Ventilation/Perfusion Lung Scintigraphy

Perfusion lung scintigraphy (also called V/Q scan) is a noninvasive technique allowing the visualization of pulmonary perfusion through intravenous injection of albumin macroaggregates labeled by technetium-99m.The macroaggregates are trapped in approximately 0.1% of the pulmonary capillary vessels and may be imaged by a gamma camera. Pulmonary hypoperfusion is not highly specific for an embolus, since any disease that narrows the airways or fills the alveoli with fluid will result in hypoxic pulmonary vasoconstriction, a protective mechanism designed to minimize the shunt effect due to poorly ventilated alveolar units. A perfusion defect corresponding to a segment or a large part of a segment is more specific for PE. The addition of ventilation scintigraphy (by Xenon 133, Krypton 81m or aerosolized technetium-99m) further increases specificity, a so-called mismatched defect (perfusion defect with normal ventilation) usually representing PE. The interpretation of lung scan has long been based on criteria validated in the landmark Prospective Investigation On Pulmonary Embolism Diagnosis (PIOPED) study,[19] and their subsequent revisions. More recently, it has been greatly simplified and lung scan results are now classified into three categories: normal (no PE), high probability (PE), and nondiagnostic.[57] The high negative predictive value of a normal lung scan has been confirmed by several studies, and is recognized as a valid criterion for excluding PE. The positive predictive value of a high probability scan is approximately 90%, and most clinicians consider such a result to rule in PE. Recent evidence suggests that the ventilation scan may be validly replaced by chest x-ray with an overall agreement of 88% and a positive predictive value of 86% for a scintigraphic mismatch.[58] The proportion of diagnostic ventilation–perfusion lung scans (i.e., normal or high probability) varies between 50% and 70% according to the patient population studied and the adopted diagnostic criteria. The combination of clinical probability and CUS allow reaching a clinical decision in most cases. In a series of 1,239 patients, Wells et al.[59] withheld anticoagulant treatment in 702 (57%) patients who had a nondiagnostic scan, a low or intermediate clinical probability of PE, and normal serial CUS, and the 3-month thromboembolic risk was only 0.5% (95% CI 0.1% to 1.3%).

Whether a baseline lung scan should be systematically performed in patients with suspected PE and a proximal DVT shown by CUS remains controversial. Recurrent PE is quite a rare event in treated patients, and the interpretation of a lung scan performed for a suspected recurrence is not always straightforward. In our experience, a baseline lung scan is rarely useful, and is unlikely to be cost-effective (see specific section on recurrent VTE below). Whatsoever, except in some dedicated centers, lung scan has been largely replaced by computed tomography angiography (CTA).

Computed Tomography Angiography

The rapid acquisition of high contrast images by spiral (also called helical) CTA scanning allows an adequate visualization of the pulmonary arteries up to at least the segmental level (FIGURE 83.5).[60] Two systematic overviews on the performance of single-detector computed tomography angiography (SDCTA) in suspected PE reported wide variations regarding both CT sensitivity (53% to 100%) and specificity (73% to 100%).[61,62] Variations in image acquisition protocols, selection bias, and flaws in the design of the older studies may partly account for these differences. Two clinical studies[63,64] have shed new light on the performance of CTA. They included a wide spectrum of patients with suspected PE; the diagnostic criteria for PE were appropriate and both spiral CT and reference diagnostic tests were read in a blinded fashion. They both report a sensitivity around 70% and a specificity of 90%. As in previous series, CTA was technically inadequate in 5% to 8% of patients because of motion artifacts or insufficient opacification of the pulmonary vessels.

Sensitivity of CT is higher in central pulmonary emboli than in segmental and subsegmental arteries. MDCTA, which allows both a thinner collimation (1 to 2 mm collimation) and a better definition without increasing image acquisition time, will likely improve sensitivity.[65] To what extent this will be at the expense of specificity remains to be evaluated. Indeed, in the Geneva series, the positive predictive value of CTA decreased from 100% to 85% at the main pulmonary or lobar artery level, respectively, and to 62% at the segmental level, demonstrating that specificity of CTA is also dependent on the vascular level. Moreover, the clinical significance of isolated segmental and subsegmental emboli is widely debated, and patients with no DVT, a negative CTA, and a low or intermediate clinical probability of PE left untreated may have a very low thromboembolic risk.[66] In summary, CTA showing a thrombus down to the segmental level can be taken as adequate evidence of PE, whereas the necessity to treat isolated subsegmental thrombi in a patient without a DVT is unclear. A negative SDCTA alone does not rule out PE. Finally, the probability of PE is very low in patients with a low or intermediate clinical probability, absence of proximal DVT, and a negative SDCTA. Second generation MDCTA exhibits enhanced sensitivity at the cost of slightly reduced specificity. Thus, in a meta-analysis the negative predictive value of a negative MDCTA was as high as 99.1%.[67]

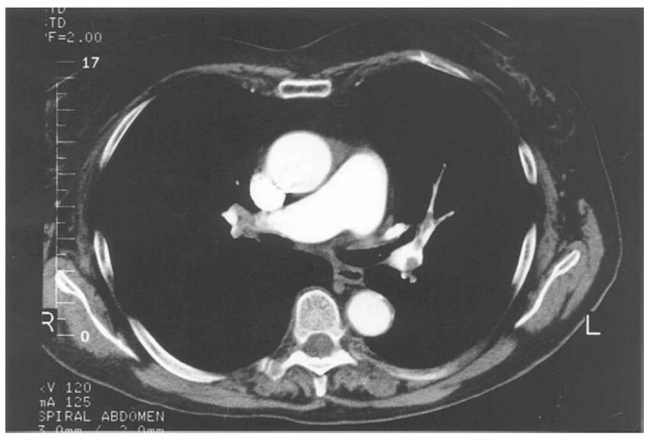

FIGURE 83.5 MDCTA showing filling defects of the contrast dye in the right pulmonary artery and in several segments of the left pulmonary artery tree (*arrows*).

Some groups proposed a combined CT phlebography of lower limbs and abdominal veins together with CTA of the pulmonary arteries, allowing a complete examination of VTE in one session.[68] Although appealing at first glance, the exam is more costly and results in greater irradiation of the patient. Moreover, patients with suspected PE in whom a DVT is found by CUS do not require a CT exam at all and are thus spared the irradiation, contrast dye administration, inconvenience, and costs of CT.

Dual energy CTA provides a morphologic analysis similar to the perfusion scan. Cardiac gated CTA is useful to rule out not only PE but also aortic dissection and coronary artery disease, but it takes longer and the radiation dose is higher.

Magnetic Resonance Pulmonary Angiography

Because it is devoid of irradiation, magnetic resonance imaging (MRI) is a potential candidate for diagnosing PE. Recently, the accuracy of gadolinium-enhanced magnetic resonance pulmonary angiography and magnetic resonance venography (MRV) for diagnosing PE has been studied in a prospective, multicenter accuracy study on 371 adults with diagnosed or excluded PE from seven North American hospitals.[69] The reference standard diagnosis was made by using various tests, including computed tomographic angiography and venography, ventilation–perfusion lung scan, venous ultrasonography, DD assay, and clinical assessment. MRA, averaged across centers, was technically inadequate in 25% of patients (92 of 371). Of note, the proportion of technically inadequate images ranged from 11% to 52% across centers. Including patients with technically inadequate images, magnetic resonance angiography (MRA) identified 57% (59 of 104) of those with PE. Technically adequate MRA had a sensitivity of 78% and a specificity of 99%. Technically adequate MRA and MRV had a sensitivity of 92% and a specificity of 96%, but 52% of the patients (194 of 370) had technically inadequate results. Therefore, MRA should be considered only in centers with an adequate experience of the technique only in patients for whom standard tests are contraindicated, which will limit its use to a small minority of patients at the present stage.

Echocardiography

Doppler echocardiography has several uses in suspected PE, including in risk stratification. In a small subset of patients with PE (4% in a recent registry),[70] transthoracic echocardiography allows direct visualization of the clot in the right heart chambers or in the right main pulmonary artery. Direct imaging of part of the left main pulmonary artery requires transesophageal echocardiography. However, transesophageal echocardiography is uncomfortable for patients, and its sensitivity in suspected PE does not appear to be significantly higher than that of transthoracic echocardiography. In fact, the most frequent echocardiographic manifestations of PE are indirect and reflect the hemodynamic changes caused by an acute increase in pulmonary arterial resistance and pulmonary hypertension.

Pulmonary arterial pressure may be estimated in most patients by the tricuspid regurgitation velocity. A cutoff value of 2.7 m/s for the presence of pulmonary arterial hypertension was adopted in several series. Signs of RV strain include dilation of the right ventricle, RV hypokinesis, and in severe cases, paradoxical motion of the interventricular septum. Several echocardiographic measurements have been proposed to quantify RV dilation, of which the most standardized is the right ventricle over left ventricle diameter ratio. However, a visual estimate appears to be as accurate in the eyes of an experienced observer.[71] A particular pattern of RV hypokinesis characterized by hypokinesis of the mid-free wall and preservation of apex motion appears to be quite specific for acute as opposed to chronic pulmonary hypertension.[72] Conversely, RV hypertrophy and pulmonary artery pressures above 60 mm Hg suggest chronic pulmonary hypertension. The sensitivity of these signs that are often combined lies between 40% and 70% in clinically suspected PE, and their specificity is approximately 90%, provided the patient does not have another disease causing chronic pulmonary hypertension. Echocardiography is the first-line test in suspected massive PE (see Section 5.2.2). Indeed, in patients with shock, it is extremely effective for differential diagnosis with tamponade and cardiogenic shock. Moreover, absence of pulmonary hypertension and/or RV dilation and hypokinesis in that situation renders PE as the cause of shock unlikely.

In patients with suspected nonmassive PE, echocardiography may also represent a useful tool for prognostic stratification of patients,[6] a process that is not followed yet by specific therapeutic measures.

RISK STRATIFICATION

The goal of risk stratification is twofold: identifying low-risk patients who may be managed with a very short hospital stay or even as outpatients, and non–high-risk patients who have an intermediate risk of death and might benefit from more aggressive management than anticoagulants alone, although the superiority of thrombolysis in these patients is still unproved.[6,73] Several instruments allow stratifying patients with PE into various risk categories (Table 83.1).[6] Clinical evaluation is a necessary first step as shock or systemic arterial hypotension carries a very high mortality and requires aggressive treatment, usually thrombolysis, without any further risk stratification. In non–high-risk patients, clinical prognostic scores allow identifying patients with a low risk of mortality due to PE. The intermediate-risk category is defined by the presence of RV dysfunction detected by echocardiography (Table 83.1). More recently, several biomarkers, mainly natriuretic peptides (NT-proBNP and BNP) and troponin have been evaluated as alternatives or additions to echocardiography.

Clinical Prognostic Scores

Clinical prognostic scores fall into two categories: those designed to identify low-risk patients, such as the Geneva risk score[74] or the pulmonary embolism severity index (PESI)[75] and its simplified version[76], and scores aimed at targeting intermediate-risk patients with a mortality high enough to warrant aggressive treatment, such as the PREP index (Table 83.5).[77] The Geneva risk score predicts the 3-month risk of death, recurrent thromboembolic event, or major bleeding, and requires a lower limb venous ultrasound as finding a DVT increases the risk. The prognostic importance of concomitant DVT has been confirmed recently in a registry in which the risk of all-cause mortality in patients with concomitant DVT was 2.0 and PE-related mortality 4.2 compared with patients with no DVT.[78] The Geneva risk score has been externally validated and the 3-month unfavorable

outcome rate was low (5%) in the low-risk category, albeit higher than in the derivation sample (2.2%).[79] The PESI score is entirely based on clinical variables and has been extensively validated,[80–82] but it has the drawback of being complicated to calculate and includes ambiguous items. Recently, a Spanish group proposed a simplified version of the PESI score[76] based on part of the original items that seems to retain a similar accuracy (Table 83.5). Although validated in the RIETE registry,[76] this potentially very useful score requires a prospective validation. Finally, the PREP index[77] that incorporates DD and BNP measurement and echocardiographic assessment of RV function was designed to predict higher-risk patients without shock. It is able to identify patients with a 22.2% 30-day adverse outcome risk, albeit with a wide CI and still requires external validation. Interestingly, only a small proportion of the patients in PREP cohort (9 of 570) had a high risk.

Echocardiography

RV dysfunction on echocardiography appears to be associated with higher mortality in acute PE. In a classic study by Grifoni et al.[83] around 30% of normotensive patients with acute PE had RV dysfunction on echocardiography, defined as RV dilatation, RV/left ventricular end-diastolic diameter ratio >1, paradoxical

septal systolic motion, or pulmonary hypertension. Six of those 65 patients developed PE-related shock, of whom 3 died compared with none of the patients with normal blood pressure and no signs of RV dysfunction. An analysis of the ICOPER registry[84] yielded similar results, albeit with much higher mortality rates (16.3% 30-day mortality in normotensive patients with RV dysfunction compared with 9.4%). In a monocenter French registry, the odds ratio of dying (2.7) in patients with an RV/LV ratio ≥0.9 was similar even after adjusting for other prognostic factors including shock but mortality rates were much lower (3.3% vs. 1.1%).[85]

Collectively, those results suggest that echocardiography may be an adequate risk stratifier in patients with acute PE but without shock. Nevertheless, mortality rates appear to be lower in series with nonselected patients, approaching the risk if an intracranial bleed due to thrombolytics.[86] Moreover, echocardiography criteria for RV dysfunction are far from uniform, rendering the comparison of those studies difficult.[6]

Biomarkers

Since only 5% to 10% of patients with PE present with shock and only around 30% of the remainder have echocardiographic evidence of RV dysfunction, systematic risk stratification by echocardiography would require performing that test unnecessarily in 60% of patients. Therefore, several biomarkers have been evaluated as first-line tests to identify low-risk or intermediate-risk patients. Brain natriuretic peptide (BNP or NT-proBNP) levels have been shown to be elevated in more severe PE and reflect RV overload.[87] In a recent meta-analysis,[88] patients with an elevated BNP or NT-proBNP concentration had a considerably higher risk of death (OR 7.6, 95% CI 3.4 to 17.0). However, although patients with a high BNP had an absolute mortality risk of 14% compared with 2.2% in those with normal BNP levels (OR 6.5), the odds ratio of dying decreased to 3.3 when the three studies that considered only in-hospital mortality were singled out. Moreover, most of those studies included patients in shock, which certainly had a great influence on the results.

Troponin T or I is a marker of myocardial injury and has been shown to be elevated in severe acute PE, probably due to subendocardial ischemia of the overloaded RV. In one of several recent meta-analyses on troponin in acute PE that focused on normotensive patients,[89] 28% had an elevated troponin level. Their mortality was 15.9% compared with 3.4% in those with a normal troponin. In a recent series of 146 patients with acute PE and without shock, NT-proBNP was elevated in all 18 patients

who had an unfavorable outcome within 3 months, while 55% of patients without complications had abnormal values (OR of complications 15.8, 95% CI 2.1 to 122).[90] The predictive accuracy of NT-proBNP was superior to that of troponin (OR 3.5, 95% CI 1.2 to 9.7) and NT-proBNP was the only independent predictor of an adverse outcome in multivariate analysis. A similar superiority of NT-proBNP was observed in a series of intensive care patients.[91] Highly sensitive troponin assays might have a higher negative predictive value. The 30-day risk for death, shock, or intubation was 0% (0 of 56) in patients with a highly sensitive troponin level <14 pg/mL in a recent series of 156 patients.[92] Finally, in a large series of 1,273 patients with acute PE and no hemodynamic compromise, troponin I and echocardiography were independent predictors of PE-related death and yielded additive information.[93] Mortality ranged from 0.7% in patients with normal troponin and no RV dilatation to 8.3% in those with both a high concentration of troponin and an enlarged RV. Other biomarkers have been assessed, such as fatty acid–binding protein (FABP)[94] or DD,[90] but the evidence is still preliminary, and they suffer from the same shortcomings as BNP and troponin, that is, lack of assay standardization, variable cutoff, low positive predictive value for adverse outcome, variable definition and time frame of adverse outcome, and low specificity.

Computed Tomography Angiography

CTA provides no information in RV function, but measuring the diameter of the heart chambers allows the measurement of the RV/LV ratio in transverse sections. Since CTA is performed in most patients for diagnosing PE, it is an attractive instrument for risk stratification. Preliminary evidence from a retrospective series of 431 patients with acute PE confirmed by CTA was encouraging.[95] Of the 276 (64%) patients with RV/LV ratio >0.9, 15.6% died within 30 days compared with 7.7% of those without RV enlargement. The association between RV enlargement on CT and mortality remained after adjusting for other prognostic variables. However, other reports have been unable to replicate this finding. A large retrospective analysis of a single-center experience including 1,193 patients did not find any association between the RV/LV ratio and mortality, and only a weak association (OR around 2.0) for ventricular septal bowing, another classic sign of RV overload.[96]

Implications for Treatment

Several conditions must be met for risk stratification of acute PE to have practical clinical implications. For identifying low-risk patients, available instruments must be easily available, inexpensive, and have a high negative predictive value for adverse outcome. Clinical scores appear to fit those requirements better than biomarkers, echocardiography, or CTA. Targeting patients with no hemodynamic compromise but a higher risk of recurrence or death who might benefit from more aggressive treatment requires tests with a high positive predictive value. As shown in the previous sections, the in-hospital PE-related mortality in patients with RV dysfunction on echocardiography or elevated biomarkers is in the range of 5% and higher figures relate to all-cause mortality during a longer time span (30 days to 3 months). The only randomized trial on the efficacy of thrombolysis in hemodynamically stable patients with acute PE and RV dysfunction was conducted by Konstantinides et al.[73] Overall mortality was only 2.2% in the control (heparin) group. Alteplase was more effective than heparin alone regarding the primary outcome, which was a composite of in-hospital death or clinical deterioration requiring treatment escalation. The absolute difference in favor of alteplase was 13.6% but was entirely driven by treatment escalation, notably rescue alteplase infusion. Therefore, the benefit of thrombolysis in stable patients with RV dysfunction remains unproved and this controversy will hopefully be settled by the ongoing PEITHO trial (NCT00639743). In the meantime, risk assessment by a clinical score to identify low-risk patients who may benefit of shortened hospital stay or outpatient treatment is warranted, but further risk stratification by biomarkers and/or echocardiography is not routinely recommended. Risk stratification by CT appears too unreliable to be clinically useful.

DIAGNOSTIC STRATEGIES

Systematic evaluation of a new diagnostic test or strategy in suspected VTE should include the following four steps[97]: (a) technical description of the method; (b) systematic comparison with a diagnostic standard to establish the critical cutoff concentration in tests with continuous values such as DD (using Receiver Operating Characteristics curve analysis), and values of sensitivity and specificity of the test for VTE; (c) use of the test in so-called management trials in which anticoagulation is withheld in patients with a diagnostic criterion ruling out VTE; a systematic 3-month follow-up allows detection of delayed events and establishment of the safety of the test; and (d) cost-effectiveness analyses comparing the « new » strategy with other management policies.

Sequential Diagnostic Strategies for Suspected DVT

Several noninvasive strategies have been reported to have a high sensitivity for diagnosing DVT.[98] Some rely on serial proximal CUS of proximal veins (common femoral, superficial femoral, and popliteal veins). The rationale for repeating CUS after 1 week in patients in whom it was initially negative is the potential detection of the rare proximally extending distal DVTs that were not searched for. Because the yield of repeat CUS after 1 week is very low (<1% to a few percent), CUS has been combined with a clinical prediction rule to lower the number of necessary repeat compression sonograms. Thus, repeat CUS was waived in patients with a low clinical probability. In another strategy,[99] repeat CUS was restricted to patients with a DD concentration above a critical cutoff level (500 μg/L), thereby avoiding about 30% of CUS exams. All these strategies are associated with a low (about 2% or less) 3-month thromboembolic risk, which is similar to that observed in suspected patients left untreated following a normal phlebogram.[17] In a randomized study, Wells et al.[26] compared the clinical outcome in 530 patients who underwent proximal CUS (control group) and 566 patients who underwent DD testing followed by proximal CUS unless the DD test was negative and the patient was considered at low clinical probability. The 3-month thromboembolic risk among patients in whom the initial diagnostic strategy had ruled out DVT was 0.4% in the DD group, compared with 1.4% in the control group. The difference did not reach statistical significance but the use of DD

resulted in a highly significant reduction in the use of CUS, since 39% of patients did not require ultrasound imaging. One major issue nowadays is to identify which patients should undergo testing. In the AMUSE study, a simple rule (male gender, use of contraceptive pill, malignancy, recent surgery, absence of leg trauma, vein distension, one point each; calf difference ≥3 cm, 2 points; abnormal POC DD, 6 points; cutoff: DVT ruled out if score ≤3) was able to avoid further testing in half of a primary care population of 1,028 patients (prevalence of DVT 13%), with a 3-month thromboembolic risk of 1.4% (0.6 to 2.9).[100] Finally, complete ultrasound, that is, examination of the proximal and distal leg veins is also an accepted strategy for diagnosing DVT. In a prospective management study, patients clinically suspected of DVT were randomized to CUS limited to the proximal veins or to complete CUS. Thrombosis was diagnosed in 59 of the 257 patients who underwent limited CUS (23%) and in 99 of the 264 patients who underwent complete CUS (38%) with a similar 3-month follow-up (four patients and two patients, respectively, being diagnosed with VTE).[101] This study highlighted that the added costs of complete CUS did not translate into added safety and might even result in added risk due to unnecessary anticoagulant treatment. Therefore, complete CUS is unlikely to be cost-effective, although this has never been formally assessed. FIGURE 83.6 displays the strategy that appeared to be most cost-effective in a formal cost-effectiveness analysis (see also specific section below).[102]

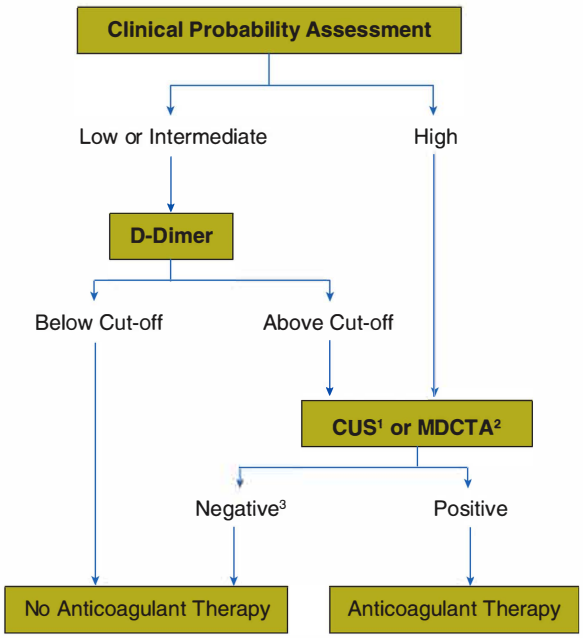

FIGURE 83.6 A contemporary simple diagnostic algorithm for suspected DVT or PE. DD refers to highly sensitive DD assays. If less sensitive assays are used, a negative DD result rules out PE or DVT only in the presence of a low (or unlikely) clinical probability (see also FIGURE 83.1). ¹ CUS (lower limb venous CUS) in case of suspected DVT. ² MDCTA in case of suspected PE.³ In case of negative CUS or MDCTA and high prior clinical probability, consider additional imaging, for example, phlebography (suspected DVT) or lung ventilation/perfusion scintigraphy or pulmonary angiography (suspected PE).

Sequential Diagnostic Strategies for Suspected PE

Diagnosis of Non–high-risk PE

In patients who are not hemodynamically compromised, fully noninvasive strategies have proven effective and safe. One such strategy relies on assessing prior clinical probability, either empirically or by a prediction rule, and on the use of ventilation/perfusion lung scanning. Using CUS at an early stage of the diagnostic workup, given that diagnosing DVT in a patient clinically suspected of PE warrants anticoagulant therapy, should be reserved for patients with contraindication to MDCTA (e.g., with renal insufficiency or allergy to iodine contrast dye), especially if clinical signs or symptoms of DVT are present. In all other situations, the strategy starts with measuring DD and withholding anticoagulants in patients with a concentration below the cutoff level,[32,103] as illustrated in FIGURE 83.6. Of note, it is associated with a very low (<1%) 3-month thromboembolic risk, similar to that associated with a normal lung perfusion scan[104] or a negative pulmonary angiogram.[20] The question of whether a DD concentration below the cutoff level using a highly sensitive assay rules out PE even in patients with a high clinical probability remains controversial, and a conservative approach is appropriate in such patients, that is, skipping the initial DD test. Although SDCTA is probably no longer used, it may be useful to stress that its sensitivity for the presence of PE is only 70%, which precluded its use as the sole diagnostic test.[63] Note that in order to rule out PE, the combination of a negative lower limb CUS and a negative SDCTA was required in patients with a low or intermediate clinical probability of PE,[105,106] and that ventilation–perfusion scintigraphy and/or pulmonary angiography was required in high-probability patients with a negative noninvasive workup.

Thanks to the improved performances of MDCTA, it was hypothesized that lower limb CUS would no longer be required to rule out PE, as suggested in two management studies.[32,107] In the prospective, multicenter Swiss-French study of patients admitted to the emergency department for clinically suspected PE, the proportion of patients with proximal DVT despite negative findings on MDCTA was very low (0.9%; 95% CI, 0.3 to 2.7).[107] Therefore, the improvement of the overall detection rate of PE by CUS was marginal in this series, and the 3-month thromboembolic risk in patients left untreated if PE had been ruled out on the sole basis of a negative MDCTA would have been 1.5% (95% CI, 0.9 to 2.7), similar to that of a negative pulmonary angiography. A strong additional support for the safety of using MDCTA as a single imaging modality arises from the CHRISTOPHER study.[32] In that series, patients with an elevated DD level or in whom PE was considered likely according to the dichotomized Wells rule (n = 1,436) underwent a CTA (multidetector CTA, 88% of the patients). The 3-month thromboembolic risk in patients not treated based on a negative CTA was 1.3% (95% CI, 0.7 to 2.0). Moreover, in the study by Ghanima et al.[108] 432 consecutive outpatients clinically suspected of PE who were sequentially submitted to clinical assessment, DD measurement, and MDCTA, a definitive diagnosis was reached in 96.5% of patients with a 3-month thromboembolic risk of 0.6% (95% CI, 0% to 2.2%). Collectively, those series support the safety of ruling out PE by DD measurement and multidetector CTA in non-–high clinical

probability patients without resorting to lower limb CUS. The final proof was given by a multicenter, randomized, noninferiority study that compared the strategies with and without CUS, and found no difference in outcome between the two arms,[103] which was confirmed in a meta-analysis.[109] Overall, the meta-analysis by Moores et al.[110] that compiled 23 studies with 4,657 patients with a negative CTA (mainly single-detector) who did not receive anticoagulation showed a 3-month rate of subsequent VTE of 1.4% (95% CI 1.1 to 1.8) and a 3-month rate of fatal PE of 0.5 (95% CI, 0.3 to 0.8).

As reviewed by Stein et al.[111] the increasing use of CTA may result in an increased incidence of radiation-related cancer in the not-too-distant future. Dangers of radiation require that protocols for CT angiography be optimized. In addition, the use of combined CT pulmonary angiography and CT venography should be questioned as it was found in PIOPED II study that only a small proportion of patients with PE or DVT would have been undiagnosed if imaging of the pelvic veins had not been done.[68] Moreover, proximal lower limb DVT can be diagnosed by CUS and it has been shown that CT venography and CUS are equivalent for diagnosing proximal DVT of the lower limbs. The radiation dose delivered to the fetus during pregnancy by ventilation/perfusion or perfusion-only lung scintigraphy and CTA are equivalent.[112] Nevertheless, preference between those tests is still debated as the radiation dose to the breast of women of child-bearing age is significantly greater with CTA. As a matter of fact, with CTA the fetus can be shielded with a lead apron, which does not work for isotopes. Of note, a Canadian randomized trial compared a V/Q scan and a CTA-based strategy for investigating suspected PE (mostly MDCTA).[31] Very few patients developed VTE during follow-up and there was no outcome difference between the CTA and the V/Q-based strategy. This is very reassuring, and offers a valuable diagnostic alternative, should CTA be contraindicated.

Diagnosis of High-risk PE

Patients with suspected massive PE have a very high mortality rate and require emergent thrombolytic or surgical treatment in the event PE is confirmed. The clinical presentation requires a differential diagnosis that includes other causes of shock such as pericardial tamponade or myocardial infarction. The clot burden is usually high in that situation, and the diagnostic yield of any imaging study, whether lung scan or CTA, is likely to be high. Therefore, the logical initial test is either MDCTA or transthoracic echocardiography, whichever is more rapidly available (FIGURE 83.7). An echocardiogram showing signs of acute pulmonary hypertension and RV strain in a patient with shock, normal left ventricular contractility, and absence of pericardial effusion is a very strong argument in favor of massive PE. In fact, most clinicians would readily begin thrombolytic treatment in such a highly unstable patient without awaiting further diagnostic information. In a patient temporarily stabilized by vasopressors (such as dopamine or norepinephrine), confirmation should be sought by MDCTA. Angiography should be avoided whenever possible since it carries the highest risk in this patient population[113] and increases the risk of a major bleed at the puncture site due to thrombolytic treatment.[114] The yield of CUS of leg veins has not been studied systematically in this situation, but data collected in patients with nonmassive PE but a high clot burden on V/Q scan suggest that it may be associated with a 20% to 30% false negative rate.[115] FIGURE 83.7 summarizes the proposed diagnostic algorithm.

SPECIAL SITUATIONS

Suspected Recurrent DVT or PE

Diagnosis of recurrent DVT is difficult because acute thrombi cannot be easily distinguished from old thrombi, unless the

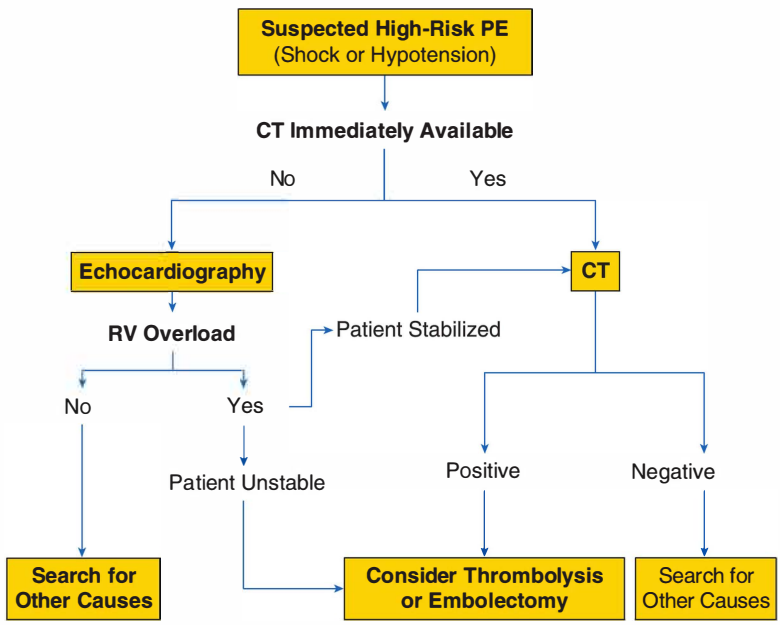

FIGURE 83.7 Diagnostic algorithm for suspected high-risk PE. The term *high-risk PE* has replaced the ambiguous term of *massive PE* and designates patients in shock or with hemodynamic compromise.

suspected recurrent event occurs in a location that is different from that of the initial event. Because initially abnormal plethysmography results return to normal in 90% of patients at 1 year, recurrent DVT in symptomatic patients might be inferred from an abnormal plethysmographic result at least 1 year after the previous event but such a conversion has a positive predictive value of only 80%.[116] Moreover, this test is no longer used. Alternatively, repeated sonographic measurements of the diameter of the common femoral and popliteal veins have been proposed as a tool to discriminate new from old thrombi.[117] The vein diameter has to be measured under compression with the transducer and compared with earlier measurements. Patients with stable or diminished vein diameters can be considered as free of recurrence. The predictive value of a stable or improved diameter to rule out recurrence was 90% (95% CI: 77% to 97%). In a prospective study of 205 consecutive patients, the policy of withholding anticoagulant treatment in patients clinically suspected of recurrent DVT in whom CUS showed stable or improved vein diameters was found to be safe.[118] The main limitation of this method is the need for iterative vein diameter measurements in DVT patients, which is cost- and resource-demanding. Moreover, it does not account for the possibility that asymptomatic events may have occurred between two measurements. In selected cases, phlebography may be the only solution, the presence of an intraluminal defect in at least two views proving the recurrence.

Diagnosis of recurrent PE is also challenging. It can only be confirmed if new emboli can be detected in locations that were previously documented as free of thrombi. For this reason, some opinion leaders strongly advise performing lung imaging in all patients with PE, including patients with proximal DVT and respiratory signs and symptoms, in whom the diagnosis could be made without lung imaging. But again, this suggestion does not account for that asymptomatic emboli may have occurred between the two imaging procedures. In selected cases, pulmonary angiography may be required to settle the case.

Recurrent VTE will be readily ruled out by a DD measurement if the concentration is below the diagnostic cutoff, but this will occur in one third of patients at best when ELISA methods or automated turbidimetric assays are used.[36] In the other cases, the diagnosis will rely upon the subjective combination of clinical findings and imaging modalities, a situation that is far from satisfying.

Suspected VTE during Pregnancy

Pregnancy constitutes an additional challenge in case of suspected DVT or PE. Hemodynamic changes interfere with the interpretation of tests for DVT, and tests using ionizing radiation may theoretically harm the fetus. Widely used noninvasive initial tests such as DD measurement or CUS are of limited value, due to a reduced specificity (DD)[42] or sensitivity (CUS). Nevertheless, a DD concentration below the diagnostic cutoff value rules out VTE. Moreover, using higher thresholds than those used in nonpregnant patients, the specificity of DD assays for the diagnosis of DVT could be improved without compromising sensitivity and safety,[49] which requires however to be validated in prospective management studies.

Many clinicians advocate using phlebography for diagnosing DVT in pregnant women but it is suboptimal under these conditions. The exam should however be performed only if CUS has not demonstrated the presence of DVT. Alternatively, MRI might be used although the experience with this modality is scarce and it lacks availability in many countries. As potential advantages, MRI may diagnose isolated iliac DVT, a condition that is more common during pregnancy, in addition to femoropoliteal DVT, and it is not associated with radiation exposure.

In suspected PE, objective testing is mandatory, and the previously described diagnostic strategy for nonpregnant women should be applied. If DD is above the diagnostic cutoff and no DVT is diagnosed on CUS, imaging should be performed. Because of the minimal radiation of V/Q scan, this exam may be preferred to spiral CT scan, although recent data suggest that CT may not deliver higher radiation doses to the fetus than V/Q lung scintigraphy.[112] Another reason to primarily resort to V/Q lung scanning is that it is the only imaging modality that has been assessed in an outcome study. Albeit retrospectively, Chan et al.[119] reviewed the outcomes of 120 pregnant patients with suspected PE in Ontario over 10 years: 75% of them had a normal V/Q scan ruling out PE, and none had an event during the remaining pregnancy. In fact, whenever possible, in this category of young women, perfusion scan alone should be performed and if perfusion is normal, PE is excluded. In case of abnormal perfusion, ventilation imaging should be performed to categorize the lung scan result as high probability or nondiagnostic lung scan. In the latter case, spiral CT should then be performed unless a priori clinical probability was low. Most experts concur that a certain diagnosis should be obtained before labeling a pregnant woman as having PE. Indeed, the risk of anticoagulant treatment throughout pregnancy and the weight of carrying that label for young women of childbearing age far outweigh the minimal risk of irradiation to the fetus.

Screening Asymptomatic Patients at High Risk of DVT

Screening patients at high risk of DVT is mainly done in the context of thromboprophylactic trials testing the efficacy of new prophylactic drugs or strategies, especially in the postoperative period. In that situation, phlebographically diagnosed DVT is the most commonly employed endpoint. There is a good basis for this policy[120]: In these situations, DVT is probably the only causal pathway leading to PE, and the reduction of adverse clinical events is related to the effect of antithrombotic drugs on asymptomatic thrombi in the legs. In the case of phlebographically diagnosed DVT, fatal PE is unlikely to occur if all phlebographically diagnosed asymptomatic thrombi are prevented. Hence, asymptomatic distal DVT may be considered as a valid surrogate endpoint to clinical events in such trials. Some investigators have advocated the use of phlebography only in symptomatic patients but using nonspecific and insensitive symptoms like leg pain or swelling especially following total hip or knee arthroplasty does not appear very promising. Other screening techniques such as thermography could not confirm initial promises.

Screening to detect and treat postoperative DVT following major orthopedic surgery has been shown not to be cost-effective, compared to systematic prolongation of prophylaxis for 4 weeks in a decision-analysis model[121] and is not recommended by international guidelines.[122] Recently, Tincani et al. screened 850 consecutive patients admitted to the rehabilitation unit for presence of DVT. In this observational study, the cumulative

incidence of DVT was 1.8% when patients were followed up for 6 to 30 months after discharge and routine screening US at the time of admission failed to reduce the rate of subsequent symptomatic VTE in patients given thromboprophylaxis, which further calls into question the practice of screening.[123]

Paradoxical Embolism

The term "paradoxical" has been coined to describe migratory thrombus from the venous circulation to the systemic circulation through a patent foramen ovale, potentially causing devastating damage, especially stroke. The topic will be discussed in Chapter 84, as well as venous thrombosis in unusual sites, for example, upper extremity, cerebral sinuses, and splanchnic veins, with their diagnosis and treatment.

COST-EFFECTIVENESS OF THE DIAGNOSTIC STRATEGIES IN SUSPECTED DVT AND/OR PE

Several diagnostic strategies have demonstrated both efficacy and safety. Selection among them in daily clinical practice is usually guided mainly by test availability and expertise. However, cost-effectiveness issues may also play a role.

Cost-Effectiveness of Diagnostic Strategies in Suspected DVT

A formal cost-effectiveness analysis compared diagnostic strategies for clinically suspected DVT: serial CUS, single CUS in patients with normal DD and second CUS only if DD level was abnormal, and single CUS in patients with an abnormal DD.[102] Under baseline conditions (prevalence of DVT, 24%), the effectiveness of all strategies was similar (4.2 to 4.4 lives saved per 1,000 patients managed). DD as a first test, followed by a single CUS only in case of an abnormal DD level (FIGURE 83.6) was the cheapest option. In a more recent analysis, diagnostic algorithms based on a combination of Wells score, DD, and CUS were the most cost-effective.[124] Use of repeat ultrasound increased incremental costs significantly for only a very small health gain. Finally, in a recent analysis, the office-based strategy evaluated in the AMUSE study (testing only selected patients after application of a prediction rule)[100] was cost-effective compared with the usual hospital-based strategies.[125] It should however be mentioned that the prediction rule incorporated point-of-care DD measurement in the physician's office, which is not very different from usual diagnostic strategies. Finally, as already discussed, complete CUS is probably not cost-effective, although this has not yet been formally assessed.

Cost-Effectiveness of Diagnostic Strategies in Suspected Nonmassive PE

Several cost-effectiveness analyses have compared current strategies for diagnosing PE. A comparison of various test combinations including spiral CTA, DD, lower limb venous CUS, V/Q scan, and/or angiography showed that the strategy including clinical probability assessment, DD and MDCTA described in FIGURE 83.6 had a favorable cost-effectiveness ratio.[126] A strategy based on V/Q scanning in patients with an elevated DD level, angiography being performed only in patients with a non–low clinical probability of PE, a negative CUS and a nondiagnostic V/Q scan was also cost-effective. Another analysis showed that patient age does not seem to influence the cost-effectiveness of the strategies.[2] However, performing proximal CUS in patients with an elevated DD level or a high clinical probability to reduce the proportion of patients undergoing MDCTA (patients with a DVT being treated without further testing) was not cost-effective. This was confirmed in a randomized clinical trial comparing two strategies based on clinical assessment, DD, and MDCTA, with and without CUS.[103] Costs were higher in the CUS arm of the study with no additional clinical benefit.

CONCLUSIONS

Diagnosis of DVT and PE has come a long way during the past two decades. Noninvasive diagnosis is now possible in almost all patients. Numerous diagnostic schemes have been validated in well-designed large-scale outcome studies and may be selected by individual institutions according to test availability and cost-effectiveness issues. Phlebography remains the ultimate diagnostic criterion standard for DVT but is no longer used outside thromboprophylaxis trials. MDCTA has become the cornerstone of PE diagnosis and supplanted pulmonary angiography, which is no longer the gold standard due to invasiveness and interobserver variability, which is increasing due to loss of expertise. However, many surveys on DVT and PE diagnosis show significant variability in clinical practice and frequent use of inappropriate criteria for ruling in or out VTE, with potential dramatic consequences to patients.[127] The most common diagnostic mistakes are the absence of clinical probability assessment, the ruling out VTE with DD in patients with a high clinical probability, or the absence of further diagnostic testing in patients with an elevated DD level. Therefore, continuing efforts to educate physicians on recommended diagnostic approaches are more warranted than ever. Moreover, research must still be pursued in two directions. Selecting patients for testing on clinical grounds is an increasing challenge. Ease of use of tests such as DD and fear of medicolegal consequences of missing DVT or PE have resulted in a dramatic drop in the proportion of patients suspected of VTE in whom the disease is ultimately confirmed. This results in useless resource consumption and, in the case of suspected PE, unnecessary irradiation. Also, increased sensitivity of our diagnostic instruments carries the risk of overdiagnosis, as evidenced by the increasing proportion of patients with isolated subsegmental PE shown by the new generation 16- and 64-detector CT scanners, and the high prevalence of distal DVT in centers routinely using complete CUS, without proof of clinical benefit of anticoagulant treatment. Likewise, diagnosing recurrent VTE remains a daily problem and a true challenge for clinicians.

Resolving those issues will require novel research approaches, such as registry analyses and international collaborations.

CHAPTER

84

Venous Thrombosis in Unusual Sites

VICTOR J. MARDER, HYLTON V. JOFFE, AND SAM SCHULMAN

Venous thromboembolism (VTE) typically presents with lower extremity deep vein thrombosis (DVT) or pulmonary embolism (PE).[1,2] Upper extremity deep vein thrombosis (UEDVT), which usually refers to thrombosis of the brachial, axillary, or subclavian veins, has become increasingly common with widespread use of central venous catheters for chemotherapy and parenteral nutrition.[3–5] Thrombosis in other deep veins, such as the cerebral or mesenteric, may be a clue to an underlying thrombophilia.[6–8] Patients with VTE in these unusual sites have distinct risk factors, signs and symptoms, diagnostic evaluations, and treatment considerations compared to patients with traditional lower extremity DVT or PE and should alert the physician to the need for specialized diagnostic tests, therapeutic approaches, and family studies.

UPPER EXTREMITY DEEP VEIN THROMBOSIS

Historically, UEDVT was considered a benign and self-limited condition.[9–11] However, recent studies have demonstrated that UEDVT may have significant complications, including PE, loss of vascular access, the superior vena cava (SVC) syndrome, and long-term arm pain and swelling.[12,13]

Anatomy

The deep venous system of the upper extremity begins at the brachial vein, which becomes the axillary vein (AV) at the lower edge of the major pectoral muscle. The superficial basilic vein joins either of these deep veins (FIGURE 84.1). The AV extends to the outer border of the first rib where it becomes the subclavian vein. The subclavian vein joins the internal jugular vein (IJV) at the inner end of the clavicle to form the brachiocephalic vein (BCV), which merges with the contralateral BCV to form the SVC.[14] The subclavian artery and vein pass under the clavicle and subclavius muscle and over the first rib. The subclavian artery travels between the anterior and middle scalene muscles, whereas the subclavian vein passes in front of the anterior scalene muscle. The brachial plexus is superior and posterior to the subclavian artery and anterior to the middle scalene muscle. The brachial plexus, subclavian artery, and subclavian vein comprise the neurovascular bundle. Compression of any component of this bundle as it exits the thoracic cavity can cause the thoracic outlet syndrome and involvement of the subclavian vein predisposes to UEDVT.[15]

Etiology

Primary UEDVT refers either to idiopathic disease or to Paget-Schroetter syndrome[7,16,17] and occurs in approximately two cases per 100,000 persons per year.[18,19] Idiopathic UEDVT has no identifiable precipitant but may be associated with occult neoplasms, especially lung cancer and lymphomas.[20,21] Paget-Schroetter syndrome refers to spontaneous UEDVT following strenuous activity, such as pole vaulting, boxing, baseball pitching, weight lifting, or rowing in young and otherwise healthy individuals.[19,22,23] In this setting, repeated injury to the intimal lining of the upper extremity veins activates prothrombotic mechanisms, eventually causing clinical thrombosis.[22] These patients sometimes have coexisting conditions that cause mechanical compression of the vasculature, including the thoracic outlet syndrome, rib anomalies, long transverse processes of the cervical spine, or musculofascial bands.[15,16,24,25]

Secondary UEDVT develops in patients with underlying comorbidities, including cancer,[20,26,27] pacemakers,[28,29] and central venous catheters,[4,30–34] and accounts for most cases of UEDVT (Table 84.1). Other conditions associated with UEDVT include intravenous cocaine use,[35,36] artificial reproductive technology (e.g., *in vitro* fertilization) especially with ovarian hyperstimulation syndrome, [37] and upper extremity surgery or plaster cast.[38] The association of oral contraceptives with UEDVT has in different studies varied from none to a 5.7-fold (95% confidence interval [CI] 2.1 to 15.7) increase of the risk.[39]

Patients with central venous catheters constitute up to one-fourth of cases of UEDVT.[4,30,40] Thrombotic risk may be higher with polyvinyl chloride catheters compared to silicone catheters.[31] Central venous catheters also predispose to UEDVT in patients with heparin-induced thrombocytopenia.[34] Likely, explanations for catheter-associated UEDVT include venous stasis and vessel wall injury[30,41] and the toxic effect of infusate on the vein.[27,42,43] Catheter tips should be positioned in the proximal SVC or at the junction between the SVC and right atrium, where blood flow is most rapid.[4,30,32,44,45] Venous thrombosis and stenosis probably develop in approximately 15% of patients with a permanent transvenous pacemaker, although most of these patients are asymptomatic.[28,29,46,47] Independent predictors of these venous lesions include previous transvenous temporary leads, the number of leads, and a left ventricular ejection fraction of 40% or less.[29]

Thrombophilia

Several studies have evaluated the prevalence of inherited and acquired thrombophilia in patients with UEDVT (Table 84.2).[39,45,48–55,56,57] Antithrombin, protein C, and protein S deficiencies are seldom present in these patients, and the prevalence of factor V_{Leiden}, antiphospholipid antibodies, and anticardiolipin antibodies varies widely so their role in UEDVT is unclear, although several studies have shown an increased prevalence of these antibodies in UEDVT.[7,13] The

D'Alessandro, http://www.anatomyatlases.org/atlasofanatomy/plate19/04overview.shtml.)

inconsistency between studies may be partially attributed to small sample sizes, different time points of blood collection, different types of coagulation tests used, and different patient populations.

Table 84.1
Risk factors for UEDVT

Primary UEDVT
Strenuous activity of the upper extremity (Paget-Schroetter syndrome)
Thoracic outlet syndrome
Idiopathic
Secondary UEDVT
Central venous catheters, including the Swan-Ganz catheter
Cancer (perhaps more prevalent in lung neoplasms and lymphoma)
Pacemakers
Implantable cardioverter-defibrillator
Upper extremity surgery or plaster cast
Fibrosing mediastinitis
Heparin-induced thrombocytopenia
Artificial reproductive technology especially with ovarian hyperstimulation syndrome
Intravenous cocaine use
Amyloidosis

Clinical Presentation

Patients with UEDVT have a wide spectrum of presentation, ranging from no symptoms to the catastrophic SVC syndrome, characterized by facial edema, blurred vision, head fullness, vertigo, and dyspnea.[13,58] A coexisting thoracic outlet syndrome may injure the brachial plexus and cause radiation of pain down the medial aspect of the arm into the fourth and fifth fingers.[15] The

Table 84.3

Advantages and disadvantages of imaging modalities used to diagnose UEDVT

	Advantages	Disadvantages
Ultrasonography	• Inexpensive • Noninvasive • Reproducible	• May fail to detect central thrombus that is directly below the clavicle or sternum
Venography or CT scan	• May detect central thrombus • May detect the presence of extrinsic vessel compression	• Contrast dye • Not fully validated
Magnetic resonance angiography	• Accurately detects central thrombus • Provides detailed evaluation of collaterals and blood flow	• Limited availability • Claustrophobia • Not suitable for some patients with implanted metal

usual symptoms of UEDVT are extremity edema, discomfort, and erythema.[13] Patients with coexisting PE may also have dyspnea, chest pain, or cough.[33]

Findings on physical examination may include fever, sinus tachycardia, arm and hand edema, supraclavicular fullness, jugular venous distension, upper extremity cyanosis, a palpable tender cord, dilated cutaneous collateral veins over the chest or upper arm, and a completely or partially occluded central venous catheter.[13,58–60] Low-grade fever may be present, but high fever is likely due to another cause, such as septic thrombophlebitis, coexisting infection, or underlying neoplasm.[61,62] Sinus tachycardia may reflect pain or anxiety but could also suggest compensation for reduced venous return to the heart and may occur in the setting of PE.[63] If thoracic outlet syndrome is suspected, the examiner should palpate the supraclavicular fossa for brachial plexus tenderness and perform provocative tests.[15,64,65]

Diagnosis

Muscle injury, superficial vein thrombosis (SVT), lymphedema, and neoplastic compression of the vasculature can mimic UEDVT.[13] Therefore, the diagnosis of UEDVT cannot be made solely on the basis of the history and physical examination but must be confirmed with objective testing. D-dimer testing may have limited usefulness for excluding UEDVT because the negative predictive value is not reliably known in this setting and a majority of patients are expected to have high D-dimer concentrations because of concomitant disease.[66]

Duplex ultrasonography (US) is recommended as the initial test for diagnosing UEDVT because it is noninvasive and appears to have good sensitivity and specificity for jugular, distal subclavian, and axillary UEDVT.[13,67–72] However, acoustic shadowing from the clavicle and sternum limits the reliability of this technique for assessing thrombosis in the brachiocephalic and proximal subclavian veins.[68,69] Based on a systematic review of published literature, compression US has a sensitivity of 97% and a specificity of 96% for UEDVT compared to venography.[73] Color Doppler does not seem to improve the test performance. However, additional studies are needed because these calculated performance characteristics of US are based on studies with important methodologic limitations such as small sample sizes and large between-study differences.

Contrast venography provides excellent characterization of the venous anatomy[74] but has several important drawbacks, including technical difficulty cannulating the vein in an edematous arm, use of an iodinated contrast agent, and radiation exposure (Table 84.3).[75] The contrast agent may cause renal injury; allergic reactions, including urticaria, bronchospasm, and anaphylaxis; or local extravasation and chemical phlebitis.[75,76] Acetylcysteine and adequate hydration may reduce contrast-induced nephrotoxicity in patients with abnormal renal function; a confirmatory large, randomized, controlled trial of acetylcysteine is underway.[77,78] Although iodinated contrast is rated pregnancy class B and radiation exposure from venography confers minimal risk to the fetus, concerns over teratogenicity limit the use of venography during pregnancy.[79] Despite these disadvantages, venography may be required to confirm or exclude the diagnosis of UEDVT when there is high suspicion for thrombosis despite a negative or inconclusive US study.[67] Venography is also required before interventions, including catheter-directed thrombolysis and angioplasty, and is used to assess the response to these treatments.[7,17,80–82]

Magnetic resonance angiography (MRA) correlates well with venography and provides a more complete evaluation of blood flow, contralateral vessels, and the SVC and the brachiocephalic vessels.[83–88] Therefore, MRA is a reasonable noninvasive alternative when venography is contraindicated or technically impossible (FIGURE 84.2).

Treatment

There are no randomized, controlled trials evaluating the optimal treatment of patients with UEDVT; the general approach used today is based on case series, retrospective reviews, and expert opinion.

Anticoagulation is the cornerstone of therapy for DVT at any site,[89,90] reducing thrombus propagation and maintaining patency of venous collaterals.[4] Usually, intravenous unfractionated heparin (UFH) is promptly started at the time of diagnosis unless there is an absolute contraindication to anticoagulation.

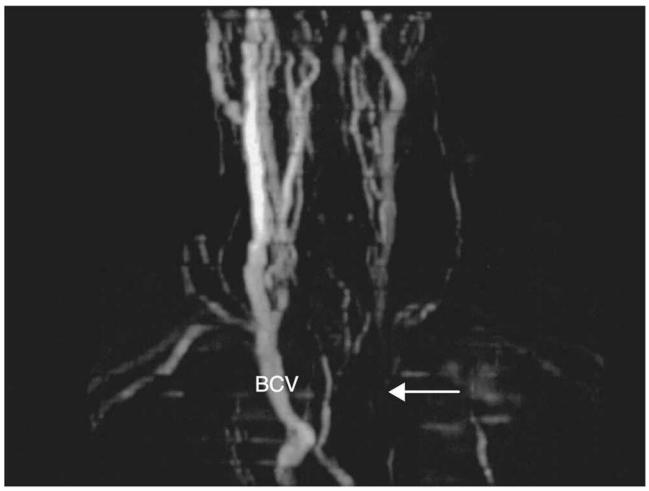

FIGURE 84.2 MRA demonstrating left BCV (*arrow*). (Adapted from Joffe HV, Goldhaber SZ. Upper-extremity deep vein thrombosis. *Circulation* 2002;106(14):1874–1880.)

Low-molecular-weight heparin (LMWH) is a safe and effective alternative and may reduce the duration of hospitalization.[91] Typically, heparin is used as a "bridge" to warfarin therapy, which is continued for a minimum of 3 months with an international normalized ratio of 2.0 to 3.0.[9,59,92] A longer duration of anticoagulation may be appropriate if there is an underlying hypercoagulable state.[63,93,94]

Thrombolysis. Several case series of UEDVT catheter-directed thrombolysis in carefully selected patients have reported excellent outcomes with only minor bleeding complications, such as occasional hematomas or oozing at catheter sites.[17,80,81,83] Although these small studies are underpowered to assess the risk of intracranial or gastrointestinal hemorrhage, the frequency of these serious events is expected to be similar to that of catheter-directed thrombolysis of lower extremity DVT.[95–97]

The best thrombolysis candidates are young, otherwise healthy patients with acute, primary UEDVT because these individuals may have significant long-term morbidity if treated only with conventional anticoagulation.[7,98–100] Other appropriate candidates for thrombolysis include patients with symptomatic SVC syndrome and those who require preservation of a mandatory central venous catheter.[81,101–103] Catheter-directed recombinant tissue-type plasminogen activator (tPA) may be administered as a continuous infusion of 1 to 2 mg/h, for at least 8 hours with serial venography used to assess treatment response (FIGURE 84.3). Percutaneous mechanical thrombectomy with devices such as the AngioJet (MEDRAD Interventional/Possis; Minneapolis, Minnesota) can be used to rapidly extract large quantities of thrombus with the goal of reducing the dose and duration of thrombolytic therapy.[104] Unlike conventional anticoagulation, thrombolysis restores venous patency early, which may minimize injury to the vessel endothelium and potentially reduce the risk of long-term complications, including the morbid postthrombotic syndrome.[59,98]

Several thrombolytic agents have been used to treat DVT. Urokinase is effective[80,81,103,105,106] but is now only approved by the Food and Drug Administration for lysis of pulmonary emboli that are massive or accompanied by unstable hemodynamics. Streptokinase has also been used successfully[107–110] but may be ineffective if previously administered. tPA is a popular choice in the United States.[111] Catheter-directed thrombolysis is preferred over systemic thrombolysis because local delivery of therapy achieves higher rates of complete clot resolution with lower doses of medication.[81,82,112,113] Heparin is usually given concurrently to prevent pericatheter thrombus formation.[59] Thrombolysis is most effective when used within several weeks of the onset of symptoms before progressive thrombus organization has occurred.[81,82,101,106]

Surgery. Although thrombolysis may successfully restore vessel patency, persistent vein compression may predispose to recurrent thrombosis and long-term morbidity.[17,59] Therefore, after successful thrombolysis for primary UEDVT, vascular surgeons may recommend early assessment for vein compression

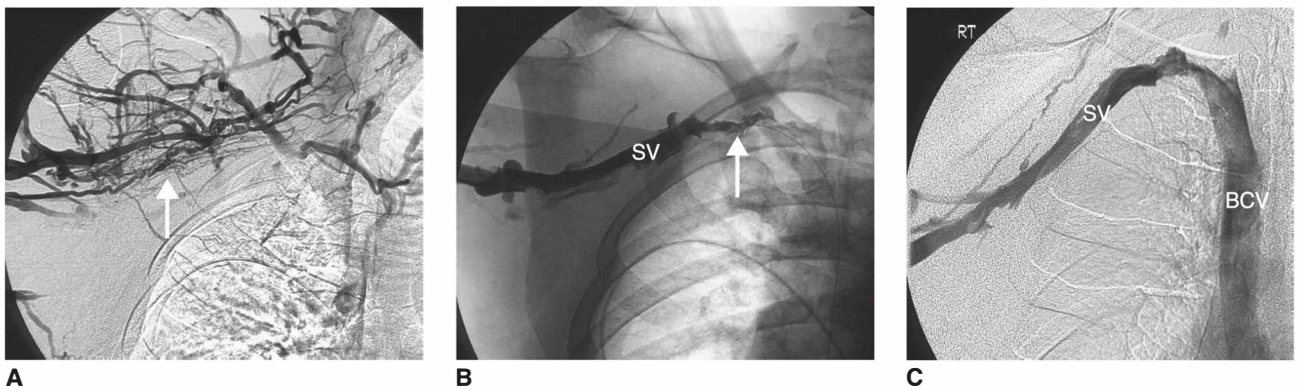

FIGURE 84.3 Multimodal therapy for UEDVT: 51-year-old weight lifter complaining of right arm pain. Initial venogram **(A)** shows occluded right axillary and subclavian veins with flow through collateral vessels (*arrow*). After percutaneous thrombectomy **(B)**, there is persistent occlusion of the proximal subclavian vein (*arrow*). After thrombolysis **(C)**, the subclavian vein (*SV*) is fully patent with flow into the brachiocephalic vein (*BCV*). (Adapted from Joffe HV, Goldhaber SZ. Upper-extremity deep vein thrombosis. *Circulation* 2002;106(14):1874–1880.)

followed by prompt surgical correction, such as resection of bone or lysis of dense, perivascular adhesions.[12,17,59,104,114–118] Persistent strictures after surgery could be treated with venoplasty and possibly vein stenting.[119,120] This multimodal approach can successfully achieve long-term vessel patency.[7,16,17,99,120–123] Although surgical thrombectomy restores venous patency, this approach is considered as a last resort because it is invasive, requires general anesthesia, and may be complicated by pneumothorax and brachial plexus damage.[59] Conservative therapy rather than prompt surgical intervention may be preferable for selected patients with the thoracic outlet syndrome because physical therapy, weight loss, and nonsteroidal anti-inflammatory medications may avert the need for surgery.[15]

SVC filters may protect against clinical PE, but there are limited data supporting their safety and efficacy.[124,125] There is concern that the benefits of SVC filters may be outweighed by their risks, including filter migration, dislodgment, fracture, and precipitation of the SVC syndrome. Potential candidates for SVC filter placement include patients with UEDVT who have an absolute contraindication to anticoagulation or those who develop PE despite adequate anticoagulation.

Prophylaxis. Early small trials suggested that the incidence of UEDVT can be reduced in patients with cancer and an inserted central venous catheter by using pharmacologic prophylaxis with either minidose warfarin (1 mg daily) or the LMWH dalteparin.[126–128] However, several subsequent trials have failed to show a benefit of pharmacologic prophylaxis in this patient population.[44,47–49,129] Similarly, it is unclear whether pharmacologic prophylaxis protects against catheter-associated UEDVT in patients without cancer.[130,131] Adding heparin to parenteral nutrition does not significantly reduce the risk of catheter-associated UEDVT, but these studies are small and underpowered.[130] These limited data may explain why pharmacologic prophylaxis of catheter-associated UEDVT is not commonly used in the United States. In a DVT registry,[33] less than one-fourth of patients with catheter-associated UEDVT and no obvious contraindication to anticoagulation were receiving prophylaxis at the time of diagnosis.

Complications

UEDVT may cause significant morbidity.[10,11,13] PE is present in up to one-third of patients with UEDVT, although fatal PE arising from UEDVT is uncommon.[13,132–134] PE may occur during removal of a central venous catheter because fibrin sheaths may peel off, break loose, and embolize.[58] Therapeutic heparinization for at least 24 hours before removal of the catheter may be a reasonable approach.

Other complications include loss of vascular access, the SVC syndrome, septic thrombophlebitis, brachial plexopathy, thoracic duct obstruction, and recurrent UEDVT.[12,50,135] The postthrombotic syndrome, secondary to venous hypertension from outflow obstruction and valvular injury, can lead to incapacitating limb pain and swelling.[136] This syndrome occurs in 7% to 44% of patients treated only with conventional anticoagulation[5] and may be less likely to occur following multimodal therapy.[7,98,100,137,138] Therefore, aggressive treatment, including thrombolysis, may be most suitable for patients with primary UEDVT who are young and otherwise healthy and more likely to be bothered by the postthrombotic syndrome than are patients with chronic medical conditions. Patients with secondary UEDVT have high short-term mortality rates compared with patients with lower extremity DVT,[139] most of them dying from underlying medical problems.

CEREBRAL VEIN AND SINUS THROMBOSIS

Anatomy and Pathogenesis

Cerebral vein and sinus thrombosis (CVST) includes thrombosis of the veins and dural sinuses of the brain.[140,141] Most often, thrombosis involves the superior sagittal sinus (FIGURE 84.4), which occupies the superior border of the falx cerebri, draining posteriorly into a "confluence of sinuses," then coursing mostly into one of the transverse sinuses, following the sigmoid sinus as it becomes continuous with the IJV. In the preantibiotic era, CVST was associated with chronic suppurant infections of the inner ear and skull, but most cases today

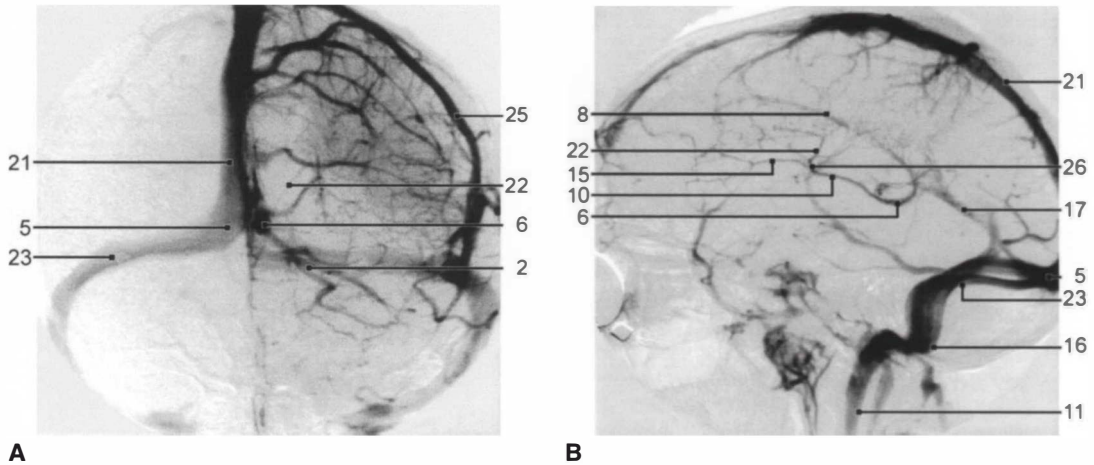

FIGURE 84.4 Venous phase of carotid angiography in the anteroposterior **(left panel)** and lateral **(right panel)** projections. The superior sagittal sinus (*21*), confluence of sinuses (*5*), transverse sinus (*23*), sigmoid sinus (*16*), and IJV (*11*) are as indicated. have no identifiable cause or are associated with head trauma, oral contraceptive (OC) usage, pregnancy or the puerperium, cachexia, dehydration, local malignancy, arteriovenous malformations, or other causes of generalized hypercoagulability. CVST is a well-recognized manifestation of the inherited and acquired thrombophilias, complicating virtually all of the known causes.[142–145,146] Of note is the danger of cerebral vein thrombosis in patients with a hereditary predisposition who have been prescribed OC agents[8] and in patients with paroxysmal nocturnal hemoglobinuria (PNH), antiphospholipid syndrome, and myeloproliferative disorders.[147–150] Following thrombus formation in a venous sinus, increased venous pressure leads to cerebral edema and even hemorrhage (FIGURE 84.5), a process that may progress to the development of large and/or multiple venous infarctions, which cross the normal boundaries of arterial supply.[151]

Clinical Aspects

Clinical features of CVST may be nonspecific and are often insidious in onset.[140,141,151] In a series of 32 cases admitted to hospital, the most frequent presenting complaints were headache (81%) and "reduced consciousness" (72%).[152] Among 17 cases initially seen in the emergency department, the presenting symptom was headache in 70% of cases; focal neurologic complaints such as weakness and aphasia were present in 29% and seizures in 24%.[153] In a large observational study, Ferro et al.[154] noted seizures in 39% of 624 cases; 6.9% of patients exhibited

seizure as an early manifestation, associated with supratentorial thrombotic lesions (OR = 3.0). Headache in combination with papilledema and absent focal neurologic signs can simulate brain tumor ("pseudotumor cerebri").[155] Nausea, vomiting, and mental confusion develop over hours to days, followed in the most severe cases by stupor and coma, but focal sensory or motor losses are not dominant features, and the cerebrospinal fluid and the electroencephalogram may show only nonspecific findings. Fever will usually accompany sinusitis or other infection that leads to direct extension of the process into a contiguous (e.g., cavernous) sinus. Diagnosis is established by magnetic resonance (MR) or computerized tomography (CT) venography,[141,156–159] which documents the important contribution of "cytotoxic edema" in the pathogenesis of cerebral venous infarction.[160] D-Dimer levels have been noted to be elevated, in correlation with the degree of thrombosis, and it is unlikely that an acute thrombotic event exists in the face of a normal D-dimer value.[161] Predictors of adverse outcomes (death, dependency) are age >37 years, coma, intracranial hemorrhage, central nervous system infection, or malignant disease.[162]

Pediatric and Elderly Patients

Neonates

A review of 52 neonates (median gestational age 39 weeks) in Amsterdam indicated an incidence of CVST of 1.4 to 12 cases per 100,000 births.[163] There was an association with assisted or complicated delivery in 62%, and seizures were the primary manifestation (56%), appearing at a median age of 1.5 days (0 to 28 day range). Anticoagulation was administered in 42% of cases, without hemorrhagic complications. Mortality was 19% and moderate to severe neurologic sequelae occurred in 38%. In a prospective study of 90 neonates followed at the Hospital for Sick Children in Toronto,[164] complete recanalization occurred in 90% by 3 months, but a "lack of anticoagulation" predicted thrombus propagation ($P = 0.0007$). Late outcomes at 2.5 years (median) included epilepsy in 17% and neurologic disability (language, sensorimotor, or cognitive/behavioral) in 56%. The importance of anticoagulation is highlighted by a retrospective study in which half of a cohort of 18 patients with CVST managed with hydration only had clot extension.[165]

Children

Presentation of CVST in the postneonatal, pediatric population resembles that seen in adults, with local symptoms reflecting cerebral edema of headache, seizures, and emesis, plus focal neurologic signs or coma and generalized complaints of lethargy and anorexia.[166] Many patients (40%) had prior chronic conditions and the remainder usually had an acute illness (infection or dehydration). Interestingly, iron deficiency or hemolytic anemia was present in 62% of cases, as commonly as was a prothrombotic disorder, which was mostly an elevated factor VIII or homozygous methylene tetrahydrofolate reductase (MTHFR) mutation.[166] A systematic study of prothrombotic associations in neonates and children with CVST [146] noted significant values for hereditary predispositions such as deficiency of antithrombin and protein C (OR 7 to 8), or protein S; factor V_{Leiden} and the prothrombin G20210A mutation (OR 2.4 to 3.2), less so for the MTHFR mutation (OR 1.6); and acquired changes of antiphospholipid antibodies (OR 6.95) and increased lipoprotein (a) (OR 6.27). A separate study of 20 children emphasized the prior occurrence of minor head trauma preceding sigmoid or transverse sinus thrombosis.[167] Of 42 patients with CVST, only 18 were anticoagulated, and follow-up at a median of 1 year showed sequelae in 62%, including pseudotumor cerebri, cognitive disability, epilepsy, and hemiparesis.[166]

Elderly

Not unexpectedly, CVST presents differently and connotes a worse prognosis in elderly patients. In a comparison of 51 patients >65 years of age with 573 who were <65, altered sensorium and mental status changes were more common presenting symptoms (43% vs. 20%, $P = 0.001$), headache (65% vs. 91%, $P = 0.001$) and papilledema (14% vs. 29%, $P = 0.016$) were less common, and seizures occurred equally in the two age groups (45% vs. 39%, $P = 0.37$).[168] The prognosis was much worse in the older patients, complete recovery only 49% versus 82% in younger patients, and death and dependency were higher in the elderly (27% and 22%) versus 7% and 2%, respectively, for younger patients.[168]

Treatment

The principles of management of cerebral CVST are to aggressively treat an identifiable underlying cause such as infection[169] and to initiate anticoagulant or, in select cases, regional thrombolytic therapy, taking care to balance the presence of cerebral hemorrhage with the thrombotic insult.

Heparin and LMWH

Controlled studies of anticoagulant therapy are limited: one in 1991 that compared UFH with placebo in 20 patients and one in 1999 that compared LMWH (nadroparin), with placebo in 60 patients.[170,171] Using an adjusted-dose intravenous UFH regimen, 8 of 10 treated patients had complete clinical recovery at 3 months, compared with 1 of 10 who received placebo. A retrospective comparison of an additional 43 patients with intracerebral hemorrhage secondary to sinus thrombosis showed complete recovery in 14 patients and mortality in 4 (15%), compared with 3 recoveries and 9 deaths (69%) in a similar (but uncontrolled) patient group that was not treated with UFH.[170] Retrospective observation of 37 patients treated with UFH showed recanalization at discharge in 60% and an "excellent" functional outcome in 89% of patients at 3 months.[172]

LMWH has been randomized against placebo for 3 weeks' treatment in a blinded manner, followed by 3 months of warfarin therapy for all patients.[171] Results at 3 weeks showed poor outcome, measured as death or low level of functioning, in both groups (20% vs. 24% for placebo) and a nonsignificant trend that favored LMWH at 12 weeks (13% vs. 21% for placebo). A 1-year follow-up evaluation of 47 patients showed a disappointing number of patients with cognitive impairment (35%), and the authors conclude that the outcome was not significantly influenced by treatment.[173] Using the Cochrane Database, the same group of authors concluded[174] that anticoagulant treatment "appeared to be safe" and was associated with a reduction in the pooled risk of death (0.33) or dependency (0.46) but that such trends were not statistically significant. A similar conclusion in favor of anticoagulant use has been proposed for children, namely, that no data to prove efficacy exists, but the long-term sequelae (death or neurologic deficit in 50% of children) warrant empiric anticoagulation.[175] Clinical outcome of

treatment has been summarized for 624 adults in 21 countries, of whom 520 (83%) received anticoagulation therapy.[162] The prognosis was better than reported earlier,[146] with 356 (57%) having no residue of the illness and 30% with minor or mild impairment. Women with CVST and a gender-specific etiology such as contraceptives, hormonal replacement, or pregnancy have a better prognosis with complete recovery in 81%.[176]

Thrombolytic Therapy

There are numerous reports[177–186] on the use of thrombolytic therapy, usually administered regionally, so this approach can no longer be considered as unduly risky in a seriously ill patient, even in the face of documented intracranial hemorrhage.[187] A Cochrane Database review in 2004 found no randomized, controlled trial of thrombolytic therapy that evaluated efficacy or safety.[188] Still, a search of the literature found 169 patients with CVST who received a plasminogen activator (urokinase in 76%), administered regionally into the thrombus in 88% of cases.[189] The aggregate experience showed death in nine cases (5%), adverse outcome (dependency) in 7%, and intracranial hemorrhage with clinical deterioration in 5%. A recent single institution experience of 20 patients with serious CVST (altered mental status, coma, large space-occupying lesions) reported results with urokinase administered regionally via jugular vein catheter.[190] Of these critically ill patients, 12 recovered, 2 survived with significant handicap, and 6 died. There were five instances of increased intracranial hemorrhage after treatment, three minor and two major. Of the six patients who died, five had herniation secondary to large hemispheric infarcts and cerebral edema prior to thrombolytic treatment, indicating that such patients are best not so-treated.

RETINAL VEIN OCCLUSION

Occlusion of the retinal veins is localized either to the central retinal vein or three to five times more commonly to a branch vein, typically at an arteriovenous crossing,[191,192] with an incidence of 1.6% per decade in an elderly population.[193] The prevalence is similar in populations of different ethnicity.[194]

Pathogenesis

Retinal vein occlusion (RVO) occurs against a backdrop of the systemic vascular complex of diabetes mellitus, hypertension, dyslipidemia, smoking, and atherosclerosis. In a meta-analysis of 21 studies, the odds ratios (ORs) for these associations with RVO were between 1.5 and 3.5.[195] There is also an association with renal dysfunction.

RVO is reported in patients with inherited thrombophilia due to the prothrombin 20210 G/A mutation,[196] familial hyperhomocysteinemia,[197] the MTHFR mutation,[198] and activated protein C resistance.[199] In one survey, the factor V_{Leiden} R506Q mutation was present in 10 of 35 (29%) patients with RVO, similar to that observed in patients with DVT (40 of 209, 19%) but with no preponderance of protein C or protein S deficiency, or lupus inhibitor.[200] Another retrospective study failed to show a factor V_{Leiden} relation.[201] A meta-analysis of 18 studies shows a significant (CI 1.19 to 2.32) but "only moderate" (OR 1.66) relationship of factor V_{Leiden} with RVO, thus explaining the disparate conclusions due to chance variation of individual small studies.[202]

A meta-analysis of 614 patients with RVO showed a significantly higher homocysteine level and lower serum folate level in comparison with those in 762 controls but no increased prevalence of the MTHFR genotype.[203] Correlations of elevated homocysteine and plasminogen activator inhibitor-1, an association with positive antiphospholipid antibody, external forces, such as trauma and increased intraocular pressure from tumor or hemorrhage have been highlighted in review articles.[204–206] Thrombosis has occurred in hematologic diseases with a commonality of hyperviscosity, including hyperleukocytosis, dysproteinemia, erythrocytosis, hemoglobinopathy, and cryofibrinogenemia.[207]

Clinical Aspects and Treatment

The primary clinical manifestation of RVO is painless loss of visual acuity, the acuteness and severity of which depend upon the degree of venous occlusion and whether the central (FIGURE 84.6) or a branch vessel is involved. The natural history of the disorder, assessed in 725 patients by the Central Vein Occlusion Study Group, indicates that 15% (81 of 547) of involved "eyes" evolve to ischemia at 4 months, 34% by 3 years, and that the strongest predictor of visual acuity at 3 years is visual acuity at the onset of disease.[208] Attempts to alter the course of illness have utilized hemodilution, with both negative and positive effect,[209,210] laser photocoagulation without benefit over placebo for visual acuity at 3 months or with protection in some eyes against neovascularization,[211-213] rheologic agents with a suggestion of positive results in preliminary studies,[214,215] thrombolytic therapy with unconvincing results,[216-219] or surgical approaches, including sheathotomy and radial optic neurotomy,[220-222] the latter even combined

with local infusion of rt-PA.[223] LMWH shows variable results in two small trials against aspirin as control treatment.[224,225] Intravitreal administration of steroids (dexamethasone) may speed visual improvement (vs. sham injections),[226] but a similar approach using triamcinolone showed no difference versus "standard" care.[227]

The major new therapeutic direction has utilized intravitreal injections of vascular endothelial growth factor (VEGF) inhibitors,[228] notably, bevacizumab,[229–231] ranibizumab,[232–236] and pegaptanib.[237] All of the trials are prospective but observational, and no comparative studies between VEGF inhibitors have been performed as yet. Results generally show some degree of improvement in visual acuity and decrease in macular edema, without significant tolerance or safety issues. However, a significant proportion of the trials indicate that repeat injections are required to maintain benefit and to prevent recurrence. A Cochrane Database review[228] concludes that ranibizumab and pegaptanib "have shown promise in the short-term" but that larger randomized and controlled trial data are needed, and the agents must still be considered experimental.

PORTOMESENTERIC VEIN THROMBOSIS

Predispositions

Symptoms of portomesenteric vein thrombosis (PVT) are often vague and nonspecific.[238–241] Nonlocalized, colicky pain that is severe and out of proportion to physical findings is nearly universal. Nausea with or without vomiting is seen in half the cases, as is anorexia, but ileus is absent until the condition evolves after days or weeks into a surgical abdomen, the harbinger of bowel infarction.[242] PVT is often not recognized in the acute phase and may present clinically as progressive splenomegaly and ascites without evidence of worsening hepatic function. The stool is often guaiac-positive, but laboratory findings are nonspecific, with mild hemoconcentration and a moderate neutrophilia. Blood-tinged ascites signifies bowel infarction as a late manifestation. In children, the initial manifestation of PVT often is upper gastrointestinal bleeding or cytopenias secondary to splenomegaly that is discovered coincidentally by routine physical examination.[243]

Conditions that predispose to PVT include myeloproliferative syndromes,[244] inflammatory bowel disease,[245] cirrhosis and portal hypertension,[246] intraabdominal neoplasm (especially carcinoma of the pancreas), intraabdominal infection (especially spontaneous bacterial peritonitis), and blunt or penetrating trauma (including abdominal surgery).[247] Local conditions may be especially prevalent with organ removal as, for example, after splenectomy, in which the incidence has been reported to be 7% (4 of 60),[248] and after liver transplantation, which carries a prevalence of 8% to 26%.[249,250] Although not common, portal vein thrombosis has been noted after umbilical vein catheterization[251] and gastric bypass surgery.[252] Relatively less traumatic laparoscopic abdominal surgery can result in PVT, as noted in a series of 18 cases that followed gastric bypass, fundoplication, colectomy, cholecystectomy, and appendectomy.[253] The main presenting symptom was nonspecific abdominal pain appearing at a mean of 14 days after surgery, suggesting that diagnosis was delayed in many cases by the subtlety of clinical findings. Of the 18 cases, 11 had "systemic predisposition" as an added risk factor.

A substantial portion of patients with "primary" PVT have an underlying thrombophilic condition,[254] and it has been reported with deficiencies of antithrombin, protein C, or protein S; mutations of prothrombin G20210A, MTHFR genotype TT677, and factor V_{Leiden}; and acquired diseases such as paroxysmal nocturnal hemoglobinuria, antiphospholipid syndrome, and as a complication of estrogen administration for contraception.[238,255–268] In patients with myeloproliferative syndrome, the presence of the JAK2 V617F mutation indicates a higher risk for vascular events[244] (see Chapter 102). There does seem to be an increased prevalence of the prothrombin mutation (40% vs. 5% in controls),[269] but some questions exist about the involvement of the factor V_{Leiden} mutation in this condition.[270,271] PVT is reported to occur in 4% to 10% and to recur in 63% of patients with antithrombin, protein C, or protein S deficiency.[272] In the pediatric population, PVT has been described in five cases after receiving chemotherapy.[273]

Apparent PVT may in fact represent tumor invasion of the vessels, notably, for pancreatic and hepatocellular malignancies.[274–276] This distinction has obvious therapeutic and prognostic implications, and criteria for establishing that only "benign" PVT exists may often prove inaccurate, as in 9 of 33 such cases in one series.[277]

Diagnosis and Management

Plain abdominal radiography and barium contrast studies are nonspecific and are of little assistance in the diagnosis.[278] Noninvasive imaging studies using US (FIGURE 84.7), MR, or CT angiography are the primary diagnostic modalities.[279–281] Two retrospective surveys reinforce a conservative approach with anticoagulation using surgery for cases of bowel infarction and potential perforation.[282,283] Anticoagulant treatment should be started with UFH intravenously until the patient is stable and

surgical intervention becomes unlikely. Then treatment can be switched to LMWH with overlap to a vitamin K antagonist. In case of liver cirrhosis with hypoprothrombinemia or otherwise high bleeding risk, it is probably safer to continue with LMWH with reduction to a prophylactic dose after 1 week. The duration of anticoagulation should be at least 3 to 6 months, longer in case of severe thrombophilia.

Early noninvasive diagnosis has allowed more efficient treatment, decreasing the mortality from 90% for untreated patients and 30% to 50% primarily for surgically treated patients[239,242,284] to more favorable outcomes of 90% or better survival.[283] A role for mechanical thrombectomy or early vascular grafting has been advocated in patients after orthotopic liver transplant.[250] In patients with contraindications to heparin, direct antithrombin agents such as argatroban or hirudin are reasonable options,[285–287] and gradual vascular recanalization is to be expected in patients who are appropriately treated with anticoagulation.[288] In a cohort of 95 (of 102) patients with acute PVT "unrelated to cirrhosis" who were treated with anticoagulation, portal vein patency was established in 39% at about 1 year, whereas failure was related to the presence of ascites and an occluded splenic vein.[289] Under proper imaging guidance, rapid lysis of thrombus can be achieved by regional thrombolytic administration and stent placement,[290–298] even in the neonatal period.[299]

SPLENIC VEIN THROMBOSIS

Splenic vein thrombosis is rarely recognized at the time of the acute event.[301] Typically, the thrombosed vein is discovered during an evaluation of vague abdominal pain with isolated splenomegaly but without ascites or significant hepatic dysfunction, or in relation to pancreatic disease (inflammatory, malignant, or traumatic).[302,303] Splenic vein thrombosis has been reported after "noninvasive" laparoscopic splenectomy[304,305] and is associated with the same acquired disorders that predispose to portal/mesenteric venous thrombosis.[306,307] Portal and splenic vein thrombosis occasionally complicate the nephrotic syndrome, as does renal vein thrombosis.[308] Anticoagulant therapy for the acute thrombosis may not be indicated, unless a significant thrombophilic process is discovered, but invasive approaches of splenic artery embolism[309] or vascular stenting[310] may be needed for complicating bleeding varices.

HEPATIC VEIN THROMBOSIS (BUDD-CHIARI SYNDROME)

Clinical Presentation

In classic hepatic venous outflow obstruction (Budd-Chiari syndrome [BCS]), the major hepatic veins and/or the inferior vena cava (IVC) is occluded. Symptoms may be acute and fulminant, with sudden abdominal pain, enlarging liver, rapid development of massive ascites, and mortality risk of up to 67%.[311,312] More often, the course is chronic and insidious, leading variably to intractable ascites, hepatic insufficiency, and gastrointestinal bleeding due to varices.[302,311,312,313,314] The process may develop so rapidly that liver function tests may be normal or near normal at presentation. Common to all presentations is an absence of hepatic venous flow.[315]

Hepatic vein thrombosis is associated with a variety of conditions. Toxins such as alkaloids found in senecio beans, comfrey tea ("bush tea"), and high-dosage alkylating agents can induce thrombosis or fibrosis of the smallest hepatic veins.[316–318] Other conditions include myeloproliferative disorders, hepatocellular carcinoma, renal neoplasm, trauma, intraabdominal infection, pregnancy, OC use, inflammatory bowel disease, and Behçet disease.[313,319–321]

Many cases are associated with hematologic disease, especially paroxysmal nocturnal hemoglobinuria and myeloproliferative syndromes[262,263,322,323] and antiphospholipid syndrome.[262,324] In a comparison of predispositions, there was a greater association of the myeloproliferative disorders, PNH, and Behçet syndrome with BCS and PVT than with ordinary DVT/PE.[323] There are reports of an association of antithrombin deficiency,[325] heparin-induced thrombocytopenia,[326] and factor V_{Leiden} mutation[270,327] with BCS. Impaired fibrinolysis may explain some cases of BCS, perhaps those occurring in patients with Behçet syndrome.[328]

"Congenital webs" have been noted in the hepatic veins[313,329] and are generally considered as contributory to the disease (FIGURE 84.8). However, the webs may constitute "organized thrombi of varying ages" and fibrous and recanalized material.[330] Therefore, in some cases at least, the "webs" represent a sequelae of thrombi rather than congenital malformations, which are especially prevalent in Asia, presenting as a more gradual obstructive illness than acute hepatic vein thrombosis.[331,332] BCS is rarely diagnosed in children, who show a similar tendency for this complication of myeloproliferative syndromes.[333,334]

Hepatic venography is sensitive and specific for advanced BCS but may be negative in the early stages of the process. US, computed tomography with contrast, and especially

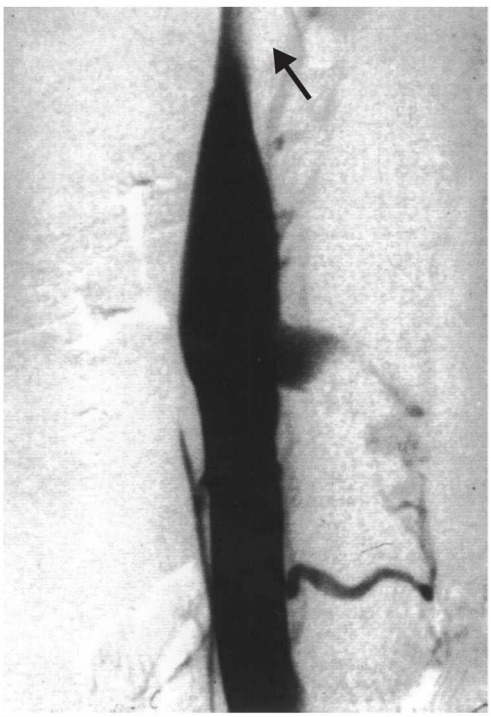

FIGURE 84.8 Inferior vena cavography. There is narrowing and occlusion (*arrow*) of the IVC at the level of the confluence of the hepatic veins caused by an endoluminal "web." (Reproduced with permission from the Encyclopedia of Medical Imaging [Medcyclopaedia].)

magnetic resonance imaging (MRI) provide documentation of pathology,[335–337] including caudate lobe hypertrophy obstructing hepatic vein drainage into the IVC.

Treatment

Anticoagulant treatment, according to principles described above for PVT, diuretics, prevention of portal hypertension, and removal of risk factors constitute the mainstay in the management. Experience with regional thrombolytic therapy has been striking in case reports, and there is sufficient foundation for its application under dire clinical circumstances.[338–342] However, one single center reports striking benefit after systemic or regional thrombolysis and did note its value as adjunct to mechanical interventions, especially with fresh thrombosis.[338] In addition to or following a thrombolysis attempt, transjugular intrahepatic portosystemic shunt is applied widely to patients with BCS, as a less invasive means of achieving hepatic vein to portal vein anastomosis than with surgical side-to-side portocaval shunting.[343,344] The procedure may improve vascular flow[345] and symptomatic aspects, but encephalopathy may worsen, restenosis may occur, and long-term anticoagulation is still required.[346,347,348] Orthotopic liver transplantation (OLT) is indicated for patients with hepatic decompensation and can be lifesaving in select cases.[349,350–352] In a large review of 248 patients with BCS who underwent OLT, survival was 76% at 1 year and 68% at 10 years.[352] Deaths were mostly in the first 3 months, due to infection and multiple organ failure in about half, about 20% secondary to graft failure or hepatic artery thrombosis.

RENAL VEIN THROMBOSIS

RVT is associated with acute illness and severe dehydration in the neonate and may also occur acutely in the adult; however, the more common form in the adult is a chronic presentation caused by the nephrotic syndrome, usually secondary to membranous glomerulonephritis.[353,354] Acute RVT (FIGURE 84.9) presents with a triad of flank pain, hematuria, and sudden deterioration of renal function, whereas the chronic form is usually asymptomatic and undetected until sought by appropriate diagnostic tests.[355,356]

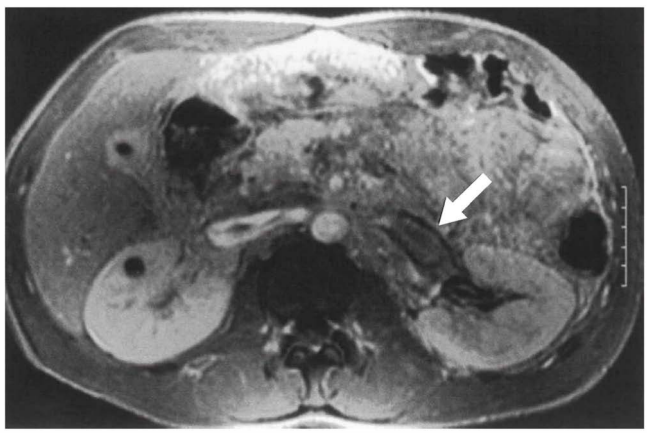

FIGURE 84.9 Renal vein thrombosis. Axial contrast-enhanced T1-weighted MRI section demonstrating thrombosis of the left renal vein (*arrow*). [Reproduced with permission from the Encyclopedia of Medical Imaging (Medcyclopaedia).]

FIGURE 84.10 Abdominal ultrasonography of inferior vena cava (*IVC*). A renal vein thrombus has extended into the IVC. (Reproduced with permission from the Encyclopedia of Medical Imaging [Medcyclopaedia].)

The nephrotic syndrome not only predisposes to RVT but also to extension into the IVC (FIGURE 84.10) and to lower extremity DVT, PE,[353,357] and to involvement of the splenic/mesenteric/portal vein system.[308,310] Several factors may contribute to the thrombotic tendency, including reduced plasma levels of antithrombin and protein C, caused by excessive urinary loss of the protein, and reduced levels of free protein S, perhaps secondary to an increase in C4b-BP.[358]

In a review of 43 patients with neonatal RVT, about half demonstrated renal failure, thrombocytopenia or anemia, and/or a renal mass on presentation,[359] and in a large retrospective survey of 271 patients with RVT, 44% had extension into the IVC.[360] Prenatal RVT has been documented on rare occasions, presenting as hydrops fetalis, fetal distress, or coincidentally upon ultrasound exam.[361]

RVT occurs in patients with inherited thrombophilias, such as deficiency of antithrombin or protein C, or the factor V_{Leiden} mutation,[362–364] and with acquired illnesses such as sickle cell disease, paroxysmal nocturnal hemoglobinuria, antiphospholipid syndrome, and Behçet disease.[149,365–369] RVT also may follow renal transplantation, as reflected by a 4% rate of postgraft thrombosis (7 out of 176 transplants), of which five grafts were lost.[370] As with portal or hepatic vein occlusion, the renal vein may be occluded by retrograde tumor spread of renal cell carcinoma, an occurrence observed in 9 of 115 cases.[371]

Patients with acute RVT are usually treated with anticoagulants. However, renal grafts that are threatened by vascular thrombosis can be salvaged by thrombolytic treatment[370,372,373] by regional or systemic routes.[374–379]

PELVIC VEIN THROMBOSIS

Pelvic vein thrombosis as a distinct entity, unassociated with extension of DVT from the lower extremities, occurs in and around the uterine adnexa and complicates 0.1% or fewer of all deliveries, perhaps as many as 1% of patients with pelvic infection.[380] Ovarian venous thrombosis is considered to be a form of septic thrombophlebitis,[381–383] usually on the right side, and because fever and pain may be present, appendicitis is the differential diagnosis. When limited to the ovarian vein, treatment with antibiotics alone may be all that is required, but if thrombosis also involves the iliac system, heparin treatment is indicated.[384]

LEFT COMMON ILIAC VEIN THROMBOSIS (MAY-THURNER SYNDROME)

Occlusion of the iliofemoral vein occurs more often on the left side than the right. In the description of this "predominantly sinistral occurrence of thrombosis of the pelvic veins," May and Thurner[385] pointed out that this clinical peculiarity had been explained since the time of Virchow[386] by "obstruction of the flow of the left common iliac vein (CIV) by the artery resting upon it." May and Thurner described pathologic "spur-like projections" into the left CIV; it seems likely that these lesions were inflammatory responses to chronic local injury caused by the pulsations of the contiguous right common iliac artery (CIA). They further explained the thrombotic event as the result of the spur, which caused venous stenosis, "hampering the flow of blood" and promoting the formation of thrombosis in the left half of the pelvis."[385] The anatomic relationship of the pelvic vessels involved in May-Thurner syndrome (MTS) (FIGURE 84.11)[387] suggests that compression of the left CIV would be a routine aspect of every person's pelvic vascular anatomy. Indeed, CT arteriograms on 50 asymptomatic patients showed >50% compression of the left CIV in 24% and more than 25% compression in 66% of subjects, most often secondary to overlying right CIA pressure against the vertebral body.[388] Women have greater left CIV compression than men (mean 41% vs. 27%, $P = 0.003$),[388] perhaps reflecting the effect of prior additional pressure on the pelvic vein by a gravid uterus. Left CIV compression has been observed in adolescents,[389,390] preteens,[391] and even in infants.[392] As with other unusual sites of thrombosis, a "second hit" thrombophilic event often precedes the thrombosis, for example, during the postpartum period,[393] with the antiphospholipid syndrome,[394] with OC use,[395] and with other typical thrombophilic predispositions.[396]

In addition to the expected signs of proximal iliofemoral thrombosis, patients with MTS may have unusual (though not unique) manifestations. One study of 470 patients with patent foramen ovale and cryptogenic stroke showed MTS in 6.3% of cases,[396] and a review of 7 patients with phlegmasia

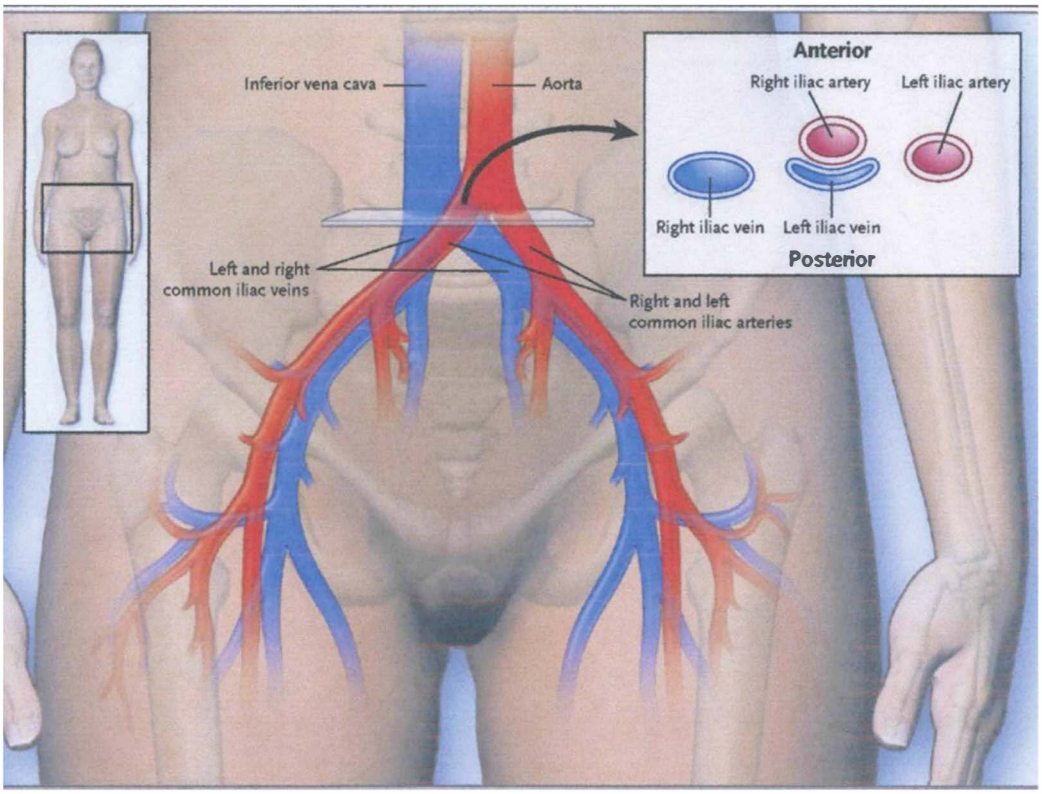

FIGURE 84.11 Relationship of pelvic arteries and veins, as related to MTS. The right common internal iliac artery crosses over and compresses the left common internal iliac vein, providing the anatomic basis for the higher incidence of pelvic venous thrombosis on the left side. (Reproduced with permission from Fazel R, Froelich JB, Williams DM, et al. A sinister development. *N Engl J Med* 2007;357:53–59.)

cerulea dolens showed that 3 had MTS.[397] A dramatic and likely unique consequence of MTS is retroperitoneal hemorrhage, presumably secondary to spontaneous acute rupture of a varix formed in the collateral circulation in response to the massive pelvic venous obstruction.[398–400]

Acute treatment is effective, consisting primarily of regional thrombolytic infusion, thrombus aspiration, and stenting.[390,397,401–403] In a study of 13 adolescents with lower extremity proximal DVT who underwent catheter-directed thrombolytic infusion, MTS was documented in 53%, all of whom had placement of endovascular stents and technical success in 94%.[390] About 40% of successfully treated patients had recurrent DVT within a month, most of whom were effectively treated with thrombolysis again. In 21 patients with venographically verified MTS, initial thrombolysis was routinely followed by balloon angioplasty and/or stent placement, with rapid symptom relief in all but one.[401] Of importance, only 2 of 18 patients who had stent placement had a recurrent thrombosis, whereas 3 of 3 who were treated without stent placement had recurrent thrombosis during the follow-up period of 11 months. An unusual complication of stent placement was embolization to the right ventricle.[404] Long-term management required anticoagulation as with other major venous thromboembolic events.

SUPERFICIAL VEIN THROMBOSIS

SVT usually occurs in a localized and self-limited form, but 5% to 30% of patients also have DVT,[405–407] estimated as a 6.3-fold increased risk.[408] In the study that showed a 29% incidence of concomitant DVT,[407] the notable risk factors were age >75 years, active cancer, inpatient status, and nonvaricose vein location. SVT that involves the greater saphenous vein has a 10% association with pulmonary embolization. The presence of factor V_{Leiden}, the prothrombin G20210A mutation, and protein C, protein S, or antithrombin deficiency can all significantly elevate the OR for formation of SVT.[409–412] In a retrospective assessment of 427 hospitalized patients with symptomatic "isolated" SVT, 19 (4.4%) developed a DVT or PE, the single important predictive factor being severe chronic venous insufficiency.[413] However, in a study of 737 patients with SVT, the prospective risk of subsequent cancer (3.5% vs. 3.9% in controls) or arterial cardiovascular events (4.3% vs. 4.4% in controls) was not increased,[414] and the 3-month follow-up of 788 such patients showed that the rate of death (1.2%) or major bleeds (0.4%) was not adversely affected by SVT.[407]

Treatment of SVT has been assessed in randomized prospective trials. One trial showed a trend (not significant) for decreased incidence of DVT after 12 days of LMWH therapy (40 mg/d or 1.5 mg/kg/d enoxaparin) (1% vs. 3.6% for placebo, $P = 0.37$).[415] A second study of 60 patients with greater saphenous vein thrombosis showed fewer symptomatic or asymptomatic DVT or pulmonary embolic events at 6 months after twice daily subcutaneous injections of either high-dose UFH (12,500 U for 1 week, then 10,000 U for 3 weeks) compared to a prophylactic dose (5,000 U for 4 weeks) (3.3% vs. 20%, $P = 0.05$).[416] However, a comparison of a weight-adjusted (therapeutic) dosage of LMWH (nadroparin) versus a fixed prophylactic dose for 1 month failed to show an advantage for the higher dose (7 of 81 vs. 6 of 83, $P = 0.74$) for SVT progression or venous thromboembolic complications.[417] Addition of a 10-day course of an anti-inflammatory agent (acemetacin) to single-dose nadroparin induced more rapid symptomatic relief of pain and tenderness,[418] but abatement of symptoms clearly does not reflect resolution of the underlying SVT.[419]

An apparently definitive study of anticoagulant treatment in 3,002 patients with isolated, acute, symptomatic SVT was published in 2010.[420] This trial compared 45 days of subcutaneous fondaparinux (2.5 mg/d) with placebo, efficacy outcome being the composite of any cause death, and symptomatic PE or DVT, SVT extension into the saphenofemoral junction or recurrence; safety outcome was primarily major bleeding. The efficacy endpoint clearly favored the active treatment arm (0.9% vs. 5.9%, $P < 0.001$), with no increase in major bleeding. The report notes that 88 patients would need to be treated to prevent one PE or DVT, and a subsequent analysis[421] concluded that the 45-day treatment "did not appear to be cost-effective when used in all patients with isolated SVT of the legs." Clearly, treatment of patients with SVT, especially with a prolonged and expensive course, will depend on concomitant clinical factors.

SUPERIOR VENA CAVA SYNDROME

SVC syndrome usually presents with edema of the upper extremities, torso, neck and face, varying degrees of cyanosis, and engorged cutaneous veins.[422] Most cases result from mediastinal tumor that compresses the SVC, sometimes with concomitant airway compromise.[422–424,425] The SVC syndrome may also be caused by bland thrombosis, almost always secondary to local effects of a foreign body, for example, intravascular devices such as dialysis[426] or central venous access,[427] catheters, and pacemakers,[429] or as a complication of a vascular inflammatory process such as Behçet disease (see Chapter 100).[430,431] Treatment modalities include mechanical interventions by angioplasty and stent placement,[424,428] anticoagulants,[429] local thrombolytic administration,[424,425,427] and bypass or decompressive surgery,[423,425] in addition to treatment of an underlying malignancy when appropriate.[422]

Sequelae of Venous Thromboembolic Disease: Postthrombotic Syndrome and Chronic Thromboembolic Pulmonary Hypertension

VITTORIO PENGO AND SUSAN R. KAHN

POSTTHROMBOTIC SYNDROME

The postthrombotic syndrome (PTS) is an important, underrecognized, chronic sequela of deep vein thrombosis (DVT). PTS develops in 20% to 50% of patients with DVT,[1,2] even when appropriate anticoagulant therapy is used to treat DVT (see Chapter 87). Clinical manifestations of PTS range from mild symptoms or signs to more severe manifestations such as intractable leg pain, severe edema, and leg ulcers that limit daily activity and ability to work.[3] PTS reduces quality of life and productivity,[4,5,6] and is costly as measured by health resource utilization, direct costs, and indirect costs.[7,8]

DIAGNOSIS OF THE POSTTHROMBOTIC SYNDROME

PTS is a Clinical Diagnosis

PTS is diagnosed on clinical grounds based on the development of characteristic symptoms and signs in a patient with prior DVT (Table 85.1). Symptoms include pain, aching, heaviness, swelling, cramps, itching, or tingling in the affected limb. These may be present in varying combinations and can be persistent or intermittent. Typically, symptoms are made worse by standing or walking and improve with rest and leg elevation. Signs noted on physical examination of the limb include edema, perimalleolar or more extensive telangiectasiae, brown pigmentation, and venous eczema (FIGURE 85.1). Secondary varicose veins may become manifest, and tender thickening of the subcutaneous tissues of the medial lower limb known as lipodermatosclerosis may occur. Venous leg ulcers may develop, which require careful medical attention and often recur. Leg ulcers can be precipitated by minor trauma and are typically chronic, painful, and slow to heal.[3,9]

The clinical picture of PTS can be nonspecific, as conditions other than DVT (e.g., primary venous insufficiency, chronic congestive heart failure) may produce similar symptoms or signs in the lower extremities. However, PTS is usually the correct diagnosis in a patient with objectively confirmed prior DVT who has typical PTS symptoms and signs in that limb. In some patients, it may take up to 3 to 6 months for the initial symptoms of acute DVT to resolve, hence a diagnosis of established PTS should be deferred until after the acute phase has passed.[10]

In the absence of clinical features of PTS in a patient with previous DVT, demonstrating the presence of venous abnormalities such as valvular reflux, persistent venous obstruction, or venous hypertension on invasive or noninvasive imaging or testing does not indicate a diagnosis of PTS. This is because while many patients with symptomatic PTS have detectable venous abnormalities, many DVT patients who do not have symptoms of PTS can also be shown to have such abnormalities.[11–14] Therefore, there is no indication to routinely perform invasive or noninvasive venous testing in patients with a clear clinical diagnosis of PTS.

Objective confirmation can be useful in patients who have a characteristic presentation of PTS but who do not have a history of previous DVT. Compression ultrasonography can assess for lack of compressibility of the popliteal or common femoral veins, along with continuous-wave Doppler to assess for reflux of their venous valves. In one study, the combination of a standardized clinical evaluation, compression ultrasonography, and continuous-wave Doppler analysis reliably diagnosed or excluded previous proximal vein thrombosis in almost 90% of patients.[15]

Clinical Tools to Diagnose PTS

Three clinical tools to measure PTS are the Villalta PTS scale,[16] Ginsberg PTS measure,[17] and the CEAP (Clinical, Etiological, Anatomical, Pathophysiological) classification for chronic venous disease.[18] The Villalta scale is a clinical scoring system that is based on the severity ratings of PTS symptoms and signs. The Ginsberg measure diagnoses PTS if both pain and swelling of the limb of more than 1 month's duration are present, are of typical character (worse at the end of the day or with prolonged sitting or standing, better after a night's rest or with leg elevation), and occur at least 6 months after acute DVT. As well, objective evidence of valvular incompetence is required. The CEAP measure combines clinical and objective findings into seven classes of chronic venous disease with subcategories to denote etiologic, anatomic, and pathophysiologic attributes. Other, less frequently used scales have been proposed as well.[19]

In a step toward harmonizing the definition and measurement of PTS in clinical studies and with a view to encouraging PTS research, a subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis has recently recommended that the Villalta scale be adopted as a standardized measure to diagnose and grade the severity of PTS.[20] This scale is a reliable and valid measure of PTS and shows responsiveness to clinical change.[21]

Table 85.1

Clinical manifestations of the PTS

Limb Symptoms	Signs on Physical Examination
Heaviness	Edema
Pain	Telangiectasiae
Swelling	Venous ectasia, secondary varicose veins
Itching	Hyperpigmentation, venous eczema
Cramping	Redness
Tingling	Dependent cyanosis
Bursting sensation	Lipodermatosclerosis Healed ulcer, open ulcer

The individual components of the Villalta scale and its scoring algorithm are shown in Table 85.2.

Distinguishing Postthrombotic Syndrome from Recurrent Acute Deep Vein Thrombosis

It is not uncommon for PTS symptoms to wax and wane over time. If new symptoms in the affected leg develop or chronic symptoms in the leg become worse and there are no associated

FIGURE 85.1 The postthrombotic syndrome.

Table 85.2

Components of Villalta PTS scale

Symptoms	None	Mild	Moderate	Severe
	0 Point	1 Point	2 Points	3 Points
Pain	❑	❑	❑	❑
Cramps	❑	❑	❑	❑
Heaviness	❑	❑	❑	❑
Paresthesiae	❑	❑	❑	❑
Pruritis	❑	❑	❑	❑
Clinical Signs	**None**	**Mild**	**Moderate**	**Severe**
	0 Point	1 Point	2 Points	3 Points
Pretibial edema	❑	❑	❑	❑
Skin induration	❑	❑	❑	❑
Hyperpigmentation	❑	❑	❑	❑
Redness	❑	❑	❑	❑
Venous ectasia	❑	❑	❑	❑
Pain on calf compression	❑	❑	❑	❑
Venous ulcer	Absent ❑	Present ❑		

Each symptom is self-rated by the patient and each clinical sign is rated by the clinician as 0 (absent), 1 (mild), 2 (moderate), or 3 (severe), except ulcer, which is marked as present or absent. All numeric points are summed to yield a total score: a score of 0–4 indicates the absence of PTS and a score of ≥5 indicates PTS (5–9, mild PTS, 10–14, moderate PTS and ≥15 or the presence of an ulcer, severe PTS).
Modified from Villalta S, Bagatella P, Piccioli A, et al. Assessment of validity and reproducibility of a clinical scale for the post-thrombotic syndrome. *Haemostasis* 1994;24:158a.

symptoms that could suggest acute pulmonary embolism (PE), patients can be advised to rest their leg and wait a day, as in most cases the symptoms are likely to be due to PTS and will settle down. However, patients with PTS are at increased risk of recurrent venous thromboembolism.[22] Hence, if leg symptoms persist or progress, especially if new clinical risk factors for DVT are present, investigation is warranted to rule out recurrent DVT. The general approach to diagnosing recurrent DVT is the same as in patients without PTS (see Chapter 83). However, diagnosis of recurrent ipsilateral DVT can be challenging, as finding a noncompressible venous segment in the same area as the initial DVT can represent new or residual thrombus. Compared with the previous ultrasonogram, an unambiguous change in the extent of thrombosis or an increase in clot diameter of 4 mm or more on the current ultrasonogram indicates new ipsilateral DVT.[23–25] Studies suggest that strategies that use D-dimer testing alone[26] or in combination with clinical probability testing[27] can reduce the need to perform ultrasonography in patients with suspected recurrent DVT.

PATHOPHYSIOLOGY OF THE POSTTHROMBOTIC SYNDROME

PTS occurs primarily as a consequence of venous hypertension, which in turn leads to reduced venous return, diminished calf muscle perfusion, impaired microvasculature function, and clinical manifestations of PTS.[9,28]

DVT leads to chronic venous hypertension by two principal mechanisms, persistent venous obstruction, and venous valvular reflux. Follow-up studies of patients with DVT who were treated with standard anticoagulants have shown that in many cases, there is only partial clearance of the thrombus.[29–32] Damage to venous valves with consequent valvular reflux is frequent after DVT, and is likely caused by thrombus-induced activation of inflammation, fibrous scarring associated with acute and resolving thrombosis, or venous dilation distal to the obstructed venous segment.[33–37] Residual venous obstruction 6 months after DVT, alone or in combination with valvular reflux, predicts the development of PTS, whereas reflux alone does not.[31,38]

Elevated levels of markers of inflammation (e.g., ICAM-1, interleukin-6, and C-reactive protein),[37,39] D-dimer,[40,41] and vein wall response to acute thrombosis[42] early after diagnosis or within a few months of DVT were associated with the development of PTS. A large, multicenter study is underway to prospectively assess the relationship between markers of inflammation and vessel injury and the development of PTS.[43]

EPIDEMIOLOGY OF POSTTHROMBOTIC SYNDROME: INCIDENCE, RISK FACTORS AND PROGNOSIS

Data from contemporary prospective studies with 1 year or longer follow-up demonstrate that 20% to 50% of DVT patients will develop PTS and 5% to 10% will develop severe PTS, which may include venous ulcers.[1,2,14,41,44–47] In most cases, PTS develops within the first 1 to 2 years after DVT.[1,2]

It is difficult to predict which DVT patients will develop PTS. A key finding from a recent prospective cohort study of 387 patients with acute symptomatic DVT was that incomplete resolution of leg symptoms and signs by 1 month after DVT strongly predicted the development of PTS during the subsequent 2 years.[2] In addition, venous thrombosis of the common femoral or iliac vein (compared with distal or popliteal vein DVT),[2,41,47,48] previous or recurrent ipsilateral venous thrombosis,[1,2,41,45,49–51] higher body mass index,[2,46,47,52,53] and older age[2,45,46] are associated with a greater risk of developing PTS. One study reported that DVT patients who had subtherapeutic International Normalized Ratios (INRs) more than half of the time during the initial 3 months treatment with vitamin K antagonists had a threefold higher risk of developing PTS,[46] thereby reinforcing the importance of close monitoring of the intensity of oral anticoagulant therapy following the initial thrombotic episode. The risk of PTS is not influenced by the patient's sex,[2] presence of the factor V Leiden, or the prothrombin mutation[2,47] or by the context of the initial DVT (i.e., unprovoked, secondary, or cancer related).[2,41,45,46]

In summary, extensive DVT, prior ipsilateral DVT, persistent venous symptoms 1 month after DVT, obesity, and older age appear to be robust clinical predictors of PTS. However, DVT patients without these features can also develop PTS.

Despite the common belief that patients with PTS have a uniformly poor prognosis, outcomes might be better than previously reported, with more than half of patients remaining stable or improving during long-term follow-up.[2,54–56] Currently, it is not possible to predict the course of PTS in individual patients.

PREVENTION OF THE POSTTHROMBOTIC SYNDROME

Preventing First and Recurrent Deep Vein Thrombosis

Preventing DVT with the systematic use of thromboprophylaxis in high-risk hospitalized patients as recommended in evidence-based consensus guidelines[57,58] will prevent cases of PTS. Furthermore, as recurrent ipsilateral DVT is an important risk factor for PTS, providing anticoagulation of appropriate intensity and duration to treat the initial DVT so as to reduce the risk of recurrent DVT is a key means of preventing cases of PTS.[59,60]

Elastic Compression Stockings to Prevent the Postthrombotic Syndrome

Graduated elastic compression stockings (ECS) decrease venous hypertension, reduce edema, and improve tissue perfusion.[61] Two trials have evaluated the effectiveness of long-term use of ECS for the prevention of PTS, started within days of diagnosis of symptomatic proximal DVT. Among 194 patients who were randomly assigned a made-to-measure 30 to 40 mm Hg knee-length ECS to be worn daily for at least 2 years or no stockings, ECS led to a decrease from 47% to 20% of mild PTS and from 23% to 11% of severe PTS.[62] A subsequent study evaluated the effectiveness of the "off the rack" knee length 30 to 40 mm Hg ECS, worn for 2 years, versus no stockings in 180 proximal DVT patients. Use of ECS reduced the risk of PTS from 49% to 26% (adjusted hazard ratio 0.5 [95% confidence interval [CI] 0.3 to 0.8] in favor of ECS).[45] Conversely, in a randomized trial of patients with proximal DVT who had not developed PTS by 1 year after the initial DVT, there was no benefit of daily use of 20 to 30 mm Hg ECS for up to 4 years, compared with use of sham stockings (1 or 2 sizes too large); PTS developed in 0/24 patients in the ECS group versus 1/23 patients in the sham

stockings group ($P = 0.49$).[13] A meta-analysis that pooled the three studies concluded that use of ECS after DVT significantly reduces the risk of any PTS (odds ratio [OR] 0.3; 95% CI 0.20 to 0.48) and of severe PTS (OR 0.39; 95% CI 0.20 to 0.76).[63] Notwithstanding these results, questions remain regarding the effectiveness, optimal duration, and feasibility of use of ECS to prevent PTS.

The above-noted trials had certain limitations, which could impact the validity of the results including modest sample size, recruitment at a single center, absence of placebo control, and lack of blinding of assessors. It is not clear if ECS actually prevent PTS or rather improve PTS symptoms, in which case it may be as effective and more convenient for patients to begin wearing ECS when symptoms develop. It is not known if lighter ECS (20 to 30 mm Hg) are as effective as 30 to 40 mm Hg ECS to prevent PTS, as the former are easier to apply and the two strengths appear to have similar effectiveness in preventing recurrent venous ulcer.[64] Finally, the use of ECS to prevent PTS after distal (calf vein) DVT has not been studied.

Interestingly, a recent trial reported that beyond an initial 6 months period of use, there was no incremental benefit in wearing ECS for an additional 18 months.[65] This finding was corroborated by a prospective management study of individually tailored duration of use of ECS.[14] Among 125 patients with proximal DVT who were advised to wear stockings for 6 months then subsequently asked to continue stockings only if PTS symptoms had developed, 17% were able to stop using stockings at 6 months, 50% were able to stop use at 1 year, and the rate of PTS at the end of 2 years was similar to that of the ECS (i.e., active treatment) arms of two previous randomized trials.[45,62] It is anticipated that an ongoing large multicenter, blinded trial that is comparing active versus placebo stockings to prevent PTS in 803 patients with proximal DVT will provide important additional information on the effectiveness of ECS.[43]

ECS are unlikely to cause harm but are difficult to apply, uncomfortable, expensive, and require replacement every few months. Based on the available published evidence and pending the results of ongoing trials in this area, a reasonable approach is to prescribe below knee, 30 to 40 mm Hg ECS to patients who have persistent leg pain or swelling after proximal or distal DVT, and if well tolerated, to continue their use for as long as the patient obtains clinical benefit.

Thrombolysis of Acute Deep Vein Thrombosis to Prevent the Postthrombotic Syndrome

Some studies support the tenet that early thrombolysis of acute DVT may reduce the occurrence of PTS, presumably by early reestablishment of venous patency and preservation of venous valve function.[66,67] A meta-analysis of 12 trials reported that thrombolysis appears to offer advantages in terms of reducing PTS.[68] However, studies of thrombolysis to date have enrolled small numbers of patients and have had various methodologic limitations including that in many cases, the primary study outcome was a surrogate measure of PTS such as vein patency or valvular reflux. Therefore, the long-term impact of thrombolysis on PTS and potential risks associated with these procedures are uncertain. The safety, effectiveness, and cost effectiveness of newer endovascular strategies such as catheter-directed thrombolysis, including pharmacomechanical catheter-directed thrombolysis (i.e., lysis in addition to thrombus fragmentation and/or aspiration), are currently being evaluated in well designed, randomized controlled trials in which PTS is the primary study outcome.[28,69,70]

TREATMENT OF ESTABLISHED POSTTHROMBOTIC SYNDROME

Elastic Compression Stockings

Compression therapy and frequent leg elevation are helpful to reduce leg swelling, heaviness, and aching in patients with established PTS.[59,71] ECS should be applied in the morning and removed in the evening or at bedtime. The main contraindication to use of ECS is symptomatic peripheral arterial disease (see Chapter 94), as the compressive effects of ECS may worsen claudication.[72] Practical limitations to using ECS include poor hand or arm strength or lack of finger dexterity to apply ECS. In these cases, assistance with ECS application can be provided by a family member of caregiver, or by using a stocking application aid (rubber gloves, fabric sleeve, plastic or metal frame).

Patients should be prescribed a knee length 30 to 40 mm Hg ECS. If this is too constricting or difficult to apply, a 20 to 30 mm Hg stocking can be tried. Some patients need greater compression strengths (e.g., 40 to 50 mm Hg) to reduce edema. Knee-length and thigh-length stockings appear to have similar physiologic benefits, but knee-length ones are easier to apply.[73]

Other Forms of Compression Therapy

In a small, randomized crossover trial, the use of an intermittent compression extremity pump twice daily for 2 months (20 minutes per session, 50 mm Hg pressure) reduced edema and improved symptoms in patients with severe PTS.[74] Recently, a randomized crossover trial in 32 patients with severe PTS evaluated a portable, battery-operated lower limb venous return assist device that is worn on the calf throughout the day. Use of the device alone or in combination with ECS for an 8-week period was associated with improvement in quality of life and reduced severity of PTS.[75]

Medications

There is limited evidence that "venoactive" or "phlebotonic" remedies such as aescin (derivative of horse chestnut seed) or rutosides may reduce symptoms of PTS. In a clinical trial of 120 patients, administration of oral hydroxyethylrutosides for 1 year improved PTS symptoms (defined by reduction in Villalta PTS score to <5, or decrease in score by at least 30% from baseline score) to a similar extent as ECS.[76] A Cochrane review of 17 trials that compared horse chestnut seed extract to placebo, compression stockings, or other medications in patients with chronic venous insufficiency reported that horse chestnut seed extract appears to be efficacious for short-term relief of symptoms such as leg pain and edema, and side effects were mild and infrequent, and included stomach complaints, dizziness, nausea, headache, and itching. However, the authors concluded that larger, methodologically rigorous trials are required to assess long-term effectiveness and safety of these medications.[77] Diuretics or nonsteroidal anti-inflammatory drugs for the treatment of PTS-related edema have not been studied and are not recommended.

Venous Ulcer Management

The goals of postthrombotic ulcer management are to reduce symptoms, promote healing, and prevent recurrence. Postthrombotic venous ulcers are primarily treated with leg elevation, compression bandages or stockings applied by a trained practitioner, and topical dressings. Multicomponent compression systems are more effective than single component ones.[78] No specific wound dressing has been shown to be superior.[79] Drugs such as oral zinc have not been shown to be effective for the treatment of venous leg ulcers.[80] The use of systemic antibiotics to promote ulcer healing is not supported by evidence, and the usefulness of topical antiseptics is unclear.[79] Surgery such as superficial and perforating vein ablation and deep vein reconstruction, and subfascial endoscopic perforating vein surgery combined with superficial vein ligation, may be of benefit in select patients when ulcers do not respond to conservative treatment,[81] but their benefit to harm profile in patients with postthrombotic ulcers has not been specifically evaluated. Recent reviews have addressed venous ulcers in more detail.[81,82]

Noninvasive Endovascular Procedures or Surgical Treatment of PTS

A few case reports or small case series published by vascular interventional radiologists or venous vascular surgeons at highly specialized referral centers suggest that procedures designed to correct obstruction or reflux such as vein dilation and stent placement, venous bypass grafting, endophlebectomy with reconstruction, valve reconstruction, and interruption of perforating veins may be of benefit to selected patients with moderate or severe PTS.[28,83] To date, however, there have been no methodologically rigorous comparative trials that have addressed the effectiveness of such procedures at improving the clinical manifestations of PTS, or their safety profile.

Prevention and management of PTS are summarized in Table 85.3.

UPPER EXTREMITY POSTTHROMBOTIC SYNDROME

PTS of the arm occurs in 15% to 25% of patients after upper extremity DVT (see Chapter 84).[84,85] Upper extremity PTS is a potentially disabling condition that has an adverse impact on quality of life, especially if the dominant arm is involved.[86] Symptoms of PTS in the arm include swelling, heaviness, and fatigue with exertion.[85,86] Dilation of the superficial veins of the upper arm and chest wall and dependent cyanosis of the arm may be noted on clinical exam. To date, there have been no controlled studies of the effectiveness of elastic bandages, compression sleeves (as are used for lymphedema), or venoactive drugs to prevent or treat PTS after upper extremity DVT. However, anecdotal evidence suggests that patients with persistent arm swelling and pain after upper extremity DVT may have relief of their symptoms with the use of elastic bandages or compression sleeves.[59]

Table 85.3

Strategies for prevention and management of PTS

Prevention
• Prevent initial DVT by administering thromboprophylaxis in high-risk patients as recommended in evidence-based consensus guidelines
• Prevent recurrent ipsilateral DVT by providing anticoagulation of appropriate intensity and duration for the initial DVT and by using appropriate thromboprophylaxis if long-term anticoagulation is discontinued
• Use knee-length, 30–40 mm Hg elastic compression stockings for up to 2 years after DVT; optimal duration of stocking use is uncertain
• The role of thrombolysis for the prevention of PTS is not yet established. Catheter-directed thrombolytic techniques require further evaluation in properly designed trials before being endorsed as effective and safe in reducing the risk of PTS.
Management
• Elastic compression stockings reduce edema and improve PTS symptoms
• Intermittent pneumatic compression units and the VenoWave device are effective for severe symptomatic PTS
• Venoactive agents such as aescin (horse chestnut extract) or rutosides may offer short-term improvement of PTS symptoms; large, controlled trials addressing long-term effectiveness and safety are needed.
• Leg elevation and compression therapy are primarily used to treat venous ulcers
• Providing support and ongoing follow-up to patients with PTS is a key component of management

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Definition

Chronic thromboembolic pulmonary hypertension (CTPH) is considered a consequence of previous PE and is characterized by an increase in the mean pulmonary artery pressure (≥25 mm Hg) associated with persistence of thrombi and vascular remodeling in the pulmonary circulation.

Epidemiology

In the early 1990s this condition was deemed rare accounting for only 0.1% of patients who survived an episode of PE.[87] Subsequent data showed that this condition is not so rare, with an incidence varying from 0.4% to 8%.[88,89,90–92,93,94,95,96–97] Variability in the incidence of CTPH may depend on patient characteristics, method of incidence calculation, severity of disease, and the referral institution.

Natural History of CTPH

After an episode of acute PE the fate of emboli may be that of an early complete resolution in most cases[98] or a complete reperfusion at lung scanning already within 1 month.[99] However, in the THESEE study,[100] residual obstruction was demonstrated 3 months after acute PE in 19% of patients and in a study by Sanchez et al.,[101] 29% of patients with PE had significant perfusion defects after a median follow-up of 12 months. It was at this point widely recognized that an incomplete reperfusion due to the persistence of thromboembolic material in pulmonary circulation might predispose to CTPH.[102] For this reason, after a course of oral anticoagulant treatment the follow-up of patients with PE is important and the evaluation should ascertain the presence of residual or new (recurrent) thrombi, the indirect measurement of pulmonary artery pressure, and complete screening for the presence of thrombophilia in selected cases. Because many cases of CTPH have no antecedent history of PE,[89] it is possible that previous PE was not diagnosed or silent (FIGURE 85.2A). Thus, it may happen that a patient first diagnosed with PE is actually affected by a recurrent PE or even by CTPH, especially when the pulmonary artery pressure is high already at the first diagnosis.[95] A pulmonary artery pressure of 50 mm Hg at the time of acute PE is associated with a threefold higher risk of persistent pulmonary hypertension after 1 year. Cases of previous PE may not have been diagnosed, if it occurred in a patient with good respiratory reserve, or in one who did not receive antithrombotic therapy. This might explain why CTPH is relatively frequent at young age as seen in a prospective study, where the mean age at the time of acute PE was 48.6 years among those who later developed CTPH versus 62.0 among those who did not.[93]

Another possibility is that after an episode of acute PE, the PE recurrence was silent or unrecognized (FIGURE 85.2B). Recurrence may be easily missed if patients are not followed up or if the recurrence is mild, for example, in patients on suboptimal oral anticoagulation. The diagnosis of recurrence might be challenging. In general, the same method used for the first diagnosis should be used again. For example, perfusion defect(s) in previously perfused areas or any perfusion defects in case a perfusion lung scintigram became negative after the acute event, make the diagnosis of recurrence very likely.[103] How the persistence of thrombi in the pulmonary circulation translates into CTPH remains to be explained. Residual thrombi undergo organization in proximal pulmonary arteries and the vascular bed subsequently undergoes peripheral vasculopathy indistinguishable from that seen in idiopathic pulmonary arterial hypertension.

Risk Factors

In an inception cohort study of patients who underwent a standardized diagnostic workup for PE, 223 patients with a first episode of PE and 82 patients with PE and previous VTE, 18 patients were diagnosed with CTPH (cases) and 287 were not (controls).[93] At multivariate analysis younger age (per decade), a previous PE, a larger perfusion defect (per decile decrement in perfusion), and idiopathic presentation were significantly associated with an increased risk of CTPH. Confirmation that a large perfusion defect is a risk factor for CTPH comes from a study by Liu et al.,[97] in which only patients with massive PE (vascular obstruction >50%) treated with thrombolytic agents were included. In contrast with data from Pengo et al.,[93] Ribeiro et al.[95] reported a higher risk of CTPH in patients older than 70 years of age at presentation. Other medical conditions increasing the risk of CTPH are splenectomy,[104,105] ventriculoatrial shunt for hydrocephalus, and chronic inflammatory disorders (such as osteomyelitis and inflammatory bowel disease).[104] A European database study confirmed previous risk factors and identified thyroid replacement therapy and a history of malignancy as additional medical conditions associated with CTPH.[106] As far as thrombotic risk factors are concerned, the rate of hereditary thrombophilia is low but elevated levels of factor VIII (>230 IU/dL) have been reported in 41% of CTPH patients compared to 22% in pulmonary arterial hypertension of other causes and 5% in

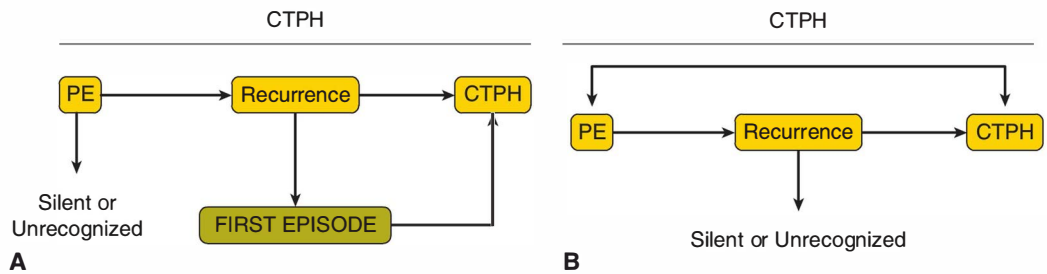

FIGURE 85.2 Possible natural history of CTPH. **A:** The first diagnosed episode of PE is a PE recurrence that predisposes to CTPH. **B:** Recurrence of PE, an important risk factor for CTPH, may be missed or silent.

controls,[107] and a high frequency of phospholipid-dependent antibodies (20%), a clear risk factor for venous thromboembolism, was consistently observed in various studies.[106,108,109]

Pathogenesis

It is not clear why in some patients thrombi persist in pulmonary vasculature, and lead to vessel restriction with increased vascular resistance and pulmonary hypertension. One possibility might be that endogenous fibrinolysis is impaired; the other might be that fibrin is resistant to fibrinolysis. In 1994, Lang et al.[110] reported that there is no endothelial cell-mediated fibrinolytic imbalance in pulmonary arteries of patients with CTPH. It was then noted that fibrin derived from patients with CTPH is resistant to "*in vitro*" lysis[111] and in some patients this may be related to the presence of a dysfibrinogen.[112] However, fibrin from patients with pulmonary hypertension other than CTPH was similarly resistant to *in vitro* lysis.[113] Another proposed mechanism is staphylococcal infection of the thrombus that delays its resolution. In fact, staphylococcal DNA was found in six out of seven thrombi obtained during endarterectomy in patients with CTPH.[114] Furthermore, genetic factors were considered to be involved in the etiology in a Japanese study.[115] The persistence of thrombi in the pulmonary arteries determines a progressive pulmonary hypertension. In 1973 on the basis of unchanged lung perfusion scintigram and increasing pulmonary hypertension over time in a patient with CTPH, Moser and Braunwald[116] proposed that the "open" pulmonary arteries had advanced changes associated with pulmonary hypertension and that the "closed" vascular bed, which had never been subjected to high pressures, had retained a normal structure. The small vessel arteriopathy is characterized by medial hypertrophy and intimal proliferation, microvascular thrombosis, and plexiform lesions resembling the alterations found in primary pulmonary hypertension. Thrombosis and vasoconstriction mediated by neurohumoral factors such as endothelin-1 promote further reduction of cross-sectional area and remodeling of vascular bed. As in nonthromboembolic pulmonary hypertension, endothelin-1 levels in CTPH closely correlated with the hemodynamic and clinical severity of disease.[117]

Clinical Presentation and Preliminary Evaluation

Signs and symptoms of CTPH are related to the stage of the disease and can be absent, mild, or severe according to the hemodynamic impairment of right ventricle secondary to the degree of pulmonary vascular resistance (PVR). Classical symptoms of effort dyspnea and fatigue correlate with the limited capacity to increase cardiac output and with the defective blood oxygenation as a consequence of increased pulmonary dead space. Less frequently, patients complain of episodes of palpitations, lightheadedness or presyncope, chest pain, or they report an episode of hemoptysis. Interpretation of symptoms may soon translate to clinical suspicion of CTPH in a patient with previous PE. However, because many patients do not provide a history of PE, CTPH diagnosis is delayed as symptoms are attributed to other diseases.[118,119] On physical examination, jugular vein distension is an important finding as it may be the marker of right heart pressure. At auscultation, an accentuation of pulmonary closure sound, a reduced splitting of the second heart sound as well as a systolic murmur related to tricuspid incompetence

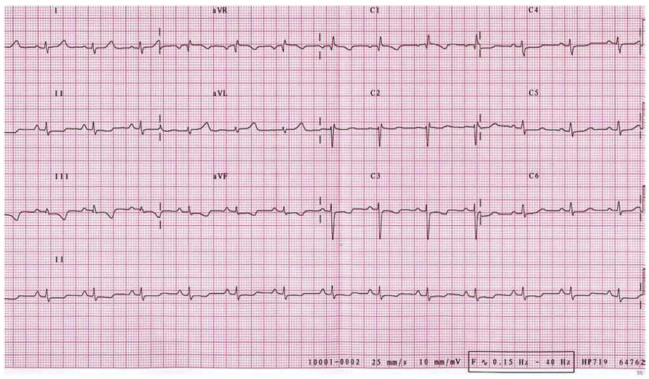

FIGURE 85.3 EKG of a patient with moderate CTPH. Negative T wave in II, III, aVF. ST depression in C3-C4-C5.

can be found. Occasionally, pulmonary auscultation reveals a systolic bruit, which is generated by the turbulence of blood flow through a restricted pulmonary artery.[120]

Electrocardiogram in the advanced stage of the disease typically shows negative T waves in precordial V1–V5 leads, and in II, III, aVF (FIGURE 85.3), pulmonary P wave and right axis deviation >90 degrees. Chest x-ray may show dilatation of main pulmonary arteries[121] and increased cardiothoracic ratio with left second and right second arc protrusions, that result from left main pulmonary artery and right atrium enlargements, respectively (FIGURE 85.4). Avascular areas and pleural thickening may be evident in the lungs. In one study comparing

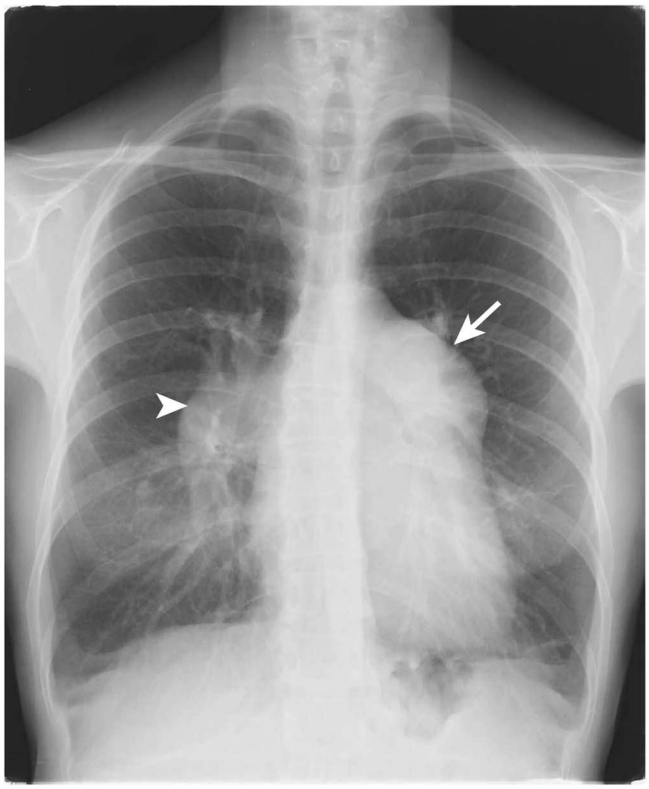

FIGURE 85.4 Chest x-ray of a patient with severe CTPH. A left second arc protrusion (*arrow*) and increased right descending pulmonary artery diameter (*arrow head*) are clearly evident.

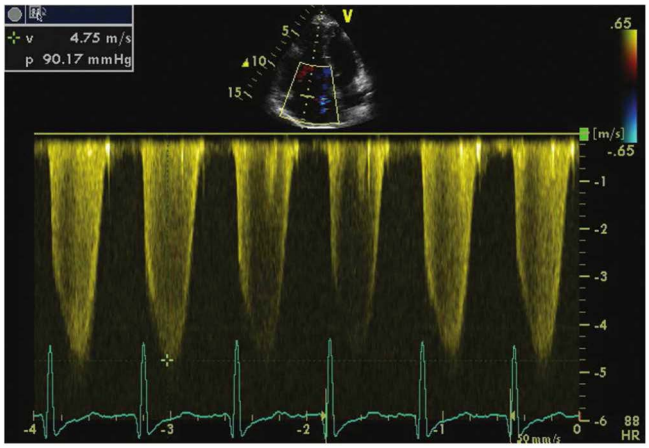

FIGURE 85.5 A patient with CTPH and severe tricuspid regurgitant jet (4.7 m/s) indicative of high systolic pulmonary artery pressure.

chest radiographs of patients with severe CTPH with those of patients with primary pulmonary hypertension,[122] the diagnostic pattern of CTPH was the presence of one of two findings, an avascular area or marked increase of the right descending pulmonary artery diameter (>20 mm) together with pleuritic change. Blood oxygen saturation may be normal at rest but impaired during exercise when taken during the 6-minute walking test. Although not specific due to the inability to distinguish between pre- and postcapillary pulmonary hypertension, echocardiography is an essential tool in the diagnostic path of CTPH. Dilatation of right ventricular (RV) is present when the diastolic diameter exceeds 30 mm. RV dysfunction, paradoxical septal motion, and a D-shaped left ventricle can be appreciated visually. Quantitative report of RV dysfunction is based on a tricuspid annular plane systolic excursion of <18 mm. A tricuspid regurgitant jet is indicative of pulmonary hypertension when its velocity exceeds 2.8 m/s[123] (FIGURE 85.5).

