aPL antibodies crossreact with heparin and heparinoid molecules and inhibit the acceleration of antithrombin activity.[77] APS patients can have autoantibodies against tissue factor pathway inhibitor (TFPI) that reduce its activity.[78] Some aPL antibodies interact with factor IXa and impair its inactivation by antithrombin.[79]

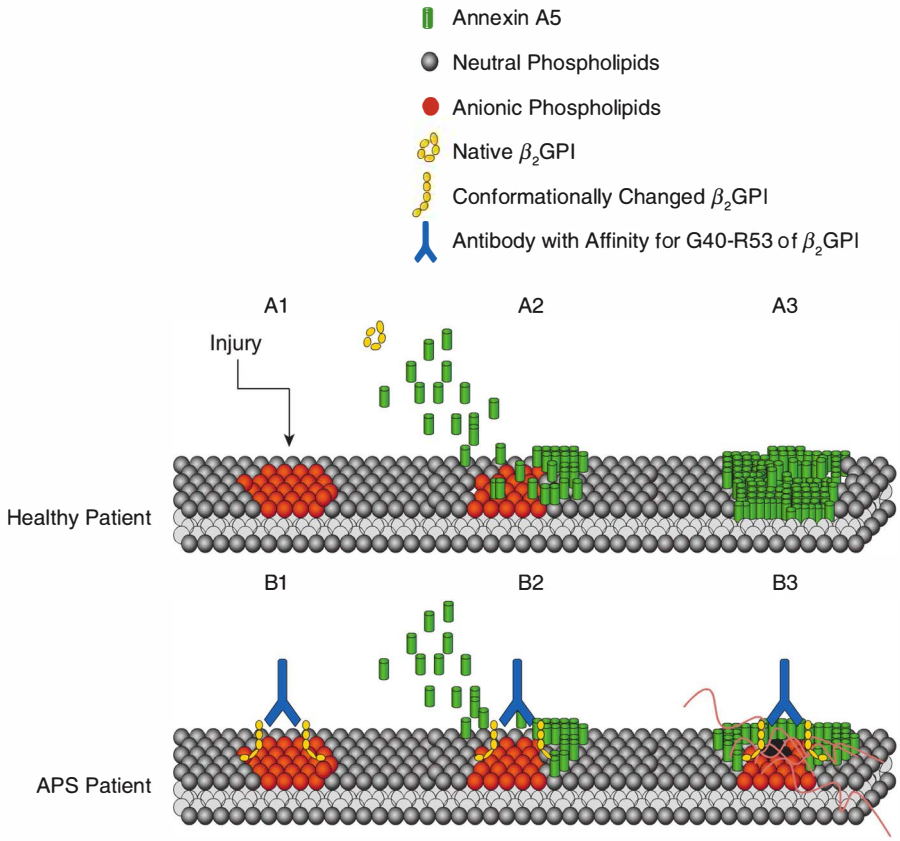

FIGURE 101.2 Proposed mechanism for thrombosis in APS. Proposed mechanism of anti-D1 IgG-mediated disruption of annexin A5 on cell surface. (*A1–A3*) Annexin A5 anticoagulant activity in absence of APS. When injury exposes anionic phospholipids on the cell surface (*A1*), annexin A5 assembles over damaged areas of endothelium, creating a shield over the endothelial surface and inhibiting anionic phospholipid-dependent coagulation reactions. (*B1–B3*) Annexin A5 disruption in the presence of APS. In the presence of antibodies against the G40-R43 epitope on domain I of β_2GPI, there is a conformational change and dimerization of β_2GPI (*B1*), and anti-β_2GPI/β_2GPI complexes displace annexin A5 on anionic phospholipid surfaces (*B2*). This creates gaps in the annexin A5 shield, exposing more anionic phospholipids to coagulation reactions and thrombosis (*B3*). (Modified from de Laat B, Wu XX, van Lummel M, et al. Correlation between antiphospholipid antibodies that recognize domain I of β$_2$-glycoprotein I and a reduction in the anticoagulant activity of annexin A5. *Blood* 2007;109(4):1490–1494.)

Interference with Fibrinolysis

aPL antibodies can interfere with fibrinolysis in several ways. Antibodies against annexin A2, an endothelial surface receptor for tissue plasminogen activator and plasminogen, have been reported,[80] and these can interfere with binding of plasminogen and tissue-plasminogen activator (t-PA) and thereby reduce plasmin formation and fibrinolysis.[81,82] Monoclonal antibodies derived from APS patients can directly interfere with plasmin activity.[83] β_2GPI is a cofactor for t-PA-mediated activation of plasminogen,[84] and antibodies against β_2GPI can also interfere with this activity. Anti-β_2GPI antibodies can inhibit the autoactivation of factor XII, with ensuing reductions of kallikrein and urokinase.[85] Also the elevated plasminogen activator inhibitor-1 (PAI-1) levels observed in women with APS may impair fibrinolysis.[58]