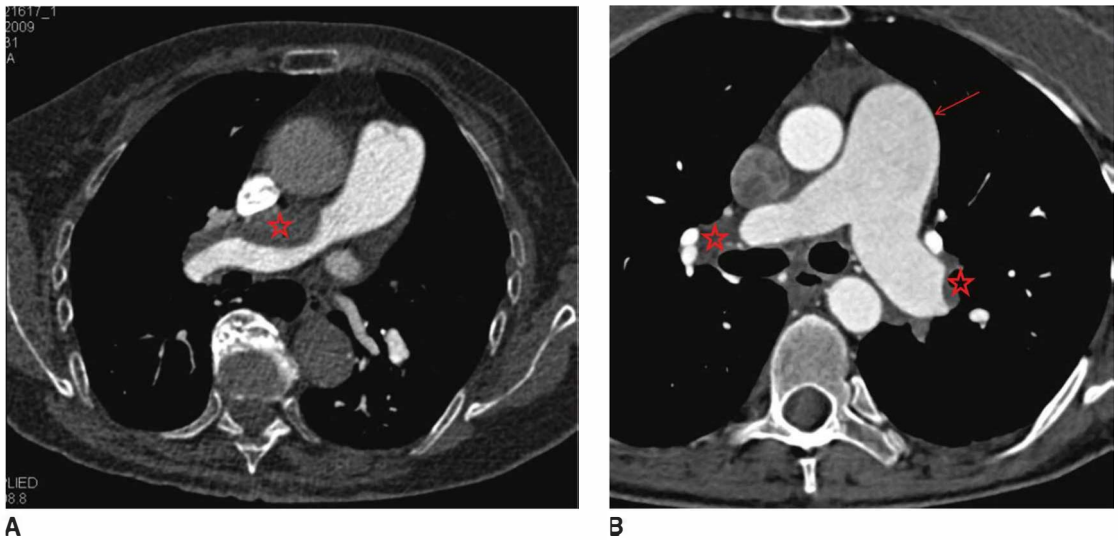
Diagnosis

After preliminary evaluation and the detection of pulmonary hypertension by echocardiography the next step is to document the thrombotic obstruction in pulmonary arteries by means of ventilation/perfusion (V/Q) lung scanning or by computed tomography (CT). If V/Q lung scanning is negative, CTPH is highly unlikely[124] but in case of high clinical suspicion a CT should also be performed. The current generation of high resolution CT scanners better defines sites of vascular obstruction distinguishing thrombi lining pulmonary vessels in either a concentric or eccentric manner (FIGURE 85.6), and also provides information on areas of mosaic pulmonary parenchyma that are often present in CTPH. If thrombotic obstructions are demonstrated, then prior to possible surgical intervention, multiplanar pulmonary angiography must be performed.

Vessel pockets, ligaments, increments, sudden changes of the vessel size, and vessel occlusion are typical angiographic findings.[125] Abrupt changes of pulmonary vessel size, with bands, webs, pouches, and dilated central vessels with irregular tapering of the peripheral vasculature, and segmental complete vessel obstruction, are characteristics of CTPH (Table 85.4).

Therapy

After CTPH is diagnosed, all the patients must receive vitamin K antagonists to maintain an INR between 2.0 and 3.0. CTPH is the only form of pulmonary hypertension amenable with surgical intervention. This procedure is not a simple embolectomy with removal of thrombi from the lumen of pulmonary vessels but implies a true endarterectomy to remove thrombi inside the vessel wall. The decision to proceed with pulmonary endarterectomy (PEA) must take into account the cardiovascular performance, site of thromboembolic obstruction, PVR, and willingness of the patient to be operated. The San Diego surgical classification[126] is based on operative findings of pulmonary artery obstruction, where patients with type 3 (disease within



A B

FIGURE 85.6 CT scan of two patients with severe CTPH. In **(A)** the main right pulmonary artery contains a large protruding thrombus remodeling the vessel wall (*star*). In **(B)** the pulmonary artery truncus is extremely dilated (*arrow*) and thrombi completely occlude right and left pulmonary arteries (*stars*).

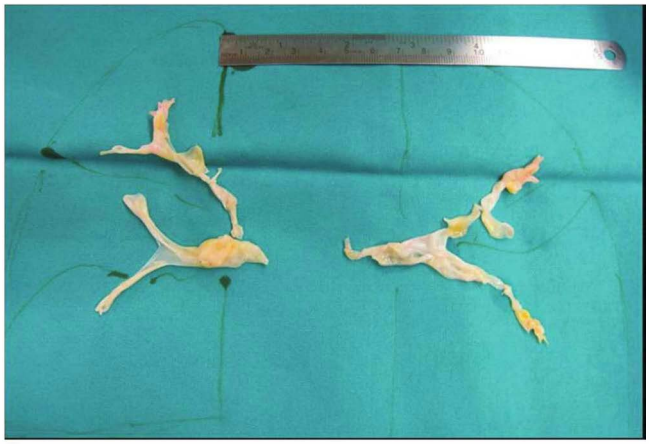
Table 85.4
Differences between idiopathic and CTPH

	Idiopathic PH	CTPH
Previous thromboembolism	Unusual	Possible
Ventilation-perfusion lung scan	Normal or subsegmental defects	Segmental perfusion defects
Contrast CT	No obstruction	Obstructions, bands, and webs
Pulmonary angiography	No vessel occlusion	Vessel occlusion, vessel pockets, ligaments, increments, sudden changes of the vessel size
Thrombophilia	Unusual	Possible

distal segmental arteries only) or type 4 disease (distal pulmonary vasculopathy) had higher postoperative pulmonary artery systolic pressure and greater postoperative PVR compared with that seen in patients with type 1 (fresh thrombus in the main-lobar pulmonary arteries) or type 2 disease (proximal pulmonary vasculopathy). Currently there is no preoperative classification system that might allow for better risk stratification.[127] Patients considered for PEA are usually those with hemodynamic imbalance and symptoms at rest or with minimal exercise (New York Heart Association [NYHA] class III and IV). If not surgically treated, prognosis in such patients is poor.[128,129] On the other hand, clinical course of patients in NYHA class II is not fully known and some of them are stable for years[93]; surgery in these patients is considered very low risk and decision to operate is largely based on patient willingness. Distal disease (segmental and subsegmental pulmonary vessels) with very high PVR implies a small benefit of PEA, while proximal large vessel disease with reasonable PVR is amenable for surgical approach. Associated diseases may increase the risk of PEA although the only absolute contraindication is the presence of severe underlying lung disease, either obstructive or restrictive. Current best practice results in operative mortality rates of 4% to 7% and the best outcomes are associated with (a) surgeon and center experience; (b) concordance between PVR and anatomic disease; (c) preoperative PVR <1,000 to 1,200 dynes/s/cm^{-5}; (d) absence of select comorbidities (e.g., splenectomy, ventriculoatrial shunts); and (e) postoperative PVR <500 dynes/cm/s^{-5}.[125]

Benefits of surgery may take ≥6 months to achieve. Postoperative patient care is crucial and includes optimized ventilation and fluid management, prone positioning, inhaled nitric oxide, prostanoid agents, and pharmacologic therapy for right heart function.[130] If this support fails in case of severe postoperative reperfusion edema, venovenous extracorporeal life support is a good therapeutic option.[131] In cases where it is only possible to perform a thromboendarterectomy in proximal vessels (FIGURE 85.7A) and the improvement of hemodynamic parameters after 12 months is poor (FIGURE 85.7B), pulmonary vessel angioplasty (FIGURE 85.7C) may be an option. Lung transplantation might be the final effective treatment in selected patients.[132]

Medical treatment may be used in CTPH patients who are not considered candidates for surgery or with persistent/recurrent pulmonary hypertension after PEA,[133] the goal being reduction of pulmonary hypertension, increased cardiac output, and alleviation of symptoms. Drugs used in this setting are endothelin-1 inhibitors, phosphodiesterase type-5 inhibitors, and prostanoids. The only randomized, placebo-controlled clinical trial that has addressed the safety and efficacy of medical treatment was the BENEFIT study.[134] Primary end points were change in PVR as a percentage of the baseline value and change from baseline in 6-minute walk distance after 16 weeks of treatment with bosentan or placebo. This study revealed a significant drop in PVR in



A

	Before-PEA	After-PEA(1 Year Later)
C.I. (L/min/mq)	2,08	2,88
PVR (UW/mq)	15,8	12
PAPm (mm Hg)	38	35
6MWT	200	400
NYHA Class	III-IV	II

B

the bosentan group but no change in the 6-minute walk test, functional class, or time to clinical worsening. In a recent meta-analysis it was shown that bosentan therapy is associated with an improvement of hemodynamics and probably exercise capacity[135] in patients with CTPH. Some authors have recently suggested a role for the medical therapy of patients awaiting PEA.[136]

CHAPTER

86 Prevention of Venous Thromboembolic Disease

MENNO V. HUISMAN, SHARIF PASHA, PATRICK MISMETTI, AND AJAY KAKKAR

Venous thromboembolic disease frequently complicates the course of patients undergoing a variety of surgical interventions. Indeed, it was in the determination of the frequency of thrombosis in general surgical patients using I^{125} labeled fibrinogen leg scanning that Kakkar et al. in 1969[1] were able to describe the natural history of postoperative deep vein thrombosis (DVT). The understanding of the natural history of this disease, and, subsequently, risk factors associated with its occurrence in surgical patients and its wider epidemiology have allowed the development of strategies to both identify patient populations at risk for the development of venous thromboembolism (VTE) in the perioperative period, quantify that risk, and thus provide methods for prophylaxis against VTE.

Beyond recognising that thrombosis commonly occurs in surgical populations, the establishment of evidence that demonstrates the adverse consequences if thromboembolic disease is not prevented has been important. Not only would patients suffer symptomatic DVT or pulmonary embolism (PE), but they may also experience, as a first manifestation of their thrombosis, a fatal PE.[2] Approximately 80% of patients who develop PE will have no evidence of peripheral venous thrombosis before their presentation with PE.[3] Because PE is frequently fatal, even if diagnosed and treated in hospital,[4] strategies based on a policy of treating massive PE or DVT as a way of preventing death from fatal PE expose surgical patients to an unacceptable risk of fatal thromboembolic complications. Beyond the consequences of the acute thrombotic episode are the long-term implications. In the intermediate term there is the need for prolonged anticoagulant therapy for a thrombotic episode. This treatment is associated with serious, if not fatal, bleeding complications.[5] Furthermore, patients with cancer or impaired inhibition of coagulation are at greater risk for the development of recurrent thromboembolism, which in some cases may be fatal.[6] Beyond this intermediate risk, patients who have suffered either symptomatic or asymptomatic DVT or PE are at greater risk for the development of the postphlebitic syndrome, the symptoms of which include leg swelling, varicose veins, venous ulceration, and other trophic skin changes, which are disabling and have impact on the patients quality of life.[7]

RISK OF VENOUS THROMBOEMBOLIC DISEASE IN GENERAL SURGICAL PROCEDURES

More than three decades of research have identified risk factors frequently associated with the development of postoperative VTE in general surgical patients. Most important amongst these are advancing age, a history of VTE, long periods of immobility, the presence of malignancy, obesity, the use of estrogen-containing oral contraception or hormone replacement therapy (HRT), and the type of surgical intervention.[8,9] The way that these risk factors interact in an individual patient to create a specific risk for the development of thrombosis is unpredictable. Therefore, although it would be possible to assign an individual surgical patient a score with regard to their risk for the development of thromboembolic episodes in the perioperative period, the use of such models has yet to be fully validated. A second approach on which decisions about thromboprophylaxis can be made is to define specific surgical risk groups in whom decisions about the use of thromboprophylaxis can be made[10] (see Table 86.1).

CLINICAL TRIALS IN VENOUS THROMBOEMBOLISM—CONSIDERATIONS ABOUT EFFICACY AND SAFETY

The adoption of any specific measure for the prevention of VTE in surgical patients must be based upon evidence for both the efficacy of a particular intervention with regard to preventing thrombosis in patients at differing risks, and the safety of the intervention, in particular for pharmacologic prophylaxis, this being the rate of the bleeding complications associated with anticoagulant therapy.

In terms of assessing the efficacy of any given method of thromboprophylaxis, a number of different efficacy endpoints have been identified. Clearly, the most important endpoint is that of the prevention of fatal PE.[11] Although this complication is rare, and trials designed with this endpoint are the most challenging, landmark studies in the field of thrombosis research have used autopsy-proven fatal PE as a primary clinical trial endpoint.[11] Demonstration that an individual method of prophylaxis is able to reduce the frequency of PE provides strong confirmation of its utility and relevance in routine clinical practice for the given patient population.

Beyond the endpoint of fatal PE, symptomatic VTE, whether it is nonfatal PE or DVT, represents an important clinical complication that occurs more frequently than that of fatal PE. The use of those clinical endpoints, objectively confirmed using appropriate diagnostic tests, is crucial in trials assessing the efficacy of various thromboprophylactic strategies.[12–14]

Most cases of thromboembolic disease are, however, asymptomatic. Therefore clinical trials comparing different methods of thromboprophylaxis that use asymptomatic DVT as an endpoint require fewer patients. Studies using either fibrinogen leg scanning or more recently venography for the detection of asymptomatic DVT have provided the foundations of our understanding of the efficacy of various methods for preventing

Table 86.1

Risk stratification for postoperative VTE and frequency of VTE without prophylaxis

	Venographic DVT		Pulmonary Embolism	
	Calf (%)	Proximal (%)	Symptomatic (%)	Fatal (%)
Low risk: <40 y and uncomplicated surgery and no additional risk factors	2	0.4	0.2	<0.01
Moderate risk: >40 y or prolonged or complicated surgery or additional "minor" risk factors	20	5	2	0.5
High risk: major surgery for malignancy or previous VTE or knee/hip surgery or heparin-included thrombocytopenia	50	15	5	2

DVT, deep-vein thrombosis; VTE, venous thromboembolism.

DVT in surgical patients. These studies form the basis of many of the guidelines on the use of antithrombotic therapy in the perioperative period.[10,15–17] It is essential, however, when using surrogate efficacy endpoints such as venographically proven DVT, that the consistency of the natural history of the thrombotic episode between the asymptomatic DVT and the potential fatal PE has been defined for the population in question. It is also essential that the study design and the antithrombotic intervention does not change that natural history, thereby potentially providing an erroneous result with the use of this surrogate endpoint.

The balance between the efficacy in preventing a thromboembolic episode versus perioperative bleeding complications must be addressed in the use of any antithrombotic agent. This balance must be considered in the specific clinical setting in which the patients find themselves The potential risk for development of thrombosis or bleeding is dependent upon the individual clinical scenario (type and site of operation, patient comorbidities, and concomitant medication).

Studies over the past three decades have established that pharmacologic prophylaxis is not only effective in preventing thrombosis but is associated with an increase in perioperative bleeding complications.[18] Thus the balance between efficacy and safety for any recommended pharmacologic thromboprophylaxis should demonstrate a desirable benefit/risk ratio and have the additional benefit of proven cost efficacy, which provides an economic rationale for routine protection against thromboembolic disease in moderate- and high-risk surgical populations.

METHODS OF PROPHYLAXIS

Mechanical Methods of Prophylaxis

Mechanical methods of prophylaxis are designed either to eliminate stasis or to interrupt thrombus progression from the deep venous system to the pulmonary circulation.

None of the currently available mechanical methods of thromboprophylaxis have been as extensively investigated as the pharmacologic methods.[10] Of those available methods, one of the most popular is graduated compression stockings. These stockings apply a decreasing pressure from ankle to thigh across the lower limb, reducing the venous cross-sectional area and thus enhancing venous flow, and reducing stasis. Other mechanical methods increase pulsatile flow such as pneumatic calf compression, electrical calf stimulation, and venous foot pumps. All of these methods enhance venous flow and can be used intraoperatively and in the postoperative period, although after surgery they are cumbersome to use to maximum effect. Another approach to the prevention of PE is with either venous ligation[19] or inferior vena cava (IVC) filters, which interrupt the transition of thrombus from venous system to pulmonary circulation. No randomized trials have been done to evaluate IVC filters for primary prophylaxis in surgical patients. They have been evaluated in patients with an established DVT for the prevention of recurrent PE, where they have been shown to be effective in reducing the frequency of PE initially, but in the longer term having been associated with an excess of VTE.[20]

Pharmacologic Methods of Prophylaxis

A more popular approach to the prevention of VTE in the perioperative period has been the use of pharmacologic methods.

Aspirin

Aspirin and other antiplatelet drugs have become the mainstay of antithrombotic therapy for patients with atherosclerosis. Aspirin is highly effective in the prevention of arterial thrombotic episodes in patients with established vascular disease. The mechanism of action is through the inhibition of prostaglandin H synthetase 1 and thus a resultant loss of platelet cyclooxygenase activity.[21]

Interestingly, although aspirin is effective in the prevention of arterial thromboembolic events, its role in the prevention of venous thrombosis remains controversial. Despite the fact that aspirin is delivered orally, studies that evaluated its use in the prevention of VTE have often been of limited size and attended by important methodologic flaws that make their interpretation very difficult.[22,23] When compared with studies using other methods of thromboprophylaxis, the studies with aspirin do not justify its routine use, as a sole agent, for VTE prevention in medium- or high-risk surgical patients. Aspirin alone is therefore not recommended as thromboprophylaxis in any patients at risk of VTE.[10]

Dextrans

The polysaccharide dextrans have been evaluated as potential thromboprophylactic agents.[24] Their mode of action appears to be that of hemodilution, combined with an inhibitory effect on fibrin polymerization and an enhancement of fibrinolysis with some antiplatelet effect. They must be given intravenously and run the risk of severe anaphylactic reaction and volume overload. They are therefore not routinely used for thromboprophylaxis in most centers.

Unfractionated Heparin

Low-dose unfractionated heparin (LDUH) has remained the mainstay of thromboprophylaxis in general surgical patients.[9,25] Indeed, it is in the evaluation of this agent that so much of our understanding of the natural history of VTE in surgical patients has been generated. Unfractionated heparin (UFH) binds and potentiates the activity of circulating antithrombin with the resultant inhibition of activated clotting factors X and II (thrombin). The agent can be given in a fixed dose of 5,000 anti-Xa units subcutaneously twice daily, commenced preoperatively, and continued in the postoperative period without need for monitoring of anticoagulant activity.

Low- and Ultralow-Molecular-Weight Heparins

Low-molecular-weight heparins (LMWHs) are derived from UFH through depolymerization.[26] A variety of different LMWHs are available for clinical practice, each of which has a different molecular weight and a different ratio of anti-Xa to anti-IIa inhibitory activity. The mechanism of action of LMWHs is the same as that of UFH, that is, the potentiation of antithrombin activity and the ability to release tissue factor (TF) pathway inhibitor and therefore inhibiting TF:VIIa activity. LMWHs achieve a lesser degree of inhibition of thrombin activity compared with UFH but a greater inhibition factor Xa activity. Advantages of the LMWHs include a longer plasma half life, the ability to dose once or twice daily subcutaneously without the need for dose monitoring, a limited effect on platelet activation, and a reduced incidence of heparin-induced thrombocytopenia[27] and osteoporosis.

A new generation of LMWHs and ultra-LMWHs is currently being investigated for the prevention of VTE.[28] Among these are bemiparin[29,30] and semuloparin,[28,31] both of which are being evaluated in major general and orthopedic surgery. These drugs have higher anti–factor Xa and only minimal anti–factor IIa activities compared with first-generation LMWHs, and may in the future offer an alternative to currently approved drugs.

Indirect Factor Xa Inhibitors

The pentasaccharide fondaparinux—the first in a new class of indirect-acting selective inhibitors of activated factor X—became available in the early 2000s. Fondaparinux has a short 5-saccharide sequence, and can bind antithrombin and potentiate its inhibition of activated factor X. The molecular length is not sufficiently long to bind and inhibit thrombin. This drug has been evaluated primarily in the prevention of thromboembolic disease in orthopedic patients undergoing high-risk hip or knee replacement procedures[32,33,34,35] and in the treatment of DVT and PE.[36]

A single study has been undertaken to evaluate its use in the prevention of thromboembolic disease in general surgical patients.[37] This study compared fondaparinux at a dose of 2.5 mg once daily with the LMWH dalteparin at a dose of 5,000 I U once daily. There were no significant differences in efficacy or safety between fondaparinux and the LMWH.

Direct Thrombin Inhibitors

Another interesting class of antithrombotic agents is the direct thrombin inhibitors. These agents, either naturally occurring or synthetic, are able to bind directly to and inhibit thrombin. They include hirudin, bivalirudin, desirudin, argatroban, melagatran–ximelagatran, and dabigatran etexilate. Most of these agents require parental administration, apart from ximelagatran and dabigatran etexilate, which are prodrugs and orally bioavailable. Development of ximelagatran ceased in 2006 following reports of hepatotoxicity.

These direct thrombin inhibitors are primarily being evaluated in either prophylaxis against thromboembolic disease in high-risk orthopedic patients undergoing joint arthroplasty,[38–40] or as a rescue antithrombotic strategy in patients with heparin-induced thrombocytopenia.[41] Desirudin has been approved in the United States for VTE prophylaxis in patients undergoing elective hip replacement surgery.[42]

New Oral Antithrombotic Agents

The limitations of UFH, LMWH as well as of vitamin K antagonists (VKAs) have led to the development of new oral antithrombotic drugs, of which specific and direct inhibitors of either thrombin or FXa are the most advanced evaluated. In contrast to LWMH and UFH, direct thrombin inhibitors inactivate both fibrin-bound thrombin and free thrombin, while direct FXa inhibitors inhibit FXa within the prothrombinase complex. In addition, both classes of new drugs have a rapid onset and offset of action, a low propensity for food and drug interactions and produce very predictable anticoagulant responses after fixed-dose administration so that routine coagulation monitoring is unnecessary.

The direct thrombin inhibitor dabigatran has been approved in many countries and is administered as the prodrug dabigatran etexilate. It has a longer half-life than the anti-Xa inhibitors (14 to 17 hours) and is eliminated to 80% via renal excretion. Two FXa inhibitors, rivaroxaban and apixaban, have been approved. They are given as active drugs and have multiple elimination pathways. All three drugs reach maximum plasma concentration after 2 to 4 hours. They are reviewed in detail in Chapter 110.

INTERPRETING DATA FROM CLINICAL TRIALS THAT HAVE ASSESSED ANTITHROMBOTIC AGENTS FOR THROMBOPROPHYLAXIS IN SURGICAL PATIENTS

Thromboprophylaxis in surgical patients presents a major challenge. Surgical trauma makes patients prone to perioperative bleeding complications. The delicate balance between efficacy (in terms of preventing VTE) and safety (in terms of not inducing excessive bleeding complications) of thromboprophylaxis has been discussed above.

Only a few antithrombotic agents have been assessed to the extent that there is a clear demonstration that their use is associated with a significant reduction in fatal PE, in well-designed randomized clinical trials.[11,43] However, in meta-analyses of methodologically sound clinical trials, where PE has been

included as one of the endpoints in the study, a number of agents have been shown to possess antithrombotic efficacy. With the use of symptomatic VTE as an endpoint, fewer patients, other than those with fatal PE, are required to demonstrate efficacy. Asymptomatic endpoints are only relevant when they predict both symptomatic DVT and potentially fatal PE.[25,44,45]

Consistent assessment of bleeding in surgical patients is difficult. Bleeding in the perioperative period is determined not only by factors inherent to the patient, but to the nature and extent of operation, the experience of the surgeon, and any other concomitant drug therapy that the patient may be receiving. These factors interact in an unpredictable way with the administration of any particular antithrombotic therapy in the intra- and postoperative period. Since bleeding is an expected complication of operation, blood loss *per se*, both intraoperatively and in the early postoperative period, and consequent requirement for transfusion are difficult surrogate markers for assessment of bleeding risk for an antithrombotic agent in the perioperative setting. This situation is contrary to that seen, for instance, in patients who are receiving antithrombotic therapy for treatment of established thrombosis where bleeding would not be expected.[46] Differences between baseline risk and risk attributed to an antithrombotic agent are necessary to identify as their occurrence outside the controlled setting of a clinical trial may have important adverse consequences.

Few perioperative pharmacologic prophylaxis trials have used endpoints that assess the potential impact of excessive bleeding on surgical outcome.[47] However, such endpoints, which include need for reoperation secondary to bleeding, wound hematoma, and in particular, the need for surgical evacuation of wound hematomas, or consequences of bleeding, resulting in either anastomotic dehiscence, wound dehiscence, or arthroplasty joint sepsis, may represent more important endpoints, when considering the potential adverse consequences. However, when looking across the board at results of clinical trials that assessed antithrombotic agents in the perioperative period, it is clear that routine antithrombotic therapy with LDUH, LMWH, or fondaparinux is not associated with a significant adverse impact in terms of bleeding on surgical outcome in the general surgical population. With any drugs that are cleared by the kidneys, however, caution must be exercised in patients with reduced renal function, particularly in elderly patients, in those with diabetes mellitus, and in patients at high risk of bleeding.[10]

GENERAL SURGERY

Frequency of Thromboembolic Events

The rate of thrombosis reported in patients without prophylaxis undergoing general surgical procedures ranges from 15% to 30%, with rates of PE ranging between 0.2% and 5% and fatal PE < 0.012%[1,9,11,25,48] (see Table 86.1). These historic rates of thrombosis may overestimate the magnitude of the current problem in surgical practice. Earlier mobilization, shorter length hospital stay, improved anesthetic techniques, greater attention to a reduction in perioperative sepsis through antibiotic prophylaxis, and greater use of thromboprophylaxis itself, have had an important impact on reducing the frequency of postoperative DVT in general surgical patients. However, against this is the clear trend for surgical procedures to be undertaken in far sicker patients, who spend longer time severely immobilized in the intensive care unit, and that procedures are now undertaken in older patients and far greater numbers of patients with malignant disease. Thus, in an era where studies using control or placebo against novel antithrombotic agents in surgical practice are no longer ethically justified, it is not possible to know the current rate of thromboembolic disease in patients who do not receive any form of thromboprophylaxis, but it would be wrong to assume that VTE is no longer a serious complication in contemporary surgical patients.[49] Indeed, the Million Women Study highlighted the ongoing risk of VTE among women undergoing inpatient surgery in the United Kingdom over the period 1996 to 2001, with an estimated 1 in 140 middle-aged women being admitted with VTE over the 3 months after surgery.[50] A U.S. study, based on data from the Nationwide Inpatient Sample, also reported a doubling between 1998 and 2005 in the number of hospitalized patients with a clinically recognized episode of acute PE among hospitalized surgical and medical patients. At the same time, the rates of bleeding and heparin-induced thrombocytopenia related to anticoagulant prophylaxis remained stable or declined.[51]

Methods for prophylaxis against VTE in general surgical patients include general measures and specific interventions with antithrombotic strategies. General measures include careful history taking to assess thrombosis risk and in particular to identify important risk factors such as increasing age, obesity, the presence of malignancy, and a history of VTE[52,53] (see Table 86.2). Careful attention to the prevention of perioperative sepsis, maintenance of fluid balance, and early mobilization also play an important role in the reduction of thrombosis risk.

Table 86.2

Risk factors for venous thromboembolic disease

Factors	Severity
General Risk Factors	
Age	Moderate
Obesity	Mild
Ethnicity	Mild
Immobilization	Moderate
Previous VTE	Severe
Estrogen therapy	Mild
Inherited thrombophilia	Severe
Malignancy	Moderate
Heparin-induced thrombocytopenia	Severe
Surgical Factors	
Orthopedic surgery	Severe
Tourniquet application	Moderate
General anesthesia >30 min	Moderate
Venous catheterization	Moderate
Major trauma	Severe
Paralysis	Moderation

Cancer chemotherapy, antiphospholipid antibodies, and hyperhomocystinemia, all recognized risk factors for venous thromboembolism (VTE) in nonsurgical patients, are also likely to increase the risk of postoperative VTE.

Patients who are taking either oral contraceptives or HRT should have this therapy discontinued, ideally 1 month before surgery.

The most popular methods for the prevention of thromboembolic disease in moderate- or high-risk general surgical patients are LDUH, LMWH, and fondaparinux. Indeed the highest quality of evidence in terms of both efficacy and safety with regard to thromboprophylaxis in the perioperative period is available with these agents.

The International Multicentre Trial published in 1975 randomized 4,121 patients aged over 40 years undergoing major surgical intervention to a control group or to receive LDUH in a dose of 5,000 U started 1 to 2 hours before surgery and continued three times daily in the postoperative period until the patient was fully mobile.[11] The primary endpoint in this study was autopsy-proven fatal PE. Nearly 70% of patients in this study who died underwent autopsy. The trial demonstrated a significant reduction in the frequency of fatal PE (16 patients in the control group vs. two in the lose-dose heparin group; $P < 0.005$) and provided the first evidence that heparin-based thromboprophylaxis not only prevented DVT, but was able to reduce the frequency of fatal PE and to have a significant impact on improving surgical outcome. The International Multicentre Trial hailed the modern era of thromboprophylaxis and has formed the basis of recommendations for thromboprophylaxis adopted throughout the world. The only safety concern was an increase in wound hematoma rates, associated with low-dose prophylactic heparin therapy ($P < 0.01$), also seen in other studies.

Numerous studies have since been completed that have assessed the use of LDUH with endpoints including PE, symptomatic VTE, and asymptomatic DVT.[25] These studies all confirm that when compared with control groups, LDUH therapy is associated with a >60% reduction in the frequency of both DVT and symptomatic thromboembolic disease.[25]

The striking feature of LDUH prophylaxis is the associated reduction in perioperative mortality, with the frequency of PE-associated mortality falling from eight to one per 1,000 operated patients, thus profoundly impacting on surgical outcome. However, concerns about potential bleeding complications as manifest by wound hematoma formation drove the quest for the development of safer antithrombotic agents in surgical practice.[11,25]

As a result, LMWH has been investigated extensively[47,48,54–58] since the first report of its use for the thromboprophylaxis in man in general surgical patients by Kakkar et al. in 1982.[59] In this study, patients were randomized to receive one of two doses of a LMWH. The study confirmed that LMWH given in a fixed dose once daily was capable of providing thromboprophylatic efficacy and was safe.

A recent meta-analysis has reviewed studies that randomized over 44,000 general surgical patients to trials comparing LMWH against LDUH.[48] In this meta-analysis, both agents provided equal efficacy and safety. The advantage of LMWH was that it may in general be administered once daily versus twice or three times daily with LDUH to achieve antithrombotic efficacy in surgical patients. LMWHs have broadly replaced LDUH for thromboprophylaxis in general surgical patients.

A recent multinational randomized study—SAVE-ABDO—compared enoxaparin 40 mg/d started preoperatively with semuloparin, an ultra-LMWH, 20 mg/d started postoperatively for the prevention of VTE in 4,413 patients with risk factors for VTE who were undergoing major abdominal surgery.[31] While semuloparin failed to achieve noninferiority over enoxaparin for the prevention of VTE and all-cause mortality, the rates of major bleeding (odds ratio [OR] 0.63; 95% confidence interval [CI], 0.46 to 0.87) and the composite of clinically relevant nonmajor and major bleeding (OR 0.71; 95% CI, 0.54 to 0.93) were lower with semuloparin. This potential benefit in terms of safety is worthy of further investigation.

The selective inhibitor of factor Xa, fondaparinux, has been evaluated in patients undergoing high-risk abdominal surgery.[37] In a trial of some 3,000 general surgical patients, most of whom underwent operation for malignant disease, there was no significant difference in either efficacy with regard to thromboprophylaxis, major bleeding complications, or death in patients who received fondaparinux commenced postoperatively with LMWH (dalteparin) commenced preoperatively. In a study involving 1,309 patients undergoing major abdominal surgery, all of whom had intermittent pneumatic compression (IPC), postoperative fondaparinux reduced the VTE rate by 70% versus mechanical prophylaxis alone, at a low bleeding risk.[60]

Mechanical Methods of Prophylaxis in General Surgery

Mechanical methods of prophylaxis have been assessed in general surgical patients.[24] Although they have no risk of bleeding complications, few trials of methodologic quality have evaluated their efficacy. In particular, no trials have demonstrated that mechanical methods of thromboprophylaxis, alone, are able to reduce the frequency of fatal PE in general surgical patients.

The use of graduated compression stockings alone is not advocated, with the exception of patients at high risk for bleeding, although recent analyses suggested a 50% reduction in the rate of DVT with their use compared with control.[61,62] However, when used in combination with LDUH, they appear beneficial. Studies have demonstrated a 75% reduction in the rate of DVT identified for patients using LDUH and graduated compression stockings compared with those who received LDUH alone.[62] There is no evidence that this method of prophylaxis alone can reduce the frequency of PE. In addition, graduated compression stockings that are used inappropriately may cause a tourniquet effect on the lower limb, resulting in a potential enhancement of the risk of thromboembolic disease.[63]

Intermittent pneumatic calf compression has been assessed for the prevention of DVT in general surgical patients.[64,65] It is not possible, however, on the basis of these small studies to make recommendations about its routine use. The results suggest either a similar efficacy to LDUH or no definite thromboprophylactic effect for the use of IPC alone. In a randomized trial of 2,551 cardiac surgical patients, the combination of pneumatic calf compression with LDUH reduced the rate of symptomatic PE to 1.5% compared to 4.0% for LDUH alone ($P < 0.001$).[66] In general surgical patients with multiple risk factors and at very high risk for VTE, a combination of pharmacologic and mechanical prophylaxis with graduated compression stockings and/or IPC is advocated.[10]

Laparoscopic Surgery

Laparoscopic surgery is a major advance in general surgical practice, providing opportunities for reducing surgical trauma, patient discomfort associated with intra-abdominal and pelvic

surgical procedures, and hospital length of stay. The problem of VTE has not been investigated extensively in patients undergoing minimal access surgical procedures.[67] From the point of view of the pathogenesis of VTE, minimal-access surgical procedures such as cholecystectomy are associated with varying reports of activation of blood coagulation, ranging from only minimal[68–70] to the same degree of coagulopathy as that observed in the open cholecystectomy procedure.[71,72] Often, laparoscopic procedures may take longer than the open surgical procedure, and during operation both the pneumoperitoneum and the reverse Trendelenburg position used in operations such as cholecystectomy or fundoplication result in profound venous stasis of the lower limbs.[73] Laparoscopic surgical procedures appear associated with a shorter hospital stay and therefore a potentially more rapid postoperative mobilization. The outcome of patients once discharged from hospital in terms of their mobility after laparoscopic procedures, compared to those who remain in hospital, has not been investigated extensively.[67]

A number of surveys have determined current surgical practice of thromboprophylaxis after laparoscopic cholecystectomy and reported rates of thromboembolic complications. In a UK study of 417 surgeons, 91% reported never having encountered a thromboembolic episode after laparoscopic cholecystectomy.[74] Most surgeons use LDUH heparin in these patients. In a similar study undertaken in Denmark, 80% of surveyed surgical departments reported no problems with postoperative VTE in patients undergoing laparoscopic cholecystectomy.[75]

Beyond these surveys, there have been a few studies using objective screening techniques that have attempted to determine the rates of VTE associated with various laparoscopic procedures. In a small study, with the screening endpoint of contrast venography 6 to 10 days after operation, no case of DVT was identified in 25 patients who underwent laparoscopic cholecystectomy without thromboprophylaxis.[76] Similarly, low rates in the absence of thromboprophylaxis have been identified in a series of laparoscopic surgical patients screened with lower limb Duplex ultrasonography.[77,78]

Registries of surgical outcome also indicate a low frequency for thromboembolic complications in laparoscopic procedures. In a North American analysis of more than 100,000 laparoscopic cholecystectomies, the rate of symptomatic VTE was 0.2% up to 3 months after operation.[78] Similar findings were identified in a further literature review including over 150,000 laparoscopic cholecystectomies where various thromboprophylactic strategies were used and where the rates of DVT, PE, and fatal PE were 0.03%, 0.06%, and 0.02%, respectively.[79] Finally, the Swedish registry of laparoscopic cholecystectomy reported a rate of VTE of 0.2% in more than 11,000 cases.[80]

As a consequence of these very low reported rates of VTE, there have been few randomized trials to determine the potential benefit of routine thromboprophylaxis in minimal-access surgical patients. In one study, patients were randomized to placebo or to the LMWH dalteparin in a dose of 2,500 IU once daily for up to 10 days after operation. There was no evidence of DVT screened venographically in either group of patients.[76] In a second trial, graduated compression stockings alone or combined with the LMWH reviparin were compared. The rate of DVT, as screened with ultrasound 5 to 7 days after operation, was below 1%.[77]

In conclusion, for simple laparoscopic procedures such as cholecystectomy or tubal ligation, VTE prophylaxis is not generally recommended. However, for patients with a history of VTE or active cancer or with more complicated procedures such as colectomy, it is indicated.

Cancer Surgery

Cancer is an important risk factor for VTE.[9,48] The frequency of thromboembolic complications in patients undergoing major cancer surgery is thought to be about twice that of patients undergoing the equivalent operation without malignant disease.[9,81,82] In general, LDUH[11] and LMWH[48] have been validated for the prevention of thromboembolic disease in patients undergoing major abdominal or pelvic procedures for cancer. In a recent subgroup analysis of more than 6,000 patients with malignant disease receiving perioperative LDUH or LMWH, compared with 17,000 patients without malignancy, fatal PE was three times as common in cancer than in noncancer surgical patients despite use of prophylaxis.[82]

In a study of more than 2,000 patients undergoing laparotomy for cancer, the hypothesis that a higher dose of LMWH would be associated with a low incidence of postoperative thromboembolic complications in cancer patients was tested. In this trial, in the two-thirds of patients undergoing operation for malignant disease, increasing the dose of the LMWH dalteparin from 2,500 to 5,000 IU once daily was associated with a reduction in the frequency of postoperative DVT from 14.9% to 8.5%. Among the patients with cancer in this trial, there was no significant increase in bleeding complications associated with increasing the dose of LMWH. For the one-third of patients without malignant disease, although there was a reduction in the frequency of postoperative DVT with the higher dose of LMWH, this was associated with a significant increase in perioperative bleeding complications.[83]

Beyond the intensity of perioperative antithrombotic therapy has been the suggestion that prolonging the duration of prophylaxis into the postdischarge period might be associated with a lower frequency of late thromboembolic complications in patients with malignant disease. This hypothesis has been tested in two recent randomized clinical trials involving LMWH.[84,85] Patients undergoing laparotomy for cancer were randomized to either 1 week of in-hospital prophylaxis or 4 weeks of in-hospital and postdischarge prophylaxis with the LMWH enoxaparin 40 mg once daily. Prolonged prophylaxis was associated with a reduction in the frequency of postoperative DVT as screened by venography at the end of the 4-week treatment period.[84] A similar study including patients with or without malignant disease demonstrated the benefit for prolonged thromboprophylaxis in cancer surgical patients randomized to in-hospital or in-hospital and postdischarge thromboprophylaxis with the LMWH dalteparin 5,000 IU once daily for up to 4 weeks.[85] In another trial of patients undergoing major general surgery, some of whom had a history of cancer, 4 weeks of therapy with dalteparin 5,000 IU once daily compared with 1 week of therapy reduced the risk of VTE with no increase in risk of bleeding.[86]

Studies involving the LMWH bemiparin have been conducted recently in patients with cancer, with the focus on identifying the optimal dosing and duration of thromboprophylaxis.[29,30] In a Spanish study, Balibrea et al.[29] reported that patients with cancer were still inadequately assessed for risk of VTE, and that bemiparin 3,500 IU/d was more effective than 2,500 IU/d, with no increase in risk of complications. Kakkar et al.[30] compared

the efficacy and safety of 1 versus 4 weeks of treatment with bemiparin 3,500 IU in patients undergoing abdominal or pelvic cancer surgery; while extended treatment did not reduce significantly or change the incidence of the composite of DVT, nonfatal PE, and all-cause mortality, the incidence of major VTE (proximal DVT, nonfatal PE, and VTE-related deaths) was reduced (relative risk reduction [RRR] 82.4%; 95% CI, 21.5 to 96.1), with no increase in the rate of hemorrhagic events. These data suggest that for certain cancer surgical patients at high risk for the development of postoperative DVT, prolonged thromboprophylaxis may be indicated, although no definite recommendations about routine use for postdischarge prophylaxis can be made on the basis of currently available studies.

SUMMARY

VTE remains an important potential complication in patients undergoing major general surgical procedures and operation for malignant disease. Routine pharmacologic thromboprophylaxis with LDUH, LMWH, or fondaparinux has been validated both in terms of safety and efficacy with or without combination with mechanical methods and should be considered for all such patients, provided they are not at high risk of bleeding complications.

ORTHOPEDIC SURGERY

Patients undergoing orthopedic surgery are at an increased risk of developing VTE,[10,87] especially in case of major procedures like hip and knee replacement or hip fracture surgery.

The risk for any DVT, proximal DVT, any PE or fatal PE after hip or knee replacement or hip fracture surgery in absence of prophylaxis is summarized in Table 86.3.[10] PE was the cause of death in 14% of the patients who died after hip fracture surgery.[88] The standardized and routine use of thromboprophylaxis has rendered fatal PE after orthopedic surgery an uncommon event. However, symptomatic VTE remains present in 1.3% to 10% of the patients.[10]

The pathologic basis for postdischarge thrombosis is still unclear. The thrombosis could be asymptomatic on discharge and become clinically overt later or could be newly developed after discharge. A study in patients undergoing elective hip replacement with a negative bilateral venography at discharge, showed a remarkable high incidence of thrombosis over the succeeding 3 weeks.[89,90] This suggests a late development of thrombosis after hospital discharge.

Table 86.3

Prevalence of VTE after major orthopedic surgery without prophylaxis

	DVT (%)		PE (%)	
Procedure	**Total**	**Proximal**	**Total**	**Fatal**
Hip replacement	42–57	18–36	0.9–28	0.1–2.0
Knee replacement	41–85	5–22	1.5–10	0.1–1.7
Hip fracture surgery	46–60	23–30	3–11	0.3–7.5

The use of antithrombotics for the prevention of VTE has been assessed in multiple randomized controlled trials in patients undergoing elective knee or hip replacement therapy and to a lesser extent in patients after hip fracture therapy. However, data on arthroscopic knee surgery, elective spine surgery, and injury of the lower extremities remain scarce. In addition, issues including the optimal timing and prolongation of prophylaxis remain debatable.

Prevention of Venous Thromboembolism in Elective Hip Replacement

Prevention of VTE is recommended in all patients undergoing elective hip replacement[10] due to the high risk for proximal DVT, and nonfatal and fatal PE (Table 86.3).[10] It could be argued that these numbers are an overestimation of current orthopedic surgery due to shorter hospitalization, earlier mobilization, improved anesthetic techniques, and the standardized use of antithrombotic agents. However, surgical procedures are undertaken in older patients, elevating the risk for VTE. Other risk factors are obesity, the presence of malignancies, and a history of VTE.[91]

Mechanical prophylaxis methods that have been studied in elective hip replacement surgery are graduated compression stockings,[92–97] IPC[98–103] and a venous foot pump.[96,104] These nonpharmacologic methods of prophylaxis give a RRR of 20% to 70% for the development of DVT. However, mechanical prophylaxis is less effective in primary prevention than currently available anticoagulant drugs.[97,99,103] Therefore, primary prevention by mechanical prophylaxis is only recommended in patients with a high risk of bleeding.[10]

In a meta-analysis, aspirin gives a reduction in fatal and nonfatal PE of 25% compared to placebo and no prophylaxis.[105] Since alternative prophylactic therapies are more effective,[23,106,107] the use of aspirin as thromboprophylaxis in elective hip replacement is not recommended.[10]

LDUH is more effective than placebo or no prophylaxis[25] and is considered safe in the preoperative and postoperative setting. However, it is considered to be less effective than other regimens available in routine clinical practice.[107–109]

The most commonly used thromboprophylaxis for total hip replacement in North America is adjusted-dose oral VKAs like warfarin.[110] The primary advantage of VKA is the delayed onset of action, hereby allowing surgical hemostasis. However, VKAs are hardly used in Europe due to the variable response between patients, the lower efficacy compared to LMWH,[108,111] interaction with other drugs, and due to the need for frequent monitoring. The dosage of VKA is adjusted to adhere to the recommended International Normalized Ratio (INR) range of 2.0 to 3.0.[10]

In Europe, the most frequently used thromboprophylaxis is LMWH, which proved to be highly effective and safe for the primary prevention of VTE. LMWH is more effective than LDUH[12,112–116] and when compared to adjusted-dose warfarin no difference in the incidence of total and proximal DVT was found.[117–119] However, in one study[120] LMWH prophylaxis started preoperatively was found to be more effective than warfarin for the prevention of thrombosis but the use of LMWH was associated with a significantly increased incidence of bleeding at the operative site and of blood product transfusion. Another study[121] found a significant reduction in total, proximal, and objectively confirmed DVT in patients using

LMWH < 2 hours preoperatively or at least 4 hours after surgery, compared to warfarin started postoperatively (2.2% vs. 4.4%). Combining the results of the five studies in which LMWHs were compared with adjusted dose warfarin,[117–121] the rates of DVT were significantly lower in the LMWH group (13.7 vs. 20.7%, $P \leq 0.01$). However, the proximal DVT rates were 4.8% and 3.4% ($P = 0.08$), respectively. Major bleeding occurred more frequently in the LMWH-treated patients (5.3% and 3.3%, $P < 0.01$). In a meta-analysis[122] in patients undergoing hip or knee replacement surgery, VKAs were less effective in the prevention of total and proximal DVT compared to LMWHs ($P < 0.01$). Subgroup analysis for patients undergoing elective hip surgery did not significantly modify the results ($P = 0.02$). In conclusion, LMWH are more effective in the prevention of DVT but cause more major bleeding than dose-adjusted VKAs.

The synthetic pentasaccharide fondaparinux has been proven to be highly effective in the prevention of DVT among patients with elective hip replacement surgery.[33,123] In one study,[123] fondaparinux 2.5 mg sc (subcutaneously) once daily 4 to 8 hours after surgery was compared to enoxaparin 40 mg sc once daily started 12 hours before surgery. The rates of VTE were 4% in the fondaparinux group compared to 9% in the enoxaparin group ($P < 0.01$). The rate of proximal DVT was lower in the patients randomized to fondaparinux (1%) compared to LMWH (2%; $P < 0.01$). In another study,[33] the identical fondaparinux regimen 2.5 mg once daily was compared to enoxaparin 30 mg bid (twice a day) 12 to 24 hours after surgery. There was no significant difference between the overall risk of VTE (6% in the fondaparinux group compared to 8% in LMWH patients), nor in the rate of proximal DVT (2% vs. 1%, respectively). In both trials fondaparinux was associated with a nonsignificant increase in bleeding ($P = 0.11$). These data indicate, by indirect comparison, that LMWH and probably fondaparinux are more effective than VKAs in the prevention of VTE in patients undergoing elective hip replacement. However, there is a slight increase in bleedings in the surgical site. The higher efficacy and higher bleeding risks could be attributable to the more rapid onset of anticoagulant effects compared to VKAs.

A number of new anticoagulant agents that block either factor Xa or thrombin have been evaluated in phase III trials and are approved for thromboprophylaxis in elective hip surgery.

In the RECORD 1 study,[124] rivaroxaban 10 mg once daily, beginning 6 to 8 hours after surgery, was compared to enoxaparin 40 mg sc once daily, given 12 hours before surgery and restarted 6 to 8 hours after wound closure. The study medication was administered for 35 days. The primary endpoint, DVT, nonfatal PE, or death from any cause occurred in 1.1% of the patients in the rivaroxaban group and 3.7% in the enoxaparin group ($P < 0.01$). Major bleeding occurred in 0.3% and 0.1% of the rivaroxaban and enoxaparin group, respectively ($P = 0.18$). In the RECORD 2 trial,[125] 10 mg rivaroxaban once daily for 35 days was compared to short-term (10 to 14 days) of enoxaparin 40 mg sc once daily. VTE occurred in 2.0% of the patients in the rivaroxaban group and 9.3% in the enoxaparin group ($P < 0.01$). Major bleeding occurred in one patient in each group (Table 86.4).

In the RE-NOVATE I study,[126] the oral thrombin inhibitor dabigatran 150 or 220 mg once daily (starting 1 to 4 hours after surgery with half the dose) was compared with enoxaparin 40 mg sc (given the evening before surgery). Study treatment was

Table 86.4

Incidence of VTE plus all cause mortality and major bleedings with new oral antithrombotic agents in orthopedic surgery

		Treatment		VTE and Death		Major Bleeding

[a]In all studies enoxaparin was the comparator.
THR, total hip replacement; TKR, total knee replacement.

continued for 28 to 35 days. VTE occurred in 8.6% and 6.0% for the dabigatran 150 and 220 mg group, respectively, and in 6.7% of the patients with enoxaparin. Both dabigatran doses met the noninferiority criteria compared to enoxaparin. Major bleeding occurred in 2.0% in the dabigatran 220 mg group, 1.3% of the dabigatran 150 mg group, and in 1.6% of the enoxaparin group (P = ns). In the RE-NOVATE II trial, dabigatran 220 mg once daily, with a half dose 1 to 4 hours after surgery, for 28 to 35 days was compared with enoxaparin 40 mg once daily, initiated the evening before surgery. The primary outcome, total VTE, and all cause mortality, occurred in 7.7% of the dabigatran group and 8.8% of the enoxaparin group ($P < 0.01$). Major bleeding was not significantly different between the dabigatran and the enoxaparin group (1.4% vs. 0.9% respectively, $P = 0.40$)[127] (Table 86.4).

Prevention of Venous Thromboembolism in Elective Knee Replacement

Most of the prophylaxis regimens discussed above are also used, although some of them with lower efficacy, for elective knee replacement.

Mechanical thromboprophylaxis is common in patients undergoing elective knee replacement surgery. However, compared to the data available for LMWH and warfarin, data about safety and efficacy of mechanical thromboprophylaxis is limited. Four small studies[102,128–130] suggest that IPC devices are efficient in this type of surgery. When applied intra-operatively or directly postoperatively and worn continuously until the patient is fully ambulant, IPC devices are most effective. Poor compliance, patient intolerability, improper use of the devices, and inability to continue the use of the device after discharge limits the efficacy of IPC. A venous foot pump was shown to be efficacious in two small clinical trials[131,132] but has been shown to be considerably less effective than LMWH in two other studies.[133,134]

Due to their limited efficacy in elective knee replacement surgery, aspirin[23,128,130,131,135,136] and LDUH[32,137] are not recommended as thromboprophylaxis in this group of patients.

Multiple randomized clinical trials have evaluated the efficacy of adjusted-dose VKAs using routine venography to screen for DVT.[23,128,130,131,135,136] The rate of venography-detected DVT, in patients receiving VKAs for 10 days after surgery, ranges between 25% and 50% and the rate of symptomatic DVT after 3 months is approximately 1%.[138,139]

LMWH is safe and effective in the prevention of thrombosis in patients undergoing elective knee replacement.[117–119,137,140–147] Considering the results of the six randomized clinical trials that compared the prophylactic use of different LMWHs with VKAs for the prevention of VTE in patients with this surgery, the rate of DVT was 48% with VKAs and 33% with LMWHs (OR 0.56; 95% CI, 0.47 to 0.67).[117–119,143–145] The rates of proximal DVT were 10.4% and 7.1%, respectively (OR 0.67; 95% CI, 0.44 to 1.00). Two of these studies observed a higher rate of bleeding in the LMWH group, but this increased risk was limited to minor bleeding.[118,145] However, two meta-analyses confirmed the superiority in efficacy of LMWH compared to LDUH and VKAs in reducing venography-detected DVT, without an increase in bleeding.[148,149]

Fondaparinux 2.5 mg sc once daily, starting 6 hours after elective knee replacement was compared to enoxaparin 30 mg bid starting 12 to 24 hours after surgery.[34] Venography-detected DVT was present in 12.5% of the patients receiving fondaparinux and 27.8% of the patients receiving enoxaparin ($P < 0.01$). Major bleeding occurred in significantly more in the fondaparinux group compared to enoxaparin (2.1% vs. 0.2%, $P < 0.01$).

In the RECORD 3 study,[150] rivaroxaban 10 mg once daily, initiated 6 to 8 hours after wound closure, was compared to enoxaparin 40 mg sc once daily, started 12 hours before surgery and given again 6 to 8 hours after surgery. Study medication was continued until day 10 to 14. The total number of VTE 13 to 17 days after surgery was 9.6% in the rivaroxaban group and 18.9% in the enoxaparin group ($P < 0.01$). Major bleeding occurred in 0.6% and 0.5% in the rivaroxaban and enoxaparin patient group, respectively. In the RECORD 4 trial,[151] rivaroxaban 10 mg once daily was compared to enoxaparin 30 mg sc bid initiated 12 to 24 hours after wound closure. In 6.9% of the rivaroxaban patient group and 10.1% of the enoxaparin patient group a DVT, nonfatal PE, or death from any cause occurred ($P = 0.012$). Major bleeding occurred in 0.7% of the rivaroxaban group and 0.3% of the enoxaparin group (P = ns). The number of major bleedings in the RECORD trials is relatively low compared to the major bleeding rates in the trials with apixaban and dabigatran (see Table 86.4). This is related to the difference in classification of major bleeding. In the trials comparing enoxaparin with rivaroxaban, rebleeding at the surgical site was excluded from the definition of major bleeding, except if the bleeding event resulted in reoperation or death.[152]

In the ADVANCE 1 trial,[153] apixaban 2.5 mg orally bid was compared to enoxaparin 30 mg sc bid. Study medication was initiated 12 to 24 hours after surgery and continued for 10 to 14 days. VTE was present in 9.0% of the patients in the apixaban group and 8.8% in the enoxaparin group ($P = 0.06$ for noninferiority). Major bleeding occurred in 0.7% of the patients who received apixaban and 1.4% in those who received enoxaparin ($P = 0.05$). In the ADVANCE 2 trial,[153b] apixaban 2.5 mg twice daily was compared to subcutaneous enoxaparin 40 mg once a day. Apixaban was found to be superior to enoxaparin for the prevention of VTE and all-cause death (15% vs. 24%, $P < 0.01$). Major or clinically relevant nonmajor bleeding occurred in 4% with apixaban and 5% with enoxaparin (P = ns).

In the RE-MODEL trial,[154] oral dabigatran 150 or 220 mg once daily was compared to enoxaparin 40 mg sc once daily. VTE occurred in 40.5% and 36.4% of the dabigatran 150 and 220 mg group, respectively, and in 37.7% of the enoxaparin group. Major bleeding occurred in 1.3%, 1.5%, and 1.3% of the groups, respectively. In the RE-MOBILIZE trial,[155] dabigatran 150 and 220 mg was compared to the North-American enoxaparin 30 mg sc bid regimen. Both dabigatran regimens were inferior to enoxaparin in the occurrence of VTE (34%, 31% and 25%, respectively). Bleeding occurred in 0.6% of the patients in both dabigatran groups and 1.4% of the patients in the enoxaparin group (P = ns) (Table 86.4).

Prevention of Venous Thromboembolism in Hip Fracture Surgery

Primary prophylaxis for VTE should be provided in all patients undergoing hip fracture surgery unless firmly contraindicated. However, less data are available in the prevention of VTE in comparison with elective hip and knee replacement surgery.

There is insufficient data available to support the use of mechanical prophylaxis to prevent DVT in patients with

hip fracture.[156] There is no research comparing mechanical prophylaxis with other regimens in patients undergoing hip fracture surgery using contrast venography to detect DVT. In a single study, IPC has been shown to be effective in comparison with no prophylaxis.[157] However, data on efficacy and safety of graduated compression stockings remain insufficient to establish a reliable recommendation and a reliable alternative to pharmacologic prophylaxis.[23,158]

The role of aspirin for prophylaxis of VTE in hip surgery patients is controversial. A meta-analysis indicated that aspirin and other antiplatelet agents are effective in the prevention of VTE.[105] In one trial more than 17,000 patients were randomized to receive aspirin 160 mg daily or placebo. Study medication was started before surgery and continued for another 35 days.[23] In approximately 24% of the patients, additional thromboprophylaxis with graduated elastic stockings, LMWHs, or LDUH was used. Aspirin showed a significant reduction in risk of fatal PE (hazard ratio [HR] 0.42; 95% CI, 0.24 to 0.73) and of clinically overt DVT (HR 0.71; 95% CI, 0.52 to 0.97). The patients administered aspirin as prophylaxis had a significant increase in wound-related and gastrointestinal bleeding. When aspirin plus LMWH/LDUH were administered the proportional reduction of VTE was similar to that with aspirin alone.

In a randomized trial in approximately 60 patients, LDUH was compared with the LMWH dalteparin.[159] In this study, LDUH of 5,000 U three times a day was more effective than dalteparin 5,000 IU once daily. However, a review showed that both LDUH and LMWH are effective in the prevention of VTE in patients with hip fracture without increasing the risk of bleeding, but was unable to determine superiority of one agent over the other.[156]

In five studies, of which four had a small sample size, LMWHs were evaluated for prevention of VTE in patients with hip fracture.[159–162] The placebo-controlled trial did not show a significant benefit from LMWH.[160] None of the trials have evaluated the effect of LMWH in comparison to VKAs in patients undergoing hip fracture surgery. No excessive risk of bleeding is associated with the use of LMWH in comparison with placebo[160] or LDUH.[159]

Use of warfarin as prophylaxis is safe and effective in patients undergoing hip fracture surgery. Postoperatively started warfarin (INR 2.0 to 2.7) was found to be more effective than aspirin, 650 mg twice daily, or no prophylaxis.[163] The rates of DVT were 20%, 41%, and 46%, respectively, and for proximal DVT 9%, 11%, and 30%. Bleeding rates were identical in the three groups. With the three studies comparing adjusted-dose VKAs with no prophylaxis taken together, a RRR of 66% for DVT and 66% reduction for proximal DVT were found.[163–165] The bleeding rates observed with VKAs ranged from 0% to 47%[163–165] and in the largest study there was no difference in bleeding compared to placebo.[163]

Fondaparinux has been investigated in patients undergoing hip fracture surgery.[35,166,167] In one of these studies,[35] patients were randomized to either fondaparinux 2.5 mg daily starting 4 to 8 hours after surgery or enoxaparin 40 mg once daily starting 12 to 24 hours after wound closure. Rates of any VTE by postoperative day 11 were 8.3% in the fondaparinux group and 19.1% in the enoxaparin group ($P < 0.01$). Major bleeding was present in 2.2% of both groups; however, minor bleeding was encountered significantly ($P = 0.02$) more in the fondaparinux group (4.1%) in comparison to the enoxaparin group (2.1%).

The efficacy of anti-Xa and antithrombin agents has not been evaluated in hip fracture surgery. However, a study compared the efficacy and safety of the factor IXa inhibitor TTP889, administered 300 mg once daily, to placebo. The occurrence of VTE did not differ significantly (32.1% vs. 28.2% respectively, $P = 0.58$) and no major bleeding was reported. This suggests a lack of antithrombotic potential for TTP889 in hip surgery patients.[167]

Prevention of Venous Thromboembolism in Elective Spine Surgery

The data available on the incidence and prevention of VTE in patients undergoing elective spine surgery is limited. Venography-detected DVT in the absence of prophylaxis is present in approximately 18% of the patients.[168,169] A review including patients undergoing lumbar spine fusion found a 3.7% incidence of symptomatic DVT and 2.2% of PE.[170]

In an observational study, the incidence of VTE in patients using IPC was 6% in comparison to 21% in the patients receiving no prophylaxis.[171] In 11 small prospective trials,[172–182] DVT was identified by ultrasound in 2% of the patients undergoing spine surgery with mechanical prophylaxis. Since a control group was absent, validity of the degree of prevention is limited.

In a study in patients undergoing laminectomy,[183] LDUH was found to be more effective than no prophylaxis. Enoxaparin was also shown to be promising in the prevention of VTE in patients undergoing elective spine surgery.[184,185] Due to the limited data available, prophylaxis using LMWH, LDUH, or perioperative IPC is only recommended in patients with an additional risk factors for VTE such as advanced age, malignancy, previous VTE, presence of a neurologic deficit, and an anterior surgical approach.[10] In patients with multiple risk factors for VTE, pharmacologic thromboprophylaxis (LMWH or LDUH) is recommended with or without a mechanical method.

Prevention of Venous Thromboembolism in Isolated Lower Extremity Injury

Injuries of the lower extremities are defined as fractures of below-knee bones, injuries of ligament and cartilages of the knee and ankle, and rupture of the Achilles tendon. These injuries are in most cases treated surgically, by plaster cast or braces. Risk factors for VTE after isolated lower extremity injury are advanced age,[186–189] bone fracture[190] rather than soft tissue rupture, and obesity.[189] Venography-proven DVT is present in 19% to 45% of the patients with these fractures not receiving any prophylaxis and the incidence of proximal DVT is 5%.[121,190–192]

The data available on the role of prophylaxis in patients with fractures of the lower extremity is limited. Five studies[188,190,191,193,194] evaluated the effect of LMWH in comparison to no thromboprophylaxis or placebo. In two[188,190] studies ultrasonography was used to assess the presence of DVT after plaster cast removal. In these studies LMWH reduced the occurrence of distal DVT significantly but not the incidence of proximal DVT. In a multicenter trial,[194] all patients underwent ultrasonography after 14 ± 2 days to detect the presence of asymptomatic DVT. In the LMWH group, two patients had thrombosis compared to three patients in the control group (P = ns). In the pooled data of two other trials,[191,193] the presence of DVT was screened by ultrasonography after ≥5 weeks in patients with below-knee

fractures. LMWH did not significantly reduce the risk of DVT (16.5% vs. 10.6%, P = ns). Based on the uncertainty of evidence, no routine thromboprophylaxis is recommended for patients with isolated lower-extremity injuries distal to the knee.[10]

Prevention of Venous Thromboembolism After Knee Arthroscopy

One of the most common orthopedic procedures is arthroscopy of the knee and arthroscopic-assisted knee surgery, including meniscectomy, synovectomy, and reconstruction of the cruciate ligaments. Data available on the risk of VTE after arthroscopy is limited and controversial.[195,196] In three large studies for arthroscopy, the incidence of VTE was up to 0.6% in patients undergoing knee arthroscopy without prophylaxis.[197–199] However, asymptomatic DVT detected by mandatory testing ranged from 3% to18%.[200] Known risk factors for VTE are therapeutic arthroscopy and the duration of tourniquet use.[201,202]

In one trial, 4% of the patients without prophylaxis had DVT on compression ultrasonography (CUS) compared to 1% of the patients with reviparin, 1,750 IU once daily for 7 to 10 days.[203] In a second study, prophylactic dalteparin for 30 days was compared to no prophylaxis in patients undergoing diagnostic and therapeutic arthroscopy. The use of prophylaxis reduced the incidence of DVT, detected by ultrasonography on day 12 and 31, from 16% to 2%.[204] No excess of bleeding was observed in patients who received prophylaxis in these studies.[203,204]

The use of thromboprophylaxis with LMWH in knee arthroscopy is recommended in patients with additional risk factors or following a complicated procedure. In the absence of risk factors only early mobilization is recommended.[10]

Optimal Initiation Time for Pharmacologic Prophylaxis

Two important facts should be taken into account to assess the optimal time of prophylaxis for patients undergoing major orthopedic surgery. The first issue is whether initiation of prophylaxis should be initiated preoperative of postoperative. The second relates to how early after wound closure the prophylaxis should be started.[205]

In the United States, LMWH prophylaxis is initiated 12 to 24 hours after surgery. In Europe, LMWH is started 10 to 12 hours before surgery. In two reviews, conflicting results on the relative value of preoperative and postoperative start of prophylaxis were provided.[121,206] To assess this issue, a study was done in patients undergoing hip replacement surgery. The patients were randomized to either preoperative dalteparin, 2,500 IU started 1 hour before surgery and continued with a dose of 2,500 IU 7 hours after surgery and then 5,000 IU once daily, or postoperative dalteparin 2,500 IU started 7 hours after surgery and then continued 5,000 IU once daily, or postoperative adjusted-dose warfarin.[121,207] Both preoperative and postoperative initiation of thromboprophylaxis was significantly better than warfarin, with rates of DVT of 10.7%, 13.1%, and 24%, respectively. Major bleeding was significantly higher in the preoperative dalteparin group than in the warfarin group. Postoperative start of dalteparin was not associated with an elevated risk of bleeding in comparison to warfarin.

Multiple systematic reviews have compared the preoperative start of LMWH prophylaxis to the postoperative regimen. One systematic review found that postoperative start of LMWH prophylaxis is comparable to preoperative initiation.[208] A second review showed that LMWH is only beneficial in comparison to warfarin in patients undergoing hip replacement surgery when LMWH is initiated in close relation to the surgery (either <2 hours before or 6 to 8 hours after surgery). However, starting LMWH just before surgery is associated with an elevated risk of bleeding.[209] A third review showed that starting LMWH preoperatively is more efficient than postoperative, but this benefit is diminished by an increased risk of bleeding.[210] In conclusion, the American College of Chest Physicians (ACCP) guidelines recommends starting either preoperatively or postoperatively in patients receiving LMWH as thromboprophylaxis. For patients receiving fondaparinux, it is recommended to start either 6 to 8 hours after surgery or the next day. [10]

Optimal Duration of Prophylaxis

The optimal duration of thromboprophylaxis after orthopedic surgery is debatable.[211] Multiple studies have shown that the risk for VTE prevails for at least 4 weeks after hip surgery.[90,197,212–217,218,219] In addition, nearly three-quarters of all symptomatic DVT occur after discharge.[90]

Multiple meta-analyses showed that prophylaxis after discharge is safe and reduces the rate of VTE. [44,45,220] No excess bleeding was observed in patients with extended prophylaxis suggesting that the risk–benefit ratio favors the use of extended prophylaxis. In a systematic review of elective hip replacement surgery, the VTE rate was 1.1% in patients with extended LMWH prophylaxis compared to 2.7% in patients only given in-hospital prophylaxis (absolute risk reduction 1.56%; 95% CI, −0.21% to 3.3%; number needed to treat 64). [221]

Six randomized controlled trials have evaluated extended prophylaxis with LMWH for up to 35 days in patients undergoing elective hip replacement.[89,207,214,218,222,223] All study results were in favor of extended thromboprophylaxis. A systematic review showed a significant decrease in DVT and symptomatic VTE in patients with extended LMWH.[224] The incidence of VTE in extended prophylaxis was 1.4% compared to 4.2% in the group constricted to in-hospital prophylaxis. One randomized controlled trial (RCT) comparing in-hospital LMWH to extended use of LMWH in total hip- or knee replacement did not show a benefit in the prevention of VTE.[225]

Postdischarge prophylaxis with VKAs in patients undergoing hip surgery had been shown to be effective and safe in the prevention of VTE.[226] However, in a trial comparing 6 weeks of LMWH with 6 weeks of VKA prophylaxis in patients undergoing hip surgery, LMWH was more effective and safer than prophylaxis with VKAs.[227]

In a trial including patients undergoing knee replacement surgery, extended LMWH prophylaxis for 4 weeks did not significantly reduce the rate of screened DVT and symptomatic VTE versus in-hospital prophylaxis.[222]

The benefit of extended thromboprophylaxis in patients undergoing surgery for hip fracture has also been assessed. In a randomized controlled trial,[35] patients received 3 weeks posthospital continuation of fondaparinux 2.5 mg once daily or placebo. At follow-up, 1.4% of the patients with extended fondaparinux had objectively proven DVT compared to 35.0% in the placebo group. Bleeding rates did not differ significantly between fondaparinux and placebo.

The 8th edition of the ACCP guidelines recommend that thromboprophylaxis in elective hip replacement and hip fracture surgery be extended beyond 10 days and up to 35 days.[10] The recommended options of prophylaxis are LMWH, fondaparinux, or a VKA.

Predischarge Screening for Deep Vein Thrombosis

Routine screening for asymptomatic DVT has been assessed in order to predict the postdischarge occurrence of VTE in patients after orthopedic surgery.[210] However, screening for asymptomatic DVT has not been shown to be effective in three studies.[138,140,228] Only 0.15% of the patients had asymptomatic DVT at discharge.[140] In the 2nd study, patients were randomized to receive predischarge CUS or a sham CUS.[138] Active CUS detected DVT in 2.5% of the patients, but did not influence the occurrence of VTE on follow-up. In a last study, patients were randomized to 10 days LMWH and predischarge ultrasonography or extension of LMWH prophylaxis for another 3 weeks.[228] CUS did not reduce the incidence of symptomatic VTE. Therefore, routine predischarge screening is not warranted.

MEDICALLY ILL PATIENTS

VTE remains a major cause of morbidity and mortality in patients who are hospitalized.[4,229–234] Despite the availability of effective treatment of DVT and PE, clinically overt VTE increases morbidity and cost, and may lead to an increase in preventable death.[235] Therefore, thromboprophylaxis has been advocated in high-risk patients.

Venous thromboprophylaxis is widely practiced in surgical patients, but, in contrast, many medical patients still do not receive it despite recommendations and guidelines.[236,237–239] There is a need for a constant reappraisal of the burden of VTE in medical patients and of the evidence from prophylactic randomized studies.

RISK FACTORS IN MEDICAL PATIENTS

Over the last few years, the incidence and prognosis of VTE appears unchanged despite prophylaxis being provided to an increasing number of patients; thus other factors may account for the observed trend.[240]

The development of noninvasive and reliable methods for the diagnosis of DVT and PE has facilitated its recognition. Widespread imaging is increasing the apparent incidence of VTE. During the last decade, several authors assessed independent risk factors for VTE in cohorts of medical patients by using multivariate analysis.[241] A systematic review of these independent risk factors for VTE in hospitalized medical patients was recently published, proposing to retain only risk factors found more than once in the literature (Table 86.5). In many countries, these factors are increasing as the population grows. The prevalence of risk factors such as heart failure or malignancy will increase because of the availability of treatments that effectively increase life expectancy.

Institutionalization (current or recent hospitalization or nursing home residence) account for 61% of cases of VTE in a community, of which 24% following medical illnesses, 23% following surgical procedures, and 14% during nursing home residence stays.[242] Thus, medical patients who are hospitalized are at particular risk of developing VTE and its complications because of the combination of chronic risk factors (e.g., age, heart failure, and prior VTE) and an acute, transient increased risk associated with conditions leading to the hospitalization and immobilization (e.g., aggravation of heart failure or respiratory failure, infectious disease, stroke, or acute myocardial infarction [MI]). These acute medical conditions are each independent risk factors for VTE[240,242] and often a cause of

Table 86.5

Independent predisposing risk factors for VTE in hospitalized medical patients found more than once

1 < OR < 1.5	1.5 < OR < 3	OR > 3
Black race	Respiratory failure	Pharmacologic sedation
COPD	Diabetes mellitus	Family history of VTE
HRT	Hypertension	Prolonged immobility
Smoking	Advanced age	Previous SVT
Obesity	History of VTE	Neurologic disease with extremity paresis
Thrombophilia (factor V Leiden)	Cancer and chemotherapy Congestive heart failure CVC or pacemaker Ischemic stroke Transfusion Renal failure Varicose veins	

OR, odds ratio; CVC, central venous catheter; HRT, hormone replacement therapy; COPD, chronic obstructive pulmonary disease; SVT, superficial vein thrombosis; VTE, venous thromboembolism.

prolonged immobilization, which is also an independent risk factor (Table 86.5).

Outpatients are also at a risk of VTE. The same chronic and triggering risk factors in medical patients who are hospitalized have been identified in a general population of outpatients.[243]

ISSUES IN THE ACCEPTANCE OF THROMBOPROPHYLAXIS STUDIES

Surveys show that many medical patients who may benefit from thromboprophylaxis do not receive it [244,245] despite clear and strong recommendations. This discrepancy is mainly explained by the idea that clinically relevant benefits of thromboprophylaxis in patients who are hospitalized with medical illness have not been demonstrated and possibly by the fear of major bleedings.

Asymptomatic Deep Vein Thrombosis as Primary Endpoint in Prophylactic Studies

The main endpoint used in most prophylactic clinical trials in medical, as well as in surgical patients, is a DVT (in most cases asymptomatic) diagnosed by imaging (e.g., venography or ultrasonography). Asymptomatic DVT has been used as a surrogate endpoint for symptomatic DVT and PE, which constitute the burden of VTE described in epidemiologic studies. Although there is no perfect surrogate endpoint,[246] asymptomatic DVT (combined with symptomatic events) has been adopted in most prophylactic studies as the main endpoint. Most thromboprophylactic anticoagulants have been approved by health authorities on the basis of this endpoint. In meta-analyses of placebo-controlled studies, there are good correlations between the incidence of asymptomatic DVT and that of symptomatic PE, and between the reduction of asymptomatic DVT and that of PE. However, in studies comparing LDUH and LMWH, the reduction of PE cannot be predicted as accurately by the reduction of asymptomatic DVT, mainly because of the wide CI around the estimate of the reduction of PE.

To overcome the limitation of using all (including *isolated calf*) asymptomatic DVT as the main endpoint, recent studies have used only asymptomatic *proximal* DVT as the major component of their primary endpoint: Proximal DVT correlates more closely than isolated calf DVT with the risk of PE and death.

Venography or Ultrasonography to Assess Asymptomatic Deep Vein Thrombosis

Venography was used in most studies in medical patients to evaluate the primary endpoint, although in one study,[247] the major component of the primary endpoint, asymptomatic proximal DVT, was assessed by systematic screening with CUS. There is, however, no convincing evidence that the technique of CUS is at least as reliable as venography for the diagnosis of asymptomatic proximal DVT.[248] CUS is more practical because it has almost no contraindication, thereby improving compliance, and it is now accepted as a diagnostic method for the evaluation of proximal DVT in prophylaxis studies by drug agencies.[249] In addition, dynamic CUS examinations can be fully videotaped and be read centrally by a core lab[247–250] as is done with venograms in other studies.

REVIEW OF EVIDENCE FOR THROMBOPROPHYLAXIS IN MEDICAL PATIENTS

Thromboprophylaxis in medical patients was mainly evaluated in hospitalized patients with an acute medical illness inducing a restricted mobility. Patients living in a nursing home with limited mobility or those needing long-term hospitalization for chronic conditions, such as paraplegia or the need for permanent respiratory assistance, may also be candidates for prophylaxis. However, no studies have been performed to evaluate the benefit of prophylaxis with the appropriate length of treatment.

Patients with cancer are at risk of VTE not only because of their disease but because anticancer drugs and central venous lines for anticancer treatments are additional risk factors. A clinically overt VTE may be the occasion for diagnosing a previously unknown cancer. The prognosis of VTE is more severe in patients with cancer than in patients without cancer.[251] A recent review of the literature showed there is no strong evidence to support the routine use of thromboprophylaxis to decrease the risk of VTE associated with central venous catheters (CVCs) or to improve survival in patients.[252] Regarding cancer patients receiving chemotherapy, the PROTECHT study recently suggested that LMWH compared with placebo in 1,150 patients could reduce the incidence of VTE from 3.9% to 2.0% in ambulatory patients with metastatic or locally advanced cancer.[253] Cancer patients suffering from an acute complication such as sepsis, heart, or respiratory failure are at very high risk of VTE.

Prophylaxis in Medical Patients with Acute Disease at High Risk of Venous Thromboembolism

Patients hospitalized for acute MI are at high risk of VTE. In a meta-analysis[254] reviewing placebo-controlled studies of antithrombotic drugs, the rate of PE in the placebo group was 3.9%. Prevention of recurrent MI rather than of VTE is the primary therapeutic objective in patients with acute MI. For this objective, patients with acute MI already receive combinations of high doses of antithrombotic agents, including fibrinolytics, antiplatelet agents (e.g., aspirin, clopidogrel, and glycoprotein IIb/IIIa antagonists) and heparin. Heparin confers incremental benefit in addition to other antithrombotic treatment for the prevention of VTE.[254]

Patients with acute hemiplegic stroke have an incidence of DVT of approximately 50% within 2 weeks in the absence of prophylaxis. Pulmonary emboli are frequent in patients who have a stroke; 13% to 25% of early deaths from stroke have been attributed to PE, most often between the 2nd and 4th weeks.[255] Aspirin given as soon as the diagnosis of ischemic stroke is confirmed can reduce the risk of recurrent stroke, improve survival, and help prevent PE (one event of PE avoided for 1,000 patients treated).[256,257] UFH, LMWH, and heparinoids have been evaluated in patients who have acute stroke. Although anticoagulants did not improve survival, LMWH was shown to reduce the risk of PE by 66% (OR, 0.34; 95% CI, 0.17 to 0.69) and DVT by 73% (OR, 0.27; 95% CI, 0.08 to 0.96). However, there was increased risk of major bleeding (OR, 2.17; 95% 1.10 to 4.28).[258] A review of studies, comparing UFH and LMWH, or heparinoids, which included five trials involving 705 patients, showed a statistically significant reduction of DVT in favor of LMWH (OR, 0.52;

95% CI, 0.56 to 0.79).[259] The recent PREVAIL study, comparing enoxaparin 40 mg once daily to UFH 5,000 U twice daily in 1,762 stroke patients, confirmed these results with a significant DVT risk reduction (RR 0.59; 95% CI, 0.46 to 0.76) in favor of enoxaparin but with a nonsignificant increase in major bleeding risk (RR = 1.66; 95% CI, 0.60 to 4.53).[260]

Prophylaxis in Other Medical Patients

There is a diversity of other acute medical conditions that may increase the risk of VTE. Thromboprophylaxis was evaluated in a number of trials with a broad spectrum of patients. Eligibility for these studies was mainly driven by the patient's global risk of developing VTE.

Mechanical Prevention

A few randomized studies performed in a limited number of patients, mainly surgical patients and patients with neurologic disorders, evaluated graduated compression stockings and IPC. The meta-analysis[62] of the studies performed in the absence of other prophylactic treatments showed an OR of 0.34 (95% CI, 0.25 to 0.46), favoring compression stockings over control for the reduction of asymptomatic DVT. There are limitations for the application of these studies in medical patients. To our knowledge, no randomized clinical trials have evaluated mechanical methods of prophylaxis in general medical patients. None of the two meta-analyses were powered to demonstrate a beneficial effect on the reduction of PE. Because of their safety, the use of mechanical prophylaxis could be recommended in medical patients with risk factors for VTE in whom there is a strict contraindication to prophylaxis with anticoagulants or in patients already receiving anticoagulant for a potential additive benefit.

Antiplatelet Agents

Antiplatelet agents, aspirin in particular, may have some benefit in preventing VTE,[23,261] but only eight randomized studies, with <600 patients, have compared antiplatelet agents versus no prophylaxis in medical patients. A meta-analysis of these clinical trials has shown a statistically nonsignificant 47% ± 17% odds reduction in asymptomatic DVT with antiplatelet agents (39 out of 261 patients vs. 61 out of 266 patients), whereas there was no effect on the bleeding risk (major event rate of <1% in the two groups).[261]

Short-Term Prophylaxis with Heparin and Low-Molecular-Weight Heparin

A meta-analysis of 15,095 patients concluded that in hospitalized medical patients heparin showed a statistically significant reduction in the risk of asymptomatic DVT by 56% (relative risk [RR], 0.44; 95% CI, 0.29 to 0.64; $P < 0.001$) and the risk of PE by 52% (RR, 0.48; 95% CI, 0.34 to 0.68; $P < 0.001$).[262] There was a nonsignificant ($P = 0.08$) adverse trend for major bleeding and a neutral effect for total mortality. There were limitations for the interpretation of the results of the meta-analysis such as the heterogeneity of the different studied populations and the relative small number of patients in most of them. Since these meta-analyses, three placebo-controlled studies have been designed with more solid methodology to evaluate the benefit of thromboprophylaxis in acutely ill medical patients.[250,263,264] The three studies included patients hospitalized for acute medical illness requiring temporary immobilization and sufficient VTE risk factors, to ensure a moderate level of VTE risk (see Table 86.6). Higher-risk patients, such as patients with acute stroke or acute MI, were not eligible. The three studies showed consistent efficacy results for enoxaparin, dalteparin, and fondaparinux—a reduction of VTE in the range of 50%. The RRs for each study are: MEDENOX[263]: 0.37 (95% CI, 0.22 to 0.63), PREVENT[250]: 0.55 (95% CI, 0.38 to 0.80), and ARTEMIS[264]: 0.53 (95% CI, 0.31 to 0.92). The overall estimate of the RR from these three trials is 0.50 (95% CI, 0.38 to 0.66). When looking at the reduction of asymptomatic proximal DVT or symptomatic VTE in the three studies, there is again a consistent approximate 50% reduction in favor of the prophylaxis (see Table 86.7). The previous meta-analysis was then updated with the results of these three studies and showed that during prophylaxis there is a significant risk reduction in symptomatic PE: RR = 0.43 (95% CI, 0.26 to 0.71), in fatal PE: RR = 0.38 (95% CI, 0.21 to 0.69), and without any significant increase in major bleeding: RR = 1.32 (95% CI, 0.73 to 2.33).[265]

The internal comparison of LMWH to LDUH in this setting was addressed in meta-analysis.[262] Two additional studies were published in 2010 with 3,564 patients.[266,267] Combining these new data with the previous meta-analysis, LMWH appears to be as effective as LDUH but safer in terms of major bleeding risk: RR = 0.54 (95% CI, 0.31 to 0.94), $P = 0.03$ (unpublished data).

Long-Term Prophylaxis with Heparin and Low-Molecular-Weight Heparin

In all the previous trials, the active pharmacologic prophylaxis was given for a mean duration of 2 weeks. A more prolonged VTE prophylaxis was recently assessed in the EXCLAIM study in 5,963 acutely ill medical patients.[268] In this double-blind study, a long term-prophylaxis (28 ± 4 days) with enoxaparin 40 mg once daily was compared to a short-term duration (10 ± 4 days) with the same drug. The overall results showed a significant risk reduction in VTE from 2.5% to 4.0%: absolute risk difference = −1.53 (95% CI, −2.54 to 0.52) counterbalanced by a significant increase in major bleeding risk from 0.3% for the shorter duration to 0.8% for the longer duration; absolute difference risk = 0.51 (95% CI, 0.12 to 0.89).[268] The interpretation of this study is complicated because the protocol had to be amended during the study in order to increase the VTE risk profile of the studied population.

Thromboprophylaxis with New Oral Anticoagulants

Two direct anti-Xa inhibitors have been tested for VTE prophylaxis in acutely ill medical patients with two similar studies comparing long-term prophylaxis with rivaroxaban or apixaban, respectively, to short-term prophylaxis with enoxaparin (MAGELLAN study: ClinicalTrials.gov Identifier NCT00571649) and long-term Apixaban to short-term enoxaparin (ADOPT study: ClinicalTrials.gov Identifier NCT00457002). In the Magellan study, 8,101 patients were randomized to rivaroxaban 10 mg once daily for 35 days or the standard approved dose of enoxaparin (40 mg once daily by subcutaneous injection for 10 days). Patients included had one or more acute medical conditions, including infectious disease, heart failure, respiratory insufficiency, ischemic stroke, active cancer, or inflammatory/rheumatic diseases; 30% had two or more such conditions. The primary efficacy outcome, a composite of asymptomatic proximal DVT (detected by ultrasonography), symptomatic DVT, symptomatic nonfatal PE, and VTE-related death was reached at 35 days in 4.4% of patients on rivaroxaban versus 5.7% in patients on enoxaparin (HR 0.77; 95% CI, 0.62% to 0.96). The primary safety outcome, a composite of treatment-related major bleeding and clinically

relevant nonmajor bleeding, was increased with rivaroxaban at 10 days (2.8% vs. 1.2%; HR 2.3; $P \leq 0.0001$) and at 35 days (1.4% vs. 0.5%; HR 3.0; $P \leq 0.0001$).

APPLICATION OF THROMBOPROPHYLAXIS IN MEDICAL PATIENTS: FROM RANDOMIZED STUDIES TO REAL LIFE

One alleged limitation to these studies was that patients enrolled did not represent real-life patients. In fact, requiring risk assessment in the selection of patients in the latest studies, rather than a specific disease, makes the results more applicable to all patients who present with similar levels of risk. Subgroup analyses have confirmed that the proportional risk reduction in favor of prophylaxis applies to almost all subgroups of patients.[268,269] Patients receiving antiplatelet treatment, for example, for coronary disease, benefit from the addition of heparin or LMWH.[270] Similarly, the effect of mechanical prevention, such as compression stockings,[62] seems to be additive to pharmacologic thromboprophylaxis. On the other hand, the benefit to risk ratio of thromboprophylaxis with anticoagulants deserves to be discussed especially for patients at risk for bleeding, such as stroke patients, renally impaired patients as well as the use of long-term prophylaxis. Relevant to this point is a bleeding score that recently was developed by performing regression analysis in the patients of the EXCLAIM study.[271] The score consists of several items related to bleeding, for example, age, renal insufficiency, current malignancy. When applied, approximately 90% of the total population had a bleeding risk score of at least 7.0 points. More than one-half of all major bleeding (54%), and more than one-third (36%) of any bleeding (major or nonmajor but clinically relevant) occurred in the 10% of acutely ill hospitalized medical patients who had a bleeding risk score of 7.0 points (for the group of patients for whom bleeding contributed to death, the mean score was 8.6). Both major bleeding and any bleeding were uncommon in patients with a bleeding risk score of <7.0. This score has however two disadvantages, that is, it has been

Probability of Bleeding

Major: 0.1%

Clinically Important: 0.5%

FIGURE 86.1 The International Medical Prevention Registry on Venous Thromboembolism (IMPROVE) bleeding risk tool, a web-based tool for calculation of risk score for bleeding in medically ill patients. This is available at www.outcome-umassmed.org/IMPROVE. This model provides an estimate of the risk of major or clinically important bleeding of in-hospital patients from admission up to 14 days after admission. Answering one or more of the questions with "yes," being male, elevated age and lowered glomerular filtration rate increase probability of bleeding. Probability of bleeding is automatically calculated based on the bleeding risk score. Decousus et al. published a plot in which the bleeding rate could approximately be determined using the risk score. (See Decousus H, Tapson VF, Bergmann JF, et al. Factors at admission associated with bleeding risk in medical patients: Findings from the IMPROVE investigators. *Chest* 2011;139(1);69–79.)

derived post hoc and contains a large number of items, making it difficult to memorize. However, all items can be entered into a web based score calculator. (http://www.outcomes-umassmed.org/IMPROVE/bleeding_risk_score.cfm) (FIGURE 86.1). When proven to be consistent in prospective studies, this score could potentially help clinicians to estimate the bleeding risk for an individual patient.[241] Finally, a systematic assessment of both VTE and bleeding risks could improve the optimal use of thromboprophylaxis.

Questions Still to be Appropriately Addressed

Should outpatients at risk of VTE be given thromboprophylaxis? There is still a substantial number of VTE occurring outside the hospital, and risk factors in outpatients are the same as in patients who are hospitalized. The benefit and feasibility of outpatient prophylactic, as well as curative treatment with anticoagulants, has long been established for a variety of indications. Many patients at risk for VTE remain in nursing homes and may well benefit from thromboprophylaxis. Additionally, patients treated at home with similar diseases and risk factors as those evaluated in hospital studies should probably benefit from thromboprophylaxis. However, the risk-to-benefit ratio should be carefully considered in these patients who may be less compliant.

For how long should treatment be given? Typically, in the clinical trials performed so far, UFH and LMWH prophylaxis did not exceed 2 weeks. The preliminary results provided by the EXCLAIM study[268] should be confirmed with other anticoagulants in order to determine whether extended prophylaxis confers systematically additional benefit.

CONCLUSIONS

VTE remains a public health burden. The results of recent, well-conducted clinical trials reinforce the evidence-based recommendations for more systematic assessment of global risk of VTE in medical patients and for the wider use of thromboprophylaxis. Patients should be carefully selected for high risk of both VTE as well as bleeding.

CHAPTER

87 Treatment of Venous Thromboembolic Disease

SAM SCHULMAN, JEFFREY GINSBERG, AND JAMES DOUKETIS

The management of venous thromboembolic disease has in some respects taken recent giant leaps forward but has in other domains remained stagnant. Whereas the anticoagulant treatment during the past two decades has become simplified and more patient-friendly, the prevention and treatment of long-term sequelae has not improved significantly. Knowledge regarding the molecular biology of thrombosis risk factors and the pharmacogenomics of vitamin K antagonists (VKAs) has undergone a remarkable expansion. However, to date, this has had very limited effect on the practical management of patients with venous thromboembolism (VTE). This chapter focuses on the treatment of deep vein thrombosis (DVT) in the lower extremity and of pulmonary embolism (PE), which are by far the most common locations, often simultaneous, of VTE. Thrombophlebitis will also be discussed herein, whereas Chapter 84 has been devoted to all other types of venous thrombosis.

INITIAL THERAPY

First Anticoagulant Dose in Relation to Diagnosis

As soon as a DVT or PE is suspected, it is crucial to promptly assess the patient to optimize management, which usually includes initiating anticoagulant therapy in those with established DVT or PE and as an interim measure until definitive diagnostic testing is performed. Treatment should start before the diagnosis of DVT or PE has been confirmed in two common scenarios. The first is the patient arriving at the emergency room with symptoms suggestive of DVT and in whom lower limb venous ultrasound is not available and has to be deferred until the next morning. If a standardized clinical prediction rule (see Chapter 83) shows that DVT is likely and the patient has a low risk of bleeding, a dose of low molecular weight heparin (LMWH) should be given while awaiting definitive diagnostic testing.[1] If the bleeding risk is high, it is acceptable to defer therapy until the diagnosis of DVT has been verified; in such patients, best efforts should be made to establish a definitive diagnosis on the day of presentation.

The second scenario occurs in the patient with likely PE according to a clinical prediction rule, in whom it is unacceptable to defer anticoagulant therapy until the diagnosis of PE is confirmed.[1]

Patients with Low Benefit of Therapy

In two randomized controlled trials (RCTs), in which 254 patients with DVT were treated with heparin or placebo and had 3 to 24 weeks of follow-up observation, the risk for disease recurrence was 7% and 21% in the treated and untreated groups, respectively, calculated to a convincing number-needed-to-treat of only seven patients to prevent one recurrent thrombosis.[2,3] However, the need to treat isolated calf DVT has been questioned, based on observational data showing low risk of progression or recurrence without anticoagulation.[4] A comparison of nadroparin versus placebo (CACTUS trial) in patients with isolated calf DVT is ongoing and may resolve this uncertainty (ClinicalTrials.gov NCT00421538). In the meantime, for patients with isolated calf DVT and minimal or no symptoms, it may be reasonable to withhold anticoagulation, perform repeat venous ultrasound testing for 2 weeks, and initiate anticoagulation only if there is thrombus progression into proximal veins. An increasingly prevalent patient group is one with asymptomatic, incidentally identified PE, typically detected by contrast-enhanced computed tomography pulmonary angiography (CTPA) while assessing another disease. On one hand, anticoagulant-treated patients with cancer and incidental PE have similar high risks of recurrent VTE, bleeding, and death as patients with symptomatic PE.[5] On the other hand, the introduction of multiple-detector CTPA has doubled the rate of diagnosis of subsegmental PE compared with single-detector CTPA (9.4% vs. 4.7%) without any change in the 3-month risk of symptomatic VTE.[6] It therefore seems reasonable to withhold anticoagulant treatment of incidental subsegmental PE, particularly if the patient has no active cancer.

Treatment Options for the Initial Phase

The initial therapeutic options are schematically depicted in FIGURE 87.1. The first decision for patients with extensive VTE should be whether thrombolytic therapy (or in rare cases surgical removal) is indicated.

Massive PE, defined as symptomatic PE associated with hemodynamic instability or respiratory failure, is immediately life threatening, with a 90-day overall mortality rate of 53%.[7] Thus, in case of hemodynamic instability (systolic blood pressure <90 mm Hg, tachycardia, elevated jugular venous pressure, clinical evidence of poor tissue perfusion, hypoxemia), there is a need for rapid resolution of the pulmonary artery obstruction. Anticoagulants have too slow an effect and, unless absolutely contraindicated due to active bleeding or recent hemorrhage in the central nervous system, systemic thrombolytic therapy should be administered as soon as the diagnosis has been verified. Thrombolysis is also indicated if the patient deteriorates while receiving anticoagulant therapy. Further details on thrombolytic therapy can be found in Chapter 112.

If thrombolytic therapy fails to improve hemodynamic instability, emergency surgical embolectomy is indicated but requires surgical expertise.

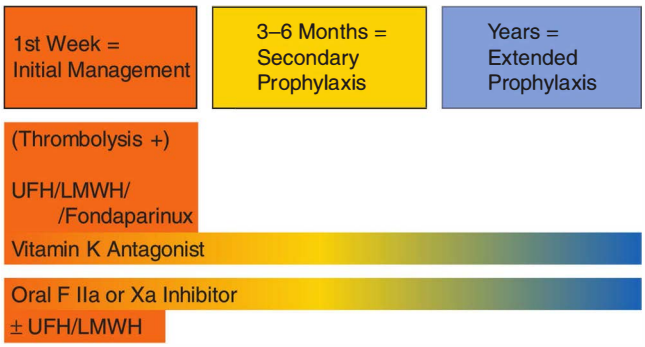

FIGURE 87.1 The pharmaceutical options and phases of treatment of VTE.

For patients with submassive PE, defined as PE without hemodynamic instability or respiratory insufficiency, there is, to date, no compelling evidence to support the use of thrombolytic therapy. In a systematic review, when thrombolytic therapy was compared with heparin for patients with submassive PE, there was no significant difference in the risk for death (odds ratio [OR], 0.89; 95% confidence interval [CI], 0.45 to 1.78), recurrent VTE (OR, 0.63; 95% CI, 0.33 to 1.20), or major hemorrhage (OR, 1.61; 95% CI, 0.91 to 2.86).[8] An RCT (PEITHO) comparing thrombolysis with anticoagulant therapy in patients with PE and acute right ventricular dysfunction or enlargement based on echocardiography or CTPA is ongoing (ClinicalTrials.gov NCT00639743).

Massive DVT, defined as DVT that is associated with limb ischemia or involving the iliofemoral veins, also warrants consideration of thrombolytic therapy. The evidence to support such treatments, however, is weak so far. Systemic thrombolytic therapy has been compared to anticoagulant therapy in several small RCTs, which consistently show more complete and rapid thrombus dissolution, but higher bleeding rates. Further, the studies do not show convincing evidence that the incidence of postthrombotic syndrome (PTS), the important long-term sequel to DVT, is reduced. Two RCTs have assessed catheter-directed thrombolysis for iliofemoral DVT, with the objective of reducing the risk of PTS.[9,10] This treatment is usually performed in a specialized clinical setting such as an intensive care unit and involves catheterization of the popliteal or femoral vein, infusion of a thrombolytic agent over a 1- to 2-day period, and repeat venography to monitor the treatment effect. Such treatment also confers an increased risk of bleeding related to the thrombolytic agent and the invasive procedure. More rapid resolution of massive DVT can be obtained with a combined pharmacomechanic and thrombolytic approach, which also should reduce the dose of the thrombolytic agent, thereby potentially reducing the risk of bleeding. This approach is being evaluated in the ATTRACT trial, which includes patients with DVT that involves the femoral or more proximal veins (ClinicalTrials.gov NCT00790335).

Patients with DVT associated with severe symptoms (*phlegmasia cerulea dolens* or *phlegmasia alba dolens*, see Chapter 83) are at high risk for developing the PTS and, occasionally, limb loss and should be considered for catheter-directed or systemic thrombolytic therapy. Ideally, patients should receive this treatment within 14 days of the onset of symptoms.

The majority of patients, without these potentially life- or limb-threatening conditions, should receive one of the treatment options summarized in Table 87.1.

Table 87.1

Initial treatment of patients with VTE who do not have an indication for thrombolysis or surgery[a]

Treatment	DVT	Nonmassive PE[b]
UFH		
Intravenous[c]	According to aPTT[d]	According to aPTT[d]
Subcutaneous	According to aPTT[d]	According to aPTT[d]
Subcutaneous	Weight-adjusted dose[e]	Weight-adjusted dose[e]
LMWH (All Subcutaneous)		
Dalteparin	200 IU/kg once daily	As DVT or 120 IU/kg b.i.d.
Enoxaparin	1.5 mg/kg once daily	As DVT or 1 mg/kg b.i.d.
Nadroparin	171 IU/kg once daily	85 IU/kg b.i.d.
Tinzaparin	175 IU/kg once daily	As DVT
Fondaparinux (Subcutaneous)		
	7.5 mg once daily[f]	7.5 mg once daily[f]
Direct Xa Inhibitor (Oral)		
Rivaroxaban	15 mg twice-daily (first 3 wk)	15 mg twice-daily (first 3 wk)

[a]The drugs or doses may not be approved in all countries or jurisdictions.
[b]Patients who are hemodynamically stable.
[c]Continuous infusion.
[d]aPTT range corresponding to anti-Xa levels 0.3 to 0.7 IU/mL. Starting dose is with intravenous bolus of 80 U/kg, followed by 18 U/kg/h intravenously or with 17,500 IU/kg b.i.d. subcutaneously.
[e]Given twice daily, first dose 500 IU/kg, then 333 IU/kg, without aPTT monitoring.
[f]5 mg for patients with body weight <50 kg; 10 mg for patients with body weight >100 kg.

Initial Treatment with Unfractionated Heparin

Intravenous unfractionated heparin (UFH), which was the initial treatment standard until 10 to 15 years ago, is currently mainly used for special patient groups summarized in Table 87.2. It is usually recommended to initiate UFH treatment with a bolus dose of 80 IU/kg followed by an infusion of 18 U/kg/h.[1] This UFH regimen is based on three RCTs totaling 292 patients,

Table 87.2

Patients suitable for initial intravenous UFH therapy rather than subcutaneous LMWH

Population	Reason for Intravenous Heparin
High risk of bleeding	Quickly eliminated on discontinuation
	Effective antidote available
Candidates for thrombolysis	Quick elimination before next step or surgery
Very ill patients	Poor subcutaneous absorption

which compared this or a similar regimen with fixed initial dosing.[11–13] The dose is then adjusted according to the results of an activated partial thromboplastin time (aPTT) performed 4 to 6 hours after initiation of UFH to keep the aPTT in a therapeutic range. aPTT reagents vary in their sensitivities to UFH so that an aPTT range that corresponds to an anti-factor Xa heparin level of 0.3 to 0.7 IU/mL should be targeted.[1] Subcutaneous injection of UFH versus intravenous therapy, both adjusted according to the aPTT, was compared in a meta-analysis of six trials totaling 783 patients[14] and demonstrated favorable results with subcutaneous UFH for recurrent VTE (relative risk [RR], 0.62; 95% CI, 0.39 to 98) and major bleeding (RR, 0.79; 95% CI, 0.42 to 1.48). A subcutaneous, weight-adjusted, unmonitored UFH regimen (250 IU/kg twice-daily dosing after a 333 U/kg initial dose) was compared with LMWH therapy in an RCT (FIDO) of almost 700 patients with DVT or PE.[15] There was no statistically significant difference in the incidence of recurrent VTE (3.8% vs. 3.4%) or major hemorrhage during the first 10 days (1.1% vs. 1.4%) with fixed-dose, unmonitored UFH and LMWH. This is the only UFH regimen that allows for convenient outpatient therapy, which actually was achieved entirely for 72% of the patients in this treatment group in the study.

Initial Treatment with LMWH

Over the past 10 to 15 years, the initial treatment of DVT with LMWH has become standard therapy due to its convenience of once-daily subcutaneous dosing, and no requirement for laboratory monitoring. For patients with PE, a twice-daily LMWH regimen is usually recommended (Table 87.1). Several meta-analyses have compared the efficacy and safety of LMWH with UFH. The results of the systematic review by van Dongen[16] are summarized in Table 87.3, showing that in addition to the convenience of administration and the compelling data on the safety without laboratory monitoring, LMWH also has a lower potential for heparin-induced thrombocytopenia (HIT) than UFH. As for individual LMWH regimens, a meta-analysis of five trials totaling 1,508 patients compared once- versus twice-daily LMWH regimens and showed no significant difference in recurrent VTE (OR, 0.82; 95% CI, 0.49 to 1.39), major hemorrhage (OR, 0.77; 95% CI, 0.40 to 1.45), or death (OR, 1.14; 95% CI, 0.62 to 2.08).[17]

Initial Treatment with New Anticoagulants

Fondaparinux is an indirect inhibitor of factor Xa that is produced synthetically, with a lower risk for allergic reactions and a negligible risk for HIT. However, its elimination half-life is longer than that for LMWH (17 hours vs. 4 to 5 hours), which may be a drawback in cases of bleeding or perioperative management. The treatment dose of fondaparinux is 7.5 mg once daily (5 mg for body weight <50 kg; 10 mg for weight >100 kg). This dose regimen was compared in the MATISSE trials against LMWH (enoxaparin 1 mg/kg twice daily) in approximately 2,200 patients with DVT and against intravenous UFH in 2,200 patients with PE.[18,19] The efficacy (recurrent VTE) and safety (major bleeding) were similar for fondaparinux and LMWH (or UFH) in these trials. Fondaparinux is currently the preferred initial anticoagulant in patients with recent HIT, occurring within the preceding 100 days. Rivaroxaban, a direct factor Xa inhibitor, is so far the only available oral anticoagulant shown to be effective for the initial treatment of VTE, although at the time of writing it has not been approved for this indication. In the phase III trial (EINSTEIN DVT), rivaroxaban was given at a dose of 15 mg twice daily for 3 weeks, followed

Table 87.3

Outcomes in meta-analysis of trials comparing fixed-dose LMWH with adjusted-dose UFH for the treatment of VTE

Outcome	Studies	Odds Ratio	95% Confidence Interval
VTE Overall			
Recurrence			
During initial treatment period	15	0.68	0.48–0.97
At 3 mo	13	0.68	0.53–0.88
At 6 mo	6	0.68	0.48–0.96
At end of follow-up	18	0.68	0.55–0.84
Major hemorrhage	19	0.57	0.39–0.83
Death at end of follow-up	18	0.76	0.62–0.92
Proximal DVT Alone			
Recurrence at end of follow-up	9	0.57	0.44–0.75
Major hemorrhage	8	0.50	0.29–0.85
Death	8	0.62	0.46–0.84
PE Alone			
Recurrence at end of follow-up	4	0.88	0.48–1.63

van Dongen CJJ, van der Belt AGM, Prins MH, et al. Fixed dose subcutaneous low molecular weight heparins versus adjusted dose unfractionated heparin for venous thromboembolism. *Cochrane Database Syst Rev* 2004;(4):CD001100.

by a dose of 20 mg once daily, whereas standard therapy with enoxaparin was given for 5 to 10 days followed by a VKA.[20] Rivaroxaban was noninferior to standard therapy for recurrent VTE during the entire study period (how long was the study period?) (2.1% vs. 3.0%; hazard ratio [HR], 0.68; 95% CI, 0.44 to 1.04); moreover, there was no excess in recurrent VTE events during the initial treatment period. Clinically relevant bleeding was seen in 8.1% of patients in each group.

A similar treatment strategy is used in the ongoing phase III trial with the oral factor Xa inhibitor apixaban in the treatment of VTE (AMPLIFY; ClinicalTrials.gov NCT00643201). Apixaban is given at a dose of 10 mg twice daily for the first week, followed by 5 mg twice daily and compared with standard therapy of an LMWH and a VKA.

Studies with the oral factor Xa inhibitor, edoxaban tosylate (NCT00986154), and the oral direct thrombin inhibitor, dabigatran etexilate (RE-COVER trial),[21] assessed treatment only after an initial 5 to 10 days of treatment with an LMWH (or UFH).

Outpatient Treatment of VTE

In the large majority (>80%) of patients with DVT, anticoagulant therapy can be done out-of-hospital by subcutaneous LMWH, which can be self-administered by the patient or with assistance from a family member or a health professional. Most trials supporting outpatient management are designed in a way that makes interpretation of the results difficult since the comparator group was in-hospital treatment with UFH.[1] One study directly compared outpatient versus inpatient treatment with LMWH in 201 patients with VTE and found no difference in clinical outcomes but a 56% cost reduction with outpatient therapy.[22] For patients with PE, a clinical prediction rule for risk stratification such as the Pulmonary Embolism Severity Index (PESI)[23] may be used to assess the safety of outpatient management (see Chapter 83). Several retrospective cohort studies have assessed out-of-hospital management of patients with hemodynamically stable PE who did not require oxygen or narcotic analgesics and were at low risk for bleeding.[24,25] After 3 months of follow-up, there were no cases of fatal PE. A recently published RCT compared inpatient and outpatient treatment for 344 patients with PE at low risk of death, defined as PESI class I or II.[26] The mean stay in hospital was 3.9 and 0.5 days, respectively. During the 90-day follow-up, there was one death but no recurrent VTE or major bleeding among those treated as inpatients compared to one death, one recurrent VTE, and two major bleeding events (within 14 days) among those randomized to outpatient therapy, fulfilling the preset noninferiority criteria. Taken together, these studies suggest that most patients with DVT and at least 40% of patients with PE[23]—after careful risk stratification and documentation—can be treated entirely as outpatients.

Inferior Vena Cava Filter for the Treatment of VTE

An RCT (PREPIC) involving patients with proximal DVT assessed whether, in addition to anticoagulant therapy, placement of an inferior vena cava (IVC) filter, compared with anticoagulation alone, would improve clinical outcomes.[27] After 2 years of follow-up, patients with an IVC filter had a reduction of asymptomatic or symptomatic PE at 12 days (OR, 0.22; 95% CI, 0.05 to 0.90) but were at increased risk for recurrent symptomatic DVT at 2 years (OR, 1.87; 95% CI, 1.10 to 3.20) compared to patients without a filter. Mortality rates were similar in both groups. These results were corroborated in an 8-year follow-up of the same population.[28] Insertion of an IVC filter should considered only if (a) there is an absolute contraindication to anticoagulation therapy, or (b) a treatment failure occurs despite adequate anticoagulation manifest by a new symptomatic DVT or PE (see also Chapter 114).

Initial Supportive Therapy for VTE

Patients with acute DVT who are treated in hospital are sometimes kept in bed due to presumed fear of thrombus detachment and embolization with ambulation. However, a systematic review of five RCTs (3,048 patients) that compared bed rest versus early ambulation after DVT or PE showed that early mobilization did not increase the risk for new PE (RR, 1.03; 95% CI, 0.65 to 1.63) or death (RR, 0.79; 95% CI, 0.40 to 1.56).[29]

Leg edema associated with DVT may be treated with leg elevation and graduated compression stockings. It may be preferable to defer the use of compression stockings until the edema and associated leg pain and inflammation have subsided, which may take 1 to 3 weeks. In one small randomized trial, early start with a compression stocking was associated with decreased thrombus resolution when assessed by venous ultrasound,[30] although opposite findings were reported in another randomized trial.[31]

Treatment of DVT with NSAIDs alone versus UFH has been studied in two small RCTs, and a Cochrane review reported that the poor methodological quality of these studies precluded conclusions about treatment efficacy.[32]

SECONDARY PROPHYLAXIS

It is necessary to continue anticoagulant therapy for at least 3 months in the majority of patients with VTE. In an RCT involving 51 patients with calf DVT, all of whom received compression stockings, treatment with UFH alone was compared with 3 months of treatment consisting of UFH and a VKA.[33] After 3 months of follow-up, there were eight recurrent VTE events in the UFH-only group and no recurrences in the UFH plus VKA group. In another RCT of 68 patients with proximal DVT, treatment with 4 weeks of a VKA was compared with fixed, low-dose UFH (5,000 IU twice daily for 14 days) and recurrent VTE occurred in 0 and 9 patients treated with a VKA and heparin alone, respectively.[34] When coupled with indirect evidence from large RCTs comparing short (4 to 6 weeks) with longer duration VKA therapy,[35,36] there is compelling evidence that a short, 10- to 14-day, course of anticoagulant therapy is not sufficient to protect patients with acute VTE from subsequent recurrent disease.

Vitamin K Antagonists—Initiation

The current standard of practice to manage patients with DVT or PE is anticoagulation with a VKA for 3 to 6 months, which should be followed by an assessment to decide if longer-duration treatment is warranted. Due to the delay until therapeutic international normalized ratio (INR) levels are reached after VKA initiation, such treatment should be started simultaneously with UFH or LMWH therapy. Four RCTs (807 patients)

compared immediate versus delayed start of VKA after VTE and showed no difference in clinical outcomes, but the length of hospitalization was shortened by 4 days with immediate VKA treatment.[37–40]

Warfarin is usually started at a dose of 5 mg daily, with dose adjustments at 2 to 3 days and as needed to attain an INR target of 2.5 (INR range: 2.0 to 3.0) (see Chapter 106). There is no difference in clinical outcomes using a higher ("loading") dose of warfarin, compared with no loading dose.[41–45] Two cohort studies (1,054 outpatients) used a warfarin nomogram with 10 mg daily for the first 2 days and demonstrated a 3-month recurrence rate of VTE of 1.9% and major bleeding of 1.0%,[46,47] results that are clinically acceptable. Irrespective of the warfarin initiation regimen, treatment with LMWH or UFH should continue for at least 5 days, with a purpose of achieving a therapeutic INR for 2 consecutive days.

Vitamin K Antagonists—Maintenance

The intensity of anticoagulation with VKA for patients with VTE is the same as for most other clinical indications, with an INR target of 2.5 (range: 2.0 to 3.0).[48] It was thought that patients with antiphospholipid syndrome-related thrombosis should have a higher intensity INR, but studies failed to show therapeutic benefit with an INR of 3.0 to 4.0 or 3.0 to 4.5 compared with an INR range of 2.0 to 3.0.[49,50]

LMWH for Secondary DVT Prophylaxis

In a meta-analysis of seven RCTs (1,379 patients) of long-term treatment with LMWH compared with VKA therapy,[51] with variable once-daily LMWH dosages,[50–56] there was no significant difference for recurrent VTE (OR, 0.66; 95% CI, 0.41 to 1.07), major hemorrhage (OR, 0.45; 95% CI, 0.18 to 1.11), or death (OR, 1.11; 95% CI, 0.78 to 1.83).[51] Excluding the study with the highest dose of LMWH[52] did not alter the results.

In an RCT (CLOT trial) that compared LMWH with VKA treatment of VTE (672 patients with cancer),[53] LMWH therapy (dalteparin 200 IU/kg/d for 1 month, then 150 IU/kg/d for 5 months) conferred a significant reduction in recurrent VTE (HR, 0.48; 95% CI, 0.30 to 0.77) with no significant difference in major bleeding or death. Another study of 146 patients with cancer and VTE ("CANTHANOX"), which compared LMWH (enoxaparin 1.5 mg/kg/d) with VKA, did not detect any difference in recurrence, but there was a trend to fewer major hemorrhages and deaths with LMWH therapy.[54] Thus, there seems to be a clinical advantage of continuing with LMWH rather than transitioning to a VKA in patients with VTE associated with cancer. LMWH is effective despite chemotherapy-related emesis, and interruption of LMWH for invasive procedures is easier than with VKA therapy. Accordingly, LMWH is considered the drug of choice for patients with cancer-associated symptomatic VTE.[1]

Secondary Prophylaxis with the New Oral Anticoagulants

A phase III trial compared the oral factor Xa inhibitor rivaroxaban (15 mg b.i.d. for 3 weeks followed by 20 mg/d) without initial treatment with LMWH or UFH, with long-term VKA treatment for secondary VTE prophylaxis.[20] Clinical outcome rates were similar to those with VKA therapy, without the need for laboratory monitoring or dose adjustments.

Dabigatran etexilate, a prodrug that is converted after absorption to the active metabolite dabigatran, was compared with warfarin as secondary prophylaxis for 6 months in 2,539 patients with DVT or PE (RE-COVER).[21] Dabigatran (150 mg b.i.d.) was noninferior to warfarin for recurrent VTE or related death (HR, 1.10; 95% CI, 0.65 to 1.84). The risk for major bleeding was similar (HR, 0.82; 95% CI, 0.45 to 1.48), but there was a significant reduction of clinically relevant (major and nonmajor) bleeding (HR, 0.63; 95% CI, 0.47 to 0.84). There was no difference in overall deaths, elevation of liver enzymes, or occurrence of acute coronary syndrome. As with rivaroxaban, dabigatran does not require laboratory monitoring or dose adjustments. These drugs, and other drugs currently under investigation (see Chapter 110), will become valuable alternatives to VKA for this indication.

Shorter Duration of Secondary Prophylaxis

Anticoagulant therapy should continue for at least 3 months to minimize the risk of recurrence. However, patients with distal DVT occurring in association with a reversible risk factor, such as the postoperative state, have a low risk of recurrence, 9% over 6 years.[55] In a Swedish study comparing 6 weeks versus 6 months of VKA after VTE (DURAC I),[36] 6 weeks of treatment was sufficient to prevent VTE recurrence. In a French study assessing different durations of VKA therapy (DOTAVK), there was no difference in VTE recurrence between 6 and 12 weeks of treatment of patients with distal DVT.[56] Thus, select patients with distal, provoked DVT may be treated for only 6 weeks, in which cases it may be easier to simply treat with LMWH rather than a VKA.

Additional Management Options during the Period of Secondary DVT Prophylaxis

Graduated compression stockings (worn for 2 years after DVT) may decrease the overall incidence of PTS by 70% (OR, 0.30; 95% CI, 0.20 to 0.48), with a similar reduction of severe PTS manifestations (OR, 0.39; 95% CI, 0.20 to 0.76).[57] The studies had design flaws, mainly that the investigators and patients were not blinded, but a recently completed double-blind RCT (SOX) that assessed stockings against sham stockings will provide valuable information.[58] At 2 to 4 weeks after the diagnosis of DVT, persistent leg swelling and pain predicts an increased risk for PTS,[59] in which case compression stockings should be used. Additional risk factors for PTS are recurrent DVT, extensive DVT, obesity, and advanced age (see Chapter 85).

Investigation for occult malignancy in patients with unprovoked (or idiopathic) VTE is an often-debated issue. Previously undiagnosed cancer has been found in 6.1% of patients with newly diagnosed VTE (95% CI, 5.0% to 7.1%) and in 10.0% (95% CI, 8.6% to 11.3%) in the next 12 months.[64] Limited screening increased the proportion of patients found to have previously undiagnosed cancer to 49.4% (95% CI, 40.2 to 58.5) and CT of the abdomen and pelvis increased the proportion further to 69.7% (95% CI, 69.1 to 77.8). However, extensive screening is not associated with a reduction of cancer-related mortality.[60] Patients with bilateral DVT, concomitant superficial thrombophlebitis, or VTE progression despite adequate

therapy have a higher risk of malignancy. The SOMIT trial, in which 201 patients with unprovoked VTE were randomized to extensive screening for malignancy or no screening, and CT scanning of the chest, abdomen and pelvis provided the highest yield for occult cancer.[61]

Investigation for thrombophilia in patients with VTE is also widely debated. The yield of the investigation is low in the elderly and for provoked VTE, and in most patients, the results do not alter management. The presence of heterozygous factor V Leiden or prothrombin gene mutation (G20210A) is common but not associated with a clinically important increased risk for disease recurrence (see Chapter 81, Table 81.3). An algorithm for thrombophilia work-up suggests classifying available tests into three levels of priority.[62] We have removed homocysteine from the high-priority tests, based on the HOPE-2 trial. In this study of 5,522 patients with cardiovascular disease or risk factors, folic acid, vitamin B_6, and vitamin B_{12} reduced homocysteine levels by 2.2 μmol/L, in comparison with placebo, but had no effect on VTE (HR, 1.01; 95% CI, 0.66 to 1.53).[63] An algorithm for thrombophilia workup that takes into account the interpretation of protein C and protein S while a patient is receiving VKA therapy is shown in FIGURE 87.2 and Table 87.4.

Table 87.4

Priority of tests for thrombophilia

High-Priority Tests	Low-Priority Tests
Resistance to activated protein C	Fibrinogen level
Factor V Leiden mutation	Thrombin clotting time and further
Prothrombin G20210A	Analyses for dysfibrinogenemia
Factor VIII	Factor IX
Lupus anticoagulant	Factor XI
Cardiolipin/β_2-glycoprotein I antibodies	Homocysteine
Antithrombin activity	JAK2 mutation[a]
Protein C activity	
Protein S antigen, free fraction	

[a]JAK2 mutation is mainly of interest in patients with unexplained visceral vein thrombosis or in patients with features of myeloproliferative disease and unexplained thrombosis.
Modified from Seligsohn U, Lubetsky A. Genetic susceptibility to venous thrombosis. *N Engl J Med* 2001;344:1222–1231.

EXTENDED VTE PROPHYLAXIS

Duration of Anticoagulation After VTE

The risk of VTE recurrence after stopping anticoagulation is lower after distal than proximal DVT, but similar after PE and proximal DVT (Table 87.5).[64] Stopping anticoagulation after 3 months of treatment confers a similar risk of recurrence as discontinuation after 6 months or more (HR, 1.19; 95% CI, 0.86 to 1.65). These trials confirm that continuing anticoagulation in patients with unprovoked VTE prevents recurrent VTE, but only for as long as the patient takes anticoagulants. Consequently, a key management aim is to identify patients at low risk for recurrent VTE in whom long-term (or lifelong)

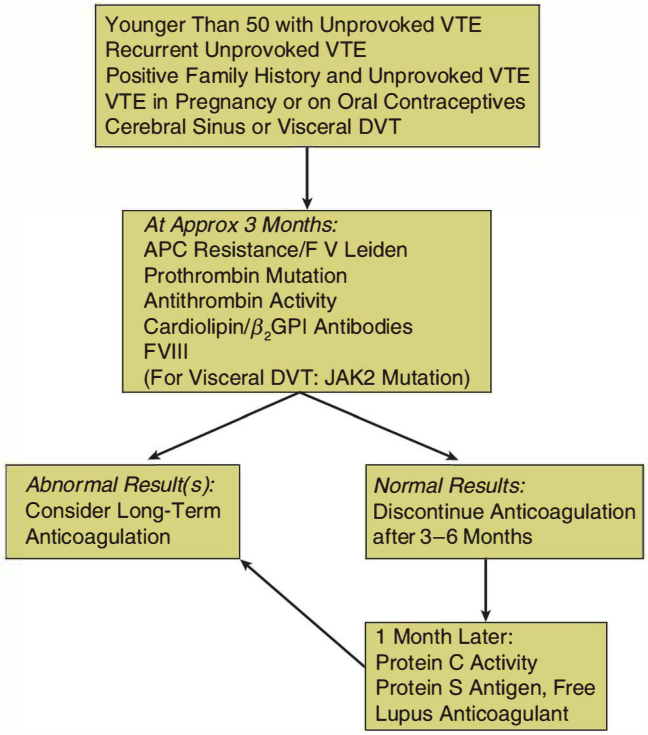

FIGURE 87.2 Algorithm for thrombophilia workup.

Table 87.5

Risk of recurrent VTE after discontinuation of anticoagulation

Variable	Hazard Ratio	95% Confidence Interval
Location of VTE—proximal DVT	1.0	(reference)
Distal DVT	0.49	0.34–0.71
PE	1.19	0.87–1.63
Unprovoked VTE	1.0	(reference)
Provoked VTE	0.55	0.41–0.74
Duration of anticoagulation—3 months	1.0	(reference)
1–1.5 mo	1.28	0.82–2.01
6 mo	0.80	0.51–1.25
12 or 27 mo	0.88	0.57–1.36

Multivariable Cox regression analysis of individual patient data (n = 2,925) from seven trials.
DVT, deep-vein thrombosis; VTE, venous thromboembolism.
Boutitie F, Pinede L, Schulman S, et al. Influence of preceding length of anticoagulant treatment and initial presentation of venous thromboembolism on risk of recurrence after stopping treatment: analysis of individual participants' data from seven trials. *BMJ* 2011;342:d3036.

anticoagulation can be avoided and patients at high risk for recurrence in whom long-term anticoagulation is justified. Identifying patients at low risk for VTE recurrence should consider patient gender, D-dimer levels, select thrombophilic abnormalities, and residual deep vein occlusion (Table 87.6), as well as patient preferences.

The PROLONG trial assessed the clinical utility of using D-dimer levels, when measured about 1 month after stopping anticoagulation to determine risk for recurrence and whether continued anticoagulation for more than 3 months is warranted.[65] Patients with abnormal D-dimer results who were randomized to remain off anticoagulation had a VTE recurrence rate of 15.0% versus 2.9% in patients who resumed anticoagulation (HR, 4.26; 95% CI, 1.23 to 14.6). Patients with a negative D-dimer who did not resume anticoagulation had a VTE recurrence rate of 6.2%. A pooled analysis of 1,818 patients with unprovoked VTE followed for 27 months after anticoagulation was stopped showed an annual recurrence rate of 3.7% (95% CI, 3.4 to 4.3) in patients with a normal D-dimer level and a recurrence rate of 8.8% (95% CI, 6.2 to 11.3) in patients with an elevated D-dimer result.[66] The timing of postanticoagulation D-dimer measurement (<3 weeks, >5 weeks, or 3 to 5 weeks), as well as the D-dimer assay technique used, did not affect the ability of the assay to distinguish patients at low and high risk for VTE recurrence. A 646-patient cohort study that measured D-dimer before stopping anticoagulation found an increased risk for recurrence in those patients with an elevated D-dimer level, although a normal D-dimer value may not predict a low recurrence risk because of the effect of concomitant VKA therapy.[67]

Table 87.6

Facts to consider for the decision on anticoagulation for 3–6 months versus extended prophylaxis

	Limited Duration	Extended Prophylaxis
Risk of recurrent VTE	Distal DVT	Proximal DVT or PE
	Provoked VTE	Unprovoked VTE
	First VTE	Recurrent VTE
	No serious thrombophilia[a]	Serious thrombophilia[b]
Risk of bleeding	History of bleeding	No history of bleeding
	Unstable INRs	Stable INRs
	Need for antiplatelet therapy	No/few other drugs
Patient preferences	Monitoring is inconvenient	Fear of recurrent VTE

[a]Heterozygous form of factor V Leiden or prothrombin mutation increases the risk mildly and does not justify on their own indefinite duration.
[b]Serious thrombophilia consists of homozygosity for factor V Leiden or prothrombin gene mutation; double heterozygosity (factor V Leiden and prothrombin gene mutation); hereditary antithrombin, protein C, or protein S deficiency; persistently positive (on two separate occasions at least 12 weeks apart) lupus anticoagulant or cardiolipin antibodies.

Additional predictors of increased VTE recurrence include male sex (HR, 1.8; 95% CI, 1.2 to 2.5)[68] and residual venous occlusion, although the predictive value of the latter may be less in patients with unprovoked VTE.[69,70] A validated clinical prediction rule is needed to better discriminate patients at low and high risk for recurrence and progress that has been made.[67,71]

Extended VTE Prophylaxis with a VKA

Long-term treatment with warfarin is very effective for the prevention of recurrent VTE, as shown in the DURAC II trial, in which 227 patients with a second VTE event were randomized to 6 months or indefinite duration.[72] Analysis after 4 years showed a risk of recurrence of 20.7% in the 6-month group versus 2.6% in the long-term group (RR, 8.0; 95% CI, 2.5 to 25.9) at the expense of a trend to more (how many more?) major hemorrhages with extended duration.

Low-Intensity VKA Therapy

A reduced intensity VKA regimen (INR goal of 1.5 to 2.0) for extended (6.5 months) prophylaxis, with the intent to reduce the risk of bleeding and the frequency of monitoring, has been investigated in two RCTs (PREVENT trial, 508 patients).[73,74] Compared to placebo, the low-intensity regimen reduced the risk of recurrent VTE (HR, 0.36; 95% CI, 0.19 to 0.67), without a significant increase in major hemorrhage.[74] However, compared to standard-intensity VKA therapy (INR 2 to 3) during a 12-month follow-up evaluation (ELATE trial), the low-intensity regimen was associated with an increased risk of recurrent VTE (HR, 2.8; 95% CI 1.1 to 7.0), without a reduction in major hemorrhage (HR, 1.2; 95% CI, 0.4 to 3.0).[73] Thus, the preferred long-term anticoagulant regimen utilizes an INR goal of 2 to 3. Reduced frequency of monitoring (every 8 weeks in the PREVENT trial) is probably feasible in such patients whose INRs are stable on standard VKA therapy.[75]

Extended Prophylaxis with New Anticoagulants

Rivaroxaban was evaluated for extended prophylaxis after 6 or 12 months of prior anticoagulation in 1,196 patients with VTE (EINSTEIN Extension).[20] Randomization was to rivaroxaban 20 mg once daily or placebo for another 6 or 12 months, and recurrent VTE was significantly less frequent in rivaroxaban-treated patients (1.3% vs. 7.1%, HR, 0.18; 95% CI, 0.09 to 0.39). Clinically relevant bleeding occurred in 5.4% and 1.2%, respectively (OR, 4.14; 95% CI, 1.89 to 9.07), but without any significant difference in the incidence of major hemorrhages.

Dabigatran (150 mg b.i.d.) has also been evaluated for extended prophylaxis after VTE in two trials.[76,77] Compared to warfarin as active control (RE-MEDY), 2,856 patients with 3 to 12 months prior anticoagulation were treated for another 6 to 36 months, and recurrent VTE occurred equally often (1.8% with dabigatran vs. 1.3% with warfarin, HR, 1.44; 95% CI, 0.78 to 2.64), thus fulfilling noninferiority criteria. There was a strong trend for a decrease in major bleeding with dabigatran, 0.9% versus 1.8% (HR, 0.52; 95% CI, 0.27 to 1.01), and a significant reduction of any bleeding (HR, 0.71; 95% CI, 0.61 to 0.83). Acute

coronary events were more common with dabigatran than with warfarin (0.9% vs. 0.2%), whereas there were no differences in deaths or other adverse events.[77]

In the second trial, dabigatran was compared with placebo (RE-SONATE) in 1,343 patients with 6 to 18 months of prior anticoagulation who were treated for another 6 months.[76] The incidence of recurrent VTE was reduced with dabigatran (HR, 0.08; 95% CI, 0.02 to 0.25) with only two major bleeds versus none on placebo; clinically relevant bleeding occurred more often on dabigatran (HR, 2.9; 95% CI, 1.5 to 5.6), and there was one acute coronary event in each group.

In conclusion, the new oral anticoagulants, which are given at a fixed dose without monitoring, are safe and effective as extended-duration anticoagulant therapy.

SUPERFICIAL THROMBOPHLEBITIS

Migratory and/or recurrent superficial thrombophlebitis (as part of Trousseau syndrome) may occur in the presence of a malignancy and often heralds the development of major DVT and/or PE. More often, thrombophlebitis is a benign manifestation of sluggish blood flow in varicose veins, resulting in an inflammatory reaction and secondary thrombus formation that may obliterate and eliminate the varicosity, only for new ones to subsequently develop. Whereas thrombophlebitis of the calf usually is self-limiting and benign, the prognosis is different for the greater saphenous vein, as concomitant DVT is present in 12% to 44% of patients.[78]

As to anticoagulant management of superficial thrombophlebitis, when low-dose LMWH (nadroparin 2,850 IU/d) was compared with weight-adjusted therapeutic-dose nadroparin in a double-blind RCT of 164 patients[79] there was no difference in thrombotic extension or development of VTE (8.6% vs. 7.2% after 3 months). Another placebo-controlled RCT that assessed 45 days of fondaparinux (2.5 mg/d in 3,002 patients) (CALISTO)[80] showed progression or recurrence of the superficial thrombophlebitis or a diagnosis of DVT/PE in 0.9% versus 5.9% in placebo-treated patients (RR, 85%; 95% CI, 74 to 92). However, it still remains to be shown how patients should be selected for this relatively prolonged parenteral therapy.

Overall, thrombophlebitis that is limited to the calf veins can be effectively treated in most cases with oral or topical NSAIDs, but more extensive involvement of thigh veins, and especially if thrombophlebitis encroaches the adductor canal, with the potential to migrate into the deep veins, warrants anticoagulant therapy.

CONCLUSIONS

Substantial improvements in the treatment of VTE have occurred in the past decades due to the introduction of LMWHs, which have changed management from a 1-week hospitalization with intravenous UFH to outpatient therapy with unmonitored, once-daily subcutaneous injections. New oral anticoagulants are emerging as treatment options and will eliminate most of the laboratory monitoring required for VKA therapy. Patient education will be one of the major challenges to maintain good treatment compliance.

CHAPTER 88

Overview of Arterial Thrombotic Disorders

SAM SCHULMAN AND VICTOR J. MARDER

In comparison with venous thromboembolism, which has a relatively uniform pathophysiology and standardized treatments, arterial diseases have disparate anatomic origins and pathogenetic mechanisms. Arterial thrombotic disorders may originate in (a) the atherosclerotic plaque (myocardial infarction, carotid stroke, peripheral vascular disease, chronic mesenteric ischemia, retinal artery occlusion); (b) in areas of low shear stress, causing a venous-type clot (cardioembolism, paradoxical embolism); (c) in the arterial wall after fibromuscular degeneration, leading to stenosis and aneurysm (renal artery occlusions); and (d) in the inflamed vessel wall, by often-unknown mechanisms (vasculitides such as Takayasu arteritis).

THE ATHEROSCLEROTIC PLAQUE

In the first stage of the atherosclerotic disease, an abnormal constellation of plasma lipoproteins, carrying an excess of cholesterol, penetrate sites with minute endothelial damages due to high shear stress in the arterial tree. The lipid deposits in the intima (fatty streaks) then start a plethora of reactions aimed at modifying (by oxidation), retaining or removing the lipids. Now the inflammatory orchestra enters the stage with all its members such as monocytes, macrophages,[1] T-helper cells, cytotoxic T cells, regulatory T cells, natural killer T cells,[2] dendritic cells,[3] cytokines, and differentiation factors. Even B-cells have been implicated, although more at a distance than in the plaques. The studies on the roles of these inflammatory components have been marred by the variability between species and also by the changing phenotypes of certain cells with different cytokine environments.[1] Platelets are also involved relatively early and become activated, release platelet-derived growth factor and transforming growth factor β, resulting in proliferation of smooth muscle cells, and they interact with the inflammatory process. The coagulation cascade is participating with thrombin generation that can be beneficial for tissue repair but also stimulate more inflammation. Early thrombin formation occurs at the site of small endothelial denudations that uncover lipid laden foam cells.

A protective fibrous cap over the plaque is generated via several mechanisms, including platelet-induced collagen synthesis, smooth muscle cell migration, and inhibited fibrinolysis by locally deposited plasminogen activator inhibitor type 1.

When the overloaded atherosclerotic plaque has reached a certain size, large endothelial denudations, perhaps due to apoptosis, or fractures of the fibrous cap can occur; thrombi form and may then occlude the artery resulting in infarction. A detailed description of the pathophysiologic process rather than this simplified summary will meet the reader in Chapter 89. It is interesting to note that the large number of participants in this disease process challenges us to find new and very different therapeutic options to complement the antithrombotic agents.

CARDIOEMBOLIC DISEASE

Atherosclerosis in large vessels is the etiology for only 20% of ischemic stroke in the Western world[4] and more commonly in Southeast Asia. Cardioembolism accounts for about 30% of the ischemic strokes,[4] and of those, only a small and rather questionable percentage of events are due to paradoxical embolism from true venous vessels. It has been difficult to establish the causal relationship between an often small patent foramen ovale and ischemic stroke.[5]

The focus has instead been on the intracardiac clot formation, most commonly in the left atrial appendix, sometimes in the left ventricle and rarely on the mitral valve or from an atrial myxoma. Atrial fibrillation has been strongly associated with the generation of left atrial clots, typically ascribed to stasis and accounting for 25% of ischemic strokes in the Western world.[6] In addition to stasis as the etiologic factor, there have been many speculations that other mechanisms are involved in the atrial clot formation. Thrombophilic abnormalities have usually demonstrated an association with stroke in small studies, but whenever large studies or meta-analyses were performed, the results became negative or contradictory. The role of an inflammatory component or the lack of atrial boost with resulting cerebral hypoperfusion is even more speculative.[6] More details on the etiology and risk factors for stroke are provided in Chapter 91.

After excluding atherosclerotic or cardioembolic origin for ischemic stroke, we remain with the lacunar infarcts due to cerebral microangiopathic disease and a number of rare conditions as well as a proportion of cases with unexplained origin. The size of this residual proportion depends on how well the patient has been investigated.

FIBROMUSCULAR DEGENERATION

The pathogenesis of fibromuscular degeneration is still an enigma, but there is no atherosclerosis or inflammation in the lesions. The most common form is medial fibroplasia, which has predominance in women of 20 to 60 years of age.[7] Hence, female hormones might play a pathogenetic role. Fibromuscular degeneration is responsible for 5% to 10% of cases with renal artery stenosis, as described in Chapter 95, and it appears to have an asymptomatic prevalence of 2% in the general Western population.[8] The second most common location is the coronary artery, but the pathology has been reported in almost every artery in

the body. The clinical picture corresponds to the affected site: renal artery—hypertension; coronary artery—angina; carotid or vertebral artery—transient ischemic attacks (TIAs), stroke, or dissection.

INFLAMED VESSEL WALL

The heterogeneous groups of vasculitides reflect the diversity of the immune system with a large variety of clinicopathologic pictures. The diseases can be classified as large, medium-sized, or small-vessel vasculitis, and important members are giant cell arteritis, Takayasu arteritis, rheumatoid vasculitis, IgG4-related aortitis, polyarteritis nodosa, Kawasaki disease, Wegener granulomatosis, Churg-Strauss syndrome, microscopic polyangiitis, Henoch-Schönlein purpura, cryoglobulinemic vasculitis, drug-induced vasculitis, infection-related vasculitis, systemic lupus erythematosus-related vasculitis, Behçet disease, and Cogan syndrome. The pathology includes granulomatous—sometimes caseating, giant cell, necrotizing, lymphoplasmacytic, leukocytoclastic, neutrophilic (with microabscesses), eosinophilic, aneurysmatic, and/or arteriovenous shunting components. The vasculitides are described outside of this section in Chapter 100.

POPULATION HEALTH AND RISK FACTORS

Acute Coronary Syndromes and Stroke

This section of the textbook contains chapters dealing with dominating population health problems. Coronary heart disease and stroke are well-recognized major causes of death in the developed world. From a global perspective, over 80% of the burden of cardiovascular disease originates in low- and middle-income countries.[9] The INTERHEART study evaluated associations between nine risk factors and myocardial infarction in 52 countries and different ethnicities by examining about 15,000 cases and as many controls. Most of the risk factors were simple, not requiring any sophisticated equipment to assess, and together they were responsible for 90% of the population attributable risk (PAR) globally and in most of the regions (Table 88.1).

Dyslipoproteinemia, smoking, diabetes, hypertension, abdominal obesity, and psychosocial problems had additive effects and daily intake of fruit and vegetables, exercise, and, to a very small extent, alcohol had protective effects. The contribution of each of these risk factors was relatively consistent although with some differences across the geographical regions and ethnicities. The effect of the risk factors was stronger in the young individuals than in the elderly, indicating the importance of early intervention. Primary prevention with anticoagulants is not justified and primary prevention with antiaggregants, usually aspirin, has only a favorable risk/benefit ratio in individuals at higher risk.

Similar results were recently published regarding risk factors for stroke in 3,000 patients and as many controls from 22 countries.[10]

The entire spectrum of risk factors for atherosclerosis is discussed in Chapter 89, in terms of management in the setting of acute coronary syndromes in Chapter 90, for ischemic stroke in Chapter 91, and for peripheral arterial disease in Chapter 94.

Less Common Sites of Arterial Occlusion

In addition to the coronary, cerebral, or peripheral arteries, we sometimes need to investigate and manage diseases affecting arteries in other anatomical regions, that is, the renal, mesenteric, and retinal arteries (Chapter 95). The etiologies are quite heterogeneous and accordingly also the therapies available. The vast majority of patients with renal artery stenosis have atherosclerotic origin and thus similar risk factor to those discussed above. Due to the relatively low prevalence of these arterial disorders compared to the cardiac and cerebral vascular diseases, there are few well-designed therapeutic trials to base treatment strategies on. For renal artery stenosis, five randomized controlled trials have actually been performed, and it appears that medical therapy alone should be the standard choice for the majority of patients. The situation is very different for acute

Table 88.1

Risk factors, their association with myocardial infarction and PAR in the INTERHEART study

Risk Factor	Prevalence Controls	Prevalence Cases	Adjusted OR (95% CI)	PAR (95% CI)
ApoB/ApoA-1	20.0%	33.5%	3.25 (2.81, 3.76)	49.2 (43.8, 54.5)
Current smoking	26.8%	45.2%	2.87 (2.58, 3.19)	35.7 (32.5,39.1)
Diabetes	7.5%	18.4%	2.37 (2.07, 2.71)	9.9 (8.5, 11.5)
Hypertension	21.9%	39.0%	1.91 (1.74, 2.10)	17.9 (15.7, 20.4)
Abdominal obesity	33.3%	46.3%	1.62 (1.45, 1.80)	20.1 (15.3, 26.0)
Psychosocial	—	—	2.67 (2.21, 3.22)	32.5 (25.1, 40.8)
Vegetables and fruits daily	42.4%	35.8%	0.70 (0.62, 0.79)	13.7 (9.9, 18.6)
Exercise	19.3%	14.3%	0.86 (0.76, 0.97)	12.2 (5.5, 25.1)
Alcohol	24.5%	24.0%	0.91 (0.82, 1.02)	6.7 (2.0, 20.2)
All combined			**129.2 (90.2, 185.0)**	**90.4 (88.1, 92.4)**

Adapted from Yusuf S, Hawken S, Ounpuu S, et al. Effect of potentially modifiable risk factors associated with myocardial infarction in 52 countries (the INTERHEART study): case-control study. *Lancet* 2004;364:937–952.
PAR, population attributable risk.

mesenteric ischemia, which is considered a surgical emergency, and even a "second look" is often recommended. Likewise, chronic mesenteric ischemia is preferably managed by surgical methods, although there is controversy whether open surgery or endovascular procedures should be preferred.

Retinal artery occlusions are usually associated with systemic atherosclerotic disease and thereby again the typical risk factors. Although a few randomized controlled trials have been performed, they were all underpowered (<100 patients). The challenges are the short time until irreversible damage (hours) and the potential harm of thrombolytic therapy or invasive procedures.

ADVANCES IN PHARMACOLOGIC MANAGEMENT

Patients with acute coronary syndromes will inevitably be prescribed a number of medications, partly for risk factor modification and partly for secondary prophylaxis. The statins lower low-density lipoproteins and cholesterol but also decrease expression of tissue factor in atherosclerotic plaques, alter prenylation of G-proteins, and activate a transcription factor. This results in reduced production of endothelial cell-derived microparticles and regulation of inflammatory processes with reduction of C-reactive protein, as discussed in Chapter 89. If not already given as primary prophylaxis, statin therapy should be started early in patients with acute coronary syndromes to reduce the risk for unfavorable clinical outcomes (Chapter 90). A somewhat surprising additional effect of statins is a reduction of the risk for venous thromboembolism.[11]

Disappointingly, concomitant elevation of the high-density lipoprotein levels, particularly with nicotinic acid (niacin)[12] or with fibrates[13,14] has not translated into any clinical benefits.

Hypertension is being treated more vigorously than ever before and, interestingly, old agents have manifested their important role. Thiazides remain the basis for most treatment regimens. Conversely, the novel angiotensin receptor blockers are not better than angiotensin converting enzyme inhibitors.

Platelet inhibition with antiaggregant therapy has seen its ups and downs. The dose of aspirin has come down from 325 to 80 mg without any loss of effect but with fewer side effects. The number of antiaggregants used concomitantly has increased, with the introduction of the P2Y12 inhibitors—initially ticlopidin, now replaced by clopidogrel (both prodrugs) and moving to the even more effective, active drug ticagrelor, which binds reversibly to the receptor—but for which there is so far nothing that can quickly eliminate its effect. After acute coronary syndromes or coronary stenting, it is now routine with dual antiplatelet agents for up to 1 year.

Whereas glycoprotein IIb/IIIa inhibitors turned out effective when given intravenously in the acute setting of percutaneous coronary intervention (PCI), the corresponding oral inhibitors xemilofiban, orbofiban, and sibrafiban failed in phase III clinical trials due to increased risk for bleeding and all-cause death, and they were withdrawn.

Patients with stroke benefit from antiaggregants if the pathology is in the large arteries, typically the carotids, and again, low doses of aspirin should be used. Addition of dipyridamole for patients with TIAs or minor stroke reduces the risk for recurrence, as reviewed in Chapter 93.

Patients with peripheral arterial disease mainly benefit from antiaggregants through their reduction of cardiovascular events. There is, however, also evidence for some improvement of walking distance, as reviewed in Chapter 94.

Anticoagulants have a limited role in the acute coronary syndromes, but the direct thrombin inhibitor bivalirudin is gaining terrain in the setting of PCI. Bivalirudin has similar effect as the combination of unfractionated heparin and a glycoprotein IIb/IIIa inhibitor and with a lower risk for bleeding.[15] The factor Xa-inhibitor fondaparinux given at a prophylactic dose for 1 week after acute coronary syndromes has similar effect as therapeutic dose low molecular weight heparin but with a lower risk for major bleeding or death.[16] Secondary prophylaxis with warfarin is beneficial mainly in patients with anterior myocardial infarction or with left ventricle thrombus for a period of 3 months on top of the antiaggregant therapy. Evaluation of the new oral anticoagulants added to antiaggregants after acute coronary syndromes have provided mixed results with a phase III trial with apixaban prematurely discontinued due to increased bleeding,[17] but a trial with rivaroxaban successfully completed.[18] There is undoubtedly an increased risk of bleeding with any combination therapy, and the challenge is to find the dose that still provides a net clinical benefit.

In stroke prophylaxis, the dominating problem has been the underuse of warfarin for patients with atrial fibrillation due to the fear of bleeding complications combined with inconvenience of anticoagulant management. With meta-analyses demonstrating net clinical benefit of warfarin over aspirin for most patients with atrial fibrillation,[19] there is a slow increase in the use of warfarin for these patients. Well-managed vitamin K antagonist therapy is of benefit even for patients with atrial fibrillation and a single additional risk factor. New oral anticoagulants have now been evaluated against warfarin in large trials, described in Chapter 92, and the advantage of no routine laboratory monitoring or dose adjustment is very appealing. There are, however, still remaining problems with these drugs such as uncertainty regarding optimal management of major bleeding complications, management perioperatively, and the financing of the drugs. Clearly, the very low cost of warfarin is not representative of the total societal cost since the management of warfarin is much more expensive than the drug, but that part is usually included in a different budget. For patients who are doing well on warfarin and thereby monitored with long intervals, there is a favorable cost-benefit relation, and they should not be switched without good reason to the new drugs.

In peripheral arterial disease, evidence does not support the addition of anticoagulants to antiaggregants.[20] In acute limb ischemia due to a thromboembolic event, heparin should be given and followed by warfarin if there is reason to believe that the embolic source remains. For patients with multiple reconstructions for critical limb ischemia, obviously failing on antiaggregants alone, it is hard to resist adding long-term anticoagulant therapy.

Thrombolytic therapy in ST-elevation myocardial infarction is losing ground to primary PCI, although prehospital reperfusion with a fibrinolytic agent reduces all-cause mortality.[21] Still, when primary PCI is compared with fibrinolysis in randomized trials, it performs better regarding most clinical outcomes.[22]

For acute stroke and with careful patient selection, treatment with plasminogen activators within 3 hours increases the chance of neurologic improvement. When given 3 to 4.5 hours after

onset of symptoms, there is also a certain increase of this probability. The fibrinolytic therapy is usually given intravenously, and there is less experience from intra-arterial infusion.

For acute limb ischemia, intra-arterial fibrinolytic therapy is, on the other hand, the preferred route. It reduces the need for open surgery, and it is, for some patients, the only possible option.

NOVEL DEVICES IN THE TREATMENT OF ARTERIAL DISEASE

Coronary stents are effective in reducing symptoms of ischemia and decreasing the risk for restenosis compared to angioplasty alone. Coronary thrombectomy and endarterectomy, performed in association with coronary artery bypass surgery, are evolving tools.

Carotid stenting for patients with TIAs has, on the other hand, not fulfilled its promises and appears to be associated with an increased risk for stroke.[23] Suction thrombectomy and thrombus retrieval devices should be considered experimental for patients with stroke and limited use in the setting of clinical trials is advisable.

In peripheral arterial disease, stenting of iliac artery lesions to maintain vessel patency or of more distal arteries after unsuccessful percutaneous transluminal angioplasty to salvage the leg, is often beneficial.[24] Drug-eluting stents may reduce the risk of restenosis further, similarly to the coronary artery setting, but there are controversial results for peripheral arterial disease as reviewed in Chapter 94.

For patients with renal artery stenosis, angioplasty with or without stenting has almost entirely replaced surgery. A recent randomized controlled trial failed, however, to demonstrate clinical benefits compared to medical therapy. There are remaining questions whether certain subsets of patients benefit from revascularization (Chapter 95).[25]

The ideal device should be nonthrombogenic and not cause leukocyte activation. This has to be combined with exceptional strength and durability in, for example, mechanical heart valves. Stainless steel and nickel-titanium are used for such devices, whereas catheters and vascular implants are made from polymers. To decrease thrombogenicity, binding of heparin or its derivatives to the surface has been tested but without convincing benefits. Another possibility is to seed the biomaterial with endothelial cells. This is reviewed in Chapter 96.

CONCLUSION

Although many novel therapies have become available, there is still need for better alternatives to prevent restenosis of coronary arteries without increased risk for bleeding. The proportion of patients with acute ischemic stroke eligible for fibrinolytic treatment is unsatisfactory low. Neuroprotective agents to salvage the penumbra are sought, but so far, the candidates have not been effective. In peripheral arterial disease, stem cell and progenitor cell therapy as well as gene therapy are being investigated and may bring improved remedy for these unfortunate patients.

CHAPTER

89 Pathophysiology of Atherothrombosis

PETER LIBBY, PAUL M. RIDKER, AND KEVIN CROCE

Advances in contemporary vascular biology have contributed enormously to increased understanding of the pathogenesis of atherosclerosis and its thrombotic complications, and have increased our understanding of the mechanisms by which therapeutic interventions can alter the course of this disease. This chapter reviews some of this progress, highlighting the emerging links between atherogenesis, inflammation, and thrombosis: three processes classically considered separately. Indeed, the tendency to view atherosclerosis and thrombosis as distinct has deep historical roots. During the mid-19th century, Karl von Rokitansky[1] postulated that incorporation of thrombi into the artery wall caused atherosclerosis; the celebrated cellular pathologist Rudolph Virchow[2] ridiculed this view. Virchow considered atherosclerosis a disease predicated on proliferation and death of vascular wall cells, complicated by cholesterol accumulation and inflammation. Virchow's eminence deterred acceptance of the relation between thrombosis and atherogenesis.

The role of thrombosis in atherogenesis has resurfaced periodically since the time of these pioneers. Duguid,[3] in the middle of the 20th century, revived von Rokitansky's view that accorded a key role to the incorporation of thrombi in the formation of atheromatous lesions. Hand and Chandler[4] found that induction of thrombi could induce lesions resembling atheroma in experimental animals. Various investigators who used increasingly sophisticated biochemical methods, including Smith and Bini, localized products of thrombosis such as fibrin in human atheromatous plaques.[5,6]

We now recognize that both views in this polarized debate apply to the pathobiology of atherosclerosis, and that thrombotic and inflammatory cellular pathways are inextricably intertwined. Although the very earliest lesions of atherosclerosis may not involve platelets or coagulation, thrombosis nonetheless contributes to all subsequent stages of atherosclerosis. Indeed, some experimental evidence suggests a role for platelets even in early murine atherosclerosis.[7] Moreover, compelling laboratory and clinical evidence now provides growing support for the role of inflammation in both atherogenesis and the pathophysiology of its thrombotic complications. This discussion highlights the interactions between inflammation, thrombosis, and atherosclerosis during various stages of atherogenesis.

THREE THEMES IN ATHEROTHROMBOSIS

Several themes recur while considering the interfaces between atherogenesis, inflammation, and thrombosis. First, the pathogenic effects of thrombosis in the context of atherogenesis reflect dysregulation of fundamental biologic mechanisms of importance in normal homeostasis. The products of coagulation can alter vascular wall cells function in a manner that promotes fibrosis and healing. Substances released from activated platelets, such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β), can augment the synthesis of collagen by smooth muscle cells (SMCs).[8] PDGF is a potent chemoattractant that stimulates the migration of SMCs.[9–12] Thrombin, generated during the clotting cascade, is both a smooth muscle mitogen and a proinflammatory mediator that regulates the expression of many other genes that influence vascular injury responses.[13–16] All of these processes may prove essential during wound healing and tissue repair. Yet, these usually salutary functions can become pathogenic in the context of the artery wall. The interface of atherosclerosis with thrombosis invokes the same conundrum that applies to the inflammatory aspects of atherosclerosis. Normal homeostatic mechanisms expressed inappropriately or in excess actually contribute to the pathogenesis of plaques.

A second recurring theme concerns the balance between stimulatory and inhibitory limbs of regulatory pathways. This concept, pertaining to the opposing poles of proteases versus antiproteases, or thrombosis versus fibrinolysis, is quite familiar to students of thrombosis. We shall see subsequently how altered balances between such pathways contribute to atherogenesis.

A third recurring theme has emerged more recently. We increasingly recognize that inflammation can heighten thrombosis and that mediators of thrombosis can play roles not only in clot formation, but also in augmenting inflammation (FIGURE 89.1). For example, thrombin can elicit inflammatory mediators, notably CD40 ligand (CD154), which can induce tissue factor expression on vascular cells and macrophages (MΦ), the principal source of this potent procoagulant in the atheroma.[17,18] In turn, platelets, when activated, can release CD40 ligand; myeloid-related protein 14 (MRP-14), regulated on activation, normal T cell expressed and secreted (RANTES); and other proinflammatory mediators.[19,20] Inflammatory mediators can sensitize vascular muscle and endothelial cells (ECs), as well as mononuclear phagocytes, to undergo programmed cell death or apoptosis. Dying vascular cells and macrophages can elaborate tissue factor-rich microparticles that can promote thrombosis. Therefore, reciprocal reinforcement of inflammation by thrombosis, and *vice versa*, results in amplification of these pathologic processes.

RISK FACTORS FOR ATHEROSCLEROSIS

Work conducted over the last half century has defined several risk factors for development of atherosclerosis and its complicating events. The concept of risk factors has gained widespread

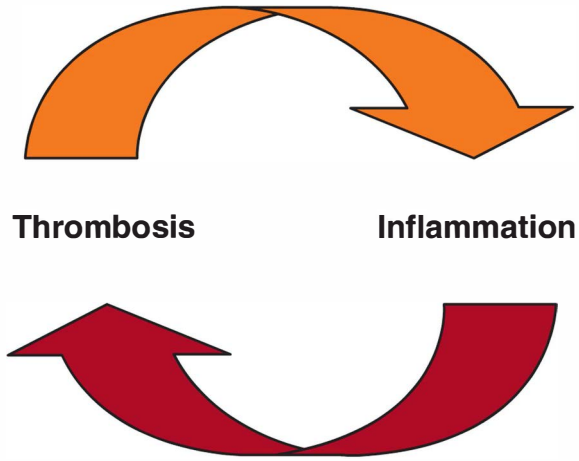

FIGURE 89.1 Accumulating data linking inflammation and thrombosis support the scheme illustrated here, that inflammation begets thrombosis and *vice versa*. An untested corollary of this concept posits that anti-inflammatory therapies may limit thrombosis, and that antithrombotic therapies may reduce vascular inflammation. (From Libby P, Simon DI. Inflammation and thrombosis: the clot thickens. *Circulation* 2001;103:1718–1720, with permission.)

clinical application in generating algorithms for predicting an individual's likelihood of having a future cardiovascular event. The concept of risk factors has led to interventions to reduce cardiovascular events. In the context of the present consideration of pathophysiology, the relationship of certain factors of risk to atherosclerosis and its clinical manifestations suggests hypotheses regarding mechanisms of development of the disease and the mechanisms of its complicating events. A complete exposition of risk factors, risk prediction algorithms, and intervention studies exceeds the scope of this chapter. Many authoritative reviews treat these subjects.[21] This overview of the risk factors for atherosclerosis will consider traditional risk factors, both nonmodifiable and modifiable, as well as emerging risk factors.

Nonmodifiable Risk Factors for Atherosclerosis

Age

Age predicts most potently an individual's risk for an atherosclerotic event.[22] This recognition has important implications, given the anticipated accumulation of the proportion of elderly individuals in many developed countries. From the perspective of thrombosis, the increase in older individuals with atherosclerosis has important implications, as these individuals have higher risk of adverse effects from some therapeutic interventions, including antiplatelet and anticoagulant therapy.

Sex

Sex strongly influences cardiovascular risk. Although women enjoy relative protection from cardiovascular risk premenopausally, their cardiovascular risk increases following menopause. The accumulation of elderly individuals in many populations alluded to above will yield a preponderance of elderly women as an important pool of cardiovascular risk in coming decades. Despite a considerable body of observational data that supported a protective role of hormone therapy against atherosclerotic disease in women, large-scale randomized clinical trials have not affirmed reductions in cardiovascular event rates in women receiving hormonal therapy, particularly in those with established disease.[23] Indeed, several of these studies have shown elevated risk of thrombotic events in women receiving estrogen or estrogen plus progesterone supplementation.[23]

Family History and Genetic Predisposition

A family history of coronary heart disease before age 60 in a parent adds to the other traditional risk factors in estimating the likelihood of a cardiovascular event.[24,25]. Some single-gene mutations clearly contribute to enhanced cardiovascular risk—for example, those that cause loss of function of the low-density lipoprotein (LDL) receptor, such as familial hypercholesterolemia, familial defective apo B, or autosomal dominant hyperlipoproteinemia. Yet these well-understood monogenic causes of atherosclerosis contribute a small portion of population-attributable risk of this disease. Thus, genetic predisposition to atherothrombotic events appears to depend on polygenic inheritance, with each variant contributing a small increment in risk. Most single-nucleotide polymorphisms associated with coronary artery disease have proved poorly reproducible or generalizable.[26]

The introduction of genome-wide association approaches has, in contrast, led to reproducible identification of regions that confer cardiovascular risk in human populations. Notably, the chromosome 9p21 locus consistently associates with augmented cardiovascular event rates in several populations.[27–29] The exploitation of the results of genome-wide association scans for atherosclerosis (and many other chronic diseases) should yield exciting new insights into pathophysiology and potential therapeutic targets in the future. From a practical standpoint at present, however, a simple clinical query regarding family history of premature coronary artery disease appears to confer as much information regarding risk as an assortment of newly emerged genetic markers.[30] Thus from a clinical perspective, genetic testing today adds little to cardiovascular risk assessment over and above the traditional risk factors, including a simple query regarding family history. The 2010 American Heart Association (AHA) guidelines for risk assessment in asymptomatic adults reflect this conclusion.[31]

Modifiable Risk Factors for Atherosclerosis

Lipids

Of the modifiable risk factors, lipids have led the way. The appreciation of links between cardiovascular risk, atherosclerosis, and hypercholesterolemia emerged over the last century. In particular, LDL, a major carrier of cholesterol in humans, participates causally in atherogenesis (FIGURE 89.2). LDL levels correlate with cardiovascular risk in populations.[32] Genetic abnormalities that yield excess LDL correlate with increased individual risk of cardiovascular events.[33] Interventions that lower LDL confer protection from cardiovascular events.[34] A large body of experimental data supports a causal role for LDL in altered cellular events that sow the seeds for atherosclerosis.[35,36] For example, excess LDL correlates with accumulation in the arteries of lipid-laden macrophages, cells that participate importantly in atherothrombosis. Moreover, lowering cholesterol levels by diet alone or by statin treatment can decrease expression of tissue factor within plaques, the procoagulant implicated in triggering many atherothrombotic events.[37]

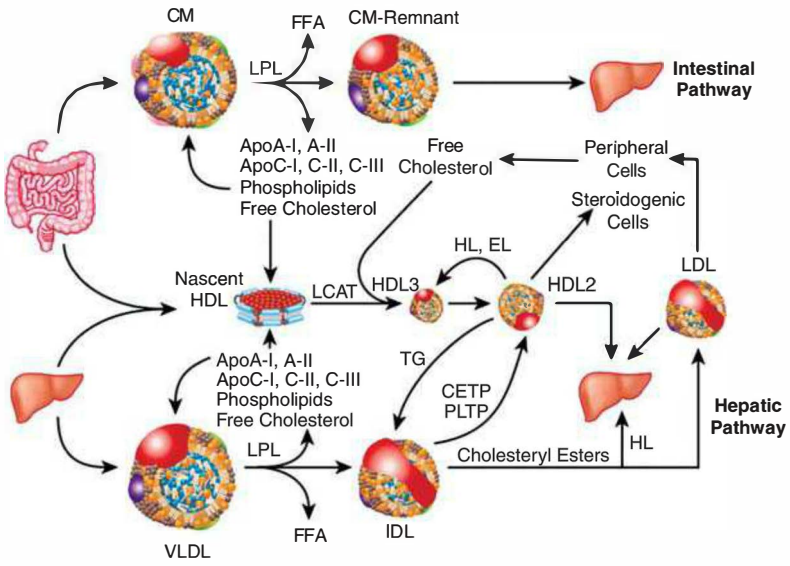

FIGURE 89.2 Schematic diagram of the lipid transport system. EL, endothelial lipase; HL, hepatic lipase. (From Genest J, Libby P. Lipoprotein disorders and cardiovascular disease. In: Bonow RO, Mann DL, Zipes DP, et al., eds. *Braunwald's heart disease: a textbook of cardiovascular medicine*, 9th ed. Philadelphia, PA: Elsevier Saunders, 2011:975–995, copyright Elsevier, with permission.)

Low-Density Lipoprotein

LDL particles exhibit heterogeneity. Small, dense LDL particles confer particular risk and associate with high levels of triglycerides and low levels of high-density lipoprotein (HDL), a triad characteristic of "diabetic dyslipidemia." Larger and less dense LDL particles appear less likely to provoke clinical complications. Several advanced tests can characterize lipoprotein particles. In particular, measuring the levels of LDL's major apolipoprotein, apolipoprotein B (apo B), provides an excellent estimate of particle number, as each LDL bears one apo B moiety. Canadian guidelines recognize apo B measurements as appropriate for clinical use. Yet, for most practitioners, inspection of the lipid profile can provide sufficient information for the management of most patients, without the need for advanced testing.[31]

Inhibitors of the rate-limiting enzyme in cholesterol synthesis, hydroxymethylglutaryl coenzyme A—a class of drugs known as statins—strikingly lower LDL levels. These drugs likely accomplish LDL lowering largely by increasing levels of LDL receptors and enhancing clearance of LDL. Treatment with statins has lowered cardiovascular event rates in broad categories of patients, ranging from those who have already sustained myocardial infarctions (MIs) with high levels of LDL to individuals with no prior history of cardiovascular disease and average or even below-average levels of LDL.[34] Statins undoubtedly reduce cardiovascular events through LDL lowering, but this class of drugs also alters prenylation of small G proteins such as ras, rac, or rho, important in controlling functions of cells involved in atherosclerosis.[38] Statin-mediated reduction of rho function limits the production of prothrombotic microparticles from ECs.[39] Statins also activate the transcription factor Kruppel-like factor 2 (KLF2), which regulates a number of inflammatory functions of ECs, including thrombomodulin gene expression.[40,41] Thus statins may also produce cardiovascular benefit through pathways independent of LDL lowering. Subsequent sections will deal at greater length with putative anti-inflammatory actions of statins.

Triglycerides

Triglycerides have engendered considerable controversy as independent risk factors for atherosclerosis and its complications. Triglyceride-rich lipoproteins include very low-density lipoprotein, a lipoprotein that like LDL, bears apo B as its signature apolipoprotein. Levels of triglycerides typically rise following meals, particularly those rich in fat. Recent studies, however, have indicated that random measurements of triglyceride levels serve well as estimates of future cardiovascular risk, obviating the need for obtaining fasting levels in clinical practice.[42]

Although triglyceride levels correlate well with prospective cardiovascular risk, when adjusted for covariates such as levels of HDL, the incremental risk conferred by triglycerides appears negligible.[43] Moreover, clinical trials have not shown that interventions that lower triglyceride levels, such as fibric acid derivatives, consistently lower cardiovascular events or mortality even in diabetic individuals who have a predisposition to hypertriglyceridemia.[44,45]

High-Density Lipoprotein

Abundant observational data have established low HDL as a consistent and important risk factor for atherosclerosis. From a pathophysiologic perspective, HDL may mitigate atherogenesis through several mechanisms. As proposed originally by Glomset,[46] HDL particles can mediate reverse cholesterol transport, ferrying cholesterol out of cells such as macrophages. Experimental data support the ability of HDL particles to efflux cholesterol from lipid-loaded macrophages. Apolipoprotein A-I (apo A-I) interacts with the ATP-binding cassette transporter ABCA1, a process important in generating nascent HDL particles. Mature HDL particles can efflux cholesterol using a "half" transporter, homologous to ABCA1, known as ABCG1.[47] Animal experiments have documented HDL's function in cholesterol efflux from storage sites to bile acids and ultimately the feces,[48] but only a small fraction of total body reverse cholesterol transport probably occurs from atheromatous lesions in humans. Moreover, HDL efflux from macrophages appears to be independent of HDL itself as a determinant of vascular disease and thus may provide a link between HDL, thrombosis, and inflammation.[49]

In addition to functioning as an acceptor for reverse cholesterol transport, HDL carries many proteins that may help modulate aspects of atherothrombosis, locally in plaques and in innate immunity systemically.[50] In addition to a long appreciated binding capacity for bacterial endotoxin, recent proteomic analyses have demonstrated that HDL associates with modulators of proteinase activity, complement activation, lipid metabolism, and inflammation.[51] Experimental studies both *in vitro* and *in vivo* determined that HDL may exert anti-inflammatory actions relevant to atherothrombosis.[52] Despite this biological plausibility, a large Mendelian randomization study has not supported HDL as a causal risk factor in atherosclerosis.[53]

Although HDL levels indubitably correlate with risk for atherosclerotic events, interventions that raise HDL have not yet proven effective in reducing cardiovascular risk.[54] Clinical trials are evaluating various strategies for raising HDL in patients at risk for cardiovascular disease. Inhibition of cholesteryl ester transfer protein (CETP) raises HDL levels. Yet, one inhibitor of CETP provoked harm rather than benefit in a large clinical trial.[55] The particular agent used in this study, torcetrapib, exerted mineralocorticoid agonist properties that raised blood pressure, lowered potassium, and may have contributed to adverse outcomes. A large clinical endpoint study with another CETP inhibitor, dalcetrapib, halted in 2012 apparently for futility. Two CETP inhibitors that appear not to share the off-target actions of torcetrapib (anacetrapib and evacetrapib) are currently in clinical development. The results of trials with these agents should establish whether CETP inhibition to raise HDL could yield clinical benefit.[56]

Fibric acid derivatives (agents such as fenofibrate, gemfibrozil, or bezafibrate) weakly induce apo A-I transcription through activation of peroxisomal proliferation activating receptor α.[57] This family of drugs can substantially lower triglycerides and slightly raise HDL. A well-understood drug–drug interaction precludes the safe combination of gemfibrozil with statins, agents mandated for use in most individuals eligible for pharmacotherapy of lipid disorders.[58] Several recent studies with fenofibrate have failed to show benefit on cardiovascular outcomes or mortality in people with diabetes, as noted above.[44,45] The clinical role of fibrates in treating individuals with low HDL levels, particularly those already receiving statins, remains unproven.

Nicotinic acid substantially raises HDL levels, and when combined with statins, produces highly favorable, effects on the lipid profile, raising HDL and lowering LDL. While some older clinical trial data show reduction in MI in individuals treated with nicotinic acid, the added benefit of nicotinic acid to the contemporary standard of care remains uncertain. One recent trial (AIM-HIGH) stopped early due to futility [NEW REFERENCE T/K]. Another clinical trial currently in progress is testing whether combinations of statins with sustained release or nicotinic acid and an inhibitor of prostaglandin D intended to reduce flushing may provide added benefit over the current standard of care [NEW REFERENCE T/K].

Hypertension

In addition to lipids, high blood pressure constitutes a major modifiable risk factor. Actuarial data established striking relationships between mortality and blood pressure levels at a time when many physicians thought that hypertension represented an adaptive response to arteriosclerosis that inevitably accompanied aging. Indeed, until the last few decades, many considered hypertension a beneficial adaptation to aging arteries. Consistent cohort studies and cross-sectional data have established the importance of even slight elevations in blood pressure as a contributor to cardiovascular risk.[59] Current thinking accords a primary role to systolic blood pressure as a determinant of cardiovascular risk, although pulse pressure also independently associates with elevated cardiovascular risk. Some elegant analyses of relatively rare genetic abnormalities have inculcated abnormalities in renal electrolyte handling as etiologic in hypertension.[60] Yet the vast majority of patients with hypertension do not have monogenic or well-defined endocrine causes of elevated blood pressure.

Intervention studies have established blood pressure lowering as an important public health goal and an avenue to reducing individual cardiovascular risk.[61] In particular, pharmacologic intervention to reduce blood pressure lowers the risk of cerebrovascular accidents. Although more difficult to establish, current data indicate reduced MI as a benefit of blood pressure control. While dietary measures (as illustrated by the DASH diet) and other lifestyle interventions (such as engaging in regular physical activity) can help control blood pressure,[62] most individuals with established hypertension will also require pharmacotherapy. Several large-scale clinical trials have compared various antihypertensive drugs, and this ensemble of data ultimately suggests that for the most part, effective blood-pressure lowering—regardless of the particular agents used—can lower cardiovascular events. Distilling recent clinical trials for some practical precepts, a thiazide-type diuretic should be part of most antihypertensive regimens. Current practice employs lower doses of thiazides than used previously—12.5 or 25 mg of chlorthalidone or hydrochlorothiazide daily, for example.[63] Beta-adrenergic blocking agents should be used primarily in individuals who have already sustained an MI, and generally should not be first-line antihypertensive agents for others. Black individuals may benefit more from calcium channel blockers than from angiotensin-converting enzyme (ACE) inhibitors. Clinical trials have established no clear-cut benefit of angiotensin receptor blockers (ARBs) over ACE inhibitors in preventing atherothrombotic events, and there is ongoing controversy on whether ARB use associates with increased risk of maliganancy.[64] Studies do not support the combination of ACE inhibitors and ARBs.

Cigarette Smoking

Active cigarette smoking confers considerable cardiovascular risk.[65] Mechanisms by which cigarette smoking augments atherothrombotic events remain uncertain, although observational and experimental data provide some hints in this regard. Cigarette smoking may augment oxidative stress, thought to promote atherogenesis. Cigarette smoking can also lower HDL. Smoking cessation leads to a rapid decline in cardiovascular event rates, yielding benefits in <1 year. As many consider this too short a period to modify atherosclerotic plaques *per se*, some have interpreted this rapid return toward baseline event rates after smoking cessation as an indication that smoking particularly heightens thrombotic diathesis. While the mechanisms remain unproven, smoking cessation should be a priority of practice and public health intervention.

Emerging Risk Factors for Atherosclerosis

In addition to the traditional risk factors enumerated above, several more recently recognized risk markers have come to the fore as potential tools for sharpening risk prediction, and

perhaps shedding mechanistic light on the pathogenesis of atherothrombosis. One such emerging risk factor, hyperhomocysteinemia, has particular relevance to thrombosis.[66] Monogenic defects that lead to hyperhomocysteinemia, such as defects in beta-cystathionine synthase, associate with a thrombotic diathesis in childhood. More modest elevations of homocysteine in adult populations also associate with elevated atherothrombotic risk, although when adjusted for confounders, high levels of homocysteine account for only a modest enrichment in the relative risk of cardiovascular disease.[67,68] Folic acid administration can lower homocysteine levels. Recent trials have evaluated the efficacy of folate supplementation in reducing cardiovascular events. These studies have uniformly shown no benefit from such vitamin therapy, despite lowering of homocysteine.[69–71] As grain and cereal products currently undergo folate enrichment in the United States, as part of a public health intervention to reduce neural tube defects, pharmacologic intervention to lower cardiovascular risk by lowering homocysteine levels with folate or other vitamins appears unwarranted.

Lipoprotein a [Lp(a)]

Lp(a), pronounced "L P little A," denotes a subclass of LDL characterized by an apo B moiety covalently bound to apolipoprotein a. Curiously, Apo(a) bears striking homology to plasminogen, including a variable number of repeats of the kringle structure characteristic of plasminogen, particularly kringle 4. Despite the sequence similarity to plasminogen, Apo(a) appears to lack enzymatic capacity. The distribution of Lp(a) levels in the population is skewed. Those with high levels of Lp(a) have heightened risk of atherothrombotic events. Genome-wide association studies and Mendelian randomization studies support a causal role for Lp(a) in atherothrombosis.[72] Over an entire population, due to the skewed distribution of Lp(a) levels, Lp(a) accounts for a small portion of events (a low population-attributable risk). In individuals with higher levels of Lp(a), however, the incremental risk may substantially elevate the risk of atherothrombotic events. Unfortunately, specific interventions to lower Lp(a) are few, notably nicotinic acid treatment. Studies designed to lower Lp(a) have not been conducted. Current management strategies for those with high levels of Lp(a) include LDL lowering by lifestyle measures and statin therapy.

Oxidative Stress

A great deal of preclinical data and biomarker studies in human populations indicate a role for oxidized low-density lipoprotein in the pathogenesis of atherothrombosis.[73] Yet, a variety of interventions aimed at reducing LDL oxidation have failed to produce clinical benefit. Several studies with antioxidant vitamins have shown no improvement in cardiovascular event rates. A lipophilic antioxidant agent that effectively reduced LDL oxidation experimentally, likewise failed to reduce cardiovascular endpoints in a large clinical trial.[74] Thus, despite the large body of experimental and biomarker data supporting a role for oxidized LDL in the pathogenesis of atherothrombosis, no antioxidant intervention has thus far proven successful in limiting cardiovascular risk.

Other specific oxidant pathways may also contribute to atherothrombosis. Inflammatory cells associated with plaques, notably a subpopulation of macrophages in atheromata, can contain the enzyme myeloperoxidase (MPO), which can generate the potent oxidant species hypochlorous acid (HOCl).[75,76] HOCl can mediate chlorination of tyrosyl residues in proteins. Indeed, the products of HOCl modification accumulate in plaques, indicating the action of MPO *in situ* in human lesions. In particular, the modification of a specific tyrosyl residue in apolipoprotein A-I can impede reverse cholesterol transport mediated by HDL.[77,78]

MPO constitutes a considerable portion of the protein content of granulocytes. Although sparse in undisrupted atherosclerotic lesions, arterial thrombi can trap granulocytes. Thus, MPO-generated HOCl levels may increase selectively at sites of fresh thrombosis. The pathophysiologic implications of this local oxidative stress in aggravating the consequences of arterial thrombosis remain poorly explored.

One of the drivers of hypertension, angiotensin II, not only acts as an arterial vasoconstrictor, but also augments oxidative stress. In particular, angiotensin II can increase the activity of NAD(P)H oxidases in artery wall cells, notably smooth muscle.[79] These oxidases produce superoxide anion, a potential contributor to local oxidative stress in arterial plaques. Whether some of the clinical benefit ascribed to interventions that limit angiotensin II production or signaling arises from reduced superoxide anion production remains speculative.

Infection in Atherosclerosis

Among emerging risk factors, infectious agents, both viral and bacterial, have received periodic attention as promoters of atherogenesis through the decades. The seroepidemiologic associations between infectious agents and atherosclerosis have proved subject to considerable confusion.[80–82] The more recent well-powered and appropriately adjusted seroepidemiologic surveys show little or no consistency in the association of infectious agents with atherothrombotic events. Some have advocated a relationship between burden of exposure to infectious agents and atherosclerotic risk, rather than infection with a specific etiologic virus or microbe.[81]

In situ studies have localized infectious agents or their products to many human atherosclerotic plaques.[83] Whether these invaders or their products promote the disease process remains unproven. In particular, some well-powered intervention trials with antimicrobial agents, including macrolides and a fluoroquinolone, have not shown reduction in recurrent cardiovascular events in individuals who have known coronary heart disease.[84]

While infectious agents may not promote atherogenesis through local actions in the plaque itself, systemic responses to infection could quite reasonably contribute to heightened risk for atherothrombotic events. For example, bacterial products, through ligation of pattern recognition receptors including members of the toll-like receptor family, can augment the expression of proinflammatory cytokines.[85] Ultimately, cytokines produced in response to bacterial products including endotoxins can substantially augment circulating levels of interleukin-6 (IL-6). IL-6 regulates the acute-phase response of hepatocytes and markedly increases production by the liver of fibrinogen and the endogenous inhibitor of fibrinolysis—plasminogen activator inhibitor-1 (PAI-1) (FIGURE 89.3). Thus, infectious agents can tip the homeostatic–hemostatic balance, from one that favors fibrinolysis and limits thrombosis to a pathologic situation characterized by enhanced thrombotic potential and reduced fibrinolytic capacity. These changes

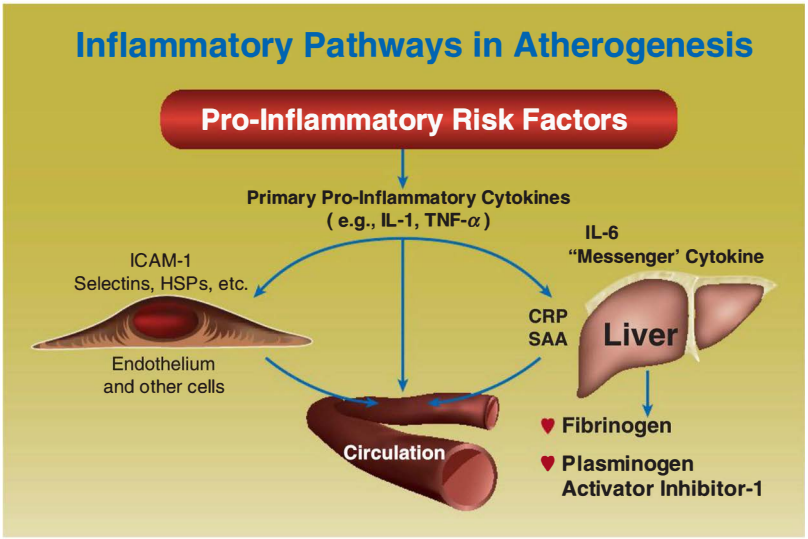

FIGURE 89.3 Pathways by which vascular and extravascular sources of inflammation result in circulating levels of serum markers that provide a reflection of the underlying inflammatory response. Systemic or local inflammation, either in the blood vessel itself or elsewhere, triggers the production of multipotent proinflammatory cytokines, denoted here as "primary" (e.g., IL-1β or TNF-α). These primary cytokines can directly elicit production by endothelial and other cells of adhesion molecules, procoagulants, and other mediators that may be released in soluble form into circulating blood. Primary cytokines also stimulate the production of the "messenger" cytokine IL-6, which induces expression of hepatic genes encoding acute-phase reactants found in blood, including CRP and serum amyloid-A (SAA). These markers in serum therefore provide a window on the inflammatory status of the individual, otherwise inaccessible in the intact subject. (From Libby P, Ridker PM. Novel inflammatory markers of coronary risk: theory versus practice. *Circulation* 1999;100:1148–1150, with permission.)

pertain not only to the "fluid phase" of blood, but also locally at the level of the plaque (FIGURE 89.4). Several cell types in the atherosclerotic plaque can also increase the local production of PAI-1, a function that can promote thrombus accumulation. So infectious agents, even if not driving pathogenesis of atherosclerosis *per se*, can augment the likelihood of thrombotic complications of this disease secondarily.

Inflammation in the Pathogenesis of Atherosclerosis

Considerable current information implicates inflammation as a major participant in the pathogenesis of atherosclerosis and its complications. In particular, many of the traditional risk factors may produce their atherogenic effects by harnessing proinflammatory pathways ordinarily involved in host defenses (FIGURE 89.3). For example, oxidized phospholipids associated with modified LDL particles can augment inflammatory functions in vascular wall cells and macrophages. Angiotensin II can increase levels of proinflammatory mediators, including leukocyte adhesion molecules (such as vascular cell adhesion molecule-1) and proinflammatory cytokines (including IL-6). Thrombin itself not only generates fibrin, but through interaction with protease-activated receptors, also can elicit proinflammatory functions from cells implicated in atherogenesis.

Indeed, platelets not only participate in clot formation, but their granular constituents also include proinflammatory mediators, including RANTES and CD40 ligand (CD154) (FIGURE 89.5). Thus inflammation and thrombosis beget one another, inextricably linking these two branches of host defenses. Numerous experimental studies conducted in cultured cells and in animals, such as genetically altered mice, assert a causal role for inflammatory mediators in the aggravation of atherosclerosis.[86] Biomarker studies in humans support the relevance of these laboratory experiments to the human disease, as discussed in detail below. Of emerging biomarkers, those reflecting inflammation have come most rapidly into clinical practice, as discussed later in this chapter.

INITIATION OF ATHEROSCLEROTIC LESIONS

As noted earlier, the very first steps in the evolution of atheroma may be the only aspects of this disease that do not involve thrombosis. Atherosclerosis usually develops in the context of elevated risk factors. An altered pattern of plasma lipoproteins is a well-established risk factor for lesion initiation.

We have learned much about the earlier stages of atherogenesis by studying experimental animals, which develop atheromatous lesions when they consume diets enriched with cholesterol and saturated fat. Such animal experiments likely represent a caricature of human atherosclerosis, because the achieved levels of lipoproteins exceed by far those found in most human patients with atherosclerosis. Despite the convenience of hypercholesterolemic models of atherogenesis, many other risk factors contribute to this disease. Nonetheless, these well-studied experimental preparations have afforded considerable insight into one pathway for lesion initiation.

Extracellular lipid tends to accumulate in the intima when high levels of plasma lipoproteins bearing cholesterol circulate in plasma (FIGURE 89.6).[87] Part of this accumulation may result from increased permeability of the endothelial layer to lipoproteins at sites of lesion predilection,[88,89] undoubtedly related to hydrodynamic changes at these locations, which typically localize

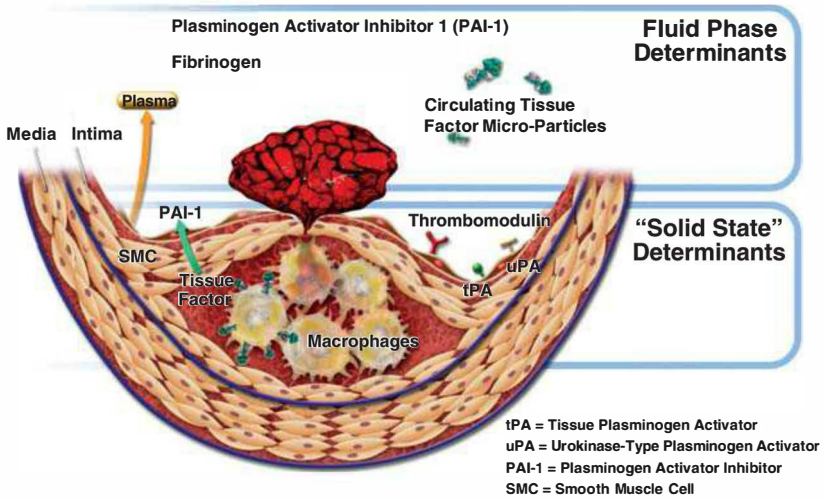

FIGURE 89.4 A two-state model of atherothrombosis. The high-risk atheroma has a thin fibrous cap overlying a large lipid core that contains tissue factor–bearing macrophages. When the fibrous cap fractures, coagulation proteins in the fluid phase of blood gain access to tissue factor–associated macrophages and tissue factor–bearing microparticles derived from apoptotic cells in the solid state of the plaque. These events trigger thrombus formation on the ruptured plaque. The clinical consequences depend on the amount of tissue factor and apoptosis in the plaque's core and on the levels of fibrinogen and PAI-1 in the fluid phase of blood. The interaction of the fluid phase with the solid state will determine whether a given plaque disruption provokes a partial or transient coronary artery occlusion (that can be clinically silent or, less commonly, cause an episode of unstable angina) or a devastating persistent and occlusive thrombus that can precipitate an acute MI. Inflammation regulates the thrombotic/fibrinolytic balance in both the solid state and the fluid phase, as PAI-1 and fibrinogen are both acute-phase reactants and because the inflammatory mediator CD40 ligand (CD154) induces tissue factor expression. EC, endothelial cell; PAI-1, plasminogen activator inhibitor 1; SMC, smooth muscle cell; tPA, tissue plasminogen activator; uPA, urokinase-type plasminogen activator. (From Libby P, Theroux P. Pathophysiology of coronary artery disease. *Circulation* 2005;111:3481–3488, with permission.)

near branch or flow dividers in the arterial tree. In addition to increased penetration into the artery wall, increased retention of lipoprotein particles can contribute to accumulation of lipid.[90] Whatever causes them to accumulate in the intima, lipoproteins provoke biologic reactions that seem to initiate atherogenesis.[91] Lipoprotein particles undergo modification in the arterial intima.[92] In particular, binding of lipoproteins to proteoglycan in the intima may both retard the egress of these particles and render them more susceptible to modification by oxidation.[93,94] These findings have stimulated the formulation of a "response-to-retention" model for the initiation of atherosclerosis.[95] Glycation in the presence of hyperglycemia represents another form of modification of LDL particles in the intima.[96]

Modified lipoproteins can elicit inflammatory mediators, such as proinflammatory cytokines, from the resident cell types in the normal artery: ECs and SMCs.[97–99] Such cytokines, protein mediators of inflammation, can elicit the expression of leukocyte adhesion molecules on the surface of ECs. Leukocytes attached to such "activated" ECs at sites of lesion predilection can enter the intima by diapedesis between EC junctions.[100,101] Chemotactic cytokines, such as macrophage chemoattractant protein-1 (MCP-1) and other chemokines, probably cause such directed migration of leukocytes. Atheromata overexpress these mediators, perhaps partly in response to modified lipoprotein particles. Once resident in the intima, mononuclear phagocytes can imbibe the modified lipoproteins that have accumulated extracellularly. The phagocytic cells bind and internalize these modified lipoprotein particles using "scavenger receptors."[102] The lipid-laden macrophage so produced constitutes the foam cell—the hallmark of the initial lesion of atherosclerosis, the fatty streak (FIGURE 89.6).

We owe much of our knowledge about the initiation of atherosclerosis to studies in well-defined animal preparations. But none of the available animal preparations mimic human atherosclerosis perfectly, not even the power offered by genetically altered mice (discussed later). Hence, the concurrent study of human lesions has proven an important complement to the animal work. With regard to the initiation of lesions, some human studies have furnished insight. Autopsy studies on young Americans, including those killed in armed conflicts in the 1950s and 1960s, showed a high prevalence of fatty streaks and even raised lesions in coronary arteries.[103,104] Systematic study of arteries collected from Americans younger than 35 years and dying of noncardiac causes has affirmed the high prevalence of nascent atheroma in humans in the third and fourth decades of life.[105,106] The general pattern of disease morphology agrees with the inferences made by extrapolation from atherosclerotic animals.

COMPLICATION OF THE ATHEROSCLEROTIC LESION

During formation of the fatty streak, the endothelium generally remains intact, albeit activated, as gauged by the expression of markers such as leukocyte adhesion molecules.[107–110] As macrophages continue to accumulate in the intima and inflammation

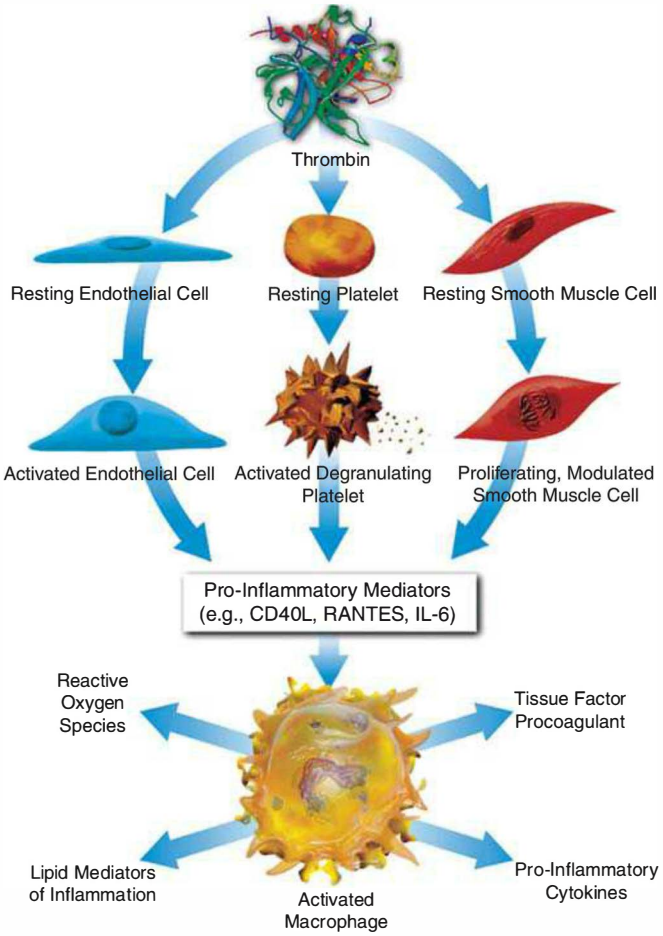

FIGURE 89.5 Thrombin-induced inflammatory processes play a central role in the development and complications of atherosclerotic vascular disease. Thrombin stimulation initiates secretion of platelet, EC, and SMC factors that stimulate macrophage production of tissue factor, proinflammatory cytokines, lipid mediators of inflammation, and reactive oxygen species. By these mechanisms, thrombin stimulates vascular inflammation, and inflammation promotes additional thrombin production through amplification loops that perpetuate atherogenic signals. (From Croce K, Libby P. Intertwining of thrombosis and inflammation in atherosclerosis. *Curr Opin Hematol* 2007;14:55–61.)

persists, small areas of endothelial desquamation occur. Careful examination of the arteries of cholesterol-fed monkeys by scanning electron microscope shows microthrombi occurring at such sites of very focal and limited EC loss.[111] Typically, these microthrombi consist of clusters of platelets adherent to macrophage foam cells uncovered by desquamation of ECs. Scanning electron microscopic studies of human hearts with severe but stable atherosclerosis, removed at the time of cardiac transplantation for ischemic cardiomyopathy and perfusion-fixed immediately, also disclose frequent microthrombi resembling those seen in the cholesterol-fed nonhuman primate.[112–115] The platelets at these sites of microthrombosis, upon degranulation, release mediators that promote SMC migration (e.g., PDGF) and collagen synthesis (e.g., TGF-β), and inhibit fibrinolysis (e.g., PAI-1). Inflammatory activation promotes evolution of the fatty streak toward a more fibrous lesion consisting of an admixture of SMCs, with mononuclear leukocytes, and increased interstitial collagen, a major extracellular protein of the advanced atherosclerotic plaque. Local inhibition of fibrinolysis caused by deposition of PAI-1 may also promote fibrosis of plaques.[116] Observations on advanced human atheroma have documented the presence of each of these platelet-derived mediators in atheroma, although cells within the lesion can also elaborate PDGF, TGF-β, and PAI-1.[117,118]

Initially, the SMCs that migrate and secrete collagen may derive from SMCs resident in the human arterial intima early in life. Other SMCs may migrate into the intima from the tunica media in response to chemoattractant factors, such as PDGF, released from platelets.[9,12] ECs, among other cell types in the artery wall, can also produce PDGF in response to stimuli such as thrombin, which is generated during thrombosis and can present at the sites of early mural microthrombosis.[119] As the lesion progresses, SMCs and the matrix they elaborate form a structure know as the "fibrous cap" near the luminal aspect of the plaque. This cap overlies a central zone known as the "lipid core" or "necrotic core," filled with lipid-laden macrophage foam cells, their debris, and extracellular lipid, including cholesteryl esters and cholesterol monohydrate crystals (FIGURE 89.7). We now recognize that apoptosis contributes to cell death in this region of the plaque.[120,121] Indeed, some of the accumulation of cellular detritus in the lipid core may result from ineffective clearance of apoptotic cells, a phenomenon we referred to as "mummification" in 1995,[122] now deemed due to a defect in "efferocytosis," or efflux or engulfment of dead or dying cells.[123] In the context of thrombosis, the accumulation of debris from macrophages in this region of the plaque has great import, as tissue factor derived from these cells,[124] and associated with cell-derived microparticles,[125] can serve as a major trigger to thrombosis following plaque disruption by mechanisms described in detail below.

Curiously, during much of the early life history of a given atheromatous plaque, atheroma growth proceeds in an abluminal direction. This compensatory enlargement, or "positive remodeling," permits the growth of the atheroma without impinging on the lumen.[126,127] In this manner, the lesion can grow without causing clinical symptoms related to reduced blood flow. This finding may account for the prolonged and usually clinically silent period of asymptomatic progression of atherosclerosis. This phenomenon also may explain why atherosclerosis often presents as an acute thrombotic complication without prior warning because of luminal narrowing. Lesions very likely grow in size and eventually encroach upon the lumen because of bouts of local microhemorrhage with healing and fibrosis.

The growth of new microvessels within the evolving atheroma may contribute to lesion complication. Neovascularization of the atheroma likely occurs in response to angiogenic growth factors, such as acidic fibroblast and vascular endothelial growth factor.[128–130] These microvessels seem to arise by extension of vasa vasorum in the adventitia and the outer third of the tunica media of many arteries. These neovessels may be friable and easily disrupted, resembling those in the diabetic retina. Therefore, the plaque's microvessels may provide a nidus for hemorrhage *in situ* within the plaque. Such breeches in microvascular integrity might well entrain local microthrombosis within

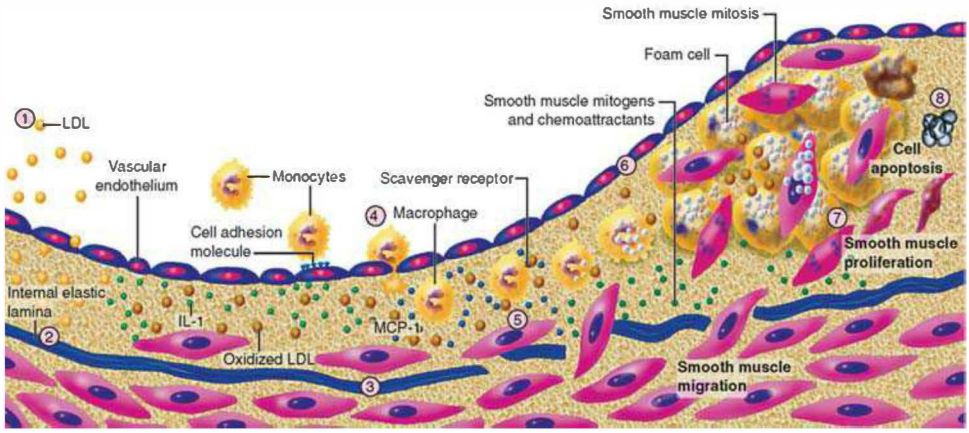

FIGURE 89.6 Schematic of the evolution of the atherosclerotic plaque.

1. Accumulation of lipoprotein particles in the intima. The modification of these lipoproteins is depicted by the darker color. Modifications include oxidation and glycation.
2. Oxidative stress, including products found in modified lipoproteins, can induce local cytokine elaboration.
3. The cytokines, thus induced, increase expression of adhesion molecules for leukocytes that cause their attachment and chemoattractant molecules that direct their migration into the intima.
4. Blood monocytes, on entering the artery wall in response to chemoattractant cytokines such as monocyte chemoattractant protein 1 (MCP-1), encounter stimuli such as macrophage colony-stimulating factor that can augment their expression of scavenger receptors.
5. Scavenger receptors mediate the uptake of modified lipoprotein particles and promote the development of foam cells. Macrophage foam cells are a source of mediators, such as additional cytokines and effector molecules like hypochlorous acid, superoxide anion (O_2^-), and MMPs.
6. SMCs migrate into the intima from the media.
7. SMCs can then divide and elaborate extracellular matrix, promoting extracellular matrix accumulation in the growing atherosclerotic plaque. In this manner, the fatty streak can evolve into a fibrofatty lesion.
8. In later stages, calcification can occur (not depicted) and fibrosis continues, sometimes accompanied by SMC death (including programmed cell death or apoptosis), yielding a relatively acellular fibrous capsule surrounding a lipid-rich core that may also contain dying or dead cells and their detritus. Philadelphia, PA: Elsevier Saunders, 2011:897–913, with permission.)

the atherosclerotic intima, thus potentiating local lesion growth through the aforementioned fibrogenic mechanisms, including PDGF-, TGF-β-, and thrombin-activated proliferation and secretory responses.

As the atherosclerotic lesion evolves, the constituents of the extracellular matrix tend to accumulate. In addition to interstitial collagen, such matrix constituents include proteoglycans, elastin, and microfibrillar proteins.[131] The extracellular matrix of the atheroma may actually constitute most of the volume of certain atherosclerotic plaques, particularly at later or more advanced stages. These matrix constituents interact with the thrombotic and hemostatic mechanisms in several ways. Collagen is a classical platelet activator, and hence may promote thrombosis when exposed to the blood. On the other hand, endogenous heparinoid molecules may bind and activate antithrombin, acting as an anticoagulant.

Complex atherosclerotic lesions often contain calcium. The mechanisms of calcification are currently under intense scrutiny.[132,133] Interestingly, binding of calcium to proteins with carboxyglutamate residues may contribute to lesion calcification. This chemistry resembles that which operates in proteins of the coagulation system. Recent works support a link between inflammation and calcification in atherogenesis.[134]

PLAQUE DISRUPTION AND ATHEROTHROMBOSIS

As lesions evolve, larger patches of endothelial denudation may occur, giving rise to larger mural thrombi. Such superficial erosion of coronary arteries can lead to occlusive thrombosis and sudden death.[135] The degree to which these desquamative lesions arise in bland or inflamed areas remains controversial.[135,136] In a selected population of individuals who have died suddenly and whose cases were then referred to a cardiac pathology group by medical examiners, such superficial erosions with occlusive thrombi account for up to one-third of sudden death cases caused by acute MI. Careful study of the clinical variables in these cases suggests that such superficial erosions occur more frequently in women than in men.[137] Other associations with superficial erosions as the nidus for thrombosis include hypertriglyceridemia, a low HDL level, and diabetes mellitus.[138]

Fracture of the plaque's fibrous cap causes most acute MIs (FIGURE 89.7).[139–141] Sites of fibrous cap fracture invariably bear signs of inflammation.[136,142] The type of atheroma that typically causes thrombosis on the substrate of a fissured fibrous cap includes the presence of numerous mononuclear phagocytes and large lipid pools. The macrophages in the lipid-rich core of

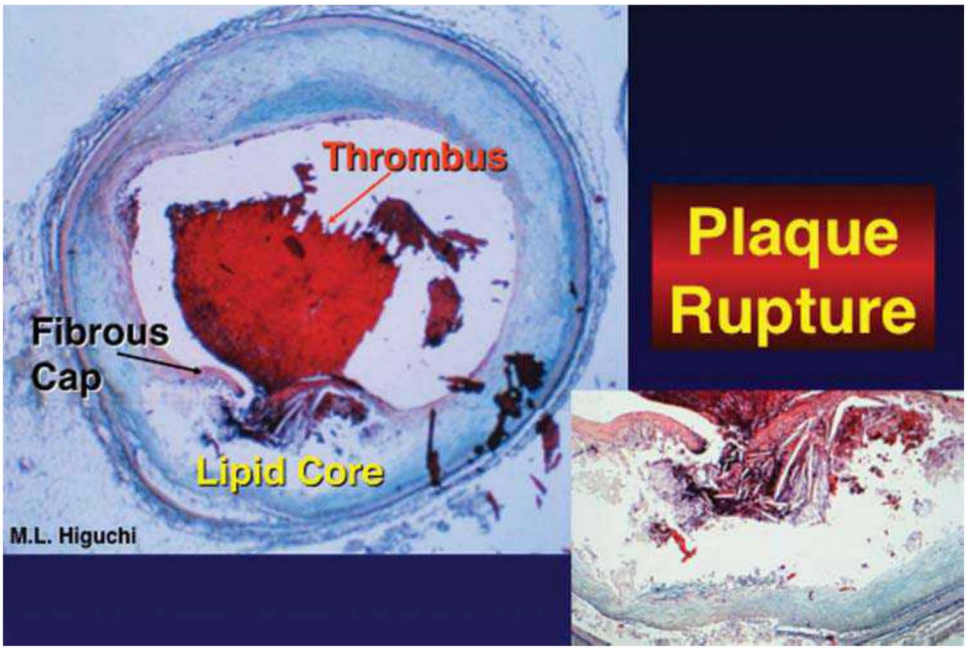

FIGURE 89.7 Plaque rupture: a common cause of coronary thrombosis. The fibrous cap overlying the lipid core of this plaque has ruptured, allowing the blood to contact the plaque's thrombogenic lipid core. Note that the lumen of this plaque is not critically narrowed. The **inset** shows a detail of the site of rupture, illustrating the fracture of the collagenous fibrous cap that caused the thrombus. This is how approximately two-thirds of fatal coronary thrombi form. (Courtesy of Dr. Maria de Lourdes Higuchi, Department of Pathology, University of São Paulo, Brazil.)

such atheroma contains high levels of tissue factor.[143,144] Because it can bind labeled factors VIIa and Xa *in situ*, tissue factor in atheromata appears to retain biologic activity.

When the plaque's protective fibrous cap ruptures, coagulation factors in blood gain access to tissue factor that can trigger thrombus formation. Moreover, as noted earlier, the collagen within the atheroma can activate platelets, further aggravating thrombus formation. Such fibrous cap fractures cause approximately two-thirds of acute MIs, as determined in autopsy studies. As noted earlier, however, plaque disruption appears commonplace in patients with atherosclerosis, and most plaque disruptions do not cause sustained occlusive thrombi, such as those that produce acute MI in the coronary circulation.[145,146]

The balance between procoagulant and anticoagulant factors and fibrinolytic and antifibrinolytic factors likely determines the consequence of any given plaque disruption. In the presence of a robust fibrinolytic system, a mural thrombus might undergo rapid lysis, limiting its clinical consequences. In the presence of elevated prothrombotic factors such as fibrinogen or the fibrinolytic inhibitor PAI-1, however, thrombi would be more likely to grow to the point of arterial occlusion. Nonocclusive mural thrombus, whether produced by superficial erosion or fracture of the fibrous cap, may incorporate into the plaque, as hypothesized by von Rokitansky in the 19th century.[1] Indeed, human atheromata contain a considerable amount of fibrin.[5,6] By means of the fibrogenic mechanisms detailed earlier, mural thrombi can promote smooth muscle migration, proliferation, and matrix secretion. This mechanism could ultimately lead to the evolution of a lipid-rich lesion into one of much more fibrotic character. Such episodes of thrombosis-induced plaque growth may lead to the formation of stenotic lesions capable of limiting blood flow and thereby producing clinical symptoms.

The dichotomy of the so-called vulnerable versus stable plaques is useful conceptually, but it substantially oversimplifies reality (FIGURE 89.8). Indeed, lesions of both morphologies often coexist in a given arterial tree and can even occur serially within a given artery, in close proximity or side by side at branch points.[147] Therefore, the arterial tree of a patient with atherosclerosis probably includes lesions of diverse morphologies: uncomplicated fatty streaks; raised lesions not complicated by thrombosis; lesions that have disrupted, causing acute mural thrombosis; and lesions that have evolved to a more fibrous character, perhaps by healing due to a previous mural thrombosis.

PATHOPHYSIOLOGY OF PLAQUE DISRUPTION

In view of the importance of plaque disruption as a substrate for thrombosis, we consider some current notions regarding the pathophysiology of this process. As noted earlier, two major mechanisms of plaque disruption account for most coronary thromboses: superficial erosion and rupture of the fibrous cap.

Local denudation of ECs characterizes superficial erosion of the arterial intima. Indeed, denuding injury of endothelium was considered primary in the pathogenesis of atherosclerosis for many years.[148] Although we now recognize that the endothelium remains largely intact over atheroma, patchy areas of denudation do occur and represent an important substrate for thrombosis.

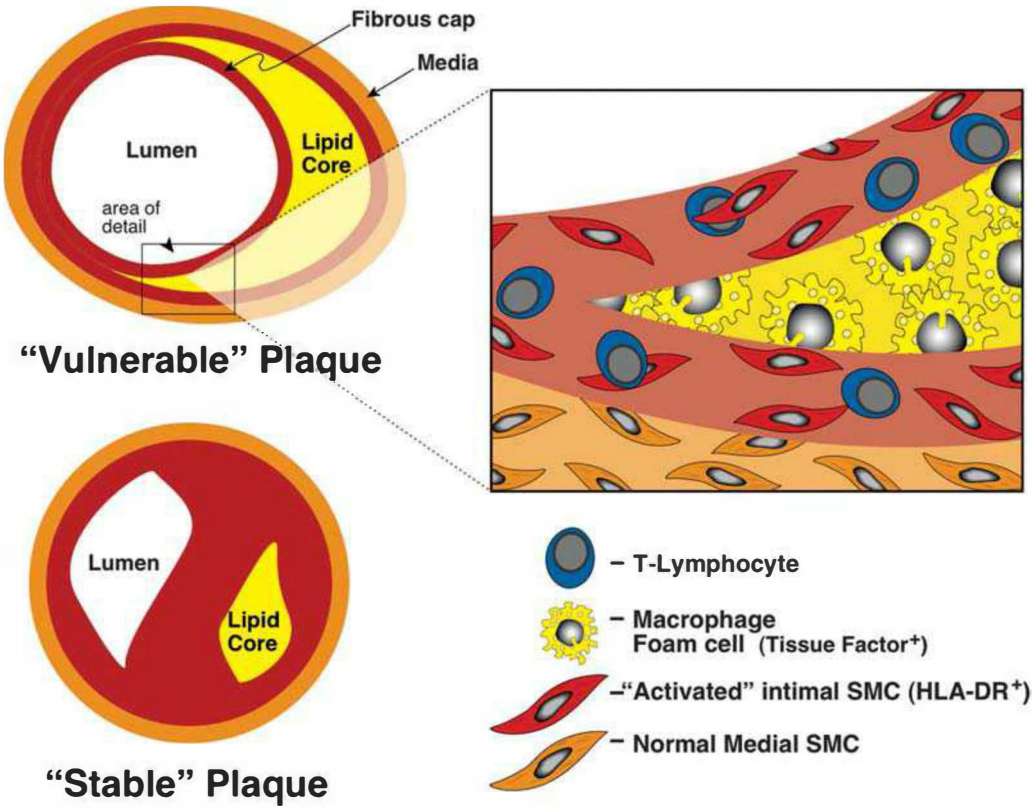

FIGURE 89.8 The characteristics of "vulnerable" plaques and "stable" plaques. Vulnerable plaques often have a well-preserved lumen, because plaques grow outward initially (compensatory enlargement or "positive remodeling"). The vulnerable plaque usually has a large lipid core and a thin fibrous cap separating the tissue factor in macrophages and other cells from circulating coagulation factors. Sites of lesion disruption often contain activated SMCs, detected by their expression of the histocompatibility antigen HLA-DR. In contrast, stable plaques tend to have a relatively thick fibrous cap protecting the lipid core from contact with the blood. (From Libby P. Molecular bases of the acute coronary syndromes. *Circulation* 1995;91:2844–2850, with permission.)

Initially, mechanical injury was considered most important as a cause of denuding endothelial injury. Mechanical denudation certainly applies to atherogenic endothelial injury—produced, for example, by interventions such as balloon angioplasty or stenting. Endothelial desquamation due to hemodynamic stresses was also considered a cause for endothelial denudation. But sites where plaques form are generally considered areas of low shear stress. Although circumferential or "hoop" stresses may be increased in hypertension, the effect of hypertension on endothelial desquamation focally remains uncertain.

Biologic rather than mechanical mechanisms—very likely apoptosis or death of ECs at areas of lesion predilection—might furnish one such pathway to focal endothelial denudation. Although apoptosis is generally considered a noninflammatory process, during atherogenesis, inflammation may actually promote apoptosis.[149] In addition, proteolysis could sever proteins involved in adhesive interactions that anchor ECs to the subendothelial basement membrane. ECs can overexpress matrix-degrading proteinases, including matrix metalloproteinases (MMPs), inducibly in response to inflammatory mediators or oxidized lipids known to localize in atheroma.[150–152] In addition, enzymes generally considered important in fibrinolysis, such as urokinase-type plasminogen activator and tissue-type plasminogen activator (uPA, tPA), may influence matrix degradation in two ways. Plasmin generated by these PAs can directly degrade components of the arterial extracellular matrix.[153,154] Moreover, plasmin can process the inactive zymogen forms of MMPs into their enzymatically active forms. Thrombin can activate latent MMP-2, a matrix-degrading enzyme constitutively produced by vascular cells.[155] The typical basement membrane constituent type IV collagen is a classical substrate for active MMP-2. Therefore, both thrombin and fibrinolytic enzymes may participate in the regulation of proteolysis that could render ECs prone to desquamation.

Proteolysis also likely contributes to fracture of the fibrous cap, the other major mechanism of plaque disruption (FIGURES 89.9 and 89.10). The inflammatory cells that appear quite numerous in rupture-prone atherosclerotic plaques can also produce enzymes capable of degrading structurally important constituents of the extracellular matrix in the plaque's protective fibrous cap.[156] Macrophages in human atheroma, for example, overexpress interstitial collagenases (including MMP-1 and MMP-13).[157–159] These cells can also produce the elastolytic enzymes, cathepsins S and K.[160] Further contributions to elastolysis in atheroma can derive from overexpression of MMP-12, matrix metalloelastase.[161] Additionally, macrophages in

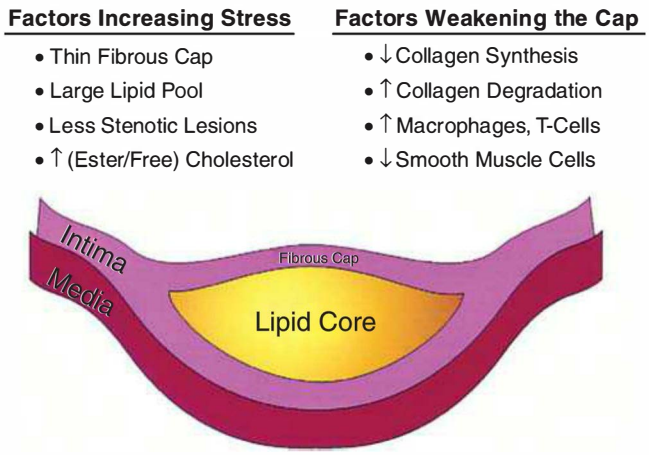

FIGURE 89.9 Biomechanical and biochemical features contribute to disruption of atheromatous plaques and their thrombotic complications. See text for explanation. (From Lee R, Libby P. The unstable atheroma. *Arterioscler Thromb Vasc Biol* 1997;17:1859–1867, with permission.)

atheromatous lesions can elaborate gelatinases, including MMP-2, MMP-9,[157] and MMP-14, among many other proteinases.[162]

The interstitial forms of collagen that lend strength to the plaque's fibrous cap can also diminish in vulnerable plaques because of decreased *de novo* synthesis by SMCs. T lymphocytes comprise an important component of the leukocytic infiltrate in human atheroma. T cells, when activated, can secrete interferon γ (IFN-γ), an inhibitor of SMC collagen synthesis.[8] Considerable evidence supports the activation of T cells in human atheroma and the presence of IFN-γ.[163] Therefore, impaired ability of SMCs to synthesize new collagen to reinforce and maintain the extracellular matrix of the fibrous cap can also lead to thinning and weakening of the structure, characteristic of plaques that tend to rupture and cause thrombosis.[164]

Indeed, SMCs may serve an important function as protectors of the plaque's fibrous cap, due to their ability to synthesize collagen and other structurally important components of the arterial extracellular matrix (FIGURES 89.9 and 89.10). In this regard, SMC death within atheroma may promote plaque disruption.[122] As noted earlier, inflammatory pathways in atheroma likely promote apoptosis. In particular, combinations of inflammatory cytokines can trigger cell death by apoptosis in human SMCs *in vitro*.[165] Moreover, activated T cells within lesions, by expression of Fas ligand, can engage Fas on the surface of SMCs and, in conjunction with inflammatory cytokines including IFN-γ, trigger the deaths of these cells.[149] Therefore, just as in the case of superficial erosion, where ECs are the target, fibrous cap rupture may depend on both proteolysis and cell death. Inflammatory pathways appear to participate decisively in the destabilization of the plaque that triggers thrombosis in both superficial erosion and fibrous cap rupture.

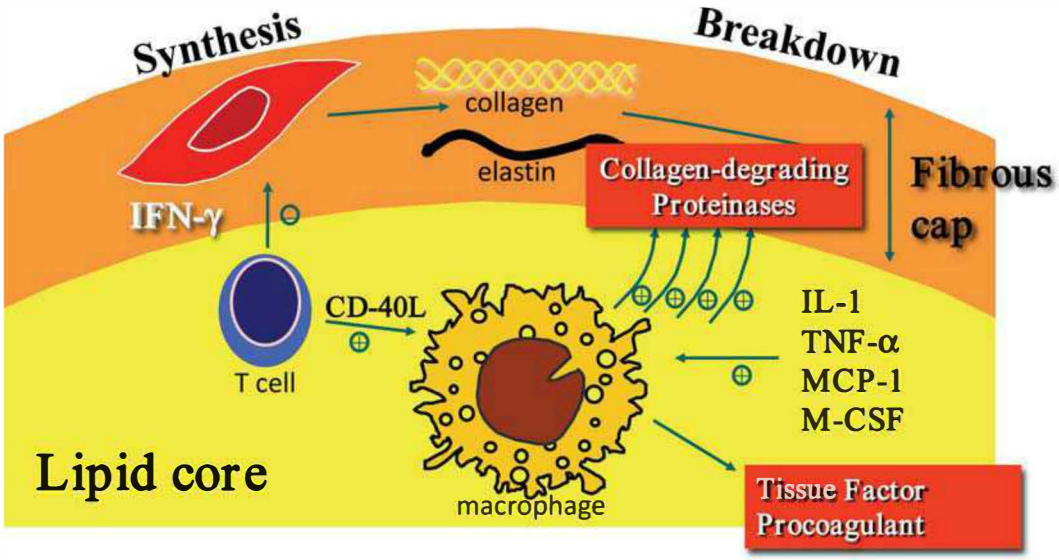

FIGURE 89.10 Molecular mechanisms regulating the stability of atheroma. The vascular SMCs synthesize the collagen and elastin in the atheroma's fibrous cap. When inflammation is present, as characteristic of plaques that cause fatal thromboses, interferon γ (IFN-γ) secreted by activated T cells may inhibit collagen synthesis, impeding the repair and maintenance of the collagenous framework of the plaque's fibrous cap. The activated macrophage secretes proteinases that can degrade both collagen and elastin. The breakdown of these structural molecules of the extracellular matrix can weaken the fibrous cap, rendering it particularly susceptible to rupture and precipitation of the thrombotic complications of atheroma. The macrophage, in turn, undergoes activation by IFN-γ derived from the T lymphocytes and by CD40 ligand (CD154) expressed on the surface of these cells. Platelets also can express active CD40 ligand. Plaques contain other activators of macrophages not derived from T cells, including tumor necrosis factor-α (TNF-α), macrophage-colony–stimulating factor (M-CSF), and macrophage chemoattractant protein-1 (MCP-1), among others. (After Libby P. Molecular bases of the acute coronary syndromes. *Circulation* 1995;91:2844–2850, with permission.)

MECHANISMS BY WHICH THERAPEUTIC INTERVENTIONS CAN ATTENUATE RISK OF ATHEROSCLEROTIC EVENTS

As described above, thrombosis triggered by plaque disruption causes most fatal acute coronary events. The physical integrity of the plaque, notably of the extracellular matrix of the fibrous cap overlying the atheroma's thrombogenic lipid core, thus governs the most important clinical manifestations of atherosclerosis. Atheromata with a "stable" morphology generally have thick fibrous caps and smaller lipid pools than lesions that have ruptured and caused fatal MIs. Considerable evidence points to inflammation as a key regulator of features that govern the biomechanical stability of human atherosclerotic plaques. Experimental studies indicate that lipid lowering reduces inflammation in the atheroma by decreasing the number of plaque macrophages and by decreasing macrophage expression of extracellular matrix-degrading proteases, as outlined above.[166] *In vivo* imaging studies show reduced inflammation in atherosclerotic mice treated with statins, despite only modest decreases in cholesterolemia.[167] Moreover, the collagen content of plaques increases during chronic lipid lowering, rendering plaques less friable and more resistant to rupture. Lipid lowering also reduces tissue factor expression in experimental atheromata.[37] Thus, therapy that treats dyslipidemia may not only render plaques less likely to rupture, but may decrease their thrombogenicity in tandem. Recent clinical studies show prompt decreases in recurrent ischemic events in high-risk patients following aggressive lipid lowering that outstrip the degree and rapidity of atheroma "regression." Biomarkers of inflammation fall in concert with cardiovascular event reduction.[168] Thus, a combination of experimental and clinical trial data indicate that reduction of plaque inflammation partly accounts for the important clinical benefits of lipid lowering.

THE CLINICAL APPLICATION OF INFLAMMATORY BIOMARKERS AND THE ATHEROTHROMBOTIC PROCESS

As described earlier, inflammation participates in plaque initiation, progression, and rupture. In particular, inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α) trigger increased expression of cell adhesion molecules, including ICAM-1, VCAM-1, and P-selectin, leading to early leukocyte adhesion on the endothelium and enhanced fatty streak formation (FIGURE 89.3). Mononuclear cells within this infiltrate subsequently express growth factors that lead to the proliferation of SMCs, and platelet- and T-cell–derived proinflammatory cytokines such as CD40 ligand induce tissue factor production that in turn can promote thrombosis (FIGURE 89.5). In the aggregate, interactions of multiple inflammatory pathways contribute importantly to plaque growth and instability.

Current approaches to disease detection exploit this role of inflammation in atherothrombosis, and measurement of inflammatory biomarkers has become increasingly common in clinical practice. To date, several inflammatory biomarkers, including TNF-α,[169] ICAM-1,[170,171] P-selectin,[172] macrophage inhibitory cytokine-1 (MIC-1),[173] lipoprotein-associated phospholipase A_2 (Lp-PLA_2),[174,175] IL-1, IL-6, and IL-8,[176–178] MPO,[179,180] pregnancy-associated plasma protein A (PAPP-A),[181] CD40 ligand,[182,183] and MRP-14[20,184] have all shown correlation with events either in the setting of primary disease detection or in acute coronary ischemia. Because of its ease of measurement and long-term stability, the downstream acute-phase reactant C-reactive protein (CRP) (FIGURE 89.3), measured by a highly sensitive assay (hsCRP), has emerged as the most useful of these inflammatory biomarkers and is the only marker endorsed by the Centers for Disease Control and Prevention (CDC) for clinical use.[185,186]

Circulating CRP consists of five 23-kDa subunits and belongs to the pentraxin family of molecules that play major roles in human innate immunity. CRP derives largely from hepatocytes in response to IL-6 stimulation. Although hsCRP serves as a robust and reliable risk marker, Mendelian randomization studies suggest that CRP does not participate crucially in the causal pathway for atherogenesis.[187,188]

C-Reactive Protein in Primary Prevention

To date, more than 50 prospective epidemiologic studies have evaluated CRP with "high-sensitivity" assays. In each of these, CRP levels were increased at baseline among apparently healthy individuals at high risk for future MI, stroke, peripheral arterial disease, and sudden cardiac death.[189] Several large primary prevention studies have also shown that CRP adds important prognostic information at all levels of LDL cholesterol and across the full spectrum of Framingham risk scores (FIGURE 89.11).[175,190–196]

Importantly, CRP levels do not correlate with total or LDL cholesterol, and therefore, the addition of CRP evaluation to cholesterol screening has emerged as a powerful new method for vascular risk detection. Individuals with elevated levels of CRP but low levels of LDL cholesterol have higher absolute and relative risks of developing future vascular disease than those with elevated levels of LDL cholesterol but low levels of CRP (FIGURE 89.12), an observation important to global risk prediction algorithms.[191] CRP levels do track with obesity, hypofibrinolysis, and insulin resistance, and thereby increase with prevalence of the so-called metabolic syndrome.[197] In this regard, several major studies have also shown that CRP levels add prognostic information on risk at all levels of metabolic syndrome (FIGURE 89.13).[197,198] Moreover, CRP levels in healthy individuals predict future development of hypertension[199] and of type 2 diabetes.[200–203]

Recognizing the importance of these data, the CDC and the AHA issued the first clinical guidelines for use of hsCRP, and suggested that this biomarker be used among those identified as "intermediate risk" according to usual measures of global vascular risk.[186] Following analyses from both the Physicians Health Study[190] and the Women's Health Study,[169,178] those initial CDC/AHA guidelines indicated that hsCRP levels of <1, 1 to 3, and >3 mg/L represented lower, moderate, and higher vascular risks, respectively. The AHA guidelines for assessment of cardiovascular risk in asymptomatic adults assigned a IIb level of evidence to the use of hsCRP in cardiovascular risk assessment in asymptomatic intermediate-risk men 50 years of age or younger, or women 60 years of age or younger.[31] Individuals with marked elevations of CRP (values chronically in excess of 10 mg/L) have even higher absolute risk, and therefore false-positive elevations of CRP in people without acute inflammatory states occur rarely.[204] Categorization of hsCRP values provides incremental information on vascular risk in all major studies to date, even

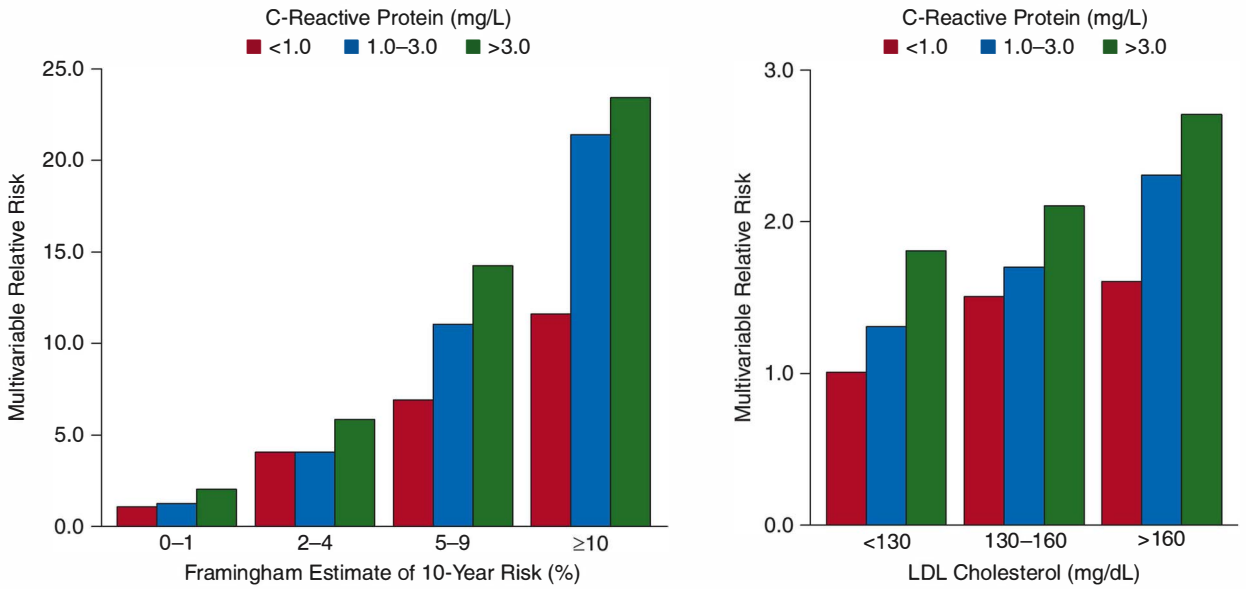

FIGURE 89.11 C-reactive protein levels add prognostic information on risk of future cardiovascular events at all levels of low-density lipoprotein (LDL) cholesterol (**right**) and at all levels of calculated Framingham risk (**left**). after full adjustment for all components of the Framingham risk score (FIGURE 89.14). Computational approaches have generated risk calculators that include hsCRP in addition to traditional risk factors and family history of premature coronary artery disease: The Reynolds Risk Scores for men and women.[24,25] Application of these risk algorithms correctly reclassifies risk assessment in substantial numbers of individuals.

C-Reactive Protein in Acute Coronary Ischemia, Chronic Stable Angina, and Secondary Prevention

In addition to a predictive role in primary prevention, CRP levels have utility as an adjunct to troponin in the setting of acute coronary ischemia. Multiple studies have shown that those who present with acute ischemia and elevated levels of CRP are at increased short- and long-term risk of vascular death, even when troponin levels are normal.[205] CRP levels may identify those who might benefit more or less from specific therapeutic interventions including aspirin, thiazolidinediones, and glycoprotein IIb/IIIa inhibitors.

C-Reactive Protein Levels and Statin Therapy

Beyond its role in the detection of cardiovascular risk, data have emerged suggesting that the use of CRP levels can improve the targeting of statin therapy. The observation that statins lower CRP levels first emerged from the analysis of the Cholesterol and Recurrent Events trial, in which the long-term use of pravastatin reduced CRP levels in a largely LDL-independent manner.[206] Subsequent studies have shown this to be a class effect, with all statins lowering CRP levels.[207,208]

Post hoc analyses of the Air Force Coronary Atherosclerosis Prevention Study/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) demonstrate that those with elevated levels of CRP but low levels of LDL cholesterol not only have high risk for first vascular events, but also appear to benefit from statin therapy.[209] This observation suggests that statin therapy reduces vascular risk even among those without hyperlipidemia. In contrast, this analysis showed no benefit from statin therapy among those within AFCAPS/TexCAPS who had neither increased lipids nor increased CRP, a group representing approximately 25% of the general population. Moreover, analyses performed within the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE IT-TIMI-22) clinical trial, comparing atorvastatin (80 mg) to pravastatin (40 mg), among 3,745 patients with acute coronary syndrome, showed that levels of both LDL cholesterol and CRP attained after 30 days of therapy correlated with reduction in recurrent adverse events.

This evidence bears directly on the inflammatory hypothesis of atherothrombosis because it demonstrates that CRP reduction *per se* may improve clinical outcomes. Moreover, within the PROVE IT trial, the best cardiovascular event–free survival occurred among those who not only lowered LDL levels below 70 mg/dL, but who also lowered CRP levels below 2 mg/L (FIGURE 89.15).

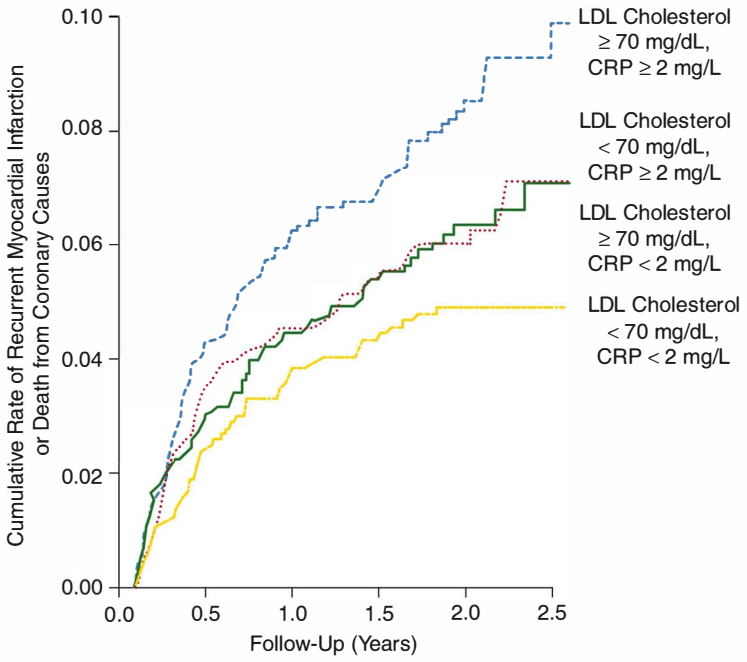

FIGURE 89.15 Incidence rates of recurrent cardiovascular events among patients with acute coronary syndrome, treated with statin therapy according to achieved low-density lipoprotein (LDL) cholesterol and achieved C-reactive protein (CRP) levels. (From Ridker PM, Cannon CP, Morrow D, et al. C-reactive protein levels and outcomes after statin therapy. *N Engl J Med* 2005;352:20–28.)

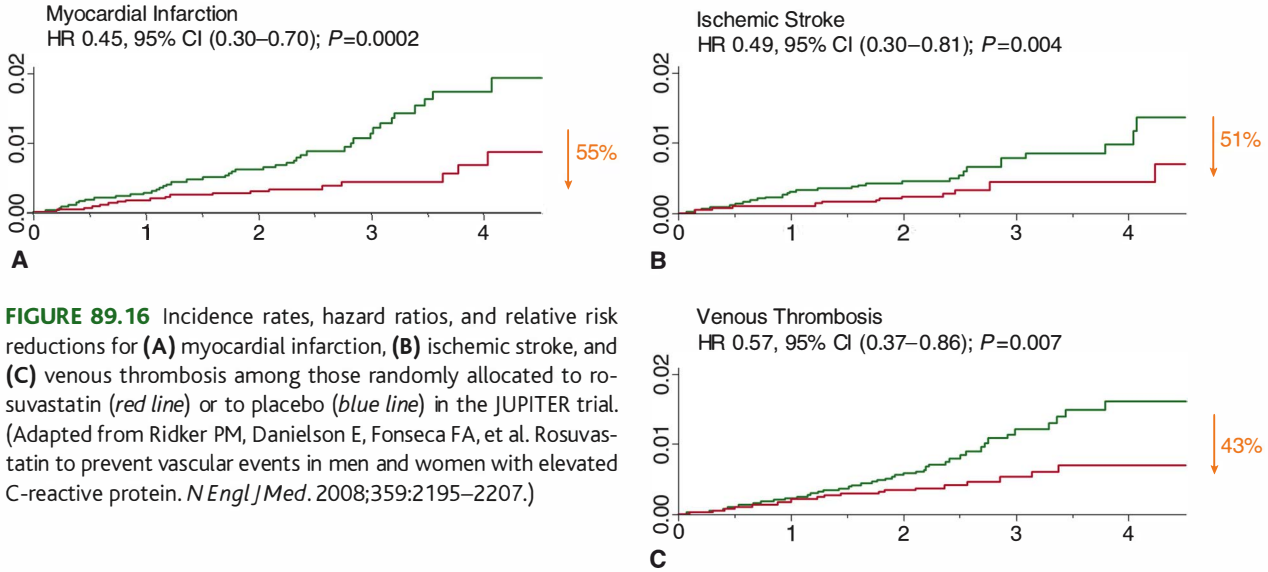

FIGURE 89.16 Incidence rates, hazard ratios, and relative risk reductions for **(A)** myocardial infarction, **(B)** ischemic stroke, and **(C)** venous thrombosis among those randomly allocated to rosuvastatin (*red line*) or to placebo (*blue line*) in the JUPITER trial. (Adapted from Ridker PM, Danielson E, Fonseca FA, et al. Rosuvastatin to prevent vascular events in men and women with elevated C-reactive protein. *N Engl J Med*. 2008;359:2195–2207.)

The *post hoc* observation from AFCAPS/TexCAPS that individuals with above-median levels of hsCRP but below-median levels of LDL benefitted from statin therapy inspired a prospective study—Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER). This trial tested the hypothesis that individuals with low LDL levels (<130 mg/dL) but above-median levels of CRP (>2 mg/L) benefit from statin therapy. Statin treatment markedly reduced events that contributed to the combined endpoint, as well as the prespecified components of this endpoint.[210] In particular, events attributable to arterial thromboses (acute MI and ischemic stroke) fell strikingly (FIGURE 89.16A,B). Based on JUPITER and other evidence, the Canadian guidelines from 2009 and the AHA guidelines for assessment of cardiovascular risk in asymptomatic adults endorse targeting statin treatment according the JUPITER criteria.[31,211]

An additional indication of the antithrombotic action of statins emerged from JUPITER. Observational retrospective analyses of several populations suggested that statin treatment lowered the risk of venous thromboembolic events. No observational data link high levels of LDL with the risk of venous thromboembolism. Yet because of the observational data, the JUPITER protocol prespecified a test of the hypothesis that individuals with above-median CRP levels would have reduced venous thromboembolic events when treated with statins. Indeed, statin treatment reduced both provoked and unprovoked venous thromboembolic events by more than 40% in JUPITER (FIGURE 89.16C).[212] Current mechanistic studies are exploring the pathophysiologic basis of such a reduction in thrombotic events on the venous side due to statin therapy.

Although experimental studies and human biomarker investigations implicate inflammation in atherothrombosis, we lack intervention studies that establish a causal role for inflammation in atherothrombosis, or that prove that anti-inflammatory strategies may improve cardiovascular outcomes. Although aspirin indubitably reduces cardiovascular event rates in individuals with heightened baseline risk, the doses of aspirin that have proven effective in cardiovascular prevention do not produce systemic anti-inflammatory effects, although they effectively inhibit platelet aggregation. Other antiplatelet therapies, however, may mute inflammation, further highlighting the interdependence between inflammatory and thrombotic activation pathways in the pathobiology of atherothrombosis. Specifically, smaller studies show that the platelet ADP receptor antagonist clopidogrel and inhibitors of platelet glycoprotein IIb/IIIa reduce levels of circulating CD40L and the number of circulating leukocyte platelet aggregates, suggesting that these therapies share antithrombotic and anti-inflammatory function.[213,214] We need further studies to validate the efficacy of targeting inflammation directly as a mechanism of atheroprevention.

SUMMARY

Thrombosis causes the most dreaded clinical consequences of atherosclerosis and likely contributes to lesion formation as well, hence the term "atherothrombosis." The interrelationships between lipids, inflammation, thrombosis, and atherosclerosis have recently provided new mechanistic and therapeutic insight into this disease. Current thinking accords a crucial role for thrombosis in the evolution, complication, and acute manifestations of atherosclerosis. In turn, inflammatory signaling pathways appear central in regulating both the formation and thrombotic complications of atherosclerotic lesions. Advances in therapeutics targeting the hemostatic pathways have already permitted reductions in morbidity and mortality in patients with acute MI. The refinements currently under evaluation should provide further inroads to reducing the ravages of late-stage atheroma. Because platelets can elaborate inflammatory mediators and thrombin can stimulate inflammatory functions of cells involved in atherosclerosis, antiplatelet and anticoagulant therapy might even quell aspects of the inflammatory processes that operate during atherogenesis and plaque complication. Loss of myocardium caused by coronary ischemia is a major cause of heart failure. By mitigating the consequences

of plaque thrombosis, and perhaps also by slowing lesion progression, antithrombotic therapy can be viewed as a preventive measure against heart failure, the leading cause for hospitalization in the elderly. The past, studded with controversy about the role of thrombosis in atherosclerosis, has given way to an era in which the intimate links between these processes are not only widely acknowledged but have also given rise to major therapeutic advances. The interdependence of inflammation and atherothrombosis has yielded practical applications that help hone risk stratification and guide and monitor therapy in the clinic. Few areas of medical investigation have witnessed such rapid translation to practice, and the pace of progress in this area promises continued acceleration in the coming years.

CHAPTER

90

Acute Coronary Syndromes: Manifestations and Management

JOHN PAUL VAVALLE, JOHN H. ALEXANDER, AND MATTHEW T. ROE

Coronary heart disease (CHD) is a global health epidemic that contributes to more than 7 million deaths per year and is the most frequent cause of death worldwide. Currently, more than half of the global burden of CHD is found in developing countries, and this percentage is growing rapidly.[1] Within the United States, there has been a decrease in deaths from CHD over the last three decades due equally to improved therapeutics and risk factor modification. Nevertheless, the prevalence of CHD in the United States remains high with over 1 million hospitalizations for acute coronary syndrome (ACS) annually.[2,3]

ACS is a term that refers to the clinical syndrome of acute myocardial ischemia typically resulting from atherosclerotic plaque rupture that leads to occlusive or subocclusive intracoronary thrombus causing downstream myocardial ischemia or infarction. The term ACS encompasses three conditions: unstable angina (UA), non–ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI).

The presence of myocardial necrosis, assessed by measurement of cardiac biomarkers such as troponin and creatine kinase MB (CK-MB), differentiates acute NSTEMI and STEMI from UA. STEMI is further distinguished from NSTEMI by the presence of ST-segment elevation on the electrocardiogram (ECG). Rapid identification, triage, and implementation of evidence-based therapies for ACS are essential to reducing the morbidity and mortality associated with this life-threatening condition.

PATHOPHYSIOLOGY OF ACS

The hallmark of ACS is myocardial ischemia that results from insufficient oxygen delivery to meet the oxygen demands of the myocardium. This phenomenon most commonly results from obstructed coronary blood flow due to intracoronary thrombus that has generated on the surface of a ruptured atherosclerotic plaque. However, other mechanisms of ACS have been described, including dynamic coronary obstruction from coronary spasm or vasoconstriction, progressive mechanical obstruction as would be observed with progressive atherosclerosis, coronary artery inflammation, coronary dissection, and secondary angina—where the increased oxygen demands of the myocardium outstrip a preserved supply (Table 90.1).[3,4]

Atherosclerosis

Coronary atherosclerosis develops over decades and is characterized by the progressive deposition of lipids, fibroblasts, and inflammatory cells beneath the endothelial layer within the arterial wall (see Chapter 89). In the coronary arteries, the majority of these atherosclerotic plaques never progress to cause an ACS event. However, the so-called vulnerable plaques that eventually rupture do so as a result of the disruption of the fibrous cap that exposes the thrombogenic lipid core to circulating blood and stimulates the formation of thrombi. A newly utilized term, atherothrombosis, has been developed to describe this process.

Plaque Inflammation and Rupture

Plaques prone to rupture have been termed vulnerable plaques and have been characterized histologically. Typically, these plaques have a lipid-rich or necrotic core with a thin fibrous cap.[5] Activated macrophages and other inflammatory cells are generally present in higher concentrations in vulnerable plaques. Metalloproteinases and other enzymes secreted by these inflammatory cells can lead to thinning of the fibrous cap, making them prone to rupture. Autopsy studies have demonstrated dense infiltration of inflammatory cells into ruptured culprit plaques as compared to stable nonruptured plaques, supporting this notion of the inflamed vulnerable plaque.[6]

Identifying these plaques prone to rupture prior to an ACS event is an area of intense research, but virtual histology using intracoronary ultrasound, intracoronary optical coherence tomography, and molecular imaging with magnetic resonance imaging (MRI) or computed tomography (CT) has shown promise.[7]

Thrombosis

Intracoronary thrombosis is fundamental to the pathophysiology of ACS. At the moment of plaque rupture, platelet and plasma thrombosis transform a stable atherosclerotic plaque into an unstable coronary lesion. Intracoronary thrombi at the time of an ACS event have been demonstrated by angiography, atherectomy, and autopsy studies showing thrombus originating from the site of plaque rupture.[8–10] Markers of coagulation activity, such as elevated plasma fibrinogen levels, prothrombin fragments, fibrinopeptide, and D-dimers, have all been detected in patients with ACS, but are nonspecific markers and cannot be used in isolation.[11,12]

At the core of the thrombotic process is platelet aggregation that begins when plaque rupture exposes collagen and tissue factor to circulating platelets. Platelet activation initiates with the binding of the glycoprotein Ib receptor with von Willebrand factor, resulting in conformational changes of the platelet, as well as release of α-granules, thromboxane A_2 (TXA_2), and other platelet chemoattractants.[13] Mediators such as thrombin, adenosine diphosphate (ADP), and epinephrine amplify the platelet response by recruiting other platelets to the forming thrombus. The final pathway involves the activation of the glycoprotein IIb/IIIa (GP IIb/IIIa) receptor. Once activated, it is responsible for platelet aggregation and stabilization by binding fibrinogen, which cross-links the GP IIb/IIIa integrins between platelets.

Table 90.1

Causes of unstable angina and non–ST-elevation myocardial infarction[a]

Thrombus or thromboembolism, usually arising on disrupted or eroded plaque
• Occlusive thrombus, usually with collateral vessels[b]
• Subtotally occlusive thrombus on preexisting plaque
• Distal microvascular thromboembolism from plaque-associated thrombus
• Thromboembolism from plaque erosion
Non–plaque-associated coronary thromboembolism
Dynamic obstruction (coronary spasm[c] or vasoconstriction) of epicardial and/or microvascular vessels
Progressive mechanical obstruction to coronary flow
Coronary arterial inflammation
Secondary UA
Coronary artery dissection[d]

[a]These causes are not mutually exclusive; some patients have two or more causes.
[b]DeWood MA, Stifter WF, Simpson CS, et al. Coronary arteriographic findings soon after non–Q-wave myocardial infarction. *N Engl J Med* 1986;315:417–423.
[c]May occur on top of an atherosclerotic plaque, producing missed-etiology angina or UA/NSTEMI.
[d]Rare.
From Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304. Modified with permission from Braunwald E. Unstable angina: an etiologic approach to management. *Circulation* 1998;98:2219–2222.

The activated platelet serves as the substrate upon which coagulation occurs. Tissue factor, released at the time of plaque rupture, leads to activation of factor X, converting it to factor Xa. Through multiple positive feedback loops involving both platelets and soluble coagulation factors, factor Xa leads to thrombin generation (factor IIa) that in turn converts fibrinogen to fibrin in the final step of thrombus formation.

As a result of the critical role that platelets and soluble coagulation factors play in ACSs, antiplatelet and anticoagulant therapies have become fundamental to the treatment of ACS. Current proven antiplatelet therapies include aspirin for the inhibition of TXA_2 formation, $P2Y_{12}$ receptor antagonists (clopidogrel, ticlopidine, prasugrel, and ticagrelor) for the inhibition of the ADP receptor pathway, and GP IIb/IIIa receptor antagonists that directly inhibit platelet aggregation. In addition, thrombin receptor antagonists that inhibit thrombin activation of platelets are currently under investigation. Currently proven anticoagulants include unfractionated heparin (UFH) and low molecular weight heparin (LMWH), indirect factor Xa inhibitors such as fondaparinux, and direct thrombin inhibitors (DTIs) such as bivalirudin. A number of additional anticoagulants, including the direct factor Xa inhibitor otamixaban and the RNA aptamer factor IXa inhibitor pegnivacogin, are currently under investigation.[14,15]

Other Mechanisms of ACS

Vasoconstriction

Dynamic coronary obstruction can occur as a result of intense focal vasoconstriction of a segment of an epicardial coronary artery. This is commonly labeled Prinzmetal (variant) angina. This focal spasm is the result of vascular smooth muscle hypercontractility and endothelial dysfunction.

Patients presenting with ACS from vasoconstriction usually have sudden onset of chest pain at rest without any antecedent increase in oxygen demand. Attacks can be precipitated by exposure to cold, emotional stress, adrenergic stimuli, exercise, and cocaine use.[16–18] Variant angina episodes usually do not lead to acute myocardial infarction (MI), but prolonged episodes may result in acute myocardial necrosis, arrhythmias, and even sudden death.[19,20] The diagnosis of variant angina is suspected by transient episodes of chest pain at rest that may be accompanied by dynamic ST-segment changes on ECG and may also be responsive to vasodilators such as nitroglycerin.

Progressive Mechanical Obstruction

Severe narrowing of the epicardial coronary arteries, in the absence of focal spasm or thrombus, may occur as a result of progressive atherosclerosis or may be due to intimal hyperplasia causing restenosis at the site of a previous percutaneous coronary intervention (PCI). In general, these patients present with angina symptoms that have been progressively worsening concurrent with the progression of the myocardial obstruction.

Coronary Inflammation and Dissection

Although much less common than other causes of ACS, it is important to recognize coronary artery inflammation and dissection as causes of coronary obstruction, as they may have devastating consequences. Coronary artery dissection is the most common cause of ACS in peripartal women and often present with acute MI.[21] Inflammatory states such as graft-versus-host disease or infections such as Kawasaki disease may lead

to intense inflammation of the coronary arteries and result in complete coronary occlusion.[22,23] Identification and treatment of these etiologies is dependent upon recognizing and treating the underlying diagnoses.

Secondary Unstable Angina

Secondary UA results from an inability to meet the oxygen demands of the myocardium and usually occurs in the presence of some degree of obstructive coronary artery disease (CAD) that limits the flow reserve of the coronary circulation at times of increased myocardial workload. The causes of secondary angina are varied, but all result in increased myocardial oxygen requirements. Examples include fever, tachycardia, thyrotoxicosis, hyperadrenergic states, hypertensive emergency, and anemia among others. Because of the underlying condition, secondary angina is usually a marker for end-organ dysfunction and may have worse outcomes than other forms of angina.[24]

PRESENTATION, RECOGNITION, AND TRIAGE OF ACS

Presentation

While stable angina typically presents with angina pectoris associated with exertion and is relieved with rest, patients presenting with ACS classically present with rest angina or newly progressive angina. Three principal presentations of UA have been described: (a) rest angina, (b) new-onset angina, and (c) increasing angina (Table 90.2). Patients suffering an STEMI may present with the above symptoms but typically present with the new onset of a prolonged or stuttering episode of pain at rest.

The first step for patients before they can receive possibly life-saving treatment is to recognize their symptoms as being potentially serious and to seek medical attention. Despite attempts to shorten the delay to seeking medical care, the average person with UA/NSTEMI waits approximately 2 hours prior to seeking attention, and in the face of attempts to improve this, there has been little change over the last decade.[25,26] Often times, reasons cited for delay include atypical symptoms such as arm pain, jaw pain, or shortness of breath, or the expectation that the symptoms would be more severe.[27,28] Studies trying to understand reasons for delay in seeking care have demonstrated that older patients, blacks, women, and Medicaid-only recipients are more likely to delay.[25,29]

Patients experiencing an ACS event may not always present with chest discomfort.[30] An analysis of the National Registry of Myocardial Infarction showed that about one-third of the 434,877 patients with MI did not present with chest pain.[31] In this study, this resulted in delays in seeking care, delays to diagnosis by the providers, less implementation of evidence-based therapies, and higher in-hospital mortality. In particular, women, older patients, and those with a history of diabetes or heart failure are more likely to present with silent MIs, and those caring for these patients must be vigilant in their evaluation.

Table 90.2

Presentations of ACS

Class	Presentation
Rest angina[a]	Angina occurring at rest and prolonged, usually >20 min
New-onset angina	New-onset angina of at least CCS class III severity
Increasing angina	Previously diagnosed angina that has become distinctly more frequent, longer in duration, or lower in threshold (i.e., increased by 1 or more CCS class to at least CCS class III severity)

[a]Patients with NSTEMI usually present with angina at rest.

ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

Evaluation and Diagnosis

Because there is substantial overlap in the presenting symptoms of STEMI, NSTEMI, and UA, the initial evaluation of all patients presenting to a health care facility with symptoms concerning ACS should be the same (FIGURE 90.1). Patients should be evaluated in an acute care setting, with providers and staff equipped to perform critical care.

Because of the possibility of an immediate life-threatening condition, the initial evaluation must focus on rapidly identifying clinical instability and assessing for ST-segment elevation on an ECG if not done prior to arrival by emergency medical personnel. ST elevation in the setting of symptoms compatible with ACS should set the patient on a predefined treatment algorithm for urgent reperfusion therapy with fibrinolytics or primary PCI.[32] The importance of the ECG in the initial evaluation has led the American Heart Association and the American College of Cardiology in its joint treatment guidelines to give its strongest recommendation possible (class I) to obtaining an ECG within 10 minutes of arrival. Rapid evaluation and implementation of treatment for ACS can translate into significant improvements in outcomes and ultimate cost savings.

THE ACUTE MANAGEMENT OF STEMI

Urgent Identification, Triage, and Reperfusion

In acute STEMI, there is complete occlusion of the epicardial coronary artery, leading to transmural myocardial ischemia and infarction. Generally, STEMI results from plaque rupture, leading to an occlusive thrombus composed of fibrin, platelets, and inflammatory cells. Acute STEMI represents a true medical emergency, and management strategies focus on urgent coronary reperfusion therapies to open the occluded coronary vessel and minimize myocardial necrosis. This may involve primary PCIs, fibrinolytic therapy, or a combination of both depending on patient characteristics and available resources and capabilities. The old adage of *time is muscle* holds true for STEMI patients,

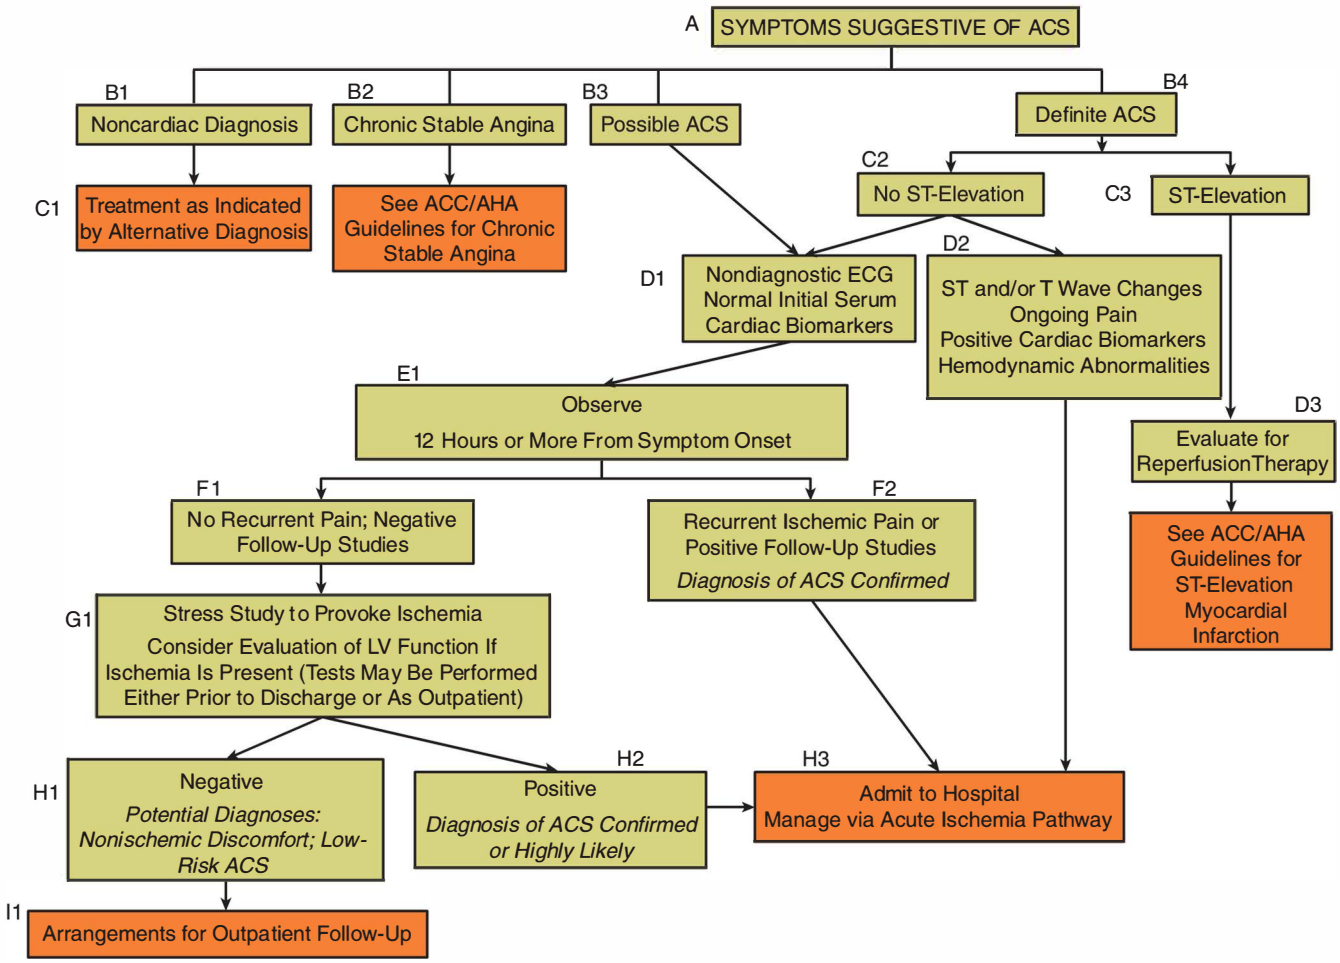

FIGURE 90.1 Treatment algorithm for patients with suspected ACS. ACC/AHA, American College of Cardiology/American Heart Association; ECG, electrocardiogram; LV, left ventricular. (From Anderson JL, Adams CD, Antman EM, et al., ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction. *Circulation* 2007;116(7):e148–e304.)

with each minute of delay associated with an increase in mortality.[33] Reperfusion therapy to open the occluded artery with either fibrinolytics or primary PCI should be implemented urgently.

The diagnosis of STEMI is made in the right clinical context in conjunction with anginal symptoms when at least 1 mm of ST elevation is present in two contiguous leads or a new left bundle branch block is detected on the ECG. Acute ST-segment elevation is associated with the highest risk of early death, and the presence of such findings indicates the need for immediate reperfusion therapy. This diagnosis should trigger a preplanned algorithm to initiate a reperfusion strategy with either fibrinolytics or primary PCI. The initial assessment of a patient with STEMI should focus on evaluating for hemodynamic and arrhythmic complications and on rapidly evaluating for the optimal reperfusion strategy.

Delays in reperfusion can arise from a number of sources. Reasons cited for delay include a lack of initial recognition of the symptoms by the patient, inefficient transportation to medical centers, and delays in initiating reperfusion therapy once the patient arrives. A well-coordinated STEMI response team comprised of cardiologists a emergency departments, and the emergency medical services (EMS) is needed to minimize delays.

Often, the first medical contact with a patient is by EMS. EMS personnel need to be well trained in the recognition and acute management of STEMI. The ability by EMS to perform and interpret 12-lead ECGs can lead to an accelerated diagnosis of STEMI and a more rapid reperfusion.[34] In addition, EMS should be equipped to handle complications that might arise from STEMI and have the ability to perform advanced cardiac life support, defibrillation, and intubation with mechanical ventilation when needed. Although not widely used, prehospital reperfusion with fibrinolytic agents given by appropriately trained personnel has been studied, and in a meta-analysis of six trials, it was shown that prehospital thrombolysis preceded the in-hospital thrombolysis by a mean of 58 minutes and reduced the all-cause hospital mortality with an odds ratio (OR) of 0.83 (95% confidence interval [CI], 0.70 to 0.98).[35]

Given the significant importance of time to reperfusion, benchmark guideline times have been put in place and are used to assess quality outcomes of health systems. Currently,

for fibrinolytic therapy, the recommended door-to-needle time is ≤30 minutes. This means that from the minute the patient arrives in the emergency room to the minute the fibrinolytic infusion is begun, the time elapsed is not >30 minutes. For primary PCI, the established benchmark is a door-to-balloon time of ≤90 minutes.[32]

Reperfusion Therapy for STEMI

Despite strong evidence for improved outcomes with early reperfusion therapy in STEMI, not all eligible patients receive this therapy. Currently, approximately 30% of STEMI patients receive no reperfusion therapy despite a lack of contraindications, and of those treated, <50% receive fibrinolytic agents within the recommended door-to-needle time of 30 minutes and <40% receive PCI within the recommended 90 minutes.[36] However, more recent data in at least one study suggest improvement in this trend, with the percentage of eligible patients in contemporary practice not receiving reperfusion therapy being closer to 10%.[37]

Both fibrinolytic therapy and primary PCI are suitable options for revascularization in STEMI. Choosing between the two therapies is based on a number of factors, but the important common denominator is that the chosen strategy be implemented as rapidly as possible. In general, primary PCI is favored over fibrinolytic therapy when available in a timely fashion, especially in those who are at high risk or presenting late after symptom onset.[38]

A pooled analysis of 23 randomized trials comparing primary PCI to fibrinolysis for STEMI showed that primary PCI was better than fibrinolytic agents for nearly all endpoints, including mortality (OR, 0.73; 95% CI, 0.62 to 0.86), reinfarction (OR, 0.35; 95% CI, 0.27 to 0.45), and stroke (OR, 0.46; 95% CI, 0.30 to 0.72).[39] However, when a patient presents to a hospital where PCI is not immediately available, the decision to transfer to a PCI-capable hospital versus immediate administration of fibrinolytic agents is a complex one.

Factors to consider when deciding between primary PCI and fibrinolysis include such factors as contraindications to fibrinolysis, the presence of cardiogenic shock, time from symptom onset, bleeding risk, diagnostic certainty of STEMI, and the time required to transfer for primary PCI.[32,40] Contraindications to fibrinolytic therapy are listed in Table 90.3 and include both absolute and relative contraindications. Patients meeting any of the absolute contraindications should not receive fibrinolytics and should be considered for primary PCI. The risks of administering fibrinolytics to a patient with a relative contraindication to reperfusion must be weighed carefully.

Primary PCI

One of the most substantial systematic barriers to obtaining primary PCI as the reperfusion modality is the lack of facilities and the time required to transfer a patient from a non-PCI hospital to a PCI-capable hospital. In many rural areas, primary PCI is not readily available and either transfer to a PCI center must be arranged or fibrinolytic therapy administered. In general, if the added time to obtain primary PCI over fibrinolytic therapy is more than 60 minutes, the mortality advantage gained by primary PCI is felt to be largely lost.[38] In many rural hospitals, fibrinolytic agents are the standard of care due to the long distances to the closest primary PCI centers. The focus at these institutions should be on initiating fibrinolytics as quickly as possible.

Table 90.3

Contraindications to fibrinolytic therapy in the management of STEMI

Absolute Contraindications
Any prior cerebral hemorrhage
Known structural central nervous system lesion (arteriovenous malformation, tumor, etc.)
Ischemic stroke within 3 mo UNLESS acute ischemic stroke of <3 h onset
Significant closed head or facial injury within 3 mo
Suspicion of aortic dissection
Active bleeding (excluding menses) or bleeding disorders
Relative Contraindications
History of chronic, severe, and poorly controlled hypertension, or severe hypertension on admission (systolic blood pressure > 180 mmHg or diastolic blood pressure > 100 mmHg)
Traumatic or prolonged (>10 min) CPR or noncompressible vascular punctures
Major surgery or internal bleeding within 3–4 wk
Other central nervous disease (structural or dementia) not noted above
Pregnancy
Active peptic ulcer disease
Current use of anticoagulants (the higher the INR, the higher the risk of bleeding)
Prior exposure to or prior allergic reaction to streptokinase or anistreplase, if using these agents

Adapted from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. *Circulation* 2004;110:588–636.

Fibrinolytic Therapy

Among the first studies to demonstrate the effectiveness of fibrinolytic therapy for the treatment of STEMI was the GISSI trial published in 1986.[41] In this study, streptokinase used to treat STEMI was associated with a significant reduction in mortality at 21 days (10.7% vs. 13%; RR, 0.81; $P = 0.0002$). Early administration of fibrinolytic therapy is critical to maximizing its effectiveness in restoring coronary blood flow. In general, the earlier fibrinolytics are administered after the onset of symptoms, the larger the mortality benefit that is derived from this therapy.[42] Currently, it is recommended that fibrinolytic therapy can be given to patients up to 12 hours after the onset of symptoms. Those receiving fibrinolytic agents more than 12 hours after the onset of symptoms derive little benefit, while those who receive fibrinolytic agents within 1 hour from the onset of symptoms have a significant reduction in mortality.

Several fibrinolytic agents are available and have been studied for the treatment of STEMI (see Chapter 112). These include streptokinase, tissue plasminogen activator (tPA; alteplase), reteplase, and tenecteplase (TNK). All agents can be used for this indication, but tenecteplase and reteplase are generally favored due to their relative ease of bolus dosing.

Overall, the choice of which fibrinolytic agent to use is less important than the early and rapid administration of fibrinolysis to appropriate patients without contraindications suffering from an acute STEMI (Table 90.3). In many parts of the world, fibrinolytics remain the reperfusion therapy of choice, largely due to the unavailability of primary PCI. For those that do not have resolution of anginal symptoms or at least 50% of the ST-segment elevation on ECG 1 hour after administration of fibrinolytics, plans should be made for urgent rescue PCI with a cardiac catheterization team.

THE ACUTE MANAGEMENT OF NSTEMI/UA

Assessing Risk in those with NSTEACS

After the initial triage, patients presenting with ACS without ST-segment elevation (non–ST-elevation ACS [NSTEACS]) or hemodynamic compromise can be evaluated in a more systematic manner, with the intent of determining the probability that the patient's symptoms are due to coronary artery disease (CAD). This involves a careful review of the patient's symptoms and physical findings, analyzing the ECG for ischemic changes such as ST-segment depression or T-wave inversion, reviewing the patient's medical record for a personal history of CAD or risk factors for heart disease, and evaluating serial serum biomarkers such as troponin to assess for MI.

The initial history is critical to assessing the probability of ACS. Typical angina is usually described as a deep substernal chest discomfort that can radiate to the arm and jaw and is associated with shortness of breath or diaphoresis. In ACS, these symptoms may present with rest pain or accelerating angina that occurs with lessening degrees of activity. For older patients, women, and diabetics, these typical features may not be present and are unreliable. Despite the widely held belief to the contrary, the relief of chest pain by sublingual nitroglycerin does not predict the presence of ACS.[43]

The ECG provides important prognostic and diagnostic information at the time of initial triage. It is an essential component of the early triage algorithm. Findings of old Q waves on the ECG are important because they indicate likely prior MI and a higher risk for CAD. A normal ECG does not exclude the diagnosis of ACS, but patients who have an unchanged ECG when compared to a prior one have a low risk of adverse events.[44]

Cardiac Biomarkers

The evaluation of cardiac biomarkers is an essential component to early triage and risk stratification. The clinical diagnosis of MI hinges on the detectable elevation of these cardiac biomarkers in conjunction with other findings of ischemia such as symptoms or ECG changes. Biomarkers are released into the peripheral circulation from infarcted cardiac myocytes when necrosis occurs (Table 90.4). The most widely used cardiac biomarkers currently are CK-MB and the cardiac troponins I and T (TnI and TnT). Myoglobin is rarely used clinically today. These proteins are found in high concentrations within the cardiac myocytes, making them specific for myocardial cell damage, and circulate at low levels within the peripheral circulation in the absence of cardiac myocyte necrosis (FIGURE 90.2). The cardiac troponins are highly sensitive and specific for MI and may be detectable in the blood as soon as 2 hours after the onset of symptoms and may stay elevated for as long as 14 days after an infarct.

The elevation of cardiac biomarkers has important and well-validated prognostic significance beyond that obtainable from the ECG and the patient's clinical parameters. An elevated troponin level is independently associated with an increased risk of death, and there is a direct and proportional relationship between the degree of elevation and this risk of death[45–47] (FIGURE 90.3).

Risk Stratification in NSTEACS Using Risk Scores

Once other causes of the patient's symptoms have been excluded and ACS is felt to be the diagnosis, early risk stratification is important to determining appropriate management. Doing this can aid in selecting the appropriate level of care needed for the patient, guiding the choices of the most appropriate medical therapies, and assisting in deciding between an early invasive strategy in the catheterization laboratory and a more conservative strategy initially with medical therapy.

Early risk stratification can help differentiate patients with NSTEMI and UA who often present with very heterogeneous symptoms. Multiple factors determine the likelihood of obstructive CAD and prognosis. Several risk scores have been developed to help clinicians identify high-risk patients rapidly. These include the Thrombolysis in Myocardial Infarction (TIMI) risk score and the Global Registry of Acute Coronary Events (GRACE) risk score (FIGURE 90.4 and Table 90.5).[48,49]

The TIMI risk score was developed as a simple tool comprising seven questions rating risk on presentation designed to assess patients with suspected UA or NSTEMI. For details on the score, see legend to Table 90.5. The TIMI risk score provides an estimate of death, MI, or recurrent ischemia requiring urgent revascularization within 14 days from presentation. It has been validated in several studies and is a quick and relatively easy bedside tool to help clinicians stratify patients based on risk.

The GRACE prediction score is a model that can be used to predict in-hospital mortality and mortality from discharge to 6 months in patients presenting with ACS.[49,50] The GRACE model for predicting 6-month postdischarge mortality uses factors such as age, personal history of heart failure and MI, initial blood pressure and pulse, ECG, and laboratory findings (FIGURE 90.4). It is a useful clinical tool for patients with NSTEMI, STEMI, and UA to predict 6-month mortality.

Initial Invasive Versus Initial Conservative Therapy

For patients presenting with NSTEMI or UA, one of two treatment pathways is usually decided upon based on patient risk and clinical stability. One pathway is labeled the "early invasive" strategy, while the other pathway for treatment is called the "initial conservative" or "selective invasive" strategy.[3] This terminology refers to the chosen angiographic strategy for the patient and the intended timing of diagnostic angiography with planned PCI. In both pathways, patients receive the usual

Table 90.4

Cardiac biomarkers

Marker	Advantages	Disadvantages	Point-of-Care Test Available?	Comment	Clinical Recommendation
Cardiac troponins	Powerful tool for risk stratification Greater sensitivity and specificity than CK-MB Detection of recent MI up to 2 wk after onset Useful for selection of therapy Detection of reperfusion	Low sensitivity in very early phase of MI (<6 h after symptom onset) and requires repeat measurement at 8 to 12 h, if negative Limited ability to detect late minor reinfarction	Yes	Data on diagnostic performance and potential therapeutic implications increasingly available from clinical trials	Useful as a single test to efficiently diagnose NSTEMI (including minor myocardial damage), with serial measurements. Clinicians should familiarize themselves with diagnostic "cutoffs" used in their local hospital laboratory
CK-MB	Rapid, cost-efficient, accurate assays Ability to detect early reinfarction	Loss of specificity in setting of skeletal muscle disease or injury, including surgery Low sensitivity during very early MI (<6 h after symptom onset) or later after symptom onset (more than 36 h) and for minor myocardial damage (detectable with troponins)	Yes	Familiar to majority of clinicians	Prior standard and still acceptable diagnostic test in most clinical circumstances
Myoglobin	High sensitivity Useful in the early detection of MI Detection of reperfusion Most useful in ruling out MI	Very low specificity in the setting of skeletal muscle injury or disease Rapid return to normal range limits sensitivity for later presentations	Yes	More convenient early marker than CK-MB isoforms because of greater availability of assays for myoglobin; rapid-release kinetics make myoglobin useful for noninvasive monitoring of reperfusion in patients with established MI

ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

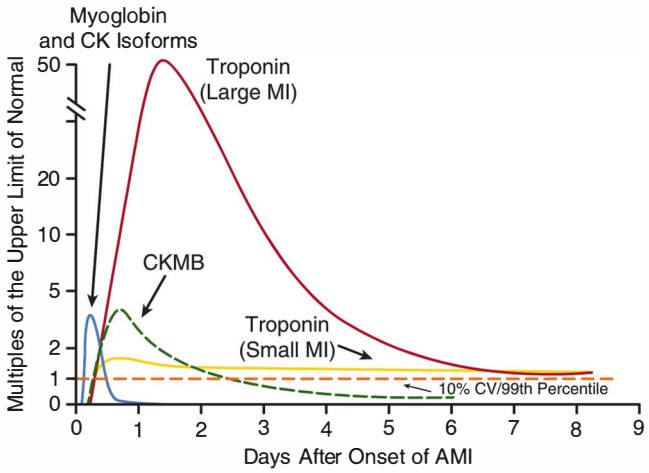

FIGURE 90.2 Release of biomarkers into the serum after acute myocardial infarction. The biomarkers are plotted showing the multiples of the cutoff for acute myocardial infarction (AMI) over time. The *dashed horizontal line* shows the upper limit of normal (ULN; defined as the 99th percentile from a normal reference population without myocardial necrosis; the coefficient of variation of the assay should be 10% or less). The earliest rising biomarkers are myoglobin and CK isoforms (*leftmost curve*). CK-MB (*dashed curve*) rises to a peak of 2 to 5 times the ULN and typically returns to the normal range within 2 to 3 days after AMI. The cardiac-specific troponins show small elevations above the ULN in small infarctions (e.g., as is often the case with NSTEMI) but rise to 20 to 50 times the ULN in the setting of large infarctions (e.g., as is typically the case in STEMI). The troponin levels may stay elevated above the ULN for 7 days or more after AMI. CK, creatine kinase; CKMB, MB fraction of creatine kinase; CV, coefficient of variation; MI, myocardial infarction. medical therapy for NSTEMI and UA that includes antianginal, antiplatelet, and anticoagulant therapy (FIGURES 90.5 and 90.6).

In the early invasive strategy, patients usually undergo coronary angiography within 24 to 48 hours after admission. In the initial conservative strategy, patients do not undergo coronary angiography initially unless they have failed medical therapy or have documented ischemia, such as that demonstrated by a stress test, despite optimal medical therapy.

Deciding between an early invasive and conservative strategy is based largely on patient characteristics. High-risk features favor an early invasive strategy. These may include refractory ischemia, elevated cardiac biomarkers, dynamic ECG changes, hemodynamic or arrhythmic instability, prior revascularization, an elevated risk score (TIMI or GRACE), or left ventricular dysfunction (Table 90.6). In addition, patients treated with an early invasive strategy include those without ST-segment elevation who undergo urgent cardiac catheterization due to clinical instability or refractory symptoms despite medical therapy. Patients at lower risk, or those with extensive comorbidities, where the risks of angiography may be considered to be too high, are typically treated with an initial conservative strategy.

For patients being treated with a conservative strategy, medical therapy is pursued with the intent of delaying the decision to proceed to coronary angiography until further clinical data are obtained. Generally in this group, the decision to go to diagnostic angiography is based upon results of a functional stress test showing objective evidence of ischemia, or upon persistent symptoms despite medical therapy.

The reasoning behind a conservative strategy is to avoid an invasive procedure and its inherent risk until the patient demonstrates objective evidence for ischemia or has not responded to medical therapy. The benefits to this strategy include the fact that many patients will stabilize on medical therapy and not require coronary angiography, thus reducing the use of an invasive and costly procedure. Patients treated in this pathway should have a stress test prior to discharge as well as an assessment for left ventricular function.

The early invasive strategy provides an angiographic method for risk stratification and a definitive evaluation for CAD. This strategy can differentiate those patients with no CAD from

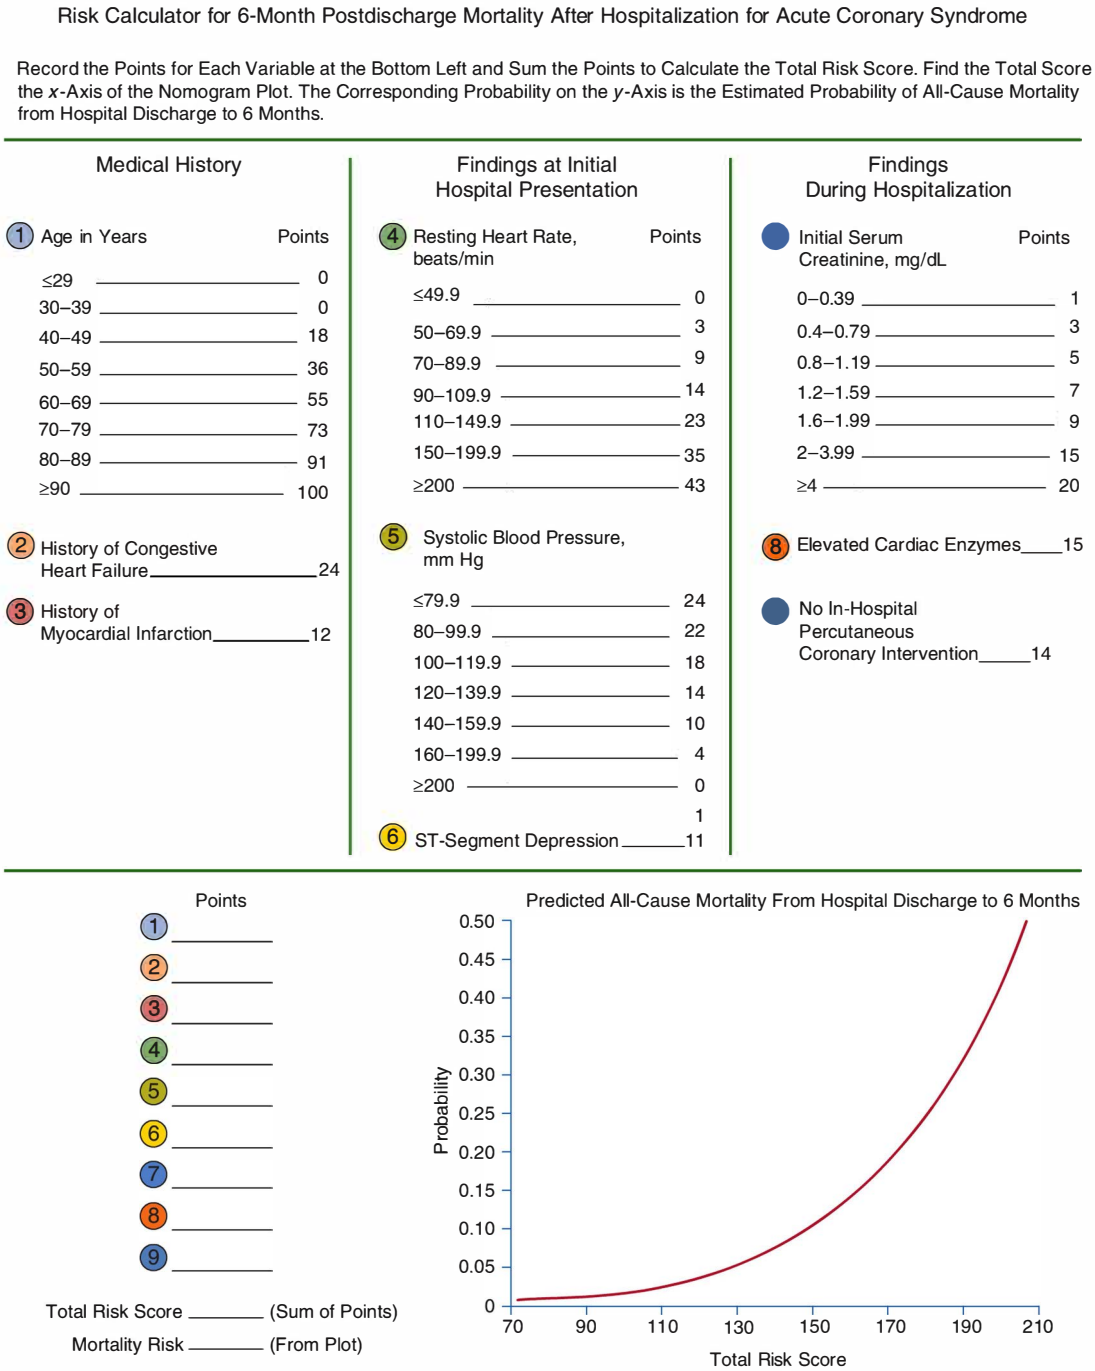

FIGURE 90.4 GRACE risk prediction model. (Adapted from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304. Copyright © 2004 American Medical Association.)

those with severe CAD who may benefit from revascularization.[51,52] Furthermore, percutaneous revascularization of the culprit lesion may lead to a reduced risk for rehospitalization and reduced angina after discharge.[53]

Several trials have compared the early invasive strategy to the initial conservative approach. A meta-analysis of these trials concluded that a routine invasive approach is superior to a conservative strategy in reducing death or MI (14.4% vs. 12.2%;

Table 90.5

Thrombolysis in myocardial infarction risk score[a]

TIMI Risk Score	All-Cause Mortality, New or Recurrent MI, or Severe Recurrent Ischemia Requiring Urgent Revascularization through 14 d After Randomization (%)
0–1	4.7
2	8.3
3	13.2
4	19.9
5	26.2
6–7	40.9

[a]The TIMI risk score is determined by the sum of the presence of seven variables at admission: 1 point is given for each of the following variables: age 65 years or older; at least three risk factors for CAD; prior coronary stenosis of 50% or more; ST-segment deviation on ECG presentation; at least two anginal events in prior 24 hours; use of aspirin in prior 7 days; elevated serum cardiac biomarkers. Prior coronary stenosis of 50% or more remained relatively insensitive to missing information and remained a significant predictor of events.
MI, myocardial infarction.
Adapted from Antam EM, Cohen M, Bemink PH, et al. The TIMI risk score for unstable angina/non-ST elevation MI: a method for prognostication and therapeutic decision making. *JAMA* 2000;284:835–842; Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

OR = 0.82; 95% CI, 0.72 to 0.93).[54] This analysis showed an 18% relative reduction in death or MI, as well as a sustained reduction in mortality following discharge from the hospital with the invasive approach. In addition, the invasive strategy led to a reduction in angina, fewer hospitalizations, and improvements in quality of life.

A second meta-analysis of more contemporary randomized trials in NSTEMI also showed benefit with an early invasive approach.[55] The results showed a long-term improvement in mortality and morbidity with the invasive strategy, including a reduction in MI and rehospitalizations (FIGURES 90.7 and 90.8). These improvements seem to be sustained for years after the event. An analysis from FRISC-II (FRagmin and fast Revascularization during InStability in Coronary artery disease-II) showed that the reduction in death or nonfatal MI is sustained for up to 5 years, and data from RITA-3 (Third Randomized Intervention Treatment of Angina) also demonstrated a reduction in death and MI at 5 years.[56,57]

Overall, the objective is to identify those patients who are most likely to benefit from an aggressive early invasive approach and minimize the exposure to potential harm in those less likely to benefit. The decision to proceed to early coronary angiography, versus a delayed and more conservative approach, is an individual one that should consider the wishes of the patient and family as well as the patient's comorbidities. It must also be emphasized that ACS is a dynamic process where the clinical stability of a patient and the perceived benefit of an aggressive approach may change rapidly.

Mechanical Reperfusion

Mechanical reperfusion of the coronary arteries can be performed percutaneously or surgically. PCI can restore coronary blood flow through a number of approaches that include balloon angioplasty, intracoronary stenting, or removal of existing thrombus with thrombectomy devices. Used in the appropriate settings, such as for the treatment of acute MI, these therapies can be life saving. Surgical revascularization with coronary artery bypass grafting (CABG) involves the surgical implantation of venous or arterial grafts to the coronary arteries. This procedure is generally reserved for those patients with severe diffuse CAD not easily approached percutaneously.

Percutaneous Coronary Interventions

The development of intracoronary stents marked a significant improvement in the ability to revascularize coronary arteries percutaneously. Previously, balloon angioplasty alone was plagued by very high rates of coronary restenosis. The implantation of bare metal stents significantly reduced the rate of restenosis, but the problem is still seen in about 25% of cases where bare metal stents are used. Systemically delivered therapies, except for cilostazol, have not been able to demonstrate any attenuation in the rate of restenosis.[58] The development of drug-eluting stents has been able to address the problem of restenosis due to intimal hyperplasia by the local delivery of drugs that inhibit the proliferative and inflammatory response to vascular injury that occurs with stent implantation. The currently available stents within the United States elute antiproliferative drugs such as paclitaxel, sirolimus, everolimus, and zotarolimus. Early studies of drug-eluting stents showed a marked reduction in the rates of restenosis by about 75% to 90%.[59–61] However, there is a tradeoff with an increased risk of late stent thrombosis that is theorized to be a result of inhibited endothelial coverage of the stent struts from the eluting drug.

An evolving tool in the armamentarium of the interventional cardiologist for the treatment of intracoronary thrombus in the setting of ACS is intracoronary thrombectomy. These devices use a catheter-based system to mechanically remove with suction visible coronary thrombus seen on angiography. The routine use of thrombectomy devices has been shown to improve measures of myocardial reperfusion, reduce infarct size, improve the incidence of LV remodeling, and reduce mortality when performed at the time of PCI in the management of STEMI, although the data supporting this is still somewhat mixed.[62]

Coronary Artery Bypass Grafting

For select patients, there appears to be a survival benefit to surgical revascularization over PCI. A patient registry of consecutive patients with CAD compared 5-year survival rates for medical management, PCI, and CABG between 1984 and 1990.[63–66] All patients with three-vessel disease and those with two-vessel disease with a severe proximal left anterior descending artery stenosis had a survival benefit with CABG over medical therapy or PCI. Another subgroup that appears to derive benefit from CABG over medical or percutaneous therapy for CAD includes those with diabetes. In the BARI (Bypass Angioplasty Revascularization Investigation), survival benefit for CABG was restricted to those with diabetes (76.4% survival after CABG vs. 55.7% after PCI; $P = 0.001$).[67]

FIGURE 90.5 Treatment algorithm for UA/NSTEMI patients treated with initial invasive strategy. (From Anderson JL, Adams CD, Antman EM, et al., ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.)

The appropriate management of antithrombotic therapy prior to, during, and after CABG surgery is critical to improving the outcome of the patient. Prior to surgery, it is important to assess for the risk of bleeding and thrombotic complications. Historical features such as a history of previous open-heart surgeries, end-stage renal disease, a personal or family history of coagulation disorders, and immobility are all important factors in the risk of both bleeding and thrombotic complications. Table 90.7 lists the timing for discontinuation of antiplatelet and anticoagulant therapies prior to CABG as recommended by the AHA/ACC practice guidelines.

Although many of the risks are not modifiable, they should guide appropriate antithrombotic therapy to minimize risk. Preoperatively, an effort should be made to minimize the operative risk of bleeding by discontinuation of unnecessary antithrombotic agents. Aspirin use in the days leading up to surgery has been associated with greater blood loss, but not clearly linked to other adverse outcomes.[68] However, the use of the ADP receptor antagonists like clopidogrel prior to surgery has been linked to increased bleeding and adverse events like increased chest tube drainage.[69] Currently, it is recommended that clopidogrel be discontinued 5 to 7 days prior to any planned cardiac surgery to reduce the risk of bleeding complications. Additionally, the preoperative use of GP IIb/IIIa inhibitors such as abciximab and the vitamin K antagonists such as warfarin is also linked to an increased risk of bleeding.[70,71] Careful monitoring of anticoagulation at the time of bypass, platelet transfusions, and discontinuation of warfarin allowing for the normalization of the international normalized ratio (INR) are measures that may reduce bleeding risk.

THERAPY—MEDICAL MANAGEMENT OF ACS

Patients being treated for ACS should be admitted to an inpatient unit for observation and continuous telemetry monitoring. Treatment should be carried out in a dedicated cardiac unit with physicians and staff trained in the evaluation and management of acute coronary disease. The evaluation of these patients

ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.)

should include monitoring for symptoms of recurrent ischemia, hemodynamic instability, or arrhythmic complications from ACS. For those with continued ischemic symptoms, hemodynamic compromise, or significant rhythm disturbances, admission to a coronary care unit (CCU) is advisable. Admission to the CCU allows for a more frequent assessment of stability, quick defibrillation in the event of ventricular fibrillation or pulseless ventricular tachycardia, and staff who are trained to perform critical care.

The treatment of ACS patients in dedicated cardiac units with physicians and staff knowledgeable of the therapies used to treat CAD promotes the use of evidence-based therapeutics. The acute therapy of ACS can be divided into four groups of medical therapy: (a) antiplatelet therapies, (b) anticoagulants, (c) anti-ischemic therapies, and (d) heart failure and/or secondary prevention therapies.

Antiplatelet Therapy

The currently available classes of antiplatelet therapy that are approved for use in ACS include aspirin, the ADP receptor ($P2Y_{12}$) antagonists, and the GP IIb/IIIa inhibitors (see Chapter 111) (FIGURE 90.8). Aspirin should be initiated with the first medical contact in anyone suspected of having ACS, unless a contraindication exists. A $P2Y_{12}$ inhibitor, such as clopidogrel, should be used in the medical management of ACS for those in

Table 90.6

Clinical features favoring an early invasive strategy versus an initial conservative strategy

Preferred Strategy	Patient Characteristics
Invasive	Recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy Elevated cardiac biomarkers (TnT or TnI) New or presumably new ST-segment depression Signs or symptoms of HF or new or worsening mitral regurgitation High-risk findings from noninvasive testing Hemodynamic instability Sustained ventricular tachycardia PCI within 6 mo Prior CABG High-risk score (e.g., TIMI, GRACE) Reduced left ventricular function (LVEF < 40%)
Conservative	Low-risk score (e.g., TIMI, GRACE) Patient or physician preference in the absence of high-risk features

CABG, coronary artery bypass graft; GRACE, Global Registry of Acute Coronary Events; HF, heart failure; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; TIMI, Thrombolysis In Myocardial Infarction; TnI, troponin I; TnT, troponin T.

whom a noninvasive strategy is selected and is generally started before diagnostic angiography (upstream) in those undergoing an invasive strategy. The GP IIb/IIIa inhibitors are generally used at the time of PCI for their powerful antiplatelet effect and reduction in acute stent thrombosis. However, they can also be used upstream in conjunction with, or instead of, a $P2Y_{12}$ inhibitor in those at high risk where early cardiac catheterization is anticipated. Table 90.8 lists the AHA/ACC class I recommendations for antiplatelet use in UA or acute MI.

Aspirin

Some of the oldest and strongest evidence for antiplatelet therapy in the treatment of ACS is with aspirin.[72,73–75] Through irreversible inhibition of COX-1, aspirin inhibits the formation of TXA_2 and inhibits platelet aggregation. Aspirin is useful for both the acute treatment of ACS and secondary prevention of cardiovascular events and is one of the most important therapies for ACS.

For patients with acute STEMI, aspirin significantly reduces mortality. The ISIS-2 trial (Second International Study of Infarct

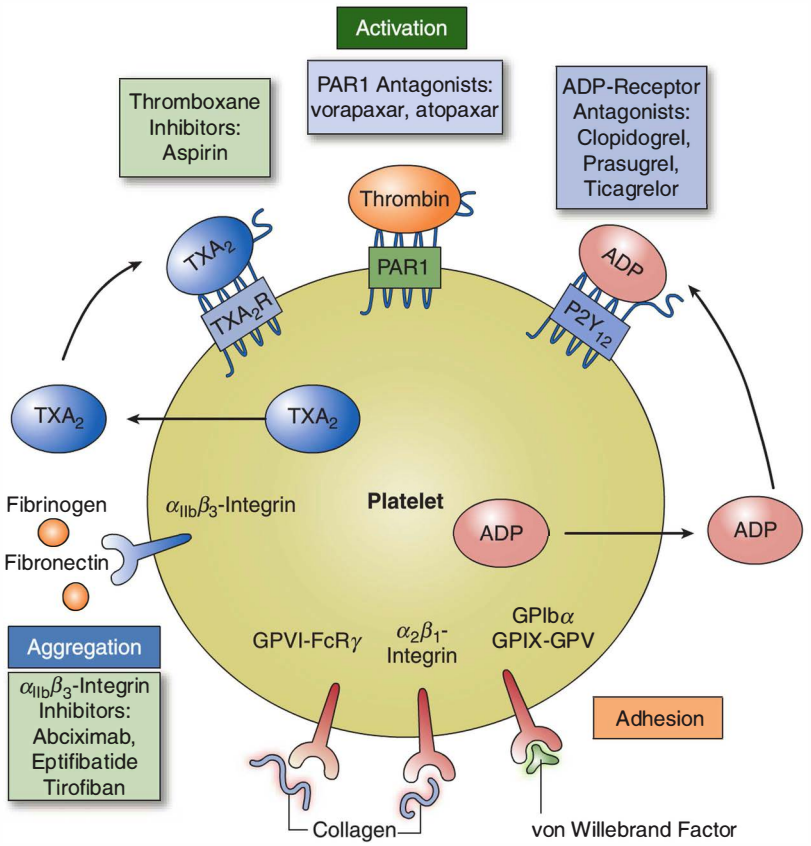
FIGURE 90.8 Targets for antiplatelet therapy.



Survival) demonstrated a significant 23% reduction in 5-week cardiovascular mortality with aspirin—a treatment effect similar to that seen with streptokinase in the same trial.[76] Similarly, powerful results were demonstrated with NSTEMI/UA. Some of the earlier trials with aspirin in NSTEMI/UA showed marked reductions in MI or death by more than 50%.[75,77]

The dose of aspirin used clinically varies widely, and there remains debate as to the optimal dose. A meta-analysis of over 140,000 patients showed similar reductions in outcomes, with doses ranging from 75 to 1,500 mg but a reduction in efficacy with doses <75 mg.[78] Data from the CURE trial (Clopidogrel in Unstable angina to prevent Recurrent Events) showed no difference in ischemic outcomes with different doses of aspirin but an increasing risk of bleeding with escalating doses.[79] The CURRENT OASIS-7 (Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent Events/Optimal Antiplatelet Strategy for

Table 90.8

Class I AHA/ACC recommendations for antiplatelet therapy for UA/NSTEMI

1. Aspirin should be administered to UA/NSTEMI patients as soon as possible after hospital presentation and continued indefinitely in patients not known to be intolerant of that medication. *(Level of Evidence: A)* (FIGURES 90.7 and 90.8)
2. Clopidogrel (loading dose followed by daily maintenance dose) should be administered to UA/NSTEMI patients who are unable to take ASA because of hypersensitivity or major gastrointestinal intolerance. *(Level of Evidence: A)* (FIGURES 90.7 and 90.8)
3. In UA/NSTEMI patients with a history of gastrointestinal bleeding, when ASA and clopidogrel are administered alone or in combination, drugs to minimize the risk of recurrent gastrointestinal bleeding (e.g., proton-pump inhibitors) should be prescribed concomitantly. *(Level of Evidence: B)*
4. For UA/NSTEMI patients in whom an initial invasive strategy is selected, antiplatelet therapy in addition to aspirin should be initiated before diagnostic angiography (upstream) with either clopidogrel (loading dose followed by daily maintenance dose) or an intravenous GP IIb/IIIa inhibitor. (*Level of Evidence: A*) Abciximab as the choice for upstream GP IIb/IIIa therapy is indicated only if there is no appreciable delay to angiography and PCI is likely to be performed; otherwise, intravenous eptifibatide or tirofiban is the preferred choice of GP IIb/IIIa inhibitor. (*Level of Evidence: B*)
5. For UA/NSTEMI patients in whom an initial conservative (i.e., noninvasive) strategy is selected, clopidogrel (loading dose followed by daily maintenance dose) should be added to ASA and anticoagulant therapy as soon as possible after admission and administered for at least 1 mo *(Level of Evidence: A)* and ideally up to 1 y. *(Level of Evidence: B)* (FIGURE 90.6)
6. For UA/NSTEMI patients in whom an initial conservative strategy is selected, if recurrent symptoms/ischemia, HF, or serious arrhythmias subsequently appear, then diagnostic angiography should be performed. *(Level of Evidence: A)* (FIGURE 90.6). Either an intravenous GP IIb/IIIa inhibitor (eptifibatide or tirofiban; *Level of Evidence: A*) or clopidogrel (loading dose followed by daily maintenance dose; *Level of Evidence: A)* should be added to ASA and anticoagulant therapy before diagnostic angiography (upstream). *(Level of Evidence: C)*

ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

Interventions) trial was designed, in part, to compare high-dose (300 to 325 mg) to low-dose (75 to 100 mg) aspirin in ACS and showed no difference in its primary outcome of cardiovascular death, MI, or stroke and no difference in major bleeding.[80] Current recommendations from the ACC/AHA guidelines are to use 162 to 325 mg daily after stent implantation, but to use 75 to 162 mg daily for medically treated patients and for those being treated indefinitely on aspirin.[3]

$P2Y_{12}$ Inhibitors

Clopidogrel, ticlopidine, and prasugrel are thienopyridine derivatives that block the binding of ADP to the ADP receptor ($P2Y_{12}$) and inhibit platelet aggregation. Ticagrelor is a nonthienopyridine agent that directly blocks the $P2Y_{12}$ receptor and inhibits platelet aggregation through a similar mechanism. As a group, these four agents can be referred to as the "$P2Y_{12}$ inhibitors." Because the mechanism of action for platelet inhibition is different than that from aspirin, there is felt to be an additive benefit to these drugs when given in conjunction with aspirin.

Clopidogrel

Clopidogrel is currently the most commonly used $P2Y_{12}$ inhibitor. It has largely replaced ticlopidine due to the adverse effects associated with ticlopidine, which include severe neutropenia, gastrointestinal upset, and a risk for a potentially fatal complication known as thrombotic thrombocytopenic purpura (see Chapter 99).[81] When compared to ticlopidine, clopidogrel was better tolerated with similar rates of stent thrombosis and major complications.[82] Table 90.9 lists the major clinical trials evaluating clopidogrel in the management of ACS.

Dual therapy with aspirin plus clopidogrel in NSTEMI/UA was evaluated in the CURE trial.[79] In this study, patients presenting with NSTEMI/UA within 24 hours were randomized to receive aspirin alone or aspirin plus clopidogrel and were followed for 3 to 12 months. The group receiving clopidogrel had a significant reduction in cardiovascular death, stroke, or MI (11.5% vs. 9.3%; $P < 0.001$). The reduction in ischemic events was noted within the first few hours after randomization and was sustained for up to 1 year. This study supports the early administration of clopidogrel to those presenting with NSTEMI/UA, especially in those being treated noninvasively where the risk for CABG-related bleeding is small. Based on this study, treatment with clopidogrel in those medically managed for ACS should continue for at least 1 month, and ideally for up to a year and is given a class I recommendation by the ACC/AHA guidelines (Table 90.8).[3]

A subset of patients from the CURE study who underwent PCI was studied in the PCI-CURE trial.[83] In this analysis, pretreatment with clopidogrel reduced the primary endpoint of cardiovascular death, MI, or urgent target vessel revascularization within 30 days of PCI from 6.4% to 4.5%. In addition, there was a 31% reduction in the endpoint of cardiovascular death or MI. In the CREDO (Clopidogrel for the Reduction of Events During Observation) trial, patients referred for cardiac

catheterization with a high likelihood to receive PCI (many of whom had ACS) were randomized to receive a loading dose of 300 mg of clopidogrel or placebo prior to PCI, as well as long-term (12 months) or short-term (28 days) clopidogrel after PCI.[84] Long-term therapy with clopidogrel for 1 year reduced events as compared to short-term therapy with a relative reduction in the combined risk of death, MI, or stroke of 26.9% (95% CI, 3.9%–44.4%; p = 0.02).

The use of clopidogrel in the management of ACS should begin with a loading dose of 300 mg, followed by the administration of 75 mg once daily. With a loading dose of 300 mg, the target level of platelet inhibition is reached within 4 to 6 hours; without it, this level is not reached until 3 to 5 days.[85] The use of a 600-mg loading dose results in effective platelet inhibition in about 2 hours.[86]

The use of the 600 mg load for patients undergoing PCI was studied in the ISAR-REACT-2 trial (Intracoronary Stenting with Antithrombotic Regimen-Rapid Early Action for Coronary Treatment).[87] In this study, all patients received 600 mg of clopidogrel at least 2 hours prior to cardiac catheterization, and they were randomized to abciximab (GP IIb/IIIa) plus reduced-dose heparin or placebo plus full-dose heparin. In those with a negative troponin, there was no difference in events, suggesting adequate platelet inhibition with clopidogrel loading alone. For those high-risk patients with positive troponin levels, it appears that the addition of abciximab to clopidogrel is safe and effective at further reducing events.

Clopidogrel resistance has been well described and is an area of intense research. Decreased clopidogrel responsiveness seems to correlate with an increased risk for ischemic events and appears to, at least in part, be related to polymorphisms in the CYP2C19 alleles coding for enzymes responsible for converting the prodrug to its active metabolite.[88,89] Observational studies have also linked the use of proton-pump inhibitors, especially omeprazole, with a decreased antiplatelet effect of clopidogrel—presumably through inhibition of the CYP2C19 enzyme.[90,91] A recently published trial using omeprazole in conjunction with clopidogrel refutes this analysis and does not show an increased risk with the coadministration of omeprazole with clopidogrel.[92] Furthermore, in patients with high platelet residual activity (a marker for clopidogrel resistance) on standard-dose clopidogrel, double-dose clopidogrel does not appear to improve outcomes at 6 months in patients receiving drug-eluting stents.[93]

Prasugrel

Prasugrel was approved for use by the US Food and Drug Administration in July 2009. The phase II trial JUMBO-TIMI 26 established the dosage of 60 mg load and 10 mg daily maintenance.[94] The PRINCIPLE-TIMI 44 trial demonstrated higher platelet inhibition with standard-dose prasugrel, both with loading and maintenance, as compared to high-dose clopidogrel (600 mg load, 150 mg daily maintenance).[95] The TRITON-TIMI 38 trial was a large phase 3 trial that compared prasugrel to clopidogrel in over 13,000 patients with high-risk ACS.[96] Prasugrel (60 mg load, 10 mg daily maintenance dose) showed a 19% relative reduction in the primary endpoint of cardiovascular death, nonfatal MI, or nonfatal stroke; which was primarily driven by a reduction in the rate of nonfatal MI. The components of the composite endpoints that were statistically improved with prasugrel over clopidogrel were nonfatal MI (HR = 0.76), urgent target vessel revascularization (HR = 0.66), and stent thrombosis (HR = 0.48).

The tradeoff for ischemic benefit in the TRITON trial was an increase in the rate of major bleeding, including life-threatening bleeding. Subgroup analyses identified two groups of patients in

whom caution is advised (≥75 years old, <60 kg in weight) and one group in whom the drug should be avoided altogether—those with a history of a transient ischemic attack or stroke. The groups of patients that appear to derive the most benefit from prasugrel are those presenting with STEMI and those with diabetes.

The TRILOGY ACS (Targeted platelet inhibition to clarify the optimal strategy to medically manage ACS) trial evaluates the use of prasugrel for the prevention of ischemic events when started within 10 days of presentation with a UA or NSTEMI event selected for a medical management strategy without revascularization. Using what was learned from the TRITON study, 5 mg, as opposed to 10 mg, of prasugrel is studied in those felt at highest risk for bleeding (≥75 years of age or <60 kg) in an attempt to reduce bleeding risk, while maximizing reductions in ischemic events.[97]

Ticagrelor

The most recently studied $P2Y_{12}$ inhibitor, ticagrelor, appears to have a more potent inhibition of platelet function with a more rapid onset of action and slightly more rapid reversal of action after discontinuation.[98] It was compared to clopidogrel in the PLATO (Platelet Inhibition and Patient Outcomes) trial that enrolled over 18,000 patients with ACS.[99] At 1 year, the primary endpoint of cardiovascular death, MI, or stroke was reduced in the ticagrelor groups as compared to the clopidogrel group (9.8% vs. 11.7%; HR = 0.84; 95%CI, 0.77 to 0.92; $P = 0.0003$). The hazard ratios for MI (HR = 0.84), cardiovascular death (HR = 0.79), or definite stent thrombosis (HR = 0.67) all favored ticagrelor and were statistically significant. When compared on bleeding endpoints, there was no difference in overall bleeding, but a higher rate of non–CABG-related bleeding was seen with ticagrelor as compared to clopidogrel (4.5% vs. 3.8%; $P = 0.03$). Also noted was a higher rate of self-reported dyspnea with ticagrelor. Ticagrelor, unlike clopidogrel and prasugrel, is administered twice daily with a 180-mg loading dose and a 90 mg twice-daily maintenance dose.

Glycoprotein IIb/IIIa Inhibitors

The binding of fibrinogen to the GP IIb/IIIa receptor is a critical component to the formation of platelet thrombi and is the final pathway for platelet aggregation.[100] The GP IIb/IIIa receptor antagonists occupy these receptors and inhibit this binding. The three most commonly used GP IIb/IIIa inhibitors include abciximab, eptifibatide, and tirofiban. They are used for the prevention of ischemic events associated with PCI and as part of the medical therapy for patients with ACS.

Abciximab

Abciximab is an Fab fragment of a humanized murine antibody, which strongly binds to the GP IIb/IIIa receptor. Its role is primarily in the catheterization laboratory, where it is used to reduce the rate of periprocedural MIs at the time of PCI and minimize the need for urgent revascularization. The CAPTURE trial evaluated the use of abciximab in patients with ACS undergoing angioplasty.[101] Abciximab reduced the combined event rate of death, MI, or urgent revascularization at 30 days when compared to placebo (11.3% vs. 15.9%; $P = 0.012$). The GUSTO IV-ACS trial compared a 24-hour and 48-hour infusion of abciximab to placebo in NSTEMI/UA patients for whom an early revascularization was not planned.[102] In this trial, there was harm associated with abciximab with an increased risk of death at 48 hours with an odds ratio of 2.9 for those who received the 48-hour abciximab infusion versus placebo (95% CI, 1.28 to 6.44; $P = 0.008$). As a result, abciximab should not be used for the management of ACS in patients for whom PCI is not planned.

Eptifibatide

Eptifibatide is a cyclic heptapeptide containing the KGD (Lys–Gly–Asp) sequence and has a strong affinity for the GP IIb/IIIa receptor and a short half-life. After discontinuation of the drug, platelet aggregation returns to normal in 4 to 8 hours. Eptifibatide was studied in over 10,000 patients with NSTEMI/UA in the PURSUIT trial.[103] Eptifibatide was here added to the medical management of ACS and continued for 72 hours or longer if PCI was performed. Eptifibatide was shown to reduce death and nonfatal MI up to 30 days after the index event (14.2% vs. 15.7%; $P = 0.04$). As a result, eptifibatide can be used in patients treated medically for ACS or with planned PCI; however, its use is now generally restricted for peri-PCI use in ACS as a result of the EARLY-ACS trial (see below).[104]

Tirofiban

Tirofiban is a nonpeptide mimetic of the RGD (Arg–Gly–Asp) sequence of fibrinogen. It too has a strong affinity for the GP IIb/IIIa receptor and a relatively short half-life. Two of the larger trials evaluating tirofiban are PRISM (Platelet Receptor Inhibition in Ischemic Syndrome Management) and PRISM-PLUS (Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms).[105,106]

The PRISM study compared tirofiban to heparin in patients with NSTEMI/UA and showed a reduction in the composite outcome of death, MI, or refractory ischemia at 48 hours with tirofiban that did not persist at 30 days. However, a significant reduction in mortality alone was observed at 30 days in the tirofiban group (2.3% vs. 3.6%; $P = 0.02$), with most of the benefit confined to those with elevated serum troponin levels.

The PRISM-PLUS trial compared tirofiban to UFH and the combination of both in patients with NSTEMI/UA. Excess mortality was seen in the tirofiban alone arm, leading this arm to be discontinued early. The combination of tirofiban and UFH, as compared to UFH alone, significantly reduced ischemic endpoints such as death and MI to 6 months. Tirofiban, in combination with heparin, can be used in the treatment of patients with ACS whether treated medically or with PCI. In general, however, the variable study results seen with tirofiban are felt to be a result of the lack of optimization of dosage.

Summary of GP IIb/IIIa Inhibitors

Overall, a meta-analysis of the trials evaluating GP IIb/IIIa inhibitors found that the ACS patients who benefited the most from these agents were those at higher risk defined by elevations in serum troponin and those patients planned for invasive strategy with PCI.[107] However, the administration of GP IIb/IIIa inhibitors to patients with ACS is not without risk. Most notable is the increased risk of bleeding, which generally occurs in mucocutaneous tissue or vascular access sites. In addition, the risk for profound thrombocytopenia, while small, can be significant and lead to life-threatening situations.

Applying the results of many of these GP IIb/IIIa studies, which were performed before the era of routine clopidogrel loading, to contemporary practice is challenging. The EARLY-ACS trial was designed to help answer this question and compare the early routine administration of the GP IIb/IIIa inhibitor eptifibatide to delayed provisional use in a high-risk cohort of UA/NSTEMI patients with planned PCI.[104] Overall, there was no clinical benefit from the upstream use of eptifibatide in this study, with an increased risk of bleeding. However, consistent with previous observations in earlier trials, in those with elevated troponin, a nonsignificant trend toward benefit was seen with early routine administration of eptifibatide. In those with a negative troponin, a trend toward harm was observed with early eptifibatide.

Anticoagulant Agents

As previously described in this chapter, anticoagulant therapy in addition to antiplatelet therapy is fundamental to the treatment of the underlying pathologic process of intracoronary thrombus formation in ACS. Several different anticoagulant agents have been studied in the treatment of ACS and are now available. These include UFH, LMWH, DTIs, and factor Xa inhibitors. Deciding on the best anticoagulant for an individual patient is complex and hinges on several factors. Among others, these include patient characteristics, ease of dosing, cost, comfort level of the provider with that drug, bleeding risk, and the likelihood of an invasive or surgical procedure. The class I recommendations for the use of anticoagulants from the AHA/ACC guidelines for the management of UA and MI are listed in Table 90.10.

Many clinical trials have been conducted to compare different anticoagulants in the management of ACS. However, because of differences in patients studied, dosing strategies, and antiplatelet use, comparison across trials is difficult. The currently available data suggest that the initial choice of which anticoagulant to use should be guided in part by whether an invasive strategy with early catheterization is chosen as opposed to a conservative strategy with medical therapy. What follows is a brief overview of the available anticoagulants for the treatment of ACS. For a detailed review, please see Chapter 105.

Unfractionated Heparin

UFH is an anticoagulant that works indirectly by binding to and generating a conformational change of antithrombin, which thereafter inactivates factors IIa (thrombin), IXa, and Xa more rapidly. UFH is comprised of polysaccharide chains of varying size. For the management of ACS, it is administered via the intravenous route with frequent laboratory monitoring of its activity.

UFH has been evaluated in the treatment of ACS.[108–111] In these early studies, the use of heparin reduced the risk of death or MI by up to one-half. A meta-analysis of studies evaluating UFH with endpoints up to 12 weeks suggested early benefit, with attenuation of the benefit of anticoagulation over time.[112] This may be due in part to a reactivation of the thrombotic process after discontinuation of the anticoagulant and has been observed with several of the anticoagulants including UFH.[113,114]

One of the biggest limitations of UFH is its marked variability in anticoagulant effect among patients.[115] As a result, the use of UFH must be guided by laboratory monitoring of activated partial thromboplastin time (aPTT). Current guidelines recommend a weight-adjusted regimen of an initial bolus of 60 U/kg (maximum 4,000 U) and an initial infusion of 12 U/kg/h (maximum 1,000 U/h), with titration to an aPTT of 60 to 80 seconds. Another limitation of the heparins, and especially UFH, is the risk for heparin-inducted thrombocytopenia (HIT)—an autoimmune-induced reaction to heparin that results in severe thrombocytopenia and thrombosis (see Chapter 108). This is a life-threatening complication that requires immediate cessation of the heparin drug and should prompt the consultation of a hematologist knowledgeable in the management of HIT.

Low Molecular Weight Heparins

The LMWHs are derived from depolymerization of the larger polysaccharide chains that form the UFH and have a greater anti-Xa effect than anti-IIa effect. They have a longer half-life than UFH and can usually be administered subcutaneously once or twice daily with no laboratory monitoring and less risk for HIT.[116]

Table 90.10

Class I recommendations for anticoagulation use for the management of UA or MI

Anticoagulant therapy should be added to antiplatelet therapy in UA/NSTEMI patients as soon as possible after presentation
For patients in whom an invasive strategy is selected, regimens with established efficacy at a *Level of Evidence: A* include enoxaparin and UFH (FIGURE 90.5), and those with established efficacy at a *Level of Evidence: B* include bivalirudin and fondaparinux (FIGURE 90.5)
For patients in whom a conservative strategy is selected, regimens using either enoxaparin or UFH *(Level of Evidence: A)* or fondaparinux *(Level of Evidence: B)* have established efficacy (FIGURE 90.6).
In patients in whom a conservative strategy is selected and who have an increased risk of bleeding, fondaparinux is preferable *(Level of Evidence: B)* (FIGURE 90.6)

Adapted from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

Early evaluation of the use of LMWH in ACS was performed in trials such as the FRISC (Fragmin during Instability in Coronary Artery Disease) study.[117] In this trial, over 1,000 patients with NSTEACS were randomized to dalteparin (a LMWH) or placebo, with therapy continuing for up to 45 days. In the dalteparin group, there was a 63% reduction in MI or death during the first 6 days, and this benefit continued to a lesser degree out to 40 days and was confined only to smokers.

In the ESSENCE (Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events) and TIMI 11B trials, enoxaparin showed a significant benefit in the occurrence of death, MI, or recurrent ischemia over UFH in patients with NSTEACS.[118,119] Those with higher risk, such as ST-segment changes on ECG or elevated serum troponin levels, seemed to derive the most benefit with enoxaparin.

In the early trials evaluating enoxaparin, the rates of cardiac catheterization and PCI were low. For example, only 13% to 17% of patients in the ESSENCE trial underwent PCI. A more contemporary evaluation of enoxaparin compared to UFH in patients with ACS undergoing an early invasive strategy and a high use of GP IIb/IIIa inhibitors is the SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa inhibitors) trial.[120] In this study, enoxaparin was shown to be noninferior to UFH in the prevention of death or MI at 30 days with an increase in bleeding.

A *post hoc* analysis of the SYNERGY data suggested that some of the excess bleeding seen with enoxaparin was due to crossover to UFH at the time of PCI.[121] This suggests that avoiding crossover of anticoagulants at the time of PCI can reduce bleeding risk, but this observation may have in fact limited the adoption of enoxaparin for those being treated with an early invasive strategy as the effect of enoxaparin is more difficult to monitor in the catheterization laboratory than UFH, and it is less effectively reversed with protamine.

In STEMI patients treated with fibrinolytic therapy, the ASSENT-3 (Assessment of the Safety and Efficacy of a New Thrombolytic Regimen), ENTIRE (Enoxaparin and TNK-tPA with or without GP IIb/IIIa Inhibitor as Reperfusion strategy in ST elevation MI)–TIMI 23, and EXTRACT (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment)–TIMI 25 trials evaluated the use of enoxaparin as compared to UFH in conjunction with fibrinolytics.[122–124] In each of these trials, the use of enoxaparin as compared to UFH was associated with a reduction in ischemic outcomes. However, an increase in intracranial hemorrhage was seen in older patients (>75 years old) treated with enoxaparin.[125] As a result, the EXTRACT–TIMI 25 trial used a reduced dose of enoxaparin in patients at least 75 years old. In this study, there was a significant reduction in MI and need for urgent revascularization at 30 days but not death with enoxaparin. This was offset to some degree by an increased risk in major bleeding (2.1% vs. 1.4%; $P < 0.001$) but not intracranial hemorrhage.

Despite favorable outcomes in reducing ischemic outcomes and ease of use, there are several limitations to the use of enoxaparin. In addition to its more cumbersome use in the catheterization laboratory and diminished reversibility, one of the major limitations of enoxaparin is its limited use in patients with renal insufficiency. Because this is a renally cleared drug with a longer half-life than UFH, the use of enoxaparin in patients with renal insufficiency should be closely monitored by measuring anti-Xa activity and avoided in those who are dialysis dependent. Meta-analyses comparing UFH to LMWH in the treatment of ACS have not shown significant differences in either their safety or their efficacy[126,127] for the treatment of NSTEMI, but suggest that LMWH may be more effective than UFH at reducing reinfarction.

Direct Thrombin Inhibitors

The DTIs bind directly to thrombin and have a powerful anticoagulant effect by inhibiting its action. Bivalirudin has emerged as an important therapy in the management of ACS for patients undergoing PCI. It is not recommended for ACS patients undergoing a conservative medically managed strategy. Two pivotal trials that demonstrated the utility of bivalirudin in reducing bleeding complications when compared to the heparin agents while being noninferior on ischemic endpoints were the ACUITY (Acute Catheterization and Urgent Intervention Triage strategY) trial in NSTEACS patients and the HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial in STEMI patients.[128,129]

In the ACUITY trial, patients with NSTEACS who were treated with an early cardiac catheterization were studied. The main comparisons were made between patients randomized to heparin (UFH or enoxaparin) with GP IIb/IIIa inhibition versus bivalirudin with GP IIb/IIIa inhibition versus bivalirudin with provisional GP IIb/IIIa inhibition. Bivalirudin plus GP IIb/IIIa inhibition compared to heparin plus GP IIb/IIIa inhibition was noninferior at 30 days in composite ischemia and major bleeding. Bivalirudin alone when compared to heparin plus a GP IIb/IIIa inhibitor was noninferior with respect to composite ischemia, but significantly reduced major bleeding (3.0% vs. 5.7%; $P < 0.001$).

The HORIZONS-AMI trial was a similar study to ACUITY comparing bivalirudin alone to heparin plus a GP IIb/IIIa inhibitor, but was designed to evaluate patients presenting with STEMI undergoing primary PCI. Again, in this study, there was a significant decrease in major bleeding in the bivalirudin group (4.9% vs. 8.3%; $P < 0.001$) as well as a significant reduction in all-cause mortality at 30 days (2.1% vs. 3.1%; $P = 0.047$), but no significant differences in the composite ischemic events.[129]

Factor Xa Inhibitors

Upstream from thrombin in the coagulation cascade is factor Xa. Inhibition of factor Xa for the treatment of ACS has been extensively studied with the agent fondaparinux. This drug is a synthetic pentasaccharide and is attractive because of its once-daily subcutaneous (SC) administration and lower bleeding risk when compared to the heparins. It too does not require laboratory monitoring of its effect.

The OASIS-5 trial evaluated the use of fondaparinux in the treatment of UA and NSTEMI.[130] In this trial, patients were randomized to fondaparinux 2.5 mg SC daily or enoxaparin and were treated for a mean of 6 days. For the patients in the enoxaparin group, UFH was used at the time of PCI. In the fondaparinux group, additional intravenous fondaparinux was used at the time of PCI depending on the timing from the last SC dose. At 9 days, the number of patients with the primary outcome of death, MI, or refractory ischemia was similar between the two groups. However, there was significantly less major bleeding at 9 days with fondaparinux as compared to enoxaparin (2.2% vs. 4.1%; $P < 0.001$) as well as a reduction in death at

30 and 180 days (HRs and 95% CI, 0.83; 0.71 to 0.97 and 0.89; 0.80 to 1.00, respectively).

The OASIS-6 trial, which evaluated the use of fondaparinux in the treatment of STEMI, demonstrated a reduction in death with fondaparinux when compared to UFH or placebo (HR, 0.88; 95% CI, 0.79 to 0.97) without a reduction in major bleeding.[131] However, the benefit of fondaparinux was seen only in patients *not* treated with primary PCI.

In both trials, the use of fondaparinux alone in patients undergoing PCI was associated with a significantly higher rate of guiding catheter thromboses. As a result, it is recommended that any patient being anticoagulated with fondaparinux needing PCI be given a bolus of UFH at the time of cardiac catheterization. For patients in whom an invasive strategy is planned with likely PCI, fondaparinux is not the recommended anticoagulant for the management of ACS.

Anti-Ischemic Therapies

The American College of Cardiology/American Heart Association (ACC/AHA) class I recommendations for anti-ischemic therapy in ACS are listed in Table 90.11. These include supplemental oxygen, nitroglycerin, beta-blockers, and inhibitors of the renin angiotensin system.

Nitroglycerin

One of the most commonly used medications for the treatment of ischemic symptoms is nitroglycerin, which decreases myocardial ischemia by reducing the oxygen demand of the myocardium and increasing myocardial oxygen delivery. Nitroglycerin is a venous, and to a lesser extent, arterial dilator. It therefore reduces the preload to the heart by reducing venous return and reduces afterload on the heart by reducing systemic resistance. Because of its vasodilatory effects, nitroglycerin cannot be given to patients actively using phosphodiesterase inhibitors such as sildenafil, as this may result in a sudden drop in blood pressure with potentially catastrophic complications including death.[132]

There is little evidence to demonstrate that nitroglycerin causes a reduction in major adverse events. The Fourth International Study of Infarct Survival (ISIS-4) and the Gruppo Italiano per lo Studio della Sopravivenza nell'infarto Miocardico (GISSI-3) trials evaluated the effect of nitroglycerin on mortality in patients with suspected MI and found no reduction in the risk of death.[133,134] However, nitroglycerin has proven to be an important therapy in the treatment of coronary ischemia and is an effective drug for many in the relief of symptoms.

Morphine Sulfate

In those whose symptoms persist in the face of nitroglycerin and other anti-ischemic therapy, morphine sulfate can be used to provide relief to the patient. Although not formally evaluated in clinical trials, in addition to its potent analgesic effect, morphine provides some beneficial hemodynamic changes. These include a reduced heart rate, blood pressure, and preload. Morphine sulfate must be used cautiously as it can cause unsafe drops in blood pressure and suppression of the respiratory drive. Its use in the treatment of ischemic pain was downgraded in the 2007 AHA/ACC guidelines for the management of NSTEMI/UA from class I to IIa as a result of a registry analysis of over

Table 90.11

Class I recommendations for anti-ischemic therapy[a]

Bed/chair rest with continuous electrocardiographic monitoring
Supplemental oxygen with an arterial saturation <90%, respiratory distress, or other high-risk features for hypoxemia. Pulse oximetry can be useful for continuous measurement of SaO_2.
Nitroglycerin 0.4 sublingually every 5 min for a total of three doses; afterward, assess need for intravenous nitroglycerin
Nitroglycerin intravenously for the first 48 h after UA/NSTEMI for treatment of persistent ischemia, heart failure, or hypertension
Decision to administer nitroglycerin intravenously and dose should not preclude therapy with other mortality-reducing interventions such as beta-blockers or ACE inhibitors
Beta-blockers (via oral route) within 24 h without a contraindication (e.g., heart failure) irrespective of concomitant performance of PCI
When beta-blockers are contraindicated, a nondihydropyridine calcium channel blocker (e.g., verapamil or diltiazem) should be given as initial therapy in the absence of severe left ventricular dysfunction or other contraindications
ACE inhibitor (via oral route) within the first 24 hours with pulmonary congestion, or LVEF ≤0.40, in the absence of hypotension (systolic blood pressure <100 mm Hg or <30 mm Hg below baseline) or known contraindications to that class of medications
Angiotensin receptor blockers should be administered to patients with UA/NSTEMI who are intolerant of ACE inhibitors and have either clinical or radiologic signs of heart failure or LVEF ≤0.40

[a]Recurrent angina and/or ischemia-related electrocardiographic changes (0.05 mV or greater ST-segment depression or bundle branch block) at rest or with low level activity; *or* ischemia associated with symptoms of heart failure, S_3 gallop, or new or worsening mitral regurgitation; *or* hemodynamic instability or depressed left ventricular function (LVEF <0.40 on noninvasive study); *or* serious ventricular arrhythmia.

ACE, angiotensin-converting enzyme; LVEF, left ventricular ejection fraction; UA/NSTEMI, unstable angina/non–ST-elevation myocardial infarction.

Adapted from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). *Circulation* 2007;116(7):e148–e304.

50,000 patients with UA or NSTEMI showing an increased odds of death among all subgroups in those receiving morphine.[135]

Beta-Blockers

Beta-blockers are beneficial in the management of ACS. They work to reduce the oxygen demand of the myocardium by slowing the heart rate, reducing contractility, and decreasing systemic blood pressure. Trials mostly conducted in the prethrombolytic era demonstrated a reduction in infarct size, reinfarction, and mortality in both STEMI and NSTEMI patients.[136] For patients with ACS undergoing PCI, beta-blockers have been associated with a reduction in the short-term risk of death.[137] However, more recent studies, and a systematic review of early beta-blocker therapy in STEMI by Freemantle et al.,[138] have questioned the benefit of routine beta-blocker therapy early in the treatment of ACS. In the COMMIT study of over 45,000 patients with STEMI and NSTEMI, early intravenous beta-blockade did not result in a reduction in the composite endpoint of death, reinfarction, or cardiac arrest, but was associated with an increased rate of cardiogenic shock.[139] As a result of these data, it is now recommended that greater caution be used in the early administration of intravenous beta-blockers, and that this be avoided in those with heart failure or high risk for the development of cardiogenic shock. Current guidelines recommend the initiation of oral beta-blockers within the first 24 hours only to patients who are hemodynamically stable and at low risk for developing in-hospital heart failure or cardiogenic shock.

Renin–Angiotensin–Aldosterone System Inhibitors (ACE Inhibitors, Aldosterone Receptor Blockers)

Angiotensin-converting enzyme (ACE) inhibitors have been demonstrated to reduce mortality in a broad range of patients with CAD, MI, or left ventricular dysfunction.[140–143] The beneficial effect of this class of medications appears prolonged, as demonstrated in the TRACE (TRAndolapril Cardiac Evaluation) trial, which showed a continued reduction in mortality and hospitalization rates in patients followed for at least 10 to 12 years.[144]

In STEMI patients, there is substantial evidence for the benefit of early ACE inhibition. In the GISSI-3 trial, a 12% reduction in mortality was seen with the early initiation of lisinopril.[134] In the ISIS-4 study, the administration of captopril was associated with a 7% reduction in mortality.[133] For patients with concomitant left ventricular dysfunction, the benefits of early ACE-inhibitor therapy appear even more pronounced, with considerable benefit evident in the first several days after an MI. In the Survival and Ventricular Enlargement (SAVE), TRACE, and Acute Infarction Ramipril Efficacy (AIRE) trials, mortality was reduced by up to 30% with oral ACE inhibition.[145–147]

The benefit to early ACE inhibition in NSTEMI/UA is less clear. In the ISIS-4, GISSI-3, and CCS-1 (Chinese Cardiac Study) trials, little to no reduction in mortality was observed with ACE inhibition in patients without ST elevation.[133,134,148] Despite the lack of data for early benefit in NSTEMI/UA patients, there still appears to be a significant benefit to the long-term administration of ACE inhibitors in these patients as well as in those with chronic CAD.[140,149]

Consequently, the current recommendations for ACE inhibitors in patients with ACS include the initiation of oral ACE inhibitors within 24 hours for patients with STEMI, pulmonary congestion, or a left ventricular ejection fraction of ≤40%. Even in the absence of these findings, the current data would support the initiation of long-term ACE inhibitors for all patients presenting with ACS, provided they do not have a contraindication such as hypotension.

Angiotensin receptor blockers (ARBs) have been compared to and studied with ACE inhibitors in patients with ACS and heart failure. Because they directly block the angiotensin II (AT II) receptor, they theoretically provide greater protection against AT II than do ACE inhibitors. In the VALIANT (Valsartan in Acute Myocardial Infarction Trail) study, valsartan was compared to captopril as well as the combination of both drugs in patients with left ventricular dysfunction after acute MI.[150] In this study, mortality rates were similar for both drugs, but the combination of the two led to an increase in adverse events without a reduction in mortality. The CHARM (Candesartan in Heart failure Assessment in Reduction of Mortality)-Overall program evaluated candesartan for the treatment of chronic heart failure and demonstrated a reduction in cardiovascular death and hospital admissions.[151]

Aldosterone is another part of the renin–angiotensin–aldosterone system, and inhibition of its receptor with either eplerenone or aldosterone has been shown to reduce mortality in patients with heart failure, both chronically and in the setting of an acute MI. In the EPHESUS (Eplerenone Post–acute myocardial infarction Heart failure Efficacy and SUrvival Study) trial, eplerenone reduced mortality when used in patients with left ventricular dysfunction complicating MI and with diabetes or heart failure.[152] Spironolactone, another aldosterone receptor antagonist studied in the RALES (Randomized ALdactone Evaluation Study) trial, reduced mortality in those with severe heart failure.[153]

STATIN THERAPY IN THE ACUTE SETTING

The 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors, also known as statins, have been shown to provide substantial benefit for the long-term prevention of cardiovascular events. In the management of ACSs, they have also demonstrated favorable outcomes. In the Aggrestat to Zocor (A to Z TIMI-21) trial, early aggressive simvastatin reduced cardiovascular events in patients with ACS.[154] The PROVE IT-TIMI 22 (Pravastatin or Atorvastatin Evaluation and Infection Therapy—Thrombolysis in Myocardial Infarction-22) trial studied intensive lipid-lowering therapy (atorvastatin 80 mg daily) versus a standard lipid-lowering strategy (pravastatin 40 mg daily) in patients presenting with ACS.[155] Not only was there a stronger reduction in serum cholesterol levels with intensive statin therapy, but the risk of death, MI, UA, revascularization, or stroke was reduced by almost 20% at 2 years. These data support the use of intensive statin therapy at the time of ACS, with a meta-analysis of four large trials enrolling over 27,000 patients showing that intensive, high-dose, statin therapy leads to a significant 16% odds reduction in coronary death or MI ($P < 0.00001$) and a 16% odds reduction in coronary death or any cardiovascular event ($P < 0.00001$).[156]

SECONDARY PREVENTION OF ACS

When a patient presents with ACS, plans for secondary prevention should begin immediately. Smokers need to be educated on the importance of quitting. Identifiable risk factors

such as hypertension, diabetes, obesity, and hyperlipidemia should start being addressed while the patient is hospitalized for the acute event. For most patients, a hospitalization for a cardiac event is a motivating experience to improve lifestyle habits.

Cardiac rehabilitation is also an important component of recovery from an ACS event and is underused.[157] Cardiac rehabilitation is designed to address physical and psychological effects of cardiac disease. It is a long-term program that emphasizes exercise, lifestyle changes, and risk factor modification, while also providing medical evaluation and education. Importantly, participation in cardiac rehabilitation after an MI has been associated with a 28% reduction in the risk of recurrent MI (RR, 0.72; 95% CI, 0.52 to 0.99; $P = 0.049$) and a 56% improvement in survival (RR, 0.44; 95% CI, 0.36 to 0.54; $P < 0.001$) in a cost-effective manner.[158,159]

CHAPTER

91 Pathophysiology of Thromboembolic Stroke

EMER R. MCGRATH AND MARTIN J. O'DONNELL

Stroke is defined by the World Health Organization (WHO) as "rapidly developing clinical signs of focal (at times global) disturbance of cerebral function, lasting more than 24 hours or leading to death with no apparent cause other than that of vascular origin."[1] This definition is conventionally considered to include ischemic stroke, intracerebral hemorrhage (ICH), and subarachnoid hemorrhage (SAH). Clinical presentations lasting <24 hours are defined as transient ischemic attacks (TIAs). Recently, there has been a proposal to change the definition of stroke and TIA to a tissue-based definition, that is, one based on the presence or absence of acute ischemia or hemorrhage on neuroimaging.

EPIDEMIOLOGY OF STROKE

Incidence and Prevalence of Stroke

Stroke is the leading cause of acquired adult disability worldwide and the second most common cause of death after cardiovascular disease.[2,3] The WHO estimates that 15 million people suffer a stroke each year, and of these, 5 million people are left with permanent disability.[4] In the absence of further effective population-based interventions, a projected 18 million first-time strokes will occur in 2015, rising to 23 million first-time strokes in 2030.[3] Typical estimates for stroke prevalence (the number of individuals living with a previous history of stroke) are approximately 500 per 100,000 people in developed countries. The estimated prevalence of stroke survivors worldwide was 62 million in 2005, and this is projected to increase to 67 million in 2015 and to 77 million in 2030.[3]

Stroke-Related Mortality

In 2005, there were an estimated 5.7 million deaths due to stroke, accounting for approximately 10% of total deaths worldwide. It is projected that 6.5 million stroke deaths will occur in 2015 and 7.8 million deaths in 2030. A small decrease in age-specific stroke mortality rates has been projected from 2005 to 2030, which is largely due to a decline in high-income countries. However, due to an increasingly ageing population worldwide, crude stroke mortality rates are actually projected to increase, from 89 per 100,000 in 2005 to an estimated 98 per 100,000 in 2030. The increase in stroke mortality will be most marked in developing countries, where increases in stroke incidence are most prominent.[3]

Socioeconomic Consequences of Stroke

Disease burden may be measured using disability-adjusted life years (DALYs). One DALY is 1 year of healthy life lost, due to premature death or living with a disability. The global burden of stroke is currently projected to rise from an estimated 38 million DALYs in 1990 to 61 million DALYs in 2020.[4] Globally, stroke accounts for approximately 2% to 4% of total health care costs, while in high-income countries, stroke is responsible for more than 4% of direct health care budgets.[5] The estimated direct and indirect cost of stroke in the United States for 2010 was $73.7 billion. The estimated mean lifetime cost of ischemic stroke in the United States is currently $140,048, encompassing immediate inpatient care, rehabilitation services, and follow-up care costs (including long-term care).[6] A cost analysis study by Brown et al.[7] estimated that the total cost of stroke for the United States from 2005 to 2050 will be US $2.2 trillion, based on 2005-dollar prices. The decline in case fatality of stroke reported in many high-income countries is expected to impact on health care resources in these countries, given the increased requirement for rehabilitation services and long-term care facilities.

Global Variation in the Burden of Stroke

Worldwide, stroke demonstrates significant geographical variations, in terms of incidence (and temporal trends), prevalence, case fatality, and case mix (i.e., stroke subtypes). A systematic review of population-based studies by Feigin et al. found that from 1970 to 2008 there was a 42% decrease in the incidence of stroke in high-income countries, compared to a more than 100% increase in the incidence of stroke in middle- and low-income countries. In addition, from 2000 to 2008, overall stroke incidence rates in low- to middle-income countries exceeded rates in high-income countries for the first time, by over 20% (117 per 100,000 and 94 per 100,000, respectively).[8] In 2005, 87% of deaths due to stroke occurred in middle- and low-income countries. Moreover, this figure rose to 94% of global deaths due to stroke in those under the age of 70 years, where projected age-standardized death rates from stroke in people aged 30 to 69 years were higher for middle- and low-income countries than for high-income countries. For example, the age-standardized death rate for stroke in Nigeria was more than 120 per 100,000 people, compared to rates of approximately 20 per 100,000 people in the United Kingdom and <15 per 100,000 people in Canada. Finally, stroke mortality from 2005 to 2030 is predicted to increase by almost 33% in middle-income countries, from approximately 3 to 4 million deaths, while a small or negligible change is predicted for high-income countries.[3] Therefore, regional variations in the burden of stroke are projected to become more marked in the coming decades. The determinants underlying these changes may include variations in the stages of the epidemiologic transition, differing access to

risk factor modification therapies, and availability of evidence-based acute stroke interventions (e.g., stroke units).

ETIOLOGY OF ISCHEMIC STROKE

Heterogeneity of Stroke

Unlike acute coronary syndrome, which is mostly due to large-vessel atherosclerosis, the underlying mechanisms for ischemic stroke are more heterogeneous. For each ischemic stroke subtype, thrombogenesis is the usual underlying pathophysiological mechanism, although the local factors responsible for development of thrombosis differ by ischemic stroke etiology.[9] Ischemic stroke may be categorized into distinct etiological subtypes, including large vessel, small vessel, cardioembolism, mixed etiology, and cryptogenic.

Etiological Criteria for Ischemic Stroke

Stroke can be classified based on primary etiological mechanism into ischemic stroke and hemorrhagic stroke. In North America and Europe, approximately 85% to 90% of strokes are due to ischemia, with the remaining 13% occurring due to hemorrhage. In developing countries, a larger proportion of strokes are due to ICH.[8] Within ischemic stroke, there are five subcategories based on the Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification system. The TOAST classification documents the pathophysiological mechanism of ischemic stroke based on clinical features and the results of investigations that include brain imaging (computed tomography [CT]/magnetic resonance imaging [MRI]), cardiac imaging (transthoracic and transesophageal echocardiography) and cardiac rhythm monitoring (e.g., Holter monitor), neurovascular imaging (duplex ultrasound, CT or MR angiography, and contrast angiography), and laboratory tests (Table 91.1). For secondary ischemic stroke prevention, the cornerstones of evidence-based therapy are lifestyle modification (e.g., smoking cessation), antiplatelet therapy, antihypertensive therapy, and statin therapy. Identification of certain ischemic stroke etiologies does inform additional evidence-based management approaches, most notably for atrial fibrillation (AF) (introduction of oral anticoagulant therapy) and significant carotid artery disease (carotid endarterectomy). The five categories in the TOAST classification system are (a) large-artery atherosclerosis, (b) cardioembolism, (c) small-artery occlusion or lacunar ischemic stroke, (d) stroke of other determined etiology, and (e) stroke of undetermined etiology ([i] two or more causes identified, [ii] negative evaluation, or [iii] incomplete evaluation).[10] The etiology of hemorrhagic stroke can be due to primary ICH or SAH, with ICH often topographically subclassified into lobar and deep hemorrhage.

Table 91.1

Etiology of thromboembolic ischemic stroke

Etiological Mechanism	Frequency (%)
Large-artery atherosclerosis	~20
Cardioembolism	~20–30
Lacunar	~20–30
Cryptogenic	15–40[a]

[a]Depending on the extent of etiological diagnostic workup.

Large-Artery Atherosclerosis

Large-artery stroke is usually a consequence of atherosclerosis in the extracranial (carotid or vertebral) and/or intracranial arteries (e.g., middle cerebral or basilar artery), where plaque rupture and thrombus formation can result in local occlusion or distal occlusion due to artery-to-artery thromboembolism. Vascular locations that have a predilection for development of atherosclerosis include the arch of the aorta, the origin and bifurcation of the common carotid artery, the distal end of the internal carotid artery, the terminal segments of the vertebral arteries, the basilar artery, and less commonly, the middle cerebral and posterior cerebral arteries.[11,12] In large arteries, thrombosis typically occurs at the site of an atherosclerotic plaque, termed atherothrombosis. Ischemic stroke may result from atherothrombosis due to artery-to-artery thromboembolism or, less commonly, by acute occlusion with resultant hypoperfusion (e.g., watershed infarction).[13,14] Large-vessel atherosclerosis accounts for about 20% of all ischemic stroke in high-income countries and is predominantly extracranial in origin (e.g., carotid artery).[15] Large-vessel disease is reported to be more common in parts of Asia, with an apparent predominance of intracranial artery stenosis (e.g., middle cerebral artery). For example, atherosclerosis of intracranial vessels has been reported to account for up to 33% to 50% of ischemic strokes in China and Thailand, based on some hospital-based registries.[16–18] The factors underlying this global variation in the proportion, and location, of large-vessel disease are largely unexplained, but may relate to differences in risk factors profiles (e.g., smoking and hypertension) or underlying genetic susceptibility. From a management perspective, carotid artery stenosis is the most important source of large-vessel stroke to identify, as timely carotid endarterectomy dramatically reduces the risk of recurrent ischemic stroke in patients with recent minor ischemic stroke or TIA, based on the results of large randomized controlled trials. For large-vessel intracranial disease, a recent clinical trial (SAMMPRIS trial) did not report a benefit of endovascular stenting (plus aggressive medical management) over aggressive medical management alone; the trial was stopped early due to excess rate of stroke and death, within 30 days, in the endovascular group.

Less common large-vessel mechanisms of ischemic stroke include arterial dissection,[19] fibromuscular dysplasia,[20] Moyamoya disease, and large-vessel arteritis (e.g., Takayasu arteritis and giant cell arteritis) (see Chapter 100).[11] Arterial dissection, usually of the extracranial vessels, is the third leading cause of ischemic stroke in young people and can lead to ischemic stroke by either local occlusion or distal thromboembolism.[19] Predisposing factors include direct trauma,[21,22] family history,[23] migraine,[24] and underlying arteriopathies, such as Moyamoya disease[25–27] or fibromuscular dysplasia.[28,29] Takayasu arteritis is a chronic granulomatous inflammatory condition of the aorta and its major branches. It occurs most commonly in Asia and is rare in Western Europe and North America. It predominantly affects the media and adventitia of the arterial wall, leading to stenosis or aneurysm formation.[30]

Approximately 10% to 20% of patients with Takayasu arteritis will have a TIA or ischemic stroke.[31]

Cardioembolism

Cardioembolism is the mechanism responsible for approximately 20% to 30% of all ischemic strokes.[15] There are a number of conditions that predispose to cardiac sources of emboli, which may originate from the venous system (paradoxical embolism), intracardiac (e.g., AF, left ventricular impairment) or postcardiac (aortic arch disease). Although the aortic arch is a large-vessel structure, it is conventionally included as a cardioembolic source, likely because it is usually identified on transesophageal echocardiography.

Paradoxical Embolism

Paradoxical emboli are proposed to occur when emboli that arise in the venous circulation, for example, from a deep vein thrombus, cross into the arterial circulation through a patent foramen ovale (PFO) or atrial septal defect, or through a pulmonary arteriovenous malformation (PAVM). Paradoxical embolism can be quite difficult to diagnose, and it is usually presumed, rather than confirmed, based on visualizing a right to left communication and/or shunt. PFO is common in the general population, present in about 20% of people. An association between PFO and ischemic stroke was first reported in younger patients (<55 years),[32] but the association has also been reported in older adults more recently.[33–37] However, while case–control studies report a positive association between PFO and cryptogenic ischemic stroke (odds ratio [OR] 3.12; 95% confidence interval [CI] 1.98 to 5.10),[35] two prospective cohort studies have failed to demonstrate an independent association between PFO and an increased risk of stroke, after a mean follow-up of 5 years[38] and 7 years.[39] In addition, studies have failed to show that the presence of an isolated PFO is a risk factor for recurrent ischemic stroke. Diagnostic investigations include transthoracic echocardiogram, transesophageal echocardiogram (TEE), and transcranial Doppler with contrast.[40] TEE is the gold standard investigation for diagnosis of PFO and estimation of PFO size, with a specificity and sensitivity of 100% for color Doppler TEE and 100% and 89%, respectively, for contrast TEE.[41] The optimal management strategy for patients with PFO and cryptogenic ischemic stroke remains controversial, due to difficulties in establishing a true causal relationship between PFO and ischemic stroke and a lack of randomized controlled trials delineating the best treatment options.[42] Although some studies have suggested an adjunct role for thrombophilic disorders,[42–45] the role for thrombophilic testing also remains uncertain. In healthy individuals with PFO, primary prevention with antithrombotic therapy is not currently recommended. The American Stroke Association/American Heart Association (ASA/AHA) currently recommends antiplatelet therapy for patients with ischemic stroke or TIA and a PFO to prevent a recurrent event (class IIa, level B evidence). There are no randomized controlled trials comparing oral anticoagulation to antiplatelet therapy, other than a subgroup analysis of the WARSS trial, which did not find a difference in recurrence stroke rates between treatment groups. An emerging management approach has been PFO closure, which may be achieved by transcatheter device closure, percutaneous device-less closure, and surgical closure by open or thoracoscopic access.[47] However, the recently presented CLOSURE trial did not report a benefit from PFO closure in approximately 900 participants after ischemic stroke, who were randomized to receive PFO closure or usual medical care, but did report an associated increased risk of new AF in the closure group on follow-up.[48] Other randomized controlled trials, evaluating other approaches to PFO closure following ischemic stroke, are ongoing. Management challenges are faced in patients with large PFO, PFO associated with atrial septal aneurysm[33,49] or in younger patients with no other risk factor for ischemic stroke, especially in those who experience a recurrent episode of ischemic stroke despite antiplatelet therapy.

An atrial septal aneurysm is a protrusion of part of the atrial septum through the fossa ovalis into the right or left atrium or both,[50,51] TEE is considered to be the investigation of choice for detection of atrial septal aneurysm.[52] An atrial septal aneurysm is associated with an increased risk of ischemic stroke, especially in association with a PFO. A meta-analysis of case–control studies comparing patients with ischemic stroke to controls reported ORs of 1.83 for PFO, 2.35 for atrial septal aneurysm, and 4.96 for both PFO and atrial septal aneurysm, indicating a greater risk of stroke from the combination compared to either condition alone.[53] Other potential explanations for the increased risk of stroke associated with atrial septal aneurysm include a predisposition toward atrial arrhythmias, thrombus formation, and left atrial dysfunction.[51,54–56]

PAVMs, which are commonly congenital in origin, are abnormal connections between pulmonary arteries and veins. They are also associated with an increased risk of ischemic stroke,[57] and paradoxical embolism is considered to be the most likely underlying mechanism.[58] The reported incidence of stroke in studies of patients with PAVM has ranged from 2.6% to 25%.[59–63] The gold standard for diagnosis of PAVM is pulmonary angiography, although less invasive techniques such as contrast and helical CT, magnetic resonance angiograms, and contrast echocardiography are also useful.[64] Treatment is recommended for patients with PAVMs who are symptomatic or who have feeding vessel diameters >3 mm. Embolotherapy is the current treatment of choice for PAVMs. Surgical resection is reserved for those who fail to respond to, or are unsuitable for, embolotherapy.[65]

Intracardiac Sources of Thromboembolism

Left-sided cardiac sources of emboli include left atrial thrombus secondary to AF or flutter,[66–68] left ventricle (LV) thrombus subsequent to a transmural myocardial infarction (MI),[69,70] an old MI with akinetic segments of myocardium and ejection fraction ≤28%,[71] cardiac tumors such as left atrial myxoma,[72] and abnormalities of the mitral valve, both native and artificial.[73]

AF is the most common cardiac arrhythmia and is a significant risk factor for stroke, associated with a fivefold increase in risk.[74] Irregular contractions of the atria lead to stasis of blood and an increased risk of thrombus formation, particularly in the left atrial appendage. This in turn predisposes to intracardiac thrombosis and, subsequently, ischemic stroke. In high-income countries, about 25% of all ischemic strokes and 36% of strokes in patients >80 years are due to AF.[75]

AF may be categorized as valvular (mostly associated with mitral valve disease) or nonvalvular.[76] Aspirin reduces the risk of ischemic stroke by about 22%, the addition of clopidogrel reduces the risk of recurrent stroke by a further 18% (ACTIVE-A)

while anticoagulant therapy (warfarin; international normalized ratio [INR] 2 to 3) reduces the risk of ischemic stroke by 66% compared to control, and warfarin (INR 2 to 3) is superior to combination aspirin and clopidogrel (ACTIVE-W). Recently, large randomized controlled trials have reported on the effectiveness of novel anticoagulants (apixaban, dabigatran, and rivaroxaban), which all appear very promising as replacements for warfarin in patients with AF, see Chapter 92.[77]

Other Cardiac Causes: Coronary heart disease is a known risk factor for ischemic stroke, mediated through a number of mechanisms. After an MI, mural thrombi, and subsequently cardioemboli, can arise due to the presence of left ventricular aneurysms, akinetic segments of left ventricular myocardium, or new-onset AF or flutter. A greater degree of myocardial injury and left ventricular dysfunction after anterior MI have been shown to increase the risk of stroke in the early postinfarct period.[78–80] The risk of mural thrombi, and therefore early stroke, is much greater after anterior wall MI rather than inferior wall MI.[81,82] The reported incidence of stroke in the first 2 weeks after MI ranges from 0.7% to 4.7%.[71]

Left ventricular hypertrophy (LVH) has also been associated with an increased risk of stroke both from electrocardiogram- and from echocardiogram-based studies, and this risk is independent of other risk factors. One proposed explanation for this association is that LVH can predispose to left atrial dilatation and in turn AF, largely medicated though the effect of hypertension.[83–85]

Valvular Heart Disease: Valvular heart disease may be native (e.g., rheumatic) or prosthetic. Of native valvular disease, mitral stenosis has the strongest association with ischemic stroke,[86] and, less commonly, mitral annular calcification and mitral valve prolapse.[87] Mitral stenosis is commonly associated with AF, which further increases the risk of ischemic stroke. Rheumatic heart disease remains a common cause of mitral valve disease, and an important risk factor for cardioembolic ischemic stroke, in many regions of the world (e.g., Africa and India). Emboli can also arise from valvular vegetations consisting of fibrin and platelets in nonbacterial thrombotic endocarditis[88,89] and from infected valvular vegetations in infective endocarditis.[90] Patients with mechanical mitral and aortic valves, particularly mitral valves, have a sufficiently high risk of ischemic stroke that justifies indefinite oral anticoagulant therapy. In contrast, bioprosthetic valves require a finite course of antithrombotic therapy, usually 3 months after surgery, unless there is an alternative indication for indefinite therapy (e.g., AF).

Congestive heart failure (CHF) is an independent risk factor for stroke, associated with a twofold to threefold increase in the relative risk (RR) of stroke.[75,91–93] Various mechanisms have been proposed to explain this association. Dysfunction of the LV in CHF can promote stasis of blood in the LV and left atrium (ejection fraction < 30%[94]), thereby predisposing to thrombus generation and risk of cardioembolic stroke, while transient arrhythmias such as AF are more common in this patient population.[95] In South and Central America, Chagas disease (tropical parasitic disease *Trypanosoma cruzi*) is an important cause of dilated cardiomyopathy and risk factor for stroke, especially in younger patients.

Postcardiac sources: The prevalence of severe atheroma of the aortic arch (>4 to 5 mm) is approximately 30%, and its presence is associated with a fourfold increase in the risk of ischemic stroke and peripheral embolism.[96] Emboli can also arise from atherosclerotic plaques in the aortic arch, proximal to the left subclavian artery, and enter the cerebral circulation leading to an ischemic stroke.[97]

Small-Vessel Disease

Approximately 20% to 30% of all ischemic strokes are due to lacunar infarcts.[15] Lacunar infarcts occur due to occlusion of small deep penetrating arteries, such as the lenticulostriate branches of the anterior cerebral artery and middle cerebral artery. The terminal pathophysiological mechanism underlying small-artery occlusion is believed to be local thrombosis, secondary to microatheroma and lipohyalinosis. Microatheroma is thought to be the most common mechanism underlying symptomatic lacunar infarcts,[98] while lipohyalinosis is proposed to predominantly account for many asymptomatic lacunar infarcts, causing occlusion of very small penetrating arteries <200 μm in diameter.[99] A microatheroma is characterized by lipid-laden macrophages, cholesterol deposits, and subintimal fibroblast proliferation.[100] Lipohyalinosis is believed to be an intermediate stage between fibrinoid necrosis and microatheroma, having characteristics of both arterial (atheromatous lipid deposits) and arteriolar (hyalinization) disease.[101] Fibrinoid necrosis typically occurs in the setting of malignant hypertension and affects cerebral, retinal, and renal arterioles and capillaries.[100] It is characterized histologically by intensely eosinophilic and finely granular deposits in the arteriolar wall.[102] Other causes for small-artery occlusion include microemboli,[103] cholesterol emboli from atherosclerotic plaques,[104] polycythemia,[105] antiphospholipid antibodies,[106] amyloid angiopathy,[107] cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL),[108] Sneddon syndrome,[109] and various types of vasculitis.[110]

CADASIL is an uncommon inherited disorder that predominantly affects the small arteries of the brain, leading to an increased risk of early-onset strokes, typically lacunar infarcts, in the periventricular and basal ganglia regions. A study in Scotland estimated the prevalence at almost 2 per 100,000 adults, which is believed to be an underestimate.[111] Other clinical consequences include subcortical dementia, migraine with aura, and psychiatric symptoms.[112] It is caused by a mutation in the *Notch3* gene on chromosome 19, which leads to the deposition of the ectodomain of the *Notch3* receptor protein and granular eosinophilic material on vascular smooth muscle cells of arteries, resulting in their gradual degeneration.[113] The degeneration of arterial vascular smooth muscle cells results in progressive fibrosis and luminal stenosis of small penetrating arteries in the brain, reduced blood flow, and subsequently, lacunar infarcts.[114,115] Cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL) has a similar pattern of early-onset cerebral ischemia to CADASIL and is due to a mutation in HTRA1.

Sneddon syndrome is a rare disorder characterized by cerebrovascular disease occurring in association with livedo reticularis, an ischemic dermatopathy of the skin, and the absence of an infection or collagen vascular disease.[109,116] The definitive etiology is unknown, although it is thought to be autoimmune medicated.[117] Hypertension is reported in approximately 60% of patients with Sneddon syndrome, while 35% are noted to have antiphospholipid antibodies.[118] Previous neuropathological reports have noted multiple small infarcts, together with

smooth muscle cell hyperplasia and fibrotic occlusion of small- to medium-sized cerebral arteries, as well as occasional arterial thrombi. These findings suggest that the underlying pathogenesis for ischemic events in Sneddon syndrome is a noninflammatory arteriopathy affecting the small- to medium-sized cerebral arteries.[109,119]

Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) is an inherited progressive disorder due to mitochondrial dysfunction. It is characterized by early onset of stroke, typically before the age of 40.[120] The underlying pathophysiology for cerebrovascular events in MELAS has not been fully determined. MRI diffusion-weighted images in these individuals have demonstrated multiple hyperintense cortical laminar lesions, which do not follow the distribution of any single large artery.[120,121] The mitochondrial angiopathy hypothesis suggests that the lesions are secondary to ischemia which is caused by mitochondrial and vascular dysfunction of cerebral small arteries.[120]

Stroke of Other Determined Etiology

Other uncommon and rare causes of ischemic stroke are considered in the category of "stroke of other determined etiology," according to the TOAST classification system. This category can include hematological disorders, hypercoagulable states, nonatherosclerotic vasculopathies, and arterial dissection.[10] *Cerebral venous sinus thrombosis* accounts for <1% of ischemic strokes and typically affects younger people.[46,122] The superior sagittal sinus, the transverse sinuses, and the cavernous sinuses are most commonly affected by thrombosis.[100] Venous thrombosis results in localized edema and venous infarction, which often becomes hemorrhagic, as well as raised intracranial pressure.[122] Reported risk factors for cerebral venous sinus thrombosis include inherited prothrombotic states such as factor V Leiden (FVL) mutation[123] and prothrombin gene mutation 20210A (PT G20210A)[124]; acquired prothrombotic states such as antiphospholipid antibodies,[125] pregnancy, and the puerperium[126]; infections such as otitis, sinusitis, and mastoiditis[127]; chronic inflammatory conditions such as Wegener granulomatosis and sarcoidosis[128]; and trauma such as a head injury,[129] dehydration, and injury to the jugular veins or sinuses from neurosurgical procedures.[122] MRI combined with MR venography is the most sensitive and specific diagnostic test.[130] A hyperintense signal from thrombosed sinuses on MRI together with corresponding absence of flow on MR venography confirms the diagnosis.[122] AHA/ASA guidelines indicate that anticoagulation is probably effective for patients with acute cerebral vein thrombosis (class IIa; level of evidence B), although definitive clinical trials are lacking. In the absence of trial data to define the optimal duration of anticoagulation for acute cerebral vein thrombosis, it is recommended to administer anticoagulation for at least 3 months, followed by antiplatelet therapy (class IIa; level of evidence C).[46]

Stroke of Undetermined Etiology

In some cases, the cause of stroke cannot be definitively determined and the stroke is classified as "stroke of undetermined etiology." A stroke may be classified in this category when one of the following two conditions are met: (a) an extensive evaluation is negative, which includes large-vessel imaging and complete cardiovascular assessment, or (b) the diagnostic evaluation is incomplete.[10] Clearly, the most important determinant of the proportion of patients labeled as cryptogenic is the extent of the diagnostic testing, which makes between-study comparisons of etiological case mix difficult.

Covert Stroke

Clinically overt stroke is considered to represent only a fraction of all episodes of cerebral infarction. The advent of contemporary MRI sequences has identified a large burden of subclinical cerebrovascular disease, which includes covert infarction, white matter hyperintensities, cerebral atrophy, and microbleeds. Moreover, the presence (pattern and burden) of covert stroke has been associated with an increased risk of cognitive decline, dementia, depression, vascular parkinsonism, and gait impairment.[131,132,133–136] Previous studies report a twofold to fourfold increase in the risk of clinically overt stroke in the presence of covert cerebral infarcts, independent of other vascular risk factors.[135,136] Given their chronic clinical consequence, the term "covert" rather than "silent" has been adopted. A systematic review of eight population-based studies reported a prevalence of silent brain infarcts in the general elderly population of 8% to 28%.[132] Previous studies indicate that the strongest risk factors associated with silent cerebral infarcts are age, hypertension, diabetes mellitus, and smoking.[132]

TRADITIONAL RISK FACTORS FOR ISCHEMIC STROKE

Both ischemic and hemorrhagic stroke are strongly associated with a number of conventional risk factors, namely hypertension, smoking, diet, sedentary lifestyle, obesity, diabetes mellitus, and exercise. Many of these risk factors exert their effect through a number of intermediate mechanisms. For example, hypertension increases the risk of ICH, small-vessel disease, atherosclerosis, and AF.

The INTERSTROKE study, which included 6,000 participants from 22 countries, reported that 10 key risk factors were associated with 90% of the population-attributable risk (PAR) of ischemic stroke, namely hypertension, smoking, waist-to-hip ratio (WHR), diet, physical activity (PA) level, diabetes mellitus, alcohol intake, psychosocial stress and depression, cardiac causes such as AF, and ratio of apolipoprotein B (ApoB) to apolipoprotein A1 (ApoA1) (after adjustment for age and sex)[137] (Table 91.2). Since many of these risk factors are common and modifiable, these findings suggest that population-based programs, which target key risk factors, may have an enormous impact on the incidence of stroke.

Age

Age is the strongest independent risk factor for stroke. The incidence of stroke increases with age, with up to 75% of strokes occurring in individuals over the age of 65 in high-income countries.[138] For every 10 years above the age of 55, the risk of stroke more than doubles.[4,139,140] A 5-year follow-up of a population-based cohort of over 4,000 people >65 years reported a hazard ratio (HR) of 1.74 per 10-year increase in age over 65.[138]

Table 91.2

Traditional risk factors for ischemic stroke

Risk Factor	OR (99% CI)
Hypertension (self-reported history)	2.37 (2.00–2.79)
Current smoking[a]	2.32 (1.91–2.81)
Diabetes mellitus	1.60 (1.29–1.99)
Ratio of ApoB to ApoA1	2.40 (1.86–3.11)
Obesity (waist-to-hip ratio)	1.69 (1.38–2.07)
Regular physical activity	0.68 (0.51–0.91)
Diet risk score	1.34 (1.09–1.65)
Alcohol consumption[a]	
1–30 drinks per month	0.79 (0.63–1.00)
>30 drinks per month	1.41 (1.09–1.82)
Psychosocial factors	
Psychosocial stress	1.30 (1.04–1.62)
Depression	1.47 (1.19–1.83)

Odds ratios for waist-to-hip ratio and diet risk score are for the highest tertile compared to the lowest tertile.
[a]Comparator for current smoker and alcohol intake is never or former.
OR, odds ratio; CI, confidence interval; Apo, apolipoprotein.
From O'Donnell MJ, Xavier D, Lisheng L, et al. Risk factors for ischaemic and intracerebral haemorrhagic stroke in 22 countries (the INTERSTROKE study): a case-control study. *Lancet* 2010;376:112–123.

Sex

Population-based studies have demonstrated sex differences in the risk of stroke, with men having a greater risk of stroke than women.[139,141,142] The incidence of stroke in men has been reported to be 25% higher than the incidence in women.[143] However, women tend to live longer than men and so have a higher incidence of stroke in the subgroup of individuals over 85 years.[144]

Hypertension

Hypertension is the most important modifiable risk factor for stroke. In the INTERSTROKE study, approximately 35% of all stroke cases could be attributed to a patient reported history of hypertension (OR 2.64). Using a less stringent definition of hypertension, patient-reported history of hypertension, or a blood pressure >160/90 mm Hg, the PAR of stroke increased to almost 52%[137] (see Table 91.2), a finding that is consistent with a previous review.[145] The relationship between blood pressure and cardiovascular risk is "continuous, consistent, and independent of other risk factors."[146] Hypertension is a stronger risk factor for intracerebral hemorrhagic stroke than for ischemic stroke, and the preferential reduction in ICH in high-income countries is believed to be primarily due to improved blood pressure control.[137] According to the National Health and Nutrition Examination Survey (NHANES) 2003 to 2006, an estimated 33.6% of United States adults have hypertension, defined as blood pressure ≥140/90 mm Hg, equating to over 74 million people.[6] The worldwide prevalence of hypertension in 2000 was reported to be 26%, an estimated 972 million people.[147]

Hypertension increases the risk of ischemic stroke by causing endothelial damage, altering blood–cell endothelial interaction, and predisposing to thrombus formation. It accelerates atherosclerosis, particularly at extracranial sites such as the carotid bifurcation, and predisposes to cardiac conditions like AF and MI that promote cardioembolic stroke.[148] Meta-analyses of randomized controlled trials have shown a 30% to 40% decrease in stroke risk with lowering of blood pressure interventions. A dose–response relationship with a greater decrease in stroke risk for larger reductions in blood pressure has also been demonstrated.[149,150] Excess salt intake is an important, modifiable determinant of blood pressure and a risk factor for stroke.

Smoking

Smoking is an independent risk factor for stroke, associated with a twofold increase in risk for ischemic stroke overall[151] and a twofold to fourfold increase in risk of hemorrhagic stroke.[152,153] A meta-analysis of 32 studies in the late 1980s found that compared to nonsmokers, smokers had almost double the risk of ischemic stroke, with an RR of ischemic stroke of 1.9.[154] The INTERSTROKE study reported an increased risk of stroke in smokers (OR 2.09) compared to nonsmokers, and smoking was a consistent risk factor for stroke across all regions and patient subgroups[137] (see Table 91.2). There is a dose-response relationship between smoking and risk of stroke, with an increasing stroke risk with increasing numbers of cigarettes smoked per day.[137,154] In the Framingham study, heavy smokers (>40 cigarettes per day) were reported to have twice the RR of a stroke compared to light smokers (<40 cigarettes per day). According to WHO estimates, the prevalence of tobacco smoking in the United States is 23.6%, and there are currently about 1.2 billion individuals smoking tobacco worldwide.[155] Smoking contributes to atherosclerosis by causing vascular endothelial dysfunction[156–158] and also promotes a procoagulant state by increasing fibrinogen concentration, decreasing fibrinolysis, and enhancing platelet aggregation.[159–161] Cessation of smoking is associated with a reduction in the risk of stroke and other cardiovascular events to a level approaching, but not reaching, that of individuals who have never smoked.[162–164] Recent evidence also supports that exposure to environmental tobacco smoke is an important risk factor for stroke.[165,166]

Diabetes Mellitus

Diabetes mellitus predisposes to an increased risk of atherosclerosis and subsequently ischemic stroke. Epidemiological studies have shown that the increased risk of stroke in patients with diabetes is independent of other risk factors. In the Honolulu Health program study, Japanese American men with asymptomatic hyperglycemia and overt diabetes mellitus had an increased risk of thromboembolic stroke compared to those with low glucose levels 22 years after follow-up (RR 3.45 and 1.43, respectively).[167] A population-based cohort study in California was carried out amongst almost 4,000 adults aged 50 to 79 years, with an average follow-up of 12 years. It was found that individuals with either a history of diabetes or a fasting blood glucose level >7.8 mmol/L had a greater age-adjusted risk of stroke morbidity and mortality compared to normoglycemic individuals (RR 1.8 for men and RR 2.2 for women). This risk was again found to be independent of other cardiovascular risk

factors.[168] The estimated prevalence of diabetes amongst the US adult population is 8%.[169] The estimated worldwide prevalence of diabetes across all age groups in 2,000 was 2.8%, representing approximately 171 million people.[170] Three large randomized controlled trials of intensive glycemic control in individuals with diabetes and additional cardiovascular risk factors or a history of cardiovascular disease or stroke have failed to demonstrate a benefit of intensive glycemic control in the reduction in risk of stroke.[171,172,173] The results of these trials indicated that there was no benefit in lowering HbA1c < 6.5% in such patients.

Lipids

Elevated levels of total cholesterol (TC) and reduced levels of high-density lipoprotein cholesterol (HDL-C) have been established as important modifiable risk factors for coronary heart disease.[174] However, epidemiological evidence to date has provided mixed results for the association between lipoproteins and ischemic stroke risk.[175–178] A population-based cohort of over 14,000 men and women with a mean follow-up of 10 years found weak and inconsistent associations between risk of ischemic stroke and five lipid factors—HDL-C, low-density lipoprotein cholesterol (LDL-C), ApoB, ApoA1, and triglycerides.[178] A recent prospective cohort study of almost 28,000 women ≥45 years with 11 years of follow-up found that when comparing the highest to the lowest quintiles, the HRs for ischemic stroke were 2.13 for TC, 1.68 for LDL-C, and 2.26 for non-HDL-C, after adjustment for other risk factors. After multivariable adjustment, no significant association was found between HDL-C and ischemic stroke risk.[179] In the INTERSTROKE study, while increased HDL-C concentration was associated with a decreased risk of ischemic stroke, no association was recorded with total or non-HDL cholesterol. Increased ApoA1 concentration was associated with a decreased risk of stroke, whereas increased ApoB was associated with an increased risk[137] (see Table 91.2). Apolipoproteins were more strongly associated with ischemic stroke than lipoproteins, a finding that was also noted for carotid artery disease in the NOMASS study.[180] The prevalence of hypercholesterolemia (total serum cholesterol levels > 240 mg/dL) amongst US adults over 20 years is 16.2%, an estimated 35 million people.[181] Results from trials of statin therapies have consistently reported a reduced risk of ischemic stroke with statin use.[182–187] In addition, a meta-analysis of over 90,000 patients included in trials of statin therapies reported a greater reduction in stroke risk with larger reductions in LDL-C.[188]

Obesity

A high body mass index (BMI) as a measure of general obesity and a high WHR as a measure of abdominal obesity are both associated with an increased risk of stroke, and this risk persists after adjusting for other established stroke risk factors.[189,190] In the INTERSTROKE study, individuals with a WHR in the higher tertile had an increased risk of stroke (OR 1.65) compared to those in the lowest tertile[137] (see Table 91.2). A prospective cohort study of over 20,000 male physicians found that during 12.5 years of follow-up, those with a BMI ≥ 30 kg/m^2 had twice the risk of total stroke (adjusted RR 2.0) compared to those with a BMI < 23 kg/m^2. In addition, for every unit increase in BMI, there was a 4% increase in the adjusted RR for all stroke.[189] A population-based case–control study in Northern Manhattan found that individuals with a WHR in the third and fourth quartiles had a higher risk of ischemic stroke (OR 2.4) compared to those in the first quartile, after adjustment for other risk factors including BMI.[190] A Swedish study which followed over 7,000 healthy males for 28 years also found an increased risk of stroke in those with a BMI > 30 kg/m^2 (adjusted HR 1.93) compared to those with a BMI of 20 to <23 kg/m^2.[191] Although adiposity and percentage body fat can increase as people grow older, a stable or decreasing BMI can also occur due to a loss of lean body mass and muscle.[192–194] This could explain the observation that WHR appears to be a better predictor of stroke than BMI.[190] There are a variety of proposed mechanisms for the association between obesity and stroke. To date, no clinical trials have reported a reduced risk of first or recurrent stroke with weight loss, although large long-term clinical trials are lacking.[46,151]

Physical Inactivity

Moderate and higher levels of PA have been associated with a decreased risk of stroke, even after adjusting for major cardiovascular risk factors.[195] A meta-analysis of 31 observational studies found that moderately intense levels of PA decreased the risk of all stroke subtypes, and this effect was seen with both occupational PA (RR 0.64) and leisure time PA (RR 0.57).[196] In the Physicians' Health Study, there was a 14% reduction in RR of stroke among those men who exercised vigorously ≥5 times per week, after adjustment for other risk factors.[197] In the Framingham study, medium-level PA was associated with a decreased risk of stroke (RR 0.41) with no additional benefit occurring with higher levels of PA.[198] A more recent observational study of over 47,000 Finnish people followed up for a mean of 19 years looked at the relationship between various types of PA and risk of stroke. The HR for total stroke in individuals with moderate (>4 hours per week of walking, cycling, or light gardening) and high (>3 hours per week of jogging, swimming, heavy gardening, or regular sports) levels of leisure time PA was significantly decreased, compared to individuals with low levels of PA (HR 0.86, 0.74, and 1.00, respectively). In addition, there was a decreased HR for total stroke in individuals with active commuting (>30 minutes daily) (HR 0.89).[195] The beneficial effects of exercise are believed to be mediated by its impact on other known risk factors for stroke. PA leads to decreased blood pressure, body weight, and LDL-C; increased HDL-C; and increased glucose tolerance and insulin sensitivity.[199,200] Other possible mechanisms for the decrease in stroke risk with PA include a decrease in platelet aggregation,[201] a decrease in fibrinogen,[202] and increased fibrinolysis.[203,204]

Diet

A diet with consumption of grains, fruit and vegetables, and fish has been associated with a decreased risk of stroke. In the INTERSTROKE study, increased consumption of fruit (OR 0.61) and fish (OR 0.78), but not vegetables was associated with a significantly decreased risk of stroke. Increased risk of stroke was associated with higher consumption of red meat, organ meats, or eggs (OR 1.35); higher consumption of fried foods, pizza, or salty snacks (OR 1.16); and cooking with lard (OR 1.66)[137] (see Table 91.2). A meta-analysis of seven prospective

cohort studies found an 11% decrease in the risk of stroke for each additional portion of fruit per day consumed, after adjustment for factors known to be more likely amongst consumers of fruit such as higher education, more regular exercise, and decreased likelihood of smoking. There was no significant decrease in stroke risk with vegetable intake.[205] Another study found that consumption of over six servings of fruit or vegetables per day provided little further reduction in the risk of ischemic stroke, compared to five or six servings.[206] In the Nurses' Health Study of over 75,000 women, compared to individuals in the lowest quintile for whole-grain intake, those in the highest quintile had a decreased RR of stroke (RR 0.69), after adjustment for known cardiovascular risk factors.[207] The Nurses' Health Study also investigated the association between fish and risk of stroke. Compared to women who ate fish less than once per month, those who ate fish more frequently had a decreased risk of stroke, after adjustment for other cardiovascular risk factors: one to three times per month (RR 0.93), once per week (RR 0.78), two to four times per week (RR 0.73), and ≥5 times per week (RR 0.48).[208]

Alcohol

The relationship between alcohol and stroke risk depends on the amount of alcohol consumed and the stroke subtype. For ischemic stroke, a J-shaped association has been reported.[137,209] Compared to moderate alcohol intake, both high levels of alcohol consumption and minimal or no alcohol consumption have been associated with an increased risk of ischemic stroke. The risk of hemorrhagic stroke appears to increase with the amount of alcohol consumed in a more linear fashion.[210] A meta-analysis of 35 observational studies found that compared to abstainers of alcohol, consumption of <12 g/d (one standard drink) was reported to be associated with a decreased risk of ischemic stroke (RR 0.80), as was consumption of 12 to 24 g/d (one to two standard drinks) (RR 0.72). However, consumption of >60 g/d (five standard drinks) was associated with an increased risk of ischemic stroke (RR 1.69).[209] A recent prospective cohort study of over 38,000 male physicians with a mean follow-up of 14 years found that compared with abstainers of alcohol, individuals who consumed one to two standard drinks per day on more than 4 days per week had a decreased risk of ischemic stroke (RR 0.68).[211]

There are various proposed mechanisms for the association between alcohol consumption and stroke risk. High alcohol intake can predispose to hypertension, AF, and cardiomyopathy, thereby increasing the risk of ischemic stroke.[212–215] One proposed explanation for the reduction in ischemic stroke risk with moderate alcohol intake is that alcohol tends to increase HDL-C levels,[216,217] reduce platelet aggregation,[218] enhance fibrinolysis,[219] and decrease the levels of fibrinogen.[220]

Psychosocial Factors

Chronic stress at home or in the workplace, social isolation, and anxiety are believed to be associated with an increased risk of stroke.[4] In the INTERSTROKE study, the presence of psychosocial stress, defined as a combined measure of general stress at home and in the workplace (permanent or several periods of stress versus no or some periods of stress in the past year) was reported to be associated with an increased risk of stroke (OR 1.30). Depression, defined as feeling sad, blue, or depressed for two or more consecutive weeks during the past 12 months, was also noted to be associated with an increased risk of stroke (OR 1.35, PAR 5.2%)[137] (see Table 91.2). A prospective cohort study of elderly Australians reported that, compared to individuals in the lowest tertile for depression score, those in the third tertile had a 41% greater risk of ischemic stroke (adjusted RR 1.4).[221] A second prospective study reported an increased risk of stroke/TIA in individuals with depressive symptoms >65 years (adjusted HR 3.43), but not in those >65 years.[222] Major life events have also been associated with an increased risk of stroke.[223]

EMERGING RISK FACTORS

Genetic Factors

A family history of stroke is considered a risk factor for stroke. Evidence for such an association comes from population-based studies,[224–226] family studies,[227,228] and twin studies.[229] In the Family Heart Study, a positive history of paternal or maternal stroke was associated with an increased risk of stroke, with adjusted ORs of 2.00 (95% CI 1.13 to 3.54) and 1.41 (0.80 to 2.50), respectively.[227] The increased risk of stroke in individuals with a positive parental history can be due to (a) genetic heritability of cerebrovascular risk factors such as hypertension and diabetes; (b) an inherited susceptibility to the effects of cerebrovascular risk factors; (c) familial sharing of the same environmental and lifestyle factors such as diet and levels of PA; and (d) the interaction between genetic factors and the environment.[227] Many stroke risk factors have both genetic and environmental elements, such as hypertension and diabetes.[230,231]

Twin studies also provide evidence of a genetic susceptibility to stroke, with markedly higher concordance rates for stroke in monozygotic twins (17.7%), compared to dizygotic twins (3.6%), and an almost fivefold increase in stroke prevalence in monozygotic, compared to dizygotic, twins.[229] Some cases of ischemic stroke can be caused by monogenic disorders with a Mendelian pattern of inheritance, such as CADASIL,[112] CARASIL, and sickle cell disease (SCD).[232] However, the majority of ischemic stroke cases are sporadic and of multifactorial origin. Genetic involvement in the pathogenesis of multifactorial ischemic stroke is likely to be polygenic, involving more than one gene. The genetic influence on stroke risk can be mediated in several ways; the presence of several genes may have an additive effect on risk (gene–dose effect), a synergistic effect with a multiplicative increase in risk, or genes may interact with acquired risk factors, such as smoking, and modulate their effects.[233]

The different phenotypes of ischemic stroke, such as cardioembolism and large-artery atherosclerosis, may reflect these differences in genetic influences, as for each subtype genetic factors may act differently, for example, predispose to typical stroke risk factors, modulate the effect of these risk factors, or independently increase the risk of stroke.[15,233]

Recent genome-wide association studies have found an association between various single-nucleotide polymorphisms (SNPs) and both stroke subtypes and risk factors, such as diabetes and AF. The CHARGE study identified two SNPs at a genetic locus on chromosome 12p13 associated with an increased risk of stroke.[234]

Monogenic disorders that have been associated with ischemic stroke include hematological disorders, such as FVL mutation[235] and protein C deficiency[236]; connective tissue disorders, such as Ehlers-Danlos syndrome type IV[237]; metabolic disorders such as MELAS[120] and hyperhomocysteinemia[238]; and inherited small-vessel disease, such as CADASIL.[112] Examples of polygenic disorders associated with ischemic stroke include Marfan syndrome,[239] familial Moyamoya disease,[240] and familial hemiplegic migraine.

HEMATOLOGICAL RISK FACTORS FOR STROKE

Thrombophilia and Ischemic Stroke

Inherited prothrombotic disorders include FVL mutation, protein C deficiency, protein S deficiency, antithrombin deficiency, and PT G20210A. Acquired disorders of coagulation that predispose to a hypercoagulable state include the antiphospholipid syndrome, hyperhomocysteinemia, malignancy, dysfibrinogenemia, elevated von Willebrand factor (vWF) levels, and elevated plasminogen activator inhibitor-1 levels.

The FVL mutation, the most common inherited disorder leading to a hypercoagulable state, leads to resistance of FV to degradation by activated protein C.[241] It is the most frequent genetic risk factor predisposing to venous thrombosis worldwide.[242] However, large prospective and nested case–control studies,[243,244] as well as two meta-analyses,[245,246] have failed to demonstrate a significant association between FVL mutation and risk of ischemic stroke in adults. Some small case–control studies have reported an increased risk of ischemic stroke in women using oral contraceptives who had either the FVL or PT G20210A mutation.[247–249] Other studies in children have suggested that FVL may be a risk factor for ischemic stroke in this group, although sample sizes were small.[250,251]

Protein C is a vitamin K–dependent factor that when activated, along with its cofactor protein S, induces proteolysis of factors V and VIII:C, thereby inhibiting the coagulation cascade and thrombus formation.[252] Deficiency of protein C and/or protein S leads to a hypercoagulable state and an increased risk of venous thrombotic events, most commonly deep venous thrombosis, pulmonary embolism, and superficial thrombophlebitis.[242,253,254] Studies investigating an association between protein C deficiency and ischemic stroke in adults have produced conflicting results. Some smaller case–control studies and case reports have reported a significant association between protein C deficiency and ischemic stroke,[236,255] but this has been contradicted in larger studies.[256,257] A prospective cohort studies and a meta-analysis have reported a significant association between protein C deficiency and ischemic stroke in children.[250,258] An association between protein S deficiency and ischemic stroke is also uncertain. Small studies and case reports have reported a possible association between protein S deficiency and risk of ischemic stroke[259,260]; however a larger case–control study failed to confirm an association.[256] A meta-analysis of case–control studies also failed to demonstrate a significant association in children.[250]

The PT G20210A mutation leads to an increase in plasma levels of prothrombin (factor II), a key enzyme in the coagulation cascade and the precursor of thrombin. Carriers of the mutation have an approximately threefold increased risk of venous thrombotic events.[261,262] Studies investigating the possible association between PT G20210A and risk of ischemic stroke have produced conflicting results. Two large prospective population studies, the Physicians' Health Study and the Cardiovascular Health Study, failed to demonstrate a significant association between PT G20210A and stroke risk[263,264]; however, a large meta-analysis of 19 case–control studies reported a modest, but significant, association.[265] Antithrombin is a serine protease inhibitor that inactivates thrombin and activated coagulation factors such as FX, FIX, FXI, and FXII, thereby inhibiting coagulation.[265] Deficiency of antithrombin results in a hypercoagulable state and an increased risk of venous thrombotic events. The deficiency can also be acquired, for example, due to severe liver disease, nephrotic syndrome, acute thrombosis, and disseminated intravascular coagulation or through the use of medications such as oral contraceptives or heparin.[265] There is no substantial evidence to date to demonstrate an association between antithrombin deficiency and risk of ischemic stroke in adults or children based on a prospective cohort study,[266] a large case–control study,[256] and a meta-analysis of eight case–control studies in children.[250]

The antiphospholipid syndrome (APL) syndrome is a systemic autoimmune disorder characterized by recurrent thrombosis or pregnancy morbidity, in association with increased levels of antiphospholipid antibodies.[242] The pathophysiological mechanism underlying the association between APL syndrome and an increased risk of recurrent venous and arterial thrombosis is still debated but is mainly believed to be caused by antiphospholipid antibody-mediated activation of endothelial cells and platelets.[267] Studies investigating the association between APL syndrome and the risk of ischemic stroke have produced contradictory results. Some case–control studies, such as the RATIO study, have reported a positive association between APL antibodies and an increased risk of ischemic stroke,[268,269] while others have failed to report such an association.[270,271] In the APASS case–control study of patients presenting with first ischemic stroke, anticardiolipin antibodies were detected in 9.7% of stroke patients, compared to 4.3% of controls. The OR for stroke risk independently associated with anticardiolipin antibody positivity was 2.31.[272] A large prospective cohort study demonstrated an association between elevated serum concentration of anticardiolipin antibodies and ischemic stroke risk in women, but not in men.[273] Several studies in young adults have demonstrated an association between APL antibodies and ischemic stroke.[274,275]

Homocysteine is an amino acid derived from methionine in the diet. Hyperhomocysteinemia can be inherited, due to inborn errors of amino acid metabolism such as cystathionine β-synthase deficiency, or more commonly it is acquired, for example, due to dietary deficiency of vitamin B_{12} or folic acid, increased age, or renal failure.[276] Homocysteine promotes atherogenesis and thrombosis[277]; however the pathophysiological mechanism underlying the association between hyperhomocysteinemia and risk of ischemic stroke is poorly understood.[242] Studies have consistently reported a strong and independent association between elevated plasma homocysteine levels and stroke risk, and a meta-analysis of eight prospective studies demonstrated a significant association between elevated homocysteine levels and risk of stroke.[238,278] Several large randomized trials, such as vitamin intervention for stroke prevention (VISP) and more recently vitamins to prevent stroke (VITATOPS), have failed to demonstrate an overall benefit from vitamin supplementation

(folic acid, vitamins B_6 and B_{12}) in reducing the recurrence of major vascular events such as stroke.[279,280]

Fibrinogen is a key factor in the coagulation cascade and in the promotion of thrombosis. High levels of fibrinogen are consistently associated with an increased risk of ischemic stroke.[281–283] One large meta-analysis of 31 population-based prospective studies reported a significant association between high plasma fibrinogen levels and ischemic stroke risk (HR 2.06, per 1 g/L increase in typical fibrinogen levels).[284]

vWF is a glycoprotein that is produced in the endothelial cells and platelets and plays a key role in hemostasis. It mediates platelet adhesion and aggregation at sites of endothelial injury and serves as a carrier protein for coagulation factor VIII.[285] Studies investigating the possible association between high vWF levels and ischemic stroke risk have produced inconsistent results. One case–control study reported a significantly increased risk of first ischemic stroke in patients with high vWF activity and antigen levels.[286] The Atherosclerosis Risk in Communities (ARIC) prospective study found a significant association between vWF levels and ischemic stroke risk[287]; however another large prospective study failed to demonstrate a similar association.[288]

Essential thrombocythemia (ET), one of the myeloproliferative disorders, is an uncommon cause of ischemic stroke, accounting for <1% of cases.[289] The hypercoagulable state in ET is believed to be due to increased platelet activation and turnover, an acquired protein C resistance and decrease in protein S levels, as well as endothelial activation.[289]

SCD is associated with an increased risk of stroke, particularly in those with the homozygous HbSS genotype.[46] The risk of stroke is up to 11% by 20 years of age, 15% by 30 years, and 24% by 45 years.[290] The most common mechanism underlying ischemic stroke in SCD is believed to be large-artery arteriopathy, secondary to hyperplasia of the intima from repeated endothelial injury.[291–293]

Thrombotic thrombocytopenic purpura (TTP) is a rare systemic disorder that increases the risk of ischemic stroke. It is characterized by thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, and neurological abnormalities,[294] although the full pentad of clinical features rarely occurs. It can occur in familial or acquired forms. Familial TTP typically appears in childhood, although familial cases can also present later in life.[295] Acquired TTP occurs in older children and adults and is typically characterized by one episode, although recurrences do occur in 11% to 36% of individuals.[296–299] It is generally idiopathic, although it can also occur secondary to clopidogrel[300] or ticlopidine use,[301] malignancies, or occasionally during pregnancy or the peurperium.[302] Systemic aggregation of platelets in the microvasculature, mediated by large vWF monomers, leads to platelet-rich thrombi which can occlude the microvasculature and lead to ischemic events such as stroke.[295] The activity of ADAMTS 13, a vWF-cleaving metalloprotease, has been noted to be <5% of normal levels in the majority of patients with familial or acquired TTP.[295]

CONCLUSION

Ischemic stroke can be categorized into distinct etiological subtypes, which include large-vessel, small-vessel, cardioembolism, and cryptogenic subtypes. Unlike acute coronary syndrome, the mechanisms underlying the subtypes of ischemic stroke demonstrate greater heterogeneity. However, thrombogenesis is the underlying pathophysiological mechanism, common to all ischemic stroke subtypes.

Clinically overt stroke is considered to represent only a fraction of all strokes. The advent of contemporary MRI sequences has identified a large burden of subclinical cerebrovascular disease, which includes covert infarction, white matter hyperintensities, cerebral atrophy, and microbleeds.

Risk factors for stroke can be classified as traditional risk factors, such as hypertension, smoking, diabetes mellitus, and obesity; hematological risk factors, including FVL mutation, protein C deficiency, and antithrombin deficiency; and emerging risk factors namely, SNPs and monogenic and polygenic disorders. Many stroke risk factors have both genetic and environmental elements. The majority of ischemic stroke cases are sporadic and of multifactorial origin.

CHAPTER

92

Prevention of Thromboembolic Stroke in Patients with Atrial Fibrillation, Valvular Heart Disease, or Cardiomyopathy

THOMAS L. KAWANO AND JONATHAN L. HALPERIN

Patients with various forms of cardiac disease are at risk of ischemic stroke and systemic embolism due to migration of thrombus that forms on endocardial or prosthetic valve surfaces or in the cardiac chambers. The risk varies with the nature of the underlying heart disease, but clinically these events are typically severe, resulting in substantial disability and mortality. Highly effective prophylactic therapy is available in the form of anticoagulant drugs, but treatment is associated with a risk of bleeding complications. Hence, an understanding of the pertinent pathophysiology, clinical factors responsible for variation in individual risk, and evolving management alternatives is crucial to optimum patient care.

ATRIAL FIBRILLATION

Atrial fibrillation (AF) is the most common sustained cardiac rhythm disturbance and an important independent risk factor for ischemic stroke. AF affects approximately 2.5 million individuals in the United States[1,2] and millions more worldwide. Prevalence is greater in men than in women[3–5] and increases with age, rising rapidly beyond the 6th decade to approximately 10% among those older than 80 years (see FIGURE 92.1).[2–6] The median age of patients with AF is approximately 72 years. As the population ages, the number of individuals with AF is likely to increase substantially in the coming decades.[2]

Patterns of AF

AF can be classified according to pattern of occurrence as paroxysmal, persistent, or permanent, based on the duration of the arrhythmia and reversibility.[7] *Paroxysmal* AF may occur once or multiple times, but involves self-terminating episodes. *Persistent* AF does not convert to normal sinus rhythm (NSR) spontaneously but NSR can be restored, at least temporarily, with pharmacologic or electrical cardioversion. *Permanent* AF is refractory and implies a clinical decision to allow AF to continue. Either paroxysmal or persistent AF may occur as a single or recurrent episode. Risk factors associated with the future development of AF have led to the concept that some patients may have "pre-AF," and the early success of catheter-based ablation therapy has created a cadre of patients with "post-AF," who merit special considerations with respect to antithrombotic therapy.

Risk of Stroke Associated with AF

As a result of disorganized and ineffective atrial systole, the fibrillating atria become passive conduits of blood from the systemic and pulmonary venous systems to the ventricles. Impaired atrial emptying leads to stasis and increases the risk of thrombus formation, particularly in the left-atrial appendage (LAA).[8] The factors that promote embolism of intracardiac thrombus and subsequent ischemic events (including stroke and peripheral arterial occlusion) are incompletely understood.[9,10] In addition to cardiogenic embolism, patients with AF commonly have other cardiovascular disease states, such as hypertension and atherosclerosis, which raise the risk of ischemic events.

Approximately 15% of all strokes are attributed to AF.[11] The rate of ischemic stroke among patients with AF not given antithrombotic therapy averages 4.5% per year,[12,13] approximately fivefold greater than in age- and gender-matched individuals with NSR. In the Framingham Heart Study, the risk of stroke attributable to AF rose from 1.5% in patients aged 50 to 59 years to 23.5% in those aged 80 to 89 years.[14] Because both the prevalence of AF and the risk of stroke increase with patient age, the problem of stroke prevention is amplified among the elderly; AF is the most common cause of stroke in women older than 75 years.[15] When compared to ischemic stroke due to other causes, ischemic stroke due to AF is typically more severe and carries a significantly higher mortality rate.[16] Several hypotheses have been advanced to explain the pathogenesis of stroke in patients with AF and the poor clinical outcomes associated with these events. Embolism of thrombus from the LAA may cause complete occlusion of relatively large cerebral arteries, consistent with the relatively frequent finding of large cortical infarcts on brain imaging and less frequent lacunar infarcts.[17] Chronically reduced cerebral blood flow, due either to the arrhythmia itself or to more extensive cerebrovascular disease associated with AF due to hypertension or atherosclerosis, may compromise collateral perfusion when acute infarction develops and contribute to greater stroke severity.

AF in the Setting of Valvular Heart Disease

Patients with AF and rheumatic mitral valve disease or mechanical or biologic prosthetic heart valves have been considered at high risk of stroke[10] and were excluded from most randomized

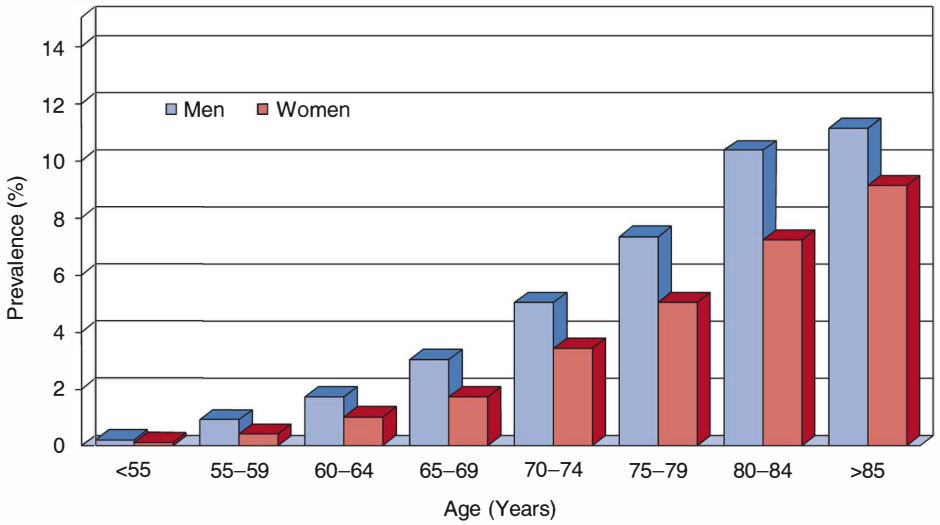

FIGURE 92.1 Prevalence of atrial fibrillation according to sex and age.

trials of antithrombotic therapy because of the perceived need for anticoagulation. Hence, available empirical data pertain mainly to patients with nonvalvular AF.

Atrial Flutter

Sustained atrial flutter is uncommon because the rhythm typically either degenerates to AF or reverts to NSR. Patients with persistent atrial flutter may have periods of AF and *vice versa*. There are scant data from longitudinal studies assessing the thromboembolic risk associated with isolated, sustained atrial flutter. Echo-Doppler examinations of patients with atrial flutter demonstrate more organized atrial mechanical function and greater LAA flow velocities than are typical in patients with AF.[18] Despite this functional distinction, intra-atrial thrombus and stroke have been documented in patients with atrial flutter.[6,19] In a transesophageal echocardiographic (TEE) study before cardioversion, 25% of patients with atrial flutter of slightly longer than 6 months mean duration had spontaneous echocardiographic contrast, a marker of stasis thought to represent a prethrombotic state, and 7% had LAA thrombus.[20] In patients with prior cerebral ischemic events, the prevalence of intra-atrial thrombus associated with atrial flutter was even higher.[21] A retrospective study of 100 patients with persistent atrial flutter found a higher than anticipated risk of stroke.[22] Although the role of anticoagulant therapy for patients with atrial flutter has not been evaluated in clinical trials, current treatment guidelines recommend that antithrombotic therapy follows the same risk-stratification approach applied to patients with AF.

Stroke Risk Stratification in Patients with AF

A combined analysis of untreated control groups in five primary prevention trials found a stroke rate of over 8% per year in patients with AF older than 75 years who had one additional clinical risk factor (hypertension, diabetes mellitus, heart failure (HF), or prior stroke or transient ischemic attack [TIA]). For patients of any age with a history of thromboembolism, the annual risk of stroke was 12%.[12,23] In a study of elderly nursing home patients who were not anticoagulated, the 3-year stroke rate exceeded 50%.[24]

Risk factors that increase the risk of stroke among patients with AF not treated with anticoagulants have been determined from randomized trials of antithrombotic therapy.[23–28] The most commonly cited risk-stratification strategies were generated from pooled analyses of five trials by the Atrial Fibrillation Investigators (AFI)[12] and from the Stroke Prevention in Atrial Fibrillation (SPAF) cohorts.[25,28] The AFI group[12] found the following independent risk factors: age (relative risk [RR] 1.4 per decade), prior stroke or TIA (RR 2.5), a history of hypertension (RR 1.6), and diabetes mellitus (RR 1.7). Analysis of 854 patients assigned to aspirin from the first two SPAF trials[29] identified three independent risk factors for stroke: women older than 75 years (RR 3.7), systolic hypertension >160 mm Hg (RR 2.2), and impaired left ventricular (LV) function defined as recent (within 3 months) HF, moderate-to-severe systolic dysfunction as assessed by two-dimensional echocardiography, or fractional shortening <0.25 by M-mode echocardiography (RR 1.8). Extending the analysis to 2,012 patients allocated to the aspirin or combination therapy arms of the SPAF-I to SPAF-III studies[30] identified five characteristics significantly associated with an increased risk of stroke: prior thromboembolism (RR 2.9), age (RR 1.8 per decade), female gender (RR 1.6), history of hypertension (RR 2.0), and systolic blood pressure >160 mm Hg (RR 2.3).

Although prior stroke or TIA, older age, and hypertension were identified as risk factors for stroke in patients with AF in both the AFI and SPAF risk-stratification schemes, there was a differential impact of age in these cohorts. The AFI scheme classified all patients with AF 65 years or older as at elevated risk, whereas the SPAF criteria classified women 75 years or younger and men of any age without other risk factors as at low risk. Uncertainty about risk in either gender aged 65 to 75 years and in men of any age without other risk factors applies to approximately 20% of the population with nonvalvular AF.[31]

Current guidelines recommend a risk-based approach to selection of patients with AF for oral anticoagulation to prevent stroke.[7] The main clinical risk factors are presented

Table 92.1

Principal clinical risk factors associated with stroke and systemic embolism in patients with nonvalvular atrial fibrillation[a]

High-Risk Factors
Mitral stenosis
Prosthetic heart valve
History of stroke or TIA
Moderate Risk Factors
Age > 75 y
Hypertension
Diabetes mellitus
HF or ↓ LVEF
Less Validated Risk Factors
Age 65–75 y
Coronary artery disease
Female gender

[a]Patients with any of the high-risk factors should be anticoagulated. Those with one moderate risk factor also benefit from anticoagulation, but the number of patients needed-to-treat with an anticoagulant as compared with aspirin is considerably larger, so some patients with one moderate risk factor may choose platelet inhibitor therapy. The moderate risk factors shown here and prior thromboembolism form the basis for the $CHADS_2$ risk score (see Table 92.2), while the less-validated risk factors have been incorporated into the CHA_2DS_2VASc score (see Table 92.3).
LVEF, left ventricular ejection fraction.
Adapted from Singer DE, Albers GW, Dalen JE, et al. Long-term antithrombotic therapy for chronic atrial fibrillation or atrial flutter: anticoagulants and antiplatelet agents. In Seventh ACCP Consensus Conference on Antithrombotic Therapy: Antithrombotic Therapy in Atrial Fibrillation. American College of Chest Physicians. *Chest* 2004;126(Suppl):429S–456S; Fang MC, Singer DE, Chang Y, et al. Gender differences in the risk of ischemic stroke and peripheral embolism in atrial fibrillation: the AnTicoagulation and Risk factors In Atrial fibrillation (ATRIA) study. *Circulation* 2005;112:1687–1691.

in Table 92.1. A modified scale, $CHADS_2$ (Cardiac failure, Hypertension history, Age >75 years, Diabetes, and Stroke or TIA [doubled]), integrates elements from the AFI and SPAF schemes in assessing the annual risk of stroke. This index allots two points for a history of stroke or TIA and one point each for age over 75 years, history of hypertension (not further defined), diabetes mellitus, recent clinical HF, or impaired LV systolic function (generally taken as an ejection fraction ≤35%) (Table 92.2). The scheme was initially evaluated in 1,733 Medicare beneficiaries with nonvalvular AF aged 65 to 95 years who were discharged from hospital off warfarin[32] and has been validated in several cohorts.

The $CHADS_2$ index has the advantage of simplicity, but classifies a relatively large proportion of patients with AF as at intermediate risk and has imperfect predictive capacity overall (c-statistic ~0.6). Additionally, many of those designated as low risk carry as high as a 1.3% annual risk of stroke. Additional risk factors, albeit less well validated than those that comprise the $CHADS_2$ index, should be considered in the stratification of stroke risk in patients with AF. Women with AF appear at higher risk than men with otherwise comparable risk profiles.[33–35] Vascular disease, including peripheral arterial disease, coronary disease (specifically prior myocardial infarction [MI]),

Table 92.2

$CHADS_2$ score[a]

	Score (Points)	Prevalence (%)
Congestive HF	1	32
Hypertension	1	65
Age > 75 y	1	28
Diabetes mellitus	1	18
Stroke or TIA	2	10
Moderate–high risk	≥2	50–80
Low risk	0–1	40–50

[a]For estimation of thromboembolic risk in patients with nonvalvular atrial fibrillation. One point each is assigned for a history of clinical HF or impaired left-ventricular systolic function (corresponding roughly to ejection fraction ≤35%), hypertension (not further defined), and diabetes mellitus and two points for prior ischemic stroke, TIA, or systemic arterial embolism. The approximate prevalence in the Euro Heart survey cohort is shown in the right-hand column, and proportion of patients falling into low-, intermediate-, and high-risk strata is given at the bottom.
Adapted from van Walraven C, Hart RG, Wells GA, et al. A clinical prediction rule to identify patients with atrial fibrillation and a low risk for stroke while taking aspirin. *Arch Intern Med* 2003;163:936–943; Nieuwlaat R, Capucci A, Lip GY, et al. Antithrombotic treatment in real-life atrial fibrillation patients: a report from the Euro Heart Survey on atrial fibrillation. *Eur Heart J* 2006;27:3018–3026.

and morphologically complex atheromatous plaque involving the thoracic aorta, is also associated with an increased risk of stroke, but its independent predictive value is controversial. An updated risk-stratification scheme, the CHA_2DS_2VASc score (Table 92.3), incorporates vascular disease (V) and female sex (S) into the risk-stratification schematic, assigning each of these factors one point, and distinguishes two age categories to

Table 92.3

CHA_2DS_2VASc risk-stratification scheme[a]

	Weight (Points)
Congestive HF or LVEF ≤ 35%	1
Hypertension	1
Age >75 y	2
Diabetes mellitus	1
Stroke/TIA/systemic embolism	2
Vascular disease/peripheral arterial disease/aortic plaque	1
Age 65–74 y	1
Sex: category (female)	1
High risk	≥2
Low risk	0–1

[a]This scheme has the advantage of assigning fewer patients than the $CHADS_2$ score to the intermediate-risk category. This score was adopted in the European clinical practice guidelines for management of patients with AF in 2010 but is not universally accepted as superior to the $CHADS_2$ score.
LVEF, left ventricular ejection fraction.
Adapted from Lip GYH, Halperin JL. Improving stroke risk stratification in atrial fibrillation. *Am J Med* 2010;123:484.

account for the continuous relationship of risk to age, allocating one point to patients with AF beyond age 65 and two points to those over 75 years.[36] The CHA_2DS_2VASc score was validated in the Euro Heart Survey cohort, anticoagulated clinical trial cohorts, and a national patient registry of patients with AF who were not anticoagulated.[37] When compared with the $CHADS_2$ risk score, CHA_2DS_2VASc had greater negative predictive value for stroke for patients classified in the low-risk category and classified fewer patients as intermediate risk, but the c-statistics still indicated imperfect capture of all attributable risks.[36]

The controlled clinical trials of warfarin included mainly patients with chronic, persistent, and permanent AF and smaller proportions of patients with paroxysmal AF.[7] For the purpose of determining stroke risk, the distinction between paroxysmal, persistent, and permanent AF proved immaterial. Patients with paroxysmal AF typically have a lower risk of stroke than those with persistent or permanent AF, as they are often younger and have fewer associated risk factors,[38,39] but multivariate analyses of prospectively followed cohorts found that the pattern of AF was not a significant predictor of stroke risk.[12,40] Current recommendations for anticoagulation, therefore, do not distinguish patients on the basis of the pattern of AF, though the available evidence does not address transient self-limited AF caused by acute medical illness or recent cardiac or noncardiac surgery.[7]

Postoperative Atrial Fibrillation

Patients who develop AF after undergoing cardiothoracic surgery are also at an increased risk of thromboembolic stroke. While there is a small but significant increased risk of in-hospital stroke in patients who develop AF after surgery involving cardiopulmonary bypass, the risk of stroke seems related to underlying comorbidities rather than to AF itself. This was demonstrated in a series of close to 4,000 patients who had cardiac surgery on cardiopulmonary bypass. The rate of AF after surgery was reduced with prophylactic therapy, but the incidence of stroke was not reduced.[41]

The decision to anticoagulate patients with AF in the postoperative period is confounded by the risk of bleeding and its associated sequelae (cardiac tamponade, hematoma, hemothorax, etc.). Additionally, a significant percentage of patients who develop AF postoperatively convert back to sinus rhythm. The duration of AF postoperatively, the associated risk of thromboembolic stroke, and the decision of when to anticoagulate are unclear. Practice guidelines differ on when to start anticoagulation for postoperative AF. At the time of this writing, the American College of Chest Physicians (ACCP) guidelines recommend initiating anticoagulation with vitamin K antagonist (VKA) 48 hours after a patient has developed AF. The American Heart Association/American College of Cardiology (AHA/ACC) guidelines recommend starting a VKA after 24 hours of developing AF. Both guidelines agree that anticoagulation should continue for 4 weeks following reversion to and maintenance of sinus rhythm, but the level of evidence supporting this duration of therapy is low.

Echocardiographic Markers of Stroke Risk

Although left-atrial size and LV systolic function can be assessed by transthoracic (precordial) echocardiography, TEE is necessary to consistently visualize abnormalities of the LAA and aortic arch linked with thromboembolism. This approach is used not only as an adjunct to elective cardioversion (see below) but sometimes in patients with persistent AF to assist in thromboembolic risk assessment.[42,43] Visible thrombus or dense spontaneous echo-contrast in the left atrium (LA), and particularly in the LAA, is associated with a two- to fourfold increased risk of stroke.[7,8] In the SPAF-III study, patients with atheromatous plaque in the thoracic segments of the aorta that had complex morphology (mobility, pedunculation, ulceration, or thickness >4 mm) had high stroke rates. Because many of these abnormalities were observed in the descending aorta beyond the origins of the cerebral vessels, the association with stroke may reflect either associated cerebrovascular disease or the pathogenic role of risk factors such as hypertension that are common both to atherosclerosis and to conditions of atrial stasis in patients with AF.[43]

Other Potential Stroke Risk Factors in AF

Other characteristics that may augment stroke risk include genetic polymorphisms, abnormalities of hemostatic and thrombotic function, increased platelet activation and aggregation, endothelial dysfunction,[44,45] and serum levels of troponin and B-type natriuretic protein, but none have yet proven sufficiently robust for routine clinical use. Thyrotoxicosis is a poorly understood risk factor for stroke among patients with AF, because patients with thyrotoxicosis were excluded from the randomized trials of antithrombotic therapy. AF develops in 10% to 15% of patients with hyperthyroidism, and thyrotoxicosis is evident in 2% to 5% of patients with AF.[46] A high frequency of stroke and systemic embolism has been reported in some[47–51] but not all studies.[52] The association, if real, may be mediated partly by concomitant HF.

Antithrombotic Drug Therapy for Prevention of Thromboembolism in Patients with AF

Oral Anticoagulant Therapy with a Vitamin K Antagonist

Several randomized trials demonstrated the efficacy of adjusted-dose warfarin for prevention of first or recurrent ischemic stroke in patients with AF with relative risk reductions (RRR) of 47% to 86% versus placebo or no therapy. Results from these trials are summarized in FIGURE 92.2. In a pooled analysis, adjusted-dose warfarin reduced the risk of stroke by about two-thirds.[27,46] The magnitude of benefit was fairly consistent among trials despite variations in design and in the intensity of anticoagulation. Compared with aspirin, adjusted-dose warfarin reduced the overall risk of stroke by 36% (95% CI 14% to 52%) and ischemic stroke by 46% (95% CI 27% to 60%).[30] The discrepancy is driven largely by the results of the SPAF-II trial (mean international normalized ratio [INR] 2.6), which involved an older patient cohort than enrolled in most other studies,[53] and the risk of intracranial bleeding among patients receiving adjusted-dose warfarin was substantially increased among patients more than 75 years old. Exclusion of SPAF-II data from the meta-analysis revealed a 49% reduction in the risk of all stroke for adjusted-dose warfarin compared with aspirin (95% CI 26% to 65%).[30] Anticoagulation lowered all-cause mortality by 33% (95% CI 9% to 51%) and the combined outcome of stroke, systemic

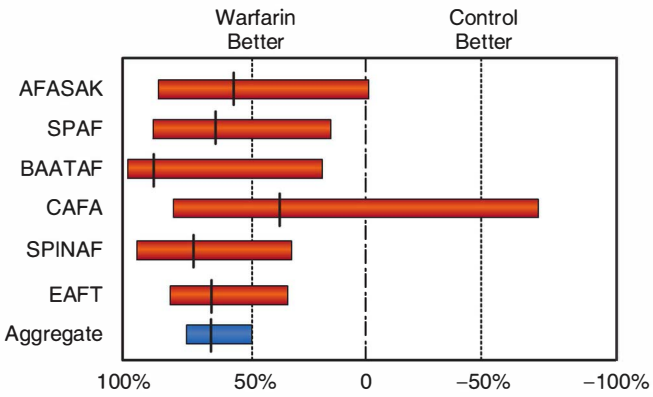

FIGURE 92.2 Stroke risk reductions with warfarin compared to control (placebo or no treatment) in patients with nonvalvular atrial fibrillation. The first five trials listed mainly involved primary prevention, whereas the last was confined to patients with prior nondisabling stroke or TIA. Values shown were obtained according to intention-to-treat analysis. AFASAK, Atrial Fibrillation, Aspirin and Anticoagulation trial; SPAF, the Stroke Prevention in Atrial Fibrillation trial; BAATAF, the Boston Area Anticoagulation Trial for Atrial Fibrillation; CAFA, the Canadian Atrial Fibrillation Anticoagulation trial; SPINAF, the Veterans Administration Stroke Prevention in Atrial Fibrillation trial; EAFT, the European Atrial Fibrillation Trial. (Adapted from Hart RG, Halperin JL. Atrial fibrillation and stroke: concepts and controversies. *Stroke* 2001;32:803.)

embolism, and death by 48% (95% CI 34% to 60%).[12] Due to concern about bleeding, particularly intracranial hemorrhage, when warfarin is given to elderly patients, the BAFTA trial compared open-label warfarin and aspirin in patients 75 years of age and older during treatment by primary doctors in the UK.[54] The annual risk of the primary outcome of (ischemic or hemorrhagic) stroke, other intracranial hemorrhage, or systemic embolism was significantly lower in the warfarin group than in patients randomized to aspirin (yearly risk 1.8% vs. 3.8%, RR 0.48, 95% CI 0.28 to 0.80, $P = 0.003$).[54] These data support the advantage of treating older patients who have AF with warfarin, unless there are other contraindications.

AF had been present for months or years in most of the patients enrolled in these studies, yet each was terminated earlier than planned because of the large benefit of antithrombotic therapy (most often warfarin) for prevention of ischemic stroke and systemic embolism. In aggregate, by intention-to-treat analysis, the annual stroke rate was reduced from 4.5% in the control arms to 1.4% with adjusted-dose warfarin. The effect was consistent across studies with an overall RRR of 68% (95% CI 50% to 79%).[12] The absolute risk reduction implies prevention of 31 ischemic strokes each year for every 1,000 patients treated (or 32 patients needed-to-treat [number needed to treat for 1 year] to prevent a single stroke).[12]

The efficacy of anticoagulation with warfarin was consistent across all patient subgroups and for preventing strokes of all degrees of severity. Most strokes occurring in the warfarin arms involved patients who had stopped warfarin or in whom the INR or prothrombin time ratio fell below the therapeutic range. In summary, evidence for the efficacy of anticoagulation with warfarin in patients with AF is strong and consistent, based on several adequately powered, randomized trials, though an important caveat is that these were mostly open-label studies. The one trial that involved double-blind treatment included no women.[55]

In these trials, anticoagulation proved relatively safe when the upper limit of the therapeutic range was less than INR 3.0, but whether comparable safety can be reliably achieved in less carefully selected patients outside the rubric of clinical research protocols is a persistent controversy. Pooled analysis of the first five primary prevention trials reported a 1.0% per year rate of major bleeding in control patients versus 1.3% in those treated with warfarin. Several schemes have been developed to predict the risk of bleeding in patients with AF during anticoagulant therapy, and though several have been validated in various cohorts none has been uniformly accepted (Table 92.4).

Intracranial hemorrhage is the only complication of anticoagulation that regularly produces deficits more severe than the ischemic strokes the therapy is intended to prevent, and in these trials the rate of intracranial hemorrhage was 0.3% per year in anticoagulated patients compared with 0.1% in the control groups.[12] Intracranial hemorrhage is more common in patients with prior ischemic stroke, hypertension, and advanced age.[56] One reason intracranial hemorrhages occurred at a low rate in these trials may have been the exclusion of patients considered at high risk of bleeding. Even when aggregated, these trials contribute less to understanding the determinants of intracranial hemorrhage than do large observational studies, which show a correlation with the intensity of warfarin anticoagulation (INR > 4.0),[56,57] although even with INR values in the

Table 92.4
HAS-BLED score[a]

	Weight (Points)
Hypertension (>160 mm Hg systolic)	1
Abnormal renal or hepatic function	1–2
Stroke	1
Bleeding history or anemia	1
Labile INR (TTR < 80%)	1
Elderly (age > 75 y)	1
Drugs (antiplatelet, NSAID) or alcohol	1–2
High risk (>4% per y)	≥4
Moderate risk (2%–4% per y)	2–3
Low risk (<2% per y)	0–1

[a]One of several risk scores for predicting bleeding in anticoagulated patients with atrial fibrillation. Although adopted in some clinical practice guidelines, no single scheme has yet been widely accepted to guide selection of patients for anticoagulant therapy for prevention of thromboembolism, and bleeding risk must be considered in the context of the patient's inherent risk of thromboembolism.
INR, International Normalized Ratio of prothrombin suppression; TTR, percent time in therapeutic range; NSAID, nonsteroidal antiinflammatory drug.
Adapted from Pisters R, Lane DA, Nieuwlatt R, et al. A novel user-friendly score (HAS-BLED) to assess one-year risk of major bleeding in atrial fibrillation patients: the Euro Heart Survey. *Chest* 2010;138(5):1093–1100; Lip GYH, Frison L, Halperin JL, et al. Comparative validation of a novel risk score [HAS-BLED] for predicting bleeding risk in anticoagulated patients with AF. *J Am Coll Cardiol* 2010;57:173–180.

therapeutic range of 2.0 to 3.0 warfarin doubles the risk.[58] Even more important is that intracerebral hemorrhage in anticoagulated patients is usually catastrophic and often fatal.

Efficacy of Aspirin

Evidence that aspirin is effective for prevention of thromboembolism in patients with nonvalvular AF is considerably weaker than that supporting warfarin. Meta-analysis of five controlled studies[23,59–64] found a 22% (95% CI 2% to 38%) reduction in stroke rates.[27] Four of these were placebo-controlled trials,[64] with aspirin doses ranging from 50 to 325 mg daily. A patient-level meta-analysis of data from the placebo-controlled AFASAK-1, SPAF-I, and EAFT trials estimated that the RRR was a marginally significant 21% (95% CI 0% to 38%).[67] The SPAF-I trial, in which the RRR was significant at 42%, had two randomized cohorts, one of patients eligible for randomization to warfarin and the other deemed ineligible on the basis of age, physician judgment, or patient refusal. In warfarin-eligible cases, the RRR afforded by aspirin was striking (94%), whereas that in the ineligible cohort was minimal (8%, not significant [NS]), similar to findings in the AFASAK-1 and EAFT studies. In other studies involving patients with AF, the efficacy of aspirin for prevention of thromboembolism was negligible or inconsistent.[61,62,64,66] Aspirin may be more efficacious for patients with AF and hypertension and diabetes[65] and for preventing noncardioembolic rather than cardioembolic ischemic strokes.[67] Cardioembolic strokes are, on average, more disabling than noncardioembolic strokes,[68] and aspirin appears to prevent nondisabling more than disabling strokes[27]; therefore, the greater the risk of disabling cardioembolic stroke in patients with AF, the less protection afforded by aspirin.[68]

In trials that compared the two therapies, oral VKA therapy was considerably more effective than aspirin.[20,23,49,53,54,59,62,63,68,69] Meta-analysis of six studies found an RRR of 46% (95% CI 27% to 60%) with oral anticoagulation compared with aspirin for ischemic stroke and 36% (95% CI 14% to 52%) for all (ischemic or hemorrhagic) strokes related to AF.[27] The hazard ratio (HR) for major bleeding associated with anticoagulation was 1.7 (95% CI 1.2 to 2.4).[70] Hence, treatment of 1,000 patients with AF with adjusted-dose oral anticoagulation instead of aspirin for 1 year would avoid 23 ischemic strokes but cause nine additional major bleeds.

Other Platelet-Inhibitor Agents and Lower-Intensity Anticoagulation

A randomized trial comparing adjusted-dose warfarin with the platelet inhibitor indobufen found no significant difference in rates of the combined endpoint of stroke, MI, pulmonary embolism, or vascular death (12% with indobufen vs. 10% with warfarin over an average follow-up of 12 months; $P = 0.47$).[71] None of the patients treated with indobufen developed major bleeding, which occurred in 0.9% of those treated with warfarin.

Trials of very low-intensity anticoagulation with or without aspirin have generally not identified a suitable alternative to adjusted-dose warfarin at INR 2.0 to 3.0 for prevention of thromboembolism in patients with AF. Meta-analysis of three studies[64,69,72] comparing fixed, low-dose warfarin (1.25 mg daily) with adjusted-dose warfarin (INR 2.0 to 3.0) found a mean RRR of 38% (95% CI 20% to 68%) favoring more intensive dosing.[27] Aspirin may augment protection against ischemic coronary events but raises the risk of hemorrhage in anticoagulated patients, and the incremental coronary benefit of adding aspirin to oral anticoagulation seems modest.[73] The SPAF-III trial compared a combination of warfarin (targeting INR initially to 1.2 to 1.5 with a maximum daily dose of 3 mg) plus aspirin (325 mg daily, enteric coated) with adjusted-dose warfarin (target INR 2.0 to 3.0). The trial was terminated early because of a higher rate of ischemic stroke and systemic embolism in patients taking the combination therapy (7.9% per year) than in those assigned to conventional warfarin (1.9% per year). There was no significant difference in rates of major hemorrhage between the two groups, and no significant advantage in terms of coronary outcomes because of the relatively low frequency of such events.

Two small-scale studies have addressed the use of lower-intensity warfarin. In one, targeting a lower INR value (1.9) was comparable to more conventional warfarin therapy (target INR 2.5) for secondary stroke prevention in patients with nonvalvular AF and was associated with a lower frequency of severe bleeding ($P = 0.0103$).[74] Patients in the conventional therapy group who developed bleeding complications were older (mean age 73.7 years), but the results must be interpreted cautiously because the study was terminated prematurely while the sample size was small ($n = 115$). The other trial compared low-intensity (target INR 1.8) and standard (target INR = 2.5) warfarin therapy for primary stroke prevention in patients over 75 years old.[75] There was no significant difference in the combined rate of thromboembolism or major bleeding with the two regimens (HR 0.7, 95% CI 0.4 to 1.1, $P = 0.1$). Despite a combined endpoint constellation, the event rate was lower than expected, and the results raise the possibility that less intensive anticoagulation may be adequate for primary stroke prevention in low-risk patients with AF.

Dual Antiplatelet Therapy

Although monotherapy with aspirin offers marginal benefit for thromboembolism prevention in patients with AF, the combination of aspirin plus clopidogrel, which blocks platelet aggregation through inhibition of adenosine diphosphate-dependent pathways,[76] reduces the incidence of ischemic events compared to aspirin alone. Early studies of clopidogrel showed a reduction of ischemic events with clopidogrel when added to aspirin therapy[77] or in place of aspirin[78] in patients with AF and atherosclerosis. The ACTIVE (Atrial fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events) studies compared dual antiplatelet therapy with aspirin and clopidogrel to adjusted-dose warfarin (ACTIVE-W) and to aspirin alone (ACTIVE-A) in patients with AF and a high risk of stroke ($CHADS_2$ score > 1).[79,80] The ACTIVE-W study was terminated early because of the overwhelming superiority of warfarin (RR with aspirin plus clopidogrel = 1.44, 95% CI 1.18 to 1.76, $P = 0.0003$) without any increase of the risk for major hemorrhage. ACTIVE-A was a randomized, double-blind study of 7,554 patients with AF who were not considered candidates for VKA therapy. Reasons for enrollment in ACTIVE-A included specific risk of bleeding (22.9% of patients), physician's judgment that the patient was a poor candidate for anticoagulation (49.7%), or the patients' preferences (26%). The primary endpoint included major vascular events (strokes, noncentral nervous system systemic embolic events, MIs, and deaths from vascular causes). The main secondary outcome was stroke. In ACTIVE-A, the combination of aspirin plus clopidogrel was

superior to aspirin alone for prevention of the primary outcome (RR 0.89, 95% CI 0.81 to 0.98, $P = 0.01$) and stroke alone (RR 0.72, 95% CI 0.62 to 0.83, $P < 0.001$). There was, however, a significantly higher risk for major bleeding with dual antiplatelet therapy (RR 1.57, 95% CI 1.29 to 1.92).

Novel Oral Anticoagulants

Despite their unequivocal efficacy against ischemic stroke in patients with AF, the narrow therapeutic margin of oral VKAs and interactions with numerous drugs and foods require frequent INR testing and dose adjustments. The quest for safer, more convenient alternatives has been particularly active and productive in recent years. Clinically available agents and others in advanced stages of development fall into two broad categories: direct inhibitors of thrombin (factor IIa) and inhibitors of activated factor X (factor Xa). The pharmacology of these agents is addressed elsewhere in this textbook.

Direct Thrombin Inhibitors

Ximelagatran was an orally administered prodrug converted after absorption to the active direct thrombin inhibitor melagatran. SPORTIF III and V were two long-term trials that compared ximelagatran to warfarin for prevention of stroke and systemic embolism in patients with AF.[81–83] While both studies found ximelagatran noninferior to warfarin (INR range 2.0 to 3.0), the compound was withdrawn from further development because of potential hepatotoxicity.

Dabigatran etexilate is another oral prodrug converted by a ubiquitous esterase to dabigatran, a potent direct inhibitor of thrombin. Its utility for prevention of thromboembolism in patients with nonvalvular AF was addressed in the RE-LY trial, a multicenter study of over 18,000 patients comparing dabigatran in twice-daily doses of either 150 or 110 mg to adjusted-dose warfarin (INR range 2.0 to 3.0).[84] This open-label study involving patients with a mean $CHADS_2$ risk score or 2.1 found dabigatran, 150 mg twice daily, superior to warfarin for prevention of stroke or systemic embolism (RR 0.66, 95% CI 0.53 to 0.82, $P < 0.001$). The rate of major bleeding with this dose of dabigatran was similar to that with warfarin. The 110 mg twice daily dose of dabigatran was noninferior to warfarin for prevention of stroke or systemic embolism and associated with a significantly lower risk of major bleeding (RR 0.80, 95% CI 0.69 to 0.93, $P = 0.003$) (FIGURE 92.3).[84] There was a higher risk of major gastrointestinal bleeding with dabigatran at 150 mg twice-daily dose than with warfarin (RR 0.91, 95% CI 0.85 to 0.97, $P = 0.005$),[84] but a lower risk of intracerebral hemorrhage (0.12 vs. 0.38% per year, $P < 0.001$). There was no indication of hepatic toxicity, but dyspepsia occurred more often in the dabigatran groups, sometimes limiting treatment. The FDA approved dabigatran in the 150 mg twice-daily dose for use in the United States; a dose of 75 mg twice daily was also approved for patients with impaired renal function (creatinine clearance 15 to 30 mL/min) based on pharmacokinetic modeling, but clinical experience with this low dose is limited. Regulators in Canada approved both the 110 and 150 mg twice-daily doses; and the European regulatory agency (EMA) also approved the drug.

Factory Xa Inhibitors

Several inhibitors of factor Xa have been investigated as therapeutic agents for prevention of thromboembolism

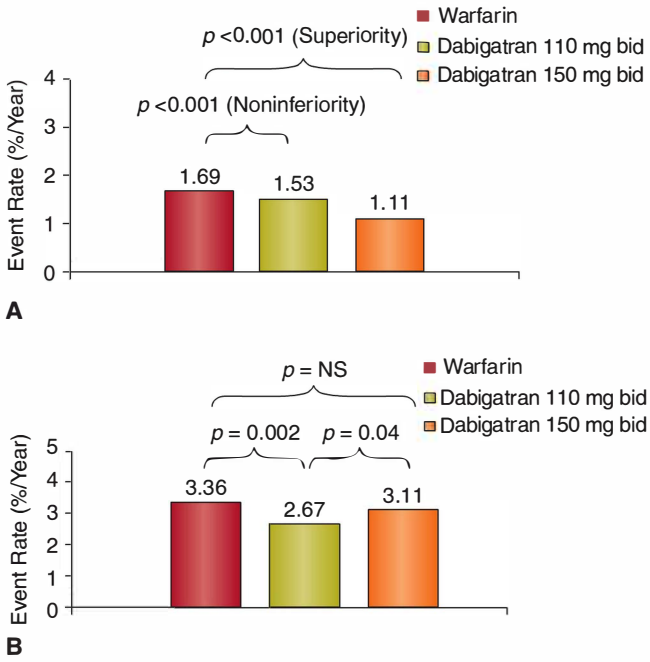

FIGURE 92.3 Main results of the RE-LY trial of the fixed-dose, oral, direct thrombin inhibitor, dabigatran etexilate, versus adjusted-dose warfarin (target INR 2.0 to 3.0) in patients with nonvalvular atrial fibrillation. **A:** Rates of the primary events (all strokes [ischemic and hemorrhagic] and systemic embolic events). **B:** Rates of major bleeding (bleeding that was fatal, was permanently disabling, involved a critical anatomic site, resulted in a ≥2 g/dL decline in hemoglobin content, or required transfusion of ≥2 units of whole blood or packed red blood cells). (Adapted from Connolly SJ, et al. Dabigatran versus warfarin in patients with atrial fibrillation. *N Engl J Med* 2009;361:1139.)

in patients with AF. Rivaroxaban is an orally active, direct factor Xa inhibitor effective for prevention and treatment of venous thromboembolism. It was evaluated in the multicenter, double-blind ROCKET-AF trial of 14,264 patients comparing rivaroxaban, 20 mg once daily (15 mg daily for patients with creatinine clearance 30 to 49 mL/min), to adjusted-dose warfarin (INR range 2.0 to 3.0) for prevention of stroke or systemic embolism in patients with AF at increased risk of stroke (mean $CHADS_2$ score = 3.5).[85] Rivaroxaban proved noninferior to warfarin (HR 0.79, 95% CI 0.66 to 0.96, $P < 0.001$) without increasing the risk of major bleeding. By intention-to-treat analysis, rivaroxaban was not superior to warfarin (2.20% vs. 2.40% per year, HR 0.91, 95% CI 0.78 to 1.07, $P = 0.26$). Based on the data from ROCKET-AF, the 20 mg daily dose of Rivaroxaban has been approved by the FDA for the prevention of stroke and systemic embolism in patients with nonvalvular AF.

Another direct factor Xa inhibitor, apixaban, has been investigated as a potential alternative to vitamin K antagonism. The AVERROES trial compared apixaban, 5 mg twice daily, to aspirin (81 to 324 mg daily) in patients with AF with at least one additional stroke risk factor who were not considered candidates for therapy with warfarin.[86] The study was stopped on

the advice of the Data Safety Monitoring Committee because of the superior efficacy of apixaban for prevention of stroke or systemic embolism in this patient population (RR = 0.46, $P < 0.001$). There was no significant difference in major bleeding between the two therapies, but there was an excess of minor bleeding in the group given apixaban, a substantial proportion of which was taking aspirin concurrently, and early termination of the study may have prevented detection of a difference in rates of major bleeding. The Apixaban for the Prevention of Stroke in Subjects with Atrial Fibrillation trial[87] compared apixaban, 5 mg twice daily, versus warfarin (target INR 2.5) in 18,201 moderate- to high-risk patients ($CHADS_2 \geq 1$) with nonvalvular AF. The primary outcomes were stroke or systemic embolism, and the key secondary efficacy outcome was death from any cause. The primary safety outcome was major bleeding defined as clinically overt bleeding accompanied by a decrease in the hemoglobin level ≥2 g/dL or transfusion of ≥2 units of packed red cells. Over a median follow-up of 1.8 years, apixaban was associated with a 21% reduction in primary events (HR 0.79, 95% CI 0.66 to 0.95, $P = 0.01$), a 31% reduction in the risk of bleeding (HR 0.69, CI 0.60 to 0.80, $P < 0.001$), a significant reduction in intracerebral bleeding, and an 11% reduction in all-cause mortality (HR 0.89, CI 0.80 to 0.99, $P = 0.047$) but no significant reduction in rates of ischemic stroke or cardiovascular mortality compared to warfarin. As with rivaroxaban, there was a trend toward lower rates of MI with apixaban compared to warfarin, but this was not statistically significant (0.53% vs. 0.61%, HR 0.88 [0.66 to 1.17], $P = 0.37$). Unlike dabigatran or rivaroxaban, apixaban therapy was associated with a lower rate of gastrointestinal bleeding than warfarin.

A third oral factor Xa inhibitor, edoxaban, is currently in phase 3 investigation in the ENGAGE-AF TIMI 48 trial of patients with AF.[88] Several other agents in this class (including betrixaban and darexaban) have completed phase 2 studies, but adequately powered phase 3 trials have yet to begin.

Other molecules under development for this indication include antagonists of the initial phase of tissue factor activation of factor VII and agents that stimulate fibrinolysis. Evaluation of each will require large trials because available active comparators (e.g., warfarin) are highly effective, resulting in low event rates.

Until recently, warfarin was the sole anticoagulant proven effective for patients with AF at risk of stroke; but its narrow therapeutic margin and variable dose response compromised clinical utility. The emergence of new anticoagulants that offer equal or superior efficacy, the convenience of fixed oral dosing, and greater safety, particularly with respect to reduction in the rate of intracerebral hemorrhage—the most feared complication of antithrombotic therapy and in many respects the sole complication that often leads to worse outcomes than the ischemic strokes treatment is intended to prevent—may make warfarin the less preferred option for many patients. Clinical practice guidelines undergoing revision to address these alternatives may support a multiplicity of options for anticoagulation therapy in patients with AF, but the limitations of crosstrial comparisons and lack of prospective comparative effectiveness studies addressing the newer agents will challenge clinicians to select therapy based on economics, availability, tolerability, convenience, and other factors.

Nonpharmacologic Therapy for Prevention of Thromboembolism

Cardioversion

Systemic embolism is the most serious complication of direct-current or pharmacologic cardioversion of AF to NSR. Observational evidence favoring anticoagulation has impeded trials comparing anticoagulation to no therapy.[89–93] In the prospective cohort study of Bjerkelund and Orning,[94] cardioversion without anticoagulation was associated with a 5.3% incidence of clinical thromboembolism versus 0.8% in patients selected for treatment with a VKA. Most ischemic events are presumed to result from embolism of either preexisting thrombus or new thrombus forming in the LA or LAA when atrial mechanical dysfunction worsens.[95–99] Most published guidelines recommend anticoagulation with adjusted-dose warfarin (INR 2.0 to 3.0) for 3 to 4 weeks before and after elective cardioversion of patients with AF.[100,101] Serial TEE studies have demonstrated resolution of thrombus after 1 month of warfarin in most patients with AF of recent onset,[8,18,102] but thrombus may persist in a minority of cases.[104] In addition, a month of anticoagulation may enhance thrombus organization and adherence to the endocardial surface, reducing the risk of embolism.

In the prospective Assessment of Cardioversion Using Transesophageal Echocardiography (ACUTE) trial,[104] the incidence of clinical thromboembolism in 603 patients after treatment with warfarin (INR 2.0 to 3.0) for 3 weeks before cardioversion was 0.5%. During the conventional treatment phase of the Ludwigshafen Observational Cardioversion study,[103] 357 patients undergoing successful cardioversion had a 0.8% incidence of neurologic events.

Most information on cardioversion-related thromboembolism is based on electrical cardioversion, but anticoagulation is also recommended for patients undergoing pharmacologic conversion. Following restoration of normal atrial electrical activity on the surface ECG after cardioversion, normal mechanical contraction of the LA may be delayed for more than a week[105–107] and appears related to the duration of AF before cardioversion.[108,109] Anticoagulation should be continued for 1 month following apparently successful cardioversion and for longer in patients with additional stroke risk factors, as AF may recur without symptoms.

Transesophageal Echocardiography-Guided Cardioversion

The accuracy of TEE for detection of thrombus in the LA and LAA and the association of this finding with the risk of thromboembolism following cardioversion[8,110] offers an opportunity to perform cardioversion earlier in patients without thrombus. In several studies,[8,18,99,102,104,107] rates of thromboembolism were similar to those associated with standard therapy for 3 to 4 weeks of anticoagulation before cardioversion, with the advantages of an earlier recovery of atrial mechanical function, ease of anticoagulation management, elimination of readmission for elective cardioversion, and potential cost-effectiveness.[111] Limitations of the TEE approach include patient discomfort, rare procedural complications, and limited availability at some centers. Despite the absence of LAA thrombus on precardioversion TEE, stroke has been described among patients who did not receive anticoagulation during the pericardioversion period and for at least 3 weeks after cardioversion.[112–115]

The ACUTE trial enrolled 1,222 patients with AF for whom elective electrical cardioversion was planned to compare the conventional and TEE-guided approaches.[7] In the TEE-guided arm, five ischemic neurologic events occurred among 619 subjects compared with three events among 603 patients managed conventionally (P = NS). Most adverse events in the TEE-guided group were associated with recurrent AF and subtherapeutic anticoagulation intensity (INR < 2.0). Many of the patients in the conventional management arm converted to NSR spontaneously during the month of anticoagulation before scheduled cardioversion. In general, cardioversion occurred earlier in the TEE-guided group, but there was no difference in the prevalence of NSR by 8 weeks following randomization. In smaller, nonrandomized studies in which the duration of AF was <3 weeks, however, the rate of recurrent AF was lower and the likelihood of NSR at 1 year greater among subjects undergoing TEE-guided cardioversion.[116]

When AF is known to have been present for <48 hours, cardioversion is commonly performed without either prolonged antecedent anticoagulation or TEE examination. In a study of 357 patients with symptomatic AF for <48 hours,[117] 250 converted spontaneously and 107 underwent pharmacologic or electrical cardioversion without prolonged anticoagulation or TEE before cardioversion, and the risk of clinical thromboembolism was <1%. In another retrospective study of 258 patients undergoing cardioversion for AF of <2 days duration, one ischemic event occurred among 198 patients not anticoagulated before or following cardioversion (0.5%) compared with none among 60 patients treated with anticoagulation.[118] Given the limitations of these studies, heparin is generally recommended immediately before and during cardioversion and warfarin for 4 weeks following cardioversion of patients with AF of known recent onset (<48 hours duration). In an analysis of patients in the RE-LY trial undergoing cardioversion, the frequencies of stroke and major bleeding within 30 days of cardioversion on dabigatran etexilate were low and comparable to those on warfarin with or without TEE guidance,[119] making dabigatran an alternative to warfarin in patients requiring cardioversion. For high-risk patients, it seems prudent either to perform TEE or to delay cardioversion for a month to allow prior anticoagulation. When emergency cardioversion is necessary to terminate AF associated with a rapid ventricular response causing angina, HF, hypotension, or syncope, heparin is generally recommended at the time of cardioversion followed by oral anticoagulant therapy for at least 3 to 4 weeks.

Alternatives to Antithrombotic Therapy

Antiarrhythmic Therapy

Until recently, most physicians favored cardioversion and a strategy of rhythm control over rate control for patients with AF of recent onset, presuming that restoration and maintenance of NSR would avoid the adverse hemodynamic consequences of AF and reduce the risk of thromboembolism. Several randomized studies, most notably the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM)[120] and the comparison of Rate Control and Rhythm Control in Patients with Recurrent Persistent atrial fibrillation (RACE)[121] trials, demonstrated that the frequency of ischemic events was equal regardless of whether a rate control or rhythm control strategy was followed. Most of these events occurred after warfarin was stopped or when the INR fell below the therapeutic range. The largest trial, AFFIRM,[120] enrolled 4,060 patients with recurrent AF older than 65 years or with other risk factors for stroke or death who had no contraindications to anticoagulation. All were initially anticoagulated, but warfarin was sometimes withdrawn from those in the rhythm control arm who appeared to maintain NSR. After a mean follow-up of 3.5 years, 35% of patients in the rate control group were in NSR, compared to 63% of those in the rhythm control group. More than 85% of patients in the rate control arm were treated with warfarin, compared to 70% in the rhythm control arm. All-cause mortality was not reduced by rhythm control (26.7% vs. 25.9%, P = 0.08), and there was no significant difference in ischemic stroke between the rhythm control and the rate control strategy (7.1% vs. 5.5% respectively, P = 0.79).

The RACE trial enrolled 522 patients with recurrent AF or atrial flutter of <1 year duration undergoing cardioversion on one or two occasions over a period of 2 years, randomized to rate control or to rhythm control strategies.[121] The primary outcome was a composite of death from cardiovascular causes, HF, thromboembolism, bleeding, pacemaker implantation, and severe adverse drug effects. After 2.3 years follow-up, there was a trend toward a lower incidence of the primary endpoint with rate control than with rhythm control (17.2% vs. 22.6%, HR 0.73, 90% CI 0.53 to 1.01). There was no difference in cardiovascular mortality (6.8% vs. 7%) and a trend toward more nonfatal endpoints among patients in the rhythm control arm. The results were marred, however, by imbalance between arms in the prevalence of hypertension.

The ATHENA trial compared the antiarrhythmic drug dronedarone against placebo in patients with paroxysmal AF.[122] Patients randomized to dronedarone had a lower incidence of the primary outcome of first hospitalization due to cardiovascular events or death.[122] A *post hoc* analysis of ATHENA demonstrated that dronedarone was also associated with a lower rate of stroke and TIA (HR = 0.66, 95% CI 0.46 to 0.96, P = 0.027).[123] It is not clear, however, whether this benefit accrued as a consequence of successful rhythm control or some other effect of dronedarone.

Although both rate and rhythm control approaches are reasonable clinical options, the foregoing findings support continuation of anticoagulation in high-risk patients even after NSR is restored following spontaneous, pharmacologic, or direct-current cardioversion. One reason for the failure of rhythm control to reduce thromboembolism is that AF recurs in 40% to 60% of patients by 1 year following initially successful cardioversion, even when antiarrhythmic drug therapy is employed,[124,125] and many of these episodes of recurrent AF are asymptomatic.[126] Another potential explanation for the frequency of ischemic events following apparently successful cardioversion is that patients with AF typically have associated cardiovascular diseases such as atherosclerosis and hypertension that are independently implicated as causes of stroke and responsive to antithrombotic therapy.

The Maze Operation and Catheter-Based Pulmonary Vein Isolation

A cardiac surgical operation, the Maze procedure, involves creation of scars on the endocardial surface of the atria to interrupt reentrant circuits and maintain NSR; concurrently, the LAA is either amputated or closed.[127] For carefully selected patients in

the hands of experienced operators, the long-term success of the Maze procedure in preventing recurrent AF exceeds 90%,[128] and this combination of rhythm control and obliteration of the LAA may reduce the risk of thromboembolism, although no controlled studies have been conducted. In a series of 306 patients followed for 11.5 years, there were two perioperative strokes and one later stroke, corresponding to an annual risk well below 1%, comparable to that reported by other investigators.[31,129,130] Although the original procedure was scalpel based, modifications using intraoperative delivery of radiofrequency, microwave, or cryoablation energy have been described.[131] Because patients and physicians are reluctant to embrace major surgery as a strategy for management of AF, the Maze procedure has been largely restricted to adjunctive use during other cardiac operations, such as coronary bypass or valve repair or replacement operations, although less invasive options are under investigation.[132]

An alternative treatment involves catheter-based radiofrequency ablation of intra-atrial pathways that participate in the initiation or perpetuation of AF. On the basis of the observation that regions in the LA proximate to the insertions of the four pulmonary veins are a common site of earliest activation of atrial ectopic beats that engender AF, radiofrequency encirclement, and electrical isolation of the pulmonary veins has become an accepted form of catheter-based treatment.[108,133] A nonrandomized, multicenter, prospective study of 79 patients documented freedom from recurrent AF in 84% over follow-up of approximately 1 year,[109,134] but larger studies are needed to address the safety and efficacy of this procedure.

No adequate studies have yet been published that specifically assess the risk of thromboembolism in patients who have undergone radiofrequency pulmonary vein isolation. Although some patients undergoing ablation or the Maze operation may be poor candidates for long-term anticoagulation, there is presently a dearth of evidence to support withdrawal of anticoagulation following either procedure. In the absence of trial-based conclusions, consensus recommendations advocate treating such patients longer than those undergoing apparently successful cardioversion of AF, basing the duration of anticoagulation more on the patient's intrinsic risk of thromboembolism than on the likelihood of arrhythmia recurrence.[135]

Left-Atrial Appendage Closure

Because the LAA has been implicated as an important source of thrombus formation in patients with nonvalvular AF,[136] closure or obliteration of the appendage offers a potential alternative to anticoagulation for prevention of embolism. Percutaneous, catheter-based devices for occlusion of the LAA have been developed. Limited observational data in North America and Europe suggested that the Percutaneous Left-Atrial Appendage Transcatheter Occlusion (PLAATO) device delivered by the transseptal approach and deployed in the LAA[137] was effective and relatively safe in patients with AF who are not candidates for warfarin therapy, but the device is no longer manufactured and no comparative studies are available. The WATCHMAN LAA closure device is a self-expanding device with a polytetrafluoroethylene membrane and nitinol frame that secures it to the ostium of the LA. The device is deployed into the LAA using a transseptal approach under fluoroscopic and TEE guidance. The device eventually becomes endothelialized, but because the membrane is permeable to blood, patients treated to date have been given anticoagulation therapy for at least 45 days after implantation; TEE is used to confirm proper device position and absence of flow into and out of the LAA before stopping anticoagulation therapy. PROTECT-AF, a randomized, multicenter study, compared the WATCHMAN device to standard long-term warfarin therapy in patients with nonvalvular AF and risk factors for thromboembolism.[138] In this study, the device compared favorably for prevention of stroke, systemic embolism, and cardiovascular or unexplained death (RR 0.62, 95% CI 0.35 to 1.25), but those treated with the device faced procedural complications including bleeding (RR 1.69, 95% CI 1.01 to 3.19). Other devices are under development, including not only catheter-based methods for LAA occlusion but investigational methods for obliteration of the LAA under thoracoscopic guidance.[139] These approaches are currently confined mainly to patients with relative contraindications to chronic anticoagulation with warfarin, but their use might eventually be extended to a wider array of patients once safety and efficacy are established.[140] Amputation, ligation, or plication of the LAA has become conventional during cardiac surgical operations involving the mitral valve, though definitive evidence that this is associated with a lower rate of postoperative thromboembolism is lacking.

CARDIOMYOPATHY

Though death in patients with chronic HF is usually caused by progressive hemodynamic failure, thrombotic coronary occlusion, or ventricular arrhythmias, patients with systolic HF are also at risk of thromboembolic stroke.[141] One or more components of Virchow's triad (stasis, endothelial injury, or a hypercoagulable state) predispose patients with systolic dysfunction to formation of mural thrombus in the LV. Wall motion abnormalities, particularly when they involve the LV apex, create zones of stasis, as occurs when a ventricular aneurysm develops following MI. Stagnant blood can occasionally be distinguished by spontaneous echo contrast on echocardiography as a result of interaction between red blood cells and plasma proteins, particularly fibrinogen. Spontaneous echo contrast is a precursor of thrombus development and a proven risk factor for stroke.[142]

Impaired release of nitrous oxide (NO) from endothelial cells has been implicated as a cause of vasoconstriction in patients with HF, and reduced NO release promotes monocyte and platelet adhesion. This mechanism and elevated levels of von Willebrand factor, a marker of endothelial damage, predispose to thrombus formation.[143,144] Circulating platelet aggregates are increased in patients with HF.[145] Compared to patients with coronary artery disease, patients with HF display higher levels of D-dimer and thrombin activity but varying degrees of platelet activation.[146,147] Elevated levels of fibrinopeptide A and thrombin–antithrombin complex have been correlated with increased LV end-diastolic volume and diminished fractional shortening, while levels of platelet factor 4, β-thromboglobulin, and plasmin–α_2-plasmin inhibitor complex are comparable in patients with HF and controls. Plasma viscosity in patients with HF is negatively correlated with LV ejection fraction,[148] and hemorheologic indices improve after treatment with angiotensin-converting enzyme inhibitors but not with β-blockers.[149]

The reported incidence of thromboembolism in the setting of HF varies substantially from as high as 50% in historical autopsy series to as low as 1% per year for those in sinus rhythm

in more recent clinical reports.[150–159] Fuster et al. reported an 18% prevalence of arterial thromboembolism (3.5 per 100 patient-years) in a review of 104 patients with idiopathic dilated cardiomyopathy,[160] but in that series the strongest independent predictor of thromboembolic events was AF. A later study of 264 patients with mean left-ventricle ejection fraction (LVEF) of 27% reported a cerebral ischemic event rate of 1.7% per year and higher thromboembolism and mortality rates when LV mural thrombus was detected.[161] These findings were substantiated in a series of 224 patients awaiting transplantation, in whom the risk of systemic embolism during follow-up was 3.2% per year.[162]

PREVENTION OF THROMBOEMBOLISM

The Survival and Ventricular Enlargement (SAVE) trial reported an inverse relationship between stroke risk and EF, with an 18% increase in risk for every 5% reduction in EF, relating thromboembolism to HF and severity of LV dysfunction.[154] The annual risk of thromboembolism in stable patients with chronic HF is relatively low (1% to 3% per year), even when the EF is severely reduced or LV thrombus is evident by echocardiography. This low annual risk limits the ability to detect a benefit of anticoagulation if it exists.[154]

Observational data from early studies have yielded conflicting results regarding the advantage of anticoagulation for prevention of thromboembolism. In the SAVE trial, treatment with warfarin was associated with an 81% lower risk of stroke.[154] A retrospective analysis of 6,767 patients with EF < 35% enrolled in the Studies of Left Ventricular Dysfunction (SOLVD) trials found an overall risk reduction of 32% in cardiovascular and sudden death with warfarin.[163] While the cohort included a high proportion of patients with ischemic heart disease, a benefit of warfarin was also seen in those without coronary disease. The SOLVD trials failed to demonstrate a reduction with warfarin in the combined rate of fatal and nonfatal thromboembolic events. Observational analysis of the Vasodilator Heart Failure Studies (V-HeFT) provided additional, albeit contradictory, data on the effect of anticoagulation. In V-HeFT I, there was no reduction in thromboembolic events during treatment with warfarin (2.9% vs. 2.7% per year in those not receiving chronic oral anticoagulation). In the V-HeFT II study, in contrast, the incidence of thromboembolism was higher in those receiving warfarin ($P < 0.01$), but antithrombotic therapy in these studies was not randomized.[164]

A Cochrane systematic review concluded that the limited evidence from observational studies regarding a reduction in mortality and cardiovascular events and the lack of controlled trials did not support routine use of anticoagulation in patients with HF in sinus rhythm.[165] The authors also concluded that there was no evidence that the efficacy of anticoagulation was superior to aspirin in this disease state.[166] Large, randomized trials of anticoagulation in patients with HF conducted over 50 years ago included patients with AF and rheumatic heart disease, and few trials were designed to address the issue in patients with HF in sinus rhythm. The available evidence does not show a clear advantage to anticoagulation therapy for prevention of thromboembolism in this situation. The Warfarin and Antiplatelet Therapy in Chronic Heart Failure (WATCH) trial was a randomized, double-blind trial intended to determine the optimum antithrombotic regimen for patients with HF ($n = 1,587$) and reduced LVEF in sinus rhythm based on the hypothesis that warfarin would be superior to antiplatelet therapy with aspirin and that clopidogrel would be superior to aspirin in preventing major cardiovascular events.[167] The primary endpoint was the constellation of all-cause mortality, nonfatal MI, and nonfatal stroke; secondary endpoints were the three components of the primary endpoint considered individually. The study was terminated early because of slow enrollment, however, and the statistical analysis was adjusted for reduced sample size. In conflict with the primary hypothesis, the number of primary endpoints was similar across treatment groups. While the overall incidence of nonfatal stroke was low in all three treatment groups, there was a statistically significant lower rate of nonfatal strokes in the warfarin arm than in the antiplatelet arms of the study ($P < 0.01$). This difference was eliminated, however, when fatal stroke and intracranial bleeding were included.

Because 9% of patients with a stroke have a left-ventricular EF ≤30%, finding the optimum treatment to reduce the probability of recurrent stroke is of clinical significance, yet there are no large randomized studies to resolve this conundrum. The Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) study is comparing warfarin (INR 2.5 to 3.0) versus aspirin (325 mg daily) in the 3 to 5-year event-free survival for the composite endpoint of death or stroke (ischemic or hemorrhagic) among 2,860 patients with an LVEF ≤35% who do not have AF or mechanical heart valves.[168] The results may help guide clinicians in selecting optimum antithrombotic therapy for patients with reduced LVEF with or without clinical HF.

While the benefit of anticoagulation in patients with HF in NSR is not yet clear, clinical practice guidelines generally support the use of anticoagulation in patients with HF and AF. Given the lack of compelling evidence for patients with NSR, the use of warfarin is not well defined and is recommended when there is another clear indication for anticoagulation or a disorder associated with increased thromboembolic risk (e.g., amyloidosis or noncompaction of the ventricular myocardium—a condition in which the LV myocardium consists of a highly trabeculated layer with deep recesses in addition to the normally "compacted" myocardium) and in those with familial dilated cardiomyopathy and a history of thromboembolism in first-degree relatives, but these recommendations are based more on consensus than empirical evidence.[169]

The Risk of Embolic Events Associated with Intracardiac Thrombus

Whereas the presence of an LV thrombus in a patient who has suffered a recent, large MI likely increases the risk of thromboembolism, the significance of mural thrombi in the setting of chronic HF is less clear. The incidence of mural thrombus after acute anterior MI ranges from 21% to 41%.[36,170] Several longitudinal studies failed to demonstrate consistent resolution of thrombus by echocardiography, though these studies suggested protection against stroke for patients managed with chronic anticoagulation.[37–44,171–178] Because the sensitivity of echocardiography may be insufficient to reliably predict systemic embolism in patients with dilated cardiomyopathy and intracavitary thrombus, treatment is largely empirical.[41,42,175,176] Guidelines recommend long-term anticoagulation for those with LV thrombus complicating acute MI based on meta-analysis of limited studies.[45,46,179,180] Consistent data support the

notion that mobile or protuberant mural thrombus conveys a high risk of thromboembolism, and patients with this characteristic should generally be anticoagulated.[47–49,181–183]

VALVULAR HEART DISEASE

Valvular heart disease spans a diverse range of endocardial pathology. While data support antithrombotic therapy with either aspirin or warfarin for prevention of thromboembolism in relation to specific valve lesions (e.g., mitral stenosis [MS]), there is relatively scant evidence with regard to other forms of valvular heart disease. This section addresses specific valvular pathology where an association with thromboembolic disease has been established and where antithrombotic therapy may be appropriate.

Diseases of Native Heart Valves Associated with Thromboembolism

Rheumatic Mitral Stenosis

MS is usually caused by rheumatic fever; congenital MS and MS due to other etiologies (e.g., annular calcification, carcinoid syndrome) are relatively rare. MS carries a 10% to 20% lifetime risk of clinically apparent systemic embolism (incidence 1.5% per year),[10,184,185] though the risk increases nearly sevenfold in the presence of AF. Following an initial thromboembolic event, the risk of recurrence over the patient's lifetime is up to 65%, and two-thirds of these recur within the first year after the initial event. Most clinical trials and meta-analyses involving prevention of cardiogenic embolism associated with AF have been restricted to patients with nonvalvular (nonrheumatic) AF. Patients with MS at highest risk are those with prior events or AF, who benefit substantially from anticoagulation. Patients with rheumatic MS who remain in NSR also carry a risk of thromboembolism. It remains unclear, however, whether patients at higher risk of embolism without AF or prior embolism uniformly benefit from anticoagulation.

While systemic embolism in patients with MS is thought to originate from left-atrial thrombus, the presence or absence of thrombus does not correlate closely with clinical ischemic events.[186] In a prospective analysis of 534 patients with MS, risk factors for embolism in patients with NSR included increasing age, diminishing mitral orifice area, atrial thrombus, and aortic regurgitation.[187] In this analysis, early balloon mitral valvuloplasty (BMV) was a negative predictor for the development of systemic embolism. The frequency of embolism was not directly related to the transmitral gradient, cardiac output, HF symptoms, or diameter of the LA.

The need for yearly echocardiograms for patients with MS is controversial and not currently recommended unless change in symptoms or functional status occurs. Asymptomatic patients with MS should be followed annually by clinical evaluation that includes an ECG. For patients who complain of palpitations, Holter monitoring or cardiac event monitoring is reasonable to detect AF, the finding of which warrants anticoagulation.

Current practice guidelines recommend anticoagulation for patients with MS who have AF, a history of systemic embolism (even when sinus rhythm is present), or atrial thrombus detected by TEE, though the evidence supporting these recommendations is limited to observational reports.[186] Anticoagulation may be considered for patients with hemodynamically severe MS, atrial enlargement >55 mm diameter, or in those with spontaneous echo contrast (class IIb).

Balloon Mitral Valvuloplasty

BMV is contraindicated when atrial thrombus is detected, owing to the potential for dislodgement during catheter manipulation. To avoid this complication, TEE should be performed prior to the procedure to exclude thrombus, and if thrombus is detected, BMV should be deferred until resolution of the clot is proven by repeat TEE after at least 3 weeks of anticoagulation with a VKA (INR 2.5 to 3.5) or heparin (target-activated partial thromboplastin time twice the control value).[188] Predictors of clot resolution include NYHA functional class II or better, thrombus diameter ≤1.6 cm, less dense spontaneous echo contrast, and INR ≥ 2.5.[189] Following BMV, recommendations for anticoagulation therapy are the same as those prior to the procedure.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) refers to billowing of redundant tissue of one or both mitral leaflets during systole. The condition is often congenital but may result from breakdown of one or more components of the mitral valve apparatus (papillary muscles, chordate tendineae, leaflets, or annulus). It is commonly accompanied by mitral regurgitation (MR) and is the etiology of up to 50% of cases of pure MR.

Whether MVP is associated with an increased risk of TIA or stroke has been debated since Barlow and Bosman[190] in 1966 described a 28-year-old woman with MVP who had transient left-arm weakness. Subsequently, a case-controlled study of 60 patients <45 years old who experienced ischemic stroke or TIA found MVP in 40%, compared with prevalences of 6.8% in 60 age-matched controls, and 5.7% in 42 stroke victims >45 years old.[191] In contrast, survival in asymptomatic or minimally symptomatic patients with MVP was similar in an age-matched cohort over a follow-up of >6 years.[192] Only patients with redundant mitral valve leaflets had significant complications, including infective endocarditis or cerebral embolism.

Variation in the echocardiographic criteria for diagnosis of MVP confounds assessment of the association of this valvular lesion with cerebral embolism and casts doubt on the conclusions of earlier studies. Current diagnostic criteria require superior displacement of the mitral valve >2 mm beyond plane of the annulus in the parasternal long-axis view. In a prospectively followed cohort of 777 patients in Olmsted County, MN, with MVP based on these criteria, there was an excess lifetime risk of ischemic neurologic events compared to the expected risk in the community (RR 2.2, 95% CI 1.5 to 3.2, $P < 0.001$).[193] Patient age, AF, MV thickening, and, to a lesser degree, LA enlargement were independent predictors of ischemic neurologic events by multivariate analysis.

The exact mechanism of TIA or stroke in relation to MVP is not clear. Possible explanations include endocardial disruption and fibrin deposition on denuded surfaces of the valve, mural thrombus at the junction of the prolapsed leaflet with the atrial wall, fibrinous endocarditis, and intrinsic abnormalities of platelet function linked to β-receptors.[194,195] No randomized trials have tested the efficacy of antithrombotic therapy or the superiority of one therapy over another in patients with MVP for prevention of thromboembolism. Given the uncertain

association of MVP with cerebral ischemic events, guidelines issued by various organizations differ. Some recommend aspirin (75 to 325 mg daily) for patients with MVP who have experienced stroke or TIA and those <65 years old with MVP and AF without MS, hypertension, or HF.[186] Warfarin is recommended for patients >65 years old with MVP and AF or a history of hypertension, HF, MS, or murmur of MR. Additionally, for patients with MVP and a history of stroke, anticoagulation should be employed if there is a history of MS, MR, AF, or LA thrombus. Anticoagulation is recommended as well for patients with a history of stroke and thickened valve leaflets (>5 mm) and for those with recurrent TIA despite aspirin therapy.

Thromboembolism Associated with Prosthetic Heart Valves

Available heart valve prostheses can be broadly categorized into biologic and mechanical types. Mechanical prostheses carry the advantage of greater long-term durability, but the potential for thromboembolic complications exceeds that of bioprosthetic valves. The structural integrity of bioprosthetic valves diminishes over time, resulting in valve failure at a certain point. In early studies, approximately 50% of bioprosthetic valves implanted in patients younger than 40 years failed within 10 years of implantation. Mechanical valves have a low rate of structural deterioration, but require long-term anticoagulation therapy with warfarin to prevent thromboembolism and therefore impose on the patient an inherently greater risk of bleeding. With improvement in the durability of newer generation bioprosthetic valves lowering the risk of a second or third operation and the potential for percutaneous approaches to valve replacement that might reduce the need for reoperation in the future, there has been a trend in the United States to prefer bioprosthetic valve replacement even in younger patients.

Mechanical Valves

All patients with mechanical prosthetic heart valves require anticoagulation, but the target intensity varies from INR range 2.0 to 3.0 to as high as 3.0 to 4.5 depending on the type of prosthesis, valve position, and presence or absence of additional risk factors. These risk factors, which are largely anecdotal and not derived from high-quality randomized trial databases, include AF, previous thromboembolism, hypercoagulable states, and LV dysfunction. A minimum INR range of 2.5 to 3.5 is recommended for patients with any of these risk factors regardless of the valve replacement or type of mechanical prosthesis, though higher intensities of anticoagulation are necessary for patients with older models that are more prone to thromboembolic complications. Additionally, an INR range of 2.5 to 3.5 is recommended for patients with tilting-disc or Starr-Edwards valves in the aortic position and for all mechanical prostheses in the mitral position. Bileaflet prostheses associated with high orifice-to-annulus ratios, manufactured from modern thromboresistant materials like pyrolytic carbon such as the St. Jude Medical or Medtronic-Hall prostheses placed in the aortic position, are associated with relatively low rates of thromboembolism and require less intensive anticoagulation (target INR 2.0 to 3.0) in the absence of other risk factors. In addition to warfarin, it has been recommended that patients with mechanical valve prostheses be treated with low-dose aspirin (50 to 100 mg daily) in addition to warfarin unless there is a contraindication due to gastrointestinal intolerance or bleeding.[196] A systematic review (*Cochrane Database Syst Rev* 2003;(4):CD003464.), however, showed that the reduced risk for thromboembolic events (OR 0.39) was counterbalanced by an increased risk for major bleeding (OR 1.66). Even with anticoagulation, the annual risk of thromboembolism is approximately 1% to 2%.[197] The risk is greater with mitral valve prostheses, which carry a risk roughly twice that of aortic valves,[197] and greater for caged-ball devices and multiple prostheses.[198]

While there are scant data to support the use of unfractionated heparin (UFH) as a bridging therapy, it is often initiated early after valve replacement surgery once anticoagulation therapy is safe from the standpoint of postoperative bleeding, usually 24 to 48 hours after the operation. Heparin can be stopped after 3 to 5 days of warfarin therapy, once the INR has reached the therapeutic range.

Data supporting the use low molecular weight heparin (LMWH) is also meager. A "black box" warning on the package insert of LMWH preparations cautioning that use in patients with mechanical heart valves was not adequately studied has been removed. The ACCP guidelines for antithrombotic therapy endorse the use of LMWH as a modality for bridging therapy following valve replacement surgery or when VKA therapy must be interrupted.[199] The AHA/ACC guidelines list a class IIb recommendation regarding bridging therapy with LMWH when anticoagulation must be stopped for noncardiac surgery or other invasive medical or dental procedures in a patient with mechanical cardiac valve prosthesis.

None of the novel oral anticoagulants (dabigatran, rivaroxaban, apixaban, edoxaban, or others) has been studied to determine their safety or efficacy for bridging or long-term therapy in patients with mechanical prosthetic heart valves and thus should not be used as a substitute for warfarin, UFH, or LMWH in this situation.

Bioprosthetic Valves

Over the long term following implantation, the frequency of thromboembolism in patients with biologic prosthetic heart valves without anticoagulation is similar to that in patients with mechanical valves receiving therapeutic anticoagulation.[198] Bioprosthetic heart valves, however, are associated with an elevated risk of thromboembolism in the first 90 days after implantation, especially when the valve has been placed in the mitral position.[200] Aside from the early postoperative state, factors associated with thromboembolism are older patient age, AF, absence of anticoagulation, and previous thromboembolism. Anticoagulation with warfarin for 90 days after valve implantation should be considered in patients with bioprosthetic valves, though this is not routine at all centers.[186] After the initial 90-day period, anticoagulation therapy can be withdrawn unless the patient has AF, a previous thromboembolic event, hereditary thrombophilia, or other hypercoagulable condition, in which case long-term anticoagulation is usually required, though the evidence supporting this approach is relatively weak.

Interruption of Anticoagulation in Patients with Prosthetic Heart Valves

When a patient requires noncardiac surgery or another type of invasive medical or dental procedure associated with an escalated risk of bleeding, the risks of thromboembolism as a result

of interrupting anticoagulation must carefully be weighed against the risks of procedure-related bleeding. If periprocedural bleeding is unlikely or inconsequential, as is usually the case with prophylactic dental hygienics or ocular surgery, anticoagulation should be continued near the lower end of the range of therapeutic intensity. When the risk of serious bleeding is greater, anticoagulation therapy should be adjusted or interrupted accordingly. Bridging with UFH or LMWH should be initiated when the INR falls below 2.0 to 2.5 in patients who are at high risk of thromboembolism, including patients with mechanical heart valve prostheses in the mitral position, patients with bileaflet mechanical valves in the aortic position who have additional risk factors for thromboembolism, and patients with bioprosthetic valves who have AF. The parenteral anticoagulant can be interrupted 6 to 12 hours prior to the invasive procedure, restarted as early after the procedure as considered safe to do so while warfarin is resumed, and continued until the INR has returned to the therapeutic range. Patients who are not at high risk, including those with bileaflet mechanical aortic valve prostheses without other thromboembolism risk factors, do not generally require parenteral bridging therapy. These individuals can interrupt warfarin approximately 3 days prior to the procedure and resume the VKA 24 hours following the intervention. For patients taking antiplatelet therapy, aspirin therapy should be stopped 1 week prior to the procedure and clopidogrel 5 days prior. For reversal of anticoagulation in patients requiring urgent or emergency procedures, administration of fresh-frozen plasma or four-factor prothrombin complex concentrate is preferred over low-dose (<5 mg) intravenous or oral vitamin K, which takes 12 to 24 hours to reach full effect; high-dose vitamin K (10 mg or more) is contraindicated because resistance to warfarin may continue for several weeks.

Thromboembolism Associated with Abnormalities of Atrial Septation

A remnant of the fetal circulation, patent foramen ovale (PFO) develops when there is failure of the septum primum and septum secundum to fuse after birth, allowing for left-to-right shunting at atrial level. It is a common finding with a prevalence of 15% to 25%[201] that is sometimes associated with an atrial septal aneurysm (ASA), in which the redundancy of atrial septal tissue results in >10 mm excursion during respiration. The prevalence of ASA is much lower (1% to 2%) than that of PFO. Though usually benign, PFO has been associated with cryptogenic ischemic stroke in otherwise apparently healthy, younger individuals. A meta-analysis in 2000 found an OR of 3.1 (95% CI 2.29 to 4.21) for the association of PFO with cryptogenic stroke in patients younger than 55 years old.[202] The data from patients 55 years and older were less impressive, though there was still a trend toward increased risk (OR 1.27, 95% CI 0.8 to 2.01). While a PFO provides an anatomic substrate for paradoxical embolism of thrombus from the peripheral venous system and thrombus in transit has occasionally been documented, deep-vein thrombosis is found in only a small proportion of patients with cryptogenic stroke and PFO. Other possible mechanisms of stroke in PFO include embolism of thrombus formed on the rim or left-atrial side of the PFO itself, asymptomatic paroxysmal AF, or passage through the shunt of nonthrombotic, vasoactive humoral substances that escape degradation of the pulmonary bed.

The treatment for prevention of initial or recurrent stroke in patients with a PFO remains controversial. Most studies have focused on secondary prevention of cryptogenic stroke in patients with PFO. The French PFO-ASA study followed 216 patients younger than 55 years who had a cryptogenic stroke up to 4 years[203]; all were treated with aspirin. Patients with a PFO alone had the same risk of recurrent stroke or TIA at 4 years as those with no identified atrial abnormality (HR 1.34, 95% CI 0.62 to 2.90, $P = 0.45$). The risk of stroke was significantly higher in those who had both PFO and ASA (HR = 3.91, 95% CI 1.59 to 9.59, $P = 0.003$), raising the possibility that patients with both lesions might benefit from more aggressive therapy (anticoagulation or anatomical closure). Similarly, the PFO in Cryptogenic Stroke Study (PICSS) found no significant difference in time to recurrent stroke or death between patients with and without PFO treated with aspirin over 2 years (event rates 14.8% vs. 15.4%, HR 0.96, 95% CI 0.62 to 1.48, $P = 0.84$).[204] Comparing aspirin to warfarin in patients with PFO, the PICSS investigators found no significant advantage of warfarin for prevention of subsequent stroke, though the study was underpowered to exclude a treatment benefit. Current AHA/ASA and ACCP guidelines recommend antiplatelet medication as the initial therapy for patients with PFO and cryptogenic stroke,[199] based on "insufficient data to establish whether anticoagulation is equivalent or superior to aspirin for secondary stroke prevention in patients with PFO."

Should recurrent stroke occur in a patient with PFO (with or without ASA) and no other apparent cause, it has been common practice to close the PFO using direct surgical patch or ligation or percutaneous catheter-directed techniques. No devices designed specifically for the closure of PFO are currently approved for use by the U.S. Food and Drug Administration. No randomized studies comparing medical therapy with antiplatelet agents or anticoagulants, percutaneous therapies, or surgical correction have provided clear evidence of the superiority of one approach over another for secondary prevention of stroke in patients with PFO. The CLOSURE I trial was an multicenter, open labeled trial that randomized 909 patients aged 18 to 60 with a PFO and a history of TIA or stroke to the STARFlex closure device plus antiplatelet therapy or medical therapy alone. After 2 year follow up there was no significant difference between the two groups in the primary endpoint of recurrent stroke or TIA.[206]

CHAPTER

93

Ischemic Stroke: Acute Thrombolytic Therapy, Antithrombotic Approaches, and General Management

GREGORY J. DEL ZOPPO AND JEFFREY L. SAVER

PREVENTION AND TREATMENT OF ACUTE STROKE

Stroke is a syndrome of fixed or transient neurologic deficits that result from atherothrombotic events, thromboembolism, subarachnoid hemorrhage, intracerebral hemorrhage, lacunae, and other cerebrovascular causes (Table 93.1).[1,2] Atherothrombotic stroke refers to cerebral arterial occlusions from either *in situ* arterial thrombosis or artery-to-artery emboli originating in intracranial arteries or the internal carotid artery (ICA), the aortic arch, and the vertebral-basilar (VB) artery system.

Platelet-fibrin thrombi arise on arteriosclerotic lesions in the extracranial portion of the ICA (i.e., at the flow divider) or in the aortic arch and can embolize downstream, predominantly into the middle cerebral artery (MCA) and anterior cerebral arterial territories. A similar process can send emboli from atheromata at the subclavian-vertebral artery junctions into the basilar artery. Emboli from the heart originate from left ventricular mural thrombi formed during myocardial ischemia (infarction) (MI) or other injury; from atrial thrombi formed in association with (nonvalvular) atrial fibrillation (AF); from valvular injury; from prosthetic valves; or, in association with patent foramen ovale and atrial septal aneurysm. Less common than atherothrombotic stroke, thrombosis of small, penetrating cerebral arteries leads to lipohyalinosis and lacunae formation.[3] Studies employing angiography within 6 hours of onset of carotid artery territory ischemic stroke have shown a high frequency of atherothrombotic or thromboembolic arterial occlusions in the symptomatic territory (FIGURE 93.1).[4,5,6,7,8,9,10]

NATURAL HISTORY OF CEREBRAL ATHEROTHROMBOTIC AND THROMBOEMBOLIC DISEASE

Transient ischemic attacks (TIAs) are often accompanied by subsequent stroke or other cardiovascular disease. Completed stroke has been reported in 40% to 75% of individuals with one or more TIAs,[11,12] with a prevalence of approximately 30% per year.[11,12] Among individuals with a premonitory TIA, approximately 50% may have a stroke within the 1st year.[13] The early risk of stroke is high, occurring in 3% to 5% of patients within 48 hours after TIA and in 8% to 14% within 3 months.[14] Stroke-related death and cardiac death occur in 28% and 37% of TIA individuals, respectively, indicating that cardiovascular mortality is significant in the population of patients with stroke.[13] More recent evaluations, which have included data from placebo groups in large trials of antithrombotic efficacy, suggest a lower mortality. For example, the combined outcome events of stroke, MI, and death occurred in 14% of individuals treated with placebo for more than 2 years in the United Kingdom transient ischemic attack (UK-TIA) Study Group Trial.[15] Approximately 64% of individuals with TIAs showed evidence of cerebral infarction in their initial computed tomography (CT) scan.[16]

Patients presenting with an ischemic stroke are at risk for recurrence, often within the same vascular territory. The 5-year cumulative incidence of secondary stroke was 42% among men in one prospective follow-up study. A separate study noted a 32% 7-year cumulative incidence for recurrent stroke.[17] Again, the highest recurrence of stroke is within the 1st year following the initial event.

Stroke-related mortality during the first 7 days after ictus was examined prospectively by Silver et al.[18] Cerebral edema from large, hemispheric ischemic lesions led to transtentorial herniation and death in 78% of 46 patients who died in that interval. This is consistent with the number of fatal events (82%) in one retrospective pathology study.[19] Generally, however, mortality is not considered to be the primary outcome in current acute stroke intervention trials because of its low incidence and multifactorial basis.

Improvements in neurologic outcome are commonly observed among patients who survive a stroke. Both neurologic presentation and outcome depend on stroke subtype.[20] Patients with lacunar strokes fare better than those patients with thromboembolic events. The conditions under which stroke occurs can alter outcome. It has been recently appreciated, both clinically and experimentally, that female patients have a better 1-year survival and lower infarct volume than male patients, although the reasons are unclear.[21–23] Experience from two statin intervention trials for prevention of MI demonstrated a significant reduction in stroke incidence in patients treated with the 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors.[24–28] Although, epidemiologic studies have not established cholesterol levels as a risk factor for ischemic stroke,[29] in both situations, the mechanisms of protection are unknown.

STROKE AS A SYSTEMIC DISORDER

Stroke is a systemic disorder, and as such, in the acute and early postictal phase, a number of conditions can influence stroke outcome. These require acute and intensive medical attention. Systemic *oxygen desaturation* exacerbates brain injury that originates from focal cerebral ischemia. One-third of ischemic stroke patients suffer aspiration acutely,[30] while pneumonia

Table 93.1

Etiology of focal cerebral ischemia

Source	Frequency (%)
Ischemic Stroke	
Atherothrombotic events	40–57
Thromboembolism	16–23
Lacunae	14
Hemorrhagic Stroke	
Intracerebral hemorrhage	4–18
Subarachnoid hemorrhage	10–19

complicates acute stroke in 5% to 12% of patients.[31] All stroke patients should be monitored for hypoxia, with a goal of maintaining O_2 saturation levels of >95%.

Focal ischemia impairs autoregulation in the injured territory so that regional cerebral blood flow (rCBF) fluctuates with mean arterial pressure.[32–34] Management of postischemic *hypertension* is problematic, and the approaches have been open to debate.[35] In select patients carefully managed in intensive care, induced hypertension can improve cerebral perfusion and may favorably influence the clinical course.[36] It is recommended that antihypertensive treatment be withheld in the first few hours after ischemic stroke onset, unless the systolic blood pressure is above 220 mm Hg or the mean arterial pressure >130 mm Hg on two consecutive measurements at least 5 minutes apart.[37,38] This approach is recommended unless the patient has a concurrent condition that independently requires moderation of blood pressure (e.g., acute MI, aortic dissection, or early hemorrhagic transformation of cerebral infarct). Notable, to minimize the risk of cerebral hemorrhagic transformation, is the requirement that in the first 24 hours after thrombolytic treatment the systolic blood pressure should be maintained at <180 mm Hg and diastolic blood pressure <105 mm Hg.

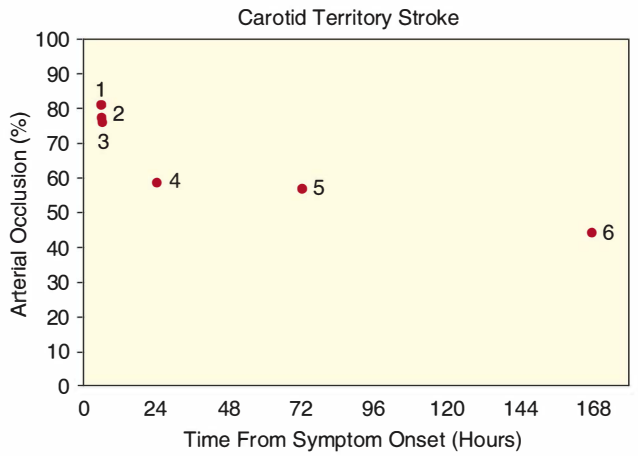

FIGURE 93.1 Series of angiography-based studies from separate trials demonstrating the frequency of carotid artery territory obstruction accompanying symptomatic ischemic stroke. Data points 1 to 6 are derived from citations[4,5,7,8,9,10] in order.

Careful *fluid management* is mandatory in patients with acute cerebral ischemia. This is usually accomplished with intravenous administration of normal saline with infusion rates of 75 to 125 mL/h to maintain intravascular volume.[37]

Hyperglycemia is the most common metabolic derangement in acute ischemic stroke, and elevated blood glucose at admission in acute ischemic stroke correlates with poor outcome.[39] However, it has not been demonstrated whether this association reflects a direct adverse effect of hyperglycemia upon outcome, or an epiphenomenon of severe initial brain injury producing a secondary rise in blood sugar. In patients receiving intravenous thrombolysis, acute hyperglycemia is a risk factor for hemorrhagic transformation.[40] It is suggested that severe hyperglycemia should be treated promptly in acute stroke, aiming to maintain a glucose level of <200 mg/dL.[41,42]

Hyperthermia on admission is an independent risk factor for poor outcome from acute ischemic stroke, and increased core temperature markedly worsens ischemic and cerebral injury in animal models.[43] It is sometimes uncertain whether hyperthermia is a consequence of severe stroke, rather than a promoter of increased injury. Induced hypothermia is beneficial as a neuroprotective treatment in human global brain ischemia after cardiac arrest and has been a promising strategy in focal ischemic stroke. Interventional trials are underway to determine whether systemic or selective cerebral hypothermic treatment can improve stroke outcome. Fever should be investigated for a source of infection and treated, and the elevated temperature reduced promptly with antipyretics and cooling blankets if necessary.

HEMOSTASIS AND CEREBROVASCULAR ISCHEMIA

Thrombosis and thromboembolism play a central role in focal cerebral ischemia, as suggested by clinical, angiographic, and laboratory observations. The findings of migrating thromboemboli in the retinal artery and refractile bodies in patients with focal cerebral ischemia[44–46] and of thrombi in cortical arteries during cerebral ischemia and on affected carotid arteries support a pathogenic role for these thrombotic events.[47,48]

Select acute angiographic studies have documented cerebrovascular occlusions in individuals with focal ischemia. In three prospective studies, symptomatic occlusion of a brain-supplying artery within the carotid territory was documented in 81% of patients within 8 hours of symptom onset.[9] Separate angiographic studies have shown arterial occlusions in 59% of patients at 24 hours and in 41% at 1 week after symptom onset in patients with focal cerebral ischemia.[4,5,7,8,9] Furthermore, large-artery events in the carotid territory are primarily thrombotic or embolic in origin. VB ischemia results from *in situ* thrombosis on atheromata in the basilar or vertebral arteries or from emboli from more proximal sources.[49] Indeed, atherosclerosis of brain-supplying arteries is a thrombophilic state (FIGURE 93.2).

There are differences among races with regard to thrombosis predisposition. For instance, among white populations, cardiogenic thromboemboli or extracranial arterial sources are common, whereas *in situ* intracranial atherosclerosis with supervening thrombosis is more frequent in the Japanese population.[50] Thrombi derived from the ICA or brain-supplying arteries have mixed architectural features of erythrocytes and fibrin, rather than one or the other, with fibrin/platelet deposits interspersed with linear collections of monocytes and

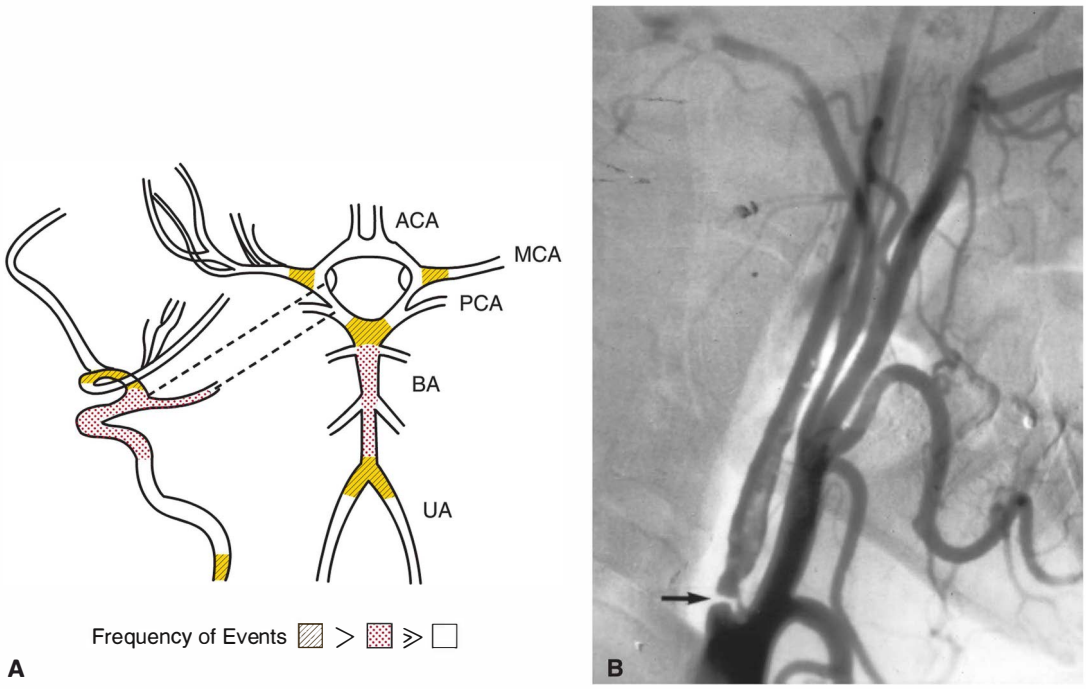

FIGURE 93.2 Atherosclerosis as a source of thrombotic and embolic obstruction of arterial circuits in the central nervous system (CNS). **A**: Predilection sites for atheromata in brain-supplying arteries. **B**: Example of severe (99%) stenosis of the ICA in patient with TIAs (*arrow*). ACA, anterior cerebral artery; MCA, middle cerebral artery, PCA, posterior cerebral artery; BA, basilar artery; UA, uncal artery.

polymorphonuclear leukocytes and confined erythrocyte-rich regions.[51] It has been suggested that red cell and mixed thrombi frequently produce hyperdense middle cerebral artery (HMCA) signs sometimes observed on CT and hypointense artery signs on magnetic resonance imaging (MRI).[52]

Indirect evidence for the involvement of thrombi in cerebrovascular ischemia derives from observations of platelet, coagulation, and fibrinolytic system activation in patients with thrombotic stroke or TIAs.[53–57] Platelet activation, spontaneous platelet aggregation, and circulating platelet aggregates have been reported in patients with recent atherothrombotic and thromboembolic cerebral ischemia.[53,56–63] Experimental studies confirm the deposition of fibrin and activated platelets in microvessels of the ischemic regions shortly after MCA occlusion.[64–69] These observations implicate the local activation of hemostasis in the ischemic microvascular bed.

HEMORRHAGIC TRANSFORMATION IN CEREBRAL ISCHEMIA

Hemorrhage accounts for approximately 10% to 15% of all strokes.[1,6,7,9,70–75] Normal platelet function appears necessary to maintain the integrity of the cerebrovascular beds and to prevent clinically detectable hemorrhage. Antithrombotic agents increase hemorrhagic risk in the ischemic territory.[76] Increases in the incidence of symptomatic intracerebral hemorrhage were observed with aspirin (acetylsalicylic acid [ASA]) in the UK-TIA Study, the International Stroke Trial (IST), and the European Stroke Prevention Study-2 (ESPS-2) trial.[72,73,77] An increased risk of intracerebral hemorrhage is associated with advanced age (>75 years), the intensity of anticoagulation, and the concomitant use of antithrombotics.[76]

Hemorrhage within the ischemic lesion occurs normally during thromboembolic stroke and is classified as hemorrhagic infarction (HI), parenchymal hematoma (PH), or both (FIGURE 93.3). HI refers to petechial or confluent petechial hemorrhage in the area of ischemic injury, typically involving cortical or basal ganglia gray matter.[78–81] HI occurs in 50% to 70% of individuals in postmortem studies,[78–80] in 10% to 43% of nonanticoagulated individuals with acute cerebral infarction in CT scan-based studies,[82,83] in 37.5% of patients with cardiogenic cerebral embolism, but in only 1.9% of patients with carotid territory thrombosis.[84] Petechial hemorrhage can result from ischemia-related degradation of the microvessel basal lamina matrix components.[85,86]

PH is a homogeneous mass of blood (coagulum) that can displace brain tissue. It is most often the cause of symptomatic hemorrhage. Many reports of PH in patients with cerebral embolism are associated with anticoagulant treatment.[87,88] In addition, PH can result from the rupture of small penetrating arteries (FIGURE 93.4).

THE PENUMBRA

Astrup and colleagues depicted the development of the core of ischemic injury destined for tissue destruction (infarction), as a circumferential region, or "penumbra," of metabolically metastable tissue that has the potential for full recovery, following occlusion of a brain-supplying artery.[89,90–93] This depiction has greatly influenced the concept of ischemic stroke following occlusion of brain-supplying arteries and the attempts to enhance tissue recovery clinically in the acute phase. This

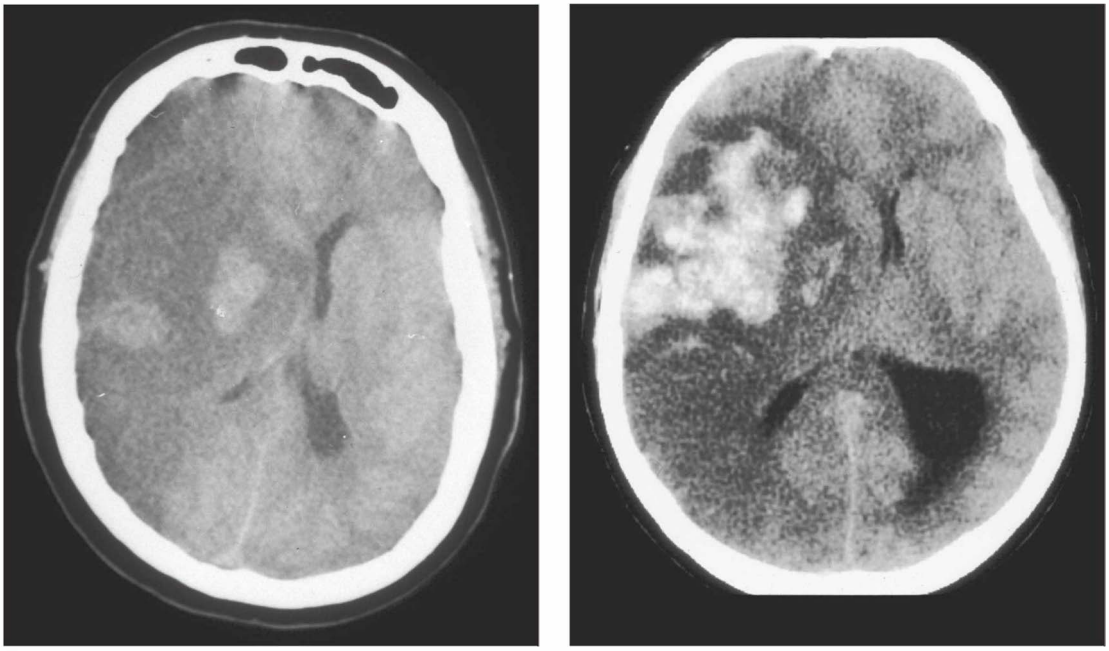

FIGURE 93.3 Hemorrhagic transformation. **A**: HI typified by regions of confluent petechiae 24 hours after MCA occlusion. concept encompasses characteristic electrophysiologic changes, biochemical and molecular alterations, microvessel responses, metabolic changes, and regional differences in tissue perfusion and H_2O diffusion as displayed by imaging studies (e.g., the DEFUSE study).[93–95] By positron emission tomography, the infarction corresponds to rCBF below 12 mL/100 g/min and a cerebral metabolic rate for oxygen ($CMRO_2$) below 65 μm/100 g/min.[96] The penumbra has been defined as rCBF decreased to 12 to 22 mL/100 g/min, $CMRO_2$ above 65 μm/100 g/min, and an oxygen extraction fraction of 50% to 90%.[96] Experimental data from vascular and molecular modeling studies as well as recent imaging work indicate that the penumbra is dynamic and

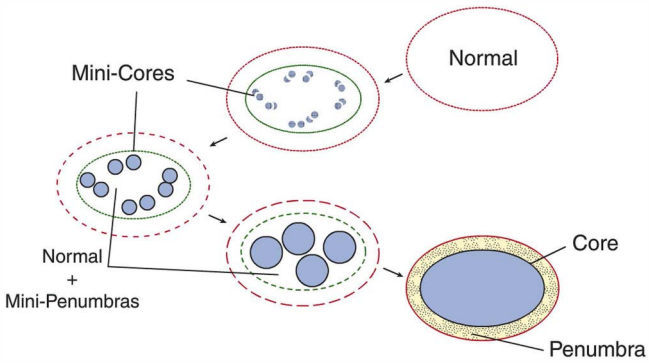

FIGURE 93.5 A proposed construct of the "penumbra" that takes into account the heterogeneous evolution of injury within the 1st hours of ischemia onset after the occlusion of a brain-supplying artery. The lesions and their reversibility depend upon the time and location of the reduction in regional cerebral blood flow (rCBF) in the territory-at-risk. If the injury stimulus cannot to be curtailed, the mini-cores coalesce with the duration of rCBF reduction devouring micro-penumbras. The evolution from normal function to the final lesion may depend upon a number of factors, including the territory of vascular supply, depth of reduction of rCBF, inflammatory state at baseline and/or degree of inflammatory response, and other factors.[93]

demonstrates that in the early minutes and hours after ischemia onset the core contains pockets of injury surrounded by "mini-penumbras."[93] It has been hypothesized that failure to resolve these mini-penumbras into viable tissue leads ultimately to homogenous injured tissue (FIGURE 93.5). The cell and microvessel events in large part relate to local microvascular flow and may underlie recoverability of the ischemic territory-at-risk when flow is reestablished. Normal collateral arterial circuits protect cerebral cortical tissue and may contribute to the reversibility of the ischemic penumbra. Importantly, acute reperfusion of the occluded artery (arteries) is taken to decrease the penumbra and recover normally functioning tissue.

IMAGING OF CEREBRAL TISSUES/VASCULATURE

To define the regions of evolving injury, imaging approaches provide information about tissue status, vessel patency and morphology, and cerebral perfusion. With acquisition times of only 10 to 20 minutes, both CT scans and MR imaging can distinguish infarction from hemorrhage, identify the site of vascular occlusions, and delineate already irreversibly infarcted tissue from potentially reversible penumbra.

Brain Parenchymal Imaging

Tissue injury. Noncontrast CT excludes hemorrhagic transformation and other nonischemic causes of acute neurologic deficits (e.g., tumor, infection). It has the advantages of being rapid and inexpensive with widespread availability. CT imaging can identify signs of early injury (e.g., loss of gray-white differentiation, hypodensity, and sulcal effacement) and of cerebral artery occlusion infarct signs (HMCA sign). These signs occur in up to 80% of patients within 6 hours from symptom onset.[97] Pathophysiologic studies suggest that early infarct signs represent edema. The presence of early infarct signs can be associated with a poorer outcome.[98,99]

MR imaging is sensitive to tissue injury. Within the first few hours of ischemia onset, standard MR protocols (T1-weighted, T2-weighted, and proton density–weighted sequences) are relatively insensitive to ischemia, showing abnormalities in <50% of cases.[100] The earliest changes, seen as increased signal on T2-weighted and fluid attenuated inversion recovery sequences, are due to a net increase in tissue water content. Although the most ischemic lesions are evident on both CT and conventional MR by 24 hours, standard MR is superior to CT in identifying posterior fossa and subcortical lesions.

Extravasated blood can be reliably detected with gradient recalled echo or echo-planar susceptibility-weighted MR imaging.[101] MR is at least equally accurate to CT in distinguishing acute intracerebral hemorrhage from acute ischemic stroke.[102,103]

Diffusion-weighted images (DWI) allow visualization of regions of cerebral ischemia within minutes of symptom onset, indicating lesion size, lesion age, neuroanatomic site, and the vascular territory involved.[104–107] Decreased flux of free H_2O from the extracellular to intracellular space, during the early moments of ischemia, can be quantified on the apparent diffusion coefficient (ADC) maps. While the increased DWI signal may persist for several weeks or longer partially due to a T2 effect, the ADC returns to normal or increased levels within 7 to 10 days from ischemia onset.[108] DWI has a high sensitivity (95% to 100%) and specificity (95% to 100%) for acute ischemia.[109–111] The initial diffusion lesion volume correlates well with final infarct volume, as well as neurologic and functional outcomes in stroke patients.[105,112,113] Early reperfusion can normalize DWI images.[114,115] Therefore, DWI can distinguish acute from chronic ischemia[104,116,117] and provide frequent*** visualization of multiple acute lesions in different vascular territories in patients who have only one clinically symptomatic acute insult, providing evidence of an embolic stroke mechanism.[118]

Perfusion Imaging

Perfusion CT assesses rCBF, identifying regions of irreversible tissue injury as areas of reduced cerebral blood volume (CBV).[119] Perfusion CT has the advantage of rapid data acquisition and rapid postprocessing and can be performed in conjunction with the baseline head CT and CT angiography scans. *MR perfusion-weighted imaging* follows rapid injection of an intravenous paramagnetic contrast agent and relies upon generation of concentration–time curves throughout the tissue under study. Perfusion measures derived from this technique include mean transit time, relative CBV, and rCBF. Baseline MR perfusion lesion volumes correlate well with final infarct volume as well as neurologic and functional outcome.[113] Perfusion lesion volume likely identifies all tissue-at-risk of infarction if vessel recanalization does not occur, while diffusion imaging identifies only tissue that has already sustained advanced metabolic failure.

Vascular Imaging

Digital subtraction angiography (DSA) is the standard imaging modality to assess vessel anatomy and pathology, capable of visualizing medium and small vessels, collateral circulation,

and specific vascular lesions (e.g., arterial dissection, small caliber vessels such as vasculitis). Imaging of the cervicocephalic vessels to demonstrate evidence and site of stenosis and occlusions is achieved by contrast-enhanced *helical CT angiography.*[120] Image postprocessing permits the data to be visualized using multiplanar reformatting, surface or three-dimensional volume rendering, and maximum-intensity projection techniques.[121] *MR angiography* has sensitivity and specificity ranges of 70% to 100% when compared to DSA for the detection of cervical and intracranial stenoses.[122] In the intracranial vasculature, MRA is useful in identifying acute proximal large-vessel occlusions, but cannot reliably identify distal or branch occlusions. Combined with data from DWI, MRA substantially improves acute diagnosis of stroke mechanism.[106] Contrast-enhanced MRA techniques that employ gadolinium contrast to outline vascular structures provide more reliable images of the thoracocervical vasculature. Flow artifacts can occur, including in-plane flow saturation, susceptibility to turbulent or complex flow, and flow-like effects from adjacent short T1 substances, such as thrombus and fat, which distort the degree of stenosis.

Carotid and transcranial Doppler (TCD) ultrasound techniques offer another noninvasive method to assess the neurovasculature acutely. Ultrasound studies of the carotid bifurcation are a well-established noninvasive test in the diagnosis of stroke. A full carotid ultrasonography battery includes continuous-wave Doppler measurement of blood velocity, B-mode imaging of vessel anatomy, and color-flow imaging of flow direction and lumen caliber. Carotid ultrasound visualizes only the proximal cervical carotid arteries and very limited segments of the cervical vertebral arteries. TCD ultrasound employs a low-frequency probe to penetrate the skull and interrogate the major basal intracranial arteries.[123] TCD offers a practical, noninvasive assessment of intracranial vessel status that provides early diagnostic and prognostic information in patients with acute stroke.[124] In addition, TCD can be used to monitor cerebral hemodynamic status and response to recanalization therapy.[125]

ANTITHROMBOTIC APPROACHES TO CEREBRAL ISCHEMIA

The direct and indirect evidence that platelet activation, acceleration of coagulation, and thrombosis underlie most ischemic strokes supports the use of antithrombotic agents in the management of cerebrovascular ischemia. Plasminogen activators (PAs) have been used to limit the consequences of recent transient or fixed neurologic deficits in the acute phase. Recombinant tissue plasminogen activator (rtPA) is now used in patients within 3 (to 4.5) hours of symptom onset and in the absence of detectable cerebral hemorrhage to reduce injury or to improve clinical outcome. Antiplatelet agents and anticoagulants have also been used as prophylaxis against recurrence of ischemia (i.e., secondary prevention). Antiplatelet agents play a role in the reduction of TIAs and ischemic strokes associated with thromboemboli of atherosclerotic origin. Anticoagulants are employed for prevention of cardiogenic emboli, arising in the setting of nonvalvular AF, ventricular dysfunction, or valvular injury or prostheses. Both approaches have been combined, but neither has been used in acute treatment of thrombotic stroke.

TRANSIENT CEREBRAL ISCHEMIA (TRANSIENT ISCHEMIC ATTACKS)

Because TIAs and ischemic stroke (e.g., transient monocular blindness [amaurosis fugax])[126–128] can often be manifestations of ongoing platelet and coagulation activation and of vascular injury in brain-supplying arteries, antiplatelet agents have been applied with benefit.[4,5,6,7,8,44,46,57,63,86,129]

Antiplatelet Agents

Aspirin (Acetylsalicylic Acid). In ischemic cerebrovascular disease, ASA can reduce the incidence of TIAs and subsequent ischemic strokes. Despite the large number of prospective evaluations of ASA, a small number of well-conducted level I studies "drive" the efficacy of ASA in the carotid artery territory (Table 93.2).

The Aspirin in Transient Ischemic Attacks (AITIA) study—which randomized patients with a 3-month history of TIAs, who were not considered candidates for carotid endarterectomy, to ASA (1,300 mg/day) or to placebo—demonstrated a reduction in stroke and vascular death at 6 months with ASA exposure.[130] There was a considerable decrease in the combined outcomes of recurrent TIAs, cerebral/retinal infarction, and death among those receiving ASA, but no reduction by life-table analysis at the 24-month follow-up and no reduction in stroke incidence. In the Canadian Cooperative Study Group trial, patients with a history of TIAs were randomized to ASA (1,300 mg/day), sulfinpyrazone (800 mg/day), and the combination ASA/sulfinpyrazone, or placebo.[131] Patients who received ASA had a significant decrease in the incidence of stroke and death compared to sulfinpyrazone or placebo.[131] The risk reduction for stroke and death with ASA was most significant for men. Among patients with a history of TIAs in the double-blind "Accidents, Ischemiques Cerebraux Lies a l' Atherosclerose (AICLA)" trial who were randomized to ASA (990 mg/day), the combination of ASA (990 mg/day) with dipyridamole (225 mg/day), or placebo, those who received ASA or the combination demonstrated a reduced incidence of stroke, MI, and death compared to patients who received placebo.[132] Efficacy in the combined outcome seemed to be associated with an ASA dose range of 990 to 1,300 mg/day.

However, the ASA doses used were associated with considerable side effects. This was confirmed by the UK-TIA aspirin trial, which randomized 2,435 individuals with TIAs or minor ischemic stroke to "high dose" ASA (1,200 mg/day), "low-dose" ASA (300 mg/day), or placebo.[15] The 4-year incidence of nonfatal MI, nonfatal major stroke, and death was significantly reduced by 18% in a dose-dependent manner in patients who received ASA. But, gastrointestinal side effects were more common with the high-dose regimen, and excess mortality was attributed to intracranial hemorrhage in the ASA-treated groups. In a separate study, a decrease in major hemorrhagic events, including fatal intracerebral hemorrhage, was associated with lower ASA doses (30 vs. 283 mg/day).[133]

The Swedish Aspirin Low-Dose Trial (SALT) Collaborative Group reported an 18% risk reduction of stroke and death among TIA patients who started ASA (75 mg/day) within 1 to 4 months of their initial symptoms compared to patients who received placebo.[134] A 16% to 20% reduction in the risk of stroke, frequent TIAs, and MI was also observed.

[a]Extended-release dipyridamole.
ASA, aspirin (acetylsalicylic acid); UK-TIA, United Kingdom Transient Ischemic Attack; AITIA, Aspirin in Transient Ischemic Attacks; TIA, transient ischemic attacks; SALT, Swedish Aspirin Low-Dose Trial.

The results of those trials, and meta-analyses of all clinical series, suggest that even low doses of ASA benefit early stroke and vascular mortality in patients with a history of TIAs or minor ischemic events.

Combination ASA/Dipyridamole. Clinical use of the combination of ASA with dipyridamole has been based upon positive interactions between the agents in both preclinical experiments and in clinical platelet survival studies.[135–137] The efficacy of this combination, however, has been challenged.[136] Dipyridamole (400 to 800 mg/day) alone did not affect stroke incidence or related mortality compared with placebo in one limited double-blind, level I randomized trial.[138]

The European Stroke Prevention Study (ESPS) Group demonstrated a 33% reduction in risk of stroke and death with ASA (975 mg/day) and dipyridamole (225 mg/day) compared to placebo.[139] The three-arm "AICLA" study also demonstrated the benefits from the combination of ASA with dipyridamole over placebo (but no difference with ASA alone) for patients with TIAs when the outcome events of stroke, MI, and mortality were combined.[132] However, there was no difference in stroke or mortality between the combination of ASA (1,300 mg/day) and dipyridamole (300 mg/day) and ASA alone in the American-Canadian Cooperative Study Group.[140]

On the basis of experimental evidence suggesting that sustained release extended-release dipyridamole (ER-DP) could produce elevated plasma adenosine levels, the relative efficacy of the fixed combination of low-dose ASA (50 mg/day)/ER-DP (400 mg/day) was tested in the ESPS-2 against ER-DP, ASA, or placebo. At 2-year follow-up, low-dose ASA alone and dipyridamole alone (relative risk reduction [RRR] for stroke, 15.8% and 17.7%, respectively) and the combination (RRR, 36.7%) were found to be superior to placebo in limiting stroke, death, or both for individuals with a history of TIAs or recent stroke.[77,141]

The European/Australian Stroke Prevention in Reversible Ischaemia Trial (ESPRIT) Group examined the impact of combination ASA (30 to 375 mg/day)/dipyridamole (400 mg/day) or ASA alone on vascular death, nonfatal stroke, nonfatal MI, or major hemorrhage in patients presenting with TIA or minor ischemic stroke.[142–144] With a mean follow-up of 3.5 years, the combination of ASA/dipyridamole was superior to ASA alone (HR = 0.80, 95% CI = 0.66 to 0.98) in reduction of the primary outcome events. While headache occurred in the combination, overall ASA/dipyridamole improved outcome in this trial and produced a decrease in ischemic events.[143] The greater efficacy of the combination supports its use in the clinical setting.

In a separate study, clopidogrel was prospectively compared to the combination of aspirin/ER-DP with or without the angiotensin receptor blocker telmisartan in the Prevention Regimen for Effectively avoiding Second Strokes (PRoFESS) study of first recurrent stroke in a 2 × 2 factorial design.[145] In total, 20,332 patients were randomized within 120 days of the initial event and followed for a mean of 2.5 years. There was no difference in the incidence of recurrent strokes between the two groups, although there were more hemorrhagic events in the aspirin/ER-DP arms. This trial did not meet the predefined criteria for noninferiority.

Sulfinpyrazone. The Canadian Cooperative Study Group compared ASA, sulfinpyrazone (800 mg/day), a uricosuric agent with antiplatelet effect, and placebo but found no significant difference in the incidence of stroke and mortality between sulfinpyrazone and placebo over 2.2 years.[131] Sulfinpyrazone (800 mg/day) and placebo were also tested in a double-blind, crossover trial.[146] A nonsignificant reduction in TIAs and in stroke and mortality at 4-month follow-up was recorded in patients receiving sulfinpyrazone. Another level I study comparing sulfinpyrazone (800 mg/day) and ASA (1,000 mg/day) in individuals with TIAs concluded that there was a higher incidence of stroke, MI, and vascular death in the sulfinpyrazone cohort at 11-month follow-up.[147]

Adenosine Diphosphate Receptor Antagonists. Thienopyridines irreversibly block the adenosine diphosphate platelet receptor $P2Y_{12}$ and inhibit other downstream events, thereby blocking platelet activation. Ticlopidine found benefit in patients with TIA/minor stroke[148] and in prevention of secondary stroke (see below). Ticlopidine (500 mg/day) was associated with a statistically significant 12% reduction in the risk of stroke and death from any cause over ASA (1,300 mg/day) and a 21% reduction in the risk of secondary outcomes of stroke and stroke-related death following TIAs. Reversible leukopenia occurred in 0.8% of patients taking ticlopidine, whereas gastrointestinal symptoms were more common in patients receiving ASA. Intracerebral hemorrhage occurred equally in both groups. Because of concerns about the frequency of thrombotic thrombocytopenic purpura, ticlopidine has been supplanted by the related thienopyridine clopidogrel.

In summary, ASA reduces the risk of stroke, MI, and mortality in individuals with a history of TIAs or minor stroke. This risk reduction is obviously not dose dependent. The fixed combination of low-dose ASA/ER-DP also produces a substantial risk reduction. Ticlopidine was more effective than ASA in preventing stroke and mortality after TIAs in one study but is seldom used now because of unwanted side effects. When used alone, dipyridamole and sulfinpyrazone have little demonstrated benefit.[149,150]

Anticoagulation

Changes in plasma thrombin concentration and FDP levels occur following ischemic stroke that suggest that interruption of coagulation may be beneficial. In the 1960s and 1970s, clinical experience with anticoagulation in patients with TIAs or minor stroke was limited.[151–154] Uncontrolled reports suggested that heparin could decrease the incidence of basilar artery TIAs.[155,156] Fisher observed a transient reduction in the incidence of TIAs in 97% (of 29) patients treated with anticoagulants, with TIAs returning in 60% of those in whom anticoagulation was discontinued.[157] Two studies reported that long-term anticoagulation decreased the incidence of strokes and/or vascular death among patients with recent TIAs[158,159]; a third study showed that despite a decrease in TIA frequency, there was no decrease in the incidence of stroke or vascular death.[160] Two other studies failed to show superiority of anticoagulation over its comparator for the incidence of stroke or death.[161,162] In a small Medical Research Council (MRC)-sponsored trial of phenindione, patients with TIA receiving fixed "low-dose" anticoagulation had a lower incidence of vascular events, stroke, and death than those patients receiving an adjusted "high-dose" regimen.[163] Only the Cerebral Embolism Study Group trial indicated a benefit from immediate anticoagulation for cardiogenic embolism.[164]

Subsequently, there have been few controlled prospective randomized level I studies. The Warfarin-Aspirin Recurrent Stroke Study (WARSS) found no difference in outcome between TIA and stroke patients treated with oral anticoagulation under tight control compared to patients treated with ASA.[165] There was no increase in intracerebral hemorrhage in the anticoagulated group, most probably because of the rigid control of the international normalized ratio (INR).[165]

The risk of intracerebral hemorrhage increases with age in patients treated with oral anticoagulants which inhibit vitamin K activity.[166,167] With careful monitoring and dose adjustment, this risk can be reduced.[167] The Stroke Prevention in Reversible Ischemic Trial[168] was terminated because of an unacceptably high incidence of intracranial hemorrhages in the group at a high target INR of 3.0 to 4.5.

In summary, excluding individuals with AF or cardiac valvular prostheses, the results of various small studies do not convincingly support a role for anticoagulation in patients with TIA or minor stroke, considering the risk of hemorrhage. The risk of intracerebral hemorrhage is increased for patients receiving oral anticoagulants at INRs in excess of 3.0 to 4.5.

Direct Thrombin Inhibitors

A single small safety study of the parenteral thrombin inhibitor argatroban in patients presenting with TIAs or minor ischemic stroke suggesting no detriment has appeared.[169] No

phase III experience exists; however acute use has been under limited study.[170]

Plasminogen Activators

The use of fibrinolytic agents in patients with cerebral ischemia is confined to acute intervention in ischemic stroke; there is no indication for the use of these agents in TIAs.

STROKE-IN-PROGRESSION

Progressive deterioration following ischemic stroke has been ascribed to (a) anterograde extension of *in situ* thrombus to occlude critical arterial branches or (b) recurrent embolism. The role of anticoagulation in patients with stroke-in-progression, however, remains unsettled, in large part, because of the difficulty in defining what constitutes "progression" at entry and uncertainties about the pathogenesis of "evolving stroke." Early studies also reveal methodologic weaknesses and conflicting outcomes of this diagnosis.[171–173] Furthermore, deterioration following ischemic stroke may be due to edema, hemorrhage, or a combination of the events that lead to tissue swelling and injury.[174]

The Trial of Org 10172 in Acute Stroke Treatment (TOAST), a level I prospective randomized placebo-controlled study of the heparinoid danaparoid for stroke-in-evolution, demonstrated no benefit to the anticoagulant regarding disability indices, neurologic status, or mortality.[175–177] Entry was opened to all patients with hemispheric stroke symptoms for up to 24 hours.[175] A short-lived reduction in stroke incidence was seen. Serious intracerebral hemorrhage was significantly more frequent in patients who received danaparoid (14 of 646 patients) compared to placebo (4 of 635 patients). Danaparoid decreased the incidence of deep venous thrombosis (DVT). Stroke-in-progression is no longer identified as a separate entity for which a specific treatment is required.

COMPLETED STROKE

Prospective CT scan and MRI[178–180] have confirmed the experimental observation that the ischemic lesion stabilizes, as an infarct, by 24 hours after occlusion of the supply artery.[181,182] These congruent findings suggest that antithrombotic interventions beyond 24 to 72 hours after symptom onset are unlikely to have a beneficial impact on the initial ischemic stroke. Following a first-time ischemic stroke, the rate of subsequent ischemic stroke, MI, death, or vascular-related death is 10% to 12% per year.[183–185] Hence, the initial ischemic stroke offers a target for antithrombotic agents to reduce the incidence of second ischemic events (secondary prevention).

Antiplatelet Agents

Meta-analyses suggest benefit from antiplatelet agents in patients with TIAs or first stroke.[186,187] When considered with TIAs, ASA or ticlopidine can significantly decrease the risk of second cerebral ischemic events (Table 93.3). The combination of low dose ASA and ER-DP considerably reduces the incidence of second stroke and/or death in patients presenting with a history of TIAs or stroke compared to ASA or dipyridamole alone.[141]

The IST randomized 19,435 patients with presumed ischemic stroke within 48 hours of symptom onset to placebo, ASA (300 mg/day) alone, subcutaneous heparin (low dose, 10,000 IU/day; or medium dose, 25,000 IU/day), or both ASA and heparin for 14 days in a 3 × 2 factorial design.[72] ASA was associated with an overall statistically significant reduction in total recurrent ischemic strokes within 14 days ($P < 0.001$) and also a significant 0.1% increase in symptomatic intracranial hemorrhage. At 6 months, a modest decrease in the risk of death or dependency was seen. The Chinese Acute Stroke Trial (CAST) demonstrated similar outcomes.[188,189] Together, the IST and CAST demonstrated that ASA is associated with a small reduction in the incidence of recurrent stroke and mortality in the first weeks after signal stroke. This did not persist.

Ticlopidine was found to be superior to placebo in reducing the risk of second stroke, MI, and vascular mortality when patients were treated within 1 to 16 weeks following the signal thromboembolic stroke.[183] Side effects related to ticlopidine, including reversible leukopenia, diarrhea, or rash, occurred in 8% of the treated patients. Concerns about the side effects of ticlopidine prompted a study of the efficacy of the related thienopyridine derivative clopidogrel.

The Clopidogrel versus Aspirin in Individuals at Risk of Ischaemic Events (CAPRIE) study, a prospective, randomized, double-blind level I comparison of clopidogrel (75 mg/day) against ASA (325 mg/day) in patients presenting with ischemic or lacunar stroke, MI < 35 days old, or symptomatic atherosclerotic peripheral arterial disease (PAD), demonstrated a statistically significant 8.7% reduction in the combined risk of ischemic stroke, MI, or vascular-related death by clopidogrel compared to ASA.[190] The overall benefit associated with clopidogrel was driven by the PAD outcome; there was no independent significant difference in outcome in the stroke cohort. Because of the near equivalent frequency of intracranial hemorrhage (clopidogrel = 0.33% vs. ASA = 0.47%), clopidogrel is now used clinically. The large (7,599 patients) Management of Atherothrombosis with Clopidogrel in High-risk patients trial compared the efficacy of ASA (75 mg)/clopidogrel (75 mg) to clopidogrel (75 mg) alone for ischemic events including stroke. No difference was seen in outcome between the two groups, although the ASA/clopidogrel combination was associated with significantly higher incidence of life-threatening hemorrhage (including intracranial hemorrhage).[191] The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance trial, a prospective double-blind placebo-controlled study of combination ASA (75 mg)/clopidogrel (75 mg) *versus* ASA (75 mg)/placebo for patients with multiple atherothrombotic risk factors, demonstrated no significant difference for the primary efficacy endpoint (the composite of MI, stroke, or cardiovascular mortality).[192] Long-term clopidogrel use was associated with an increased risk of hemorrhage, particularly in the first year.[193] Overall, there was no clear benefit in stroke efficacy outcome (a *post hoc* analysis of secondary prevention) with the combination over ASA alone. That study has provided much for discussion. The PRoFESS study and its outcomes have been mentioned above.

A recently undertaken trial, the Platelet-Oriented Inhibition in New TIA and minor ischemic stroke trial (http://clinicaltrials.gov/ct2/show/NCT00991029), is a randomized double-blind multicenter study to investigate whether clopidogrel (75 mg/day) alone is superior to aspirin (50 to 325 mg/day) in improving survival free from major ischemic vascular events (ischemic stroke, MI, and ischemic vascular death). The projected sample size is 4,150 patients.

The novel antiplatelet agents sulfinpyrazone[194] and suloctidil[185] failed to demonstrate benefit over placebo in separate trials. Neither agent is now used in stroke management.

The value of the glycoprotein IIb/IIIa (integrin $\alpha_{IIb}\beta_3$) antagonist abciximab given within 24 hours of the onset of ischemic stroke was examined in a phase II study.[195] No significant improvement in outcome efficacy or increased risk of intracerebral hemorrhage was seen in 74 patients at the doses tested.[195] The follow-on phase III randomized, placebo-controlled double-blind study stratified for time (<3 to 6 hours from symptom onset) and severity was terminated at 808 of the projected 1,800 patients due to excessive symptomatic or fatal intracranial hemorrhage (~5.5% abciximab vs. 0.5% placebo-treated patients).[196] Hence, this strategy has been abandoned. This observation contrasts with experimental studies with polypeptide or organic molecule integrin $\alpha_{IIb}\beta_3$ inhibitors in experimental models of focal ischemia that demonstrate reduction in injury volume.[65,69]

Those clinical studies confirm that in the setting of ischemic stroke, some antiplatelet agents given alone are beneficial in outcomes of recurrent stroke but when used in combination can potentially increase the risk of significant hemorrhage.

To test a related notion (i.e., the acute use of an antiplatelet agent in combination), a prospective randomized trial of acute intervention rtPA with or without the GPIIb-IIIa antagonist eptifibatide (the Combined Approach to Lysis Utilizing Eptifibatide *a*nd rtPA in Acute Ischemic Stroke) defined a dose of eptifibatide that was safe.[197] Recently, the Combined Approach to Lysis Utilizing Eptifibatide and rtPA in Acute Ischemic Stroke—Enhanced Regimen has begun comparing rtPA (0.6 mg/kg total) and eptifibatide (bolus 135 μg/kg and 2-hour infusion at 0.75 μg/kg/min) compared to standard-dose rtPA (0.9 mg/kg) in patients with ischemic stroke that can have the rtPA initiated within 3 hours of symptom onset.

Because of the effects on stroke outcome in patients with TIAs, ASA is recommended for secondary prevention. ASA/ER-DP has been shown to be superior to ASA in secondary prevention. On the basis of its similar mode of action to ticlopidine, clopidogrel has been substituted in practice. Current American College of Chest Physicians recommendations for

secondary prevention in noncardioembolic ischemic stroke are management with ASA (50 to 100 mg/day), ASA/ER-DP, or clopidogrel (75 mg/day).[149,150]

Anticoagulants

The evidence that heparin or long-term oral anticoagulation benefits patients with presumed atherothrombotic "completed" stroke is sparse. Early randomized, controlled trials and uncontrolled studies of oral anticoagulation have given the impression that anticoagulant therapy does not prevent second stroke events in patients with an initial TIA or atherothrombotic or thrombotic stroke.[161,198–202]

IST and CAST were conducted on the premise that proper use of subcutaneous unfractionated heparin (UFH) should not be associated with an increase in intracerebral hemorrhage and may therefore be safe in the treatment of presumed primary atherothrombotic stroke.[72,73,189] However, the significant increase in symptomatic intracerebral hemorrhage nullified the benefits of heparin on recurrent stroke. It is uncertain why hemorrhagic complications were so prominent in that study. Moreover, UFH used in this way is not common practice.

Low molecular weight heparins (LMWHs) have been tested with the intent to alter the outcome of first-ever stroke, usually not before 24 hours after symptom onset (Table 93.4). In the Fraxiparin in Stroke Study (FISS), patients were randomized to subcutaneous "high-dose" nadroparin (8,200 IU of antifactor Xa per day), "low-dose" nadroparin (4,100 IU/day), or placebo for 10 days beginning within 48 hours after onset of stroke.[203] A significant dose-dependent reduction in 6-month mortality and dependence was observed favoring the nadroparin arm. FISS-bis, a follow-on trial of nadroparin in stroke, compared similar doses, but demonstrated no difference in combined outcome or mortality (unpublished). In the Heparin in Acute Embolic Stroke Trial (HAEST), dalteparin produced no significant improvement in favorable outcome compared to placebo when both were delivered early following the onset of stroke.[204] No difference in detectable intracerebral hemorrhage was observed. The effect of certoparin on ischemic stroke outcome was examined in a level II dose-finding trial. No significant difference in outcome was detected among dose steps ranging from 3,000 to 16,000 U/day.[205] A modest increase in the risk of symptomatic hemorrhage was seen at the high dose. Certoparin failed to demonstrate a benefit in patients treated within 12 hours of symptom onset.[205] The Tinzaparin in Acute Ischaemic Stroke trial, a randomized double-blind trial, comparing high-dose tinzaparin, low-dose tinzaparin, and ASA patients treated within 48 hours of stroke onset displayed no difference in modified Rankin scale (mRS) at 6 months follow-up.[206] In short, no LMWH to date has been shown to demonstrate benefit in patients treated late after stroke onset. However, in animal models, acute intervention with enoxaparin has been shown to decrease injury volume by several measures.[207]

An unresolved problem has been whether anticoagulation or antiplatelet treatment is appropriate (superior) in ischemic stroke of unknown origin for recurrence. To determine this, the WARSS trial was undertaken by the National Institute of Neurological Disorders and Stroke (NINDS).[208] The study found no differential benefit of warfarin or ASA on the frequency of secondary cerebral ischemic events in patients presenting within 30 days of the signal stroke.[208] Warfarin was not associated with an increase in intracerebral hemorrhage, probably because of the tight monitoring of the INR.

At present, there is no evidence of an advantage to the use of anticoagulants for completed stroke.[209,210] This conclusion is reflected in a Cochrane analysis of some 24 trials, in which the majority of patients were treated late after stroke onset.[210] However, none of those studies instituted anticoagulants in the acute phase.

Plasminogen Activators

Early experience with PAs in patients with completed stroke failed to demonstrate efficacy when symptomatic improvement and death were the primary outcomes. Level I clinical trials evaluating intravenous infusion of thrombolytic agents in completed stroke were inconclusive. Fletcher et al.[211] observed no benefit in 31 patients treated with urokinase plasminogen activator (uPA) within 10 to 12 hours of symptom onset, but observed a very troublesome incidence of symptomatic intracranial hemorrhage and related mortality. Consequently, the use of PAs in individuals with stroke was generally contraindicated.[212] The long interval to treatment after the stroke onset and the possibility that the stroke was caused by undiagnosed hemorrhage (scanning technologies were not available) were common concerns with those early studies.[213] A group of prospective, randomized, controlled low-dose studies of intravenous uPA or tPA in patients with stable focal neurologic deficits of <5 days duration demonstrated no difference in clinical outcome or in the incidence of symptomatic intracerebral hemorrhage.[214–217]

ACUTE INTERVENTIONS IN ISCHEMIC STROKE

A major change in the approach to ischemic stroke followed the proposal that PAs should be applied acutely (within 6 to 8 hours) after symptom onset.[213] Conceptually, it was reasoned that rapid and adequate return of flow to the metastable, potentially reversible, zones of neuron and tissue injury in the ischemic vascular territory, the "penumbra," should provide benefit.[89,218] The contributions of local vascular anatomy and collateral vascular protection to tissue perfusion, as well as the predominantly thrombotic basis for focal cerebral ischemia, underlie attempts to achieve early recanalization with PAs.

Acute intervention with PAs in patients selected by strict CT scan and clinical criteria is associated with evidence of benefit.[6,74] In contrast, although experimental studies suggest that acute interventions with antiplatelet agents and anticoagulants could increase vascular patency and decrease injury, no clinical studies of acute intervention in ischemic stroke patients have been pursued.

Systemic Infusion of Plasminogen Activators

Recanalization of ICA occlusions by plasminogen activities is infrequent (0% to 25%),[6,9,214,215,219,220] but partial or complete arterial recanalization has been reported in 34% to 59% of patients with distal carotid artery territory occlusions who were treated within 6 to 8 hours of symptom onset.[6,219,220,221] Mori et al.[219] demonstrated, in a randomized controlled trial, that patients treated with 20 or 30 MIU of recombinant tPA (rtPA) (duteplase) had improved recanalization and considerable clinical improvement at 30 days compared to patients treated with placebo. Patients demonstrating early recanalization had better neurologic outcome than those not exhibiting recanalization. In those studies, detectable hemorrhagic transformation occurred in 29% to 53% of treated individuals,[6,219,220,221] which was similar to natural history.[79] Recanalization of vertebral or basilar artery occlusions with rtPA has been reported.[220,221]

Three symptom-based, randomized, controlled trials of the acute intravenous delivery the streptokinase (SK) in patients with ischemic stroke were terminated because of excessive early mortality and symptomatic intracranial hemorrhage in the SK treatment groups.[222–224] No preparatory dose-finding studies were performed in any of those trials. In the Multicentre Acute Stroke Trial-Italy (MAST-I),[224] the combination of ASA with SK produced excessive early case fatality. The outcome of that trial has not been explained, and the potential utility of SK in ischemic stroke has not been pursued further.

rtPA (alteplase) is approved for intravenous use within 3 hours of symptom onset under strict patient-selection criteria (Table 93.5). This is based upon the results of a two-part, level I, placebo-controlled outcome study.[6] In part 1, there was no difference in neurologic status at 24 hours between the rtPA (0.9 mg/kg) and placebo-treated groups according to the National Institutes of Health Stroke Scale (NIHSS) score. In part 2, at 3 months posttreatment, rtPA recipients displayed a statistically significant 11% to 13% absolute improvement over placebo in Barthel index, mRS score, Glasgow outcome scale score, and NIHSS for evidence of no or minimal disability/deficit. Symptomatic hemorrhage was significantly more frequent among patients treated with rtPA (6.4%) than placebo (0.6%). Mortality was unchanged, but intracerebral hemorrhage contributed to death. In follow-up, the outcome benefits in that population were sustained at 12 months and were most apparent in moderately severe strokes.[225] Independent postlicensing use of rtPA in general practice has confirmed the original experience.[226] Benefit was associated with age <75 years and absence of "early signs" of ischemic injury.[226]

Three other phase III prospective randomized safety and efficacy studies of intravenous rtPA (alteplase) broaden the impression from that study and emphasize limitations to the acute use of rtPA. The European Cooperative Acute Stroke Study (ECASS) compared parenteral infusion rtPA (1.1 mg/kg to a maximum of 100 mg) to placebo in patients within 6 hours of symptom onset. No significant difference was observed between the two groups for 90-day median mRS.[74] A subgroup of patients with evidence of ischemia on the entry CT scan, who should have been excluded ("protocol violators"), displayed increased mortality and hemorrhage when treated with rtPA. A *post hoc* analysis of the "target population" suggested an 11% to 12% absolute improvement over placebo in mRS 0 and 1 (no or minimal disability) in the rtPA-treated group, when the "protocol violator" data were excluded. However, a significantly higher proportion of rtPA patients (6.1%) had intracerebral hemorrhage causing neurologic deterioration or death (PH2) than placebo patients (2.6%). ECASS-2, the follow-on randomized double-blind nonangiographic study, required a careful review of the baseline CT scans for "early signs of ischemia" for exclusion of those patients.[98,227] There, 40.3% of patients who received rtPA within 6 hours of symptom onset had a favorable outcome (mRS = 0 or 1), an insignificant 3.2% improvement over placebo. Severe symptomatic parenchymal hemorrhage (PH2) was significantly more frequent in the rtPA group (11.7%) than in the placebo group (3.1%).

Viewed together, the results of the ECASS and NINDS studies indicate the enormous importance of individual patient selection in benefit and in reducing the hemorrhagic risk accompanying the use of PAs in acute stroke.[6,74,75] Heterogeneity among clinical studies of acute intervention with rtPA is well-recognized.[228] Today, rtPA is available for treatment of ischemic stroke in appropriately selected patients within 3 hours

of the onset of symptoms in North America and certain other countries.

In order to secure the approval for the acute use of rtPA stroke patients in Europe, two registries and a phase III trial were undertaken. One prospective registry of patient treatment experience with rtPA treatment within 3.0 hours of stroke onset (SITS-MOST) demonstrated that the incidence of symptomatic intracerebral hemorrhage was not different than a pool of randomized controlled trials. Those safety impressions and the experience with patients treated after 3.0 hours (SITS-ISTR registry) were the basis for ECASS-3. ECASS-3 was a multicenter, prospective, randomized, placebo-controlled trial comparing patients best medical treatment together with either rtPA ($n = 418$) or placebo ($n = 403$) between 3.0 and 4.5 hours from symptom onset.[229] The primary efficacy outcome in ECASS-3 (mRS = 0 to 1 at 90 days) was significantly greater with rtPA (52.4%) than placebo (45.2%) (risk ratio = 1.16, 95% CI 1.01 to 1.34, $P = 0.04$). Implications of these findings have been reviewed recently.[230]

The studies of intravenous rtPA underscore the major contributors to the risk of intracerebral hemorrhage in ischemic stroke. These include excessive time from symptom onset to treatment, low body mass, diastolic hypertension, older age, and the use of rtPA.[9,231,232] The appearance of "early signs of ischemia," marked by low attenuation and/or sulcal effacement on the initial CT scan, is associated with an increased risk of death and hemorrhage.[74,232–235]

Direct Local Infusion of Plasminogen Activators

Angiography-controlled intraarterial infusion allows delivery of higher local concentrations of PAs to the thrombus, where local flow is stagnant, and definition of both vascular anatomy and recanalization outcome. Refinements of flow-directed and guidewire-directed catheter techniques pioneered by Zeumer et al. and catheter systems for the acute delivery of thrombolytic agents in the cerebral circulation have broadened the experience with local delivery,[236] although the approach remains experimental (FIGURE 93.6). Among larger series, recanalization of symptomatic carotid artery territory occlusions has approached 46% to 90% of symptomatic patients treated with intraarterial infusion of SK or uPA within 8 hours.[237–239] Detectable hemorrhagic transformation in the ischemia territory occurred in 18% to 33% of treated patients (Table 93.6).[237–239]

Vertebrobasilar artery territory ischemia can produce considerable disability.[240,241] Nenci et al.[242] first demonstrated benefits after local intraarterial treatment of symptomatic basilar thrombosis. One retrospective comparison of the clinical outcome in 43 patients who received intraarterial uPA or SK with 22 patients who received conventional therapy (i.e., heparin) suggested considerable survival benefit in those demonstrating recanalization (who received the fibrinolytic agent).[243] Subsequent reports have supported recanalization efficacy with these agents.[236,239,244] However, significant hemorrhagic transformation also occurs in this setting.

The Prourokinase in Acute Cerebral Thromboembolism (PROACT) study was the first randomized double-blinded placebo-controlled examination of PAs by intraarterial infusion to demonstrate benefit.[7] In that phase II study, direct arterial infusion of recombinant single chain urokinase (rscuPA, recombinant prourokinase [rproUK]; dose of 6 mg) was compared with placebo for recanalization of M1 and M2 MCA occlusions and safety outcomes.[7] Overall, rscuPA produced a significant increase in MCA recanalization and in hemorrhagic transformation, which were heparin dependent. The follow-on open study, PROACT-2, randomized patients with symptomatic proximal MCA occlusions to recombinant scuPA (9 mg) or to placebo for recanalization and for 3-month disability outcome.[245] Both groups also received heparin. Recanalization was significantly

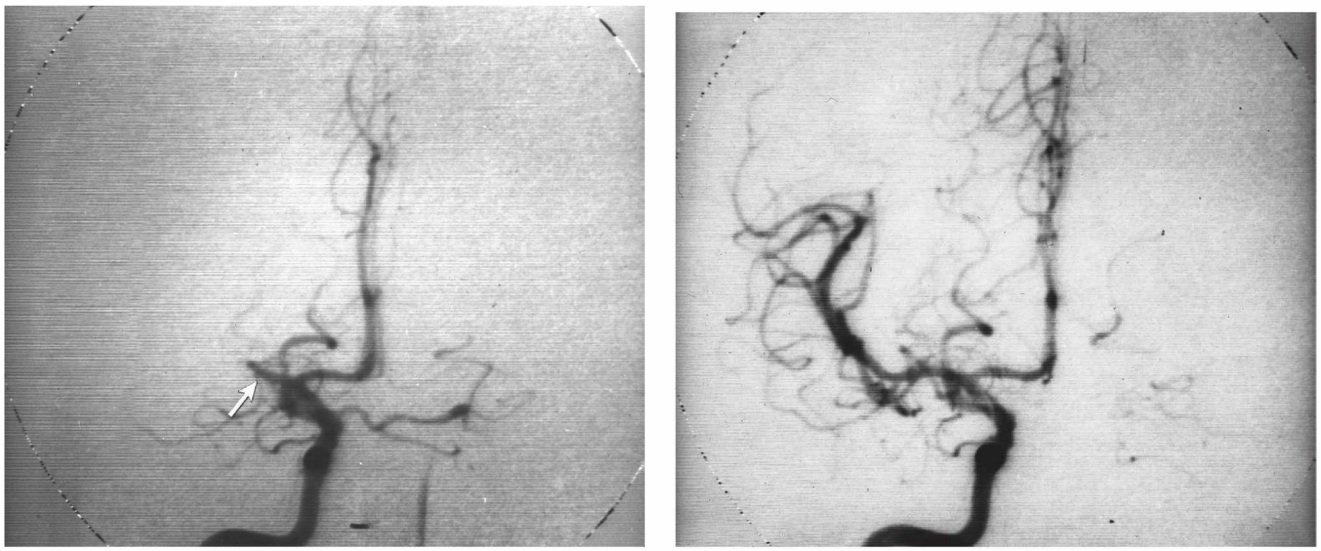

FIGURE 93.6 Recanalization of proximal middle cerebral artery (MCA) occlusion. **A**: Obstruction of the proximal MCA (M1 segment). *Arrow* indicates the site of thrombotic occlusion of the M1 segment. **B**: Relief of flow obstruction by direct intraarterial urokinase infusion, with return of downstream arterial patency (Angiograms courtesy of H. Zeumer).

greater with recombinant scuPA (65.7%) than no intervention (18.0%), as was the frequency of symptomatic intracerebral hemorrhage. Whereas the proportion of patients with no or minimal disability (mRS = 0 to 1) was not significantly different between the two groups, rscuPA was associated with an improvement in outcome measured as mRS = 0 to 2. No further exploration of rscuPA has ensued, and it is not available for clinical use.

Defibrinogenating Agents

Fibrinogen contributes to thrombus formation and to plasma viscosity. With reduction in plasma fibrinogen comes decreased viscosity, increased flow, and, potentially, limitation of thrombus formation. Reduction of fibrinogen to 100 mg/dL by the defibrinogenating agent ancrod has been considered to be safe in patients with ischemic stroke.[246,247] According to prespecified covariate-adjusted analyses (taking into account baseline stroke severity), favorable outcome was more frequent in the ancrod-treated group (42.2%) than in the placebo-treated group (34.4%) in the Stroke Treatment with Ancrod Trial (STAT).[247,248] Intracranial hemorrhage was moderately more frequent in the ancrod group. In the European Stroke Treatment with Ancrod Trial, no advantage to ancrod was observed.[249] However, differences in study design and patient recruitment with STAT were observed.[249] The potential benefit of ancrod for the acute treatment of ischemic stroke was resolved by the test of the hypothesis that rapid defibrinogenation in patients within 6 hours of stroke onset could improve efficacy and safety. No difference in the efficacy outcome (positive responder status) was observed in the combination of two studies of 500 patients randomized to multiple-day dosing with ancrod or placebo.[250] Treatment levels intended for fibrinogen were reached in >90% of the ancrod patients, however. No further work with this agent has been undertaken.

Mechanical Interventional Approaches

Coincident with the evolution of directed delivery of the PAs SK, uPA, rscuPA, and rtPA, mechanical devices designed to capture and retrieve thrombi or reestablish flow in the cerebral arterial circuit have been devised. Apparent advantages of some of these devices are the rapid achievement of recanalization and application to refractory proximal thrombi, such as carotid "T" occlusions.[251] No studies to date have demonstrated superiority or equivalence of such devices to current acute applications of the antithrombotic agents in use.

Augmented Fibrinolysis. Strategies that disrupt thrombus integrity can increase arterial perfusion. For instance, passage of the guidewire through the occlusive thrombus increases the rapidity of thrombus lysis. PROACT prohibited penetration of the thrombus with guidewire or catheter.[7] More recently, both *endovascular ultrasound* techniques, based upon limited bench studies, and the direct application of 2 MHz diagnostic TCD, developed in the clinical setting, have been shown to enhance thrombus lysis initiated by PAs.[252,253]

Angioplasty and Stenting. Angioplasty and stenting have been undertaken in select patients presenting with occlusions caused by atherosclerotic plaques. While reestablishment of flow is possible with angioplasty to 84% of patients,[254] significant generation of thromboemboli with downstream ischemia occurs. Stent placement both in the carotid artery and in downstream self-expanding stents have been promoted as less traumatic with relatively low associated symptomatic hemorrhage frequencies (~5%).[255,256] However, recently in a prospective study, placement of self-expanding nitinol stents in the carotid artery was no more efficacious than carotid endarterectomy in patients presenting with TIAs and was associated with an increased incidence of stroke.[257]

Suction Thrombectomy. Devices employing vacuum aspiration can generate significant recanalization. In a multicenter, single-arm cohort trial, the Penumbra System yielded minimal or better recanalization (Thrombolysis in Myocardial Infarction [TIMI] 2 or 3) in 81.6% of 125 target vessels.[258,259] Symptomatic intracranial hemorrhage occurred in 11.2% of patients. Functional independence was not significantly more frequent among patients in whom recanalization was achieved. Overall, similar devices can decrease the risk of uncontrolled thrombus fragmentation and downstream embolization.

Endovascular Retrieval Devices. Thrombus retrieval devices have evolved out of devices for removing coils and include the Merci Retrievers, helical nitinol coils that ensnare the thrombus. Moderate or complete recanalization by use of the device alone was achieved in 48% in one study.[260] Successful recanalization was associated with improved clinical outcome (90-day mRS 0 to 2 in 53% recanalization vs. 6% nonrecanalization, $P < 0.0001$). Symptomatic hemorrhage occurred in 5% of patients treated with the device alone and 24% treated with the device and an additional intervention (e.g., local fibrinolysis) due to incomplete recanalization response to the device. In a subsequent trial employing a later generation device, among 164 patients enrolled, moderate or complete recanalization was achieved in 57% by use of the device alone and in 70% with adjunctive approaches (intraarterial thrombolysis or angioplasty).[261] Technical advantages of using retrievable stents have been recently described.[262,263] Several multicenter trials comparing stent retrievers with earlier generation devices are underway.

For practical reasons, at some centers, patients may receive intravenous rtPA and subsequently be treated with an endovascular procedure to remove residual obstructing material. There is no apparent advantage in safety.[264,265] Such approaches must be considered experimental. All devices should be subject to controlled trials.

CAROTID ARTERY ATHEROTHROMBOTIC DISEASE

Atherosclerosis is the most prevalent arterial thrombophilic state. The carotid artery bifurcation and other large-artery branch points are predilection sites for atheroma formation and are sources of cholesterol- and thrombus-containing emboli to the cerebral hemispheres (see FIGURE 93.2). Endarterectomy of the extracranial portion of the carotid artery can resolve the local vascular flow abnormalities, but cerebral ischemic symptoms can recur.

Medical versus Surgical Intervention. TIAs and minor stroke are *symptomatic* products of carotid artery atherosclerosis. Although a major source of thromboemboli, 20% to 45% of strokes are unrelated to carotid artery stenosis (e.g., lacunes).[266] The North American Symptomatic Carotid Endarterectomy Trial and the MRC-sponsored European Carotid Surgery Trial demonstrated significant survival benefit and symptomatic relief from endarterectomy over medical (i.e., antiplatelet agent) therapy for carotid stenoses of 70% to 99%.[267,268] The benefits in reduction of ipsilateral stroke also accrue for endarterectomy of symptomatic stenosis of intermediate extent (50% to 69%), but depend on the balance of surgical risk.[269]

The surgical management of *asymptomatic* carotid artery stenosis has been controversial. The multicenter comparison of carotid endarterectomy with optimal medical management (including antiplatelet agents [ASA]) in 444 men with asymptomatic carotid artery stenosis by the Veterans Affairs Cooperative Study Group demonstrated a statistically significant

reduction in combined ipsilateral ischemic neurologic events in the surgical group (8.0% vs. 20.6%, $P < 0.001$).[270] The frequency of ipsilateral stroke was 4.7% in the surgical group and 9.4% in the medical group; however, there was no difference in stroke and stroke-related mortality at 30 days. Asymptomatic Carotid Atherosclerosis Study (ACAS) prompted examination of local single-center experiences with surgical treatment of asymptomatic carotid lesions and a meta-analyses.[271–273] Although benefit could be reproduced, postoperative mortality was a major variable.[273] Overall, experience has indicated that benefit from carotid endarterectomy for asymptomatic lesions is modest at best, with no difference between medical management or surgery for perioperative mortality or stroke, although selected patients may benefit.[273] Hence, carotid endarterectomy would be expected to benefit a select subset of asymptomatic patients and would depend upon the frequency of surgical complications.

Antiplatelet agents are adjuncts to carotid endarterectomy that lower the incidence of embolic stroke and death or decrease the incidence of carotid restenosis after carotid endarterectomy. In one prospective double-blind, placebo-controlled trial, ASA (1,300 mg/day), given within 5 days of carotid endarterectomy, reduced the incidence of stroke or death at 6 months.[274] In a separate trial, ASA (50 to 100 mg/day) started 1 to 12 weeks after carotid endarterectomy had no appreciable effect on strokes, MI, or vascular death.[275] Following a retrospective analysis of experience with ASA (1,500 mg/day),[276] a prospective comparison of presurgical ASA (1,000 mg/day) or no treatment was undertaken.[277] Survival was extended in the ASA-treated group, although cerebral events occurred equally in both. Subsequently, a prospective comparison of four doses of ASA after endarterectomy (81, 325, 650, or 1,300 mg/day) concluded that the lower dose tiers (81 and 325 mg/day) were superior in averting stroke, MI, and death within the next 3 months.[278]

Current practice is to continue patients undergoing endarterectomy on ASA (81 to 325 mg/day) after the procedure. There is little information regarding a role for anticoagulants after endarterectomy, and fibrinolytic agents are contraindicated.

Carotid Stenting/Endarterectomy. Carotid stenting has emerged as a viable alternative revascularization procedure to carotid endarterectomy on the basis of controlled trials.[257,279] The appropriate antithrombotic regimen after stent placement in the carotid system has not been defined by those trials.

CEREBRAL EMBOLISM FROM A CARDIAC SOURCE

Emboli from cardiac injury sites can cause focal cerebral ischemia. These sources include mural thrombi associated with left ventricular dyskinesia (e.g., after MI), prosthetic valves, rheumatic valvular vegetations, and thromboemboli arising during AF. Because of the thrombotic nature of most cardioembolic events, a role for anticoagulation has been suggested in both primary and secondary prevention.

Cardioembolic Stroke Following Myocardial Infarction

The incidence of systemic thromboembolism, including stroke, after MI varies from 1% to 3% per year, but may be as high as 3.7% during the first month after an MI (i.e., the acute phase).[280–285] Antiplatelet agents could be effective in decreasing the incidence of post-MI cerebral events. However, evidence continues to be scant. The CAPRIE study suggested that clopidogrel could reduce the combined events of second MI, stroke, or peripheral artery disease following an initial MI, although the benefit for MI was not significant.[190]

Anticoagulation during the acute in-hospital and in the chronic post-hospitalization phases reduces the number of cerebrovascular events.[280–286] Secondary prevention trials designed to determine the incidence of recurrent MI as the main outcome event have also examined the effect of long-term anticoagulation on stroke incidence. Level II trials suggested a trend in favor of decreased post-MI stroke incidence. In the Veterans Administration Cooperative Study, however, there was no reduction in stroke incidence 1 to 5 years after MI for patients randomized to long-term anticoagulation within 21 days of their MI.[280] The trend favoring anticoagulation for stroke was mirrored by an overall reduction in the combined outcomes of stroke, second MI, and death. A similar trend was seen in two subsequent trials and appeared independent of the type of oral anticoagulant.[282,283] The Sixty Plus Reinfarction Study randomized MI patients more than 60 years to oral anticoagulation or placebo.[284] At 2-year follow-up, anticoagulation was associated with a trend toward a lower stroke incidence.

Those studies also demonstrated an increased incidence of serious hemorrhages, which contributed to morbidity or death in the anticoagulated group.[280,282–284] In German-Austrian Aspirin Trial (GAAT) and the Sixty Plus Reinfarction studies, the number of serious anticoagulation-associated hemorrhages, including intracerebral events, was considered excessive.[283,284] In the latter, seven intracranial hemorrhages occurred in the anticoagulated group, compared to one in the placebo group, although fatal intracranial events were equal. Approximately 72% of the anticoagulated patients had an INR of 2.7 to 4.5.[284]

Two level I placebo-controlled trials demonstrated a significant reduction in stroke incidence with anticoagulation.[281,285] The Warfarin Reinfarction Study (WARIS) also reported a significant decrease in the incidence of cerebrovascular events in patients who received warfarin.[285] In both trials, hemorrhage was more common in the active treatment group. In WARIS, the target INR was 2.8 to 4.8, considered high by current measures. The follow-on randomized three-armed open trial (WARIS-II) of warfarin (INR = 2.8 to 4.2), warfarin and ASA (75 mg/day), or ASA (160 mg/day) alone in patients with MI demonstrated that the combination warfarin/ASA was superior to the other regimens for the combined outcomes of death, nonfatal reinfarction, and cerebral stroke.[287,288] While the incidence of hemorrhage was greatest in the warfarin/ASA cohort at study close, the incidence of occult hemorrhage at 3 months and 4 years was not different from normal in all three cohorts, suggesting overall benefit with INR = 2.0 to 3.0 in patients with a low or intermediate risk of hemorrhage.[288,289]

Three trials of anticoagulation during the acute in-hospital phase of MI demonstrated a decreased incidence of stroke.[290–292] In a single-blind test which randomized patients to heparin/warfarin or placebo post-MI, anticoagulation was associated with a significant decrease in strokes.[291] A second study demonstrated a trend in favor of heparin and oral anticoagulation.[290] Both studies, however, demonstrated no change in the combined outcomes of stroke, second MI, and death. A separate level I MRC-sponsored trial randomized patients to heparin/adjusted high-dose phenindione or heparin/fixed low-dose phenindione for 28 days within

Table 93.7

AF (nonvalvular): antiplatelet agents/anticoagulants

Study	Agent	Dose (per Day)	Patients (n)	Stroke (n)	Mortality (n)

[a]Numbers in parentheses indicate systemic embolic events.
[b]Patients ≤ 75 y.
[c]Patients >75 y.
[d]TTR = time in therapeutic range (INR = 2.0–3.0).

14 days of acute MI. A significant decrease in the incidence of systemic embolism with the high-dose group was seen, although there was no difference in recurrent MI or death.[292] Both the incidence and severity of hemorrhagic complications were quite low. This experience suggests that cerebrovascular ischemic events during the early post-MI period can be reduced with anticoagulation.

In summary, long-term anticoagulation can decrease the number of cerebrovascular events after recovery from MI. In practice, however, concerns about the higher incidence of serious hemorrhagic events, including intracerebral hemorrhage, have limited routine use of anticoagulants.

Cardioembolic Stroke in Atrial Fibrillation

The pathogenesis of stroke and the role of antithrombotic regimens in individuals with nonrheumatic AF have been reviewed.[293] In a retrospective study, Sage and Van Uitert[294] indicated that the risk of cerebral infarction after an episode of nonvalvular AF can be 20% per year, with a mortality rate from the initial infarct of 38% per year. This is in accordance with the experience of Hart et al.,[295] who reported a 34.8% incidence of symptomatic embolism (13% cerebral) in individuals not undergoing immediate anticoagulation. Furthermore, the population incidence of nonvalvular AF is increasing with the age. These, and other data, have suggested the need for prospective clinical trials (Table 93.7).

Primary Prevention

Vitamin K Antagonists (VKAs). The AFASAK (Atrial Fibrillation, Aspirin, Anticoagulation) study, an open randomized trial of warfarin, ASA (75 mg/day), or placebo in nonrheumatic, nonvalvular AF, demonstrated a significant decrease in cerebral embolic events in the warfarin group at the 2-year follow-up.[296] But, hemorrhagic complications were significantly more common in the warfarin group.[297,298] The Stroke Prevention in Atrial Fibrillation (SPAF) study randomized patients with AF to warfarin, ASA, or placebo (group 1) if they were eligible for warfarin, or to ASA or placebo (group 2, double-blind) if they were not warfarin eligible.[297] SPAF-I was terminated when the warfarin and ASA arms of group 1 demonstrated a statistically significant combined 81% risk reduction in ischemic stroke and

systemic embolism. The relative benefit of warfarin over ASA was not reported, but 10.9% of patients randomly assigned to warfarin were withdrawn because of drug intolerance. The Boston Area Anticoagulation Trial for Atrial Fibrillation (BAATAF), an open randomized study of long-term, low-dose warfarin or no treatment, demonstrated a significant 86% risk reduction for stroke and death in favor of the warfarin group.[298] No differences in fatal hemorrhages were seen between the warfarin and no-therapy groups. The Canadian Atrial Fibrillation Anticoagulation (CAFA) Study was terminated early based on the results of those two studies, with a 44.8% risk reduction in ischemic stroke and systemic thromboembolism favoring warfarin.[299]

Concerned that the risk of intracranial hemorrhage could be associated with warfarin-based approaches using ASA[300] or low-dose oral anticoagulation,[301] the SPAF-II trial examined the relative efficacies of warfarin and ASA in individuals with nonvalvular AF.[300] That study prospectively stratified patients into two age cohorts: ≥75 years and those <75 years. A modest, but not statistically significant, reduction in ischemic stroke events was associated with warfarin over ASA. There was a significantly greater frequency of major hemorrhagic events with warfarin in the ≥75-year cohort than in the <75-year cohort, however. The low overall annual thromboembolic event rate was a concern. Nonsignificant differences between the ASA treatment and control arms of the AFASAK study, the European Atrial Fibrillation Trial (EAFT), and ESPS-2 were observed in patients with nonvalvular AF.[175,296,302] ASA was associated with a significant 21% RRR in annual stroke events in an individual patient combined analysis of AFASAK, EAFT, and SPAF-I,[303] a conclusion supported by a broader meta-analysis.[304] Heterogeneity in the results could not be excluded.[305]

Age >80 years, intensity of anticoagulation, and prolonged prothrombin time from the therapeutic range are all contributors to an increased risk of hemorrhage.[306] The SPAF-III trial addressed the intensity of anticoagulation.[301] Patients were randomized either to adjusted-dose warfarin to maintain the INR between 2.0 and 3.0, or to low-intensity warfarin with ASA (325 mg/day) to maintain the INR between 1.2 and 1.5. That study was terminated when the annual disabling stroke rate of the combination therapy exceeded that of adjusted-dose warfarin (5.6% vs. 1.7%, respectively). When cumulative event rates were calculated, a nearly significant difference ($P = 0.07$) favoring warfarin seemed to support the results of previous studies (see Table 93.7). The results of SPAF-III led to the early termination of the AFASAK-2 study of patients with moderate risk.[307,308] A review of published data to 2001 indicated that anticoagulation is superior to antiplatelet agents for the reduction of nonfatal stroke risk in patients with AF.[309] Evaluation of the quality of anticoagulation for nonvalvular AF demonstrates that the ischemic stroke difference was significantly less among patients with INR ≥ 2.0 compared to INR < 2.0.[310] Overall, adjusted-dose warfarin to a trough INR of 2.5 is superior to antiplatelet agents or no treatment and is the current accepted management approach for nonvalvular AF.

To emphasize this observation, and despite the accepted superiority of warfarin anticoagulation over ASA, the Atrial Fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE) was undertaken to compare the combination clopidogrel/ASA with warfarin (ACTIVE-W) and with ASA alone (ACTIVE-A) for the prevention of vascular events in stroke patients with a high risk for AF. The ACTIVE-W portion of the study complex was terminated before the intended completion of the study when it was shown that oral anticoagulation (INR = 2.0 to 3.0) was superior to ASA (75 to 100 mg/day)/clopidogrel (75 mg/day) displaying annual combined risks of stroke, embolism, MI, or vascular death of 3.93% and 5.60%, respectively (RR 1.44 [1.18% to 1.76%], $P = 0.0003$).[311]

Nonvitamin K Antagonists. Oral alternatives to warfarin have been attractive, conceivably intended to be given without monitoring. Concern about the ability to sustain target levels of anticoagulation with warfarin in a number of settings and the infrastructure needed to monitor this has stimulated the search for agents that affect coagulation system differently. One direct thrombin inhibitor that could be administered orally, ximelagatran, was found to be not inferior (±2.5%) to warfarin in preventing systemic embolic events in patients with nonvalvular AF.[312,313] In the Stroke Prevention Using Oral Thrombi Inhibitor in Atrial Fibrillation (SPORTIF) III trial, warfarin generated a nonsignificant decrease in stroke incidence compared to ximelagatran.[312,313] Because of hepatic toxicity, the development of ximelagatran was stopped and the agent is not available. The parenteral factor Xa inhibitors argatroban and bivalirudin are not used for nonvalvular AF.

However, potential alternatives to warfarin in primary prevention of thromboembolic stroke in patients with nonvalvular AF have been tested recently. The Randomized Evaluation of Long-term Anticoagulation Therapy (RE-LY) trial demonstrated that dabigatran, an orally delivered direct thrombin inhibitor, was not inferior to warfarin, and dabigatran at 150 mg twice per day is indeed superior for the combined primary outcomes of stroke or systemic embolism.[314] It is now indicated for nonvalvular AF. The results of the Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF) trial have been reported.[315] The ROCKET-AF trial compared rivaroxaban, an oral direct factor Xa inhibitor, with warfarin in a double-dummy placebo-controlled format, demonstrating that rivaroxaban was not inferior to warfarin in the composite efficacy outcome of stroke (ischemic and hemorrhagic) and systemic embolism.[315,316] The novel antifactor Xa inhibitor apixaban has been shown to be superior to ASA (81 to 324 mg/day) in patients with nonvalvular AF in a prospective randomized study (AVERROES).[317] In a recently completed prospective randomized trial, Apixaban for Reduction of Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE), the antifactor Xa inhibitor was found superior to warfarin in the reduction of stroke and systemic embolism.[318]

Interestingly, while the frequency of major hemorrhagic events in RE-LY, ROCKET-AF, and ARISTOTLE was not different between the test agent and warfarin, these studies demonstrated a decrease in the frequency of intracranial hemorrhage (hemorrhagic stroke). Although the reasons for the observed reduction in intracranial hemorrhage by these antithrombotic agents are not clear, it has been suggested that neither rivaroxaban nor dabigatran affects the tissue factor:factor VIIa complex, whereas warfarin decreases factor VIIa.[319] Rosenberg and Aird[320] suggested that the cerebrovasculature has unique hemostatic features unlike other vascular beds, although these features have not been described. Fundamental studies are required to further delineate the nature of the hemostatic responses in the central nervous system that the use of these new antithrombotic agents

has uncovered. This is a potentially exciting area of research. At this writing, dabigatran and rivaroxaban are licensed for primary prevention of stroke in nonvalvular AF patients.

Secondary Prevention

Information from secondary prevention trials involving patients with AF who present with a signal stroke is limited. In an open trial of anticoagulation in patients with stroke and nonvalvular AF, Lodder et al.[321] found no difference in the incidence of second stroke or death at a mean follow-up of 2.25 years. Death from serious hemorrhage occurred in 6 of the 70 anticoagulated patients (18.6%). The Cerebral Embolism Study Group performed a randomized, open trial of immediate versus delayed anticoagulation patients with AF and cardioembolic strokes for the principal outcome event of recurrent embolism.[164] Anticoagulation was initiated immediately after a signal stroke or 10 days after the first stroke. In that small series, two patients in the delayed treatment group had second embolic events. This limited experience suggests caution in the use of anticoagulants in secondary prevention of recurrent cerebral embolism in AF. More recently, data from ROCKET-AF indicate that rivaroxaban can produce modest, but significant reduction in embolic events in secondary prevention, suggesting that other oral non-VKA agents may have this activity.[315]

In summary, the results of randomized, controlled trials of individuals with nonvalvular AF support the use of oral anticoagulation to reduce the incidence of embolic stroke.[322] For patients with a high risk to AF (with a prior TIA/stroke or systemic embolus, history of hypertension, poor left ventricular function, age >75 years, rheumatic mitral valve disease, or a prosthetic valve), the current recommended therapy is adjusted-dose warfarin anticoagulation at a target INR of 2.5 (range 2.0 to 3.0) rather than ASA.[323] New oral non-VKA agents have been found to be noninferior to warfarin, and, in the case of dabigatran and apixaban, are superior for efficacy. All such agents appear to have a lower incidence of intracerebral hemorrhage.

Stroke in Low Cardiac Ejection Disease

Patients with partly compensated left ventricular function and low cardiac output are at increased risk of ischemic stroke. Congestive heart failure is accompanied by increased prevalence of AF, which ranges from 0% to 42%.[324] Antithrombotic treatment options are uncertain. The Warfarin-Aspirin in reduced Cardiac Ejection Fraction study is a prospective double-blind double-dummy superiority trial comparing ASA with warfarin to decrease the incidence of ischemic stroke in the setting of CHF.[324] This trial is nearing completion.

VALVULAR CARDIOVASCULAR DISEASE

Rheumatic valvular disease, mechanical or xenograft prosthetic cardiac valves, and calcified mitral annuli generate thromboemboli. Clinically detectable systemic embolism from untreated rheumatic mitral stenosis and mitral insufficiency occurs with a 3.7% and 1.9% yearly incidence, respectively. Recurrent embolism occurs frequently within 6 to 12 months after the signal embolism.[325–327] The risk of cerebral embolism is greatly increased by concurrent AF.[326,328,329] And, the incidence of systemic embolism is greater for mechanical devices than for xenograft prostheses. Adjunctive antithrombotic strategies offer protection against thromboembolic complications of valve prostheses.[328,329] But, the use of xenograft prostheses has significantly altered the antithrombotic approach to prophylaxis.

Mechanical Prosthetic Cardiac Valves

The incidence of cardiac source thromboembolic events depends upon the type of mechanical valves, their location, and the age of the patient. The rate of systemic embolic events (per year) appears greatest with caged disk or ball valves (2.5%), in excess of tilting disk (0.7%) or bileaflet (0.5%) valves.[330] Generally, thromboembolic risk is higher for mechanical valves in the mitral position than in the aortic position,[331] perhaps in part because of the association of AF.[332,333] Finally, the incidence of systemic thromboembolism is greatest in the elderly (≥70 years).[330]

The use of oral anticoagulants has generally reduced the incidence of embolic events. Although individual series varies, and few prospective controlled studies have been undertaken, the higher incidence of emboli with caged devices suggests the need for increases of anticoagulation intensity. In one study of complications with bileaflet aortic valves, a greater reduction in thromboembolic rate was seen with an INR of 2.5 to 3.5.[334] In one multiseries review, this range of anticoagulation appeared efficacious.[335] For valves in the aortic position (bileaflet and tilting variety), anticoagulation to a target INR of 2.5 (range 2.0 to 3.0) is recommended, and for valves in the mitral position the target INR of 3.0 (range 2.5 to 3.5) is recommended.[331]

The addition of antiplatelet agents can increase the protection afforded by oral anticoagulation, but may increase the risk of hemorrhagic complications. Two level I studies demonstrated reduced thromboembolic risk in patients receiving combination anticoagulation with ASA over anticoagulation alone.[336,337] The rate of systemic thromboembolic or vascular death was significantly reduced by addition of ASA (100 mg/day) to oral anticoagulation at INR 3.0 to 4.5.[338,339] ASA doses of 500 to 1,000 mg/day reduced the number of cerebral embolic and systemic embolic events considerably, although the hemorrhagic risk was dose dependent.[337] In view of the gastrointestinal side effects of ASA-containing regimens, addition of dipyridamole to oral anticoagulation has been successfully tested in patients with mechanical prosthetic cardiac valves.[329] Whereas those studies suggested no increase in hemorrhage, the general experience supported an increase in major hemorrhage with this regimen.

Dipyridamole (400 mg/day) with warfarin considerably reduced thromboembolism or death compared to warfarin and placebo.[340,341] The combination of dipyridamole with oral anticoagulation (INR 2.0 to 2.5) was also associated with a low thromboembolic rate in a separate study (without a control arm).[342] In an open study of patients with mechanical prostheses, dipyridamole (400 mg/day) and warfarin were superior to warfarin and ASA (500 mg/day),[343] and major hemorrhagic complications were considerably fewer with the addition of dipyridamole.

The possibility that low-dose ASA might also further reduce embolic events in patients with heart valve replacement already managed with warfarin was tested by Turpie et al.[344] In an open prospective trial, patients randomized to 100 mg/day ASA or 650 mg/day ASA (both receiving warfarin adjusted to a target INR of 2.0 to 3.0) showed no statistically

significant difference with respect to systemic embolism, vascular death, or total death. However, the rate of hemorrhagic events in the high-dose ASA group (13.4 vs. 7.9 events per 100 patient-years) significantly exceeded that of the low-dose group. On this basis, low-dose ASA is often added to warfarin. However, meta-analysis of trials combining dipyridamole with oral anticoagulation indicated a decrease in fatal and nonfatal thromboemboli.[345,346]

A vexing issue is how to anticoagulate women with mechanical valves during pregnancy. One recent limited series indicated success with enoxaparin as treatment for varying periods during pregnancy when antifactor Xa levels were maintained at 1.0 to 1 U/mL.[347]

Xenograft Cardiac Valves

Systemic thromboembolic events occurred in 4% of patients with bioprostheses at 3 years who are in sinus rhythm and in 16% of patients with AF.[348,349] The greatest risk of thromboembolism occurred during the first 3 months after placement of the bioprosthesis.[350,351] A lower frequency of major embolic events was seen in patients with porcine biosynthetic valves receiving anticoagulation for 6 to 12 weeks in one study.[349] There was no difference in incidence of systemic emboli in patients with xenograft prostheses randomized to oral anticoagulation at an INR of 2.0 to 2.25 or at an INR of 2.5 to 4.0 (standard anticoagulation) for the first 3 postoperative months, although, clinically significant hemorrhagic events were more frequent in the group receiving standard anticoagulation.[352]

The benefit of antiplatelet agents has been evaluated in several level III studies.[353–355] Those studies implied that warfarin or ASA (1,000 or 500 mg/day) produced similar risk reduction in patients in sinus rhythm. Patients with mitral valve bioprostheses who received 500 mg ASA every 2 days were less likely to have embolic events than those who received 1,000 mg/day.[355] However, this conclusion has not been rigorously tested. Accepted clinical practice requires anticoagulation for the initial 3 months following placement of the bioprosthesis.

THROMBOTIC EVENTS ASSOCIATED WITH CENTRAL NERVOUS SYSTEM INJURY

Deep Venous Thrombosis

DVT can complicate the early course of recovery from stroke.[356] This is attributed to immobility of the affected limb or prolonged recumbency, although, contributions of the activated coagulation state is also likely. Heparinoids and LMWHs have been tested as alternatives to prophylactic UFH. Early experience with prophylactic use of two LMWH preparations, however, was mixed.[357–359] Twice-daily subcutaneous treatment with one preparation was associated with considerably reduced frequency of DVT.[359] Turpie et al.[360] demonstrated an advantage of twice-daily subcutaneous administration of a low molecular weight heparinoid over subcutaneous heparin in decreasing the incidence of DVT. In the TOAST trial, danaparoid produced a considerable reduction in the frequency of poststroke DVT, compared to placebo.[176,177,361–363] A recent review of published data and guidelines points out the concerns of conflicting information.[364] Prophylactic use of anticoagulants to decrease venous thromboembolism is reasonable in patients having suffered recent stroke, but the use must be tempered with an increased risk of hemorrhage. Patients suffering an intracerebral hemorrhage appear at particular risk of DVT.[365] Here, too, the recommendation for the use of heparin or LMWHs is tempered with caution and should not be instituted before the second day after ictus.[149,150]

Sagittal Sinus Thrombosis

Cortical vein thrombosis can accompany local inflammation, thrombophilic states (including anticardiolipin or antiphospholipid antibodies), and pregnancy, or it can be idiopathic. Although thrombolytic agents have been employed unusually, anticoagulation is the treatment of choice. Recent epidemiologic report underscores the relative lower morbidity of this condition compared to ischemic stroke.[366] Petechial hemorrhage is a common finding with sagittal sinus thrombosis.

Retinal Vascular Thrombosis

Retinal arterial occlusions are commonly related to carotid artery stenosis.[367] In one series, approximately 40% of patients with retinal vein thrombosis had evidence of circulating anticardiolipin antibodies.[368] Fibrinolytic agents have been used successfully in patients with retinal artery and retinal vein occlusion.[369,370] Partial recovery of form vision was possible in some patients with acute retinal artery occlusion.[371,372] Antiplatelet agents or anticoagulants have been used in patients with cerebral retinal thrombosis before neovascularization.[373] To date, these approaches have not been tested prospectively.

CONCLUSIONS

Atherothrombosis and thromboembolism that lead to acute cerebrovascular disease are accompanied by activation of the coagulation system and of platelets. Antithrombotic agents can preserve or reconstitute vascular patency and thereby minimize permanent injury from focal cerebral ischemia. Both patient selection and the subtype of stroke are relevant to benefit from treatment.

PAs can increase the probability of minimal disability or no abnormality in selected patients with acute cerebral ischemia. Intravenous infusion of rtPA has displayed this activity. Recanalization of symptomatic, documented carotid territory occlusions and vertebrobasilar arterial occlusions has been achieved by local intraarterial PA delivery. Recent studies have underscored the need for careful individual selection, because fatal hemorrhage is a consistent risk.

Antiplatelet agents can reduce the risk of the combined outcomes of subsequent stroke, MI, and mortality in individuals with a history of recent TIAs. For secondary prevention of recurrent stroke in patients presenting with a stable, recent focal cerebral deficit, ASA/ER-DP produces additional benefits over ASA. Thienopyridines have been associated with risk reduction in second ischemic events. When TIAs are associated with carotid artery stenosis of 70% to 99%, carotid endarterectomy and ASA are superior to ASA alone in preventing subsequent stroke and stroke-related mortality.

Patients with AF without a valvular abnormality benefit from long-term anticoagulation with VKAs with or without an antiplatelet agent. Anticoagulation can reduce the risk of systemic and cerebral embolism in individuals with a signal MI,

nonvalvular (i.e., nonrheumatic) AF, mechanical valve prosthesis, and xenograft bioprosthesis (for the initial 3 months after placement). Recent data with non-VKA oral agents indicate that they are not inferior to, and could be superior to, warfarin for primary prophylaxis of patients with nonvalvular AF. Early use of heparin in individuals with sinus venous thrombosis may produce clinical improvement.

CHAPTER

94 Medical and Surgical Treatment of Peripheral Arterial Disease

PHILIP JOSEPH, SAURABH KALRA, AND SONIA ANAND

Peripheral arterial disease (PAD) affects approximately 27 million individuals in North America and Europe, and its prevalence is increasing as life expectancy increases.[1] Atherosclerosis is the most common cause of PAD, with symptoms primarily attributable to arterial stenosis and reduced blood flow. Nonatherosclerotic PAD is far less common, resulting from vasculitis, arterial vasospasm, or thromboembolism. Moreover, the development of PAD represents one manifestation of an atherosclerotic process, which in the majority of individuals affects the entire vascular tree. Consequently, patients with PAD are at an increased risk for coronary artery disease and cerebrovascular disease.

The diagnosis and management of PAD has evolved considerably over the past few decades. Advances have stemmed from improved diagnostic modalities as well as from new medical and surgical treatments, with a greater focus on overall cardiovascular risk reduction. Despite these improvements, the successful treatment of individuals with PAD remains a challenge and encompasses a multifaceted strategy involving lifestyle modification, pharmacologic therapy, and peripheral arterial interventions. This chapter provides an overview of the pathogenesis, epidemiology, and management of PAD related to the lower extremities.

PATHOGENESIS OF PAD AND LIMB ISCHEMIA

Atherosclerotic Plaque Development (see Chapter 89)

Briefly, atherosclerosis results from adverse interactions between vessel hemodynamics, blood elements, and the vascular intima.[2] Covering the intimal surface of the vessels, the vascular endothelium regulates several important aspects of vascular homeostasis including vascular tone, leukocyte adhesion and migration, platelet function, and coagulation. Vascular homeostasis is achieved through several autocrine and paracrine factors mediated by endothelial cells. Nitric oxide is released by the endothelium, exerting vasodilatory, antiproliferative, and antithrombotic effects.[3] Endothelial dysfunction develops in the presence of cardiovascular risk factors (such as hypertension, diabetes, smoking, and hyperlipidemic disorders) and results in the decreased availability of nitric oxide or an imbalance in vascular homeostasis favoring deleterious circulating factors. The development of endothelial dysfunction promotes atherosclerotic plaque development, hypercoagulability, and thrombosis. The nascent step in atherogenesis involves the endothelial mediated migration of low-density lipoprotein (LDL) from the blood plasma into the vessel intima.[4,5] Subsequent oxidative stress and intimal inflammation lead to the increased expression of leukocyte adhesion molecules along the vascular surface. Once monocyte and T-lymphocyte adherence occurs, chemokines facilitate leukocyte migration into the vessel intima.[6–11]

As monocytes differentiate into macrophages within the vessel intima, they internalize oxidized LDL via scavenger receptors and develop into foam cells. Macrophage colony stimulating factor has been shown to be present in human atherosclerotic lesions and hypothesized to promote macrophage replication within the intima.[7] Foam cells coalesce to form early atherosclerotic plaques, commonly described as "fatty streaks" (FIGURE 94.1). Activated macrophages and T-lymphocytes cause further plaque progression through the release of inflammatory cytokines and the promotion of smooth muscle cell (SMC) migration and proliferation within the vessel intima. As foam cells, SMCs, and extracellular lipids accumulate, the atherosclerotic plaque continues to organize and grow within the intimal layer. Simultaneously, macrophage and SMC apoptosis within the plaque result in the development of a relatively acellular, collagen-based fibrous cap, which provides stability to the lipid core (FIGURE 94.2). With the continuation of these inflammatory, replicating, and apoptotic processes, the atherosclerotic plaque becomes more complex, creating an abundant extracellular matrix (comprised of interstitial collagen, proteoglycans, and elastin fibers) within the vessel wall, developing calcification, and undergoing neovascularization.[7]

Vascular Ischemia and Thrombosis

As the atherosclerotic plaque enlarges, an outward, "positive" remodeling phase initially predominates preventing luminal obstruction. However, luminal stenosis eventually develops as the enlarging plaque overcomes the vessel's capacity to positively remodel. Moreover, proteolytic enzymes exuded from macrophages degrade and weaken the fibrous cap, creating a "vulnerable plaque" susceptible to rupture.[12] With plaque rupture, the thrombogenic inner vessel becomes exposed to circulating platelets and coagulation factors, resulting in thrombosis. If thrombosis results in occlusion of the vessel, acute ischemia develops.[7] However, repetitive, subclinical thrombotic events also occur; with subsequent healing, and fibrous tissue and collagen fiber formation, resulting in progressive plaque expansion and luminal stenosis.[12] Thus, atherosclerosis progression may span many years without the development of symptoms. However, progressive obstruction of the arterial lumen eventually impedes blood flow through the affected vessel.

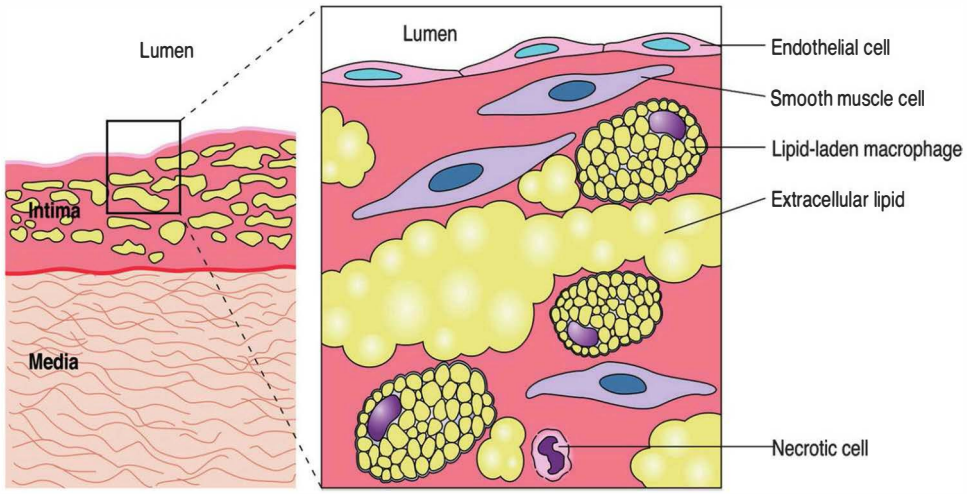

FIGURE 94.1 Fatty streak of atherosclerosis. The fatty streak, composed largely of foamy macrophages, is presumed to be an early stage in the formation of atherosclerotic lesions. Note the intimal thickening in the left panel and the infiltrating cells in the enlargement on the right. (From Rubin R, Strayer DS. *Rubin's pathology: clinicopathologic foundations of medicine*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.)

EPIDEMIOLOGY OF PAD AND VASCULAR RISK FACTORS

Prevalence and Clinical Course of PAD

Both symptomatic and asymptomatic patients with PAD are at increased risk for adverse cardiovascular events. The prevalence of asymptomatic PAD varies with the age of the population studied, from 3% in 15,106 asymptomatic individuals between the ages of 45 and 60 years[13] and 4.3% among a population >40 years of age[14] to 29% of higher risk individuals over age 70 with cardiovascular risk factors.[15] The prevalence of symptomatic PAD is 3% to 6% in the general population, also increasing with age (FIGURE 94.3).[16]

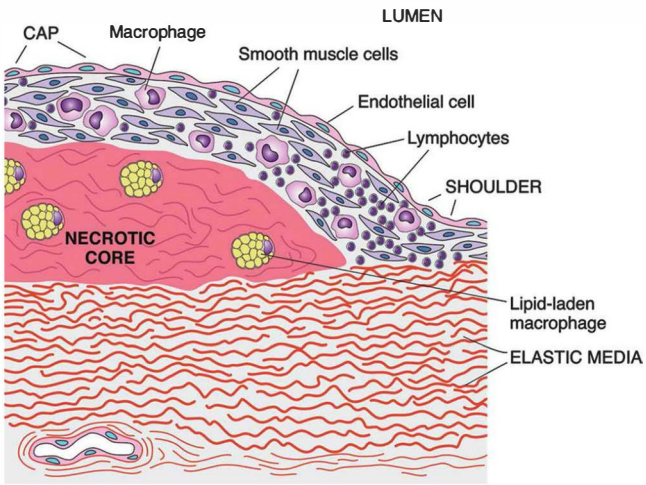

FIGURE 94.2 Fibrofatty plaque of atherosclerosis. In this fully developed fibrous plaque, the core contains lipid-filled macrophages and necrotic SMC debris. The "fibrous" cap is composed largely of SMCs, which produce collagen, small amounts of elastin, and glycosaminoglycans. Also shown are infiltrating macrophages and lymphocytes. (From Rubin R, Strayer DS. *Rubin's pathology: clinicopathologic foundations of medicine*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.)

The natural history of patients with PAD varies widely depending on disease severity and progression of atherosclerosis, with symptoms ranging from intermittent claudication to critical limb ischemia (CLI) and limb loss (FIGURE 94.4). The majority of individuals with PAD have stable leg symptoms, with worsening claudication occurring in approximately 25% of patients,[17] in association with diabetes, smoking, a low initial ankle–brachial index (ABI), and multiple stenotic lesions.[18] CLI is the presenting symptom in 1% to 3% of PAD patients,[17] and 5% to 10% of patients with previously stable PAD develop CLI over a 5-year period; risk factors being diabetes, advanced age, dyslipidemia, smoking, and an ABI of <0.5.[16] In symptomatic individuals, only 1% to 3% require limb amputation over a 5-year period,[17] but individuals with diabetes or those who present with CLI are at increased risk for limb loss.

Between 40% and 65% of patients with PAD are at increased risk for major adverse cardiovascular events (vascular-related death, myocardial infarction, or stroke),[16,19] the annual event rate being 5% to 7% and mortality related to cardiovascular disease being the most common cause of death. Coronary artery disease accounts for 40% to 60% of patient mortality, cerebrovascular disease for 10% to 20%, and other vascular events for 10% of deaths associated with PAD.[16]

RISK FACTORS FOR THE DEVELOPMENT OF PAD

The risk factors for PAD are the same as those for other atherosclerotic disease processes, modifiable ones including smoking, dyslipidemia, diabetes, and hypertension. In the National Health and Nutrition Examination Survey (NHANES), 95% of patients had at least one modifiable cardiovascular risk factor and 75% of patients had at least two cardiovascular risk factors.[14] Advanced age represents a nonmodifiable risk factor for PAD development.

Smoking causes several deleterious alterations in lipid metabolism, including reduced high-density lipoprotein (HDL) and increased LDL, triglyceride, and total cholesterol levels.[20] In

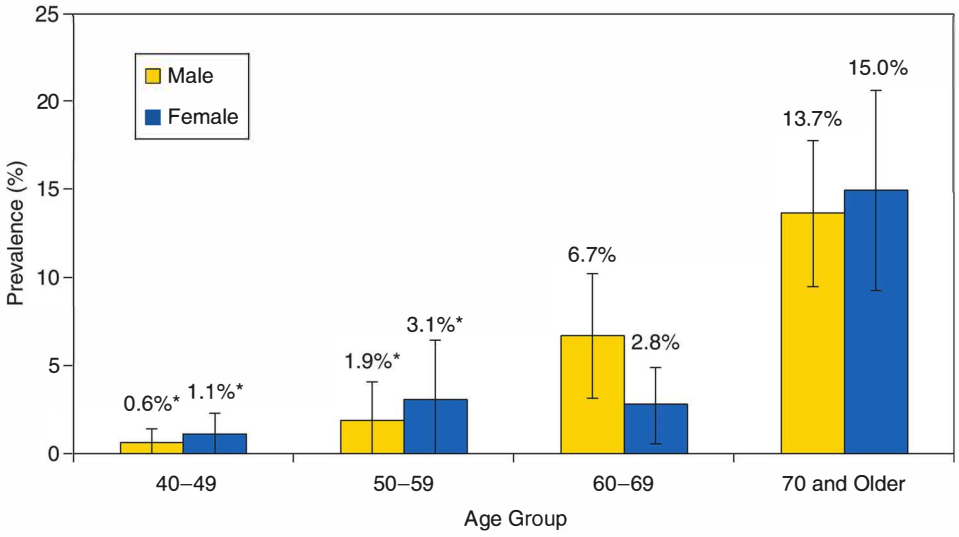

FIGURE 94.3 Prevalance of PAD in adults over 40 years by age and gender. (Reprinted from Selvin E, Erlinger TP. Prevalence of and risk factors for peripheral arterial disease in the United States: results from the National Health and Nutrition Examination Survey, 1999–2000. *Circulation* 2004;110:738–743, with Permission.)

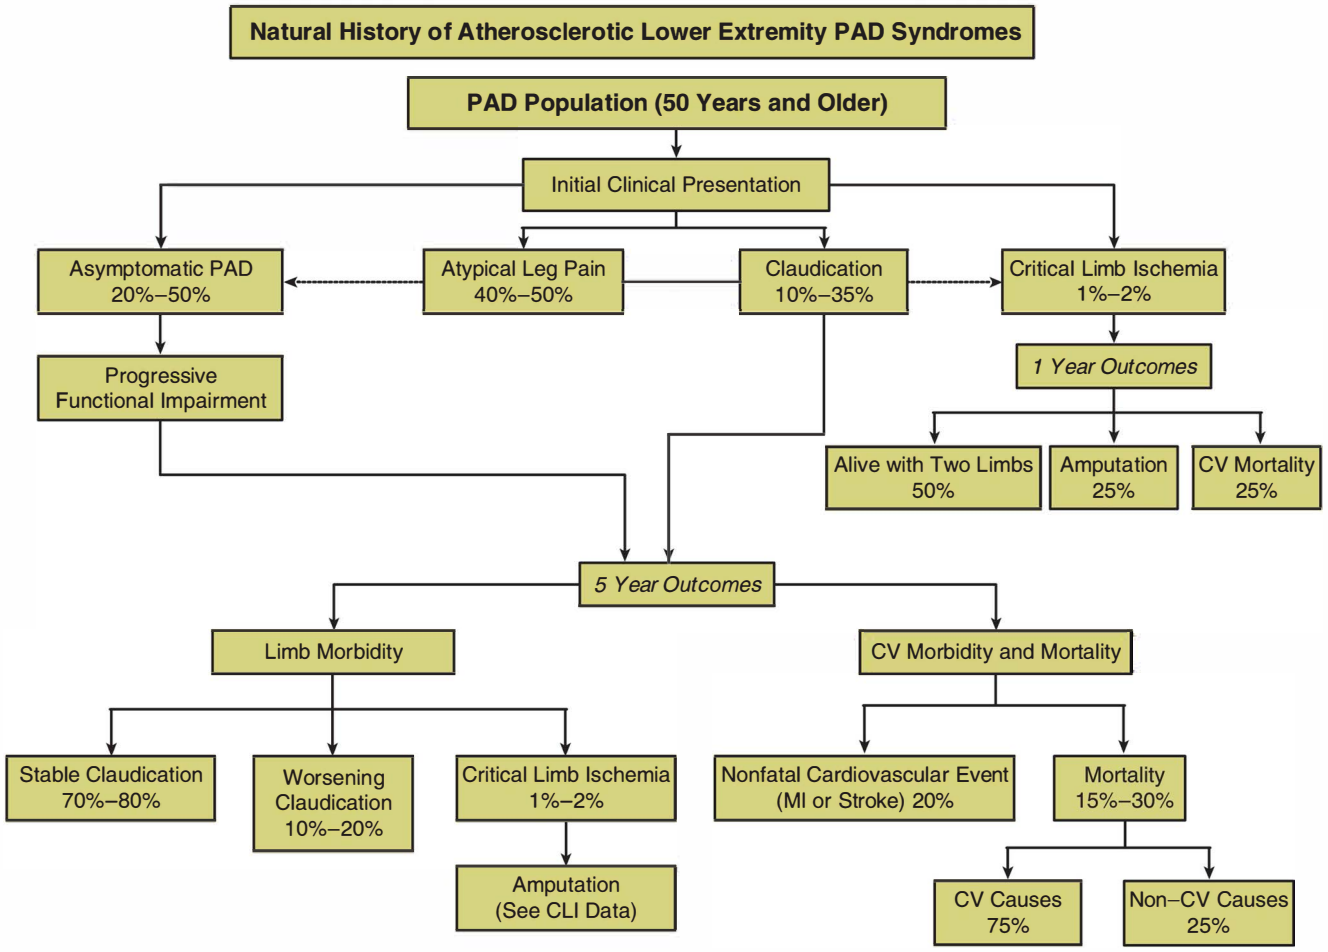

FIGURE 94.4 Natural history of lower extremity PAD. Individuals may be asymptomatic or present with symptoms of leg pain or CLI. All individuals with PAD face a risk of progressive limb ischemia symptoms, increased cardiovascular ischemic event rate, and increased mortality. CV, cardiovascular; MI, myocardial infarction. (Reprintedfrom Hirsch AT, Haskal JZ, Hertzer NR, et al. ACC/AHA 2005 practice guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic). *Circulation* 2006;113:e462–e654, with permission. ©2006 American Heart Association, Inc.)

addition, smoking directly influences atherosclerosis by causing endothelial dysfunction, inflammation, and coagulation within the vascular bed.[21] Individuals who smoke are at risk for cardiovascular events, such as sudden cardiac death, nonfatal myocardial infarction, and ischemic stroke. Active smokers are at a 4.6-fold increased risk of developing PAD compared to nonsmokers,[14] and smoking is associated with a threefold increased risk of CLI, with both PAD severity and progression directly correlated to the number of cigarettes consumed.

Diabetes is a strong modifiable risk factor for PAD, associated with a 2.71-fold increased risk.[14,22] In the Framingham registry, men were at a twofold increased risk for stroke in the presence of PAD and diabetes compared to either disease alone, and women with diabetes and claudication symptoms were at a three- to fourfold increased risk for coronary artery disease, stroke, and heart failure.[22,23] The presence of diabetes signifies a more aggressive course of PAD, with diabetic patients at a 5- to 10-fold increased risk for major limb amputation compared to those without diabetes.[16]

Several mechanisms have been proposed to explain the aggressive nature of vascular disease observed in diabetics. Clustering of cardiovascular risk factors, such as hypertension and dyslipidemia, partly account for the increased cardiovascular event rate. Patients with diabetes frequently develop dyslipidemia secondary to insulin resistance, resulting in decreased HDL, with increased LDL and triglycerides.[24] Significant deleterious effects on vascular biology also occur in the setting of insulin resistance and hyperglycemia.[25] Increased oxidative stress and platelet activation occur in the setting of hyperglycemia, placing patients with diabetes at increased risk for vascular thrombotic events. Negative effects of insulin resistance on SMC proliferation and cellular apoptosis promote further atherosclerosis progression. The development of endothelial dysfunction can impair cellular glucose transport, potentially leading to further insulin resistance and worsening diabetes.[26] Clinical studies support the causal relationship of hyperglycemia, insulin resistance, and accelerated atherosclerosis, as reflected by a direct correlation of cardiovascular disease with glycosylated hemoglobin levels in diabetic populations.[27]

Dyslipidemia: Patients with PAD demonstrate significant abnormalities in lipid metabolism; however, the associated risk appears to be lower compared to other vascular risk factors such as diabetes or smoking. In the NHANES registry, hypercholesterolemia (defined as a total cholesterol level 240 mg/dL [6.2 mmol/L]) was associated with a 1.68-fold increase in the prevalence of PAD.[14] Abnormalities in total cholesterol, LDL, very low-density lipoprotein, and lipoprotein (a) levels are associated with PAD, while serum triglyceride levels are only modestly associated with PAD.[28,29]

Hypertension results in a 1.5- to 2-fold relative risk (RR) increase for PAD.[14] Hypertension significantly alters vascular through increased endothelial dysfunction, loss of precapillary networks, and increased microvascular vasoconstriction in hypertensive animal models; all of which beget further increases in blood pressure, promoting both atherosclerosis and thrombosis.

Advanced age represents a risk factor for cardiovascular events and worse clinical outcomes in patients with established PAD. In the SMART registry of patients with symptomatic PAD, each 10-year increase in age was associated with a 1.85-fold risk increase in fatal and nonfatal vascular events.[30]

Genetic risk: The genetic contribution to PAD has not been clarified to the same extent as in other cardiovascular diseases. Several family studies suggest that PAD is in part related to genetic risk, estimating that genetic variation accounts for 21% to 48% of the interindividual variability in the ABI.[31] Genome-wide association studies have enabled further insight into the role of common genetic variants in cardiovascular disease. The genetic epidemiology network of arteriopathy study demonstrated that PAD (identified as a reduction in the ABI) was modestly heritable in African American and white hypertensive populations. Single-nucleotide polymorphisms (SNPs) associated with PAD were observed in several loci, but no single SNP reached genome-wide significance ($P \leq 5 \times 10^{-8}$).[32] A common variation of the chromosome 9p21 allele has been associated with several forms of vascular disease, particularly myocardial infarction and stroke.[33–36] In elderly individuals, Cluett et al.[37] demonstrated a modest association between the 9p21 allele and PAD detected by ABI (odds ratio [OR] 1.29, 95% CI 1.06 to 1.56). Further studies are necessary to identify common genetic variants associated with PAD development and to clarify the role of genetic testing in risk stratification of PAD patients.

DIAGNOSIS OF PAD

Symptoms of PAD

Approximately, 20% to 50% of individuals with PAD do not report any disease-related symptoms.[17] The classic symptom of PAD is intermittent leg claudication, occurring as the initial presenting complaint in 10% to 35% of patients. Caused by flow-limiting vascular stenosis, intermittent claudication is characterized by pain due to reversible muscle ischemia during activity, improving with rest.[38] Typically, claudication symptoms occur in the calves, although patients may also present with upper leg, hip, or buttocks pain. Patients frequently experience reduced exercise performance, and symptoms may potentially become debilitating.

With worsening PAD severity, CLI may develop. CLI reflects a state of persistent, reduced perfusion at rest, and is characterized by the presence of resting claudication occurring for >2 weeks, or the development of ischemia-related lesions, such as arterial ulcers or gangrene (FIGURE 94.5). Both the Fontaine

and Rutherford classification systems may be used to organize PAD severity systematically based on the degree of leg ischemia (Table 94.1). Individuals who present with symptoms suggestive of intermittent claudication or CLI should undergo objective testing to confirm the presence of PAD. Acute limb ischemia (ALI) occurs due to a sudden interruption of the blood flow to an extremity, with patients presenting with a combination of limb pain, pallor, pulselessness, paresthesia, or paralysis signifying threatened limb viability.[16]

Ankle–Brachial Index

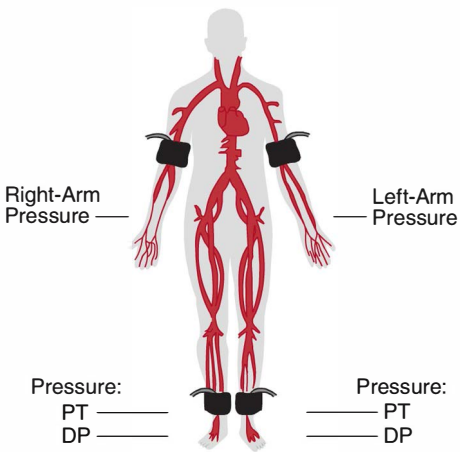
The ABI is the primary test used for the diagnosis of PAD. The ABI represents the ratio of the systolic blood pressure recorded in the brachial artery of either upper extremity to the systolic pressure recorded in either lower extremity (using the posterior tibial or dorsalis pedis artery), measured noninvasively (FIGURE 94.6). The ABI is typically measured by Doppler ultrasonography; however, studies show comparable results with auscultation techniques.[39] The ABI is an accurate measure of PAD, with value of ≤0.90 demonstrating a 95% sensitivity and >95% specificity for detecting angiographically significant arterial stenoses.[40,41] The ABI can also be used to further classify individuals into those with mild (ABI = 0.9 to 0.71), moderate (ABI = 0.70 to 0.41), or severe (ABI ≤ 0.4) disease.[25,42]

An abnormal ABI is associated with an increased mortality and a higher incidence of major adverse cardiovascular events, with lower ABI indexes predictive of a worse clinical outcome (FIGURE 94.7).[43–47] In a meta-analysis of 16 studies, the use of the ABI in asymptomatic patients altered the cardiovascular risk profile for 1-in-5 men and 1-in-3 women, when added to the Framingham risk score.[48] An ABI index >1.3 may represent a calcified and noncompliant artery and is also associated with increased vascular events, which should prompt further investigations (such as pulse volume recording, toe–brachial index measurement, or duplex ultrasound) to determine if PAD is

FIGURE 94.6 Measurement of the ABI. DP, dorsal pedis artery; PAD, peripheral arterial disease; PT, posterior tibial artery. (Adapted from Topol EJ, Califf RM, et al. *Textbook of cardiovascular medicine*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

ABI	Severity of Disease
0.91–1.3	Normal
0.71–0.90	Mild Disease
0.41–0.70	Moderate Disease
≤0.40	Severe Disease

ABI is 95% Sensitive and 99% Specific for PAD



$$\text{ABI} = \frac{\text{Lower Extremity Systolic Pressure}}{\text{Brachial Artery Pressure}}$$

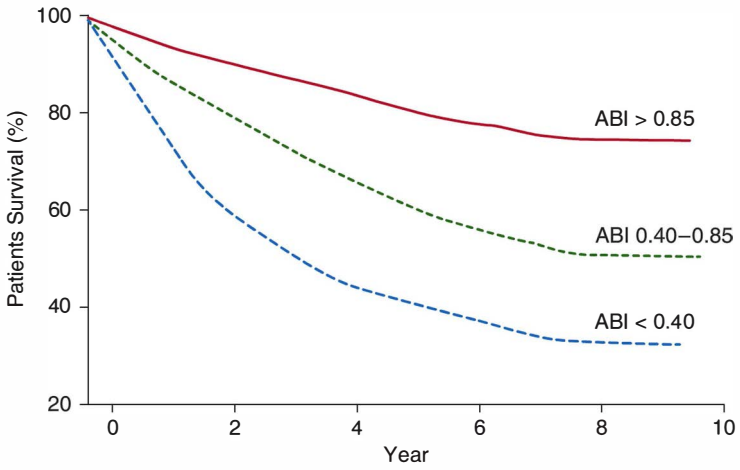


FIGURE 94.7 Survival with PAD severity based on the ABI. (From Topol EJ, Califf RM, et al. *Textbook of cardiovascular medicine*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

present.[42] Due to the accuracy of the ABI in predicting PAD, and the increased cardiovascular risk associated with an abnormal ABI measurement, patients who are asymptomatic with an ABI ≤0.9 should undergo lifestyle and pharmacologic risk factor modification in accordance with a diagnosis of vascular disease.

Additional Functional Modalities

In patients with suspected PAD but normal ABI measurements, additional measures may be performed to confirm the diagnosis, including ABI measurements after exercise, toe–brachial index, and pulse volume recording.[49] The toe–brachial index may be performed in symptomatic patients with calcified, noncompressible proximal arteries causing either a "false-negative" or significantly elevated ABI. A small occlusive cuff is placed on the great toe, with the systolic blood pressure recorded at the point when pulsatile flow is first detected by plethysmography. A toe–brachial index of <0.7 is considered specific for PAD.[17]

Pulse volume recording involves the measurement of the pulse amplitude and contour in the proximal and distal lower extremities using noninvasive thigh and ankle cuffs, with abnormalities in the lower extremity pulse amplitude or contour signifying reduced arterial blood flow.[50] The brachial artery pulse volume is recorded simultaneously as a measure of normal flow. Segmental evaluation of the lower extremities by continuous-wave Doppler ultrasound can further assist in PAD diagnosis. Abnormalities in Doppler morphology and the Doppler waveform pulsatility index suggest impaired arterial flow due to arterial stenosis.[17] Both pulse waveform and continuous Doppler can be used to establish a diagnosis of PAD in patients with equivocal ABI results, to follow PAD progression, and to potentially assess the effectiveness of revascularization.

Additional Imaging Modalities

Invasive angiography is the gold standard for the diagnosis of PAD and for the localization of arterial stenoses. However, with the introduction of accurate and readily available noninvasive imaging modalities, invasive angiography is becoming more commonly used in conjunction with revascularization, rather than to establish a diagnosis or guide treatment decisions.

Duplex ultrasonography utilizes both functional and anatomic imaging to evaluate for PAD. Markers of PAD by duplex ultrasonography include the presence of turbulent flow, alterations in Doppler waveform, and a peak-to-peak velocity ratio (measured within the obstruction and distally) >2.[17] Although Duplex ultrasonography has >90% sensitivity and specificity for detecting a significant stenosis above the popliteal artery, its accuracy is reduced in the presence of poorly visualized vessels, or with multiple stenoses.[17]

Computed tomographic angiography (CTA) is being utilized with increasing frequency to diagnose PAD, with sensitivities ranging from 89% to 99% and specificities from 83% to 100%.[51] Compared to conventional angiography, CTA allows for fast acquisition of accurate images in a noninvasive manner, although the risks related to radiation exposure and contrast-induced nephrotoxicity remain.[52] Magnetic resonance angiography (MRA) provides accurate localization of arterial stenoses noninvasively, without exposure to radiation, and may be used to diagnose PAD or to select potential candidates for revascularization (FIGURE 94.8). Disadvantages of MRA include long acquisition times, reduced diagnostic accuracy with infrapopliteal arterial segments, and the risks of renal toxicity and nephrogenic systemic fibrosis with gadolinium in patients with preexisting renal insufficiency.[51] A meta-analysis of 23 studies demonstrated that the accuracy of MRA to detect obstructive PAD has improved with advancing technology; for the detection of a >50% stenosis on invasive angiography, two-dimensional time-of-flight MRA had a sensitivity of 64% to 100% and a specificity of 68% to 96%; with three-dimensional gadolinium-enhanced MRA, the sensitivity and specificity improved to 92% to 100% and 91% to 99%, respectively.[53] While the ABI remains the primary test to diagnose PAD, several noninvasive functional and imaging modalities are available to establish a diagnosis with equivocal ABI results, and to identify potential candidates for revascularization.

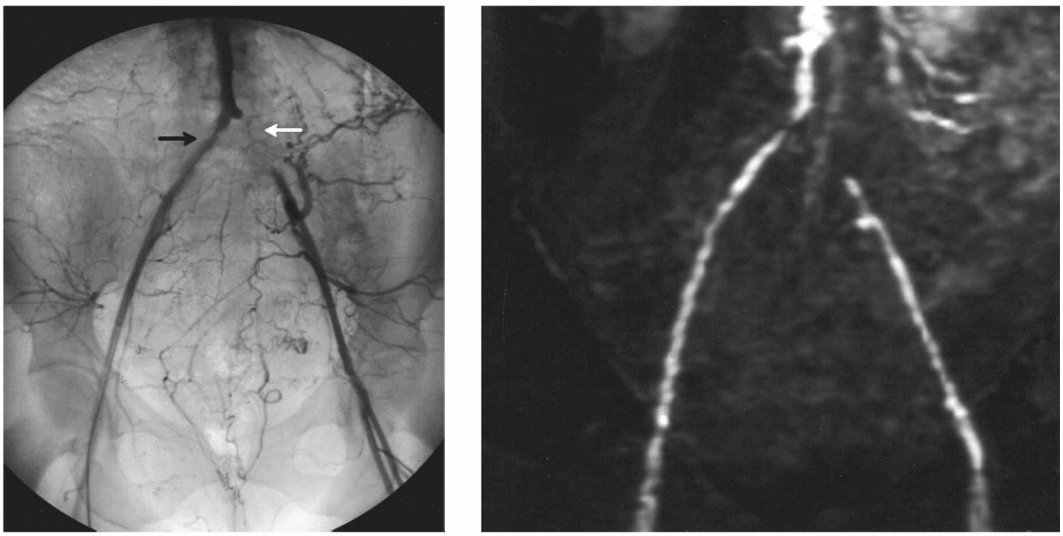

FIGURE 94.8 **A:** Pelvic arteriogram of a 75-year-old female with bilateral hip claudication. The study demonstrates diffuse infrarenal aortic atherosclerosis, right common iliac artery stenosis (*black arrow*), and left common iliac artery occlusion (*white arrow*) with external iliac artery reconstitution via collaterals. **B:** Corresponding MRA with 2-D gadolinium-enhanced technique. (From Baim DS. *Grossman's cardiac catheterization, angiography, and intervention*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

TREATMENT OF PATIENTS WITH PAD

The primary goals for PAD management are to reduce cardiovascular events and to improve PAD-related symptoms. Secondary prevention of cardiovascular disease is achieved through lifestyle modification and medical therapy (Table 94.2). This section focuses on (a) medical management to reduce cardiovascular risk, (b) the medical and surgical management of symptomatic PAD with respect to intermittent claudication, and (c) specific management issues surrounding CLI and ALI. A summary of the management of asymptomatic and symptomatic patients with PAD is shown in FIGURE 94.9.

CARDIOVASCULAR RISK MODIFICATION

Antiplatelet Therapy

Platelet activation is a crucial component of vascular atherothrombosis and mediated by several compounds including thromboxane A_2, adenosine diphosphate (ADP), serotonin, and norepinephrine.[54] The antiplatelet therapies most extensively studied in PAD are acetylsalicylic acid (aspirin) and thienopyridines (clopidogrel and ticlopidine). Aspirin reduces platelet activation through the inhibition of cyclooxygenase, a crucial enzyme for the synthesis of thromboxane A_2. Thienopyridines impair binding of ADP to the $P2Y_{12}$ receptor, consequently inhibiting platelet activation through the ADP pathway.

Antiplatelet therapy is primarily utilized to reduce the risk of cardiovascular events in patients with PAD. A large meta-analysis by the Antiplatelet Trialists collaboration involving 287 studies examined the effects of antiplatelet agents on cardiovascular outcomes in patients with a history of vascular disease. In a subgroup analysis of 42 studies involving 9,214 patients with PAD, antiplatelet therapy (primarily aspirin, alone or in combination with dipyridamole) was associated with a 23% odds reduction in subsequent vascular events.[55] In a recent meta-analysis of 18 randomized studies involving 5,269 patients with PAD, Berger et al.[56] reported a significant reduction in nonfatal cerebrovascular events with aspirin therapy compared to placebo (RR 0.66, 95% CI 0.47 to 0.94). However, no significant differences were demonstrated for all-cause mortality, cardiovascular mortality, nonfatal myocardial infarction, or bleeding. Although numerous studies have reported significant improvements in various cardiovascular endpoints with aspirin therapy, recent evidence suggests that the overall cardiovascular benefits demonstrated with aspirin may not be applicable to very low-risk patients who have asymptomatic PAD without concomitant cardiovascular disease. A large, randomized control trial of 28,980 patients with asymptomatic PAD (diagnosed by an ABI of <0.95) failed to demonstrate a reduction in cardiovascular events in participants treated with aspirin 100 mg daily compared to placebo.[57] However, the low overall mortality rate (1.9%) and mean ABI score (0.86) in the trial suggests a lower risk population compared to those evaluated in previous studies. In PAD patients undergoing revascularization, aspirin improves vessel patency after lower extremity bypass or percutaneous angioplasty. Overall, aspirin is recommended as first-line antiplatelet therapy for the majority of patients with a diagnosis of PAD.

Thienopyridines also benefit patients with PAD. The CAPRIE study showed an 8.7% RR reduction in vascular events with clopidogrel compared to aspirin therapy in patients with atherosclerotic vascular disease, including PAD.[58] The greatest benefit was demonstrated within the PAD subgroup, achieving a 23.8% RR reduction in vascular events. Thienopyridines also improve symptoms related to PAD. In a randomized study of 151 PAD patients with intermittent claudication, Balsano et al.[59] reported an improved ABI index, pain-free walking distance, and maximal walking distance with ticlopidine compared to placebo. Current guidelines support the use of clopidogrel as

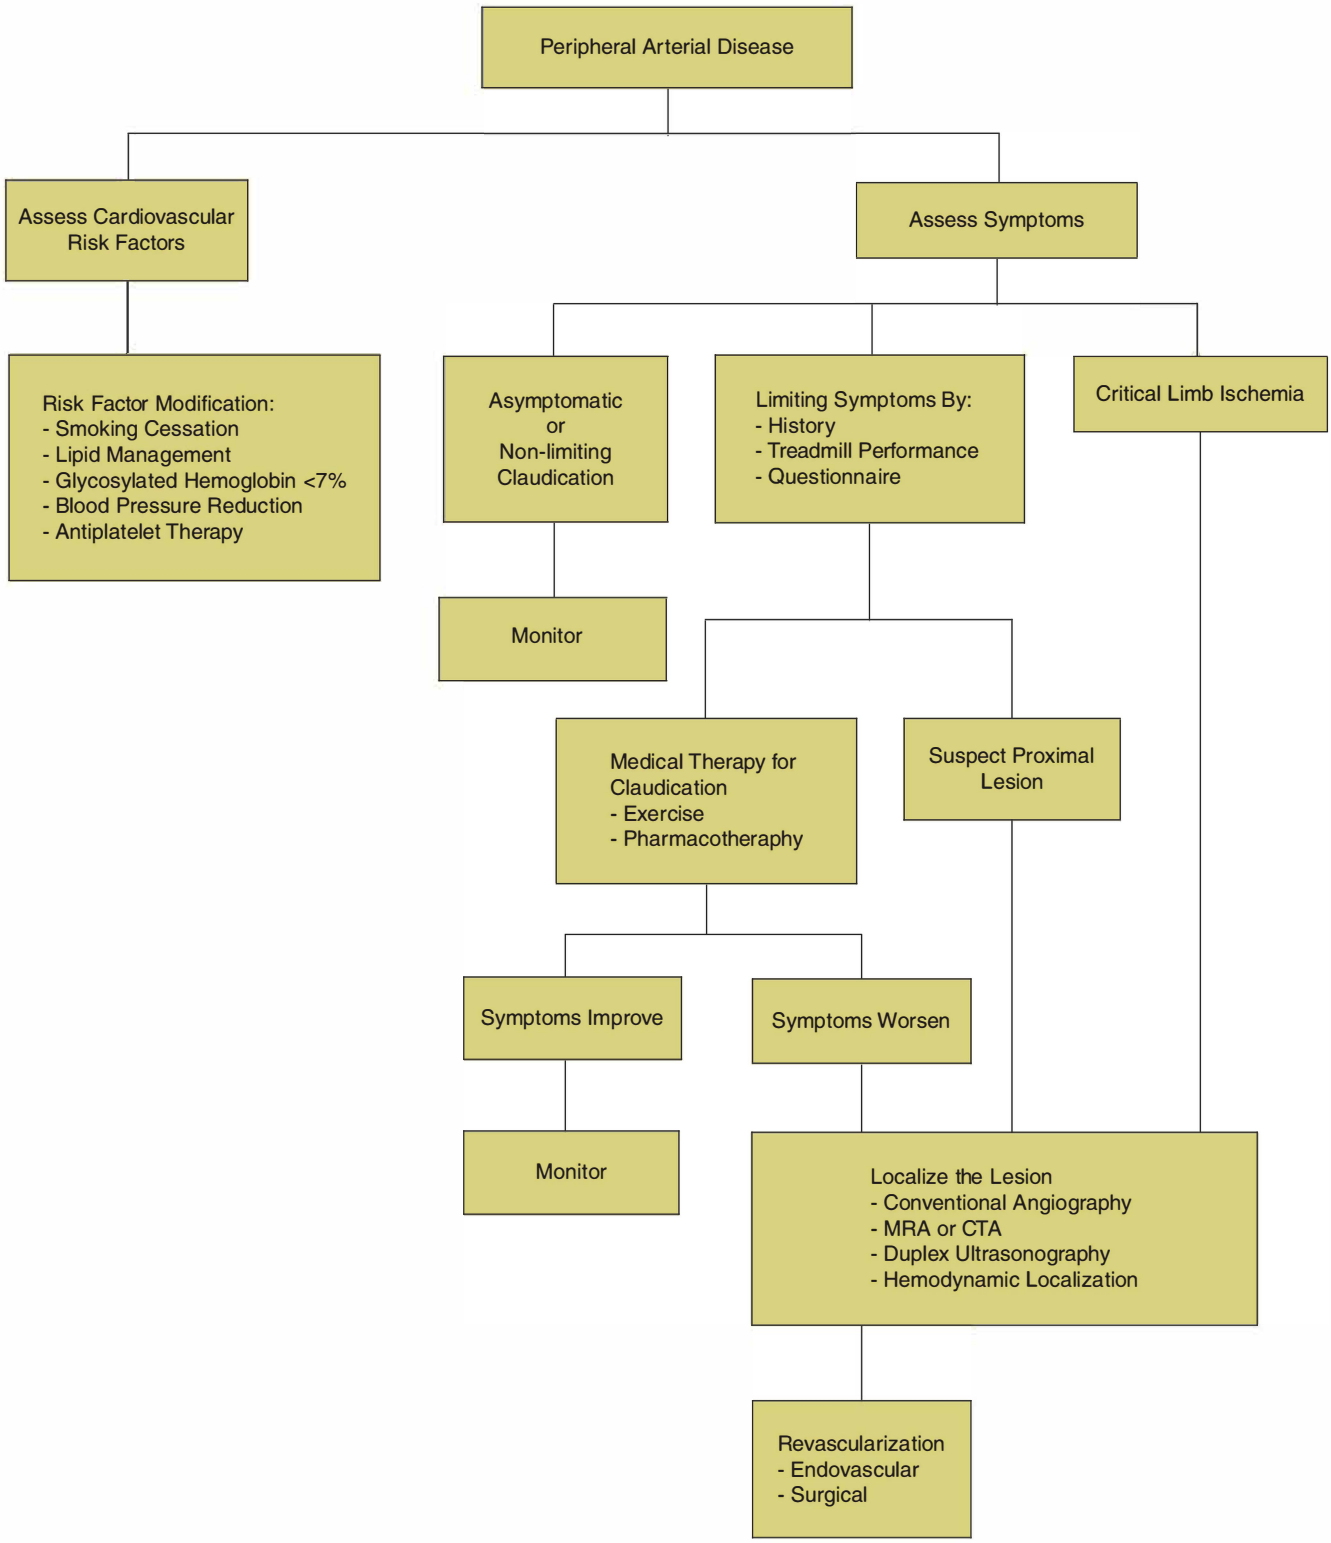

FIGURE 94.9 Overview of the management of patients with asymptomatic PAD, intermittent claudication, or CLI. (Adapted from Hiatt WR. Medical treatment of PAD and claudication. *N Engl J Med* 2001;344(21):1608–1621, with permission. © 2001, Massachusetts Medical Society. All rights reserved.)

Table 94.2

Treatment guidelines for cardiovascular risk reduction in patients with PAD

Treatment	Goals of Management
Smoking cessation	• Always address smoking cessation in PAD • Both nonpharmacologic and pharmacologic methods may be utilized
Antiplatelet therapy	• Antiplatelet therapy should be considered in all PAD patients • Aspirin (81mg daily) is the preferred antiplatelet agent • Clopidogrel (75 mg daily) may be considered as an alternative
Lipid reduction	• LDL reduction to <2.59 mmol/L (100 mg/dL) in all PAD patients • Consider further LDL reduction to <1.8–2 mmol/L (70–78 mg/dL) • HMG coenzyme A reductase inhibitors (statins) are first-line therapy for treatment of dyslipidemia in PAD
Diabetes control	• Target HbA1C level of <7.0%
Blood pressure reduction	• Target blood pressure <140/90 in PAD • Consider further reduction of blood pressure to <130/80 in patients with coexisting renal failure or diabetes • Consider ACE inhibitor for blood pressure reduction and cardiovascular protection

PAD, peripheral arterial disease; LDL, low-density lipoprotein; HbA1C, hemoglobin A1C; ACE, angiotensin-converting enzyme.

an alternative antiplatelet agent to aspirin for cardiovascular risk reduction in patients with PAD. The development of severe neutropenia, a potentially fatal side effect, has been reported in 2.1% of patients prescribed ticlopidine, which has significantly limited its use in clinical practice.[60]

The use of dual antiplatelet therapy to reduce secondary events in patients with established cardiovascular disease remains controversial. The CHARISMA study is the largest randomized trial which evaluated dual antiplatelet therapy with aspirin and clopidogrel in patients with known vascular disease or multiple vascular risk factors.[61] Dual antiplatelet therapy did not reduce cardiovascular events compared to aspirin alone and was associated with a significant increase in bleeding events. Given the results of CHARISMA, there is currently insufficient evidence to support the routine use of dual antiplatelet therapy in patients with PAD without secondary indications (i.e., post-myocardial infarction or vascular stent implantation).

Anticoagulant Therapy

While a theoretical rationale exists for improved antithrombotic effects with the addition of an oral anticoagulation agent to antiplatelet therapy, studies examining the combination have failed to demonstrate a benefit and have shown increased bleeding. The WAVE study compared the combination of warfarin and antiplatelet therapy to antiplatelet therapy alone in patients with a history of PAD.[62] Combination therapy did not reduce cardiovascular events and was associated with increased life-threatening bleeding. Combination therapy has also been studied for the prevention of graft occlusion in patients following peripheral bypass surgery with either venous or arterial grafts. In the Dutch BOA study, there were no significant differences in cardiovascular events or limb salvage with combination therapy compared to antiplatelet therapy alone in patients undergoing infrainguinal bypass.[63] Although the Dutch BOA study reported fewer ischemic events with combination therapy in patients with venous grafts, other studies have not demonstrated similar results.[64] Currently, the routine use of anticoagulants in addition to antiplatelet therapy is not recommended for routine use in patients with PAD to reduce cardiovascular risk or prevent graft occlusion.

Lipid-Lowering Therapy

As patients with PAD are a high-risk population for major cardiovascular events, aggressive lipid management is recommended. HMG coenzyme A reductase inhibitors (statins) are the principal agents for risk reduction in patients with vascular disease, with each reduction of 1 mmol/L of LDL with statin therapy associated with a 20% reduction in cardiovascular events.[65] Large randomized control trials demonstrate profound benefits with statin therapy in patients with cardiovascular disease or vascular risk factors. The Heart Protection Study compared simvastatin 40 mg to placebo in 20,536 individuals with cardiovascular disease, including 6,748 patients with PAD.[66] Simvastatin was associated with significant reduction in all-cause mortality (12.9% vs. 14.7%, $P = 0.0003$), primarily driven by a decrease in coronary-related death (5.7% vs. 6.9%, $P = 0.0005$). Moreover, aggressive lipid control provides further benefit compared to moderate lipid control in patients with cardiovascular disease. The Treat to New Targets study reported significant improvements in cardiovascular events with a reduction in LDL to <1.8 mmol/L (<70 mg/dL), compared to moderate LDL control in patients with coronary artery disease (RR 0.78, 95% CI 0.69 to 0.89).[67] Current PAD guidelines recommend aggressive LDL reduction in PAD patients to <2.59 mmol/L (100 mg/dL).[16] A number of lipid guidelines advocate for even lower LDL targets to <1.8 to 2.0 mmol/L (70 to 77 mg/dL) in patients with established vascular disease.[65]

Clinical studies suggest that statins may improve cardiovascular outcomes by reducing vascular inflammation, an important mediator of atherosclerosis progression. The PROVE-IT study reported significant reductions in C-reactive protein (CRP) levels with high-dose compared to low-dose statin therapy amongst 3,745 patients presenting with acute coronary syndromes who were followed over a mean period of 24 months. Patients with a reduced CRP had significantly fewer cardiovascular events compared to those with an increased CRP, regardless of LDL concentration.[68] Complementary results were reported in the REVERSAL study, which examined the effects of high-dose statin therapy on atherosclerosis progression in CAD patients by coronary intravascular ultrasound.[69] Participants who received high-dose statin therapy had reduced coronary atherosclerosis progression compared to those who received moderate-dose statin therapy, atheroma progression being directly related to changes in both LDL and CRP. Both PROVE-IT and REVERSAL provide support for the additional vascular benefits statins provide as potent mediators of vascular inflammation. Statin therapy also exerts positive effects on endothelial activity, likely mediated through increased endothelial nitric oxide synthase expression.[70,71] Tsunekawa et al.[72] demonstrated increased brachial artery flow-mediated vasodilation and plasma nitrate levels in prediabetic patients treated with statin therapy compared to placebo. Additional proposed vascular effects of statins include decreased oxidative stress through the downregulation of angiotensin II and NAD(P)H oxidase; and the stimulation of circulating endothelial progenitor cells which assist in ischemic tissue neorevascularization and repair.[73] In addition to cardiovascular risk reduction, several studies have reported improvements in claudication symptoms and walking performance with statin therapy in patients with PAD.[74–76]

Individuals with PAD frequently have further disorders of lipid metabolism, such as reduced HDL and elevated triglycerides. Although epidemiologic studies have demonstrated that both HDL and triglyceride disorders are associated with increased cardiovascular events, there is limited evidence supporting targeted therapy to improve HDL or triglycerides in the current era of aggressive LDL lowering using statin therapy. Lifestyle modifications, including exercise and weight loss, have beneficial effects on both HDL and triglycerides. Niacin therapy can increase HDL up to 15% to 25%, and reduce LDL by an additional 20% in patients, and may be considered as a second agent in patients with persisting lipid abnormalities despite adequate statin therapy.[65] Niacin improves surrogate markers of cardiovascular disease such as carotid artery intimal thickness, although whether this translates to a reduction in cardiovascular events in patients already receiving statin therapy remains uncertain.[77] Fibric acid derivatives (fibrates) may be considered in patients with severe hypertriglyceridemia or those with persistently increased triglycerides despite statin therapy and lifestyle modification.

Blood Pressure Control

Aggressive blood pressure is recommended in all patients with vascular disease. The intersociety consensus for the management of PAD (TASC II) guidelines suggest that patients with PAD should have blood pressure controlled to <140/90, or <130/80, in the presence of diabetes or renal impairment.[16] Weight reduction, limitation of alcohol consumption, and dietary changes are important lifestyle modifications which reduce blood pressure. In separate populations of overweight individuals, a weight reduction of 10 lbs resulted in a significant reduction in blood pressure ranging from 5 to 20 mm Hg.[78–80] Maintenance of a normal body weight (BMI 18.5 to 24.9 kg/m^2) should be targeted in all patients to improve blood pressure and reduce overall cardiovascular risk.[80,81] Alcohol consumption should be limited to no more than 2 drinks per day in men, and no more than 1 drink per day in women.[80] Dietary salt intake should be limited to 65 to 100 mmol per day in hypertensive individuals. Consumption of a diet rich in fruits, vegetables, and low-fat dairy products with limited saturated fat has been shown to lower blood pressure.[80,82,83]

Several classes of medications may be used alone or in combination for hypertension treatment in patients with PAD. Angiotensin-converting enzyme (ACE) inhibitors and thiazide diuretics are considered first-line therapies for hypertension management in PAD patients. Ostergren et al.[84] evaluated the effects of ramipril in a subset of 3,099 patients with PAD enrolled in the HOPE study. Ramipril was associated with a 25% RR reduction in vascular events in individuals with clinical PAD, with similar benefits also demonstrated in those without clinical PAD but a reduced ABI. Long-acting calcium channel blockers and angiotensin receptor blockers (ARBs) can also be used as initial monotherapy for hypertension treatment. Despite previous concerns of worsening claudication symptoms with β-adrenergic blocking drugs, multiple studies have demonstrated their safety and effectiveness in patients with PAD.[16] However, the antihypertensive effects of β-adrenergic blocking drugs are diminished in patients >60 years of age. ACE inhibitors and ARBs should not be routinely used in combination due to the increased risks of renal dysfunction and hyperkalemia.

Diabetes Management

Several studies have demonstrated significant vascular benefits from aggressive glucose control in patients with diabetes. The Diabetes Control and Complications trial reported decreased microvascular complications (i.e., retinopathy and nephropathy) and a trend toward reduced macrovascular complications (i.e., stroke, myocardial infarction, claudication, amputation, and arterial events requiring peripheral bypass) with intensive glucose control in type I diabetic patients. The UK Prospective Diabetes Study demonstrated similar microvascular benefits with intensive glucose control in patients with type II diabetes. Although single studies have not demonstrated significant macrovascular benefits with intensive glucose control, a meta-analysis of five studies involving 32,629 individuals did report significant reductions in incident cardiovascular events (OR 0.89, 95% CI 0.83 to 0.95) and myocardial infarctions (OR 0.86, 95% CI 0.78 to 0.93) with intensive therapy.[85] Current guidelines suggest a target hemoglobin A1C (HbA1C) of <7% in patients with PAD and a history of diabetes.[16,86]

Two recent studies have evaluated the effects intensive glucose control to "near euglycemic" levels on cardiovascular outcomes in diabetic patients. Both the ADVANCE and ACCORD studies demonstrated no significant cardiovascular benefits with lowering the HbA1C to ≤6.5%, with intensive treatment associated with a higher overall mortality in ACCORD.[87,88] Given the marginal benefit and potential harm observed with aggressive antiglycemic treatment to a nearly euglycemic HbA1C level, there is insufficient evidence to support further treatment of

HbA1C levels when they are below 7%, as recommended in current guidelines. The presence of small vessel disease, associated peripheral sensory neuropathy, and severity of atherosclerosis in diabetic patients place them at an increased risk of arterial and foot ulcer development. Careful foot examinations and foot care education should be advocated for all individuals with diabetes, particularly for those with documented PAD.

Smoking Cessation

Observational studies have demonstrated significant beneficial effects with smoking cessation in patients with PAD including reduced stoke, myocardial infarction, symptoms of claudication and risk of amputation, and improved graft patency after peripheral bypass surgery.[89,90] Unfortunately, long-term smoking cessation is achieved in only 2.5% of individuals who do not utilize behavioral or pharmacologic aids.[91] All patients with PAD should be advised to quit smoking. Behavior therapy includes stress management, group therapy, identification of social cues that trigger smoking, and the development of coping strategies to aid quitting. Smoking cessation rates are significantly increased with the involvement of an expert, such as a smoking councilor or physician.[92,93]

Pharmacotherapy includes nicotine replacement therapy (NRT) and non-nicotinic treatment regimens. NRT is considered safe to use in patients with stable cardiovascular disease. NRT is currently available in the form of the patch, gum, nasal spray, and inhaler. A Cochrane review of 132 studies examining NRT on smoking abstinence reported significant improvements in smoking cessation rates compared to no treatment (RR 1.58, 95% CI 1.50 to 1.66). These benefits occurred across all forms of NRT.[94] Hajek et al. compared the efficacy and compliance rates of different forms of NRT over 12 weeks of therapy. The highest compliance was reported with the nicotine patch (82%), followed by the nicotine gum (38%), nicotine spray (15%), and nicotine inhaler (12%), although there were no significant differences in overall smoking cessation rates with any form of NRT.[95]

Non-nicotinic therapies approved for smoking cessation are bupropion SR (Wellbutrin SR, Zyban) and varenicline (Champix). Studies have reported improved quitting rates in patients prescribed bupropion combined with behavior therapy. Moreover, the combination of bupropion and NRT is safe and may result in improved smoking cessation compared to each product individually.[95] Varenicline is a high-affinity $\alpha_4\beta_2$ partial agonist that promotes dopamine release and reduces nicotine craving and has been compared for up to 52 weeks of therapy with bupropion, or placebo in active smokers attempting to quit.[96] Varenicline was associated with improved abstinence from smoking compared to bupropion and placebo during the 12-week active therapy and at 24-week follow-up, but at 52 weeks, there was no significant differences in smoking cessation rates for patients who had previously received varenicline or bupropion. With the addictive properties and behavioral dependencies associated with smoking, long-term compliance remains a challenge.

MANAGEMENT OF PAD SYMPTOMS

Initial medical strategies for symptomatic PAD management involve pharmacologic therapies and lifestyle modification to improve claudication symptoms and exercise tolerance. Percutaneous or surgical revascularization procedures are reserved for patients who do not respond adequately to medical therapy, or in the management of proximal lower extremity stenosis (i.e., iliac or femoral involvement). This section discusses medical and revascularization options for patients with PAD with respect to symptoms of intermittent claudication. The treatment of CLI and ALI differ significantly and will be discussed in subsequent sections.

MEDICAL MANAGEMENT OF INTERMITTENT CLAUDICATION

Supervised Exercise Rehabilitation

Exercise can alleviate claudication symptoms through several potential mechanisms, including improved endothelial function, improved oxidative metabolism and oxygen extraction, increased ischemia threshold, reduced inflammation, and further optimization of atherosclerotic risk factors (e.g., hypertension, obesity, and dyslipidemia).[97] Several studies have reported significant benefits associated with exercise on claudication relief and functional improvement in patients with PAD. Supervised programs have shown more benefit than unsupervised regimens. A meta-analysis of 21 studies examining exercise in patients with claudication demonstrated improved distance to onset of claudication pain and distance to maximal claudication pain with supervised exercise rehabilitation. Exercise duration >30 minutes, frequency >3 times per week, program duration >6 months, walking as the primary mode of exercise, utilizing increased pain thresholds for cessation of activity, and supervised lower extremity resistance training were associated with the greatest improvements in PAD symptoms. A recent randomized control study demonstrated significant improvements in maximal walking distance and overall physical functioning with treadmill exercise and resistance training, compared to the control group, in 156 patients with asymptomatic or symptomatic PAD.[98]

A typical supervised exercise program consists of walking with a treadmill for three sessions per week, with each session ranging from 30 minutes to 1 hour in duration.[16] Treadmill intensity is modified to elicit claudication symptoms between 3 and 5 minutes of exercise. Patients should engage in a cycle of walking until moderate claudication occurs, at which point they should stop until the pain has resolved, then resume exercising until symptoms recur. Once an exercise can be performed for 10 minutes without signs of claudication, the intensity can be increased. Patients with PAD may have several barriers to participating in supervised exercise rehabilitation, including severe symptoms of claudication, coexisting angina, musculoskeletal impairments, facility distance, and financial constraints. One small study has shown the clinical utility of arm ergometry in patients with PAD, which may be used as an alternative to treadmill exercise in patients with limited mobility.[99]

Cilostazol

Cilostazol promotes arterial vasodilation through the inhibition of phosphodiesterase III. Secondary effects include inhibition of platelet aggregation, *in vitro* inhibition of vascular SMCs, and marginal benefits on lipid metabolism. A 2002

meta-analysis involving 1,751 patients concluded that cilostazol was associated with a significant increase in maximal treadmill performance from baseline (100 ± 143 vs. 50 ± 127 m, $P < 0.001$) compared to placebo.[100] Similar results were obtained in a Cochrane meta-analysis involving seven studies, which reported improved initial distance to the onset of claudication symptoms with cilostazol compared to placebo.[101] The most frequently studied dose of cilostazol (100 mg twice daily) resulted in an improvement of the initial claudication distance of 31 m (95% CI 21.3 to 40.9 m). A randomized study conducted by Dawson et al.[102] in 698 patients with symptomatic PAD showed that cilostazol was associated with a significant improvement in the mean distance to the onset of claudication, while no improvement was noted with pentoxifylline (218 m for cilostazol vs. 202 m for pentoxifylline, $P = 0.0001$). Fewer patients experienced deterioration or had no change in walking distance with cilostazol (23% vs. 34%). Studies examining cilostazol have not demonstrated any differences in cardiovascular events or overall mortality compared to placebo. Cilostazol is contraindicated in PAD patients with coexisting congestive heart failure. For patients who have limiting claudication despite antiplatelet therapy, risk factor optimization, and lifestyle modification, PAD guidelines suggest a 3- to 6-month course of cilostazol for symptom relief.[16]

Naftidrofuryl

Naftidrofuryl is a 5-hydroxytryptamine type II antagonist that inhibits the effects of serotonin.[103,104] Although the precise mechanism of its vascular effects remains elusive, increased aerobic tissue metabolism, vasodilation, and decreased platelet aggregation through the secondary expression of type II nitric oxide synthase have been observed Kieffer el al.[105] demonstrated a 92% improvement in pain-free walking distance and an 83% improvement in maximum walking distance in patients treated with naftidrofuryl. Similar benefits were reported in a Cochrane meta-analysis of 1,083 patients with symptomatic PAD treated with naftidrofuryl compared to placebo.[104] Naftidrofuryl was associated with a significant improvement in pain-free walking distance, with a number need to treat of 4.48 patients to achieve a benefit in claudication symptoms. Side effects of naftidrofuryl include hepatitis, dizziness, and headache.[106] Naftidrofuryl is not recommended in patients with hyperoxaluria or kidney stones. PAD guidelines suggest that naftidrofuryl can be used as an alternative to cilostazol in patients with claudication.[16]

Pentoxifylline

Pentoxifylline is a methylxanthine derivative, which improves blood viscosity and vascular blood flow by decreasing red blood cell rigidity. The use of pentoxifylline for the relief of claudication remains controversial. Several small studies have shown modest improvements in maximal walking distance with pentoxifylline compared to placebo, but the previously described study by Dawson et al.[102] examining pentoxifylline, cilostazol, and placebo in patients with claudication demonstrated no improvement in maximal walking distance with pentoxifylline. Moreover, current studies provide limited knowledge regarding the safety profile and frequency of side effects with pentoxifylline. Therefore, further studies examining the benefits and risks of pentoxifylline are required to determine its clinical utility in patients with symptoms of intermittent claudication.

PERCUTANEOUS REVASCULARIZATION FOR SYMPTOMATIC PAD

Percutaneous Endovascular Interventions

Percutaneous endovascular interventions are recommended for patients with limiting symptoms of claudication who have had an inadequate response to exercise rehabilitation and pharmacologic therapy.[17] These procedures include percutaneous transluminal angioplasty with ballooning, endovascular stenting, and atheroma debulking procedures.[16] Endovascular procedures displace or remove atheromatous plaque obstructing the vessel lumen, resulting in improved vascular blood flow that can relieve claudication symptoms. However, vascular injury and remodeling also occur, which may result in postprocedural vessel thrombosis or recurrent stenosis (FIGURE 94.10). Mechanical forces created during the procedure cause endothelial disruption with subsequent platelet activation and activation of coagulation. Studies have demonstrated elevations in several markers of thrombosis after intervention, including the thrombin–antithrombin complex, D-dimer, fibrinopeptide A, thrombomodulin, and von Willebrand factor.[107–110] With the activation of platelets and procoagulants, the risk of vessel thrombosis is increased in patients during the acute period (<30 days) following intervention.[111] Vessel restenosis occurs in 30% to 50% of patients after balloon angioplasty and is the consequence of three primary mechanisms: elastic arterial recoil, negative remodeling, and excessive SMC proliferation within the vessel intima.[112,113] While endovascular procedures generally achieve high periprocedural success rates, maintaining vessel patency by preventing vessel thrombosis or restenosis remains a challenge.

Patient Selection for Endovascular Intervention

Procedural success is heavily dependent on appropriate patient selection. Short- and long-term outcomes after the intervention are dependent on lesion type, lesion location, and clinical factors. TASC II guideline categorizes aortoiliac and femoral–popliteal lesions separately into four anatomic types based on length and complexity (Tables 94.3a and 3b).[16] Endovascular intervention is primarily utilized for type A and B lesions, although type C lesions are treated with increasing frequency. Long-term vessel patency is highest with revascularization of iliac stenosis compared to infrainguinal disease (i.e., common femoral, superficial femoral, and infrapopliteal arteries). A systematic review by Kandarpa et al.[114] examined initial and long-term vessel patency rates in patients undergoing percutaneous transluminal balloon angioplasty for PAD. The initial success of angioplasty in iliac disease was 91%, with a 4-year vessel patency rate of 58%. Angioplasty of infrainguinal disease had slightly inferior outcomes, with initial and 4-year vessel patency rates of 89% and 49%, respectively. Several factors unique to infrainguinal disease act to decrease vessel patency after endovascular procedures. These include a higher frequency of multiple arterial occlusion levels, biomechanical forces within the arterial tree influencing vessel patency, and poor distal run-off to the site of stenosis.[115] Reduced vessel patency is observed at a higher

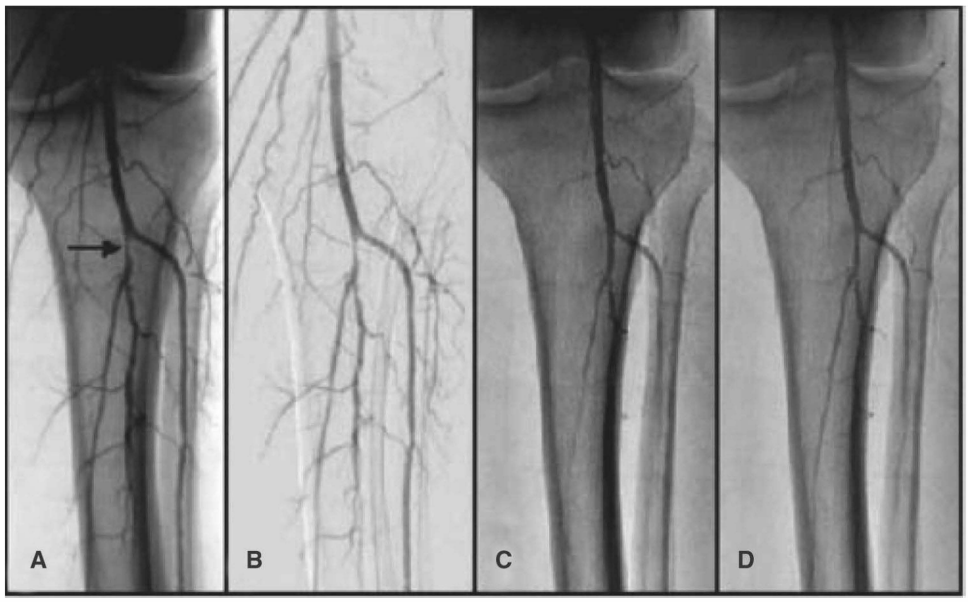

FIGURE 94.10 Infrapopliteal stenosis (**A**, *arrow*) causing lifestyle-limiting claudication. The lesion was treated successfully with balloon angioplasty, resulting in a 20% residual stenosis; however, recurrence of symptoms resulted in repeat angiography, which demonstrated significant restenosis at the site of balloon angioplasty **(B)**, which was treated with a Taxus drug-eluting stent **(C)**. Repeat angiography at 6 months demonstrated a widely patent stent but progression of other disease **(D)**. (From Baim DS. *Grossman's cardiac catheterization, angiography, and intervention*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006.)

Table 94.3a

TASC classification of aortoiliac obstructive lesions

Type A	• Unilateral or bilateral stenoses of CIA • Unilateral or bilateral single short (≤3 cm) stenosis of EIA
Type B	• Short (≤3 cm) stenosis of infrarenal aorta • Unilateral CIA occlusion • Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA • Unilateral EIA occlusion not involving the origins of internal iliac or CFA
Type C	• Bilateral CIA occlusions • Bilateral EIA stenoses 3–10 cm long not extending into the CFA • Unilateral EIA stenosis extending into the CFA • Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA • Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA
Type D	• Infrarenal aortoiliac occlusion • Diffuse disease involving the aorta and both iliac arteries requiring treatment • Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA • Unilateral occlusions of both CIA and EIA • Bilateral occlusions of EIA • Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

CIA, common iliac artery; EIA, external iliac artery; CFA, common femoral artery; AAA, abdominal aortic aneurysm. Reprinted from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (TASC II). *J Vasc Surg* 2007;45(1):S5–S67. © 2007, with permission from Elsevier.

Table 94.3b

TASC classification of femoral-popliteal obstructive lesions

Type A	• Single stenosis <10 cm in length • Single occlusion <5 cm in length
Type B	• Multiple lesions (stenoses or occlusions), each <5 cm • Single stenosis or occlusion <15 cm not involving the infrageniculate popliteal artery • Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass • Heavily calcified occlusion <5 cm in length • Single popliteal stenosis
Type C	• Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification • Recurrent stenoses or occlusions that need treatment after two endovascular interventions
Type D	• Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery) • Chronic total occlusion of popliteal artery and proximal trifurcation vessels

CFA, common femoral artery; SFA, superficial femoral artery. Reprinted from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (TASC II). *J Vasc Surg* 2007;45(1):S5–S67. © 2007, with permission from Elsevier.

frequency in patients with diabetes, renal failure, smoking, and severe claudication symptoms, and in those presenting with CLI.[17] Thus, maintaining vessel patency after the procedure is heavily dependent on a variety of vascular and clinical factors, and careful patient selection is crucial to optimizing success.

Endovascular Stenting and Atheroma Debulking Procedures

Endovascular stent placement after balloon angioplasty provides additional mechanical support to the vessel lumen, diminishing the effects of elastic recoil and negative vessel remodeling. However, vessel restenosis may still occur through excessive neointimal SMC proliferation. Angioplasty and stent deployment results in mechanical trauma and denudation of the vessel endothelium. Mechanical injury stimulates biologically active factors, promoting the migration and proliferation of vascular SMCs to the vessel intima, and forming a neointimal layer within the stent.[113] Clinical studies support the utilization of endovascular stenting as primary therapy for internal and external iliac artery lesions, and as salvage therapy for more distal lesions with supoptimal balloon angioplasty results. In iliac disease, primary stenting appears to reduce vessel restenosis. A meta-analysis of six studies involving 2,116 patients demonstrated improved long-term patency and similar complication rates with primary stenting for iliac disease compared to percutaneous transluminal angioplasty.[116] Primary stenting of infrainguinal arterial lesions is more challenging as vessel anatomy, external force applied to vessels from adjacent muscles, and axial vessel compression occurring with movement can lead to stent deformation, fracture, and reduced patency.[115] Several studies have failed to show a significant benefit with bare metal stenting compared to percutaneous transluminal angioplasty in the treatment of femoral–popliteal stenosis.[117–120] However, Schillinger et al.[121] demonstrated a benefit with routine nickel–titanium (nitinol) stenting compared to balloon angioplasty with salvage stenting in 104 patients with superficial femoral artery stenosis. Patients treated with routine nitinol stenting had reduced angiographic restenosis at 6 months (24% vs. 43%, $P = 0.05$) and improved maximal walking distance at both 6 (363 m vs. 270 m; $P = 0.04$) and 12 months (387 m vs. 267 m; $P = 0.04$).

A promising method to reduce vessel restenosis currently under evaluation is the use of antineoplastic agents to locally inhibit vascular SMC proliferation. The THUNDER study evaluated the use of paclitaxel-coated angioplasty balloons with nitinol stenting as needed in 154 patients undergoing revascularization for superficial femoral or popliteal disease.[122] Patients undergoing paclitaxel-coated angioplasty had reduced angiographical vessel stenosis at 6 months (late lumen loss 0.4 ± 1.2 mm vs. 1.7 ± 1.8 mm, $P < 0.001$) and target-lesion revascularization at 24 months (15% vs. 52%, $P < 0.001$) compared to the control group. Conversely, the SIROCCO II study failed to show a benefit of sirolimus-coated compared to bare metal stents in 57 patients with superficial femoral artery stenosis.[123] Initial studies examining the routine use of adjunct procedures such as laser or cutting balloon atherectomy have failed to show significant clinical benefits over either percutaneous transluminal angioplasty or stenting; thus, their routine use cannot be recommended in the treatment of PAD until further data are available.

Antiplatelet Therapy during and After Endovascular Intervention

The majority of patients with PAD undergoing endovascular intervention for claudication are already on antiplatelet therapy for cardiovascular risk reduction. However, studies also report benefits with antiplatelet therapy specific to revascularization. The Antithrombotic Trialists' collaboration meta-analysis of 46 studies evaluated the effects of antiplatelet therapy in patients who underwent various vascular procedures. Antiplatelet therapy was associated with a 43% risk reduction in vascular occlusive events in the subset of 3,000 patients who underwent a peripheral vascular

intervention.[124] Either aspirin or clopidogrel are considered appropriate antiplatelet agents after endovascular intervention.

Currently, there are no randomized studies examining the clinical utility of dual antiplatelet therapy after peripheral revascularization. The benefit of dual antiplatelet therapy after peripheral stenting has largely been inferred from surrogate endpoints of platelet studies and clinical trials involving coronary stenting.[125] There are limited data examining clinical outcomes with dual antiplatelet therapy in PAD patients undergoing endovascular intervention. Cassar et al.[126] compared the antiplatelet benefits of clopidogrel with aspirin to aspirin alone in patients undergoing lower limb angioplasty. A significant reduction in platelet fibrinogen binding and p-selectin expression by flow cytometry was demonstrated with dual antiplatelet therapy, indicating improved platelet inhibition. Wilson et al.[112] showed similar antiplatelet effects with dual therapy. However, no significant differences were demonstrated regarding smooth vessel proliferation, assessed *ex vivo* by extracellular signal–regulated kinases 1 and 2 activation, suggesting a mechanism of benefit primary related to reducing thrombotic events rather than vessel restenosis. Despite a lack of evaluation in randomized clinical studies, dual antiplatelet therapy is widely utilized after endovascular intervention, primarily after stent implantation, and many physicians have adopted the use of short-term clopidogrel in addition to indefinite aspirin therapy.

SURGICAL MANAGEMENT OF INTERMITTENT CLAUDICATION

Studies comparing the long-term efficacy of surgical and percutaneous endovascular revascularization have shown comparable outcomes. The BASIL study demonstrated similar 6-month amputation-free survival rates in 452 patients with severe ischemia undergoing surgical bypass or percutaneous endovascular revascularization.[127] Similarly, a randomized study of 263 patients comparing bypass surgery to endovascular revascularization showed no benefit of one therapy over the other with respect to overall survival or graft patency at 4 years.[128] However, both studies selected patients with obstructive lesions that were amenable to either intervention, while many patients who are evaluated in clinical practice have anatomic lesions that favor one revascularization strategy over another. In accordance with the TASC II anatomic classification system, focal and discreet stenoses are generally treated by endovascular therapy, while more complicated lesions and diffuse PAD should be managed surgically.[16]

Indications for surgical revascularization in patients with PAD and claudication are similar to those for endovascular treatment. Surgery is usually considered for appropriate anatomic stenosis and persistent, limiting claudication symptoms despite aggressive medical management.[16] Surgery is reserved for complicated lesions and diffuse disease, which would generally result in worse outcomes with endovascular intervention. As such, TASC II guidelines recommend surgical revascularization for type D anatomic lesions involving the iliac and femoral–popliteal arteries.[16] Although surgery is considered the preferred therapy for type C stenosis, endovascular outcomes for these lesions have improved considerably over time. Moreover, surgery portends a higher morbidity and mortality in the intraoperative and recovery period compared to endovascular procedures. Thus, assessing the patient's comorbidities in addition to anatomic disease severity is crucial for balancing the overall risks and benefits of surgery prior to proceeding with revascularization.

Surgical Management of Aortic–Iliac Disease

Surgical bypass is the preferred treatment for extensive or complicated lesions involving the aortic and iliac arteries. The most common surgical approach involves the implantation of a prosthetic conduit from the infrarenal aorta to the femoral arteries through an intra-abdominal approach. Despite the burden of cardiovascular disease and complexity of patients undergoing surgical bypass, procedural mortality and morbidity are relatively low. A meta-analysis of 23 studies, examining aortoiliac bypass outcomes since 1975, demonstrated an overall operative mortality of 3.3% and morbidity rate of 8.3% with aortobifemoral bypass surgery.[129] Moreover, favorable long-term outcomes have been demonstrated with aortofemoral bypass. For the treatment of claudication, limb patency rates at 5 and 10 years are 91% and 86%, respectively.[129] Smoking remains an important cause of graft failure after surgical revascularization. In a meta-analysis of 29 studies of both suprainguinal and infrainguinal bypass surgery, Willigendael et al.[130] demonstrated a 2.35-fold increase in graft failure in smokers compared to nonsmokers. Alternative bypass techniques are required for patients with unsuitable abdominal anatomy or significant comorbidities, which place them at increased risk with an intra-abdominal approach. In such cases, extra-anatomic bypass techniques, such as axillofemoral bypass using a retroperitoneal approach or crossover femoral bypass, may be considered. The long-term results of extra-anatomic bypass procedures are less favorable compared to aortofemoral bypass. The 5-year patency rates for axillounifemoral, axillobifemoral, and femoral–femoral bypass are 51%, 71%, and 75%, respectively.[16] Consequently, extra-anatomic bypass is reserved for situations where the perioperative risks of an intra-abdominal surgery outweigh the benefits of preserving long-term limb patency.

Surgical arterial endarterectomy is an alternative to bypass in patients with aortoiliac disease, but the procedure is less durable than surgical bypass, with 5-year vessel patency rates of 60% to 94%.[16]

Surgical Management of Infrainguinal Disease

The most important determinant of success following surgical bypass for infrainguinal disease is uncompromised flow to the inflow artery supplying the conduit. Targeting a specific arterial level for anastomosis (i.e., common femoral, superficial femoral, or popliteal) is less important than ensuring whichever inflow artery used is patent. When the inflow artery has obstructive disease, endovascular intervention or endarterectomy may be performed to improve vessel patency prior to distal bypass. The distal anastomosis site should also be based on the quality of the vessel rather on than a specific arterial level. Typically, the tibial or peroneal artery is used for the distal anastomosis, although grafting of the plantar artery has also been performed with success. Kram et al.[131] evaluated the long-term patency of infrainguinal grafting in 217 patients who underwent femoropopliteal surgery with either reverse saphenous vein or prosthetic conduits. The observed 5-year primary and secondary patency rates after femoropopliteal surgery were 61% and 78%, respectively.

Unlike aortoiliac disease, long-term graft patency in infrainguinal disease is dependent on conduit composition. Venous conduits generally have better long-term patency rates compared to prosthetic conduits. Various studies report a 5-year patency rate for above-knee femoropopliteal bypass surgery with venous grafts of 74% to 76%, compared with lower rates using polytetrafluoroethylene grafts of 39% to 52%.[16] The long saphenous vein is the preferred conduit for femoral to below-knee popliteal or distal bypass. The postoperative risk of graft failure remains higher in smokers compared to nonsmokers.[130]

Preliminary studies have reported positive results with the combination of percutaneous and surgical interventions in patients with multilevel PAD. In a study of 110 patients with PAD, combined superficial femoral artery balloon angioplasty with distal popliteal bypass grafting had comparable results to bypass grafting alone in patients with infrainguinal PAD,[132] the overall 5-year primary and secondary patency rates being 63% and 78% respectively, with 81% of patients avoiding major limb amputation. The combination revascularization strategy may become an appealing option for selected patients with multilevel vascular disease not easily amenable to either intervention alone.

Antithrombotic Therapy with Surgical Interventions

Both arterial and venous grafts are subject to thrombosis related to impairments in conduit blood flow, luminal reduction secondary to neointimal hyperplasia, and surface thrombogenicity (with prosthetic conduits).[133] Therefore, a rationale exists for the use of antithrombotic therapy to promote graft patency. In a meta-analysis of five studies involving 423 patients, aspirin therapy reduced graft occlusion following inguinal bypass surgery (RR 0.78, 95% CI 0.64 to 0.95) compared to placebo.[134] Given the beneficial effects of aspirin for maintaining graft patency, and for cardiovascular risk reduction in the PAD population as a whole, it should be considered for all patients undergoing peripheral bypass surgery.

There is limited data supporting the use of oral anticoagulation therapy routinely in patients after peripheral bypass surgery, particularly with the routine use of aspirin. Studies report improved graft patency following peripheral bypass surgery with vitamin K antagonists compared to placebo,[134,135] but these benefits were not reproduced in the large randomized Dutch BOA study of 2,690 patients receiving either aspirin or oral anticoagulation following infrainguinal bypass, in which there were similar graft occlusion rates with either therapy.[63] Subgroup analysis demonstrated that patients receiving venous grafts derived a benefit with oral anticoagulation (RR 0·69, 95% CI 0·54 to 0·88), while aspirin was beneficial for nonvenous grafts (RR 1·26, 95% CI 1·03 to 1·55). Vascular-related death and total mortality did not differ with either therapy, while major bleeding was increased in the oral anticoagulation group. A Veterans Affair study of 831 patients undergoing surgical bypass treated with aspirin with or without a vitamin K inhibitor reported no significant differences in graft patency or vascular-related mortality, with increased bleeding in the dual anticoagulation group.[136] Given the marginal benefits for preventing graft occlusion, and the increased bleeding risk compared to antiplatelet therapy, oral anticoagulation is not recommended for routine use in PAD patients following bypass surgery.[133]

MANAGEMENT OF CHRONIC CRITICAL LIMB ISCHEMIA

CLI is a chronic condition caused by severe flow limitation to the affected limb. Presentations of CLI include resting claudication and ischemia-related leg ulcers or gangrene (FIGURE 94.7). New-onset ischemic neuropathy can exacerbate leg pain, while the presence of long-standing peripheral neuropathy (which occurs in associated conditions such as diabetes) may paradoxically limit claudication symptoms. Thus, the development of arterial ulcers may follow resting claudication symptoms, or may be an initial presentation in patients with long-standing peripheral neuropathies. Considered an "end-stage" manifestation of PAD, CLI is associated with a greater severity of vascular disease, more multisegmental and distal disease, increased risk of leg amputation, and a worse overall prognosis compared to the general PAD population.[137] In a large prospective cohort following 1,586 patients with CLI, the 6-month amputation rate and 1-year mortality rate were 12% and 19.1% respectively.[138]

Once CLI is suspected clinically, the diagnosis should be confirmed by documenting reduced arterial blood flow by ABI, toe systolic pressure, or transcutaneous partial pressure of oxygen ($TcPO_2$) of the extremity. CLI complications typically develop at an ankle pressure of 50 to 70 mm Hg, a toe pressure of 30 to 50 mm Hg, and a $TcPO_2 < 30$ mm Hg.[16] Peripheral angiography may be considered to document severe PAD in indeterminate cases or if revascularization is considered (FIGURE 94.9).

MEDICAL THERAPY FOR CRITICAL LIMB ISCHEMIA

The goal of medical therapy is to reduce claudication pain, heal ischemic lesions, and avoid limb amputation. Unfortunately, patients who undergo medical therapy alone for CLI have a high incidence of adverse outcomes. Marston et al.[139] examined clinical outcomes in 142 patients treated medically for CLI and found a 1-year amputation rate of 38% and continued ischemic ulcers despite medical therapy in 50%; an ABI < 0.5 was the best predictor of a poor clinical outcome.

Secondary Prevention of Cardiovascular Events

All patients with CLI should undergo aggressive secondary prevention treatment, including antiplatelet therapy, blood pressure reduction, management of dyslipidemia, diabetes control, and smoking cessation independent of revascularization status (Table 94.2). There is some evidence supporting improved cardiovascular outcomes associated with aggressive secondary prevention in CLI. In the PREVENT III cohort, statin therapy was associated with an improved 1-year survival in patients who underwent revascularization surgery (hazard ratio 0.71, 95% CI 0.52 to 0.98).[140] The same analysis showed no improvement in survival with β-blockers or antiplatelet therapy, but given the significant benefits of antiplatelet therapy regarding cardiovascular risk reduction and following vascular intervention in the PAD population as a whole, it is recommended that patients with CLI also be treated with an antiplatelet agent.

Prostanoids

Prostanoids demonstrate several vascular actions that may potentially benefit patients with CLI, including antiplatelet and profibrinolytic effects, vasodilation, and improved endothelial function.[141] Despite these theoretical benefits, studies evaluating the role of prostanoids in patients with PAD have demonstrated inconsistent results. A randomized trial of 1,560 patients with CLI demonstrated a significant reduction in the combined endpoint of death, major limb amputation, and cardiovascular events at hospital discharge (RR 0.87, 95% CI 0.81 to 0.93) with prostaglandin E_1 compared with placebo therapy.[142] However, at 6 months, these benefits were no longer statistically significant. Similarly, a meta-analysis of seven randomized studies involving 643 patient with CLI reported a reduction in the outcome of death or amputation-free survival in patients treated with iloprost compared to placebo (22.6% vs. 36.2%, $P = 0.015$).[143] A recent Cochrane systematic review involving 20 studies evaluated the effects of various prostanoids in the management of patients with CLI. Overall, prostanoid therapy was associated with improved ulcer healing (RR 1.54, 95% CI 1.22 to 1.96) and relief of rest pain (RR 1.32, 95% CI 1.10 to 1.57) compared to standard therapy.[141] However, there were no significant differences in overall mortality (RR 1.07, 95% CI 0.65 to 1.75) or leg amputations (RR 0.89, 95% CI 0.76 to 1.04) and increased adverse effects observed with prostanoids (RR 2.35, 95% CI 1.99 to 2.78). In the subgroup of three trials comparing intravenous ilioprost to placebo, significant benefits were observed for relief of rest pain (RR 1.54, 95%CI 1.19 to 1.99), ulcer healing (RR 1.80, 95% CI 1.29 to 2.50), and major amputations (RR 0.69, 95% CI 0.52 to 0.93). No significant differences were observed for total amputations (RR 0.79, 95% CI 0.60 to 1.03), with increased adverse events noted in the ilioprost group (RR 2.05, 95% CI 1.68 to 2.49). Overall, prostanoids appear to provide improved short-term symptom control and ulcer healing in patients with CLI. However, consistent benefits have not been observed in more substantial clinical endpoints, arguing against the routine use of prostanoid therapy in patients with CLI.

Hyperbaric Oxygen Therapy

A Cochrane systemic review evaluated the effects of hyperbaric oxygen therapy (HBOT) in five studies of patients with PAD-related ulcers. Although sample size and methodologic issues limited the analysis, HBOT was associated with a significant improvement in diabetes-related major limb amputation (RR 0.31, 95% CI 0.13 to 0.71).[144] HBOT may be considered in selected CLI patients with limited therapeutic options, such as those who are not candidates for or who have responded poorly to revascularization.

Spinal Cord Stimulation

Spinal cord stimulation (SCS) has been utilized in patients with severe PAD who have failed other medical therapies and are not appropriate candidates for surgery. Although initially used to improve pain symptoms, animal models demonstrated increased vasodilation of the lower extremities, suggesting potential vascular benefits in the healing of ischemia-related ulcers.[145,146] A Cochrane review of six studies evaluated the effects of SCS compared to standard care in patients with inoperable CLI. SCS was associated with improved pain relief and limb salvage at 12 months (RR 0.71, 95% CI 0.56 to 0.90),[147] but no significant improvement in ulcer healing was observed. Limited evidence supports the use of SCS in selected patients with refractory disease and restricted therapeutic options.

REVASCULARIZATION FOR CRITICAL LIMB ISCHEMIA

Revascularization either by surgical bypass or by endovascular intervention is the optimal limb salvaging treatment for patients with CLI. Unfortunately, many patients with CLI are excluded from either or both modes of revascularization due to significant comorbidities, excessive surgical risk, or unsuitable anatomy. For surgical revascularization, risk assessment tools have been developed to help identify patients who will most benefit. The PREVENT CLI III risk score derived from five clinical variables (presence of dialysis, CAD, tissue loss, age >75, and hematocrit ≤30%) accurately predicts adverse cardiovascular events, death, and amputation-free survival following surgical revascularization for CLI.[148] Clinical risk assessment tools may be useful to assist in the appropriate selection of patients for surgical revascularization.[149]

Clinical studies have not established the superiority of surgical or endovascular revascularization techniques for CLI. The BASIL study did not show any significant difference in 5-year time to death or above-ankle limb amputation between revascularization strategies in 452 patients with CLI and infrainguinal vascular disease,[127] but surgery was associated with increased procedure-related morbidity and a longer hospital stay. Conversely, *post hoc* analysis showed that patients who survived without amputation for 2 years after surgical revascularization had a significant long-term reduction in mortality (OR 0·34, 95% CI 0·17 to 0·71) and limb loss (OR 0·37, 95% CI 0·17 to 0·77). Although not definitive, the results of BASIL suggest higher short-term complications but more durable long-term results with surgical revascularization. Following initial revascularization, partial foot amputation may be required in patients with gangrene or nonhealing ulceration after revascularization in order to preserve the rest of the limb.[16] Overall, revascularization in patients with CLI provides the best opportunity for limb preservation, but patients remain at an increased risk for limb loss, morbidity, and mortality.

Major Limb Amputation

Clinical factors associated with major limb amputation (above ankle) include diabetes, chronic renal failure, major tissue loss, and poor ambulatory status.[150] The main indications for primary limb amputation (no prior revascularization attempt) are life-threatening infection of the affected limb, extensive necrosis of the foot, or uncontrolled pain in patients who are not candidates for revascularization,[16] but it is also considered in patients with irreversible flexion contractures, terminal illness, and reduced life expectancy due to significant comorbidities.[137] Secondary amputation occurs in the context of a persistent infection or limb deterioration despite attempted revascularization.

The primary goal of major lower limb amputation is to preserve the limb at the most distal level possible in order to retain functional ability. However, as distal areas of the limb are prone to reduced blood flow, an amputation level must be chosen, which has adequate circulation to foster wound healing and prevent infection. Below-knee amputation is successful in 80% of cases, while above-knee amputation has a 90% success rate.[16] Successful lower amputation levels are generally associated with improved function and survival. Feinglass et al. examined short- and long-term mortality in 4,103 patients undergoing above- and below-knee amputation in Veterans Affairs hospitals from 1991 to 1995. Thirty-day mortality was 6.3% with below-knee amputations compared to 13.3% with above-knee amputations.[151] Three-year survival rates with the below- and above-knee amputation groups were 57% and 39% respectively.

ACUTE LIMB ISCHEMIA

ALI occurs due to a sudden interruption of the blood flow to an extremity, which often threatens limb viability.[152,153] Clinically, patients present with the "five P's" related to ischemia: pain, pallor, pulselessness, paresthesia, and paralysis, but they vary depending on the severity and duration of ischemia.[154–156] Mortality in ALI is high, from 15% to 20%,[16] and patients are at risk for permanent tissue loss and neuromuscular complications. Thus, early detection of ALI is essential, as expeditious management can improve limb salvage, while delayed recognition increases the risk for limb complications and overall mortality.

Etiology of Acute Limb Ischemia

Peripheral embolization and native thrombotic vascular occlusion are the two most common causes of ALI, additional causes being traumatic injury, postendovascular procedure thrombosis, and vascular graft-related thrombosis. Approximately 80% to 90% of peripheral embolic events are cardiac in origin, arising from thrombi secondary to postmyocardial infarction ventricular aneurysms, atrial fibrillation, native valvular disease, or prosthetic valves;[156] emboli also occur with proximal peripheral aneurysms, dislodgement of ulcerated arterial plaques, paradoxical embolization, and following endovascular procedures or vascular surgery.[133]

Unlike ALI secondary to an embolic event, thrombotic vascular occlusion is commonly associated with significant atherosclerosis. Due to the relatively protracted process of atheromatous plaque formation, progressive luminal obstruction, and collateral vessel formation, the presentation of ALI secondary to thrombosis may be delayed and less symptomatic. However, a thrombotic event occurring prior to adequate collateral formation will usually present with severe symptoms, similar to an embolic event.[156]

Initial Evaluation and Risk Stratification

The initial assessment of a patient with suspected ALI is focused on ensuring clinical stability, assessment for an etiology, and evaluating the severity of ischemia. In clinical practice, the degree of ischemia supersedes the duration of ischemia and is dependent on the anatomic level of obstruction, underlying cause, collateral circulation, and thrombus propagation. Although 6 hours has been accepted as the maximum time period of ischemia beyond which irreversible necrosis occurs, tolerance of skeletal muscle to ischemia is variable, as most patients do not have complete cessation of blood flow in the axial and collateral vessels. Not surprisingly, acceptable revascularization results have been achieved after relatively long periods of ischemia.[157,158]

The Rutherford classification is frequently utilized for initial risk stratification in patients presenting with ALI. Based on symptoms and physical examination, the affected limb is classified into one of three categories: viable (class I), threatened viability (class IIA and IIB), and irreversible ischemia (class III)[152,159] (Table 94.4 and FIGURE 94.11). When ALI is clinically suspected, impairment of vascular flow should be confirmed by Doppler ultrasonography of the peripheral pulses. Angiography by computed tomography, magnetic resonance imaging, or invasive methods may also be performed to visualize the site of obstruction, determine the extent of the disease, and guide revascularization decisions.[152]

Table 94.4

Classification of acute limb ischemia

		Findings		Doppler Examination	
Category	**Description/Prognosis**	**Sensory Loss**	**Muscle Weakness**	**Arterial**	**Venous**
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	None or minimal (toes)	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss, permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

Anticoagulation in Acute Limb Ischemia

The goal of ALI therapy is to prevent further thrombosis or embolism, and ultimately restore adequate reperfusion to the affected limb.[16] Therefore, immediate anticoagulation therapy should be considered for all patients presenting with ALI, preferably with unfractionated heparin,[160] although randomized studies demonstrating a benefit of anticoagulation therapy in ALI are lacking. Several case series have supported this practice, reporting higher limb salvage and lower mortality rates in patients treated with anticoagulantion.[161,162]

Revascularization Strategies for Acute Limb Ischemia

Restoration of blood flow to the acutely ischemic limb can be accomplished either by surgical revascularization or endovascular procedures. Surgical thrombectomy involves open dissection and the direct removal of thrombus from the site of occlusion. A focal atherosclerotic lesion at the prior site of thrombosis can be treated with surgical revision and patch angioplasty, while more diffuse atherosclerotic disease warrants surgical bypass.[159] The primary percutaneous endovascular procedure for thrombus removal in ALI is catheter-directed thrombolysis; additional procedures include percutaneous aspiration thrombectomy and percutaneous mechanical thrombectomy (utilizing hydrodynamic recirculation to dissolve and evacuate thrombus).[16] Percutaneous angioplasty may be performed to provide long-term revascularization if a residual obstructive lesion is present at the site of occlusion. Five clinical trials have compared surgery and catheter-directed thrombolysis for the initial management of ALI.[163–165,166,167] The largest trial, TOPAS, evaluated reperfusion with catheter-directed urokinase or surgery in 548 patients with ALI of <14 days in duration involving either a native artery or bypass graft.[166] The primary endpoint of amputation-free survival was similar in the thrombolysis and surgical groups at 6 months (71.8% vs. 74.8%, $P = 0.43$) and 1 year (65.0% vs. 69.9%, $P = 0.23$). The thrombolysis group underwent significantly less open surgical procedures, although major hemorrhagic complications (including intracranial hemorrhage) occurred more frequently compared to surgery. Similar results were obtained in a meta-analysis of these five trials (including TOPAS) involving 1,283 patients with ALI. Overall, there was no significant difference between the two groups regarding limb salvage at 30 days (OR 1.21, 95% CI 0.74 to 1.99), at 6 months (OR 0.86, 95% CI 0.59 to 1.26), and at 1 year (OR 0.88, 95% CI 0.62 to 1.23). Moreover, overall mortality was similar at 30 days (OR 0.58, 95% CI 0.30 to 1.33), at 6 months (OR 1.35, 95% CI 0.83 to 2.18), and at 1 year (OR 0.87, 95% CI 0.61 to 1.25).[168] However, a higher incidence of stroke (OR 6.41, 95% CI 1.57 to 26.22), major hemorrhage (OR 2.80, 95% CI 1.7 to 4.6), and distal embolization (OR 8.35, 95% CI 4.47 to 15.58) was observed with catheter-directed thrombolysis. Studies comparing the two strategies have demonstrated no clear advantage of one therapy over the other, emphasizing the need to weigh the risks of hemorrhagic complications due to thrombolysis against those related to surgery.

Percutaneous Catheter-Directed Thrombolysis

Catheter-directed thrombolysis is an excellent option for the initial treatment of patients with mild-to-moderate limb ischemia, those with significant medical comorbidities in whom surgery presents too high a risk, and in those with multiple previous surgical interventions.[152,159] Potential advantages of catheter-directed thrombolysis include low pressure reperfusion, which may reduce reperfusion injury, and additional fibrinolysis in branch vessels that are too small to be treated with other

revascularization methods.[16] Although streptokinase was initially utilized during catheter-directed thrombolysis, newer thrombolytic agents such as urokinase and recombinant tissue plasminogen activator (rt-PA) have demonstrated a more rapid response, improved safety, and greater efficacy.[169] Additional thrombolytic agents such as reteplase, prourokinase, tenecteplase, recombinant staphylokinase, and alfimeprase have undergone limited evaluation in patients with PAD.[160,169]

Several randomized trials have compared the efficacy of various thrombolytic strategies in patients with critical ischemia. Berridge et al.[170] compared treatment with intravenous rt-PA, intra-arterial rt-PA, or intra-arterial streptokinase in 60 patients with symptoms of CLI for <30 days. Intra-arterial rt-TPA was associated with an improved mean ABI and a lower rate of limb amputation at 30 days compared to the other two treatment strategies.[169,170] Conversely, intravenous thrombolysis was associated with inferior reperfusion outcomes and increased bleeding complications compared to catheter-based thrombolysis.[170]

Three randomized trials have compared intra-arterial urokinase with intra-arterial rt-PA for PAD. Schweizer et al. demonstrated improved vessel patency with rt-PA immediately after thrombolysis and at 6 months.[169,171] Meyerovitz et al.[172] reported more rapid thrombolysis at 8 hours with rt-PA compared to urokinase in patients presenting with native arterial or graft occlusions. Regarding clinical outcomes, there was no difference in mortality or bleeding complications with either rt-PA or urokinase among the three studies. Mahler et al. did note a significantly higher amputation rate in the rt-PA group (OR 0.29, 95% CI 0.08 to 1.06), although this difference was not demonstrated in the other studies.[169,173] Ouriel et al.[174] compared three dosing regimens of intra-arterial prourokinase with intra-arterial urokinase in patients with peripheral arterial occlusions and reported no statistical differences in short-term vessel patency or clinical outcomes. The heterogeneity of these studies and small number of subjects make for difficult conclusions, but the overall results suggest that intra-arterial rt-PA may be more effective intra-arterial streptokinase, while there are no significant differences regarding clinical outcomes between intra-arterial rt-PA and intra-arterial urokinase.[169] The use of systemic intravenous thrombolysis is associated with reduced reperfusion and increased bleeding compared to intra-arterial strategies[170] and is not recommended in patients presenting with ALI.

Selection of the Appropriate Revascularization Strategy

Selecting the appropriate intervention is often done on an individual basis and is dependent on several considerations such as the location and cause of the occlusion, severity of ischemia, patient comorbidities, the presence of contraindications, and local practice patterns.[16] Using anatomic references, suprainguinal occlusions are generally treated surgically, while endovascular methods are favored for the management of infrainguinal disease. Patients presenting with significant ischemic symptoms and threatened viability (Rutherford class IIB) should undergo immediate revascularization.[159] Traditionally, surgery has been the preferred method of revascularization for these patients; however, advances in endovascular techniques have led to the increased use of percutaneous procedures in patients with severe ALI. Due to continuous advancements in endovascular management, time to revascularization has become a less important factor in deciding the appropriate mode of revascularization. Moreover, although endovascular techniques such as catheter-directed thrombolysis may require a longer time period to restore complete patency, a significant improvement in perfusion is seen well before complete thrombus dissolution.[152,159] Patients with Rutherford class I or IIa symptoms generally tolerate the longer reperfusion time required for endovascular catheter thrombolysis and may benefit from the less invasive procedure if significant comorbidities are present. Intravenous anticoagulation alone is also an option for patients presenting with Rutherford class I symptoms who have significant comorbidities or those at a high risk for complications with thrombolytic therapy.

Amputation may be necessary in patients with Rutherford class III signs and symptoms due to irreversible major tissue loss. Major limb amputation occurs in up to 25% of patients presenting with ALI; as initial therapy in 10% of patients presenting with unsalvageable limb necrosis, and in an additional 10% to 15% of patients following failed revascularization.[16]

PAD THERAPY: FUTURE DIRECTIONS

Despite advances in surgical and percutaneous revascularization techniques, a significant amount of patients with PAD require limb amputation, particularly when presenting with CLI. Consequently, novel methods of limb revascularization are currently being examined to improve limb salvage, including stem cell therapy and gene therapy.

Stem Cell and Progenitor Cell Therapy

Bone marrow-derived mononuclear cells (BMMNCs) are important mediators of angiogenesis, stimulating the enlargement of preformed arterioles parallel to a vascular obstruction, and restoring blood flow distally through the development of collateral networks.[175] Impairment of this regenerative process can result in poor collateralization with subsequent limb ischemia. Circulating endothelial progenitor cells are synonymous with BMMNCs and are reduced in conditions associated with poor collateralization in vascular disease, such as advanced age, diabetes, and smoking.[176] A limited number of studies have evaluated BMMNCs in PAD and have reported promising effects. Tateishi-Yuyama et al. conducted an unblinded randomized control study involving 22 patients with bilateral CLI undergoing BMMNC or peripheral blood mononuclear cell injection in each ischemic limb. Four weeks after injection of BMMNC, significant improvements were observed in ABI (0.37 to 0.46 95% CI 0·06 to 0·11; $P < 0·0001$), $TcPO_2$ (28.8 mm O_2 to 46.3 mm O_2, $P < 0.0001$), and ischemic symptoms.[177] Smaller benefits were reported following peripheral mononuclear cell injection. Pooled effects from small studies suggest an increase in ABI between 0.1 and 0.2, 10 to 20 mm O_2 increase in $TcPO_2$, and improved walking distance by 100 to 200 m.[176] However, clinical outcomes require replication in larger randomized studies, such as the BONMOT-CLI study, in order to establish the efficacy of this therapy in PAD.[178]

Gene Therapy

Gene therapy has undergone limited evaluation as an alternate method of therapeutic angiogenesis in patients with PAD. Gene therapy strategies have focused on the transfer of nucleic acids, which promote growth factors, into ischemic tissue to promote

angiogenesis.[179] Lederman et al. reported promising effects with intra-arterial infusion of recombinant fibroblast growth factor-2 (rFGF-2) in 190 patients with intermittent claudication, demonstrating a greater change in peak walking time at 90 days with rFGF-2 compared to placebo (increase of 0.60 minutes with placebo, 1.77 minutes with single-dose therapy, and 1.54 minutes with double-dose therapy, $P = 0.034$).[180] However, subsequent studies of encoded angiogenesis factors have failed to demonstrate improvements in exercise parameters or quality of life compared to placebo.[181,182] Therefore, further studies are needed to adequately characterize the benefits and side effects of gene therapy prior to its clinical use as a revascularization strategy in patients with PAD.

CONCLUSIONS

Many effective therapies are currently available for the management of patients with PAD. Given that mortality in PAD is primarily due to a vascular cause, strategies to reduce cardiovascular risk should be provided to all patients regardless of symptoms. Individuals with intermittent claudication have several lifestyle and medication options available to improve symptoms. Patients with persistent symptoms may benefit from additional surgical or percutaneous revascularization strategies. Those presenting with chronic limb ischemia or ALI are at an increased risk for limb-related complications, amputation, and mortality compared to the general PAD population. In these patients, aggressive revascularization should be sought in order to improve limb-related morbidity and overall survival. However, because many PAD patients have significant comorbidities, which may increase the risks associated with these procedures, careful patient selection for the appropriate revascularization strategy is essential to optimize clinical success. Ongoing advances in medical therapy and revascularization techniques hold the promise for even further improvements in the clinical outcomes of patients with PAD.

CHAPTER

95 Unusual Sites of Arterial Occlusion

PHILIP A. KALRA, JON G. MOSS, AND PETER WIEDEMANN

UNUSUAL SITES OF ARTERIAL OCCLUSION

In this chapter, we consider occlusive arterial diseases as they affect three separate vascular sites, the renal, gut, and retinal vessels. In the renal vasculature, most efforts have been directed at diagnosing and treating significant renal artery narrowing, as opposed to complete occlusion, whereas the latter is more relevant in the clinical presentation of intestinal or retinal vascular diseases.

RENAL ARTERY STENOSIS AND OCCLUSION

Introduction

Renal artery narrowing, which is usually focal but can be both multiple and more diffuse, is termed renal artery stenosis (RAS), and it is of clinical importance because of its blood flow-limiting effects upon the renal circulation and consequent intrarenal ischemia. This in turn can perturb renal function, blood pressure control, and renal neuroendocrine activity, with clinical manifestations including fluid and salt retention. Interest in RAS accelerated during the 1980s and 1990s with the advent of interventional procedures that could dilate stenotic lesions, providing the possibility that renal revascularization might improve patient outcomes. However, recent trials have shown that such intervention for atherosclerotic lesions, by far the commonest cause of RAS, may not be associated with patient benefit in the majority and that there are still gaps in our knowledge regarding management of the condition.

Etiology

Atheromatous change within the main renal arteries is very commonly seen in ageing populations, but also in younger patients with risk factors or a predisposition for early development of atheroma, and hence atherosclerosis is the cause of over 90% of RAS in Western populations; the remainder is due to fibromuscular disease (FMD). The epidemiology is different in the Indian subcontinent and the Far East, with vasculitis, including Takayasu arteritis, said to be responsible for up to 60% of RAS cases.[1] The latter is discussed in Chapter 100.

As the epidemiology, clinical presentations, and outcomes after treatment of FMD and atherosclerotic RAS differ markedly, they are considered separately, with greatest attention being directed to atherosclerotic renovascular disease (ARVD), which is the preeminent condition.

Fibromuscular Disease

Epidemiology and Pathology

FMD accounts for 5% to 10% of RAS cases. However, autopsy studies and analysis of renal vascular anatomy in healthy renal donors suggest that its prevalence maybe as high as 2% in Western general populations.[2] FMD involves the renal arteries in 60% to 75% of cases, but it can involve other major arteries such as the carotids (in 30% to 60%), vertebral, mesenteric, celiac axis, and coronary vessels.[3] The pathogenesis of FMD is unknown, but there is suspicion that female hormones could be important, given the fact that up to nine times more females than males are diagnosed with the condition. Several different pathologic forms are recognized, the most common of which is medial fibroplasia, typically found in women who present in their third or fourth decades. Here the noninflammatory pathology involves areas of thinning of the intima and media of the vessel wall with loss of the elastic lamina, changes that lead to aneurysm formation. These areas alternate with localized regions of fibrotic narrowing, and so the result is the classical "string of beads" appearance at angiography (FIGURE 95.1). Stenoses tend to occur more distally in the renal circulation than atherosclerotic lesions, and they can be several centimeters in length and also present in multiple vessels; bilateral renal FMD is seen in 30% to 50% renal cases.

Clinical Picture

The classical presentation of FMD is with hypertension and usually well-preserved renal function in young adults, although there is a growing consensus that many cases present in later life. The diagnosis should certainly be considered in young patients (e.g., <35 years old) who present with severe or accelerated-phase hypertension, or in other patients where there is new-onset hypertension, deterioration in previously stable hypertension, or renal functional deterioration in patients treated with renin angiotensin blocking (RAB) agents. An abdominal bruit may be detected, but awareness of the possibility that neurologic features, mesenteric angina, or claudication may be manifestations of FMD at nonrenal arterial sites is important. Progressive narrowing of the renal arteries may be seen in a third of patients over time, but progression to complete occlusion is rare.

Management

The management of patients with fibromuscular RAS is centered upon control of hypertension. Medical therapy, most appropriately utilizing RAB agents, may be suitable in the majority. Renal revascularization with percutaneous renal angioplasty (PTRA)

FIGURE 95.1 FMD of the right renal artery. Typical "string of beads" appearance associated with medial fibroplasia.

is indicated for patients in whom blood pressure cannot be controlled to target via medical therapy, in those with accelerated hypertension, and in those intolerant of RAB. Unlike the situation for atherosclerotic RAS, success rates for hypertension control after PTRA are good in FMD, with cure (i.e., no further need for antihypertensive drugs) observed in 30% to 60% and an improvement in blood pressure control in the majority of the remaining cases.[4] The 10% of patients unresponsive to PTRA are more likely to include those with multiple FMD lesions or with intrarenal disease.

Atherosclerotic Renovascular Disease

Atherosclerotic narrowing of the renal arteries is by far the commonest cause of RAS.

The renovascular disease usually develops as part of a systemic inflammatory atheromatous syndrome and is accompanied by macrovascular disease in several other important vascular beds, notably the coronary, aortoiliac, and iliofemoral circulations. The term ARVD is preferentially used to describe all patients with atherosclerotic renal disease as around 40% have evidence of renal artery occlusion (RAO) at first clinical presentation. About 90% of RAS lesions are "ostial," that is occurring within 1 cm of the origin of the renal artery, and around 35% of patients have bilateral disease.[5]

Epidemiology and Risk Factors

ARVD is a disease of ageing. In our own local renovascular database, which comprises almost 1,000 patients with ARVD referred from a 1.5 million population over 20 years, the median age of the population is 70 years with 46% of patients in their seventh decade of life and 87.1% of patients being aged >60 years at study entry.[6] As would be expected, prevalence is increased in smokers and in patients with type 2 diabetes, and epidemiologic studies demonstrate that about 30% of typical ARVD cohorts are diabetic.[7] Although there is no clear association of ARVD with hyperlipidemia, the lipoprotein profile is similar to that found in other vascular diseases, with a very low apolipoprotein A1 concentration but only slight elevations of total and LDL cholesterol.[8]

The epidemiology of ARVD differs according to the studied population. Many patients have asymptomatic ARVD that is only identified during the investigation of other arterial conditions, and so an accurate prevalence figure for the general population is unknown. However, in North Carolina, 6.8% of 834 community-based people aged >65 years were shown to have incidental RAS of >60% by Doppler imaging.[9] Approximately, 1 in 200 (0.54%) US citizens aged over 65 years and receiving Medicare had a diagnosis of ARVD in 1998 to 1999,[7] but the prevalence is far greater in groups enriched with vascular disease, such as those with coronary artery disease (CAD) or peripheral vascular disease (PVD). Medicare data derive from the 5% annual random sample of patients aged >65 years available for analysis. New cases of ARVD were diagnosed with an incidence of 3.7 per 1,000 patient years (0.37% per year) in 2000 to 2001.[7] A study of 12 years of Medicare data (1992 to 2004) has shown a 3.35 times increase in ARVD diagnosis over the period, presumably reflecting a change in investigational and screening strategies rather than any change in frequency of disease development.[10]

Association of ARVD with Other Vascular Diseases

ARVD is often identified as an incidental or asymptomatic pathology in patients with other vascular diseases, and so it is of particular interest to the disciplines of cardiology, vascular surgery, and hypertension. Many studies have been undertaken in selected groups of patients who are likely to be enriched with ARVD. The most extensive interest in the association of ARVD with CAD has been developed by the group in Duke University Medical Centre in patients presenting predominantly with angina or myocardial infarction.[11] Up to 11% of these patients had significant unilateral RAS and 4% bilateral RAS >50% when investigated with abdominal aortography concomitant with coronary angiography. Patients with greater extent of CAD have greatest severity of RAS. As will be discussed later, the presence of RAS in this population indicates an adverse prognosis, which in part resulted in cardiologic enthusiasm to detect ("shoot the renals") and perform endovascular intervention ("drive by angioplasty") of RAS lesions during coronary investigation. In view of the frequent association of ARVD with CAD and hypertension, it is little surprise that structural heart disease can be detected in many patients with RAS and that syndromes of cardiac dysfunction are highly prevalent. Interest in the relationship between congestive heart failure (CHF) and RAS has been increasing, and estimates suggest that 30% to 50% of older CHF patients may have ARVD.[12,13] Clinical presentations with sudden-onset or "flash" pulmonary edema can be life-threatening and may be the first indication of ARVD in up to 10% of patients.[14] Its true incidence is most probably underestimated due to the fact that renovascular investigation is undertaken in a minority of patients with abrupt-onset left-ventricular failure. Patients with bilateral significant RAS or a solitary functioning kidney are those at most risk of this condition, which is one of the accepted indications for renal revascularization. As would be anticipated due to anatomical relationships, aortoiliac disease is

frequently associated with ARVD, with RAS often being detected incidentally during vascular surgical investigation. The prevalence of ARVD in patients undergoing aortography for intermittent claudication has been found to be 30% to 45%, and the presence of ≥60% RAS in patients with PVD has been associated with a 2.5-fold increased risk for major cardiovascular events and death during follow-up.[15] Carotid disease also frequently coexists with ARVD; in a Japanese study involving 729 high-risk cardiovascular patients, 22% of those with carotid artery stenosis had RAS. Conversely, carotid disease has been demonstrated in 46% of patients with RAS.[16] The above macrovascular disease prevalence figures are further emphasized in studies of the US Medicare population, and a study of ARVD patients in 20 hospitals in Spain found PVD present in 67.5%, CAD 44.8%, heart failure 32.6%, and stroke in 27.3%.[17]

ARVD Prevalence in Other Populations

In selected hypertensive populations, up to 2% of patients can be shown to have RAS, but it is quite likely that the lesion is not causal in most and that "renovascular hypertension" exists only in the minority. This assertion is based upon the fact that improvements in blood pressure are the exception rather than the rule after revascularization in the majority of patients with RAS, whereas a rigorous definition of renovascular hypertension would be cure or substantial improvement in hypertension after such procedures. Similarly, although impaired renal function is found in most patients with ARVD, its etiology is usually related to other factors causing renal injury, such as hypertension and an atherogenic milieu that predate RAS development, and the hemodynamic effects of a RAS may not necessarily be pathogenetically important. Up to 15% of patients with end-stage kidney disease (ESKD) on dialysis programs have ARVD, but in many cases the disease is a comorbid association rather than a cause of the ESKD.[18] Despite this, awareness of the association is important as some cases of ARVD will present subacutely with ESKD, and revascularization of critical RAS can occasionally lead to independence from a future of dialysis. Patients with ESKD have the poorest prognosis of all ARVD patients, presumably because of their extensive vascular comorbidities, and this will be discussed later.

Clinical Presentations of ARVD

A large proportion of patients diagnosed with ARVD are asymptomatic from the condition, and their disease is identified during investigation of other diseases (e.g., during coronary or peripheral angiography). Others are identified after referral to specific clinics (e.g., nephrology, hypertension, or heart failure clinics), whereas a minority are diagnosed during an acute hospital admission (e.g., acute kidney injury [AKI], pulmonary edema). Hypertension is usually present in patients with anatomically significant RAS; data from the angioplasty and stenting for renal artery lesions (ASTRAL) trial show that 98% of ARVD patients had this diagnosis at enrolment.[19] The typical pattern is of systolic hypertension with low diastolic pressure and widened pulse pressure, often resistant to medical therapy. Perhaps 2% of ARVD presentations are with AKI, the most likely scenarios being bilateral critical RAS (e.g., >95% RAS), acute RAO, in association with accelerated-phase hypertension or with cholesterol atheroembolization in patients with severe aortic atheroma, radiocontrast injury as a result of angiographic procedures or, most commonly, following the use of RAB therapy.

The most frequent nephrologic presentation is with asymptomatic chronic kidney disease (CKD), usually associated with hypertension, in patients referred to the nephrology clinic. The link between ARVD and sudden-onset heart failure, or CHF, has already been described, but many additional patients with primarily diastolic heart failure and hypertension have underlying contributory RAS. With all the above clinical presentations, a key pointer to the diagnosis of RAS is the presence of arterial bruits (epigastric and femoral).

Diagnosis of ARVD

ARVD should be suspected in patients with hypertension and/or CKD and any of the following:

- Audible vascular bruits
- >1.5 cm disparity in bipolar renal length on renal imaging
- Unexplained pulmonary edema
- Unexplained CKD in those with evidence of other vascular disease
- Significant deterioration of renal function in association with RAB therapy

There are several imaging techniques that can be used to diagnose RAS (FIGURE 95.2). Magnetic resonance angiography (MRA) has a sensitivity/specificity for detection of RAS exceeding 90%, but it can overestimate the degree of RAS. Contrast MRA should be avoided where possible in patients with stage 4 or worse CKD (glomerular filtration rate [GFR] of <30 mL/min) because of the risk of nephrogenic systemic fibrosis, a syndrome that can

FIGURE 95.2 Intra-arterial digital subtraction angiogram showing severe bilateral atherosclerotic renal artery stenosis (*arrowheads*).

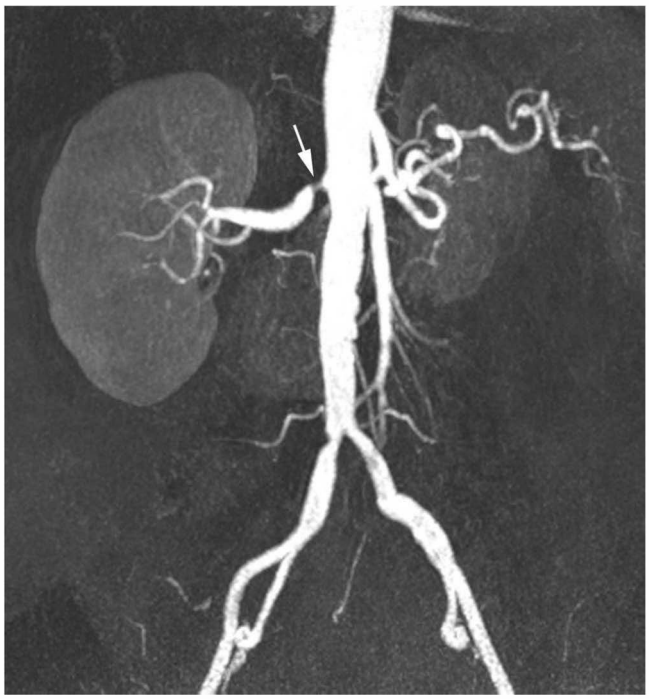

FIGURE 95.3 CT renal angiogram showing significant right atherosclerotic RAS (*arrowhead*).

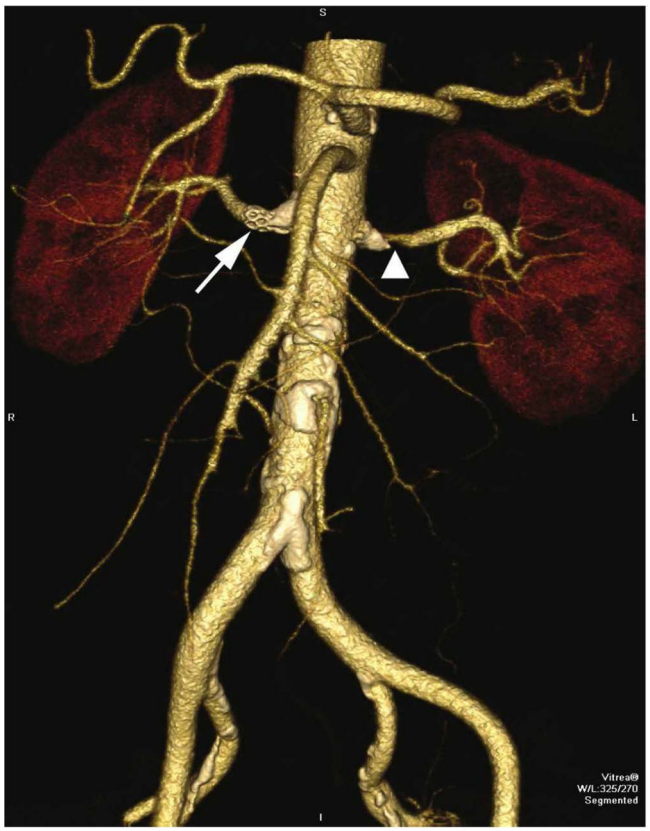

FIGURE 95.4 Spiral CT scan showing the quality of three-dimensional postprocess imaging. There is a left RAS (*arrowhead*) and a right renal artery stent (*arrow*).

be induced by certain preparations of gadolinium.[20] Computed tomography angiography (CTA) or multislice CT has similar sensitivity/specificity to MRA for RAS detection and evaluation (FIGURES 95.3 and 95.4). Its main limitation is risk of contrast nephropathy in patients with advanced CKD.[21] The likelihood of this complication occurring can be minimized by prophylactic protocols involving intravenous fluid infusion. Duplex ultrasonography is highly sensitive for the detection of RAS, and the Doppler waveforms provide information on intrarenal vascular resistance, which provides some indication of the extent of intrarenal parenchymal disease.[22] Limitations of the technique are patient body habitus and its operator dependency, but it is completely risk free and is the best screening tool for RAS in patients with advanced CKD. Conventional renal angiography (usually intra-arterial angiography) is utilized only to confirm the presence of RAS at the time of revascularization procedures, or in diagnosis of more complicated or uncertain cases. It only provides two-dimensional images, it is invasive, and use of contrast carries a risk of contrast nephropathy.

Treatment of ARVD

Medical Therapy

ARVD occurs as part of a diffuse inflammatory vascular disease process, and extrarenal vascular pathology (e.g., CAD, heart failure, cerebrovascular accident) is a major determinant of the poor outcome of the patients. Hence, although there is no evidence base to guide optimal vascular protective therapy, a sensible approach is to advise smoking cessation, and treatment with antiplatelet therapy and statins. The latter can stabilize atherosclerotic plaques, and there is also some evidence that they can ameliorate progression or even induce regression of atherosclerotic RAS.[23] The target blood pressure of <130/80 should be sought, but this may only be attained in a minority of patients, even when multiple antihypertensive agents are used in combination. Use of RAB therapy, although seemingly counterintuitive, is actually the most sensible approach for the majority of ARVD patients, especially for those with coexisting CAD and cardiac dysfunction, or proteinuria (indicative of chronic renal parenchymal injury). Careful monitoring of renal function is obviously required, particularly in patients with significant bilateral RAS, or RAS affecting a solitary kidney.

Renal Revascularization

Revascularization procedures have been undertaken to restore renal artery patency in patients with RAS for almost three decades, the rationale for treatment usually being one of the following:

- Control of severe hypertension that is unresponsive to medical therapy (e.g., blood pressure >160/90 despite four antihypertensive drugs)
- Improvement in serious associated cardiac disease, such as flash pulmonary edema
- Presentation with AKI
- Preservation of functioning renal mass by preventing RAO and renal atrophy in patients with severe RAS
- Ameliorating progressive deterioration of function in CKD

Although surgical reconstruction is still performed for complicated anatomical cases, including some cases of RAS in association with abdominal aneurysm, it has largely been replaced by percutaneous interventional techniques (angioplasty and/or stenting), which now account for >98% of all revascularization procedures.[10] Careful individualized patient evaluation is necessary as complications can occur in 5% to 10% of procedures. These are most frequently of minor seriousness (e.g., groin hematoma) or they resolve rapidly (e.g., contrast nephropathy); more serious complications such as arterial rupture, embolization or thrombosis, or significant cholesterol embolization may affect up to 2%.[24]

Despite the ready availability of interventional procedures for RAS, highlighted by the fact that 16% of Medicare patients diagnosed with ARVD during the last decade underwent a procedure within 6 months of diagnosis,[7,10] there is only limited evidence to suggest that patients benefit from revascularization. There have been five published randomized clinical trials (RCTs) investigating outcomes after percutaneous revascularization in patients with ARVD.[19,25,26–28] A meta-analysis of the first three small RCTs showed that angioplasty was associated with slightly improved systolic blood pressure control, but with no benefit to renal function.[29] The Dutch-led STAR study included 140 ARVD patients randomized equally to medical therapy or to stenting.[25] No benefit was seen with revascularization for the main outcome measure of reduced GFR, but the study was underpowered, especially as >25% of the patients randomized to revascularization did not receive the procedure; the intra- and periprocedural mortality rate was 5% in those receiving a stent. To date, the most robust evidence derives from the UK-led ASTRAL trial, in which 806 patients with significant RAS were randomized to medical therapy or medical therapy plus percutaneous revascularization.[19] The intervention led to no overall worthwhile clinical improvements in renal function (the primary outcome measure), blood pressure control, renal or cardiovascular events (10% per year in both arms), or mortality (8% per year) during a median follow-up period of 34 months. However, a serious adverse event rate of 6.8% was observed in revascularized patients. Despite the unequivocal results of ASTRAL, interpretation of the trial results must be considered in light of the investigated population. A large proportion of the ASTRAL patients had relatively asymptomatic or stable disease, presenting with CKD and hypertension, and very few patients presenting with conditions such as AKI or flash pulmonary edema were randomized as most of these would have received revascularization outside of the trial. Also, only a minority of patients (12%) had "rapidly deteriorating" renal function prior to study entry.

Notwithstanding the value and methodologic reliability of the RCT, there is a realization that overall grouped RCT results may disguise benefits in minority groups of patients. Hence, the results from some of the many retrospective, observational, or nonrandomized studies that have been reported in the literature are of value, although the latter are often flawed by selection and reporting bias. Some studies suggest that hypertension control can be improved in 50% to 85%[30] of patients, but these experiences are not uniform. There has been even more variability when considering renal function as the main outcome, but a summary of published studies suggests that overall 25% of patients show renal functional improvement, 25% deteriorate, and 50% remain unchanged following revascularization.[31–33] It is possible that intrarenal atheroembolism may be contributory for some of the patients who deteriorate, and studies using distal embolic protection in high-risk patients have shown a high yield of embolic material in the filter baskets.[34] A few investigators have shown that distal protection embolic devices benefit renal functional outcome,[35] but this has not been translated into widespread usage within the renal stenting community.

The following summarizes the current viewpoint regarding indication for revascularization therapy for ARVD[36]:

- Revascularization should not be recommended for patients with incidental or asymptomatic atherosclerotic RAS
- There is no evidence that revascularization benefits patients with stable CKD or hypertension
- Revascularization is indicated in those patients with ARVD and AKI or flash pulmonary edema (consensus view)
- Some clinicians would also recommend it being utilized in patients with RAS and very resistant hypertension, in those with rapidly deteriorating renal function, or in those intolerant of RAB, although no trial evidence is available to support this

Prognosis of ARVD

Before the introduction of statins, small studies showed that RAS lesions were likely to progress to more severe RAS or RAO. For example, an arteriographic study from the 1980s showed that progression of RAS occurred in 44% of patients, with progression to RAO in around 10% per year.[37] Hemodynamically significant RAS lesions also lead to renal atrophy; in a prospective duplex ultrasound study, the 2-year cumulative incidence of renal atrophy (defined as >1cm shrinkage in bipolar length) was 20% in patients with RAS > 60%, but interestingly atrophy was still seen in 5.5% of kidneys with normal renal arteries, the latter most prominent in patients with elevated systolic blood pressure.[38] Atrophy was associated with an increase in serum creatinine, which emphasizes the role of renal shrinkage in progression of renal impairment. Although few studies have examined the influence of statin therapy upon RAS progression, current rates of progression are undoubtedly less than that observed in the earlier studies.[23]

The severity of RAS often bears no relation to the extent of intrarenal injury and the resulting renal dysfunction.[39,40] Some patients with a severe RAS do develop a drop in renal perfusion and consequent impaired renal function simply via a hydraulic effect, but this does not explain why patients with unilateral RAS also develop renal failure or why isotope studies of individual kidney function can find similar or even worse function in the contralateral kidney supplied by a normal renal artery compared to the severe RAS kidney.[41] These observations explain why renal function in patients with severe RAS may only improve in the minority after revascularization and emphasize the importance of preexisting intrarenal parenchymal damage. Data from ASTRAL show a low rate of progressive renal dysfunction once the diagnosis of ARVD has been established. In the 403 patients randomized to medical therapy, a deterioration of 10% in renal function was noted over the first year, but only a further 1% renal functional deterioration occurred during the succeeding 3 years.[19] Analysis of our large cohort of ARVD patients in Salford shows that annual rates of progression to ESRD are low and have diminished over time with 3.2% in 1990

to 1995, 3.5% in 1995 to 2000, 2.3% in 2000 to 2005, and only 0.8% for patients diagnosed since 2005.[6] Those patients who progressed to dialysis had significantly more proteinuria and interestingly were less likely to have been treated with RAB or statins than the patients who did not progress, but these data are undoubtedly confounded by selection bias.

Patients with ARVD have a high mortality, which is largely related to their extensive vascular comorbidities and heart disease. ARVD patients in studies of Medicare had an annual mortality rate of 16.3% a decade ago, nearly six times greater than risk of developing ESKD, and three times greater than that of the non-ARVD population.[7] The major determinants of mortality seem to be worse level of baseline renal function,[42] greater proteinuria,[43] and the extent of extrarenal macrovascular disease. However, with modern vasculoprotective therapy, the survival of ARVD patients may be improving, and in ASTRAL, in which patients were followed until 2008, the overall annual mortality was 8%.[19] Once patients with ARVD reach dialysis, they have an even worse prognosis; in a large study of the US dialysis population, the annual mortality rate was around 35% in patients with ARVD, although this was no greater than the crude mortality of all other dialysis patients.[18]

Conversely, the presence of RAS confers a worse prognosis in patients with other vascular diseases. In patients with symptomatic PVD, those with severe RAS had a 2.9-fold increased risk of death compared to patients free of the condition, whereas the presence of RAS reduces survival of patients with CAD by about a third.[44] The severity of RAS was of prognostic significance in this study, patients with 50% RAS having a 4-year survival of 70%, compared to 48% for patients with >95% RAS.

MESENTERIC ISCHEMIA

Introduction

Mesenteric ischemia is a relatively rare condition, challenging to both diagnose and treat. There have been several advances over the last 20 years in particular regarding imaging and endovascular treatment. However, mesenteric ischemia still remains a serious clinical condition often diagnosed too late and having a high mortality. The pathology is usually atherosclerotic, and it frequently coexists with other vascular comorbidity. Increasingly, the diagnosis is being made in the elderly patient who is often a high-risk surgical candidate.

The broad classification is by the clinical presentation, that is, acute or chronic. Some cases of mesenteric ischemia are due to venous thrombosis, but these are discussed in Chapter 84.

Classification of Mesenteric Ischemia

- Acute mesenteric ischemia 50%
- Chronic mesenteric ischemia 35%
- Mesenteric venous thrombosis 5% to 15%

Pathophysiology

The gut is supplied by three arteries, which supply the foregut (celiac axis), midgut (superior mesenteric artery, SMA), and hindgut (inferior mesenteric artery, IMA), respectively. There is a common but variable anastomosis between these vessels through the pancreaticoduodenal arcade and marginal artery of Drummond. There is an additional communication between the internal iliac arteries and the IMA around the rectum. As a result of this collateral circulation, the gut can tolerate gradual occlusion of one and usually two of its three arteries without any clinical sequelae. However, complications will ensue if the collateral supply is disrupted, for example, after previous abdominal surgery, or when the arterial occlusion is abrupt, as with an acute SMA embolus. The cause of pain in visceral ischemia is probably due to lactate build-up as in other vascular beds, although it has been postulated that the pain may be due to a vascular steal phenomenon that deprives the stomach of blood.[45]

Although the vast majority of cases involve an arterial stenosis or occlusion, mesenteric ischemia can occur in the presence of normal vessels when there is a low-flow situation, such as in cardiogenic shock.

Acute Mesenteric Ischemia

Acute mesenteric ischemia affects females more often than males, and the mean age at presentation is 67 years. Patients almost always present as an "acute abdomen," and the pain is severe and said to be out of proportion to the clinical signs. There is often vomiting and diarrhea, and there may be a history of a previous embolic event or an arrhythmia (most commonly atrial fibrillation). The typical clinical course involves rapid deterioration of clinical status over a few hours with accompanying leukocytosis, acidosis, and endotoxemia. Breakdown of the mucosal gut barrier is followed by transmural necrosis. The SMA is the most frequently involved vessel. The etiology is often an embolus of cardiac origin, but thrombosis of an underlying stenosis can occur with plaque rupture. Other causes to consider include aortic dissection, when the dissection extends into a visceral vessel, or iatrogenic causes such as from a recent endovascular aortic procedure, for example, renal or aortic stenting, or ligation of the IMA during open aortic surgery. The diagnosis is made by maintaining a high index of suspicion and requesting urgent CTA or MRA. The diagnosis will be made in many cases as a result of a conventional CT scan performed for investigation of an acute abdomen (FIGURE 95.5), as the advances in imaging have made delineation of the visceral vessels simple.

Although there are reports of successful endovascular treatment, acute mesenteric ischemia remains a surgical emergency. The viability of the bowel is often in doubt, and this cannot be reliably assessed by CT at present. The goal of treatment is to reestablish antegrade flow in the occluded artery, and this may be achieved using a Fogarty embolectomy catheter. Bypass grafts may be necessary utilizing either an aortic or iliac donor site. If there is peritoneal contamination (due to loss of the mucosal gut barrier), then prosthetic grafts should be avoided. Unfortunately, there is often extensive small-bowel infarction rendering revascularization futile. Even when initial surgery appears to have been successful, there is sometimes a need to reoperate with a "second-look" laparotomy at 24 to 48 hours in order to check the bowel viability. Nonviable segments of small bowel will be resected, and some surviving patients may suffer a short-bowel syndrome and require long-term nutritional support, depending upon the extent of the resections. If the clinical presentation is very early and the clinical signs are favorable, then thrombolytic therapy may resolve the occlusion followed by stenting of any underlying stenosis.[46] However,

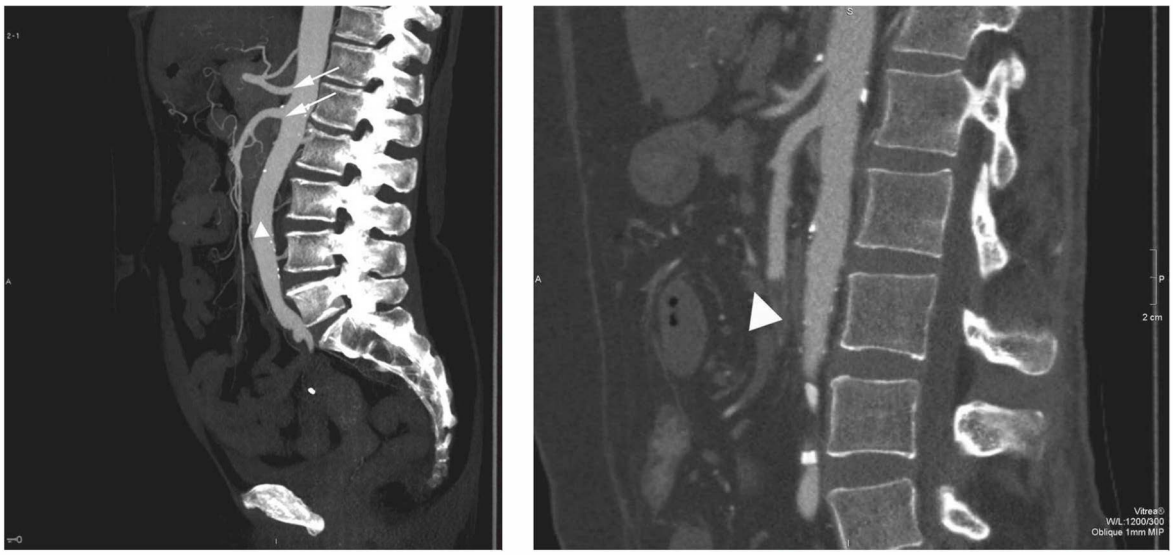

FIGURE 95.5 **A**: Normal CT angiogram in the midsagittal plane showing the celiac axis (*arrow*), SMA (*long arrow*), and IMA (*arrowhead*). All appear normal. **B**: CT angiogram in the midsagittal plane showing a large embolus in the SMA (*arrowhead*). The patient had atrial fibrillation and presented with an acute abdomen.

enthusiasm for this approach should be cautious as many emboli consist of well-organized material that is resistant to thrombolytic agents.

Chronic Mesenteric Ischemia

There are rare nonatheromatous arteritides, such as fibromuscular dysplasia, which can affect the visceral vessels and produce symptoms. However, over 95% of cases are due to atheromatous stenosis affecting the origin of the visceral arteries. The anatomical distribution is very similar to that seen with atheromatous RAS, with the plaque essentially being of aortic origin and extending into the ostium of the vessel. The median arcuate ligament syndrome is a controversial entity where the arcuate ligament of the diaphragm compresses the celiac axis. In the absence of any other vessel being involved, it should not, in theory, produce any symptoms. When it is thought to be responsible for chronic ischemia, it is necessary to surgically divide the ligament.

The presentation of chronic mesenteric ischemia is often described as "abdominal angina" as the patient suffers postprandial pain and subsequently develops a fear of eating and loses weight. Many of the patients have had a plethora of other investigations and the diagnosis is often delayed. Cross-sectional imaging is used to delineate the anatomy with either MRA or CTA (FIGURE 95.6). Although Doppler ultrasound can be used, as with renal artery disease it is operator dependent with variable results. For the reasons stated in the previous section, at least two of the three vessels should be stenosed or occluded, in patients with a convincing clinical history, in order to make a reasonably confident diagnosis of chronic mesenteric ischemia. Asymptomatic lesions rarely seem to progress to causing bowel ischemia. In a study of visceral duplex ultrasonography in 553 free-living subjects, 17.5% were found to have incidental disease of either the celiac axis or SMA. Critical mesenteric

FIGURE 95.6 Contrast-enhanced magnetic resonance angiogram in the midsagittal plane showing an occluded celiac axis (*arrowhead*) and IMA (*arrow*) and a significant stenosis of the SMA (*long arrow*). The patient presented with chronic postprandial epigastric pain typical of chronic mesenteric ischemia.

artery stenosis (MAS) was defined by the Doppler criteria; after a mean of 6.5 years, the mortality of patients with MAS was identical to those without (20%), and no deaths were attributable to intestinal infarction. MAS did not lead to development of chronic intestinal ischemia.[47]

In symptomatic patients, treatment should be aimed at improving the blood supply to the bowel by either an open surgical or an endovascular approach. There is little evidence available to help with decision making here as there have been no RCTs, and the likelihood of one being undertaken is low given the relative rarity of the condition. Many different open surgical procedures exist, and there is little consensus as to which to use. Some advocate an extensive thromboendarterectomy of the celiac and SMA origins, whereas others use some form of bypass graft either from the supraceliac or from the infrarenal aorta as the donor site. These are all major surgical procedures with considerable morbidity and reported mortality rates in the region of 5% to 10%.[48] However, the long-term patency after surgery is very good, and few patients need any further intervention, restenosis only being in the order of 10%.

An endovascular approach for the treatment of chronic mesenteric ischemia has many attractions, not least in the elderly patient with coexisting extraintestinal vascular disease. Avoidance of general anesthesia and a large abdominal incision opens up this treatment option to many patients who simply would not be surgical candidates. Initially, angioplasty was used with variable results and with a significant restenosis rate due to aortic plaque recoil. The invention of metallic stents in the late 1980s largely overcame the technical limitations of angioplasty and opened up the field of endovascular revascularization. Technical success rates vary from 88% to 100% with very low mortality and morbidity. Restenosis (usually within the stent) is not uncommon with primary patency of approximately 60%.[49] Restenosis may result in recurrent symptoms and the need for a further revascularization procedure. There have been huge efforts made by the stent industry to reduce restenosis rates in other circulations, with drug-eluting stents becoming the norm in the coronary circulation. It remains to be seen whether these benefits apply to drug-eluting stents in other arteries. Restenosis can be addressed with further endovascular options, which include angioplasty, drug-eluting angioplasty, restenting, and drug-eluting stenting.

In conclusion, the decision to perform open or endovascular revascularization is a complex one, trading off the risk of mortality and morbidity of surgery for a more durable outcome. In a young fit patient, it would be difficult to argue against an open surgical repair.

Retinal Arterial Occlusive Disease

The retina has a dual circulation. The inner retina is supplied by the central retinal artery, which is an end artery, whereas the outer retina is nourished from the choroidal circulation. Retinal artery obstructions selectively affect the inner retina only. A retinal artery obstruction is an abrupt diminution of blood flow severe enough to cause ischemia of the inner retina. Diagnosis of central retinal artery obstruction (CRAO) is straightforward when diffuse ischemic retinal whitening is present in the setting of abrupt, painless, and profound visual loss, the hallmark symptom. Examination typically reveals a visual acuity of 0.05 or worse. If a patent cilioretinal artery is present and this perfuses the fovea, normal central acuity may be permitted. The decreased blood flow results in ischemic whitening of the retina in the territory of the obstructed artery. A cherry-red spot of the macula is typical (FIGURE 95.7) and arises in this area because the nerve fiber layer is thin.[50] Fluorescein angiography shows a typical delayed arm-to-retina time and delayed arteriovenous transit, and late staining of the disc is common.

Retinal arterial obstructions are divided anatomically into central and branch, depending on the exact site of obstruction. A CRAO occurs when the blockage is within the optic nerve substance itself, and therefore the obstruction is not visible on ophthalmoscopy. Acute simultaneous obstruction of both the retinal and choroidal circulations is referred to as an ophthalmic artery obstruction. More proximal obstructions usually cause a more chronic form of visual problem—the ocular ischemic syndrome. Most CRAO result in permanent loss of vision. About one-third of patients experience some improvement in final vision, either with or without conventional treatment. On occasion, some patients experience significant restoration of normal vision. As the visual loss tends to be severe and permanent, it is fortunate that retinal artery obstructions are rare occurrences. The mean age at onset is about 60 years, with a wide range of reported ages from the first to the ninth decade of life.

Etiology of Retinal Artery Occlusions

The majority of retinal occlusions are either thrombotic or embolic in nature. As there is a strong association with systemic disease, all patients who suffer retinal artery obstructions should undergo a systemic evaluation. In the absence of local causes, this must include testing for temporal arteritis, carotid artery disease, and cardiac disease. It is important that temporal arteritis should be excluded in all patients older than 50 years of age who have a CRAO. Nevertheless, over 75% of patients with CRAO have evidence of atherosclerosis, about 60% of patients have concurrent systemic hypertension, and 25% of patients have diabetes. Less than one-third of CRAO result from emboli, and potential embolic sources are identified in about 40% of cases. However, over two-thirds of branch retinal artery obstructions are caused by emboli. Sources of emboli include hemodynamically significant ipsilateral carotid artery disease, which is present in about one-third of affected patients. An embolic source from the heart is present in <10% of patients with CRAO; however, echocardiography should be performed, especially in younger patients. Other rare associated systemic diseases include blood-clotting abnormalities.[51]

Treatment of Retinal Artery Occlusion

There is debate concerning the time period after arterial blockage before permanent visual loss occurs. Full visual recovery is possible if the blockage is removed in time. The primate retina can tolerate up to 105 minutes of ischemia before irreparable damage occurs.[52] Extrapolation to humans has led to the theory that treatment is only beneficial if commenced within 8 hours of the occlusion. Studies do suggest that shorter occlusion time results in better eventual visual recovery. The devastating nature of the condition on vision has led to a number of

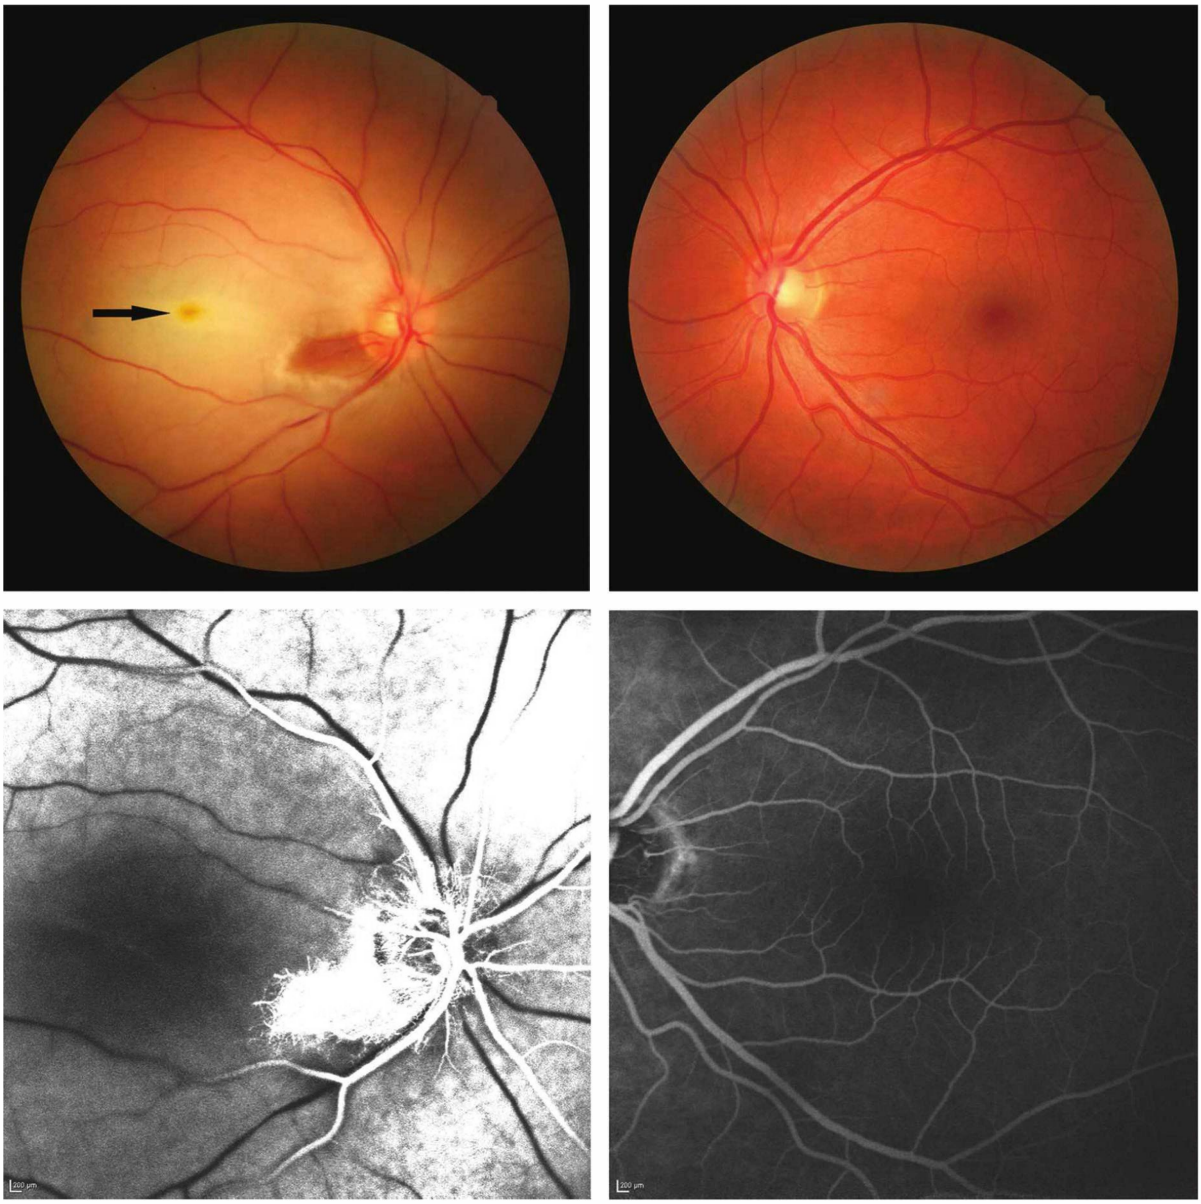

FIGURE 95.7 A 48-year-old patient with central retinal artery occlusion in the right eye. The cherry-red spot in the macula (*arrow*) and surrounding retinal edema can be seen in the fundus photography. Due to a patent cilioretinal artery, there is a perfused area in the temporal inferior segment of the retina, which can be seen with fluorescein angiography by hyperfluoresence of the dye. The left eye is normal (photography and angiography).

therapies being tried. No proven treatment exists for CRAO, but treatment strategies center around the following goals:

- To increase retinal arterial blood flow and reverse arterial obstruction
- To increase retinal oxygenation and prevent hypoxic retinal damage

The therapeutic strategies used include waiting, dilation of the artery, physical removal of the obstruction, increasing perfusion pressure by reduction of intraocular pressure, thrombolysis of the clot, antiplatelet therapy, reducing red blood cell rigidity, or use of systemic steroids. Most clinicians have used combinations of the above. No treatment is without its potential hazards, and the physician and patient must together balance the risks of these interventions with the possibility of a positive clinical effect.

An increase in retinal arterial blood flow is attempted by lowering intraocular pressure by ocular massage, paracentesis, and the administration of ocular antihypertensive medications. Medical attempts to dilate retinal arteries or block vascular spasm have been tried as well—sublingual nitroglycerin, pentoxifylline, calcium channel blockers, and β-blockers have all been used with no proof of efficacy. Few RCTs of treatment options for nonarteritic CRAO exist. One suggested a positive effect for oral pentoxifylline and the other for oral pentoxifylline

and/or enhanced external counterpulsation combined with hemodilution. However, a potentially improved retinal perfusion did not translate into better vision for the study patients. The small size of the studies and the lack of data regarding final visual recovery mean that there is no convincing evidence at present to support the routine use of pentoxifylline or of enhanced external counterpulsation in patients with CRAO. Reversal of arterial obstruction through the use of anticoagulation and fibrinolytic medications has been reported. To date, the utility of these medications has not been proved by controlled clinical trials, but anecdotal reports of success with intravenous heparin, tissue plasminogen activator, streptokinase, and urokinase do exist. In addition, an intra-arterial injection of tissue plasminogen activator, urokinase, or streptokinase during selective catheterization of the ophthalmic artery has been attempted, with reported success in some selected cases. Intra-arterial thrombolysis may produce superior visual outcomes compared with conventional treatments for CRAO when instituted in certain situations.[53] However, in the EAGLE study, 82 patients were randomized to receive conservative standard therapy or intra-arterial fibrinolysis within 20 hours of presentation with retinal artery occlusion.[54] A clinically significant improvement in best-corrected visual acuity was seen in 60% of the standard therapy patients and 57% of those receiving invasive therapy, and so the latter is not advocated as a general treatment.

CHAPTER

96 Pathogenesis and Treatment of Biomaterial-Associated Thrombosis

MAUD B. GORBET AND MICHAEL V. SEFTON

Cardiovascular device manufacturers rely on elegant device designs and systemic pharmacologic agents to work wonders with existing materials despite their thrombogenicity. Adverse effects are minimized and existing devices are, if not risk free, providing sufficient benefit to outweigh the risks. The focus of research in biomaterials is to make better materials that pose fewer risks and offer greater benefits. Many strategies for lowering thrombogenicity have been identified, and all these strategies show a beneficial effect in at least one assay of thrombogenicity. However, the perfect material is yet to be identified.

Clinical manifestations of the bioincompatibility of cardiovascular devices are numerous[1,2]: Sudden and complete occlusion of stents[3]; acute and subacute thrombotic occlusion in medium-sized grafts (4 to 6 mm); embolic complications with artificial hearts,[4] catheters,[5] and prosthetic valves[6]; and thrombotic complications during cardiopulmonary bypass (CPB)[7] and angioplasty.[8] Large-diameter vascular grafts remain thrombogenic for many years, but fewer thrombotic complications are observed because high flows disperse the coagulation proteins. Even if the risk of thrombotic complication appears to be low (varying between 1% and 10% depending on the device), the complications may have fatal outcomes, and the cost associated with the follow-up intervention is not negligible. Furthermore, these thrombotic complications with cardiovascular devices occur, despite the use of antiplatelet and anticoagulant therapies. In the absence of nonthrombogenic materials, current devices rely on avoiding irregular flow geometries (i.e., sudden contractions, recirculation zones, and poor device streamlining) so that thrombi do not accumulate within the device.[9,10] Coupled with this is the routine use of antithrombotic agents (see Spinler et al.[11] for guidelines and Gorbet et al.[12] for review). The inherent thrombogenicity of currently existing cardiovascular devices can be illustrated by the catastrophic impact that premature (prior to 6 months) discontinuation of dual antiplatelet therapy can have on the risk of thrombosis with drug-eluting stents (DES).[13]

This chapter focuses on biomaterials and their interactions with blood. We consider how each component, including leukocytes and complement, is thought to interact with biomaterials to induce thrombosis. The role that endothelial cells and diseases such as diabetes may play in exacerbating material-induced thrombosis is also discussed.

INTRODUCTION TO BIOMATERIAL-ASSOCIATED THROMBOSIS

Overview

Cardiovascular devices (except endothelial cell–seeded vascular grafts) expose a foreign surface lacking the properties of the endothelium to the circulation. This exposure triggers a complex series of events, including protein adsorption, platelet and leukocyte activation/adhesion, and the activation of complement and coagulation; the events are highly interlinked in this simplified picture (see FIGURE 96.1).

Criteria for Nonthrombogenicity

Much of the effort in biomaterials research over the last 30 years has been directed toward the development of inert materials that do not react with platelets and coagulation factors. A number of approaches, often conflicting, have been developed. For example, there is still no consensus as to whether a surface should be hydrophilic or hydrophobic.

Thrombogenicity is defined as the ability of a material to induce or promote the formation of thromboemboli.[14] In the past, we have thought of a nonthrombogenic surface as one that prevented platelet adherence and did not shorten blood clotting time. These criteria are easily met by heparinized materials,[15] but further studies have shown that some hydrogels, even with heparin, can activate platelets, leading to high platelet consumption.[16] The latter materials promote the formation of microthrombi, although the thrombi do not attach to the materials. A clotting time measurement is a reasonable way of assessing the effect of a material on coagulation. However, this assay is likely unimportant for predicting thrombosis *in vivo* under normal and pathologic conditions.

The criteria that we use as hallmarks of nonthrombogenicity are given in Table 96.1. Rather than a clotting time, a specific thrombin production rate constant, k_p, enables the extrapolation to indicate realistic situations. Experimental results suggest that k_p is of the order of 10^{-3} per second for simple materials such as polyethylene (the same scale as mass transfer coefficients in flowing blood) but $<10^{-4}$ per second for heparinized materials.[17] According to a simple flow model (see FIGURE 96.2), only the latter low k_p materials can be expected to minimize fibrin production. This is one of the reasons heparinization and other active methods of inhibiting thrombin formation are so popular as strategies for imparting low thrombogenicity. There are, however, other criteria that must also be met. It is a requirement that platelet interactions with the surface should not lead to thrombosis. Platelet activation and consumption may therefore be better indicators of platelet incompatibility than just deposition. Furthermore, some deposition may even be desirable since these deposits appear to passivate the surface to further activation. Although a nonthrombogenic surface should not support platelet adhesion, some *ex vivo* studies[18,19] have demonstrated that even in the absence of adhesion, platelets can be "consumed." That is, the platelets can be activated by the material and prematurely removed from the

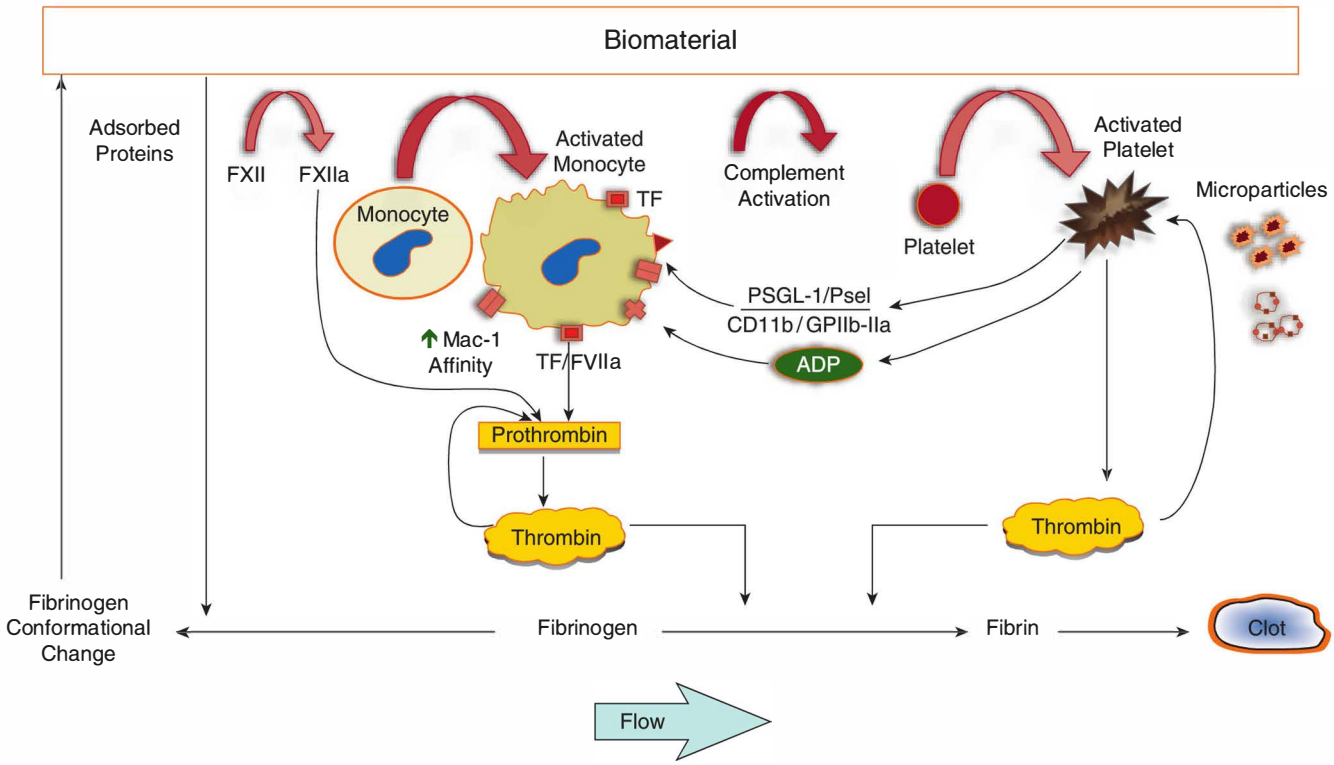

FIGURE 96.1 On or in the adsorbed protein layer, coagulation factors change their conformation or are converted into active enzymes and result in the generation of thrombin and fibrin. In parallel, platelets adhere to the surface (or adsorbed protein), become activated, change their shape, and form platelet aggregates. Both processes are linked most notably through thrombin generated on the activated platelet surface. Complement is activated on many biomaterials within the protein adsorbate and leukocytes are activated to express TF and other procoagulant activities. Flow (shear rate) is a crucial factor affecting both transport coefficients (from bulk to the surface and reverse) and the activation of leukocytes and platelets. (From Gaamangwe T, Gorbet MB, unpublished work, with permission.)

circulation (e.g., shorter platelet lifespan, decrease in systemic platelet count). This suggests that low platelet adhesion is not a sufficient criterion of *in vivo* platelet compatibility. Reduced thrombogenicity is characterized by both low platelet adhesion and low platelet activation. Leukocyte activation (and complement activation) may also be key components in thrombogenicity (see subsequent text); with further research, these factors too may become crucial parameters that define the thrombogenicity of the surface.

MECHANISTIC DETAILS

The failure to create nonthrombogenic biomaterials is directly attributable to our limited understanding of the complexity of

Table 96.1
Hallmarks of nonthrombogenicity

Conventional Wisdom	Updated Criteria
Prolonged clotting times	Thrombin production rate constant $k_p < 10^{-4}$
Few adherent platelets or thrombi	Low platelet consumption; low degree of platelet activation (e.g., MPs formation)
Spread platelets are a marker of blood incompatibility—it is better to have rounded, nonactivated platelets	Some platelet spreading (?)
Complement and leukocyte activation are not relevant to studies of thrombogenicity	Low complement and leukocyte activation (?)

(?), the validity of these criteria is subject to further verification.

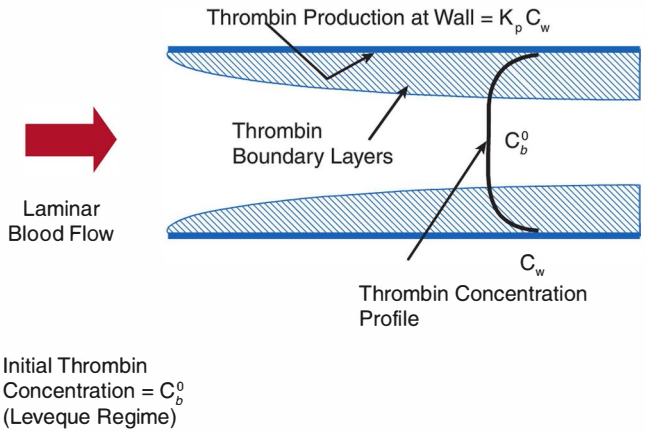

FIGURE 96.2 Model illustrating thrombin production at the surface of a tube as a balance between autoaccelerative production and mass transfer away from the wall. (From Rollasson G, Sefton MV. Measurement of the rate of thrombin production in human plasma in contact with different materials. *J Biomed Mater Res* 1992;26(5):675–693, with permission.)

biomaterial-associated thrombosis. The variety of mechanisms that are involved are summarized here.

Coagulation

In the past, the discussion of coagulation at the biomaterial–blood interface has focused on the intrinsic coagulation system and the effects of the adsorbed protein layer. Protein adsorption is certainly the first event in blood–material interactions, and adsorption of the contact-phase proteins may result in activation of the intrinsic cascade. Recent studies, however, demonstrate that tissue factor (TF) and the extrinsic coagulation system are also involved.

Early studies that were focused on protein adsorption on glass or biomaterial surfaces showed how fibrinogen is replaced over time by high molecular weight kininogen (the Vroman effect), suggesting a possible role of the intrinsic pathway in material thrombosis.[20] On the other hand, factor XII (FXII) adsorption has been observed in moderate amounts on materials used in vascular grafts[21] and hemodialysers[22] but has not been found in its activated form.[23] In some instances, *in vitro* activation of FXII and kallikrein has been reported with biomaterials;[24,25] whether this activation results in any significant coagulation is not known. Other studies have actually shown that only minute amounts of thrombin or thrombin–antithrombin complex (TAT) are generated when biomaterials are incubated with undiluted plasma alone.[26–28] Furthermore, the levels of adsorbed kallikrein and FXII on biomaterials do not correlate with TAT formation,[26] suggesting that the contact-phase proteins, by themselves, play little role in the activation of coagulation. In fact, two studies[27,29] suggested that the presence of leukocytes and/or erythrocytes is required for activation of the coagulation cascade. TAT formation on polyvinyl chloride (PVC)[27] and titanium[29] was found to be negligible in both plasma and platelet-rich plasma, whereas significant levels of TAT were observed in whole blood. *In vivo*, a small increase of FXIIa is observed during CPB,[30,31] but it appears to be in response to the surgical intervention. The establishment of extracorporeal circulation (i.e., exposure to the biomaterials of the circuit) does not further increase FXIIa levels.[31] Furthermore, no significant correlation has been observed between FXIIa and thrombin generation.[31] *In vivo* results with hemodialysis also failed to show any significant increase of FXIIa.[32] That a patient with a severe FXII deficiency showed levels of thrombin generation during CPB similar to normal patients[33] casts further doubt on the role of FXII in the initiation of coagulation with biomaterials. Taken together, these studies do not support the view that activation of the contact-phase proteins is important in the activation of coagulation by biomaterials. Rather a TF-dependent pathway of initiation for coagulation may be more important, and this is discussed in the context of leukocyte activation in subsequent text.

Platelets

Platelet activation and adhesion is known to occur during CPB and hemodialysis, as well as in vascular grafts, stents, and catheters.[2,34] The thrombotic complications associated with cardiovascular devices are clearly linked to their ability to activate platelets. Adherent platelets[35] and circulating platelet microparticles (PMPs) generated by material contact[36,37] have been shown to be procoagulant in nature. Association between platelets and leukocytes through P-selectin occurs in the presence of cardiovascular devices,[38] and such associations may directly or indirectly contribute to thrombin generation (by monocyte TF) or may participate in the removal of platelets from the circulation because several platelets can be bound to each neutrophil or monocyte. Generation of PMPs is also induced by biomaterials; when compared to balloon angioplasty alone, higher levels of PMPs have been observed within 15 minutes following coronary stenting.[39]

Following contact with the layer of adsorbed proteins on the artificial surface, platelets will either adhere or "bounce off,"[40] most likely depending on their state of activation and the ligands present at the interface.[41] Many investigators have studied the influence of surface characteristics of biomaterials (i.e., hydrophilicity/hydrophobicity, surface free energy, chemistry, charge, and roughness) on platelet adhesion *in vitro*, but the results have been contradictory and adsorbed proteins remain the crucial factor in platelet adhesion. Few platelets are found on biomaterials that preferentially adsorb albumin. Preadsorbed fibrinogen, fibronectin, vitronectin, and von Willebrand factor (vWF) support platelet adhesion *in vitro* on biomaterials. However, initial platelet adhesion on surfaces *in vitro* is mediated mainly by fibrinogen and glycoprotein (GP) IIb/IIIa.[42] No initial platelet activation is required, and binding of GP IIb/IIIa occurs through the aminoterminal of the γchain in fibrinogen.[43] A very small amount of fibrinogen appears to be necessary to support platelet adhesion (<10 ng/cm^2),[42] suggesting that a biomaterial has to be extremely resistant to protein adsorption to prevent adhesion. Such biomaterials can be characterized as "ultralow" fibrinogen-adsorbing surfaces, whereby <5 ng/cm^2 of adsorbed fibrinogen is required. Despite surface modification, such a design criterion appears difficult to meet, especially under *in vitro* conditions mimicking the *in vivo* environment (i.e., 100% plasma).[44] The role of protein in platelet adhesion on biomaterial surfaces is also highly dependent on shear rate; at low shear, platelet adhesion was reported to be dependent only on fibrinogen while at high shear both fibrinogen and vWF were reported to affect platelet adhesion.[44] Interaction with vWF

(by GP Ib/IX/V) and fibronectin (by GP IIb/IIIa) is believed to improve platelet adhesion once adherent platelets have been activated.[45–47] Adherent platelets on biomaterials become activated and undergo morphologic changes; the extent of platelet spreading or flattening is directly related to the increase in activation.[48] The state of activation of adherent platelets is also dependent on the biomaterial.[49,50] Activation of adherent platelets may result in degranulation, with the release of activation products such as β-thromboglobulin, thromboxane B_2, adenosine 5′-diphosphate (ADP) or serotonin (which can activate bulk platelets), and neutrophil-activating protein-2. In addition, adherent platelets express P-selectin (translocated to the surface during release from the α-granulae), which promotes the binding of monocytes and neutrophils. The activated adherent platelet surface supports thrombin generation (i.e., prothrombinase and tenase formation) and can also shed procoagulant microparticles (MPs) from their plasma membrane.

The absence of significant platelet adhesion does not preclude platelet activation in the bulk as shown by the generation of platelet MPs with polyvinyl alcohol (PVA) hydrogel both *in vitro*[51] and *ex vivo* in a canine shunt model.[52] In a baboon arteriovenous (AV) shunt model, the rate of platelet consumption was directly linked to the water content of hydrogels,[18] despite the absence of significant adhesion. All materials that were tested,[53] not just hydrogels, were observed to activate platelets, resulting in their premature removal from the circulation.

It is not clear whether inhibition of platelet adhesion will reduce platelet consumption or inhibit the generation of platelet MPs. It appears that the effects of antiplatelet agents vary, depending on the surface characteristics as shown by Spijker et al.[54] For example, abciximab is less effective in reducing platelet adhesion on hydrophilic surfaces than on hydrophobic surfaces. The strategies available to minimize platelet adhesion (e.g., polyethylene glycol immobilization) have not been sufficient to prevent platelet consumption.[55] The mechanism of material-induced platelet activation is often presumed to be through the generation of thrombin due to activation of the intrinsic coagulation cascade or the release of ADP from damaged red blood cells or platelets. Even in the presence of heparin, small amounts of thrombin are generated and may activate platelets. However, the inability of thrombin and kallikrein inhibitors to reduce platelet activation suggests that platelet activation is at least mediated in part by other agonists.[56] Classical pathway complement inhibitors can have some beneficial effects on platelets: pentamidine (12 mg/kg, daily, intra muscular) but neither abciximab nor low molecular weight heparin reduced PVA-induced platelet consumption in the canine AV shunt (unpublished study, Gemell CH & Sefton MV). A correlation between complement activation and thrombocytopenia has also been noted during dialysis.[57,58]

Complement activation can lead to platelet activation in many ways. Platelets possess a receptor for C1q that induces GP IIb/IIIa activation, P-selectin expression, and procoagulant activity.[59] Insertion of the complement assembly C5b-9 in platelets has also been associated with increased platelet procoagulant activity.[60]

Leukocytes

Contact with biomaterials *in vivo* activates both neutrophils and monocytes. Indicators of leukocyte activation such as L-selectin shedding and CD11b upregulation on leukocytes have been widely observed following angioplasty,[61] hemodialysis,[62] and CPB[63] (for review, see Asimakopoulos and Taylor[64]). Degranulation with the release of elastase and lactoferrin and the presence of cytokines, such as IL-1 and TNF-α, have been associated with extracorporeal circulation[65] and further demonstrate leukocyte activation. Activation of the respiratory burst is also a common response to hemodialysis.[66]

Both *in vitro*[67] and *in vivo*[68] studies have found that material-induced leukocyte activation is dependent on the exposed surface area. Monocytes express TF after coming into contact with a biomaterial.[67,69,70] Material-induced monocyte TF expression *in vitro* depends on complement activation and platelets.[71] On the other hand, the removal of platelets or the blocking of GP IIb/IIIa by monoclonal antibody (7E3) has no effect on CD11b upregulation. Contact with materials such as PVA hydrogel[72] or pellethane[73] leads to a twofold upregulation of CD11b, typical of the degree of leukocyte activation induced by phorbol esters.

Material-induced leukocyte activation results in increased adhesion to artificial surfaces. Because the biomaterial is larger than a microorganism and cannot therefore be engulfed by leukocytes, adherent neutrophils and monocytes respond with a frustrated attempt at phagocytosis, whereby these cells release their array of potent oxygen metabolites, growth factors, cytokines, and proteolytic enzymes.[74] The state of adherent leukocyte activation depends on the type of surface, the protein ligands present at the interface,[75–77] and the presence of adherent platelets.[71,78] Hydrophobic surfaces tend to promote leukocyte adhesion and activation, whereas less activation is observed in leukocytes adherent to hydrophilic surfaces.[79] *In vivo* studies have demonstrated activated leukocytes adhering to stents,[80] oxygenators,[81] and hemodialysis membranes.[82,83]

Leukocytes adhere *in vitro* to fibrinogen, fibronectin, and immunoglobulin (Ig)G adsorbed to surfaces by means of the integrin receptors CD11b/CD18 (Mac-1), CD49e/CD29 (VLA-5), and Fc receptors. Fibrinogen appears to be an important ligand in leukocyte adhesion to artificial surfaces. Monocyte adhesion correlates positively with the amount of fibrinogen adsorbed to the surface.[84] Fibrinogen is important for leukocyte adhesion *in vivo*. Fewer leukocytes are found on polymers implanted in hypofibrinogenemic mice.[85] Leukocyte binding to fibrinogen occurs by a protein kinase C–dependent pathway important for both initial and sustained adhesion. On metals such as titanium, leukocytes adhere initially through the FcγIII receptor (CD16), making IgG the ligand of preference.[86] Complement proteins[74,87] are also involved. C3a can mediate leukocyte adhesion on surfaces *in vitro* by the direct complexation with C3a receptors, whereas C5a appears to have a lesser role.[88] The iC3b is a ligand for CD11b/CD18 and is present even on low complement-activating surfaces.[89] The iC3b has been shown to play an important role in leukocyte adhesion to hemodialysis membranes.[90]

Platelets on the surface have also been reported to mediate leukocyte adhesion by the interaction between P-selectin and P-selectin GP ligand 1 and/or GP IIb/IIIa and CD11b.[91,92] Before adhesion to the biomaterials, leukocytes may roll by shedding of the L-selectin (similar to what happens on endothelial cells), but the mechanisms by which leukocytes sample a biomaterial before adhering to it have been less well characterized than with endothelial cells. Whether the mechanisms of material-induced leukocyte activation, as distinct from adhesion, are by contact with a foreign surface, by complement activation, by kallikrein,

or by platelet activation has not been fully determined. *In vitro* and *in vivo* investigations with protease inhibitors,[56,93,94] complement inhibitors,[72,95–97] and antiplatelet agents[98,99] suggest that they all play a role, but inhibition of just one pathway of activation may not be sufficient to result in a significant impact on leukocyte activation. For example, complement inhibition using sCR1 was only partially effective in reducing leukocyte activation.[91] On the other hand, a combination of sCR1 and anti–GP IIb/IIIa (which blocks platelet activation) reduced material-induced leukocyte activation to almost background levels.

Complement

Complement activation is generally treated as if it is part of the inflammatory response induced by biomaterials. For example, complement activation is known to occur during CPB and hemodialysis,[100,101] and with catheters and prosthetic vascular grafts.[102,103] It is recognized that, both in the short and in the long term, complement activation plays a role in the leukocyte-related clinical sequelae, such as leukopenia, hypotension, and pulmonary injury, which are associated with the use of cardiovascular devices.[104,105] The presence of a biomaterial is believed to activate complement by the alternative pathway. On a non-activating surface,[106] negatively charged groups such as carboxyl, sulfate, sialic acid, and bound heparin appear to promote high-affinity association between bound C3b and factor H. On the other hand, an activating surface is usually characterized by the presence of nucleophiles such as hydroxyl and amino groups. These groups will allow covalent binding of C3b and promote formation of the C3 and C5 convertase.[107] However, even in the absence of these activating groups on the surface, some biomaterials, such as polyacrylonitrile, are able to activate complement, suggesting that the mechanism of material-induced complement activation due to nucleophilic groups is not the whole story. An alternative hypothesis places emphasis on interaction of factor H with the surface; an activating material is then defined by its capacity to bind factor B rather than factor H.[107] Binding of factor H would lead to C3b inactivation by factor I and would therefore terminate the propagation of the complement cascade.

Some activating materials generate high levels of both C3b and C5b-9, whereas other materials will generate high levels of C3b but little C5b-9. The reason why the efficiency of C5 convertase formation relative to that of C3 formation differs from one activating surface to another is not well understood. However, even low amounts of C5b-9 are able to activate leukocytes,[106] and, therefore, a low terminal complement-activating material may still induce a significant inflammatory response. The question remains as to what are the appropriate levels of complement activation that the host can accept without deleterious effect.

The hypothesis that material-induced complement activation occurs exclusively by the alternative pathway has been challenged. Reports of complement activation by the classical pathway during CPB[108,109] and a delay in complement activation observed with patients deficient in C4 who are undergoing hemodialysis[110] suggest that classical activation plays a role in material-induced activation. The presence of immune complexes may allow for a rapid onset of complement activation, and then subsequently the alternative pathway may also become activated. *In vitro* studies have also demonstrated activation of the classical pathway by some biomaterials (C. H. Gemmell, *unpublished work*, 2000).[111] C1 inhibitors such as pentamidine and benzamidine are effective in lowering platelet adhesion and activation by polystyrene beads and polyethylene tubes, whereas sCR1, an inhibitor of both pathways at the level of C3, has no effect (C. H. Gemmell, *unpublished work*, 2000).[112] Pentamidine was also effective in a canine chronic shunt by eliminating the thrombocytopenia seen with a platelet-activating material (a PVA hydrogel). A role for complement in platelet activation mediated by biomaterials offers new strategies to improve the thombogenicity of surfaces. Preliminary studies with surfaces modified with amidine derivatives (which have C1 complement inhibitory properties) have shown reduced platelet adhesion.[113,114]

Although some of the consequences of complement activation are well understood, more work is needed to fully understand how a material activates complement. Controlling the differential adsorption of C3b, factor D, and factor H may be more important than preparing the so-called nonfouling, low-adsorption surfaces. The latter may lower the adsorption of all proteins, but it may be more important to alter the composition of the protein adsorbate.

Leukocyte Activation and Coagulation

Circulating monocytes and neutrophils normally roll on the endothelium and adhere to damaged or stimulated endothelial cells or adherent platelets and further contribute to localized thrombogenesis through one or more mechanisms,[12] some of which apply to biomaterials.[12,115] Leukocytes have membrane-associated procoagulant activity, which is manifested by TF expression on the cell membrane (TF-dependent coagulation pathway), by TF-independent mechanisms through factor X binding to CD11b receptors leading to factor Xa generation or fibrinogen binding to CD11b, or by binding of the prothrombinase complex on the membrane. In addition, degranulation and oxidative products have the capacity to neutralize various anticoagulant proteins and activate platelets, whereas the association between platelets and neutrophils or monocytes may lead to mutual activation and to a microenvironment protected from inhibitors.

Many investigators thought that the extrinsic pathway is not activated during blood–material interactions.[10,116,117] However, blood contact with a material represents a stimulus to induce TF expression by monocytes,[67,71] resulting potentially in blood coagulation through the extrinsic system. Material-induced TF expression on monocytes *in vitro* results in significantly shorter clotting times when compared to control.[67] The TF expression appears to be strongly dependent on the presence of platelets and increases with material surface area.[71] Following blood contact with CPB circuits or ventricular assist devices, TF expression on monocytes has been observed *in vitro*[118,119] and *in vivo*.[69,120] TF-bearing monocyte MPs have also been shown to adhere to biomaterial surfaces *in vitro* and were able to support FXa activation.[121] Leukocyte MPs have previously been observed *in vivo*, and this may represent yet another way for leukocytes to contribute to thrombogenesis. CD11b, upregulated on monocytes by CPB, has been reported to directly activate factor X[122] and platelet–leukocyte aggregates have been observed,[123] as noted in the preceding passage. The number of studies that have tried to minimize thrombus formation by the administration of drugs specifically targeted at leukocytes underscores the potential role of leukocytes in thrombogenesis.[98,124,125] Antibodies to

block leukocyte adhesion may prove to be a reasonable therapeutic approach in the prevention of thrombus formation as demonstrated in *in vivo* baboon models.[98,126,127] An *in vivo* study recently identified C5a as a significant contributor to hemodialysis-associated thrombosis via TF expression on leukocytes.[128] Complement inhibition may thus also become a successful approach to controlling thrombosis on biomaterials.

The initiation of the coagulation cascade by contact-phase activation and TF expression occur at different times after exposure of blood to a biomaterial. Because it is part of the protein adsorption "reaction," contact-phase activation occurs during the first few seconds after blood contact with a material. On the other hand, the induction of TF expression and thrombin-generating activity in monocytes requires a minimum of 60 minutes (in a healthy patient). Thrombin generation by FXIIa on materials depends on flow,[129] because of the effects of flow on mass transfer as well as direct effects of flow on platelet/leukocyte phenotype. Therefore, the relative roles of the intrinsic and extrinsic pathways in thrombin generation probably depend on both time and blood flow. More research is needed to clarify the potential contribution of leukocyte procoagulant activities to thrombogenesis and thrombotic complications associated with the use of biomaterials and cardiovascular devices.

Fluid Dynamics

Fluid dynamics affect the growth of thrombi and the deposition of fibrin. The difference between arterial and venous thrombi is one example of this effect, although the underlying mechanisms are still not well understood. Thorough reviews are available,[130,131] and we merely highlight a few key points for the purpose of completeness. Flow determines the rates of transport of cells and proteins to the surface; it can also change the level of receptor expression on platelets and leukocytes. Because platelets are an important part of the thrombus, the effect of shear on platelets has been studied extensively. Higher shear results in higher platelet and lower fibrin deposition.[132] High shear in diseased, stenotic arteries is also able to induce platelet aggregation even in the absence of any other exogenous factors.[133,134] Conflicting results have been obtained on the effect of flow on leukocyte adhesion, whereas little is known of its effect on leukocyte activation. High shear has been shown to reduce, increase, or leave unchanged leukocyte adhesion on different substrates.[135–141] These conflicting results may be explained by differences in experimental conditions, including the presence of red blood cells,[141] platelets[137–139] and plasma proteins,[137] the surface studied,[138] and the state of leukocyte activation.[140]

As for the effects of flow on the coagulation cascade, it has been a subject of very little study. Current knowledge about biomaterials is limited to factor Xa generation initiated by the extrinsic pathway and thrombin generation initiated by the intrinsic pathway. Factor Xa generation by the complex TF:VIIa increases with shear rate (and shear stress).[142,143] For thrombin generation by the intrinsic pathway, modeling has identified three types of reactions[129]: at low flow, a significant amount of thrombin is produced after a long time lag (more than 10 hours); at moderate flow, significant thrombin generation is produced in a short time (within minutes); at high flow, low levels of thrombin are produced within seconds.

Turbulent flow can be present at anastomoses, joints, and bifurcations of cardiovascular devices, and such turbulence also contributes to the observed thrombosis. It is believed to play an important role in the failure of mechanical heart valves, for example. Turbulent flow (in contrast to recirculation and stagnation zones, which may or may not have the characteristics of turbulence) results in hemolysis and/or cell activation, but the mechanisms leading to thrombus formation are still poorly understood. Platelet deposition remains the focus of most studies, but the literature on turbulent flow and thrombus formation is more limited. Nonetheless, much effort has been devoted to the design of devices so that recirculation or stagnation zones are avoided because these are known loci for thrombus growth.

Surface Modification Strategies

Many different materials are found in cardiovascular devices. Polymers such as silicone rubber, polytetrafluoroethylene (PTFE), PVC, polyethylene, or polyurethanes are used in catheters, vascular implants, ventricular assist devices, and oxygenator membranes. Stainless steel and nickel–titanium are found in heart valves, vena cava filters, and stents. Pyrolytic carbon coatings have been used on prosthetic heart valves to improve biocompatibility, whereas chemically treated natural tissues such as pig or cadaver heart valves are also implanted. To improve the blood compatibility of cardiovascular devices, various surface modifications, such as attachment of antithrombotic agents or the immobilization of polyethylene oxide (PEO), have been considered, but their success has been limited (for a complete review, see[144]). PEO treatment to reduce protein adsorption and to prevent platelet adhesion has not reduced thrombogenicity.[145] Heparin-releasing polymers (e.g., heparin ionically bound or dispersed in surfaces), polymers with immobilized heparin (covalently bound), and heparin–PEO polymer coatings have been developed.[146] However, reports on the improvement of *in vivo* biocompatibility by heparinized surfaces with CPB tubing, catheters, and coronary stents have been mixed: heparin coatings have not been shown to significantly reduce the number of postoperative complications, improve patient outcome, or reduce hospital stay.[108,147–150]

Endothelial Cells

With most cardiovascular devices, blood interacts with a bare surface and the absence of endothelial cells may have a significant impact on material thrombogenicity. Dual antiplatelet therapy for at least a year has been recommended with DES to circumvent the lack of endothelialization and delayed healing.[151–154] The controversy between DES and bare metal stents illustrates the strong relationship between material-induced inflammation and thrombosis as well as the important role that endothelial cells can play in blood compatibility. To promote endothelialization, coatings that enable what have been termed endothelial progenitor cells to adhere are being investigated in the stent industry.[155,156] New polymers for drug delivery that are more compatible to endothelial cell attachment are also being developed.[147,157]

Seeding of endothelial cells on biomaterials to enhance antithrombogenicity before implantation has been under investigation for over 30 years but remains at the research stage (for a complete review, see Pawlowski et al.[158]), although there has been clinical success in the hands of some investigators.[159] To promote adhesion and to prevent detachment upon implantation,

adsorption of adhesive proteins, such as fibronectin[160] or specific peptide sequences, such as RGD[161] or YIGSR,[162] has been explored. However, biomaterials will influence endothelial cell phenotype (for a complete review, see McGuigan and Sefton[163]), and an activated phenotype may contribute to increase leukocyte infiltration (such as through the expression of ICAM-1) or thrombogenesis (TF expression).

While a biomaterial should promote endothelialization, material-induced leukocyte activation may also affect neighboring endothelial cells. Recent studies have shown that leukocytes having contacted polyurethanes, PTFE, or polymer beads induced endothelial cell procoagulant activity.[164,165]

The Patients

Patient disease or age may also significantly affect material thrombogenicity. Increased TF expression and other procoagulant factors have been reported in diabetic patients.[166] Harrison et al.[167] showed increased activation and adhesion of mononuclear cells from type 1 and type 2 diabetics on stainless steel. Following CPB, thrombotic complications are also increased in neonates and infants when compared to older children. It has been hypothesized that the strong inflammatory reaction induced by CPB leads to TF expression on endothelial cells and resulted in a state of hypercoagulability.[168] These two examples further highlight the importance of the extrinsic coagulation system and also the interrelation between inflammation and coagulation. These provide further design criteria for the development of new materials and/or drug therapy to minimize material-induced thrombosis.

CONCLUSIONS

Given the complexity of normal hemostatic events, it is not surprising that blood contact with artificial surfaces initiates a complex response, and the mechanisms of biomaterial-associated thrombosis are not completely clear. The role of FXII is unclear, whereas that of TF has only barely been studied. The mechanisms of leukocyte and platelet activation by materials remain to be further elucidated. The timing of the events contributing to thrombin formation is also a complex issue. Both FXII activation and platelet activation are able to generate thrombin formation within minutes, whereas thrombin generation by leukocyte TF requires hours. The question of what happens over hours to days as leukocytes synthesize TF and thrombotic deposits become remodeled is almost beyond current experimental capacity. Whether thrombosis leads to passivation or embolization or some other long-term consequence is still largely unknown.

Thrombosis is viewed now more as a multicellular event rather than just a platelet event.[169] The mechanism of material-induced platelet activation is often presumed to be by the generation of thrombin due to activation of the intrinsic coagulation cascade or the release of ADP from damaged red blood cells or platelets. A role for complement in activating platelets and the potential for complement to be activated by the fibrinolytic and kinin system have rarely been considered. If complement also plays a role in activating monocytes to express TF or directly generate fibrin,[127] then this will certainly refocus strategies in order to reduce material thrombogenicity.

CHAPTER 97

Overview of Complex Thrombohemorrhagic Disorders

THEODORE E. WARKENTIN AND VICTOR J. MARDER

This overview of "complex thrombohemorrhagic disorders" emphasizes their heterogeneous clinical presentation ranging from bleeding to microvascular and macrovascular thrombosis (see Table 97.1). These conditions have in common the potential for clinical presentation without symptoms, with bleeding or thrombotic events, or with simultaneous manifestations of hemorrhage, vascular occlusion, and organ failure. Although this disparate group of disorders has varied and distinct etiologies, they nevertheless can mimic one another. For example, a patient who presents with splenic infarction could have an underlying myeloproliferative neoplasm (MPN) or infective endocarditis with splenic artery septic emboli. The former diagnosis is suggested by an elevated platelet count, whereas thrombocytopenia suggests sepsis. Consider also the patient with dyspnea and thrombocytopenia beginning 10 days after cardiac surgery for whom the differential diagnosis includes pulmonary embolism (PE) with or without heparin-induced thrombocytopenia (HIT) and acute sepsis. The diagnosis would be clarified once results of blood cultures, radiologic imaging, and serologic testing for HIT antibodies are available.

To add further complexity, these disorders may coexist. For example, patients with antiphospholipid syndrome (APS) occasionally develop thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS).[1] Acral (distal extremity) limb necrosis may develop in a patient with HIT and deep vein thrombosis (DVT) who is treated with warfarin and thereby develops a variant of coumarin necrosis, venous limb gangrene.[2] Or, consider the occurrence of HIT with a platelet count nadir of 633×10^9/L that nonetheless represented a substantial decline from the baseline level of $1{,}235 \times 10^9$/L because of preexisting essential thrombocytosis (ET).[3]

The experienced clinician acquires a "feel" for the subtle differences in clinicopathologic profile among these disorders. For example, in TTP–HUS, the presence of red cell fragments (schistocytes), thrombocytopenia, and elevated lactate dehydrogenase is usually much more marked than in a patient with disseminated intravascular coagulation (DIC) associated with acute sepsis. Although patients with HIT can have red cell fragments too,[4] this is usually present only in the subgroup with more severe thrombocytopenia and overt (decompensated) DIC. Therefore, careful correlation of the laboratory and clinical picture usually points to the correct diagnosis.

CONSUMPTIVE THROMBOHEMORRHAGIC DISORDERS

The term "consumptive coagulopathy," or the common term, DIC, does not denote a discrete diagnosis but rather a heterogeneous group of disorders that have in common increased consumption of coagulation factors and/or platelets.[5] Indeed, some of the entities discussed as separate chapters (e.g., sepsis, TTP–HUS, HIT) represent forms of consumptive coagulopathy. Therefore, consumptive coagulopathies (as with anemia) must not be regarded as a diagnosis but rather as a clinicopathologic syndrome that begs the question, "what is the underlying diagnosis?"

Systemic activation of hemostasis in pathologic settings can have a wide spectrum of clinical consequences, ranging from no clinical effect, to generalized hemorrhage, to widespread microvascular thrombosis that predisposes to multisystem organ dysfunction and acral necrosis. Bleeding tends to predominate in DIC triggered by trauma, obstetrical complications, or snakebites, whereas DIC caused by HIT or metastatic adenocarcinoma tends to produce macrovascular thrombosis affecting large veins and arteries. Some malignancies, however, produce severe bleeding, such as prostate cancer with DIC and/or hyperfibrinolysis. Microvascular thrombosis often accompanies sepsis, particularly when caused by certain organisms (meningococcus, *Capnocytophaga canimorsus*) that predispose to acral limb necrosis (sepsis-associated purpura fulminans). Contributing causes of thrombosis include severe depletion of protein C and antithrombin, ongoing thrombin production, and reduced limb perfusion secondary to shock or vasopressors.[6] To further complicate the myriad clinical features, consumption may be restricted to local processes alone, such as with a vascular malformation, aortic aneurysm, or placental abruption, any of which can cause localized activation of coagulation sufficient to deplete platelets and/or coagulation factors.[7]

THROMBOTIC THROMBOCYTOPENIC PURPURA–HEMOLYTIC UREMIC SYNDROME

The duo of microangiopathic hemolysis (red cell fragmentation) and thrombocytopenia—also known as thrombotic microangiopathy, or TMA—in the absence of an alternative explanation constitutes the modern notion of TTP–HUS.[8,9] Many, if not most, patients with "idiopathic" TTP–HUS have autoantibodies that inhibit function of ADAMTS13 (a disintegrin and

Table 97.1

Bleeding and thrombosis of complex thrombohemorrhagic syndromes

Disorder	Bleeding	Microthrombosis	Macrothrombosis
Consumptive coagulopathies (DIC)	Variable, depending on cause	Variable, cerebral (mental status), renal (oliguria), skin (purpura fulminans); limb necrosis (acquired protein C depletion)	Variable, large vein and artery thrombosis with underlying adenocarcinoma or HIT, or with use of antifibrinolytic therapy
TTP–HUS	Usually no bleeding, but petechiae and ecchymoses possible with severe thrombocytopenia	Organ dysfunction (CNS, renal) due to arterial platelet–vWF microaggregates	Occasional cerebral artery (thrombotic stroke in children with congenital form)
Vasculitides	GI bleeding (if vasculitis involves GI tract, e.g., polyarteritis nodosa); dermal hemorrhage (small-vessel vasculitis); hemoptysis (pulmonary capillaritis)	Variable, "palpable purpura" is a feature of small-vessel vasculitis; renal, neurologic, and other organ dysfunction	Macrothrombosis can be mimicked by nonthrombotic vasculitis–related vessel obstruction (e.g., intimal hyperplasia in giant cell arteritis) or large-artery dissection; aneurysm-related thrombosis
APS	Bleeding uncommon; when present, usually results from associated thrombocytopenia, low factor II, or anticoagulant therapy	Microvascular thrombosis and multiple organ failure in severe cases	Venous thrombosis in unusual sites (upper limb, abdominal, renal, cerebral), PE, coronary artery, cerebral artery (stroke, TIA), retinal ischemia, nonbacterial endocarditis; hemorrhagic adrenal infarction; recurrent fetal loss (placental infarcts)
MPN	Mucocutaneous, CNS, retinal, retroperitoneal, deep tissue, postoperative, aspirin-induced	PV and ET: intracranial (headache, visual disturbances), digital ischemia, erythromelalgia	PV and ET: cerebral artery (transient ischemia or thrombotic stroke), retinal vein occlusion, cerebral sinus thrombosis, coronary (acute MI, coronary syndromes), DVT, PE, mesenteric/portal/hepatic vein thrombosis
Stem cell transplant	Mucocutaneous bleeding with severe thrombocytopenia; diffuse alveolar hemorrhage; hemorrhagic cystitis	Hepatic veno-occlusive disease; TMA	Venous thromboembolism (DVT, PE)
Sepsis	Bleeding associated with thrombocytopenia, elevated PT or aPTT	Variable, organ dysfunction and dermal/acral necrosis	Uncommon; if DVT present, predisposes to peripheral limb ischemia/necrosis
HIT	Bleeding uncommon, except during anticoagulant therapy	Usually associated with coumarin; rarely, overt consumptive coagulopathy	DVT and PE, cerebral vein thrombosis, limb artery thrombosis, cerebral (stroke), coronary (acute MI), hemorrhagic adrenal infarction
Coumarin-induced necrosis	Early skin necrosis may resemble cutaneous hematoma	Thrombosis of subdermal venules (skin necrosis), venous limb gangrene	Associated large vein thrombosis predisposes to subtending microvascular thrombosis and acral limb necrosis

MPN, myeloproliferative neoplasms; CNS, central nervous system; PV, polycythemia vera; ET, essential thrombocytosis; DVT, deep vein thrombosis; GI, gastrointestinal; MI, myocardial infarction; PE, pulmonary embolism; DIC, disseminated intravascular coagulation; HIT, heparin-induced thrombocytopenia; PT, prothrombin time; aPTT, activated partial thromboplastin time; TTP–HUS, thrombotic thrombocytopenic purpura–hemolytic uremic syndrome; vWF, von Willebrand factor; APS, antiphospholipid syndrome; TIA, transient ischemic attack.

metalloprotease with thrombospondin 1–like domains). Because ADAMTS13 proteolyzes large multimers of von Willebrand factor (vWF) under high shear stress, reduced enzyme activity predisposes patients to formation of platelet–vWF microaggregates in small arterioles (hyaline thrombi) that constitute the pathologic hallmark of TTP–HUS. Associated organ dysfunction can cause neurologic abnormalities, oliguric renal insufficiency, myocardial ischemia, and pancreatitis. The importance of recognizing TTP–HUS relates to its special treatment by plasma exchange with fresh frozen (or cryosupernatant) plasma. This therapy reduces mortality, from >90% as occurred before 1964 to <20% today.[10] Illnesses strongly resembling TTP–HUS occur with drugs (e.g., quinine, mitomycin, cyclosporine), hematopoietic stem cell transplantation, pregnancy and the postpartum period, and autoimmune disorders (e.g., systemic lupus erythematosus, APS, acute scleroderma). Sometimes, TTP begins after surgery ("postoperative TTP"), a clinical scenario that could mimic sepsis or HIT.[11]

Classic HUS refers to a disorder in which oliguric renal failure is predominant, although 15% to 25% of patients develop neurologic abnormalities. HUS usually follows a hemorrhagic colitis that most often is caused by Shiga toxin–producing *Escherichia coli* O157:H7.[12] In 2011, a central European epidemic of Shiga toxin–producing *E. coli* O104:H4 linked to consumption of sprouts[13] was associated with a high frequency (20%) of HUS.[14] Treatment of HUS is supportive, although severely affected patients may benefit from plasma exchange or, possibly, immunoadsorption.[15]

VASCULITIDES

The vasculitides consist of a heterogeneous group of inflammatory disorders that targets and damages blood vessels.[16] Different forms of vasculitis tend to involve vessels of different sizes: large-vessel vasculitis (e.g., giant cell arteritis, Takayasu arteritis, IgG4-related aortitis), medium-sized vessel vasculitis (e.g., polyarteritis nodosa, Kawasaki disease, lupus), and small-vessel vasculitis, which is subdivided into circulating antineutrophil cytoplasmic antibody (ANCA)-positive and ANCA-negative categories. ANCA-associated small-vessel vasculitis comprises Wegener granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis, whereas those not associated with ANCA include the various immune complex small-vessel vasculitides, primarily Henoch-Schönlein purpura, cryoglobulinemic vasculitis, lupus-related, infection-related, and drug reactions, among others. Rheumatoid arthritis can be associated with either large-vessel vasculitis (rheumatoid aortitis) or small/medium-sized vessels (rheumatoid vasculitis); lupus is most likely to be associated with small-vessel leukocytoclastic vasculitis but can also be associated with vasculitis affecting medium-sized vessels.

Clinical consequences of vasculitis—such as stroke or sudden blindness—can mimic acute thrombosis, although intense intimal hyperplasia (e.g., giant cell arteritis) or marked fibrous intimal thickening (e.g., Takayasu arteritis) are more probable explanations for vessel obstruction.

ANTIPHOSPHOLIPID SYNDROME

APS is a chronic acquired thrombophilia that is strongly associated with venous and arterial thrombosis. Its *sine qua non* is the presence of autoantibodies that are detected by their effect in prolonging phospholipid-dependent coagulation assays ("lupus anticoagulant") or by immunoassays that detect reactivity against cardiolipin or other phospholipids.[17] In actuality, these "antiphospholipid" antibodies are directed against membrane proteins, most often β_2-glycoprotein 1.

"Definite APS" is defined as a clinicopathologic syndrome consisting of thrombosis and/or recurrent fetal loss plus the presence of anticardiolipin antibodies, anti-β_2-glycoprotein 1, and/or lupus anticoagulant, detected on two or more occasions at least 12 weeks apart.[18] A problem in diagnosis is that some patients have other clinical manifestations (e.g., thrombocytopenia, cardiac valvulitis, neurologic or renal abnormalities, skin ulcers) referred to as "noncriteria clinical manifestations"[19]; conversely, nonpathologic antiphospholipid antibodies can be detected in many normal individuals[20] and transiently after infection[21] or use of certain drugs such as procainamide and quinidine. Seronegative APS indicates a patient with acute thrombosis who initially has negative testing for antiphospholipid antibodies that subsequently appear and persist on later testing.[22] Rare patients develop widespread thrombosis affecting large and small vessels with associated organ failure, so-called catastrophic APS.[23]

Thrombotic events are generally treated as indicated for patients without APS,[17] except that the patients with APS with spontaneous or recurrent thrombosis should receive long-term anticoagulation. An additional consideration is that monitoring heparin or warfarin can be complicated by baseline prolongation of the activated partial thromboplastin time (aPTT) or prothrombin time (PT) because of the *in vitro* effects of the antiphospholipid antibodies.

MYELOPROLIFERATIVE NEOPLASMS

Examples of "classic" MPN include the clonal stem cell disorders, polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis.[24] Unlike most of the other disorders considered in this overview, patients with ET and PV typically have elevated platelet counts. Many patients evince both bleeding and thrombosis, for example, the patient with ET who has increased postoperative bleeding but also an increased risk of thrombotic stroke or myocardial infarction. Prominent microvascular disturbances in PV and ET include headache, lightheadedness, fleeting visual problems, acral paresthesias, and erythromelalgia (acral erythema, warmth, and pain), the latter a direct result of local platelet–endothelial interactions within the small vessels of the fingers and feet. Raised hematocrit levels are an important determinant of thrombotic risk in PV, whereas thrombocythemia is associated with increased risk of thrombosis in ET. Accordingly, phlebotomy (for PV) and hydroxyurea (for PV or ET) are often used to reduce thrombotic risk in appropriate patients. Lowering of elevated platelet counts by cytoreductive therapy, paradoxically, can improve bleeding symptoms by correcting acquired von Willebrand syndrome, which results from enhanced platelet–vWF interactions.[25]

STEM CELL TRANSPLANT-ASSOCIATED THROMBOHEMORRHAGIC DISORDERS

Thrombotic and hemorrhagic disorders are common in stem cell transplant recipients, primarily because of endothelial cell injury, profound thrombocytopenia, and acquired deficiencies in procoagulant and anticoagulant factors.[26]

Clinical consequences include thromboembolic events, hepatic veno-occlusive disease, and TMA. Unlike classic TTP, however, transplant-associated TMA is not characterized by reduced levels of ADAMTS13 or by anti-ADAMTS13 autoantibodies. Characteristic posttransplant bleeding syndromes include diffuse alveolar hemorrhage and hemorrhagic cystitis.

SEPSIS

Sepsis is a common cause of hemostatic abnormalities.[27] Coagulation testing generally reveals increased fibrin degradation products and thrombocytopenia, with some patients additionally evincing elevation in the PT or aPTT, reduced fibrinogen levels, or decreased activity of the coagulation inhibitors, antithrombin and protein C. Thrombocytopenia is associated with both increased bleeding risk and mortality,[28] as are increases of 1.5 times or more in the global coagulation times.[29,30] The association between bacteremia (or fungemia) and thrombocytopenia signifies that blood cultures are an appropriate investigation for many patients who develop thrombocytopenia without apparent cause. Microvascular thrombosis is believed to be at least in part responsible for multiple organ dysfunction.[27,31] The serious clinical sequelae of sepsis and associated DIC are best illustrated by meningococcemia, in which severely affected patients develop multiple organ failure, disseminated purpura (dermal infarction), and acral limb necrosis. In such patients, profound depletion of protein C is largely responsible for the microvascular thrombosis and associated tissue damage.[6] Large-vessel thrombosis such as DVT occurs less often in sepsis than does microvascular thrombosis.

HEPARIN-INDUCED THROMBOCYTOPENIA

HIT is a clinicopathologic disorder that can be defined as any clinical event best explained by platelet-activating antiplatelet factor 4 (PF4)/heparin antibodies ("HIT antibodies") in a patient who is receiving, or who has recently received, heparin.[32] The high sensitivity of ELISA-based assays for HIT antibodies means that negative tests virtually rule out the diagnosis.[33] The most common clinical event is thrombocytopenia, which is seen in at least 90% of patients, depending upon the definition of thrombocytopenia. Symptomatic thrombosis that involves large veins and arteries is common in HIT (relative risk, 12–15).[34] Microvascular thrombosis also can occur, usually as a complication of warfarin treatment.[2] HIT has a unique transient nature, in contrast to hereditary hypercoagulability states or other acquired severe prothrombotic disorders (e.g., APS, cancer-associated DIC). Indeed, the pathogenic HIT antibodies often become undetectable within a few weeks or months following platelet count recovery.[35] In patients who have a strong indication for heparin, such as needed for cardiac surgery, heparin is usually the best choice despite a history of previous HIT, provided that platelet-activating antibodies are not detectable at the time of repeat exposure.[36]

Another unusual feature of HIT is its well-defined time of onset between 5 and 10 days after the immunizing exposure to heparin.[35] Most commonly, heparin causes immunization when given during or immediately before or after a surgical procedure. This suggests that there is an interaction between heparin and perioperative events, such as release of PF4 or inflammatory events, in leading to antibody formation ("point immunization").[37] The characteristic temporal onset, the relatively common occurrence of HIT, and the proven benefit of anticoagulants for preventing or treating thrombosis associated with HIT provide a rationale for platelet count monitoring of patients at higher risk for this potentially life- and limb-threatening complication of heparin.[38]

COUMARIN NECROSIS

Coumarins are orally active vitamin K antagonists commonly given for long-term anticoagulation. Their anticoagulant effect results from reduction of the vitamin K–dependent procoagulant factors, especially prothrombin (factor II). However, on occasion, the reduction of one or both of the vitamin K–dependent natural anticoagulants—proteins C and S—is sufficiently severe, or occurs in a suitably susceptible patient, to cause microvascular thrombosis and tissue necrosis.[39] This pathophysiology reflects the key role of the protein C natural anticoagulant pathway to downregulate thrombin in the microvasculature. Coumarin necrosis generally involves a complex interplay of several factors that conspire to produce a transient disturbance in procoagulant–anticoagulant balance. For example, consider a patient with APS and postpartum DVT, who develops necrosis following high "loading doses" of warfarin and premature discontinuation of heparin.[40] The acute DVT and early stopping of heparin may lead to increased procoagulant activity, whereas the high initial warfarin dosing and the (presumably) impaired protein C anticoagulant pathway related to APS create a "perfect storm" resulting in microvascular thrombosis and skin necrosis.

There are two syndromes of coumarin necrosis: "classic" skin necrosis involving dermal and subdermal tissues and venous limb gangrene involving acral (distal extremity) necrosis, usually in a limb with DVT.[41] As a general rule, skin necrosis often occurs in a patient with chronic impairment of the protein C natural anticoagulant pathway (e.g., congenital deficiency in protein C or protein S, factor V_{Leiden}, antiphospholipid antibodies), whereas venous limb gangrene typically occurs in a patient with an acquired hypercoagulability state with prominent platelet activation, such as HIT or cancer-associated consumption coagulopathy.[2,42] However, these distinctions are not absolute: Some patients with HIT develop classic warfarin-induced skin necrosis,[43] and factor V_{Leiden} predisposes to venous limb gangrene in a patient receiving warfarin for DVT.

SUMMARY

Common to all of these disorders is the important role for the clinician to explain and, if possible, treat effectively the combination of bleeding or clotting (sometimes both in the same patient) associated with a wide spectrum of laboratory abnormalities that can involve various coagulation factors, platelet number or function, and even red and white blood cells. The complexity of each underlying condition warrants a careful analysis of cause, manifestation, and pathophysiology, and treatment must be both rational and individualized for each circumstance.

CHAPTER

98 Consumptive Thrombohemorrhagic Disorders

MARCEL LEVI, DONALD I. FEINSTEIN, ROBERT W. COLMAN, AND VICTOR J. MARDER

Known variously as *disseminated intravascular coagulation* (DIC), *defibrination*, or the *consumption coagulopathies*, consumptive thrombohemorrhagic disorders are a heterogeneous group of disorders that can be manifested by the entire range of hemorrhagic and thrombotic pathology. Essentially, DIC comprises a clinicopathological state in which systemic activation of coagulation occurs, leading to thrombotic obstruction of small- and mid-size vessels[1,2,3,4,5] impairing blood supply and contributing to multiple-organ dysfunction (MOD). Due to ongoing activation of the coagulation system and other processes, such as impaired synthesis of platelets and coagulation proteins, depletion of coagulation factors, protease inhibitors, and platelets may occur.[6,7] This situation leads to a severe impairment of hemostasis and results in serious bleeding, in particular in patients who are at risk for major blood loss, such as perioperative patients or trauma patients. In fact, bleeding may dominate the clinical picture of a patient with DIC.

In view of these multiple, often contrasting mechanisms that occur in patients with DIC, a consensual definition of DIC had been a matter of debate. In 2001, the subcommittee on DIC of the International Society on Thrombosis and Hemostasis proposed a definition that reflects the central role of the microvascular milieu, that is, endothelial cells, blood cells, and the plasma protease system, in the pathogenesis of DIC. This definition of DIC reads as follows: "DIC is an acquired syndrome characterized by the intravascular activation of coagulation without a specific localization and arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."[8]

The diagnosis of DIC may be hampered by the nonspecific nature of many indicators of coagulation activation, although newly developed scoring algorithms, based on readily available routine laboratory parameters, show promising diagnostic accuracy.[8,9] Owing to the complexity of the clinical presentation, the variable and unpredictable course, and the multitude of therapies given to patients with DIC, properly conducted clinical trials are extremely difficult to perform and even to devise. Management relies on limited evidence from clinical trials in combination with small studies employing surrogate outcome parameters and experience from case series, as well as an understanding of the pathophysiologic mechanisms involved, together precariously applied to the individual patient.[10]

HISTORY

One of the first reports of DIC comes from Dupuy in 1834, who described the effect of the intravenous injection of brain material in animals.[11] The animals almost immediately died, and at autopsy there were widespread clots in the circulation, presumably due to what we would now call tissue factor (TF)-dependent systemic activation of coagulation. Thirty years later, Trousseau described the thrombotic tendency and the inclination of blood to clot in patients with advanced malignant disease.[12,13] Nauyn observed gross intravascular coagulation of animal blood after infusion of hemolyzed erythrocytes,[14] and Foa and Pellacani[15] observed the same phenomenon after injection of a variety of fresh organ extracts. Mellanby recognized that the coagulation defect of DIC produced by snake venoms resulted in hypofibrinogenemia.[16,17] A more precise description of DIC and its underlying pathogenesis had to wait until 1955 when more insight into the mechanism of blood coagulation was attained and better laboratory tests had become available. Ratnoff et al.[18] describe the hemostatic abnormalities that occur in women with fetal death and amniotic fluid embolism. McKay[19] was the first to realize that DIC was an "intermediary mechanism" in many diseases. Hardaway[2] emphasized that shock and acidosis occurring in a variety of diseases could initiate clotting with consumption of fibrinogen, platelets, and other coagulation factors. Verstraete et al.[20] reported several other cases of successful heparin use in DIC and suggested that this drug might be of more general value.

CLINICAL FEATURES OF CONSUMPTIVE THROMBOHEMORRHAGIC DISORDERS

The spectrum of clinical and laboratory presentation is affected by several parameters, as listed in Table 98.1. Herein lies much of the confusion, especially because sometimes cases of so-called DIC are not disseminated, or intravascular, or even related to coagulation. These variables determine whether specific (supportive) therapy for the "consumption" is required, over and above that indicated for the underlying disease or its other complications. Table 98.2 summarizes the clinical manifestations of severe consumptive hemorrhagic disorders.

When presented with the patient with a clinical suspicion of DIC, the physician must judge whether the clinical presentation is severe enough to warrant specific therapy, and whether the coagulation disorder is likely to be a self-limiting problem that will wane on therapy for the underlying condition or will gather momentum and assume importance beyond that of the initiating stimulus. If the problem comes to the attention only as the result of a screening laboratory survey, management will depend on whether an abnormal test result is the only reflection of consumption or whether serious clinical manifestations also exist or are likely to develop. In particular, signs of ischemic organ dysfunction, macrovascular thrombosis, excessive bleeding, and fragmentation hemolytic anemia should be sought (FIGURE 98.1).

Table 98.1

Parameters that influence the clinical and laboratory presentation of consumptive thrombohemorrhagic disorders

Parameter	Variation
Tempo	Acute vs. chronic Mild vs. severe
Location	Localized vs. systemic (disseminated) Intravascular vs. extravascular
Pathologic mechanism	Tissue factor—mediated thrombin generation + impaired anticoagulant pathways + impaired plasmin formation Primary hyperfibrinolysis Isolated platelet consumption

Given that factors of tempo, location, and pathophysiology can all operate as independent variables superimposed on a variety of underlying disorders, each patient's clinical and laboratory presentation must be individually considered before rational management can be started.

Many clinical entities have been associated with DIC,[1,21] and the major conditions are listed in Table 98.3. The frequency of DIC in these diseases varies considerably, ranging from rare or doubtful according to current criteria for DIC to highly frequent (severe gram-negative sepsis). Infectious diseases and malignant disorders together account for approximately two-thirds of DIC cases in the major series.[22,23,24] Trauma was a major cause of DIC in some series, probably reflecting the specialized nature of the clinical case mix in those centers.[25]

ACUTE, SEVERE CONSUMPTION COAGULOPATHY

Acute, severe DIC could be defined as a "pathological syndrome resulting from activation (and consumption) of certain coagulant proteins, formation of thrombin, and production of fibrin thrombi."[7] Diffuse multiorgan bleeding, hemorrhagic necrosis, microthrombi in small blood vessels, and thrombi in medium and large blood vessels are common findings at autopsy, although patients who had unequivocal clinical and laboratory signs of DIC may not have consistent postmortem findings.[26,27] Conversely, some patients in whom clinical and laboratory signs were not diagnostic of DIC had typical autopsy findings.[28,29] This occasional lack of correlation among clinical, laboratory, and pathologic findings is partly due to extensive postmortem changes in the blood, for example, excessive fibrinolysis, but remains unexplained in most instances.[27] Organs most frequently involved by diffuse microthrombi are the lungs and kidneys, followed by the brain, heart, liver, spleen, adrenal glands, pancreas, and gastrointestinal organs. Most thrombi consist of fibrin monomers or polymers in combination with platelets, and activated mononuclear or other inflammatory cells and other signs of inflammatory activation.[30] In cases of long-lasting DIC, organization and endothelialization of the microthrombi are often observed. Acute tubular necrosis is more frequent than renal cortical necrosis.[26] Clinically, thrombotic occlusive events occur first, as the result of microthrombi of fibrin or platelets

Table 98.2

Clinical manifestations of severe consumptive hemorrhagic disorders

Organ	Manifestation
Skin	Purpura, bleeding from injury sites, hemorrhagic bullae, focal necrosis, acral gangrene
Cardiovascular	Shock, acidosis, myocardial infarction, cerebrovascular events, thromboembolism in all types, and caliber blood vessels
Renal	Acute renal insufficiency (acute tubular necrosis), oliguria, hematuria, renal cortical necrosis
Liver	Hepatic failure, jaundice
Lungs	Adult respiratory distress syndrome, hypoxemia, edema, hemorrhage
Gastrointestinal	Bleeding, mucosal necrosis and ulceration, intestinal ischemia
Central nervous	Coma, convulsions, focal lesions, bleeding
Adrenals	Adrenal insufficiency (hemorrhagic necrosis)

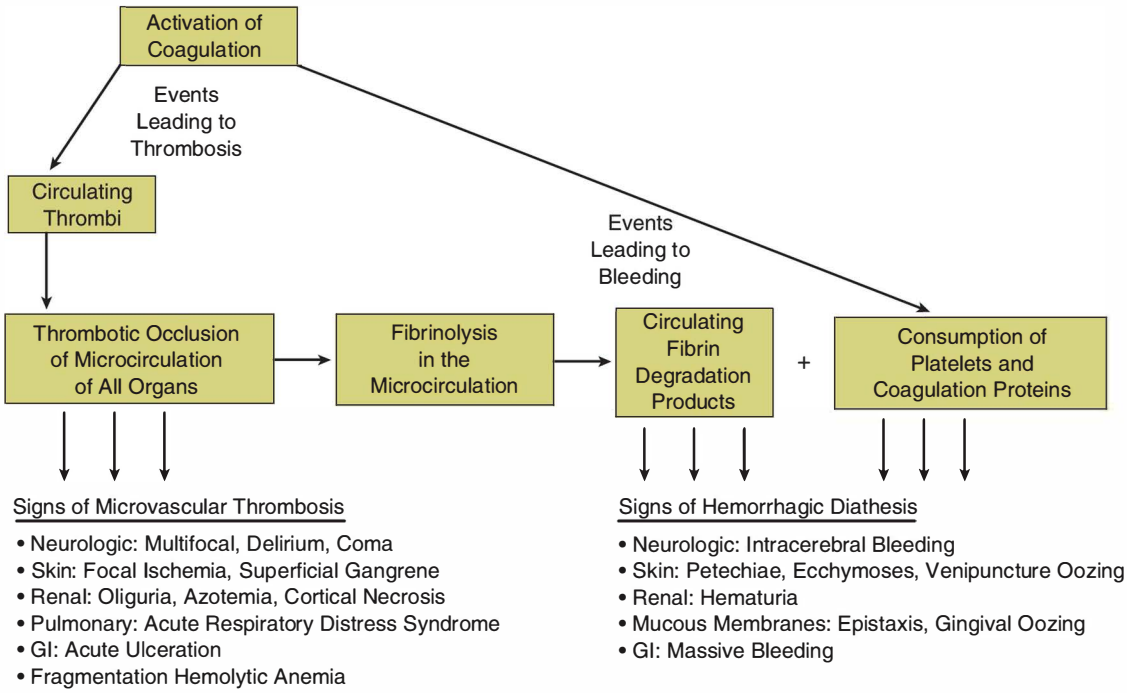

FIGURE 98.1 Sequence of events during DIC, leading to the clinical appearance of thrombotic and hemorrhagic phenomena. GI, gastrointestinal. (From Marder VJ. Microvascular thrombosis. In: Lichtman MA, ed. *The science and practice of clinical medicine*, vol 6. New York: Grune & Stratton, 1980:230–234, with permission.)

that obstruct the microcirculation of organs (FIGURE 98.1).[5] These thrombi result from clots that form either in the circulation or *in situ* in arterioles, capillaries, or venules. Circulatory obstruction produces organ hypoperfusion and even ischemia, infarction, and necrosis. The process is disseminated throughout the microcirculation; therefore, all organs are potentially vulnerable. Venous thromboembolism or arterial embolism from nonbacterial endocarditis can occur but are much more common in patients with subacute or chronic DIC, particularly in those patients with malignant disease.[23]

Renal dysfunction in patients with DIC is usually multifactorial. The conditions usually associated with DIC are frequently complicated by hypovolemia or hypotension that causes prerenal azotemia, even renal failure due to acute tubular necrosis. Thrombosis of renal afferent arterioles or glomerular capillaries by fibrin thrombi may cause ischemic renal cortical necrosis (FIGURE 98.2).

Cerebral dysfunction is most often manifested as global changes, such as an altered state of consciousness, convulsions, or coma, rather than by isolated focal lesions. Pathologic lesions affecting cerebral function may also include major vessel occlusion and subarachnoid hemorrhage, as well as multiple cortical and brainstem hemorrhages following microvascular occlusions.[31] Microthrombi, macrothrombi, emboli, and hemorrhage in the cerebral vasculature all have been held responsible for the nonspecific neurologic symptoms and signs displayed by patients with DIC.[32]

Respiratory dysfunction in DIC can manifest as transient hypoxemia in mild cases to hemoptysis, dyspnea, and chest pain caused by pulmonary hemorrhage and adult respiratory distress syndrome (ARDS) in severe cases.[33–35] Physical examination reveals rales, wheezing, and occasionally pleural friction rub, and imaging shows diffuse infiltration resulting from intra-alveolar hemorrhage. ARDS is characterized by tachypnea, auscultatory silence, hypoxemia, low lung compliance, normal wedge pressure, and "white lungs" on chest images.[36] It stems from severe damage to the pulmonary vascular endothelium, which permits egress of blood components into the pulmonary interstitium and alveoli. This situation leads to intra-alveolar hyaline membrane formation and severe respiratory insufficiency.[37] ARDS can be caused by septic shock, severe trauma, fat embolism, amniotic fluid embolism, and heat stroke, but only a fraction of patients with ARDS exhibit signs of DIC. When DIC and ARDS are simultaneously triggered, each aggravates the other.

Hepatocellular dysfunction sufficient to cause jaundice has been reported in 20% to 50% of patients with DIC,[4,25] notably in patients with infection and prolonged hypotension. Cellular necrosis around the hepatic central veins may follow shock and hypoxemia or intravascular coagulation,[26,38] leading to decreased synthesis of procoagulant and anticoagulant factors.

Adrenal cortical failure, producing the Waterhouse-Friderichsen syndrome,[39] is a consequence of hemorrhagic necrosis.

Fragmentation-type hemolysis (microangiopathy) secondary to fibrin deposition in the microvasculature may contribute to anemia[40] (FIGURE 98.3). However, overt hemolytic anemia associated with DIC occurs in only 5% to 10% of patients, and similar morphologic abnormalities occur in many other disorders not associated with fibrin formation (e.g., thrombotic thrombocytopenic purpura [TTP]).

Table 98.3

Clinical conditions that may be complicated by consumption coagulopathy

Acute, Severe Consumption Coagulopathy

- Sepsis/severe infection
- Trauma
- Heat stroke
- Snake bite
- Obstetrical conditions
  - Amniotic fluid embolism
  - Abruptio placentae
  - HELLP syndrome
- Liver disease (e.g., after peritoneovenous shunt)
- Acute hemolysis and transfusion reactions

Chronic Consumption Coagulopathy

- Malignancy
  - Solid tumors
  - Hematological malignancies
- Liver disease

Localized Intravascular Coagulation

- Vascular abnormalities
  - Kasabach-Merritt syndrome
  - Other vascular malformations
  - Aortic aneurysms

FIGURE 98.2 Kidney biopsy from a patient with sepsis-related disseminated intravascular coagulation (DIC). The picture shows intravascular fibrin in a small arteriole (*arrow*). (Photograph courtesy of Jan J. Weening, MD, Amsterdam, The Netherlands.)

Dermal ischemia and hemorrhagic skin necrosis occurs particularly in patients with acute DIC (see FIGURE 98.4), particularly those associated with severe infection, hypotension, and peripheral vasoconstriction. This complication of acute DIC is in contrast to idiopathic purpura fulminans, which typically occurs in young children who may be convalescing from an infection involving the skin and who are *not* acutely infected at the time of the appearance of purpura fulminans.[41,42]

Although the initial pathologic events are manifested by fibrin deposition in the microcirculation, the patient's initial clinical events may relate to hemorrhagic manifestations such as mucosal oozing, spontaneous ecchymoses, petechiae, and massive gastrointestinal (GI) blood loss. If the patient has had recent invasive or operative procedures, the incisions will also be vulnerable to excessive bleeding. The latter results from ongoing consumption and relatively insufficient synthesis of platelets and hemostatic factors.

Disorders Associated with Acute DIC

Infections

Virtually every type of infectious agent has been implicated in the consumptive thrombohemorrhagic disorders, usually producing mild or severe systemic intravascular coagulation, with consumption of platelets and soluble clotting factors (see also Chapter 123: *Thrombohemorhagic Complications of Sepsis*). The most flagrant examples are the Waterhouse-Friderichsen syndrome and purpura fulminans, both of which bear pathologic and histologic similarity to the experimental animal model of consumption, the Shwartzman reaction.[43] The Waterhouse-Friderichsen syndrome is most commonly seen during fulminant meningococcal sepsis, although other organisms such as *Pneumococcus* may

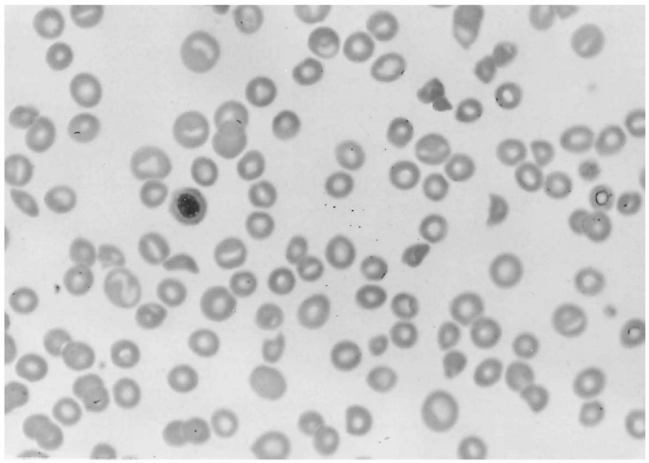

FIGURE 98.3 Microangiopathic hemolytic anemia in a patient with thrombotic thrombocytopenia purpura (TTP): A nucleated red blood cell is seen in addition to the schistocytes and other fragmented erythrocytic forms.

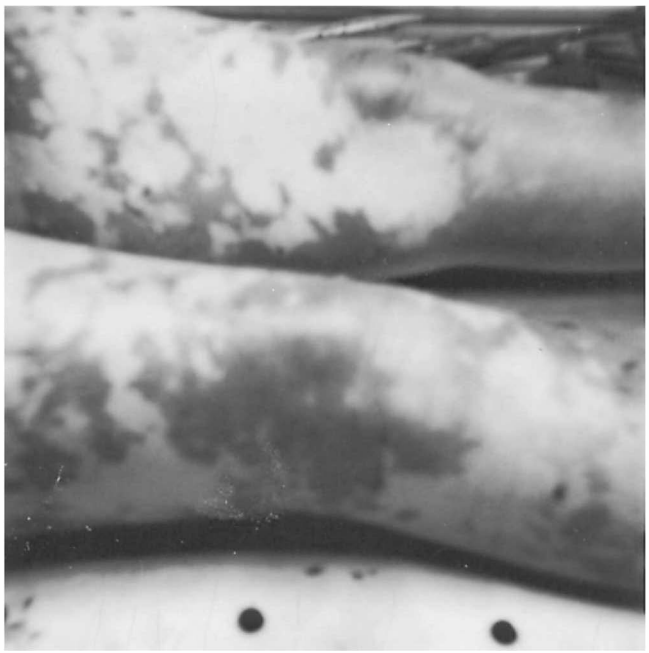

FIGURE 98.4 Patient with purpura fulminans, showing the irregular distribution of ischemic and hemorrhagic cutaneous lesions that reflect widespread occlusion of the arteriolar supply to the skin.

also cause this complication.[42,44] Widespread intravascular fibrin and platelet thrombi obstruct arterioles, capillaries, and venules of vital organs, especially causing bilateral hemorrhagic necrosis of the adrenals. This type of sepsis is associated with severe shock, which contributes significantly to high mortality. Although these clinical entities appear to be distinctive syndromes, they can be considered extreme manifestations of acute DIC. Variations in the acuteness of onset and the degree of consumption, perhaps related to the patient's age and health and the type of infectious agent, account for the wide range of clinical manifestations, including in some patients with laboratory abnormalities of consumption but without clinical signs.

Bacterial infections are among the most common causes of DIC.[1,45] Certain patients are particularly vulnerable to infection-induced DIC, such as immune-compromised hosts; asplenic patients whose ability to clear bacteria, particularly pneumococci, is impaired; and newborns whose coagulation inhibitory systems are immature. In addition, infections can aggravate bleeding and thrombosis by directly inducing thrombocytopenia, hepatic dysfunction, and shock.[46] Clinically overt DIC may occur in 30% to 50% of patients with gram-negative sepsis[47,48] and is common in patients with gram-positive sepsis.[49,50] Extreme examples of sepsis-related DIC are *Streptococcus* A toxic shock syndrome, characterized by deep-tissue infection and vascular collapse,[51] and meningococcemia characterized by extensive hemorrhagic necrosis and shock. The extent of hemostatic derangement in patients with meningococcemia correlates with prognosis.[52,53] Patients affected by *Pseudomonas aeruginosa*, *Escherichia coli*, and *Proteus vulgaris* bacteremias may have only laboratory signs of activated coagulation or may present with severe DIC, especially accompanied by shock.[54,55]

The mechanism by which DIC is elicited in *Staphylococcus aureus* bacteremia may be related to an α-toxin that activates platelets and induces IL-1 secretion by macrophages.[56] *Streptococcus pneumoniae* infection has been associated with the Waterhouse-Friderichsen syndrome particularly in asplenic patients,[57] ascribed to a capsular antigen and to antigen–antibody complex formation.[58] Clostridial bacteremia is a highly lethal disease characterized by septic shock, DIC, renal failure, and hemolytic anemia.[59]

Activation of the coagulation system has also been documented for nonbacterial pathogens, that is, viruses causing hemorrhagic fevers,[59,60] protozoa (Malaria),[61,62] and fungi.[63] Common viral infections, such as influenza, varicella, rubella, and rubeola, have rarely been associated with DIC.[64] However, purpura fulminans associated with DIC has been reported in patients with infections and either hereditary thrombophilias[65,66] or acquired antibodies to protein S.[67] Other viral infections can cause "hemorrhagic fevers" characterized by fever, hypotension, bleeding, and renal failure (see Chapter 123). Laboratory evidence of DIC can accompany Korean, rift valley, and dengue-related hemorrhagic fevers,[68–70] perhaps secondary to TF release from cells in which viruses replicate[71] and increased levels of proinflammatory cytokines.[58]

Purpura Fulminans

Purpura fulminans is a severe, often lethal form of DIC in which extensive areas of the skin over the extremities and buttocks undergo hemorrhagic necrosis.[41] The disease affects infants and children predominantly[72,73] and may occur in patients with acute bacterial infections and in patients with preexisting inherited or acquired disorders of the protein C anticoagulant pathway. Sepsis-associated purpura fulminans is much more common in children than adults,[39] *Meningococcus* being the most common (but not the sole) organism involved.[4] Onset may appear 2 to 4 weeks after a mild infection such as scarlet fever, varicella, or rubella or can accompany an acute viral or bacterial infection in patients with thrombophilia affecting the protein C pathway.[52,72] The initial presentation in sepsis-associated purpura fulminans is often that of overwhelming acute infection with hypotension and peripheral hypoperfusion; in contrast, in idiopathic purpura fulminans, the blood pressure is well preserved. The skin necrosis in sepsis-associated purpura fulminans often begins in the distal extremities (FIGURE 98.4), with subsequent proximal progression, or involves the entire body in a patchy distribution.[74] Infants who are homozygous for protein C or S deficiency may be born with skin necrosis and intravascular coagulation (hereditary purpura fulminans).[75,76] Patients who are heterozygotes for protein C or S deficiency may develop skin necrosis when placed on warfarin therapy.[77] Protein C or S levels may be low because of liver dysfunction, consumption, or, rarely, secondary to an acquired inhibitor.[78]

Trauma or Massive Tissue Necrosis

The acute coagulopathy accompanying severe trauma may complicate severe head injury, massive soft tissue trauma, multiple fractures and fat embolism, gunshot wounds, and extensive burns.[79] In a study of 16 patients with head injury who had DIC and came to autopsy within 4 days of injury, Kaufman et al.[80] noted necrosis and bleeding, most notably in the brain and lungs, and microthrombi in the central nervous system, liver, lungs, kidneys, and pancreas. Thrombi were less prevalent with

longer delays after injury, attesting to a probable fibrinolytic response in the microcirculation to dissolve these thrombi. Head injury in children is also associated with abnormal clotting tests in 71% of cases, and mortality is fourfold greater in patients with DIC than in those without DIC.[81] The high mortality rate is associated with increased bleeding and laboratory evidence of DIC and is the foundation for prognostic scoring systems.[81,82,83]

Extensive exposure of TF to blood and hemorrhagic shock probably are the immediate triggers of acute coagulopathy, but cytokines likely play a pivotal role. In fact, the changes in cytokine levels are virtually identical in trauma patients and septic patients.[84] The levels of TNF-α, IL-1β, plasminogen activator inhibitor-1 (PAI-1), circulating TF, plasma elastase released from neutrophils, and soluble thrombomodulin all can be elevated in patients with signs of DIC, predicting multiple-organ failure (MOF) (ARDS included) and death.[85,86] Careful monitoring of laboratory signs of DIC, reduced fibrinolytic activity, and perhaps low antithrombin (AT) levels also are useful for predicting the outcome of such patients.[87]

The coagulopathy can be aggravated in patients with severe trauma who require massive blood replacement because stored blood components are diluted and do not contain sufficient amounts of viable platelets and factors V and VIII. Moreover, activation of fibrinolysis may aggravate bleeding and hypotension.[88–91]

The time interval between trauma and medical intervention correlates with the development and magnitude of DIC. Experience during wars proved that fast evacuation and prompt medical care reduce the risk of DIC.[92–94]

TF exposed to blood at sites of burned tissue, the systemic inflammatory response syndrome induced by the burn, and superimposed infections can trigger DIC.[95] Bleeding, laboratory tests indicative of DIC, and vascular microthrombi in biopsies of undamaged skin have been described in patients with extensive burns.[96] Significant local consumption of fibrinogen and platelets occur in burned areas.[97] Laboratory signs of DIC are associated with organ failure, and the extent of protein C and AT deficiencies correlates with poor outcome.[96] A clinicopathologic study of 139 patients who died during treatment for a severe burn disclosed that 18% had cerebral infarctions caused by septic arterial occlusions or DIC and 4% had intracranial hemorrhage.[98]

Heat Stroke

Heat stroke is frequently complicated by consumption coagulopathy.[99,100] James Wellstead published in 1841 his book "Travels to the City of the Caliphs" (currently known as Baghdad) and vividly described that on an extremely hot day in the Persian Gulf the decks of the ship Liverpool resembled a slaughterhouse, so numerous were the bleeding patients.[101,102] Heat stroke is a syndrome characterized by a rise in body temperature to over 42°C that follows collapse of the thermoregulatory mechanism. Predisposing factors include high environmental temperature, strenuous physical activity, infection, dehydration, and lack of acclimatization.[103,104] Extensive hemorrhage, unclottable blood, and venous engorgement were found as early as 1841 in postmortem examination of patients who died of heat stroke.[102] Investigations have confirmed that a severe hemorrhagic diathesis and MOF often accompany heat stroke.[95,105–107] Diffuse fibrin deposition and hemorrhagic infarctions are found in fatal human cases. DIC associated with profound fibrin(ogen)olysis is evident in patients with heat stroke. The possible triggers of DIC in patients with heat stroke include endothelial cell damage and TF released from heat-damaged tissues.[105]

In a series of 18 critically ill patients from Paris with heat stroke during the 2003 heat wave in Western Europe,[107] patients showed very high levels of IL-6 and IL-8, a striking activation of white blood cells (β2-integrin upregulation and increased reactive oxygen species) and evidence of systemic activation of coagulation. There was a correlation between the extent of inflammation and coagulation activation and clinical severity of the heat stroke. Patients have been categorized as nonbleeders, bleeders without DIC but with slight consumption of hemostatic factors, and bleeders with typical signs of DIC.[99] Prompt cooling and support of vital functions have substantially reduced the high mortality that was commonly observed in early studies.[108]

Snakebite

The bite of certain snakes, especially vipers and rattlesnakes, causes a coagulopathy that is highly reminiscent of DIC, although it is a matter of debate whether this condition can be truly classified as DIC.[17] Prominent among these species are the *Vipera*, *Echis (E. carinatus* or *E. coloratus)*, *Aspis*, *Crotalus*, *Bothrops*, and *Agkistrodon*. Venoms of these snakes contain enzymes or peptides that exert a variety of activities[109–111]: (a) thrombin-like activity, cleaving fibrinopeptide A from the Aα chain of fibrinogen, (b) activation of prothrombin even in the absence of calcium ions, (c) activation of factors X and V, (d) fibrinogenolysis, (e) thrombocytopenia by platelet aggregation, (f) inhibition of platelet aggregation, (g) activation of protein C, and (h) endothelial damage cells. Victims of snake bites rarely experience excessive bleeding or thromboembolism, in spite of the serious derangements in hemostasis and findings that are sometimes consistent with DIC.[112–114]

Several species of snakes belonging to the Viperidae family produce venoms that have a wide range of activities affecting hemostasis. The symptoms are characterized by local tenderness and swelling, mild bleeding from the wound or from venipunctures, occasional hypotension without shock, and transient mild oliguria. The major symptoms and signs related to envenomation are vomiting, diarrhea, apprehension, hypotension, local swelling, ischemia, and necrosis. Treatment for victims of snake bites consists of immediate immobilization, administration of antivenom and fluids, and other general measures to preserve vital functions. Local incisions, cooling, and application of tourniquet should be avoided.[109] Some patients begin to recover spontaneously after 1 to 2 days and are completely normal within 1 week, whereas others demonstrate incoagulable blood for more than 3 weeks.[114,115] Active secondary fibrinolysis accounts for the rapid recovery of renal microcirculatory obstruction. Chugh et al.[116] documents severe illness after viper bites, with 45 of 157 patients having acute renal failure, and death occurring in eight of 10 with bilateral renal necrosis and in four of 23 with "less severe acute tubular lesions."

Acute Obstetric Complications

Since 1971, when DeLee[117] reported a state of "temporary hemophilia" in patients with premature separation of the placenta and a macerated dead fetus, it has been evident that a consumptive thrombohemorrhagic state is observed in a wide range of obstetric complications, including *abruptio placentae*, retained dead fetus, amniotic fluid embolism, saline-induced or septic

abortion, and occasionally toxemia. The site of consumption may be limited to a single extravascular locale (the uterus), disseminated in the blood, or present in both locations; the pathologic mechanism may involve coagulation, fibrinolysis, or both simultaneously; and the broadest range of tempo may occur, from the fulminant onset of an *abruptio placentae* to the chronic, low-grade effects of the retained dead fetus syndrome.

Pregnancy is associated with a baseline hypercoagulable state characterized by increased levels of procoagulant factors, low protein S levels, and reduced fibrinolytic activity.[118,119] Pregnancy predisposes patients to DIC for at least four reasons: (a) a hypercoagulable state, manifested by low-grade thrombin generation, with elevated levels of fibrin monomer complexes and fibrinopeptide A; (b) reduced fibrinolytic activity because of increased plasma levels of PAI-1; (c) decline in the plasma free protein S; and (d) during labor, leakage of TF from placental tissue into the maternal circulation. DIC may be difficult to diagnose during pregnancy because of the high initial levels of coagulation factors such as fibrinogen, factor VIII, and factor VII,[120,121] but progressive reductions in these factors can help confirm or exclude the diagnosis. Thrombocytopenia may be particularly helpful in determining whether DIC is present, provided other causes are excluded.[122]

Abruptio Placentae

Placental abruption is a leading cause of perinatal death.[123] Older multiparous women or patients with one of the hypertensive disorders of pregnancy are at highest risk. The severe hemostatic failure accompanying abruptio placentae is the result of acute DIC following the introduction of large amounts of TF into the circulation from the damaged placenta and uterus.[124] Amniotic fluid activates coagulation *in vitro*, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for DIC. Abruptio placentae occurs in 0.2% to 0.4% of pregnancies, but only 10% of these cases are associated with DIC.[119,122] Although in the classic study by Pritchard and Brekken[119] only 38% of patients had hypofibrinogenemia (<150 mg/dL), most patients had a relatively low fibrinogen for that stage of pregnancy. Rapid volume replacement and evacuation of the uterus is the treatment of choice.[123] Transfusion of cryoprecipitate, fresh-frozen plasma, and platelets should be given for profuse bleeding, but blood components may not be necessary in less severe cases, as coagulation factors increase rapidly following delivery. Heparin or antifibrinolytic agents are not indicated.

Amniotic Fluid Embolism

Amniotic fluid embolism was firmly established as a syndrome by the clinical and histopathologic changes described by Steiner and Lushbaugh[125] in 1941. Its incidence is 1:8,000 to 1:80,000 live births and is responsible for 10% of maternal deaths in the United States.[126] Patients predisposed to amniotic fluid embolism are multiparous women whose pregnancies are postmature and women undergoing a tumultuous labor. Amniotic fluid is introduced into the maternal circulation through tears in the chorioamniotic membranes, rupture of the uterus, and injury of uterine veins.[126] The trigger of DIC probably is TF present in amniotic fluid.[127,128] The mechanical obstruction of pulmonary blood vessels by fetal debris, meconium, and other particulate matter in the amniotic fluid enhances local fibrin–platelet thrombus formation and fibrinolysis. The extensive occlusion of the pulmonary arteries and an acute anaphylactoid response reminiscent of severe systemic inflammatory response syndrome provoke sudden dyspnea, cyanosis, acute cor pulmonale, left-ventricular dysfunction, shock, and convulsions. In patients who survive the initial episode, excessive bleeding follows in 40% of cases, usually after a latent period of 0.5 to 4 hours, and the great majority have laboratory evidence of consumption.[126] In the National Registry for amniotic fluid embolism (46 patients), cardiac arrest occurred in 87% and mortality was 61%, but only 15% of patients survived neurologically intact.[129] Seventy-nine percent of fetuses survived, but only 50% were neurologically unimpaired.

Hemorrhage is particularly severe from the atonic uterus, puncture sites, and GI tract. The best prospect for decreasing mortality lies in early termination of parturition in patients at high risk and prevention of hypertonic and tetanic uterine contractions during labor. When the syndrome is recognized, immediate termination of pregnancy under pulmonary and cardiovascular support is essential. Vigorous supportive therapy directed toward gas exchange with mechanical respiratory assistance and fluid and blood replacement to treat severe hypotension are essential. In patients in whom continued entry of amniotic fluid debris may be contributing to further intravascular clotting, heparin is a reasonable adjunct to therapy.[121] When bleeding is the major manifestation, heparin may increase bleeding, especially if adequate replacement therapy for consumed clotting factors has not been achieved. In addition to replacement therapy for treatment of dangerous bleeding, fibrinolytic inhibitors may be helpful, but the same precautions regarding their use apply as in other settings of DIC.

Septic Abortion

In contrast to the relatively mild clinical state of saline-induced abortion, septic abortion heralds the most fulminant type of severe DIC. In a group of more than 6,000 patients who had undergone abortion, 16% were infected, 4% of whom had shock and DIC, leading to death in one-half of these seriously affected patients.[130] Any of a large number of bacterial organisms, both aerobic and anaerobic, may be the inciting agent; a combination of severe hypotension and DIC complicates the clinical picture. Once established, the clinical symptoms, laboratory manifestations, and principles of therapy are as for any severe infection leading to shock, with the added consideration that evacuation of the uterus and sometimes hysterectomy are required to eliminate the infection. These patients can be the most refractory to therapy, and vigorous attention must be paid to proper antibiotic choice, maintenance of blood volume and electrolyte balance, and replacement of deficient hemostatic factors. The use of heparin in these circumstances is controversial, and there is little evidence of its benefit. As with other circumstances of acute, severe DIC, fibrinolytic inhibitors should be withheld so as not to impair the physiologic fibrinolytic response in the microcirculation of ischemic organs.

Acute Fatty Liver

Acute fatty liver of pregnancy is a rare disorder that occurs during the third trimester of pregnancy,[131] which can lead to hepatic failure, encephalopathy, and maternal and fetal death.[132–135] In 15% to 20% of cases, acute fatty liver of pregnancy is associated with fetal homozygosity or compound heterozygosity

for long-chain acyl-CoA dehydrogenase (LCAD) deficiency,[136] one mutation (G1528C) accounting for 65% to 90% of cases. The precise mechanism by which LCAD deficiency in the fetus causes the severe liver disease in the heterozygous mother is unclear. The typical histologic feature of acute fatty liver disease of pregnancy is microvesicular fatty infiltration of the liver, which is characterized by severe liver dysfunction, renal failure, hypertension, and DIC.[133,137] Exceedingly low levels of AT and other laboratory signs of DIC were observed in a series of 28 patients, but no definite clinical benefit from AT concentrate infusion was achieved.[137] The primary therapy for these patients is early delivery and supportive care, which yield a maternal survival of 90% and perinatal survival of more than 85%[133,138] Pancreatitis is a potentially lethal complication of acute fatty liver of pregnancy.[139]

Preeclampsia and "Hemolysis, Elevated Liver Enzymes, and a Low Platelet Count" (HELLP Syndrome)

The existence of DIC as a constant feature in patients with preeclampsia or eclampsia is controversial.[19,140,141] A critical analysis concluded that the thrombocytopenia in preeclamptic patients stems from endothelial injury rather than DIC,[140] but, other investigators provide evidence for DIC,[142,143] including a good correlation between the clinical severity and abnormalities in platelet counts and fibrin(ogen) degradation products.[141] The syndrome of hemolysis (H), elevated liver enzymes (EL), low platelet count (LP), and severe epigastric pain is a complication of pregnancy-induced hypertension.[144] Seventy percent of the cases occur during the third trimester of pregnancy and 30% occur during the postpartum period.[145] Hemolysis, elevated liver enzymes, and a low platelet count (HELLP) syndrome occurs more often in whites, multipara, and women older than 35 years.[146] Liver biopsy shows fibrin deposition, and laboratory tests are consistent with DIC in a significant proportion of patients.[145,147,148] Hepatic imaging in 33 patients revealed subcapsular hematomas in 13 and intraparenchymal hemorrhage in 6.[149] Although the majority of patients do not have laboratory evidence of DIC, a significant proportion have a low fibrinogen level (<300 mg/dL), which frequently is associated with evidence of abruptio placentae. MOD manifested by acute renal failure, ascites, pulmonary edema, and severe hemorrhage resulting from DIC may develop, leading to significant maternal and perinatal mortality. Management of patients with HELLP syndrome consists of supportive care, careful monitoring, and blood component replacement therapy.[150] With few exceptions, immediate delivery, not necessarily by Caesarian section, is indicated. HELLP syndrome tends to recur in subsequent gestations.[151]

Liver Disease

Advanced liver disease may result in chronic low-grade DIC (see below). However, complications of acute or chronic liver disease may trigger episodes of an acute coagulopathy, most notably in patients with peritoneovenous (LeVeen or Denver) shunts or fatty liver of pregnancy. As reviewed by LeVeen et al.,[152] peritoneovenous shunting has a mortality of <1% in "uncomplicated cirrhosis," and postoperative coagulopathies can largely be avoided. However, a substantial number of patients develop DIC shortly after shunt placement. Ragni et al.[153] detected DIC in 10 of 11 such patients, and Rubinstein et al.[154] found DIC after 14 of 27 shunt procedures and a greater tendency for this complication in patients with cirrhosis.

Acute Hemolysis and Transfusion Reactions

Acute hemolysis such as that after the transfusion of 500 mL or more of incompatible blood (major mismatch) can produce a hemorrhagic diathesis characterized by laboratory changes of hypofibrinogenemia and thrombocytopenia.[2] This pattern is compatible with acute DIC, with variable effects of intravascular thrombi on renal function depending on the acuteness and degree of defibrination and the additional presence of hypovolemia or hypotension. However, massive hemolysis (other than that associated with a major mismatch) does not uniformly produce DIC, as Mannucci et al.[155] observed in 28 patients with glucose-6-phosphate dehydrogenase deficiency who were exposed to fava beans. The DIC secondary to massive hemolysis is self-limiting, and in the absence of serious end-organ damage, patients improve rapidly with supportive measures. Treatment depends on maintenance of blood volume and organ perfusion and on blood replacement with compatible erythrocytes. DIC that accompanies incompatible blood transfusion may result from extensive antigen–antibody reaction causing release of elastase and TNF-α from neutrophils and activation of monocytes that express TF and complement, leading to assembly of the membrane attack complex inflicting damage to endothelial cells.[156,157]

CHRONIC OR SUBACUTE CONSUMPTION COAGULOPATHY

In contrast to the acutely ill patient with complicated, severe DIC, other patients may have mild or protracted clinical manifestations of consumption or even subclinical disease manifest by only laboratory abnormalities.[4,21,158] The clinical picture of subacute to chronic DIC is exemplified by the retained dead fetus syndrome, and the recalcitrant chronic hypercoagulability that may accompany malignancy. Mucin-producing adenocarcinomas may also present acutely with major vessel occlusions, nonbacterial thrombotic endocarditis with systemic arterial embolization and infarction, as well as with acute, severe DIC (Trousseau syndrome).[159] In patients with chronic DIC, laboratory manifestations are extremely variable. Some patients have all of the classic abnormalities of thrombocytopenia, hypofibrinogenemia, elevated fibrin degradation product (FDP) levels, and prolonged partial thromboplastin time and prothrombin time (PT), whereas other patients have thrombocytopenia only or virtually normal laboratory results, owing to increased synthesis of coagulation proteins and effective microvascular fibrinolysis.

Clinical Conditions Associated with Subacute or Chronic Consumption Coagulopathy

Neoplasia

Solid Tumors

Trousseau was the first to describe the propensity to thrombosis of patients with cancer and cachexia,[152] and evidence for malignancy-related primary fibrinolysis and/or DIC has since been provided.[12,160,161] In 182 patients with malignant disorders described by Sack et al. in 1977,[155] excessive bleeding was recorded in 75 cases, venous thrombosis in 123, migratory thrombophlebitis in 96, arterial thrombosis in 45, and arterial embolism resulting from nonbacterial thrombotic endocarditis in 31; 12 patients had venous thrombosis, endocarditis, and

bleeding. The overall incidence of DIC in consecutive patients with solid tumors in one series was 7%.[162]

Solid tumor cells may express TF, which forms a complex with factor VII(a) to activate factors IX and X, and a cancer procoagulant (CP), a cysteine protease with factor X-activating properties.[163,164] In breast cancer, TF is expressed by vascular endothelial cells as well as by the tumor cells,[165,166] and also is involved in tumor metastasis and angiogenesis.[167–169] CP can be found in extracts of neoplastic cells but also in the plasma of patients with solid tumors.[170,171] Interactions of P- and L-selectins with mucin from mucinous adenocarcinoma can induce formation of platelet microthrombi and probably constitute a third mechanism of cancer-related thrombosis.[172] Depending on the rate and quantity of exposure or influx of shed vesicles from tumors containing TF, nonovert or overt DIC develops.[173–175] For instance, a patient may be asymptomatic or present with venous thromboembolism if the tumor cells expose or release TF slowly or intermittently, and the ensuing utilization of fibrinogen and platelets is compensated by increased production of these components. Conversely, massive thrombosis or severe bleeding may supervene in a patient whose circulation is deluged by TF.[162,164] Another mechanism by which tumor cells may contribute to DIC involves fibrinolytic proteins.[176,177] Many malignant cells express urokinase-type plasminogen activator (u-PA) and tissue-type plasminogen activator (t-PA), but most tumors induce a hypofibrinolytic state. Virtually all pathways that contribute to DIC are driven by cytokines, for example, IL-6, which induces TF expression on cells.[178] Fibrinolysis and microvascular physiological anticoagulant pathways are mostly dependent on TNF-α.[179–181] On the contrary, anti-inflammatory cytokines such as IL-10 inhibit DIC.[182–184]

Patients with solid tumors are vulnerable to additional triggers of DIC that can aggravate thromboembolism and bleeding.[161] Risk factors include advanced age, metastatic spread, and chemotherapy or antiestrogen therapy,[176,185] and triggers include septicemia and immobilization. Unusual clinical thrombotic states, such as recurrent venous thrombi, multiple limb thrombosis, hemorrhage after reasonable doses of anticoagulation, gangrene secondary to arterial emboli, thrombocytosis, phlegmasia cerulea dolens and venous gangrene, combined thrombosis and bleeding, arterial and venous thromboemboli, or all of these in a single patient, suggest an occult neoplasm. Patients with carcinoma of the prostate may have hemorrhagic manifestations that dominate the clinical picture, and this could reflect production of fibrinolytic activators as well as procoagulants.[186] The tendency of some tumor cells to produce such clot-dissolving activity may be reflected by prolonged localized bleeding after biopsy of the tumor.[187] Direct thrombin inhibitors such as hirudin or argatroban are probably more effective than heparin for application to the hospitalized patient. Fondaparinux, low molecular weight heparin, or unfractionated heparin are reasonable agents for prolonged outpatient therapy.

Leukemia

In 161 consecutive patients presenting with acute myeloid leukemia, DIC was diagnosed in 52 (32%), and in acute lymphoblastic leukemia, DIC was diagnosed in 15% to 20%.[188] The incidence of DIC in acute leukemia patients might increase during induction chemotherapy.[189]

In patients with acute promyelocytic leukemia (APL), DIC is present in more than 90% of patients at the time of diagnosis or after initiation of chemotherapy.[24,187,190] APL is characterized by intracytoplasmic inclusions and dense granules in promyelocytes, and the hemostatic disturbance is related to interaction of the malignant cells with endothelial cells.[170,188] APL cells express TF and the CP that can initiate coagulation, and they release IL-Iβ and TNF-α, which downregulate endothelial thrombomodulin, thereby compromising the protein C anticoagulant pathway. APL cells also express increased amounts of annexin II, which augments conversion of plasminogen to plasmin. Although hemorrhagic phenomena predominate, venous as well as arterial thromboembolic complications occur, with autopsy evidence of diffuse thrombosis reported in 15% to 25% of patients.[191] The majority show a prolonged PT, hypofibrinogenemia, elevated FDP levels, and a shortened fibrinogen half-life, even in patients without clinically identifiable disease.[190] Both TF and fibrinolytic proteases can be demonstrated in promyelocytic subcellular components, but the former predominates in both *in vitro* analyses and clinical presentation.[188] u-PA and tPA have been found within APL cells in addition to low plasma PAI and α_2-plasmin inhibitor levels.[190] In addition, protease activity stemming from leukocyte elastase can also cause increased fibrinogen catabolism, degrade several clotting factors, and increase fibrinolysis.[187,192] This clinical disorder may present with serious hemorrhagic manifestations due to DIC and fibrin(ogen)olysis, further complicated by severe thrombocytopenia secondary to both the intravascular coagulation and decreased thrombopoiesis. Before the use of all-*trans*-retinoic acid (ATRA), anthracycline-based induction therapy induced complete remission in 50% to 60% of patients, but a significant number died early from intracranial hemorrhage.[193] Control of the leukemic process determines the patient's ultimate response. A consumptive disorder may be induced or exacerbated by cell lysis during chemotherapy, but the coagulopathy associated with APL has dramatically decreased with the introduction of ATRA. The coagulopathy rapidly diminishes over 2 to 6 days,[192] and the net effect of ATRA is to reduce prothrombotic potential and hemostatic consumption.[194,195] ATRA, used for induction and maintenance therapy of APL, inhibits the deleterious effect of APL cells *in vitro* and *in vivo* and has reduced the frequency of hemorrhagic death.[170,192]

Liver Disease

A major role for a consumptive thrombohemorrhagic process in patients with liver disease is controversial. For example, histopathologic changes compatible with DIC are uncommon in patients with liver disease, as reported in an autopsy study showing only four of 184 cases of acute and chronic liver disease with microthrombi in more than one organ.[196] However, the absence of fibrin thrombi in patients with chronic liver disease may be a result of a systemic fibrinolytic state. The similarities between the hemostatic defects observed in patients with liver disease and in patients with DIC are striking and have evoked an ongoing controversy as to whether DIC contributes to hemostatic derangements associated with liver disease.[197]

Observations that support the hypothesis that DIC accompanies hepatic disorders include a shortened half-life of radiolabeled fibrinogen and prolongation of fibrinogen half-life by administration of heparin[198,199]; failure of replacement therapy to significantly increase the levels of hemostatic factors (suggesting continuous consumption); and increased blood levels of D-dimer, thrombin-antithrombin (TAT) complexes, and fibrinopeptide A, all consistent with ongoing thrombin generation.[196,200,201]

Observations that argue against the hypothesis that DIC accompanies liver diseases include an extremely low incidence (2.2%) of microthrombosis in the tissues of patients who die of liver disease and causes other than, or inconsistent with, DIC for the deranged findings in liver disease.[196] Examples of alternative explanations include acquired dysfibrinogenemia to explain a prolonged thrombin time,[202] reduced synthesis to explain low levels of coagulation factors and inhibitors,[203] and primary fibrinogenolysis induced by decreased clearance of t-PA. Kinetic data show increased rather than decreased factor VIII levels,[204] loss of fibrinogen into extravascular spaces that contributes to apparently excessive consumption,[158] and normal plasma survival of fibrinogen and plasminogen.[205] Another hypothesis maintains that patients with liver disease usually do not present with DIC but are extremely sensitive to the various triggers of DIC because of their impaired capacity to clear procoagulants and to synthesize essential components of the coagulation, inhibitory, and fibrinolytic systems. Patients with primary or metastatic liver disease who undergo a peritoneovenous shunt operation for severe ascites are more likely to develop DIC than are patients with ascites who undergo the same procedure because of other causes.[206]

What, then, should be the approach to patients with liver disease and bleeding without an apparent local cause? First, possible underlying causes of DIC should be considered and identified, and then a hemostatic profile should be examined at frequent intervals in order to detect any dynamic changes that may be helpful in recognizing DIC. The sensitive assays that reflect thrombin generation (TAT complex and prothrombin fragments 1.2) or concomitant thrombin and plasmin generation (D-dimer) may help establish the diagnosis of DIC in a patient with liver disease.[207]

Retained Dead Fetus Syndrome

Retained dead fetus syndrome exists if the fibrinogen concentration falls below normal for the stage of pregnancy in the context of intrauterine fetal death. This syndrome is a slowly developing, compensated or low-grade form of DIC. Its incidence increases with longer periods of fetal retention to as much as 35% of patients with a duration of 5 weeks or longer.[208] Although an occasional patient appears to have an acute primary fibrinolytic response to the dead fetus, the evidence strongly suggests that intravascular coagulation is the sole mechanism for the defibrination in most patients. As expected in patients with slowly developing consumption, the secondary fibrinolytic response keeps pace with the formation of fibrin thrombi, and organ obstruction and ischemia are not part of the clinical picture. The low fibrinogen and platelet counts do not usually cause serious bleeding, but patients are at risk for postpartum hemorrhage if hemostatic defects are not corrected. As with other obstetric consumptive complications, the essence of treatment is to evacuate the uterus. However, in the rare instance of a twin pregnancy with a single fetal death and consequent DIC, heparin treatment can reverse DIC and save the second twin.[209]

LOCALIZED INTRAVASCULAR COAGULATION

Certain disorders are associated with the consumption of platelets and clotting factors in strictly defined, localized anatomic sites. Laboratory studies are frequently characterized by thrombocytopenia, hypofibrinogenemia, and elevated levels of FDPs or D-dimer. Occasionally, this condition may cause bleeding. However, because the consumption is usually localized, distant microvascular occlusion and organ ischemia do not occur. Two risks of not recognizing the limited disorder are inappropriate therapy for a presumed "disseminated" state and failing to recognize the form and location of a potentially reversible underlying disorder.

Aortic Aneurysm

Localized consumption of platelets and fibrinogen in aortic aneurysms can produce not only striking laboratory abnormalities but even symptomatic bleeding.[210,211] Although few patients with aneurysm demonstrate overt hemorrhagic manifestations, this complication may be particularly associated with acute extensions and enlargements of the aneurysm.[212] In some cases, dramatic manifestation of spontaneous bleeding episodes is associated with radiographic evidence of an expanding aneurysmal mass or with the sudden onset of severe pain indicative of dissection. In a series of patients with aortic aneurysm, 40% had elevated levels of fibrin(ogen)-degradation products, but only 4% had significant bleeding and laboratory evidence of DIC.[210] Several factors predispose patients with aortic aneurysms to the development of DIC: a large surface area, dissection, and expansion of the aneurysm.[212] Clinical and laboratory signs of DIC should be carefully sought in patients with an aortic aneurysm because bleeding may seriously complicate surgical repair of the aneurysm.[212,213] The initiation of localized and generalized intravascular coagulation can be ascribed to activation of the TF pathway by the abundant amounts of TF present in atherosclerotic plaques.[214] When patients present with significant bleeding or when surgery is planned, hemostatic defects should be sought and corrected.[215] Stent grafting, which is a common procedure for repair of aortic aneurysms, was complicated by DIC and death in two patients, of whom one had cirrhosis and the other underwent a lengthy procedure.[216] However, a study of 31 such patients failed to detect DIC following stent grafting of thoracic aneurysms.[217] Other anticoagulants have not been systematically evaluated in this condition.

Hemangiomas

Kasabach and Merritt[218] first described giant cavernous hemangiomas as a cause of a hemorrhagic diathesis. Primarily a disorder of infants and children, these hemangiomas are usually benign tumors that may enlarge or evolve into a convoluted mass of vascular channels that sequester and consume platelets and fibrinogen. This progression has been clearly demonstrated by physiologic studies in which the half-life of platelets is shortened and radioactive platelets and fibrinogen accumulate in the tumor.[219] Within the hemangioma, consumption of platelets and fibrinogen occurs because of localized intravascular clotting, but the channels are patent because of local, reactive fibrinolysis.[220,221] Conceivably, concomitant local activation of the coagulation pathway and release of large amounts of t-PA by the abnormal endothelium lining the tumor vessels occur. Microangiopathic hemolytic anemia and laboratory signs of DIC and fibrinolysis have been demonstrated in patients with giant hemangiomas.[222] Accelerated growth of these hemangiomas in infants is associated with augmented consumption of hemostatic factors, and treatment utilizes irradiation, glucocorticoids, and interferon. However, medical treatment is often ineffective, and surgery can be dangerous because of problems in achieving

effective hemostasis. Patients are usually managed conservatively, unless cosmetic corrections are needed or symptoms of bleeding result from severe thrombocytopenia and hypofibrinogenemia. The mass occasionally regresses spontaneously, or it may shrink after radiation or laser therapy.[219] Antithrombotic treatment with either antiplatelet agents or heparin has been attempted in order to correct the platelet count and fibrinogen level and alleviate bleeding symptoms. This rationale of first correcting the hemostatic defect by blocking the local consumption has been used in anticipation of, and in preparation for, surgical removal of the tumor under the safety of a normal hemostatic system. Regression of the tumor may occur by thrombosing the vascular channels by administering a fibrinolytic inhibitor (ε-aminocaproic acid [EACA] or tranexamic acid).[223]

Systemic Versus Localized Consumption Coagulopathy

Marked differences in the procoagulant response and underlying pathogenetic pathways exist between cells and tissues.[224] First, localization of coagulation activity may relate to a cell-specific gene expression, for example, inflammatory mediators enhance PAI-1 gene expression in a complex and tissue-specific way,[225] and the von Willebrand factor (vWF) promoter contains cell-specific elements.[226] Second, the tissue environment determines whether specific gene transcription occurs.[227] In mice with disturbances in the plasminogen–plasmin system subjected to hypoxia, the formation of fibrin is induced and is particularly evident in the lungs.[228] In contrast, these same mice respond to endotoxemia with fibrin deposition in the microvasculature of the kidney in particular. Similarly, mice with a functional thrombomodulin deficiency have a marked increase in pulmonary fibrin deposition after hypoxic challenge.[229] In addition, when mice with a functional defect in the thrombomodulin gene were challenged with endotoxin in sublethal amounts, fibrin formation was apparent in the lungs, but not in other organs.[230] Last, organs may markedly differ in their endothelial cell response toward inflammation and injury. In general, endothelial cells play a central role in the coagulation response upon systemic inflammation,[231] being directly involved in the initiation and regulation of thrombin generation, and in the inhibition of fibrin removal. Endothelial cells may express TF, the main initiator of coagulation, and physiological anticoagulant pathways, such as AT, the protein C system, or tissue factor pathway inhibitor (TFPI). Proinflammatory cytokines mediate effects on endothelial cells, which themselves may also express cytokines, thereby amplifying the coagulative response.[178] Although not completely clear, various organs may differ in all these endothelial cell-related factors influencing local coagulation activation and fibrin deposition.

CONSUMPTION RELATED TO ANTITHROMBOTIC OR HEMOSTATIC MEDICATION

Therapeutic Defibrination

Defibrinating enzymes such as ancrod (Arvin) from *Agkistrodon rhodostoma* and defibrase from *Bothrops atrox* have been purified for therapeutic defibrination and treatment of patients with venous thromboembolic disease.[115] The rationale for therapy is that plasma fibrinogen is decreased by conversion to noncross-linked fibrin, which is in turn lysed without causing any vascular occlusion or organ ischemia, leaving the patient with enough fibrinogen for normal hemostasis but sufficiently decreased to deter propagation of a thrombus. Results show that an antithrombotic state is as safe and effective as heparin.[232]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) (see Chapter 108) is a drug-induced immune reaction that causes thrombocytopenia, usually 5 days or more after heparin therapy is started or sooner in the presence of antibody.[233,234] The pathophysiologic mechanism is the induction of antibody to a heparin–platelet factor 4 complex. The antigen–antibody complex activates platelets by binding to the platelet FcγIIa receptor and activates the endothelium by binding to platelet factor 4–proteoglycan complexes. Platelet procoagulant microparticles are released, and platelet aggregation, a variable degree of thrombocytopenia, endothelial cell activation with resultant expression of TF, and venous and/or arterial thrombosis may follow. Multifocal venous and arterial thrombosis may simulate DIC because thrombocytopenia, elevated D-dimer levels, and hypofibrinogenemia can be present.

Prothrombin Complex Concentrates and Recombinant Factor VIIa

Concentrates of vitamin K–dependent clotting factors (prothrombin complex concentrates, PCCs) are used for the treatment of patients with congenital or acquired deficiencies of prothrombin or factors VII, IX, or X or (in activated form) with acquired inhibitors against factors VIII or IX.[235] Some preparations contain thrombogenic material in addition to unactivated coagulation factors, including factors VIIa, IXa, and Xa, any of which may contribute to thrombotic complications.[236,237] The modern preparations of nonactivated PCCs are probably not associated with systemic activation of coagulation.[238]

A recombinant preparation of human factor VIIa has shown significant efficacy in hemophilic patients with inhibitors to factor VIII or IX and in patients with hereditary factor VII deficiency.[239,240] The agent is also used for many other (off-label) indications in situations characterized by excessive blood loss, in particular elderly patients, and very high doses of recombinant factor VIIa may provoke thrombotic complications.[241]

Coumadin

Coumarin (see Chapter 109) anticoagulation initiated in patients with partial (heterozygous) deficiency of protein C or protein S may produce the "coumarin necrosis" syndrome or defibrination as the result of a more rapid decrease in the vitamin K–dependent inhibitors than in the vitamin K–dependent coagulation factors.[242] In patients with HIT, Coumadin-induced thrombosis may result in an exaggerated limb ischemic syndrome (venous gangrene).[243]

CONSUMPTION IN THE NEONATE

Newborns have a limited capacity to cope with triggers of DIC, because of their decreased ability to clear soluble fibrin and activated factors, their decreased fibrinolytic potential because of a

low plasminogen level, and their limited capacity to synthesize coagulation factors and inhibitors.[244,245] Criteria for diagnosis of DIC in newborns are different from those for diagnosis in adults.[246] Important to consider are the physiologic hemostatic findings common at this age, which include low levels of the vitamin K–dependent factors, reduced AT and protein C levels, and prolonged thrombin time (see Chapter 119). Laboratory evidence of DIC in the newborn is based on the progressive decline of hemostatic parameters; thrombocytopenia; and reduced levels of fibrinogen, factor V, and factor VIII.[244,247,248]

DIC occurs in sick neonates and particularly in those who are premature. More than one underlying cause usually can be identified in newborns with DIC, the most frequent underlying conditions being sepsis, hyaline membrane disease (respiratory distress syndrome), asphyxia, necrotizing enterocolitis, intravascular hemolysis, abruptio placentae, and eclampsia.[245,249] Bleeding from multiple sites is the most common manifestation of DIC in newborns, with intracranial hemorrhage being the most life-threatening condition. Clinical manifestations of DIC may not be apparent in 20% of neonates;[247] so a high index of suspicion in patients at risk is essential.

Rare cases of fulminant neonatal DIC may result from the deficiency of coagulation inhibitors, especially protein C. Such cases are seen in homozygous deficiency states and are variations of the striking thrombotic tendency that is usually manifested as multiple venous thrombi. A relative deficiency of fibrinolytic response in the neonate may reflect a decreased plasma plasminogen concentration, which could contribute to thrombotic occurrences.[247,250] Treatment depends on provision of the missing inhibitor by plasma or purified protein products, complemented by long-term anticoagulant therapy.

INITIATING PATHWAYS

TF plays a central role in the initiation of inflammation-induced coagulation in DIC,[71] and blocking TF activity completely inhibits inflammation-induced thrombin generation in experimental models of endotoxemia or bacteremia.[251,252] Most cells constitutively expressing TF are found in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels. TF is exposed to blood upon disruption of the vascular integrity, or when cells present in the circulation, such as monocytes, are triggered to express TF. *In vivo* expression is dependent on IL-6 generation, inhibition of which abrogates TF-dependent thrombin generation in experimental endotoxemia.[178,253] In severe sepsis, monocytes, stimulated by proinflammatory cytokines, express TF, which leads to systemic activation of coagulation.[254] Even in experimental low-dose endotoxemia in healthy subjects, a 125-fold increase in TF mRNA levels in blood monocytes can be detected.[255] A potential alternative source of TF may be endothelial cells and polymorphonuclear cells, and it is hypothesized that TF from these sources is shuttled between cells through microparticles derived from activated mononuclear cells.[256] However, it is unlikely that cells other than monocytes synthesize TF in substantial quantities.[254,257]

ROLE OF THROMBIN AND PLATELETS

Consumptive processes reflect the multiple actions of thrombin. Thrombin proteolytically cleaves fibrinopeptides from fibrinogen to produce fibrin monomers that either combine with fibrinogen to form soluble complexes or polymerize to form fibrin thrombi. Thrombin converts factor XIII to an active transamidase that cross-links fibrin and renders it more resistant to fibrinolysis.[258] Fibrin can also be cross-linked to other proteins such as antiplasmin, which also contributes to its plasmin resistance (see Chapter 17).

Thrombin binds to specific platelet receptors at low concentrations and initiates shape change, aggregation, and secretion. Thrombin-stimulated platelets lack both dense granules and α-granules and show functional defects, so even if the platelet count exceeds 100,000/μL, the bleeding time may be prolonged. The platelet contribution to prothrombin activation is in part due to platelet factor V bound to the platelet surface, which serves as a receptor for factor Xa. Thrombin stimulates the platelet to release (from α-granules) platelet factor V, which is then bound to the platelet membrane. Thrombin potentiates the coagulation cascade by increasing the activity of factors V and VIII; however, its continued action leads to their degradation by activated protein C (APC). Therefore, thrombin itself accounts for decreases in fibrinogen, platelets, and factors II, V, VIII, and XIII in acute consumption.[259] The decrease in other clotting factors, such as factors IX and X, is due to rapid clearance of activated clotting factors *in vivo*.

Importantly, thrombin acts at the crossroad of coagulation and inflammation by binding to protease-activated receptors (PARs), a family of the transmembrane domain, G-protein–coupled receptors.[260] PARs serve as their own ligand, and proteolytic cleavage by an activated coagulation factor leads to exposure of a neo–amino-terminus that activates the same receptor and initiates transmembrane signaling. PAR-1, -3, and -4 are thrombin receptors, whereas PAR-2 does not bind thrombin but (along with PAR-1) can be activated by the TF–VIIa complex, factor Xa, and trypsin. PARs are localized on endothelial cells, mononuclear cells, platelets, fibroblasts, and smooth muscle cells, and binding of thrombin to these cellular receptors may induce cytokine and growth factor production, thereby promoting the inflammatory response.[261,262]

TF expression on monocytes is markedly stimulated by platelets and granulocytes in a P-selectin–dependent reaction.[263] This effect may be the result of nuclear factor kappa B activation induced by binding of activated platelets to neutrophils and mononuclear cells.[174] This cellular interaction also markedly enhances the production of Il-1b, Il-8, MCP-1, and TNF-α.[264] The expression of P-selectin on the activated platelet membrane will mediate the adherence of platelets to endothelial cells and leukocytes.

ROLE OF COAGULATION INHIBITORS

Failure of natural inhibitory (anticoagulant) mechanisms, the protein C system, TFPI, and AT predisposes to or aggravates hypercoagulable states by allowing fuller expression of thrombin activity.[265,266] Therefore, adequate amounts of natural anticoagulants are necessary to dampen or modulate increased procoagulant activity. Because of increased utilization, enhanced degradation (due to elastase released from activated neutrophils), and possibly decreased production, AT and protein C levels are decreased in patients with DIC.[267]

The protein C–related inhibitor system is dependent *in vivo* on surface-oriented reactions, specifically that of thrombomodulin and endothelial protein C receptor (EPCR) on endothelial

cells, and acts to facilitate the degradation (inactivation) of factors Va and VIIIa.[268,269] In this complex molecular system, thrombin forms a bimolecular complex with the transmembrane protein thrombomodulin, at which point it loses its fibrinogen-clotting, factor XIII–activating, and platelet-stimulating activities. However, the thrombin–thrombomodulin complex can convert the inactive plasma precursor, protein C, to an active form (APC). The EPCR not only accelerates the activation of protein C several fold, but also serves as a receptor for APC, and binding of APC to this receptor may amplify its anticoagulant and anti-inflammatory effects.[270] In turn, protein APC in the presence of the facilitating cofactor protein S degrades factors Va and VIIIa to inactive forms, thereby negatively influencing the thrombotic tendency. Apart from these effects, in DIC a resistance toward APC may occur by other mechanisms, which are partly dependent on a sharp increase in factor VIII levels (released from endothelial cells), but partly occur by yet unidentified mechanisms.[271]

Levels of TFPI in patients with DIC vary,[272–274] but the potential role of TFPI in preventing DIC was provided by experiments in rabbits in which pretreatment with anti-TFPI antibody sensitized the animals to more striking laboratory and tissue evidence of DIC.[275] Moreover, in an animal model of *E. coli*–induced DIC, recombinant TFPI decreased the coagulopathy and mortality, and endothelium-targeted delivery of TFPI inhibited intravascular thrombosis in endotoxin-treated mice.[276,277]

Thrombin activity is neutralized by two inhibitory systems, which to different degrees depend on the interaction of plasma proteins with the endothelial surface. AT and heparin cofactor II neutralize thrombin slowly by complex formation (see Chapters 18 and 45). However, such neutralization occurs at markedly accelerated rates in the presence of heparin, albeit at much higher concentrations for heparin cofactor II than for AT.[278] Heparin exerts its facilitative effect in solution, for example, after administration for therapeutic purposes or as membrane-associated molecules (heparans) that contribute to the antithrombotic properties of the vascular endothelium. In addition, AT neutralizes factor IXa and Xa. During DIC, AT levels are markedly decreased owing to impaired synthesis, degradation by elastase from activated neutrophils, and, most importantly, consumption as a consequence of ongoing thrombin generation.[231] Proinflammatory cytokines can also cause reduced synthesis of glycosaminoglycans on the endothelial surface, which also contributes to reduced AT function.[279,280]

ROLE OF PLASMIN

Plasmin is a potent proteolytic enzyme capable of digesting fibrin and fibrinogen and other clotting proteins, including factors Va and VIIIa. The balance between thrombin and plasmin determines whether the clinical picture is thrombin predominant, characterized by thrombosis, organ ischemia, and bleeding, or plasmin dominant, characterized by bleeding. Increased thrombin generation unbalanced by increased plasmin formation leads to microvascular fibrin deposition, causing organ ischemia and depression of organ dysfunction.[281] If plasmin is formed in sufficient quantities in the circulation, it produces degradation products of fibrinogen, which also inhibit fibrin polymerization and degrades clotting factors V and VIII. In combination with low plasma fibrinogen concentration, low levels of plasma factors V and VIII, and thrombocytopenia, FDPs contribute to bleeding manifestations.

In experimental models of DIC, plasmin formation is initially activated but subsequently inhibited, because of an increased release of PAI-1 by endothelial cells.[252,282] In a study of 69 DIC patients (31 with MOF), higher levels of t-PA antigen and PAI-1 and low levels of α_2-antiplasmin (presumably due to consumption caused by initial plasmin generation) were observed in patients with DIC and MOF compared to DIC patients without MOF.[283] This finding supports the conclusion that fibrinolysis is an important mechanism in preventing MOF. Experiments in mice with targeted disruptions of genes encoding components of the plasminogen–plasmin system confirm that fibrinolysis plays a major role in inflammation. Mice with a deficiency of plasminogen activators have more extensive fibrin deposition in organs when challenged with endotoxin, whereas PAI-1–knockout mice, in contrast to wildtype controls, have no microvascular thrombosis upon endotoxin administration.[228]

TAFI, like PAI-1, may play a role in impeding fibrinolysis and in augmenting formation of microvascular thrombi. Studies in a DIC cohort demonstrated high levels of TAFI proportionate to thrombin generation in such patients, particularly in those with infection-associated DIC.[284] Hence, TAFI may contribute (along with PAI-1) to microvascular thrombosis-induced ischemia in organs resulting in MOF.

In some patients, in particular those with APL and advanced adenocarcinoma, an exceptional type of DIC, characterized by a marked hyperfibrinolysis, may occur. The clinical presentation of severe bleeding associated with laboratory findings of a low fibrinogen level, very high levels of fibrin split products and fibrinogen degradation products, and massive consumption of plasminogen and α2-antiplasmin (leading to inordinate high levels of plasmin–α2-antiplasmin complex levels) support that notion.[193] The precise pathogenesis of this hyperfibrinolysis has, however, not been elucidated. Plasma levels of physiological plasminogen activators (such as u-PA and t-PA) cannot explain the massive plasminogen activation nor is a role of leucocytic elastase-mediated hyperfibrinolysis likely. Some studies pointed to a potential newly described receptor for fibrinolytic proteins, annexin II, which is expressed on the surface of leukemic cells in patients with APL that could explain the hyperfibrinolysis.[285] This hypothesis, however, has not been confirmed so far.

LABORATORY TESTS AND THE DIAGNOSIS OF DIC

Because DIC is associated with a variety of underlying disorders, the laboratory manifestations in a given patient are variable and depend not only on features of DIC but also on those due to the underlying disease. In some patients, DIC is of little clinical significance, and the diagnosis is established by laboratory tests, while in other patients, the clinical severity of DIC is striking and obscures the underlying disease. Given this variability, it is not surprising that criteria for the diagnosis of DIC are inadequate.

No single laboratory test is sensitive or specific enough to allow a definite diagnosis of DIC (Table 98.4).[10,286]. However, some sophisticated laboratory tests, for example, thrombin–antithrombin complex and prothrombin fragment 1.2, are

Table 98.4

Routine laboratory value abnormalities in DIC

Test	Abnormality	Causes Other Than DIC Contributing to Test Result
Platelet count	Decreased[a]	Sepsis, impaired production, major blood loss, hypersplenism
PT	Prolonged	Vitamin K deficiency, liver failure, major blood loss
aPTT	Prolonged	Liver failure, heparin treatment, major blood loss
FDPs	Elevated	Surgery, trauma, infection, hematoma
Protease inhibitors[b]	Decreased	Liver failure, capillary leakage

[a]Note that in pure hyperfibrinolytic states the platelet count may be normal.
[b]For example, protein C, AT, protein S.

Table 98.5

Diagnostic algorithm for the diagnosis of overt DIC[a]

1. Presence of an underlying disorder known to be associated with DIC?
   If no: do not use this algorithm
2. Score global coagulation test results
   - Platelet count *(>100 = 0; <100 = 1; <50 = 2)*
   - Level of fibrin markers (soluble fibrin monomers/FDPs) *(no increase: 0; moderate increase: 2; strong increase: 3)*[b]
   - Prolonged PT *(<3 s = 0; >3 s but <6 s = 1; >6 s = 2)*
   - Fibrinogen level *(>1.0 g/L = 0; <1.0 g/L = 1)*
3. Calculate score
4. If ≥5: compatible with overt DIC; repeat scoring daily
   If <5: suggestive (not affirmative) for nonovert DIC; repeat next 1–2 d

[a]According to the Scientific Standardization Committee of the International Society of Thrombosis and Haemostasis (Taylor FBJ, Toh CH, Hoots WK, et al. Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. *Thromb Haemost* 2001;86(5):1327–1330).
[b]In validation studies, a moderate increase was above the upper limit of normal but <5× upper limit, and a strong increase was >5× upper limit of normal.

sensitive toward ongoing activation of coagulation pathways, and soluble fibrin in plasma is one of the best parameters for detecting ongoing DIC.[287–290] FDPs may be detected by specific ELISAs or by latex agglutination assays, allowing rapid and bed-side determination,[291] but these assays do not discriminate between degradation products of cross-linked fibrin and fibrinogen.[292,293] The specificity of FDP is limited, and conditions, such as trauma, recent surgery, inflammation or active major vessel occlusion, are associated with elevated FDPs.

Tests that are aimed at the detection of neoantigens on degraded cross-linked fibrin, the best example of which detects an epitope related to cross-linked γ-chains (D-dimer), distinguish cross-linked fibrin from fibrinogen or fibrinogen-degradation products,[294] but from patients with venous thromboembolism, surgery, inflammatory conditions, or serous effusions may have elevated levels.[291,295]

In routine practice, simple laboratory tests in conjunction with clinical considerations are used for establishing the diagnosis of DIC. The simple tests include platelet count, PT, fibrinogen level, and fibrin-related markers, such as FDP or D-dimer. Caution should be exercised when using these laboratory parameters in the algorithms described below, because an underlying disease by itself can cause an abnormality. For example, impairment of hemostasis and/or thrombocytopenia unrelated to DIC can arise from hepatic disease and from marrow involvement by leukemia. Conversely, elevated levels of some hemostatic components that may occur during pregnancy may obscure the presence of DIC. The laboratory criteria are, however, arbitrary, and no consensus exists. For example, because fibrinogen levels increase as an acute-phase reactant in infection, fibrinogen levels may be normal when DIC complicates the illness and fibrinogen levels can be normal in up to 57% of patients with DIC.[286] In contrast, in DIC complicating severe liver disease, a low fibrinogen level may be caused by decreased synthesis as well as by increased consumption. Similar problems may arise using other criteria of DIC, such as thrombocytopenia in the presence of splenomegaly, low protein C in the presence of liver dysfunction, increased factor VIII in the presence of infection, and elevated FDPs in the presence of systemic fibrinolysis.

A scoring system, utilizing simple laboratory tests, has been reviewed by the subcommittee on DIC of the International Society on Thrombosis and Haemostasis,[8] and a five-step diagnostic algorithm to calculate a DIC score is summarized in Table 98.5. Tentatively, a score of 5 or more is compatible with DIC, whereas a score of <5 may be indicative but is *not* affirmative for nonovert DIC. By using receiver-operating characteristic curves, an optimal cutoff for a quantitative D-dimer assay was determined, thereby optimizing sensitivity and the negative predictive value of the system.[296] Prospective studies show that the sensitivity of the DIC score is 93%, and the specificity is 98%.[9,83] The severity of DIC according to this scoring system is related to the mortality in patients with sepsis.[82] Linking prognostic determinants from critical care measurement scores such as Acute Physiology and Chronic Health Evaluation-II to DIC scores is an important means to assess prognosis in critically ill patients. In addition, certain biochemical indicators of organ dysfunction may imply a DIC risk. For example, serial assessment of arterial lactate is a reliable prognostic indicator of DIC development among patients with the systemic inflammatory response syndrome.[297]

Criteria for less overt DIC are more difficult to establish.[8,298] In the algorithm for nonovert DIC, the global coagulation tests are scored as with the overt DIC algorithm; however, when scoring by the algorithm is being serially repeated, improvement in any laboratory test confers a negative score (rather than a

zero or neutral score). This "trend" scoring allows longitudinal assessment of the patient's status and evaluation of therapy.[299,300] Measurements of several markers for assessing the risk of progression from nonovert to overt DIC and prediction of MOD are potentially valuable. For example, impaired fibrinolysis may play an important role in MOD resulting from DIC of sepsis.[281] Therefore, assaying PAI-1, plasmin–antiplasmin complexes, or TAFI in septic patients may be important, and other markers, such as APC and ADAMTS 13 (vWF protease), may help identify individuals with microangiopathy who are not prone to worsening disease.[301,302]

TREATMENT

Because of the heterogeneity of the underlying disorders causing DIC and the great variability of the manifestations of DIC in a given patient, management is controversial.[1] The cornerstone of treatment is prompt, vigorous treatment of the underlying disease and aggressive support measures. After identifying the cause of DIC and promptly instituting appropriate specific and aggressive supportive therapy for the underlying disease, questions must be asked to determine whether replacement of depleted hemostatic factors is necessary and whether interruption of DIC with anticoagulants should be seriously considered.

Bleeding. Does the patient have a low fibrinogen level, LP, or low clotting factor levels? If so, is the patient actively bleeding? If the answer to the second question is no and the patient does not require surgery or an invasive procedure, replacement therapy is probably unnecessary.[303,304] In contrast, if the patient is actively bleeding or requires an invasive procedure, it probably will be necessary to replace the deficient hemostatic factors, which usually means cryoprecipitate, fresh-frozen plasma, PCC (if available), and platelets. The argument that replacement therapy may "fuel the fire" and cause thrombosis in patients with active DIC is theoretically possible, but only on occasion has this been proved to occur.[305] However, replacement therapy is most effective in patients with very low levels of platelets and fibrinogen, in whom DIC is self-limiting or has run its course. A common problem is the failure to increase the level of hemostatic factors when the patient is bleeding because of ongoing DIC. In these cases, it may be necessary to replace the hemostatic factors under cover of anticoagulant therapy, however contraintuitive this may seem. The effect of replacement therapy should be monitored by platelet and fibrinogen levels after completing transfusion to determine whether further replacement therapy is necessary.

Thrombosis. Does the patient have clinical evidence of fibrin deposition, such as overt venous thromboembolism, dermal necrosis, oliguria, or confusion? If so, active inhibition of thrombin by anticoagulant therapy is probably indicated.[10] Patients with purpura fulminans show a rapid progression of ecchymotic areas of skin to hemorrhagic bullae and hemorrhagic ischemic necrosis, and anticoagulation reduces mortality from 90% to 18%.[306] A similar clinical picture occurs in patients with bacteremia and sepsis, with patchy hemorrhagic skin lesions, progressive symmetric digital gangrene, and even gangrene of the extremities.[243] Heparin is indicated but unfortunately is often given after frank gangrene is already present. Therefore, when dermal or acral ischemia is first noted, heparin or other anticoagulant should be given to interrupt the DIC, along with bactericidal antibiotic and aggressive supportive therapy. Although ischemia secondary to DIC has been proposed as a major cause of organ dysfunction, including ARDS and acute renal failure, fibrin deposition *per se* may not represent the direct cause of these problems.[10,149] ARDS occurs in the absence of DIC, and renal failure in patients with DIC can be due to causes other than renal cortical necrosis. Therefore, it is not surprising that heparin therapy may not curtail organ damage in a given patient.

Disorders that May Require Heparin Anticoagulation

Retained Dead Fetus Syndrome

Retained dead fetus syndrome is defined by the presence of a dead fetus associated with evidence of DIC, which is usually low grade, chronic, and frequently compensated.[119] The major goals of therapy are to deliver the fetus and to prevent excessive bleeding at the time of delivery. If the patient presents with hypofibrinogenemia, intravenous heparin (and fibrinogen replacement) is effective in increasing the fibrinogen level to normal before elective delivery.[142]

Giant Hemangiomas (Kasabach-Merritt Syndrome)

Giant hemangiomas (Kasabach-Merritt syndrome) are benign childhood tumors that may progressively enlarge and cause localized consumption of platelets and fibrinogen.[219] Surgical removal can cause massive bleeding and should be avoided in most cases. If the patient requires an elective surgical procedure for reasons other than removal of the tumor, heparin or cryoprecipitate and platelet transfusions can be used before the procedure in an attempt to normalize the platelet count and fibrinogen level. In some patients, the tumor itself has enlarged to such an extent that spontaneous bleeding ensues because of low fibrinogen or platelet levels. In these patients, an attempt to thrombose the vascular channels with selective infusions of EACA or tranexamic acid has led to significant regression of the tumor and control of the localized consumptive process.[223]

Aortic Aneurysm

Localized coagulation may occur in the aneurysm, with laboratory evidence of compensated or decompensated intravascular coagulation.[307–309] In the latter case, the patient may present with spontaneous bleeding or a history of a bleeding tendency associated with minor trauma or invasive procedures. In patients without an aneurysmal leak who undergo elective surgery, heparin may normalize hemostatic factors before surgical repair.[212] In contrast, patients who have an aneurysmal leak associated with evidence of consumption require emergency surgery, in which case heparin is contraindicated and hemostatic levels of fibrinogen and platelets should be achieved with cryoprecipitate and platelet transfusions. Patients with symptomatic bleeding require prompt treatment, because significant recent extension has probably occurred.

Solid Tumors

DIC in patients with solid tumors is usually low grade and chronic, but clinical features are widely heterogeneous.[32,161] Patients may present with very serious disease, with excessive bleeding, venous thromboembolism, nonbacterial

thrombotic endocarditis with or without arterial thromboembolism, microangiopathic hemolytic anemia, or any combination thereof. In contrast, DIC may be manifested by laboratory abnormalities only with no clinical features. Interruption of clinically evident DIC with anticoagulation may provide significant benefit. In the study by Sack et al.,[310] 29 of 48 such patients had improvement of hemostatic measurements and 19 patients had recurrent symptoms after heparin was discontinued. Prolonged outpatient therapy with a glycoseaminoglycan is effective. The newly developed oral anti-IIa and anti-Xa agents have not been evaluated in this clinical setting so far.

APL is often dominated by DIC and hemorrhagic complications.[24,188] DIC probably results from the release of procoagulant material (TF and cysteine protease) or procoagulant-stimulating activity (IL-1) from the abnormal promyelocytes, and frequently the DIC worsens during induction chemotherapy (without ATRA).[311] Fibrinolytic activity is also increased in this disorder owing to cellular u-PA and perhaps leukocyte elastase.[312] Because initial induction therapy now includes ATRA, the coagulopathy disappears within 2 to 6 days, and the use of heparin, fibrinolytic therapy, or both is unnecessary. However, if the patient is unresponsive to ATRA, either primarily or in relapse, and chemotherapy is deemed necessary, the use of heparin therapy should be considered as an adjunct to aggressive transfusion therapy. Although most of the previous data strongly suggested that heparin therapy is beneficial in APL, they are nevertheless equivocal.[313] In studies in which heparin prophylaxis was not used, the incidence of fatal hemorrhage (usually intracerebral) was 16% to 63%; the incidence in studies in which heparin was used was 0% to 44%.[188,195] Although the literature shows fewer hemorrhagic deaths (20.7% vs. 14.6%) in patients treated with heparin, no prospective or well-controlled studies have been reported, and transfusion support varies between trials. In summary, DIC associated with APL should be managed with aggressive blood component replacement in an attempt to keep the platelet count >50,000/μL and the fibrinogen level >150 mg/dL. If the patient responds to ATRA, the DIC usually subsides rapidly over a few days, but if the patient requires chemotherapy, aggressive hemostatic replacement therapy may be difficult to achieve. In those patients, the addition of low-dose heparin may help in achieving reasonable platelet and fibrinogen levels. If evidence of systemic fibrinolysis as measured by a low α_2-plasmin inhibitor level is found, EACA or tranexamic acid can be used either as a simple agent or added to heparin if DIC is also present. Usually after a week of induction chemotherapy, the DIC progressively subsides and heparin and fibrinolytic inhibitor can be discontinued; platelet transfusions are needed until normal thrombopoiesis returns.

When Heparin is Probably Not Helpful

In most instances of consumption coagulopathy, heparin therapy has not been helpful and occasionally has been harmful. Acute forms of DIC may be either brief or end with prompt treatment of the underlying disease, in which case it is difficult to evaluate the contribution of heparin. Snakebite, heatstroke, rhabdomyolysis, massive head trauma, and acute hemolysis secondary to an incompatible blood transfusion all may result in acute consumption, and the evidence for heparin benefit is mostly from individual case reports, so heparin therapy remains controversial.[45,314,315]

Sepsis

For a more extensive discussion of the supportive treatment of the coagulopathy in sepsis, please see Chapter 123. Corrigan's review of patients with septic shock and DIC found no difference in survival between patients receiving (24%) and not receiving (21%) heparin.[316] The major determinant of survival in these patients is probably the presence or absence of shock and not the presence or absence of DIC. There is less debate, however, on the use of low-dose prophylactic heparin to prevent thromboembolic complications in patients with severe illness. In a large trial in patients with severe sepsis, there was a slight, but nonsignificant benefit, of low-dose heparin on 28-day mortality,[317] likely related to the prevention of thrombotic complications rather than an effect on DIC.

Complications of Pregnancy

Abruptio Placentae

Although renal cortical necrosis with demonstrable intravascular fibrin occurs in a few patients with *abruptio placentae*, the course of the illness is usually favorable when adequate support measures are taken. Most important is that blood be given to correct hypovolemia and hypotension, improve renal perfusion, and prevent acute tubular necrosis or renal cortical necrosis. With the use of this therapy alone, vaginal delivery is usually accomplished without hemorrhagic complications, and rapid regeneration of plasma fibrinogen follows.[121] If hysterotomy is necessary or episiotomy is performed during vaginal delivery, supplementation with fibrinogen (cryoprecipitate) and platelets is reasonable to provide normal hemostasis. Heparin is contraindicated before surgery, because this could contribute to increased bleeding during vaginal delivery or hysterotomy.

Amniotic Fluid Embolism

Amniotic fluid embolism is an acute fulminant catastrophic event that induces pulmonary vascular obstruction. Sudden death follows in as many as 60% of the patients; in the remaining patients, a brief latent period (30 minutes to 4 hours) is followed by evidence of excessive bleeding from venipuncture sites and from the site of placental separation.[126] Because of its rapid course, the effectiveness of various treatment modalities has not been carefully assessed. Vigorous supportive therapy directed toward gas exchange with mechanical respiratory assistance and fluid and blood replacement to treat severe hypotension are essential. When bleeding becomes the major manifestation, however, the use of heparin may accentuate the bleeding, especially if adequate replacement therapy for consumed clotting factors has not been achieved. If intense systemic fibrinolysis complicates DIC, fibrinolytic inhibitors may be useful in patients refractory to replacement therapy to control serious bleeding. However, the same precautions regarding antifibrinolytic use apply as in other settings of DIC.

Toxemia of Pregnancy and HELLP Syndrome

Although sensitive parameters of thrombin generation are increased in toxemia of pregnancy and patients with the HELLP syndrome, and patients with severe toxemia may have fibrin thrombi in the microvasculature,[144,318–320] overt DIC occurs infrequently.[143] Therefore, it is not surprising that no significant

benefit of heparin therapy in toxemia of pregnancy (or the HELLP syndrome) has been established; in fact, the risk of intracranial bleeding in patients with severe, uncontrolled hypertension makes the use of anticoagulants dangerous. Therapy is directed primarily at controlling the eclamptic state with antihypertensive agents, magnesium sulfate, and rapid termination of the pregnancy. Because HELLP syndrome usually reverses approximately 48 hours after delivery, the cornerstone of treatment is prompt delivery of the infant.[144] If the syndrome persists beyond 72 to 96 hours, plasmapheresis and exchange with fresh-frozen plasma has been used, albeit with equivocal results.[134]

Other Treatment Modalities

Antithrombin and Other Thrombin Inhibitors

Replacement of AT with fresh-frozen plasma or AT concentrate with or without heparin should neutralize excess thrombin and dampen or moderate the intravascular coagulation process.[259] This approach should be particularly effective in patients with DIC associated with hepatic failure, because of decreased synthesis and increased consumption of AT. Although AT concentrates shorten the duration of DIC in some patients with fatty liver of pregnancy, they are not helpful in patients with DIC due to peritoneovenous shunts.[321] A low level of AT in a patient with severe infection or septic shock is a sign of poor prognosis.[322,323] In experimental animal models of sepsis and DIC, infusion of AT decreased the degree of DIC and mortality, particularly if administered before the induction of sepsis and in very high doses.[324] AT may have an anti-inflammatory effect in animal models.[325,326] A series of small clinical trials showed a modest reduction in mortality in AT-treated patients, but no trial reached statistical significance,[327] and a large-scale, multicenter, randomized controlled trial showed no significant reduction in mortality of patients with sepsis who were treated with AT.[328] Interestingly, *post hoc* subgroup analyses indicated some benefit in patients with DIC who did not receive concomitant heparin, but this observation needs prospective validation.[329] Hirudin and other direct thrombin inhibitors have shown efficacy in animal models, but trials of clinical efficacy in DIC have not yet been performed.[330–333]

Activated Protein C

APC, in the presence of protein S as a cofactor, inactivates factors Va and VIIIa. In a study by Taylor et al., APC prevented the coagulopathy and lethal effect of *E. coli*.[334] APC administered to rats given endotoxin reduced the pulmonary vascular injury and hypertension,[335] changes that were independent of its anticoagulant effect. A phase III trial of APC concentrate in patients with severe sepsis was prematurely stopped because of efficacy in reducing mortality,[336] all-cause mortality at 28 days being 24.7% in the APC group versus 30.8% in the control group (19.4% relative risk reduction). Presumably, the mortality advantage provided by APC was mediated by its ameliorating effect on DIC, which in turn decreased the occurrence of organ failure. Patients with DIC had a greater survival benefit from APC than did patients without DIC, [82] (relative risk reduction 38% vs. 18% in patients with sepsis without DIC). APC is relatively more effective in higher disease severity groups, and a prospective trial in septic patients with relatively low disease severity did not show any benefit of APC.[337]

Fibrinolytic Inhibitors

EACA or tranexamic acid should not be used in most patients with DIC because inhibition of the fibrinolytic system may lead to widespread fibrin deposition in the microcirculation, resulting in ischemic organ dysfunction or failure. In patients with pathologic fibrinogenolysis or in those in whom DIC is associated with excessive fibrinolytic activity, however, lysine analogues may be helpful.[4,10] In addition, in patients with amniotic fluid embolism after the episode of DIC has subsided, the patient may continue to bleed because of intense fibrinolytic activity, in which case EACA or tranexamic acid can be helpful in controlling bleeding.

SUMMARY OF TREATMENT

Table 98.6 summarizes the general principles of the treatment of DIC. The treatment of DIC is extremely complex because DIC complicates many different disorders and may have a variety of clinical manifestations. In addition, well-controlled studies are lacking regarding various methods of management in relatively homogeneous groups of patients. Therefore, treatment continues to be controversial and probably will remain so. Any careful clinical and laboratory observations in groups of patients with the same underlying disorder are extremely helpful in elucidating the natural history of the process and its effects on the patient, and in clarifying whether certain therapeutic interventions may be helpful. The continued accumulation of careful clinical studies will help in determining the proper management of DIC in patients with the same underlying disorder and in given individual situations.

Table 98.6

Treatment of acute, severe DIC

Modality	Rationale	Details	Expectations
Life-support measures	Self-evident	Fluids, blood, respiratory care, pressors, etc.	Maintain cardiac output, gas exchange, electrolyte balance, etc.
Treating the underlying disorder	Correct the cause of DIC	Dependent on the primary diagnosis	Inhibit or block the complicating pathologic mechanism of DIC in parallel with the response (if any) of the disorder
Antithrombotic agents	Block microthrombus formation	Heparin by continuous IV infusion (initial dose 7.5 U/kg/h), monitor with fibrinogen and platelet levels; continue as long as the predisposing clinical state persists	Prevent fibrin formation; tip the balance within the microcirculation toward physiologic fibrinolysis; allow reperfusion of the skin, kidneys, and brain
Transfusion	Reestablish normal hemostatic potential	Infuse platelets and fibrinogen (cryoprecipitate); repeat as indicated by laboratory and clinical observation	Platelet count and fibrinogen should increase significantly; bleeding should diminish and stop during an interval of hours to several days
Transfusion + heparin	Restore normal hemostasis if transfusion of hemostatic factors fails to achieve significant increment in factor levels	Infuse platelets and cryoprecipitate 2 h after starting continuous heparin infusion (7.5 U/kg/h); repeat as indicated by laboratory and clinical observation	Platelet count and fibrinogen should increase significantly if consumption is blocked; bleeding should diminish; if bleeding increases, discontinue heparin
Fibrinolytic inhibitors	Block excessive fibrinolysis and the accumulation of degradation products in blood; protect hemostatic plugs	For adults, EACA: loading dose, 4–6 g, then 1 g q12h for a limited duration (up to 48 h), adjusted dose with renal failure	Bleeding ceases rapidly but keeps vascular channels occluded with thrombus; dangerous if the thrombotic process was not previously treated with heparin

DIC, disseminated intravascular coagulation; IV, intravenous; AT-III, antithrombin III.

The Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndromes

JAMES N. GEORGE

Thrombotic thrombocytopenic purpura (TTP)[1,2] and the hemolytic uremic syndrome (HUS)[3,4] were described initially as distinct disorders. Although they may be distinct in their classic presentations, TTP in adults with acquired, severe ADAMTS13 deficiency and the diarrhea-associated typical HUS in children, in many patients this distinction is neither apparent nor important. TTP is often said to be associated with more severe neurologic abnormalities and HUS with more severe renal failure. However, many adult patients with acquired, severe ADAMTS13 deficiency have neither severe neurologic abnormalities nor renal failure,[5,6] and some children with typical HUS whose primary abnormality is acute renal failure have severe neurologic abnormalities.[7–9] There are multiple other syndromes that are described as TTP or HUS in addition to these two classic disorders in which the distinction between TTP and HUS is similarly unclear. Table 99.1 summarizes the common clinical nomenclature of these syndromes.[6]

Pathologic abnormalities are similar in both TTP and HUS. The characteristic histologic features of thrombi in terminal arterioles and capillaries are described as thrombotic microangiopathy (TMA) (Table 99.1).[10,11] FIGURE 99.1 demonstrates the characteristic pathologic features of systemic TMA in a patient with acquired, severe ADAMTS13 deficiency. TMA can also occur in multiple other disorders, such as malignant hypertension, scleroderma, antiphospholipid antibody syndrome, acute renal allograft rejection, and severe preeclampsia and the hemolysis, elevated liver enzymes, and a low platelet count (HELLP) syndrome[10]; in these disorders the TMA is usually restricted to the kidney. Microangiopathic hemolysis with red-cell fragmentation may result from the turbulence and high shear stress of circulation through partially occluded arterioles.[12] Therefore, the clinical features of all disorders associated with TMA are similar. All disorders associated with TMA may resemble the clinical features of TTP and HUS. This can make clinical decisions of definition, diagnosis, and treatment of the TTP and HUS syndromes difficult.

The definition of TTP has changed since the classic review in 1966 that summarized all previously reported cases.[13] This review defined a pentad of clinical features that became the cornerstone of diagnosis of TTP for many years: (a) microangiopathic hemolytic anemia, (b) thrombocytopenia, (c) neurologic symptoms and signs, (d) renal function abnormalities, and (e) fever. In that review,[13] the diagnosis of TTP was supported by pathologic demonstration of hyaline thrombi in 93% of patients; 90% of the patients died. In the past 30 years, the availability of curative plasma exchange treatment[14,15] has created an urgency for establishing the diagnosis of TTP, which in turn has resulted in less stringent diagnostic criteria.[6,15] Now only microangiopathic hemolytic anemia and thrombocytopenia without another clinically apparent cause are sufficient to establish the diagnosis of TTP.[6,15] Decreased stringency of diagnostic criteria has inevitably led to an increased frequency of diagnosis[16] and to a broader clinical spectrum of disorders for which plasma exchange treatment is considered. A current classification of presenting clinical features and disease associations of the TTP and HUS syndromes is presented in Table 99.2.

This chapter focuses on TTP in adults, initially describing adults with acquired, severe ADAMTS13 deficiency (defined as <10% activity) (Table 99.2). Clinical characteristics of the TTP and HUS syndromes that are associated with other apparent etiologies are discussed in subsequent sections.

TTP ASSOCIATED WITH ACQUIRED, SEVERE ADAMTS DEFICIENCY

Although patients with acquired, severe ADAMTS13 deficiency (activity <10%) are considered to be the "classic" TTP, they have represented only 23% of all 299 patients who were treated with plasma exchange for an initial clinical diagnosis of TTP or HUS in the Oklahoma TTP-HUS Registry, 1995 to 2010, and who had measurement of ADAMTS13 activity immediately before plasma exchange was begun (FIGURE 99.2).[5,6] Only 48% of 114 patients with idiopathic TTP and severe ADAMTS13 deficiency.[6] This observation emphasizes the heterogeneity of the TTP and HUS syndromes. Although patients with acquired, severe ADAMTS13 deficiency constitute only a minority of all patients with these syndromes, their pathogenesis, clinical features, and outcomes are well described and represent the basis for understanding the mechanisms of microvascular thrombosis as well as the evaluation and management of patients with clinically suspected TTP.

Pathogenesis

von Willebrand factor (vWF) abnormalities are central to the pathogenesis of TTP in patients with acquired, severe ADAMTS13 deficiency.[17–21,22] vWF is secreted by endothelial cells into the plasma where it is processed into smaller multimers that do not spontaneously interact with circulating platelets (see Chapter 13). ADAMTS13, an enzyme present in normal plasma, processes vWF by proteolysis, which is the principal mechanism in this respect. vWF may also be processed

Table 99.1

Nomenclature of the TTP and HUS syndromes

Name	Definition
Pathologic Descriptive Term	
TMA	The characteristic histologic abnormality of both TTP and HUS. Describes the microvascular features (swelling of endothelial cells and the subendothelial space) associated with thrombosis. TMA may also occur in many other disorders, such as malignant hypertension, antiphospholipid antibody syndrome, systemic lupus erythematosus, and preeclampsia.
Acquired Clinical Syndromes	
TTP	The appropriate term for all adults with microangiopathic hemolytic anemia and thrombocytopenia with or without renal failure or neurologic abnormalities and without an alternative etiology. Children without renal failure are also described as TTP. Includes but is not limited to patients with severe ADAMTS13 deficiency (<10%). In some adults with predominant acute renal failure, such as with quinine sensitivity or *E. coli* O157:H7 infection, the comprehensive term, TTP–HUS, is often used.
Typical HUS	Children with a syndrome of microangiopathic hemolytic anemia, thrombocytopenia, and renal failure with a diarrhea prodrome caused by enteric infection with *E. coli* O157:H7 or other Shiga toxin–producing bacteria.
aHUS	A syndrome of microangiopathic hemolytic anemia, thrombocytopenia, and renal failure without a diarrhea prodrome. May be caused by pneumococcal infections or acquired disorders of complement regulation.
Congenital Clinical Syndromes	
Upshaw-Shulman syndrome	Caused by congenital deficiency of ADAMTS13.
aHUS	Associated with congenital deficiencies of complement regulatory factors, resulting in unrestrained complement activation.

Adapted from George JN. How I treat patients with thrombotic thrombocytopenic purpura. *Blood* 2010;116:4060–4069.

following secretion by reduction of disulfide bonds that link the vWF dimers.[23–25] In 1982, Moake et al. observed in the plasma of patients with chronic relapsing (congenital) TTP[26] unusually large vWF multimers (ULvWF), which were comparable in size to vWF initially secreted by endothelial cells. These ULvWF multimers can directly agglutinate platelets when the vWF structure is altered by the high shear stress that occurs in arterioles.[20] In 1996 to 1998, the origin of ULvWF was documented to be a severe deficiency of ADAMTS13 activity.[17,18,27–30] In patients with acquired TTP, autoantibodies inhibit ADAMTS13 function by interacting with multiple domains, particularly the Cys-rich and spacer domains.[31] In some patients with apparently acquired, severe ADAMTS13 deficiency, no inhibitory autoantibodies are detectable. Autoantibodies may have been neutralized by previous transfusions,[5] or autoantibodies may impair ADAMTS13 function by accelerating clearance from plasma or by impairing binding to the endothelial cell surface rather than by neutralizing enzymatic activity.[32]

Undetectable ADAMTS13 activity is not always associated with evidence for disease. Approximately 20% of patients have persistent severe deficiency of ADAMTS13 activity following recovery from an acute episode of TTP.[5] These observations are similar to those of the absence of the TTP phenotype in *Adamts13*$^{-/-}$ mice[33,34] and suggest that absence of ADAMTS13 may be only one of several components causing acute episodes of TTP. However in baboons, it has been demonstrated that absence of ADAMTS13 activity is sufficient to initiate the clinical features of TTP.[22]

Risk Factors for TTP Associated with Acquired, Severe ADAMTS13 Deficiency

Similar to other thrombotic and autoimmune disorders, multiple risk factors may contribute to the onset of TTP. Similar to systemic lupus erythematosus (SLE),[35,36] middle age, female gender, and black race are important risk factors.[36,37,38] Although it had been postulated that blood group O may be protective against TTP because it is associated with lower plasma vWF levels[39–43] and a faster rate of vWF proteolysis by ADAMTS13,[42,44] blood group O is actually a risk factor for TTP associated with acquired, severe ADAMTS13 deficiency.[45] This observation suggests a novel hypothesis that higher basal levels of normal-sized vWF in people with non-O blood groups may compete with ULvWF for platelet binding, reducing the risk for ULvWF-mediated formation of platelet thrombi and providing partial protection from ULvWF-mediated thrombosis in patients with non-O blood groups. This hypothesis is consistent with previous observations that elevated plasma vWF levels are not a risk factor for the occurrence of the features of TTP in *Adamts13*$^{-/-}$ mice.[33]

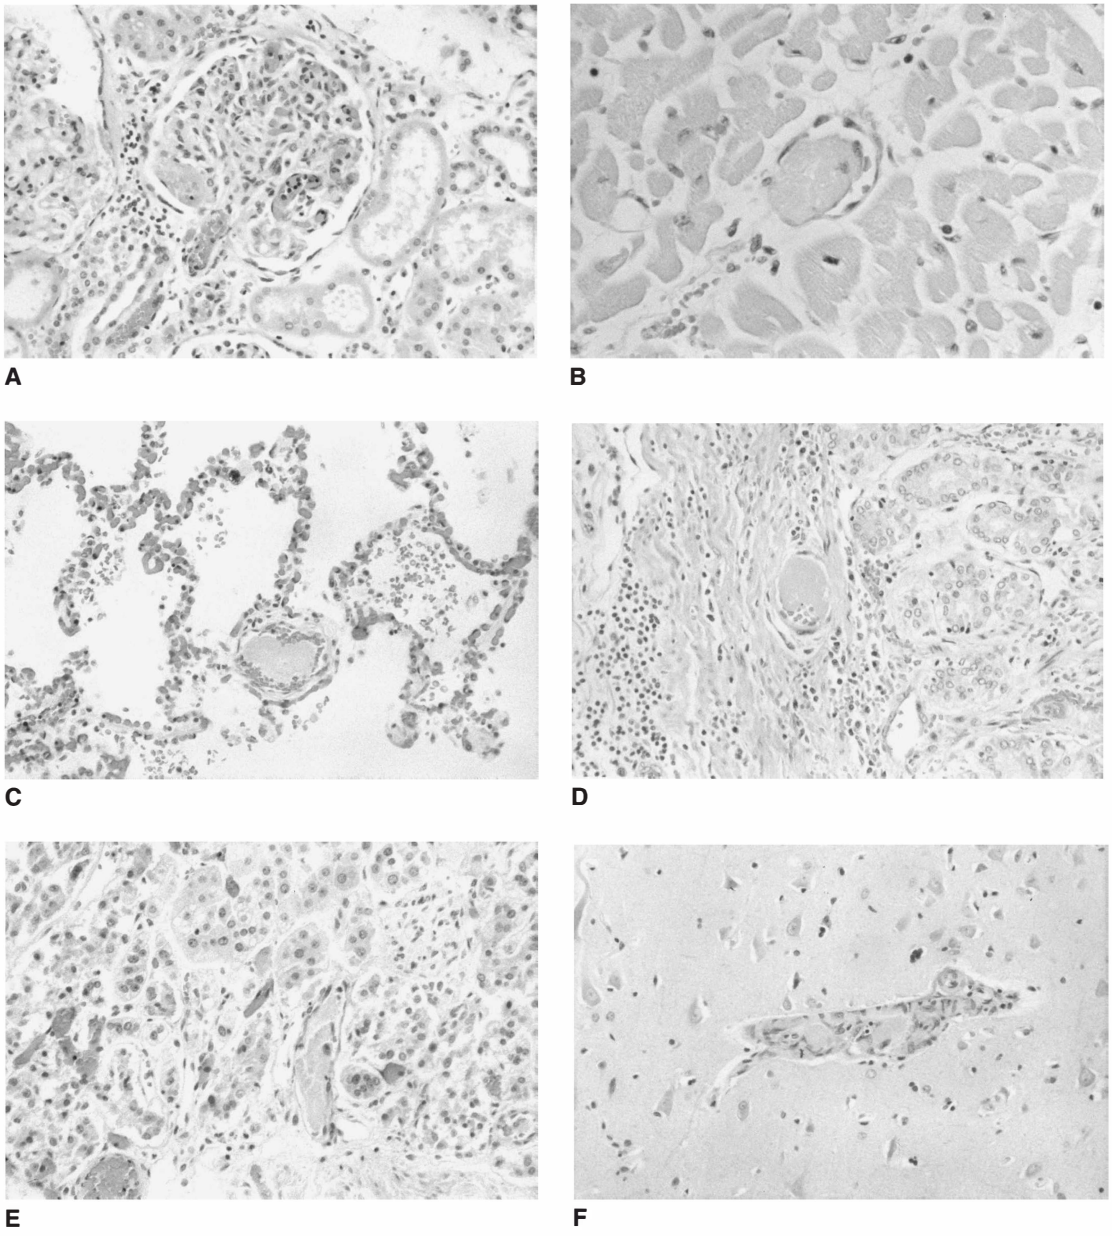

FIGURE 99.1 Systemic microvascular thrombi in TTP. These autopsy tissue sections are from a previously healthy young man who became ill with 3 days of abdominal pain, nausea, and vomiting followed by severe confusion. Clinical features on admission to the hospital were platelet count 11 × 10^9/L, hematocrit 21%, LDH 2,231 U/L, creatinine 1 mg/dL, urinalysis with proteinuria and hematuria, and no fever. He received three plasma exchange treatments plus corticosteroids but died with grand mal seizures and cardiopulmonary arrest 3 days after hospital admission. Subsequent analysis of serum collected before the initial plasma exchange treatment demonstrated ADAMTS13 activity <5% with an ADAMTS13 inhibitor of >2 Bethesda units. Tissue sections demonstrate **(A)** kidney afferent arteriole and glomerular capillary thrombi, **(B)** myocardial thrombi, **(C)** pulmonary thrombi, **(D)** gastric submucosal thrombi, **(E)** adrenal thrombi, **(F)** cerebral thrombi, and **(G)** thrombi in the choroid plexus. (Photographs by Zoltan Laszik, MD, Department of Pathology, University of Oklahoma.)

Table 99.2

Clinical features of the TTP and HUS syndromes

Syndrome	Clinical Features
Acquired Disorders	
ADAMTS13 activity <10%	Considered to be the "classic" TTP. Autoimmune ADAMTS13 deficiency occurs primarily in adult women with increased relative frequency among blacks. Acute episodes may be triggered by pregnancy or infections and may be associated with SLE or other autoimmune disorders. One-third has no neurologic abnormalities; acute renal failure and fever rare; immunosuppressive treatment required in addition to PEX. Relapse may occur in 41%.
Idiopathic TTP, ADAMTS13 activity ≥10%	Etiology unknown. Some may be associated with abnormalities of complement regulation. Compared to patients with ADAMTS13 activity <10%, these patients are older, more often have renal failure, and do not relapse. PEX appropriate because clinical distinction from patients with ADAMTS13 <10% is uncertain.
Typical HUS	Primarily occurs in children <5 years old and accounts for 90%–95% of childhood HUS; also occurs in adults. Preceded by diarrhea, often bloody, and manifested by acute renal failure. Severe neurologic abnormalities uncommon in children but more common in adults. Children managed by supportive care; PEX appropriate for adults because clinical distinction from patients with ADAMTS13 <10% is uncertain. Relapse does not occur.
aHUS	Patients in whom HUS is not preceded by diarrhea. Accounts for 5%–10% of childhood HUS; also occurs in adults. PEX may be appropriate. Relapse may occur.
Drug-induced: acute, immune mediated	Quinine is the most common and the only one with clearly documented etiology, caused by drug-dependent antibodies to platelets, endothelial cells, and other cells. Characterized by a sudden onset of systemic symptoms and anuric acute renal failure. PEX appropriate because drug etiology may be uncertain. Also reported with other drugs.[a]
Drug-induced: dose-dependent toxicity	Mitomycin C, gemcitabine, and cyclosporine are the most commonly reported drugs. Also associated with drugs inhibiting VEGF. Insidious onset with predominant renal failure. Reversibility and role of PEX are uncertain.
Congenital Disorders	
Upshaw-Schulman syndrome (ADAMTS13 deficiency)	Initial episodes may occur at any age; recurrent acute episodes are common. Plasma infusion is sufficient treatment; prophylactic plasma infusion may be required.
Deficiencies of complement regulatory factors (aHUS)	Described as aHUS since acute renal failure is predominant without a diarrhea prodrome. Initial acute episodes may occur at any age. PEX may be appropriate. Relapse may occur.

[a]Other drugs that have been associated with acute and apparently immune-mediated TTP and HUS syndromes are clopidogrel, ticlopidine, and trimethoprim-sulfamethoxazole.
PEX, plasma exchange treatment; SLE, systemic lupus erythematosus; VEGF, vascular endothelial growth factor.

In addition to demographic risk factors, there are multiple acquired risk factors that can be associated with or perhaps even trigger acute episodes of TTP in susceptible patients. Pregnancy is associated with episodes of both congenital and acquired TTP.[46–48] The increased risk for TTP during pregnancy may be related to the decreased ADAMTS13 plasma levels during the third trimester,[49] which are more severe when obstetric complications such as HELLP syndrome occur.[50] However, most pregnancies following recovery are uncomplicated.[47] Inflammatory conditions, such as pancreatitis,[51] infections,[52] and surgery,[53] may also trigger acute episodes of TTP.

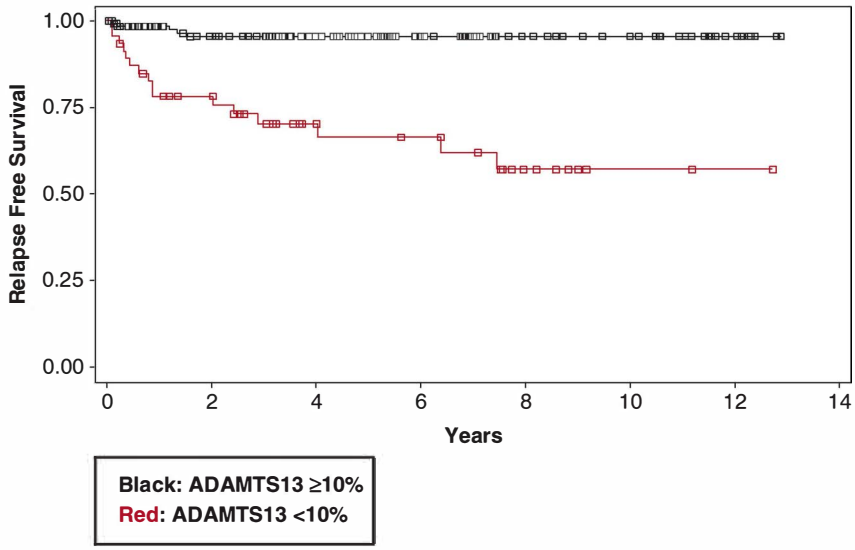

FIGURE 99.2 Kaplan-Meyer analysis of time to relapse for patients with ADAMTS13 activity <10% and patients with ADAMTS13 activity ≥10% at the time of their initial diagnosis of TTP. Data are from all 47 surviving patients who had initially presented with ADAMTS13 activity <10% and all 136 surviving patients with ADAMTS13 activity ≥10% who presented to the Oklahoma TTP–HUS Registry, 1995 to 2008. Median follow-up of all 47 patients with ADAMTS13 activity <10% was 7.5 years; median follow-up of 26 living patients with ADAMTS13 activity <10% who had not relapsed was 4.6 years. (Adapted from Kremer Hovinga JA, Vesely SK, Terrell DR, et al. Survival and relapse in patients with thrombotic thrombocytopenic purpura. *Blood* 2010;115:1500–1511.)

Clinical and Laboratory Features

Validity of the minimal diagnostic criteria of microangiopathic hemolytic anemia and thrombocytopenia, in the absence of another clinically apparent cause,[6,15] is supported by the presenting features of patients who have TTP associated with acquired, severe ADAMTS13 deficiency. Many of these patients have no neurologic or renal function abnormalities.[6] The occurrence of the "classic pentad" of diagnostic features described nearly 50 years ago[13] now rarely occurs, and then only in atypical patients[6] see Table 99.3. Serum LDH levels are typically very high, reflecting severe hemolysis and also the ischemic injury of multiple organs.[54] Case reports have described three patients who had recovered from TTP associated with severe ADAMTS13 deficiency and subsequently had stroke symptoms that were attributed to TTP even in the absence of thrombocytopenia and microangiopathic hemolytic anemia.[55,56] The role of TTP as the etiology of the stroke symptoms was postulated because of the presence of severe ADAMTS13 deficiency and apparent response to plasma exchange treatment.[55,56] The occurrence of neurologic abnormalities in the absence of microangiopathic hemolytic anemia and thrombocytopenia is probably rare, but the possibility is an important clinical concern.

Treatment

Plasma exchange has profoundly affected the prognosis of TTP, decreasing the mortality from >90% before 1964[13] to approximately 20% now.[5,15] Although plasma exchange has remarkable benefit, it also has serious risks including death from hemorrhage or sepsis in 2% to 3% of patients.[57] It has been postulated that plasma exchange is effective by removing autoantibodies to ADAMTS13 as well as replacing ADAMTS13. However, plasma exchange also appears to benefit patients who do not have severe ADAMTS13 deficiency. Among patients with idiopathic TTP, the survival of patients treated with plasma exchange is the same in patients with and without severe ADAMTS13 deficiency.[6] In patients who have severe, acquired ADAMTS13 deficiency, glucocorticoid therapy is required in addition to plasma exchange to achieve a durable remission.[6] Glucocorticoid therapy is typically given as prednisone, 1 mg/kg/d (or the equivalent dose of parenteral preparations). Glucocorticoids are continued until the platelet count is normal and plasma exchange is stopped, and then tapered and discontinued over several weeks. In patients who are severely ill with neurologic complications, short courses of larger doses of parenteral glucocorticoids, such as methylprednisolone, 500 to 1,000 mg/d for 3 days, may be used. In patients with exacerbations and relapses, more intensive immunosuppression with rituximab in addition to glucocorticoids may be required.[5,6,58,59] Rituximab is used in the standard regimen used for other indications, 375 mg/m^2 weekly for 4 weeks.

Long-Term Outcomes

Persistent, subtle cognitive abnormalities may occur in most patients following recovery from TTP[60,61] (Table 99.4). Patients commonly report problems with memory, concentration, and endurance. These patients are not disabled; they have returned to their normal lives and occupations, but daily activities are more difficult.

Relapse rarely occurs in patients who do not have severe ADAMTS13 deficiency.[5] Among patients with acquired severe ADAMTS13 deficiency, the estimated risk for relapse is 41% at 7.5 years; relapses are most common during the first year after recovery.[5] The presence of severe ADAMTS13 deficiency during

Creatinine (mg/dL)	1.1 (0.7–4.6)
Outcomes	**Number of Patients (%)**
Death	13 (20)
Relapse (in 52 survivors)	18 (35)

Data from all 65 consecutive patients with ADAMTS13 activity <10% presenting to the Oklahoma TTP–HUS Registry, 1995 to 2009. Assignment of patients to clinical categories has been previously described (From Vesely SK, George JN, Lämmle B, et al. ADAMTS13 activity in thrombotic thrombocytopenic purpura-hemolytic uremic syndrome: relation to presenting features and clinical outcomes in a prospective cohort of 142 patients. *Blood* 2003;101:60—68, Ref. 115). Additional disorders are defined as a distinct, concomitant disorder, such as systemic lupus erythematosus; alternative disorders are defined as a new diagnosis discovered after plasma exchange for TTP has begun and which explains the presenting clinical features, such as sepsis, systemic malignancy, or malignant hypertension. When an alternative disorder is diagnosed, plasma exchange treatment is stopped because it is assumed that the initial diagnosis of TTP was incorrect.
HSCT, hematopoietic stem cell transplantation.
Adapted from George JN. How I treat patients with thrombotic thrombocytopenic purpura. *Blood* 2010;116:4060–4069.

remission does not appear to indicate a risk for relapse.[5] The increasing use of rituximab for management of acute episodes may decrease the occurrence of relapses.[5,58,59] Survival with a relapse episode is better than with an initial episode because of prompt recognition and treatment.[5]

Because pregnancy is a recognized risk factor for triggering acute episodes of TTP,[62] pregnancy is often assumed to be associated with a high risk for a relapse. This assumption seemed to be supported by case reports of subsequent pregnancies associated with recurrent TTP,[47] but case reports may preferentially report dramatic events rather than uncomplicated pregnancies. In the Oklahoma TTP–HUS Registry, TTP has recurred in only 6 of 51 subsequent pregnancies (data from Ref. 47 updated through December 31, 2010).

Since severe, acquired ADAMTS13 deficiency is an autoimmune disorder, there may be an increased risk for development of other autoimmune disorders. This potential risk is also suggested by the similar demographic features of patients with severe, acquired ADAMTS13 deficiency and SLE.[6,36]

CONGENITAL TTP

In patients with congenital TTP, multiple homozygous or compound heterozygous mutations of the *Adamts13* gene can cause deficient ADAMTS13 activity.[63,64] These patients are very rare. It has been estimated that only approximately 100 patients have been identified and confirmed worldwide (Kremer Hovinga, *personal communication*). The clinical features of congenital

Table 99.4

Long-term outcomes following recovery from TTP associated with ADAMTS13 activity <10%

Outcome	Comments
Cognitive abnormalities	Problems with memory, concentration, and fatigue are common and persistent but rarely impair normal activities and careers.
Relapse	Estimated risk at 7.5 years—41%. Most relapses occur in the first year after recovery. ADAMTS13 deficiency during remission may not predict risk for relapse. Although pregnancy is recognized as a risk factor for acute episodes of TTP, most subsequent pregnancies are not associated with relapse.
Other autoimmune disorders	Serologic abnormalities characteristic of SLE are common; risk for development of overt SLE or other autoimmune disorders may be increased.

TTP are extremely variable. Although all identified patients have severely deficient ADAMTS13 activity, variation in residual enzyme activity may be important for modifying clinical features.[46,65] Whether these mutations result in type I deficiencies, with no detectable ADAMTS13 antigen, or type II deficiencies, with circulating ADAMTS13 that has defective activity, has not yet been reported. Some patients have severe microangiopathic hemolysis and hyperbilirubinemia at birth.[66,67] In other families, women have been asymptomatic until near term of their first pregnancy[48] and male siblings have remained asymptomatic.[46] Although microangiopathic hemolysis and thrombocytopenia are initially predominant, end-stage renal failure may ultimately occur.[66–68] These patients may also have severe cerebrovascular ischemic events.[29] In patients with congenital TTP, intermittent plasma infusion to replace ADAMTS13 is sufficient therapy.[65,69,70] A plasma infusion regimen of 10 mL/kg every 3 weeks is usually sufficient to achieve a safe, minimum ADAMTS13 activity level of 5%.[65] Patients with recurrent symptoms may need more frequent plasma infusions. Observations in patients with congenital ADAMTS13 deficiency have documented that the half-life of ADAMTS13 in plasma is 2 to 3 days and that the minimum plasma activity sufficient to prevent microangiopathic abnormalities is 5%.[65,70] Recombinant ADAMTS13 is being developed for treatment of TTP. The initial population for clinical trials will be patients with congenital TTP, but these trials have not yet begun.

OTHER TTP AND HUS SYNDROMES

Shiga Toxin–Producing *Escherichia Coli*

Typical HUS of young children follows acute enteric infection caused by *E. coli* serotypes (predominantly *E. coli* O157:H7) that produce Shiga toxin. The association between Shiga toxin–producing *E. coli* O157:H7 and HUS was first documented in 1983.[71] Although outbreaks traced to undercooked beef, unpasteurized milk, juices, fruits, vegetables, and water[72–76] are dramatic and widely publicized, almost all cases are sporadic rather than associated with an outbreak.[77,78] Progression of *E. coli* O157:H7 infection to HUS is estimated to be 2% to 7% in sporadic cases but up to 30% in some epidemics.[72,74,79] The peak age of infection is 6 months to 5 years, suggesting that older children and adults may acquire immunity to the Shiga toxin,[72–74] but Shiga toxin–induced TTP–HUS can occur at any age.[80]

The clinical presentation is characteristically dominated by acute abdominal pain with diarrhea that becomes overtly bloody. If HUS develops, oliguria follows the occurrence of bloody diarrhea.[81] In adults, the clinical presentation is similar, but the course is more severe, with a high rate of severe neurologic abnormalities and death.[80] Although the standard of care for children with typical HUS is supportive care, plasma exchange is appropriate for adults because of the severe clinical course and also because TTP associated with acquired, severe ADAMTS13 deficiency can also present with bloody diarrhea.[6,82] In patients with acquired, severe ADAMTS13 deficiency, microvascular thrombosis in the colon can cause hemorrhagic enterocolitis that is pathologically indistinguishable from the colitis caused by Shiga toxin.[82]

Congenital HUS can be caused by abnormalities of complement regulation resulting in uncontrolled complement activation.[83] These patients often have recurrent episodes of renal failure associated with microangiopathic hemolytic anemia and thrombocytopenia. In adult women, syndromes previously described as postpartum acute renal failure have now been identified as associated with genetic abnormalities of complement regulation.[84] The recurrent episodes distinguish these patients from patients with Shiga toxin, diarrhea-associated HUS. Because of the absence of a diarrhea prodrome, these patients are described as having atypical HUS (aHUS). Many different factors that can control complement activation have been reported to be altered in aHUS.[83,85] For children with aHUS in whom an abnormality of complement regulation is suspected, current opinion suggests that plasma exchange should be used.[85,86]

Drug Hypersensitivity

TTP can be an idiosyncratic, acute adverse reaction to a drug, mediated by drug-dependent antibodies to platelets, neutrophils, endothelial cells, and perhaps also other cells.[87,88] Because of the predominance of acute renal failure, the term TTP–HUS

is often used to describe these patients.[89] Quinine is the most common cause of immune-mediated drug-induced TTP–HUS,[6,89] and it is the only drug associated with TTP–HUS in which the etiology has been supported by recurrent acute illness with recurrent exposure to quinine[89] or by documentation of drug-dependent, platelet-reactive antibodies (unpublished data from the Blood Center of Wisconsin [the largest resource for drug-dependent antibody testing in the United States[90]], *personal communication*, Aster). The presenting clinical features are characteristic: sudden onset of severe symptoms including oliguria, severe thrombocytopenia, and microangiopathic hemolytic anemia.[89] Patients are treated with plasma exchange because the clinical features were consistent with TTP, the quinine-associated etiology is often not initially recognized, and the mortality is high.[89]

Other drugs have been reported to cause acute episodes of TTP–HUS,[91] but their causal association is uncertain. In some patients who have taken ticlopidine or clopidogrel, a severe deficiency of ADAMTS13 activity and the presence of an inhibitor of ADAMTS13 has been identified,[92,93] but no drug dependence of the inhibitor was demonstrated. It is possible that these patients had idiopathic TTP caused by acquired, severe autoimmune ADAMTS13 deficiency and that exposure to ticlopidine and clopidogrel was coincidental and not involved in pathogenesis. Although TTP–HUS associated with chemotherapeutic agents is typically a dose-dependent toxicity, acute and presumed immune-mediated TMA has been reported with oxaliplatin.[94] Oxaliplatin-dependent, platelet-reactive antibodies have been documented in patients with acute oxaliplatin-induced thrombocytopenia[95] but not yet in patients with acute TTP–HUS syndromes.

Thrombotic Microangiopathy Caused by Dose-Dependent Drug Toxicity

Chemotherapeutic agents and calcineurin inhibitors can cause dose-dependent renal toxicity resulting in TMA. Chronic and cumulative dose dependence of the toxicity has been documented for mitomycin C[96] and gemcitabine.[97–99] One patient has been reported with a toxic overdose of deoxycoformycin causing acute, severe TMA.[100] The calcineurin inhibitors, cyclosporine and tacrolimus, can also cause dose-dependent renal toxicity resulting in TMA.[101,102] For patients with TMA associated with dose-dependent drug toxicity, stopping the suspected drug may be all that is required, but patients with TMA associated with mitomycin C and gemcitabine may have persistent, severe renal failure.[96,98] Plasma exchange has no documented benefit.[98,103]

Thrombotic Microangiopathy Following Allogeneic Hematopoietic Stem Cell Transplantation

Patients who developed clinical features of TMA following allogeneic hematopoietic stem cell transplantation (HSCT) were previously described as TTP and treated with plasma exchange.[104,105] However, substantial experience failed to document effectiveness of plasma exchange treatment[106]; therefore the name of this syndrome has been changed to HSCT-associated TMA to avoid consideration of plasma exchange and other treatments used for TTP.[107,108] There are no reports of autopsies demonstrating systemic microvascular thrombosis characteristic of TTP in patients with HSCT-associated TMA, further supporting the distinction between HSCT-associated TMA and TTP.[106,109] Although many complications of HSCT may mimic TMA[110] and many diverse etiologies may contribute to TMA following HSCT,[111] HSCT-associated TMA is considered to be a specific syndrome complicating allogeneic HSCT.[107,108,109,111,112] In addition to the calcineurin inhibitors, cyclosporine and tacrolimus, a potentially important etiology of HSCT-associated TMA is sirolimus, which is also used for graft-versus-host disease prophylaxis.[113] Sirolimus, which inhibits vascular endothelial cell growth factor (VEGF), has been associated with an increased incidence of HSCT-associated TMA.[113] Bevacizumab, which also inhibits VEGF, can also cause renal TMA.[114] These clinical observations have been supported by experimental observations that VEGF inhibition, caused by gene targeting in mice to delete VEGF from renal podocytes, can cause glomerular injury resulting in TMA.[114]

CONCLUSIONS

Because of the absence of explicit diagnostic criteria, the diagnosis of the TTP and HUS syndromes remains based on clinical judgment and is often uncertain. Future studies need to provide more precision for the diagnosis. Plasma exchange is effective treatment for patients with severe, acquired ADAMTS13 deficiency, but it is a treatment with significant morbidity. Survival rates for TTP have not changed in 20 years since the introduction of plasma exchange. Future studies need to develop treatment regimens that are more effective as well as safer and more accessible.

CHAPTER

100 Vasculitides

JAMES R. STONE AND JOHN H. STONE

The vasculitides comprise a heterogeneous group of disorders characterized by inflammation that targets and damages blood vessels. Vasculitis may be caused by infection or be a result of a direct attack on the vascular wall by the body's immune system. This latter situation, the noninfectious vasculitides, will be covered here. Emphasis will be placed on classification, molecular mechanisms, and pathobiology, with specific digressions into treatment and clinical management where appropriate.

CLASSIFICATION OF VASCULITIS

The classification of vasculitis is an extremely important issue, since it forms the basis for how we approach these disorders in terms of diagnosis, patient management, and even research. It should be understood that the vasculitides have the potential to be as diverse as the complexity of the immune system itself, and thus no classification system is likely to be perfect in all situations. Nonetheless, defining specific vasculitic conditions has significant value. The ideal classification scheme would be one that is based largely on specific molecular mechanisms, predicts prognosis accurately, and guides treatment reliably. Given our limited understanding of many of the vasculitides, this ideal classification is not currently possible. However, great strides have been made utilizing a combination of clinical, laboratory, and pathologic findings.

Multiple diagnostic schemes have been proposed for subclassifying vasculitis in the clinical setting based often on limited information.[1,2] However, the most widely applied scheme for classifying the vasculitides into distinct pathologic entities was developed at the Chapel Hill Consensus Conference.[3] A key feature of the Chapel Hill System is to first consider the sizes of the vessels that are involved, resulting in the general categories of large-vessel vasculitis, medium-sized vessel vasculitis, and small-vessel vasculitis. Large vessels in this context refer to the aorta, arch branches, and distributing arteries in the extremities and head. Medium-sized vessels refer to small- and medium-sized arteries throughout the body, which includes both distributing and intraparenchymal arteries. It is a common point of confusion that in this context small arteries are defined as medium-sized vessels rather than small blood vessels. Small vessels refer to arterioles, capillaries, and venules. Of course, many vasculitides can involve more than one size of vessel. By Chapel Hill criteria, large-vessel vasculitides may involve medium-sized vessels, and small-vessel vasculitides may also involve medium-sized vessels. However, a vasculitis defined as a medium-sized vessel vasculitis should not involve small vessels.

GIANT CELL ARTERITIS

Giant cell arteritis (GCA), one of the most common vasculitides, primarily affects individuals above the age of 50. Based on clinical presentations, the prevalence of GCA is as high as 0.2% for people over the age of 50 and of European descent.[4,5] A large autopsy-based study reported that the prevalence of GCA may be as high as 1.7% in older patients, suggesting that the majority of cases of GCA are subclinical.[6] Pathologically, GCA is characterized by granulomatous inflammation that contains numerous activated epithelioid macrophages, which often coalesce to form giant cells.[7,8] This granulomatous component typically directly targets elastic laminae within the vessel walls of medium-sized and large arteries. There is also usually an accompanying lymphocytic or lymphoplasmacytic inflammatory component, which may be primarily restricted to the adventitia.[9] While almost any artery can be affected, GCA is most commonly seen in the arteries of the head and neck, particularly the superficial temporal arteries (FIGURE 100.1), and in the aorta (FIGURE 100.2). In GCA, there is injury to the arterial wall that leads to the formation of intense intimal hyperplasia. In fact, luminal obstruction is most often secondary to intimal hyperplasia rather than overt thrombosis. In medium-sized vessels, overt necrosis is typically absent or minimal compared with that seen in polyarteritis nodosa (PAN) and granulomatosis with polyangiitis (GPA). Thus, in this regard, GCA can often be viewed as a relatively chronic insidious vasculitis.

Patients often present with fever, headache, visual changes, and elevated nonspecific serum inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).[10] Jaw claudication is a relatively specific but less sensitive symptom of GCA.[11] GCA also has a known association with polymyalgia rheumatica, which causes musculoskeletal pain generally focused on the shoulder and hip girdles. Biopsy of the superficial temporal arteries can confirm the diagnosis. Glucocorticoids can prevent permanent vision loss from obstruction of the posterior ciliary, ophthalmic, or retinal arteries. Other complications of GCA include ischemic necrosis of the scalp and tongue, formation of aortic aneurysms, and life-threatening aortic dissection. Approximately 15% to 20% of patients with GCA experience permanent intracranial ischemic injury, such as blindness and cerebrovascular accidents.[10] The specific etiology of GCA remains elusive.

TAKAYASU ARTERITIS

Takayasu arteritis is a large-vessel vasculitis that primarily affects young women of Asian or Middle Eastern descent. In contrast to GCA, at the time of diagnosis the patients are usually <50 years old, but patients of almost any age may be affected. There is a striking female predominance, with a female to male ratio of 9:1.[12] In North America, the annual

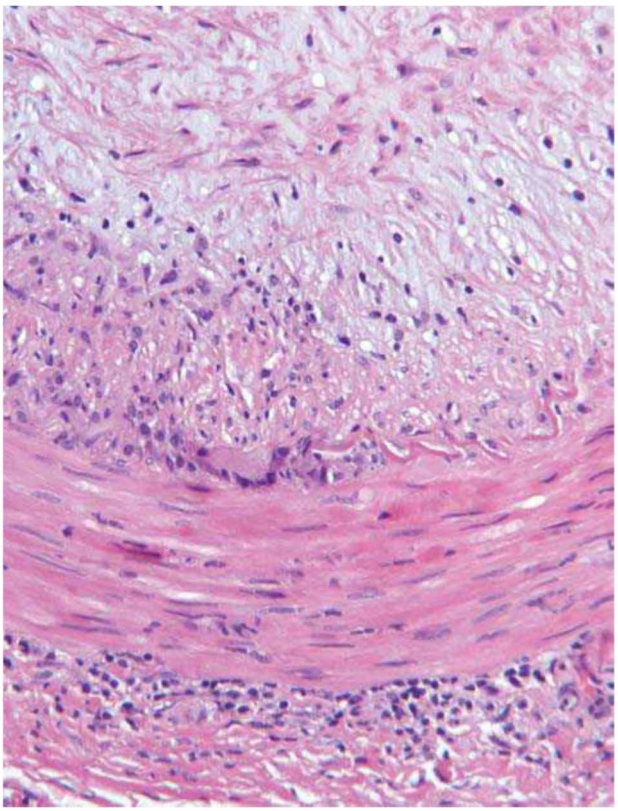

FIGURE 100.1 Giant cell arteritis. Temporal artery biopsy from a 74-year-old woman showing active GCA. There is granulomatous inflammation with a giant cell at the internal elastic lamina. A lymphoplasmacytic infiltrate is present in the adventitia **(bottom)**, and there is extensive intimal hyperplasia **(top)**.

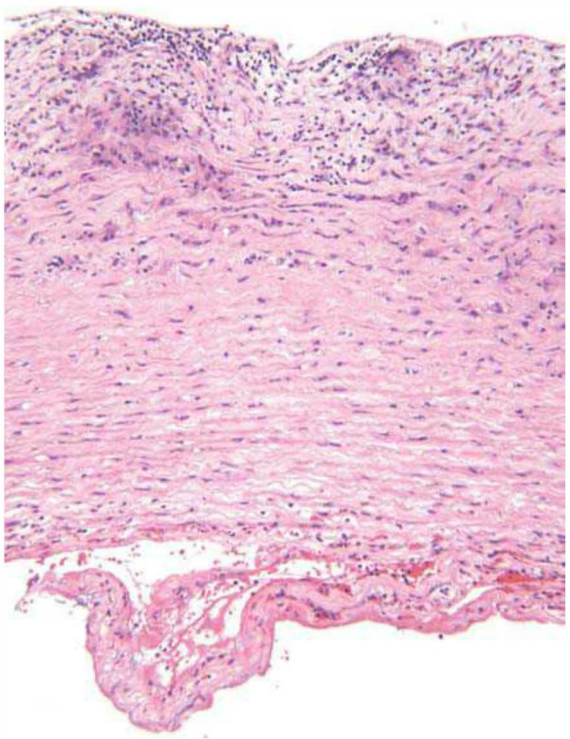

FIGURE 100.2 Giant cell aortitis with aortic dissection. An 87-year-old woman with a history of cranial GCA presented with aortic dissection. Upon surgical repair of the dissection, the aorta demonstrated active giant cell aortitis. Shown is a histologic section of the inner half of the dissected aorta. There is granulomatous inflammation with giant cells **(top)** and the dissection channel with fibrin **(bottom)**.

incidence is about 2 per million per year, making Takayasu arteritis 10- to 50-fold less common than GCA in this region.[13] In its complete presentation, Takayasu arteritis is a disease with two distinct phases. There is an acute phase characterized by fever, weakness, weight loss, arthralgias, and myalgias. This phase is followed by an occlusive phase weeks to years later. The occlusive phase is characterized by vascular occlusion most characteristically of the aortic arch branches, resulting in diminished or absent pulses and bruits on physical examination. Between the acute and occlusive phases, there may be an intervening asymptomatic phase. In addition to the aorta and arch branches, Takayasu arteritis is known to involve the vertebral arteries, renal arteries, coronary arteries, and pulmonary arteries in a significant minority of cases. While occlusive disease is most common, aneurysms also develop in a minority of patients. Fundic abnormalities including vascular tortuosity, microaneurysms, and arteriovenous shunts are also seen in a significant minority of cases.[12] Serum inflammatory markers such as the ESR and CRP are often elevated in the acute phase, but may be normal in the occlusive phase.

The pathologic features of Takayasu arteritis are granulomatous inflammation within the vessel wall and an associated lymphocytic or lymphoplasmacytic component. The disease has a predilection for the adventitia and outer half of the media.[13,14] Giant cells are not uncommon, and compact granulomas may be observed. There is usually marked adventitial scarring (FIGURE 100.3). The pathologic features overlap with those of GCA. However, compared with GCA, in Takayasu arteritis there is more severe adventitial scarring, there is more severe involvement of the outer half of the media compared with the inner half, and in some cases there are compact granulomas. In GCA, typically the inner half of the media is more affected than the outer half, adventitial scarring is less prominent, and compact granulomas are only rarely observed. In Takayasu arteritis, there is marked fibrous intimal thickening, which is responsible for the vascular occlusion (FIGURE 100.4).

Patients are most often treated with glucocorticoids to induce remission, but second-line agents may include cyclophosphamide, azathioprine, or methotrexate.[15] With treatment, the 15-year survival is approximately 80%.[12] The etiology of Takayasu arteritis remains unclear; however some studies suggest an association with infectious diseases, particularly mycobacterial infections.[16]

RHEUMATOID VASCULITIS

Rheumatoid arthritis (RA) is a common chronic destructive inflammatory disease, which primarily affects the joints. Approximately 1% of the population is afflicted, most

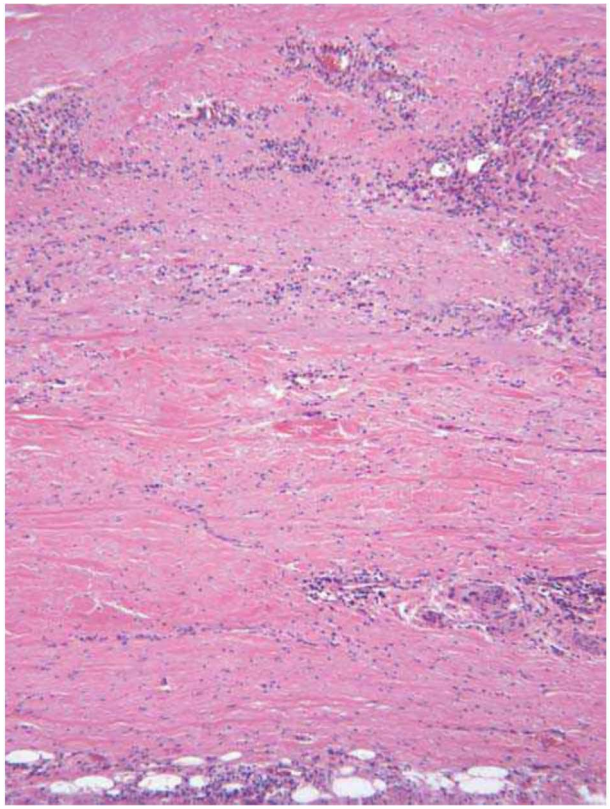

FIGURE 100.3 Takayasu aortitis. A 34-year-old woman with a history of Takayasu arteritis underwent surgical repair of an ascending aortic aneurysm. Histologic assessment of the resected aorta showed extensive granulomatous inflammation in the wall of the aorta **(top)** with marked adventitial scarring **(bottom)**.

FIGURE 100.4 Takayasu arteritis, occlusive aisease. Autopsy performed on a 61-year-old woman with a long history of Takayasu arteritis revealed occlusion of the left common carotid artery with fibrous intimal thickening. There was also marked scarring of the vessel wall, and focal recanalization of the lumen.

commonly middle-age to older adults. Women are more susceptible to the disease than are men, by a ratio of approximately 2.5 to 1. Although joints are the most common organs involved, other sites of involvement include the skin and internal organs. RA is felt to be largely due to a defect in inducing or maintaining tolerance to self, resulting in immune reactivity to multiple systemic autoantigens.[17] Both genetic factors, such as HLA-DRB1 alleles, and environmental factors, such as cigarette smoking and other respiratory exposures, contribute to disease susceptibility.[18] Relatively specific serum tests for RA include the presence of autoantibodies to the Fc portion of the immunoglobulin heavy-chain IgG (rheumatoid factor) and autoantibodies to cyclic citrullinated peptides, both of which may be present in patients prior to the onset of arthritis.

The joint pathology of RA is characterized by perivascular inflammation comprised of lymphocytes, plasma cells, and macrophages. There may be extensive destruction of the articular surface with formation of a characteristic inflammatory pannus comprised of chronic inflammatory cells, reactive synovium, granulation tissue, and activated fibroblasts. The most characteristic extra-articular pathologic feature of the disease is the rheumatoid nodule. Rheumatoid nodules are a type of caseating granuloma, consisting of a central zone of necrotic tissue surrounded by a zone of granulomatous inflammation, comprised of numerous large epithelioid macrophages, lymphocytes, and plasma cells. Macrophage giant cells are often present. This granulomatous inflammation frequently has a palisading appearance, in which the macrophages align perpendicular to the border of the necrotic zone. Rheumatoid nodules are seen in the skin in roughly 25% of patients with RA and are less commonly seen in internal organs including the spleen, lungs, pericardium, cardiac valves, and aorta (FIGURE 100.5).

A minority of patients with RA develop an associated vasculitis, which may involve primarily small- and medium-sized

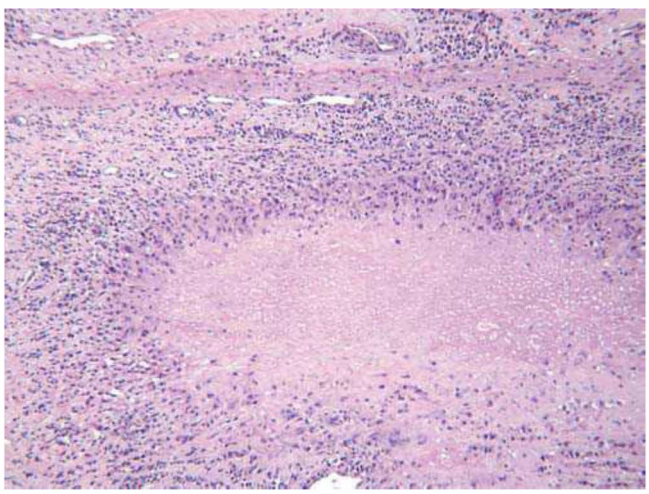

FIGURE 100.5 Rheumatoid valvulitis. A 55-year-old woman with a long history of RA underwent aortic valve replacement due to aortic regurgitation. Histologic examination of the resected valve revealed extensive inflammation and classic rheumatoid nodules.

vessels (rheumatoid vasculitis) or large arteries including the aorta (rheumatoid aortitis). These complications are typically encountered in patients with more severe disease and with cutaneous rheumatoid nodules. The onset of rheumatoid vasculitis typically occurs after many years of joint disease when the arthritis is "burned out." Rheumatoid vasculitis is characterized by lymphoplasmacytic inflammatory infiltrates within small- to medium-sized vessels with destruction of the vessel wall.[19,20] The infiltrate is often most florid in the adventitia. Fibrinoid necrosis and neutrophils may also be present. In a large autopsy series, rheumatoid aortitis was present in 5% of autopsies of patients with RA.[21] In rheumatoid aortitis, the lymphoplasmacytic infiltrate is accompanied by granulomatous inflammation, and actual rheumatoid nodules are present in the media or adventitia of the aorta in about half of the cases. The small- and medium-sized vessel rheumatoid vasculitis manifests in patients as primarily skin ulcers, nailfold lesions, or neuropathies. Rheumatoid aortitis can result in aortic aneurysms or potentially fatal aortic dissection.

Patients with RA are treated primarily to relieve joint pain and prevent joint destruction. Traditional approaches employed a variety of immunosuppressive medications, including methotrexate, hydroxychloroquine, and glucocorticoids. Newer therapies include antibodies targeting tumor necrosis factor (TNF), the interleukin-6 receptor, or the B-lymphocyte surface marker CD20.

IgG4-RELATED AORTITIS

IgG4-related aortitis is a recently identified form of large-vessel vasculitis, which occurs in the setting of IgG4-related systemic disease (IgG4-RSD). IgG4-RSD is a systemic sclerosing disease, which most commonly afflicts older men.[22] It is characterized by the presence of lymphoplasmacytic inflammation with an unusually high proportion of plasma cells expressing IgG4, and by the presence of fibrosis or scarring. The disorder was first recognized to involve the pancreas and is often referred to as autoimmune pancreatitis. IgG4-RSD can involve diverse tissues throughout the body including the liver, thyroid gland, kidneys, salivary glands, lymph nodes, the orbits, the meninges, the retroperitoneum, the mediastinum, the pericardium, and the aorta. A relatively specific serum test for IgG4-RSD is an elevated level of IgG4 within the serum. It is not currently known if the IgG4 itself is actually pathogenic or is a marker of an aberrant immunologic reaction.

IgG4-related aortitis is characterized by lymphoplasmacytic inflammation within the aortic wall.[23,24–27] In contrast to many other forms of aortitis, granulomatous inflammation is not typically present. In IgG4-related aortitis, the majority of the plasma cells express IgG4, whereas in giant cell aortitis and Takayasu arteritis, typically <30% of the plasma cells express IgG4. In some cases of IgG4-related aortitis, the lymphoplasmacytic infiltrate shows a marked adventitial distribution. Such cases may have been referred to in the past as "inflammatory aneurysm" or periaortitis. Other cases of IgG4-related aortitis show considerable infiltration within the media of the aorta itself (FIGURE 100.6). As in other tissue sites, the lymphoplasmacytic inflammatory infiltrate is typically accompanied by fibrosis, which may have a storiform pattern. In the aorta, involvement of adventitial venules leads to an obstructive phlebitis. However, occlusion of small adventitial arteries, endarteritis obliterans, which is a hallmark of syphilitic aortitis, is not typically seen in IgG4-related aortitis. IgG4-related aortitis most commonly results in aortic aneurysm formation; however aortic dissection and aneurysm rupture may also occur.

Patients typically show response to glucocorticoids, including normalization of serum IgG4 levels. In patients with an incomplete response to glucocorticoids, a more complete response can be elicited by B-lymphocyte depletion using antibodies targeting the B-lymphocyte CD20 surface antigen.[28]

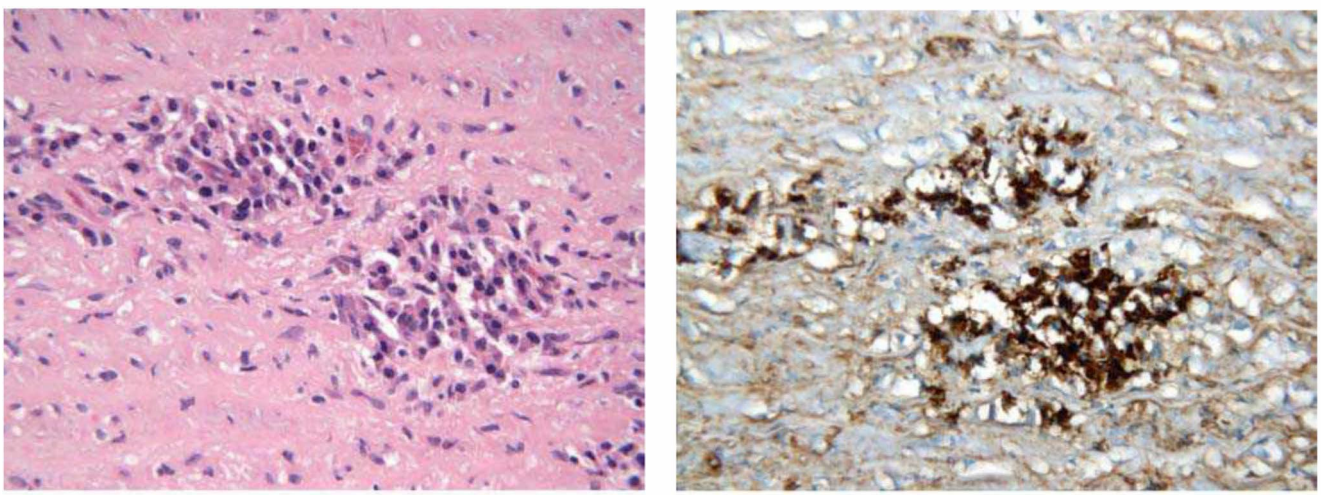

FIGURE 100.6 IgG4-related aortitis. Shown is a histologic section of an aorta from a 65-year-old man undergoing surgical repair of an aortic dissection. There is infiltration of the aortic wall by plasma cells **(A)**, the majority of which stain for IgG4 **(B)**. The patient was found to have IgG4-RSD. (See Stone JH, Khosroshahi A, Hilgenberg A, et al. IgG4-related systemic disease and lymphoplasmacytic aortitis. *Arthritis Rheum* 2009;60(10):3139–3145.)

POLYARTERITIS NODOSA

PAN is a rare necrotizing vasculitis of small- and medium-sized arteries that primarily afflicts middle-aged adults. By Chapel Hill criteria, PAN does not involve small vessels such as arterioles, capillaries, and venules, and it is not associated with the presence of antineutrophil cytoplasmic antibody (ANCA), which would signify other conditions, particularly microscopic polyangiitis (MPA), GPA, or eosinophilic granulomatosis with polyangiitis (EGPA). Understanding PAN has been complicated over the years by changing definitions. Previously in some cases, both ANCA-associated vasculitides and immune-complex vasculitides (ICVs) have been reported as being PAN. However if the small-vessel vasculitides are excluded, then true systemic PAN is a rare disorder. There is a clear association between hepatitis B virus (HBV) infection and PAN. Approximately 7% of cases of PAN are associated with HBV.[29] The annual incidence of PAN is roughly 1 to 2 per million in populations not hyperendemic for HBV.

PAN is a systemic segmental necrotizing vasculitis with a predilection for the distributing arteries in the abdomen. PAN tends to spare the lungs and aorta. The vascular inflammation can result in either aneurysm formation or arterial occlusion due to thrombosis with subsequent ischemia of distal tissues. Arterial rupture or dissection may also occur. Presenting symptoms are often nonspecific and include malaise, fever, weight loss, myalgias, and arthralgias. About half of patients experience vasculitic neuropathy, which may manifest as a mononeuritis multiplex with both sensory and motor features. Mesenteric artery involvement can lead to ischemic enteritis/colitis, bowel infarction and perforation, and abdominal hemorrhage. In addition to the systemic form of the disease, PAN can also present as an isolated self-limited disorder typically involving the skin or genitourinary tract, particularly the testes.[30]

Pathologically, PAN is characterized by a mixed inflammatory infiltrate composed of lymphocytes, macrophages, neutrophils, and eosinophils (FIGURE 100.7). There is typically marked necrosis of the vessel wall in which the necrosis acquires a homogenous eosinophilic character resembling fibrin (fibrinoid necrosis). Granulomatous inflammation is not typically present. About half of the patients with PAN can be managed with high-dose glucocorticoids, but the remaining patients will typically require treatment with cytotoxic agents. Patients with HBV-associated PAN can be treated effectively with antiviral agents and only short courses of immunosuppression, sometimes accompanied by plasma exchange.

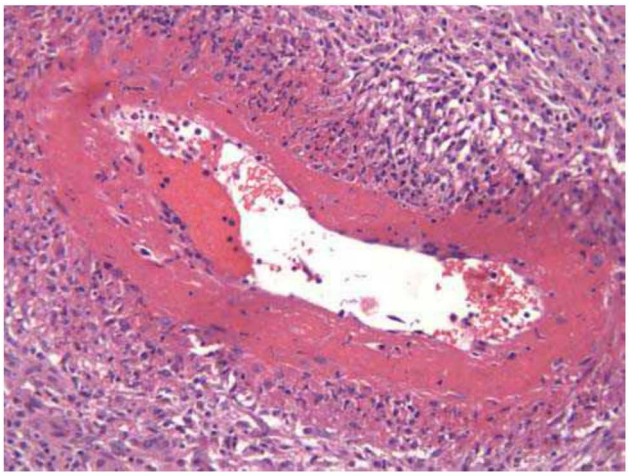

FIGURE 100.7 PAN. A 50-year-old man presented with testicular pain and unilateral inhomogeneous echotexture in the testis by ultrasound. Histologic examination of the orchiectomy specimen revealed necrotizing medium-sized vessel vasculitis with extensive fibrinoid necrosis typical of PAN. The serum was negative for ANCA, and clinically the vasculitis was limited to the testis.

KAWASAKI DISEASE

Kawasaki disease is an acute febrile illness with an associated necrotizing vasculitis of medium-sized arteries that primarily afflicts infants and young children, preferentially those of Eastern descent. The incidence ranges from approximately 10 per 100,000 children younger than 5 years of age in the United States up to 200 per 100,000 children <5 years of age in Japan.[31] The patients typically present with a constellation of signs that may include fever, conjunctivitis, erythema of the mouth and oropharynx with a strawberry tongue, red swollen hands and feet, a macular or morbilliform rash involving the trunk and extremities, and cervical lymphadenopathy.

Up to one-fourth of untreated patients develop a necrotizing vasculitis of medium-sized vessels that preferentially involves the coronary arteries. The coronary vasculitis may lead to thrombotic coronary artery occlusion and myocardial infarction or the formation of coronary artery aneurysms, which may rupture and lead to sudden death. Kawasaki disease is the most common cause of acquired heart disease in children in the United States. The vasculitis of Kawasaki disease is characterized pathologically by a transmural inflammatory infiltrate, which is predominantly lymphohistiocytic with varying numbers of plasma cells, neutrophils, and eosinophils. In some cases, the plasma cells primarily secrete IgA,[32] in contrast to the typical vascular inflammatory infiltrates in which the plasma cells show an IgG predominance. Recent provocative studies have provided evidence that the antibodies generated by these IgA-secreting plasma cells recognize viral-like cytoplasmic inclusions within the repertory epithelium of patients with acute Kawasaki disease, supporting the long-held belief that the disorder is triggered by an infectious agent.[33]

Patients with Kawasaki disease are often effectively treated with intravenous immunoglobulin and aspirin. A primary goal of treatment is to prevent or reduce coronary artery injury, which is responsible for a large proportion of the fatal complications of the disease. However, patients effectively treated for the acute phase of the disease remain at increased risk for development of premature coronary artery disease.[34]

SMALL-VESSEL VASCULITIS

The small-vessel vasculitides comprise a group of disorders characterized by a neutrophil-predominant or leukocytoclastic vasculitis involving small vessels; that is, arterioles, capillaries, and venules. The neutrophils often show degeneration or leukocytoclasia. There is typically injury to the vessel wall, which may take the form of fibrinoid necrosis, and the vessel often becomes obstructed due to thrombosis. Hemorrhage from injured vessels is a common occurrence.

The small-vessel vasculitides are divided into those associated with the circulating ANCA and those not associated with ANCA.[35,36] Those not associated with ANCA are associated with immune-complex deposition and are thus referred to as the ICVs. Immune complexes activate complement, which leads to the formation of chemotactic factors that attract neutrophils. In contrast, the ANCA-associated vasculitides are considered pauciimmune small-vessel vasculitides, as they are not associated with significant immune-complex deposition. In these conditions, the ANCA itself may be pathogenic or at least play a role in amplification of the inflammatory response.

The ANCA-associated small-vessel vasculitides include three principal disorders: GPA, CSS, and MPA. While the immune-complex small-vessel vasculitides can include essentially any condition that results in immune-complex formation, the principal disorders are Henoch-Schönlein purpura (HSP), cryoglobulinemic vasculitis, and drug reactions. Other causes of ICV include systemic lupus erythematosus (SLE), inflammatory bowel disease, infections, and paraneoplastic phenomena.[37,38]

Given the similarity of the vascular inflammation in all of these conditions, it is not surprising that many of the manifestations of these disorders are very similar. As examples, palpable purpura due to involvement of the superficial epidermal capillary plexus, hemoptysis due to pulmonary capillaritis, and hematuria due to glomerulonephritis are common to most forms of small-vessel vasculitis, particularly the ANCA-associated disorders. In addition, all small-vessel vasculitides are also capable of involving small- and medium-sized arteries and causing aneurysms and thrombotic obstructions.[39,40] There are, however, distinct differences between these various conditions.

GRANULOMATOSIS WITH POLYANGIITIS

GPA (formerly Wegener granulomatosis) and the other ANCA-associated vasculitides are small-vessel vasculitides with a predilection for involving the lungs and kidneys.[41,42,43] These conditions are associated with circulating antibodies either to proteinase-3, which stains neutrophils in a cytoplasmic pattern (C-ANCA), or to myeloperoxidase, which stains neutrophils in a perinuclear pattern (P-ANCA). Patients with GPA usually have ANCA directed against proteinase-3, often referred to as PR3-ANCA, and much less commonly ANCA directed against myeloperoxidase (MPO-ANCA).[44] GPA is an uncommon disease with an annual incidence of approximately 1 per 100,000 in European countries, afflicting a wide age range from children to the elderly.[45] In addition to lung and kidney involvement, GPA may involve any organ, but has a propensity to involve the upper respiratory tract and the ocular orbits. Chronic destruction of the tissue in the nose can result in a characteristic saddle-nose deformity (FIGURE 100.8).

Pathologically, GPA is characterized by both a small-vessel neutrophilic vasculitis and granulomatous inflammation, which is largely extravascular, but in unusual cases can cause a granulomatous vasculitis. GPA likely begins as a granulomatous disorder in the respiratory tract before becoming a disseminated small-vessel vasculitis.[46] The granulomatous component is composed primarily of activated macrophages with scattered macrophage giant cells, and often contains areas of necrosis, which may occur as discrete collections of neutrophils (microabscesses). The granulomatous component can cause destructive mass lesions in the orbits, airways, and chest cavity.

With treatment, the 10-year mortality for patients with GPA is around 12%.[42] These patients have traditionally been managed with a combination of glucocorticoids and cyclophosphamide.[41,42,47] However, treatment with antibodies that target CD20 on B cells (Rituximab) has recently been shown to be as effective as cyclophosphamide in inducing remissions and preventing relapses.[48]

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

EGPA (formerly Churg-Strauss syndrome) is an ANCA-associated vasculitis closely related to GPA. A key distinction between the two conditions is that patients with EGPA typically have asthma or allergic rhinitis and also demonstrate an elevated level of eosinophils circulating in the blood.[49,50,51] Also in EGPA, only about 40% of patients develop ANCA compared with >90% of patients with severe GPA and in EGPA the ANCA is primarily MPO-ANCA rather than PR3-ANCA. EGPA is a rare disease with an annual incidence of 2 per million per year and preferentially affects middle-aged adults.

There are distinct phases in EGPA with a prodromic phase consisting of allergic rhinitis or asthma, which is followed by a phase in which eosinophils are found within tissues along with granulomatous inflammation.[52] This is followed years later by a systemic small-vessel vasculitis primarily affecting the kidneys, skin, peripheral nerves, and lungs and less commonly other organs including the heart and brain. The pathology of EGPA is similar to that of GPA, except that in some cases increased numbers of eosinophils are identified. Patients are often managed with glucocorticoids, with addition of cyclophosphamide in severe cases.

MICROSCOPIC POLYANGIITIS

MPA is an ANCA-associated small-vessel vasculitis, which lacks the granulomatous inflammation found in patients with GPA and EGPA. It was previously regarded as a variant of PAN and was also previously referred to as microscopic periarteritis and microscopic polyarteritis. About 75% of patients with MPA have ANCA, which is predominantly MPO-ANCA.[53] Like the other ANCA-associated vasculitides, MPA frequently affects the kidneys and lungs. Kidney involvement often takes the form of rapidly progressive glomerulonephritis. In addition, skin involvement, nerve involvement (mononeuritis multiplex), and arthralgias and myalgias are also common in MPA. Medium-sized vessel involvement with microaneurysm formation occurs occasionally in MPA.

The annual incidence ranges from 2 to 12 per million per year in Europe.[54] MPA afflicts primarily middle-aged to older adults. Patients are typically treated with cyclophosphamide and glucocorticoids to induce remission. However, as with GPA, treatment with antibodies that target CD20 on B cells (Rituximab) has been shown to be as effective as cyclophosphamide in inducing remissions and preventing relapses in patients with MPA.[48]

HENOCH-SCHÖNLEIN PURPURA

HSP is an immune-complex small-vessel vasculitis due to formation of IgA1-containing immune complexes.[55,56,57] HSP is more common in children than adults and is the most common vasculitis of childhood, with an annual incidence of 10 per

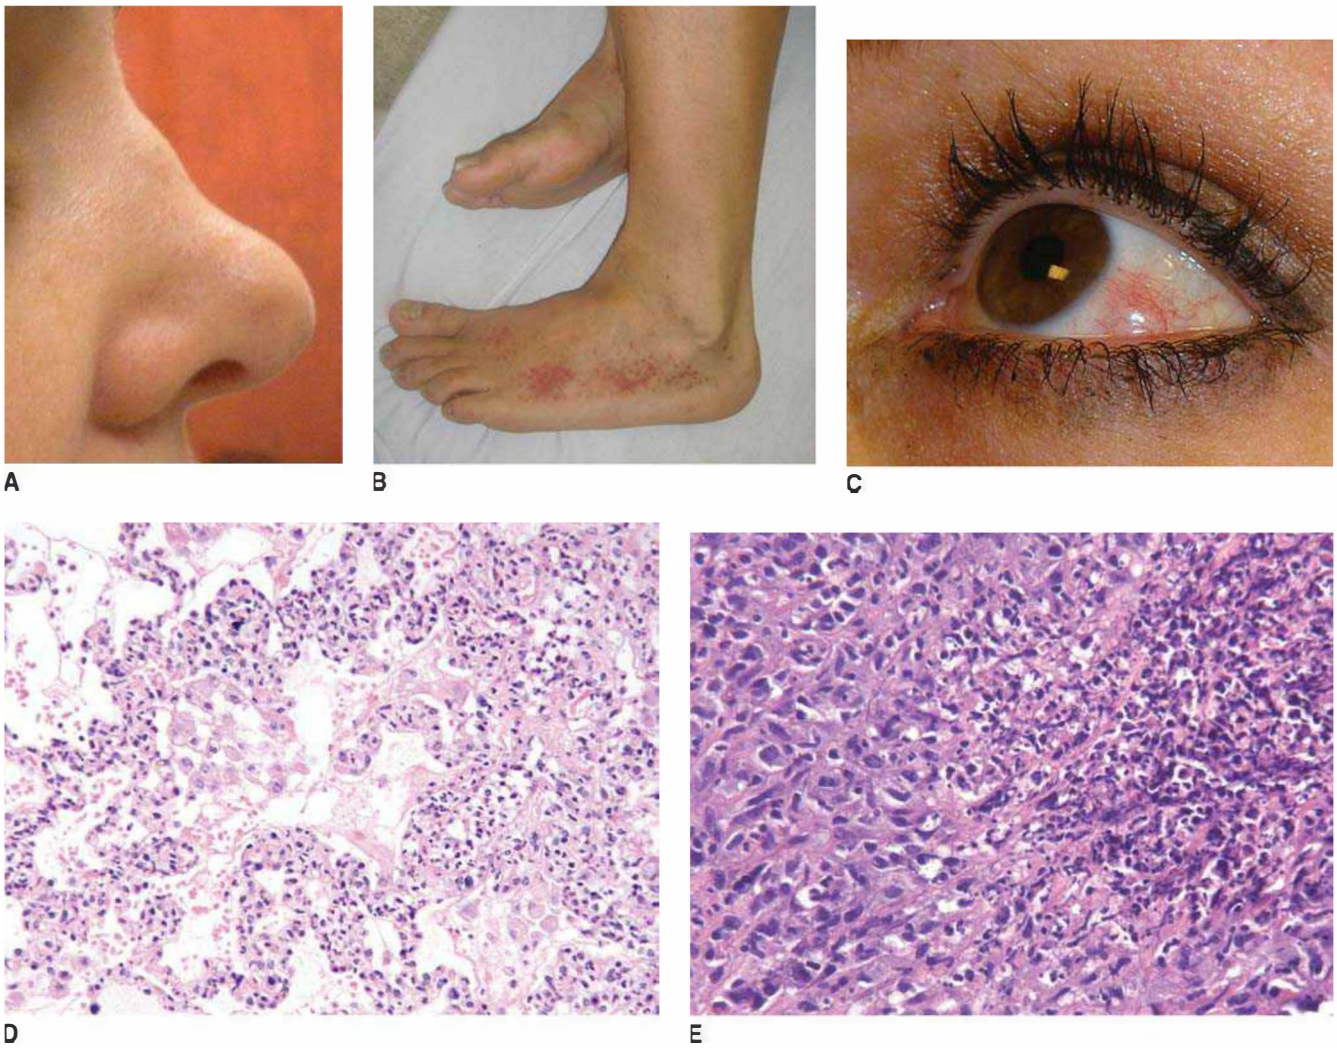

FIGURE 100.8 GPA. Shown are the gross and histologic manifestations of granulomatosis with polyangiitis. **A**: Saddle-nose deformity has a predilection for occurring in young women with GPA whose disease beyond the respiratory tract may be quite limited. **B**: Cutaneous vasculitis occurs in GPA, but is less commonly than in immune-complex vasculitis. **C**: Episcleritis can herald a disease flare, but also can continue in the absence of evidence of active disease in other organ systems. **D**: Pulmonary capillaritis may present as hemoptysis. **E**: Granulomatous inflammation with microabscess formation **(right)** is a classic pathologic feature of GPA, and in this case resulted in an intrathoracic mass surrounding the pulmonary artery.

100,000 children per year. In about 50% of cases, its appearance is preceded by an upper respiratory tract infection, suggesting an infectious trigger in some cases. In other cases, environmental triggers (such as medications) are suspected. The classic presentation includes skin involvement (palpable purpura), abdominal pain due to gastrointestinal involvement, and arthritis. Renal involvement with glomerulonephritis may also occur, particularly in older children and adults, but pulmonary hemorrhage is only rarely seen. The gastrointestinal involvement results in hematemesis or occult bleeding, and in rare occasions massive gastrointestinal hemorrhage. About half of patients will have elevated levels of IgA in the blood.

Pathologically, HSP displays the features of a neutrophilic small-vessel vasculitis detailed above (FIGURE 100.9). In addition, by immunofluorescence microscopy, IgA immune complexes are present in the acute vascular lesions. The disease is often self-limited lasting about 4 weeks. In about a third of cases, there will be recurrences over the next 4 to 6 months. Glucocorticoids have not been shown to significantly alter the disease course, and treatment is usually supportive.[55] The most common long-term complication is renal failure secondary to nephritis.

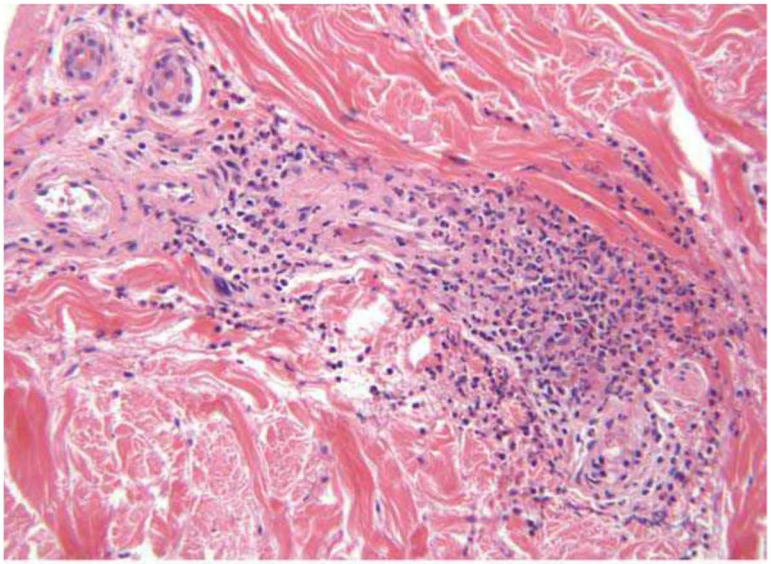
CRYOGLOBULINEMIC VASCULITIS

Cryoglobulins are circulating immunoglobulins that precipitate when serum is cooled below 37°C and dissolve upon rewarming. Type I cryoglobulins are composed of monoclonal immunoglobulins and are typically encountered in the setting of a lymphoproliferative disorder. Type II cryoglobulins are composed of polyclonal IgG and monoclonal IgM rheumatoid factor, while type III cryoglobulins are composed of polyclonal IgG and polyclonal IgM rheumatoid factor. Type II and type III

A

B

C



D

FIGURE 100.9 Immune-complex small-vessel vasculitis. **A**: A patient with a type II cryoglobulinemia not associated with hepatitis C infection developed confluent palpable purpura. In immune-complex-mediated forms of cutaneous vasculitis, the purpura is frequently confluent and diffuse, sometimes extending to the trunk and upper extremities in addition to its usual location on the lower extremities. **B**: This patient developed hypersensitivity vasculitis following treatment with naf-cillin. There was extensive palpable purpura with necrotic centers covering the upper and lower extremities and trunk. The patient also developed interstitial nephritis. **C**: HSP has a tendency to induce pustular skin lesions. This patient underwent routine presurgical prophylaxis with cefazolin, which led to palpable purpura. She then received another dose of cefazolin 10 days after the first, which resulted in an exuberant pustular rash over the lower and upper extremities. Light microscopy and immunofluorescence studies of the skin biopsy were diagnostic of HSP. The rash resolved following a short course of prednisone. **D**: A skin biopsy from a man with HSP shows leukocytoclastic vasculitis, with numerous neutrophils in and around small vessels with vascular injury.

cryoglobulins are both referred to as mixed cryoglobulins. Mixed cryoglobulinemia has been associated with multiple infectious, rheumatologic and neoplastic conditions including hepatitis C virus (HCV), human immune deficiency virus, endocarditis, Sjögren syndrome, SLE, and non-Hodgkin lymphoma.[58,59] If no underlying condition is identified, then the patient is considered to have essential mixed cryoglobulinemia. About 10% of patients with mixed cryoglobulinemia will develop cryoglobulinemic vasculitis due to deposition of immune complexes, primarily within small vessels.

Up to 90% of patients with cryoglobulinemic vasculitis are chronically infected with HCV.[60] About half of patients with HCV have circulating mixed cryoglobulins, but only 5% to 10% will develop cryoglobulinemic vasculitis. The vasculitis most commonly affects the skin, kidneys, nerves, and joints. These patients will often have additional laboratory abnormalities, particularly low levels of complement C4 and a positive rheumatoid factor. HCV-associated cryoglobulinemic vasculitis is often treated with antiviral agents, particularly interferon-α and ribavirin. There is now increasing interest in combining antiviral therapies with B-cell depletion strategies, because these two treatment approaches appear to have synergistic effects.[61]

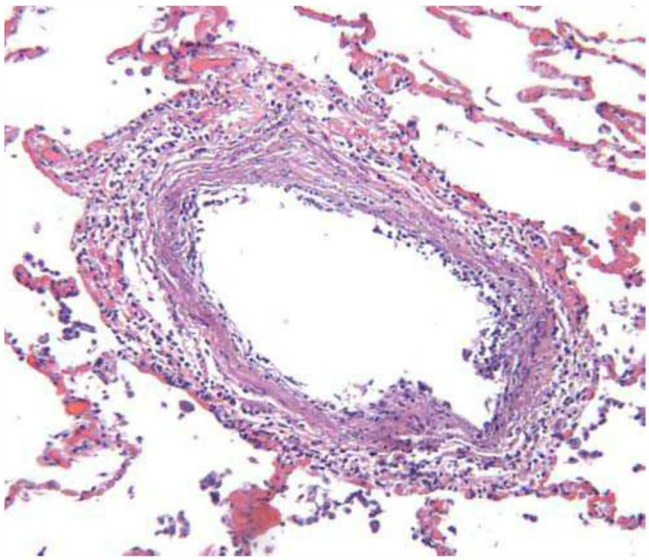


FIGURE 100.10 Medium-sized vessel vasculitis in lupus. Shown is a small pulmonary artery from an autopsy of a patient who died from florid SLE. There is a lymphocytic infiltrate in and around the vessel with necrosis of the vessel wall.

DRUG-INDUCED VASCULITIS

Drug-induced small-vessel vasculitis, often referred to as hypersensitivity vasculitis, is the most common small-vessel vasculitis in adults.[62] The disorder is triggered by the administration of a pharmaceutical drug. Agents that have been implicated are diverse and include antibiotics, propylthiouracil, hydralazine, allopurinol, *D*-penicillamine, phenytoin, isotretinoin, and methotrexate.[63–65] The drugs themselves are typically too small to serve as antigens for immune-complex formation. It is most likely that in some cases the drugs become linked to proteins, and that the drug–protein complex serves as an antigen for immune-complex formation. In other cases, drugs appear to induce the formation of ANCA, which may itself be pathologic without extensive immune-complex formation.[66]

By far, the most common clinical manifestation of drug-induced vasculitis is skin involvement, a cutaneous leukocytoclastic vasculitis resulting in palpable purpura. Less commonly, other organs including kidneys, lungs, liver, and the gastrointestinal tract may be involved. Pathologically, drug-induced vasculitis shows the features of a neutrophilic small-vessel vasculitis detailed above. By immunofluorescence microscopy, immune complexes primarily composed of IgM or IgG are often present in the acute vascular lesions,[67] in contrast to the IgA immune complexes seen in HSP. Immune complexes are not typically observed when drug-induced ANCA is present. Drug-induced vasculitis is often effectively treated by discontinuation of the drug. In severe cases, immunosuppression with glucocorticoids and even cyclophosphamide may be necessary.

MEDIUM-SIZED VESSEL VASCULITIS IN LUPUS

SLE is a systemic autoimmune disorder associated with the generation of autoantibodies. Due to the propensity for immune-complex formation, small-vessel leukocytoclastic vasculitis is a not uncommon feature of patients with SLE.[68] However, much less commonly, patients with SLE may develop a distinct form of vasculitis affecting primarily medium-sized vessels; that is, small- to medium-sized arteries.[69–74] This vasculitis most commonly involves the brain, kidneys, and gastrointestinal tract and less commonly the other internal organs. In contrast to the small-vessel immune-complex vasculitis, the medium-sized vessel vasculitis seen in patients with SLE is predominantly lymphocytic with fewer numbers of macrophages and neutrophils (FIGURE 100.10) and thus is primarily a lymphocytic vasculitis. This medium-sized vessel vasculitis typically shows necrosis of the vascular wall, which may have a fibrinoid appearance, and luminal thrombus may be present.

The key pathologic differential diagnosis includes PAN and ANCA-associated vasculitis particularly MPA. Medium-sized vessel vasculitis in SLE tends to show less overt fibrinoid necrosis than PAN. In addition, in the medium-sized vessel vasculitis associated with lupus, the inflammatory infiltrate is more lymphocyte predominant than typically seen in PAN, in which the inflammatory infiltrate is more mixed. MPA can involve medium-sized vessels; however, the composition of the inflammatory infiltrate is primarily neutrophilic rather lymphocytic. In addition, MPA has a closer relationship to the presence of ANCA than has been established for medium-sized vessel vasculitis in lupus.

BEHÇET DISEASE

Behçet disease is an idiopathic inflammatory disorder characterized by genital ulceration, oral ulcers (aphthous stomatitis), and uveitis. The condition predominantly afflicts young to middle-aged adults of Mediterranean, Middle Eastern, and Eastern descent. Prevalence rates range from approximately 1 per 100,000 in Europe up to 300 per 100,000 in Turkey. Vascular involvement occurs in about one-third of patients.[75] The vasculitis in Behçet disease may involve any size of vessel and may

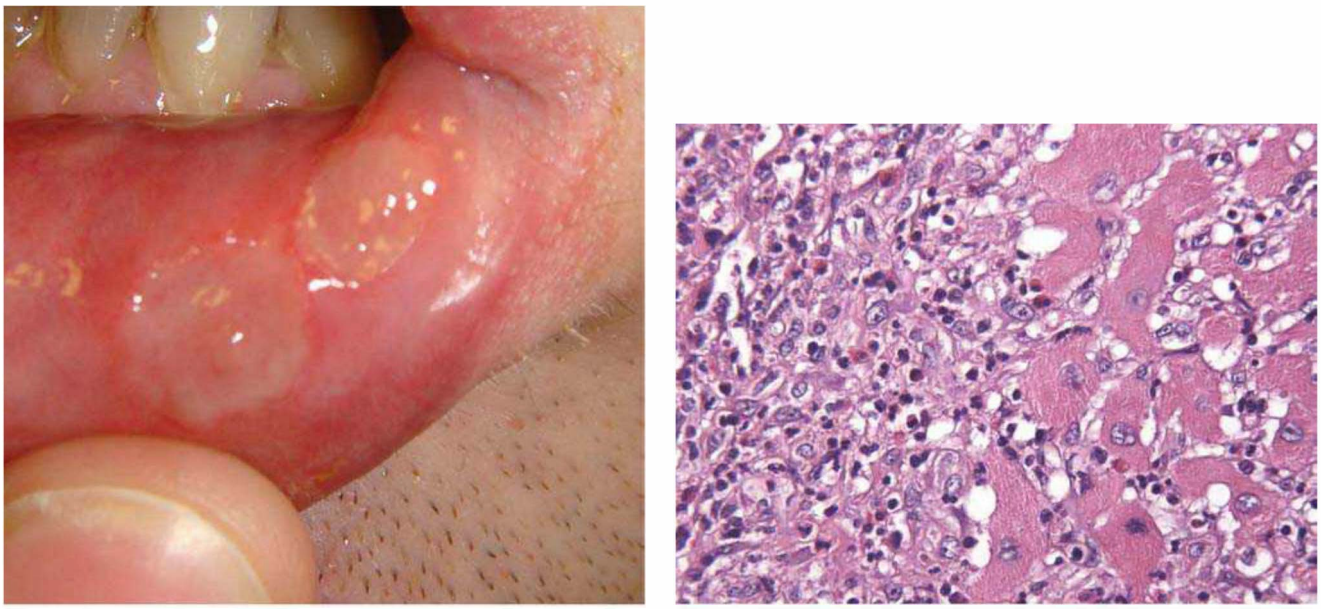

FIGURE 100.11 Behçet disease. **A**: Oral aphthous ulcers are present on the lower lip. **B**: A 16-year-old boy with Behçet disease was found to have a right-ventricular cardiac mass, which on biopsy showed mixed inflammation infiltrating into the myocardium. (See Adams EE, Aluquin VP, Bingham CA, et al. Cardiac tumor in a juvenile onset Behçet disease: case report and review of the literature. *Pediatr Cardiol* 2010;31(2):277–279.)

involve both arteries and veins. Arterial involvement may lead to aneurysms, pseudoaneurysms, or less commonly stenoses. Venous involvement results characteristically in venous thrombosis and in some cases pulmonary emboli. Involvement of the right ventricle of the heart may also cause luminal thrombosis and pulmonary emboli.

The vascular inflammation in Behçet disease ranges from an entirely mixed pattern in the heart and aorta (FIGURE 100.11) to a predominantly lymphocytic pattern in, for example, the central nervous system.[76–79] Granulomatous inflammation is not typically present. Since venous clots in these patients are thought to be due to inflammation, patients with venous thrombosis are often treated with glucocorticoids, azathioprine, and targeted inhibitors of TNF.

COGAN SYNDROME

Cogan syndrome is a rare inflammatory condition characterized by inflammation of the eye and inner ear that afflicts primarily young to middle-aged adults, with an average age of onset of around 30 years.[80,81] Only a few hundred cases have been reported, and both genders are afflicted approximately equally. The inflammation in the inner ear can result in tinnitus, vertigo, and often deafness. The inflammation affecting the eye is typically an interstitial keratitis; although, scleritis, iritis, uveitis, chorioretinitis, or even optic neuritis may be seen. About half of patients with Cogan syndrome will have systemic manifestations, primarily headache, arthralgias, fever, or myalgias. About 10% to 20% of patients with Cogan syndrome develop some form of vasculitis. In these patients, the aorta is most commonly involved, which result in aortic aneurysms or aortic dissection. Medium-sized vessel PAN-like vasculitis and small-vessel leukocytoclastic vasculitis have also been reported in patients with Cogan syndrome.[80] Involvement of medium-sized arteries such as the coronary arteries and cerebral arteries can lead to arterial occlusion with subsequent myocardial infarction or stroke, respectively.

Detailed descriptions of the pathology of the large-vessel vasculitis in Cogan syndrome are sparse.[82,83] The aortitis of Cogan syndrome is typically an acute necrotizing aortitis, containing either a mixed inflammatory infiltrate with neutrophils or even a neutrophil-predominant inflammatory infiltrate (FIGURE 100.12). Thus, the histologic pattern of inflammation in Cogan aortitis appears to differ substantially from both the granulomatous pattern seen in GCA, Takayasu arteritis, and rheumatoid aortitis and the lymphoplasmacytic pattern seen in IgG4-RSD.

There are currently no specific laboratory tests for Cogan syndrome, and the diagnosis is usually based on clinical signs and symptoms. The vestibuloauditory and ophthalmologic symptoms are typically treated with glucocorticoids.

CONCLUSION

The vasculitides are a heterogeneous group of related but distinct disorders, with characteristic clinical presentations, laboratory abnormalities, and histopathologic features. While our understanding of these diseases continues to grow, there is much yet to be accomplished in terms of developing effective treatments for these conditions. Future progress in treating these disorders will likely entail elucidating and targeting the specific pathophysiologic mechanisms underlying these conditions.

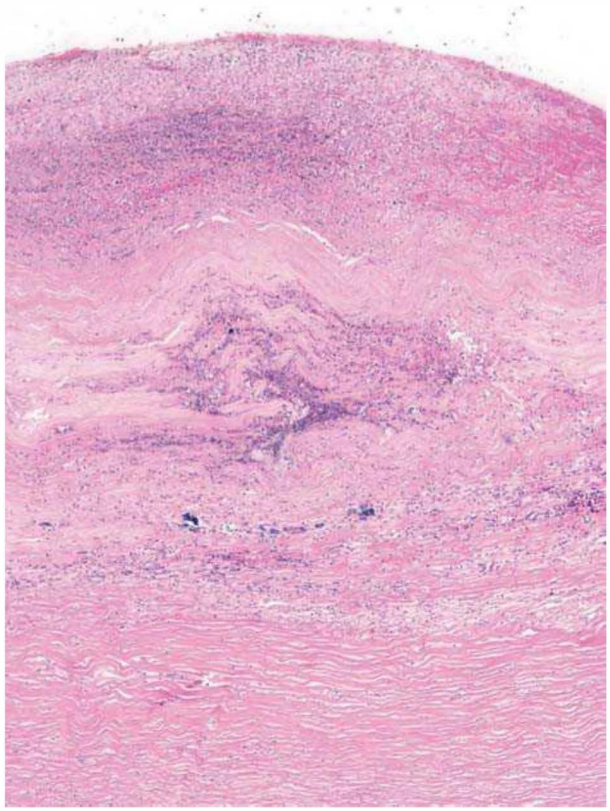

FIGURE 100.12 Aortitis in Cogan syndrome. A 17-year-old girl with Cogan syndrome underwent surgical repair of a thoracoabdominal aortic aneurysm. (See Romain PL, Miller SW, Oas JG, et al. A 17 1/2-year-old girl with a thoracoabdominal aneurysm. *N Engl J Med* 1999;340(8):635–641.) Histologic examination of the resected aorta revealed a severe aortitis comprised of a mixed inflammatory infiltrate containing numerous neutrophils with extensive necrosis. Marked adventitial fibrosis was also present **(bottom)**.

CHAPTER

101 The Antiphospholipid Syndrome

JACOB H. RAND AND LUCIA R. WOLGAST

HISTORICAL BACKGROUND

The antiphospholipid syndrome (APS) is an autoimmune thrombophilic condition that is defined by a constellation of clinical and laboratory manifestations. In retrospect, antiphospholipid (aPL) tests were first described in 1952 with the reports of the biologic false-positive serologic test for syphilis (STS)[1] and an inhibitor of the partial thromboplastin time.[2] In 1957, an association among the biologic false-positive STS, a circulating anticoagulant, and recurrent pregnancy loss was described.[3] The absence of bleeding and a paradoxical association between these coagulation inhibitors and thrombosis were recognized in 1963.[4] The term *lupus anticoagulant* (LA) for these inhibitors of phospholipid-dependent coagulation reactions was introduced,[5] because most of the initial patients appeared to have systemic lupus erythematosus (SLE), although this finding was not sustained by later studies. In the 1980s, immunoassays were developed for anticardiolipin (aCL) antibodies,[6,7] and a new "syndrome of thrombosis, abortion, and neurologic disease"[8] was named the "anticardiolipin syndrome,"[9] subsequently revised to the "antiphospholipid syndrome."[10] In the early 1990s, it was discovered that the antibodies in this autoimmune thrombotic condition did not recognize phospholipids without a protein cofactor identified as β_2-glycoprotein I (β_2GPI)[11,12] and that other phospholipid-binding proteins[13] could also fulfill this role. These antibodies were therefore referred to in literature as being "cofactor-dependent," or "β_2GPI-dependent" aPL antibodies, in contrast to the antibodies generated in patients with syphilis and other infections that recognized phospholipid directly and classified as "cofactor independent." As explained below, it is now accepted that β_2GPI itself is the major target of antibodies in APS.

CURRENT DEFINITION—DIAGNOSTIC CRITERIA AND THEIR LIMITATIONS

The current investigational criteria for APS (Table 101.1), referred to as the Sydney Criteria,[14] were not intended as absolute requirements for the clinical diagnosis. Rather, they were meant to characterize patients whom investigators could agree have "definite APS" for clinical studies." These criteria include histories of documented thrombosis and/or defined pregnancy complications together with specific laboratory tests. However, the syndrome is incompletely understood, and many patients appear to have other clinical abnormalities (Table 101.2) that are referred to as "noncriteria clinical manifestations."[15] Also, as described in the historical background above, the current laboratory assays used for defining the syndrome were derived from empiric observations and were not designed to measure disease mechanisms. Newer laboratory tests that have been developed but not yet accepted by consensus are referred to as "noncriteria laboratory tests." To complicate matters, some patients may have typical clinical manifestations of APS but entirely negative aPL antibody assays and/or LA test, a situation referred to as seronegative APS.[16] Rare patients with aPL antibodies may develop disseminated thrombosis in large and small vessels with resulting multiorgan failure, known as catastrophic antiphospholipid syndrome (CAPS). Preliminary criteria that define CAPS for clinical studies have been published (Table 101.3).[17]

PREVALENCE AND ANTIGENIC SPECIFICITIES OF "ANTIPHOSPHOLIPID ANTIBODIES"

A significant proportion of patients with venous thrombosis have elevated levels of aPL antibodies, with prevalence rates estimated at 5% to 30% for any aPL antibody, 1% to 16% for LA, and 4% to 24% for aCL antibodies. In arterial thrombosis, the prevalence is 0.1% to 10% for aCL antibodies and 0.02% to 0.3% for anti-β_2GPI antibodies. In patients with recurrent spontaneous pregnancy losses, the prevalence is estimated to be 11% for LA and 29% for aCL antibodies.[18] The prevalence of aPL antibodies in the asymptomatic "normal" population has generally been estimated at 3% to 10%,[19,20] with a prevalence of 1% to 5% for LA, 1% to 5% for aCL antibodies, and 3% for anti-β_2GPI antibodies.[18] In one group of healthy young women, who served as controls in a study, 18% had elevated aCL antibodies and 13% tested LA positive.[21] aPL antibodies that occur after infections are generally not associated with thrombosis.[22]

A significant proportion of SLE patients have elevated aPL antibodies; estimates range between 12% and 30% for aCL antibodies and 15% and 34% for LA antibodies.[23] aPL antibodies have been associated with virtually all other autoimmune conditions.[24–32] In some patients, the presence of aPL antibodies may herald the development of SLE; one study reported that 18% of SLE patients had positive aCL antibodies prior to diagnosis.[33]

Antigenic Targets for aPL Antibodies

The main antigen targeted by the APS disease process, β_2GPI, is a 50-kd glycoprotein comprised of five 60–amino acid domains with homology to other members of the complement control protein superfamily[34] (FIGURE 101.1). The biologic function of β_2GPI has not yet been established. β_2GPI binds to apoptotic cells and may aid their clearance.[35,36] The protein also binds to platelet microvesicles and promote their phagocytosis by macrophages.[37] β_2GPI binds as well to oxidized low-density lipoprotein (LDL) and may promote its clearance.[38]

Table 101.1

Sydney investigational criteria for the diagnosis of the APS[a]

Clinical

- Vascular thrombosis (one or more episodes of arterial, venous, or small-vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall
- Pregnancy morbidities attributable to placental insufficiency, including (a) three or more otherwise unexplained recurrent spontaneous miscarriages, before 10 weeks of gestation, (b) one or more fetal losses after the 10th week of gestation, (c) stillbirth, and (d) episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios that are otherwise unexplained

Laboratory

- Medium- or high-titer aCL or anti-β_2GPI IgG and/or IgM antibody present on two or more occasions, at least 12 weeks apart, measured by standard ELISAs
- LA in plasma, on two or more occasions, at least 12 weeks apart, detected according to the guidelines of the ISTH SSC Subcommittee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies

"Definite APS" is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met

aCL, anticardiolipin; aPL, antiphospholipid; β_2GPI, β_2-glycoprotein I; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin.
[a]Modified from Miyakis et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome. *Thromb Haemost* 2006;4:295–306.

Table 101.2

Clinical manifestations associated with the APS

Systemic vascular thrombosis	DVT of lower extremity, thoracic, abdominal, or pelvic veins, pulmonary embolism, arterial thrombosis with downstream ischemia and infarction
Reproductive manifestations	Recurrent fetal loss, preeclampsia, abruption placentae, miscarriage, prematurity, intrauterine fetal demise, intrauterine growth restriction, and oligohydramnios
Neurologic manifestations	Stroke, TIA, *migraines, seizures, chorea, Guillain-Barrè Syndrome, transient global amnesia, dementia, diabetic peripheral neuropathy, and orthostatic hypotension*
Cardiovascular manifestations	Thrombotic occlusion of nonatherosclerotic coronary artery, thrombotic myocardial infarction, *coronary artery disease, premature atherosclerosis, atherosclerotic myocardial infarction, peripheral vascular disease, valvular abnormalities*
Pulmonary manifestations	Pulmonary hypertension attributable to thrombotic occlusion, *other pulmonary hypertension, acute diffuse alveolar damage*
Hepatic and gastrointestinal manifestations	Esophageal necrosis with perforation, intestinal ischemia/infarction, pancreatitis, colonic ulceration, acalculous acute cholecystitis attributable to biliary vascular occlusion, mesenteric venoocclusive disease, *primary biliary cirrhosis*
Renal manifestations	Thrombosis of renal arteries or veins, renal infarction, *APS nephropathy, renal artery stenosis, minimal change disease/focal segmental glomerulonephritis, membranous nephropathy, mesangial C3 nephropathy, pauciimmune crescentic glomerulonephritis*
Skin manifestations	Ulcerations attributable to microvascular infarction, *livedo reticularis, skin ulcerations, skin necrosis, necrotizing vasculitis, livedoid vasculitis, thrombophlebitis, erythematous macules, purpura, ecchymoses, painful nodules, subungual splinter hemorrhages, Anetoderma, discoid lupus erythematosus, cutaneous T-cell lymphoma*
Retinal abnormalities	Retinal vein occlusion, cilioretinal artery occlusion, optic neuropathy
Other organ manifestations	Acute adrenal failure due to bilateral adrenal hemorrhagic infarction, *osteonecrosis without histologic evidence for microvascular occlusion or vasculitis, acute sensorineural hearing loss*
Other coagulation abnormalities	*Thrombocytopenia, ITP, hypoprothrombinemia, protein S deficiency, acquired APC resistance, acquired inhibitors to specific coagulation factors, and AvWS*

Manifestations that are not included in consensus-based diagnostic criteria are italicized.

Table 101.3

Proposed criteria for the classification of CAPS

1. Evidence of involvement of three or more organs, systems, and/or tissues[a]
2. Development of manifestations simultaneously or in less than a week
3. Confirmation by histopathology of small-vessel occlusion in at least one organ or tissue[b]
4. Laboratory confirmation of the presence of aPL antibodies (LA and/or aCL antibodies)[c]
Definite CAPS
• All four criteria
Probable CAPS
• All four criteria, except for only two organs, systems, and/or tissues involvement
• All four criteria, except for the absence of laboratory confirmation at least 6 weeks apart due to the early death of a patient never previously tested for aPL prior to the CAPS event
• Criteria 1, 2, and 4
• Criteria 1, 3, and 4 and the development of a third event in more than a week but less than a month, despite anticoagulation

[a]Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension (N180/100 mm Hg), and/or proteinuria (N500 mg/24 h).
[b]For histopathologic confirmation, significant evidence of thrombosis must be present, although, in contrast to Sydney criteria, vasculitis may coexist occasionally.
[c]If the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS.
Modified from Asherson RA, Cevera R, de Groot PG, et al. Catastrophic antiphospholipid syndrome: international consensus statement on classification criteria and treatment guidelines. *Lupus* 2003;12:530–534.

Anti-β_2GPI antibodies from different patient samples are heterogeneous in their epitope specificities and recognize all five domains of the protein. IgG antibodies against an epitope comprising Gly40-Arg43 in the domain I of β_2GPI have been reported to have a stronger correlation with thrombosis than antibodies against other epitopes.[39] Recent data have shed light on interesting changes in the conformation of β_2GPI that may have a role in the APS disease process. Circulating plasma β_2GPI was found to have a closed circular conformation due to the affinity of a portion of carboxyterminal domain V for the protein's aminoterminal domain I, where the phospholipid binding site is located.[40] The affinity for anionic phospholipids derives from (a) cationic residues from its aminoterminus that have affinity for anionic polar heads of phospholipids and (b) a hydrophobic loop which inserts into the lipid bilayer. Binding to anionic phospholipid membranes requires the protein to open from its circular conformation, which exposes an epitope in domain I that had been cryptic in the circular conformation (FIGURE 101.1).

Several other antigenic targets for aPL antibodies include prothrombin, coagulation factor V, protein C, protein S, annexin A2, annexin A5, high and low molecular weight kininogens, heparin, factor VII/VIIa,[41–44] oxidized LDLs,[45] vimentin complexed to cardiolipin,[46] lyso(bis)phosphatidic acid,[47] sulfatides, and acidic glycosphingolipids.[48]

PATHOPHYSIOLOGIC MECHANISMS

Overview

A host of mechanisms have been postulated to explain the thrombotic tendency in APS (Table 101.4). The APS disease entity is probably composed of subcategories that are attributable to specificities of the particular antibodies. aPL antibodies are highly heterogeneous even in individual patients, and these may exert different effects in different experimental

Table 101.4

Proposed pathogenic mechanisms of APS

I. Inhibition of endogenous anticoagulant and fibrinolytic mechanisms
A. Disruption of the annexin A5 anticoagulant shield
B. Inhibition of the protein C pathway—decreased activation of protein C, barrier of APC proteolysis of factor Va and VIIIa, prevention of protein C and EPCR binding
C. Interference with thrombin regulation—enhanced thrombin generation, decreased thrombin inactivation
D. Inhibition of heparinoids, TFPI, and inactivation of factor IXa
E. Interference with fibrinolysis via annexin A2, β_2GPI cofactor activity, autoactivation of XIIa, direct inhibition of plasmin, and increase of PAI-1
II. Activation of platelets
A. Activation of platelets—via ApoER2 and via β_2GPI-PF4 interaction
B. Interference of vWF-mediated platelet adhesion
III. Injury and activation of endothelial cells and monocytes
A. Direct injury
B. Signaling via annexin A2/TLR4/ApoER2-inducing proadhesive prothrombotic phenotype
IV. Complement activation

systems. In an effort to find additional clues, some investigators have recently pursued proteomic studies to identify candidate proteins that might be involved in the APS disease process.[49]

Inhibition of Endogenous Anticoagulant and Fibrinolytic Mechanisms

Disruption of the Annexin A5 Anticoagulant Shield

Annexin A5 is highly expressed by a variety of cells serving barrier functions including endothelial cells, where the protein binds to the surfaces and inhibits thrombin formation.[50] It is also expressed on placental trophoblasts on the apical membranes of the syncytiotrophoblasts that interface with the maternal blood circulation.[51] Annexin A5 forms two-dimensional crystal lattices over phospholipid bilayers[52,53] that shield them from availability for phospholipid-dependent coagulation enzyme reactions[52] (FIGURE 101.2). The protein appears to be important for maintaining placental blood circulation; pregnant mice treated with antiannexin A5 antibodies developed placental necrosis, fibrosis, and pregnancy loss.[54]

There is significant evidence that aPL antibodies interfere with the annexin A5 binding and crystallization and thereby promote coagulation reactions; this has been demonstrated through immunohistochemical studies of placental tissues,[55] cell culture experiments,[56] and atomic force microscopic imaging[52] (FIGURE 101.3). The aPL antibody-mediated disruption of annexin A5 correlates with antibody recognition of the epitope on domain I of β_2GPI, which in turn has been correlated with significantly increased risk of thrombosis.[39,57]

Inhibition of the Protein C Pathway

aPL antibodies can interfere with the protein C pathway (see Chapter 19) in several ways (Table 101.4). Antibodies against protein C and against protein S have been described,[58–60] with high levels of antiprotein C IgM correlating with increased risk of venous thrombosis.[60] Antibodies against β_2GPI may crossreact with activated protein C (APC),[61] and APS patients often exhibit acquired APC resistance,[62] an effect that has also been correlated with anti-β_2GPI domain I antibodies.[63,64] Antiendothelial antibodies in patients with APS [65,66] may interfere with the positioning of protein C on the endothelial protein C receptor (EPCR) or bind to thrombomodulin and block the activation of protein C by thrombin. Antithrombomodulin antibodies can also interfere with the activation of protein C in SLE patients.[67,68] Antiprothrombin antibodies from APS patient also interfere with the protein C pathway by reducing availability of thrombin for binding to thrombomodulin.[69,70] Antibodies against EPCR have been identified in pregnant APS patients and associated with increased risk of fetal death.[71]

Interference with Thrombin Regulation

It has been proposed that antibodies against noncatalytic epitopes on prothrombin may provoke thrombosis by crosslinking prothrombin molecules, thus increasing their density and thrombin generation on the surface of endothelial cells.[72–74] aPL antibodies and antiprothrombin antibodies can also interfere with inactivation of thrombin by antithrombin.[75] Some antiprothrombin antibodies may themselves display a catalytic function and proteolyze prothrombin to generate a thrombin-like activity.[76]

Inhibition of Heparinoids, TFPI, and Inactivation of Factor IXa