Platelet Activation

aPL antibodies can activate platelets via signaling through ApoER2′, a member of the LDL-receptor family, which binds β_2GPI via domain V.[86] IgG-mediated dimerization of β_2GPI and binding to ApoER2′ increases the sensitivity of platelets to agonists of aggregation.[87] Antibodies directed against domain I of β_2GPI can also activate platelets by binding to platelet GPIbα, which activates the phosphatidylinositol 3-kinase/Akt pathway.[88] The aPL antibody-mediated interactions with ApoER2′ and with GPIbα may be related *in vivo* since ApoER2′ has been shown to complex with GPIbα on the platelet surface.[89] β_2GPI has been shown to dampen platelet adhesion by interfering with the platelet–von Willebrand factor (vWF) interaction, and aPL antibodies may interfere with this effect, thereby promoting platelet adhesion.[90] The majority of a cohort of APS patients with neurologic manifestations were found to have activated platelets in their blood by flow cytometry measurement of CD62 positivity.[91]

Binding of anti-β_2GPI antibodies to β_2GPI complexed to homotetramers of platelet factor-4 (PF4), each of which can bind two molecules of β_2GPI, activates platelets.[92] Whereas heparin-induced thrombocytopenia and thrombosis (see Chapter 108) is associated with antibodies against PF4 that activate platelets via their Fc domains, immune complexes of anti-β_2GPI antibodies with PF4/β_2GPI activate platelets through their F(ab)2 domains.

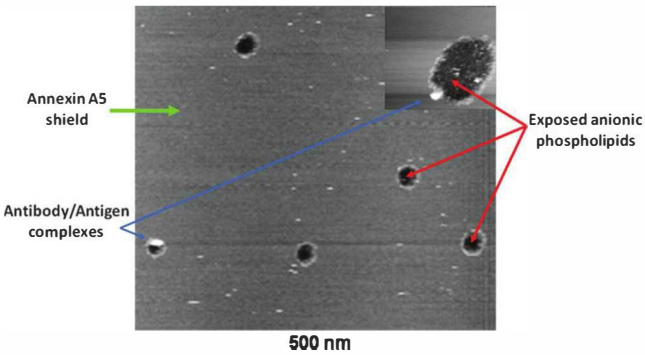

FIGURE 101.3 Disruption of annexin A5 shield by monoclonal aPL antibodies and β_2GPI. Atomic force microscopy picture showing the effect of aPL mAB IS3 on a preformed annexin A5 crystal. The figure demonstrates the smooth lipid bilayer covered by the annexin A5 crystals, disrupted by antibody–β_2GPI complexes (*white circles*) and exposing anionic phospholipids (*black holes*) to coagulation factors and accelerated coagulation. (Modified from Rand JH, Wu XX, Quinn AS, et al. Human monoclonal antiphospholipid antibodies disrupt the annexin A5 anticoagulant crystal shield on phospholipid bilayers: evidence from atomic force microscopy and functional assay. *Am J Pathol* 2003;163(3):1193–1200.)

Injury and Activation of Endothelial Cells and Monocytes

aPL antibodies can injure and/or activate cultured vascular endothelial cells.[93–96] An indicator that this may occur *in vivo* is that circulating levels of endothelial-derived microparticles are increased in the blood of patients with LAs.[97] Antibody binding to β_2GPI on the endothelial surface can also trigger signaling events that increase expression of tissue factor and adhesion molecules. This appears to occur with the involvement of annexin A2, which serves as a receptor for β_2GPI on vascular endothelium.[98] Binding of anti-β_2GPI, which cross-links the β_2GPI–annexin A2 complex, can activate signaling pathways through the Toll-like receptor-4 (TLR-4) adaptor molecule, also called myeloid differentiation factor 88.[99] This leads to the upregulation of the transcription factor and nuclear factor-κB (NF-κB) and subsequent increase in the release of cytokines such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1, IL-6, IL-8, and surface expression of tissue factor and cell adhesion molecules (FIGURE 101.4). A mutation in murine TLR-4 that results in loss of ability to bind lipopolysaccharide (LPS) attenuated the prothrombic state in wildtype mice injected with aPL antibodies.[100] However, a direct interaction between TLR-4 and anti-β_2GPI/β_2GPI complexes has yet to be confirmed. This endothelial activating effect has also been described for antibodies that bind annexin A2 directly,[81,101]— that is, without the involvement of β_2GPI.

Apolipoprotein E Receptor 2 on the Endothelial Surface

ApoER2′, whose role on platelets was described above, may also serve as receptor for anti-β_2GPI/β_2GPI complexes on endothelial cells[102] and monocytes,[103] where it can also trigger tissue factor and cell adhesion molecule expression (FIGURE 101.4). Evidence from ApoER2′$^{-/-}$-knockout mice has supported this mechanism in mediating the prothrombotic effects of aPL antibodies.[104] In accordance with this hypothesis, a soluble binding domain I of ApoER2′ that interfered with the binding of dimerized β_2GPI to ApoER2′ inhibited the effect of aPL antibodies on wildtype, that is, ApoER2′$^{+/+}$, mice.[104]

Activation of Complement Cascade

There is evidence from an animal model that complement activation can play a role in the APS disease process. Blockade of complement activation using a C3 convertase inhibitor or genetic deletion of C3 protected mice from pregnancy complications induced by aPL antibodies.[105,106,107] These effects on pregnancy appeared to be due to stimulation of tissue factor expression by myeloid cells[108] and appear to involve protein-activated receptor-2 signaling.[109] Those results suggested the interesting concepts that thrombin can be pathogenic via both its stimulation of fibrin formation and via its stimulation of signaling pathways, and that complement activation can be pathogenic in two ways—via both direct injury and downstream signaling.

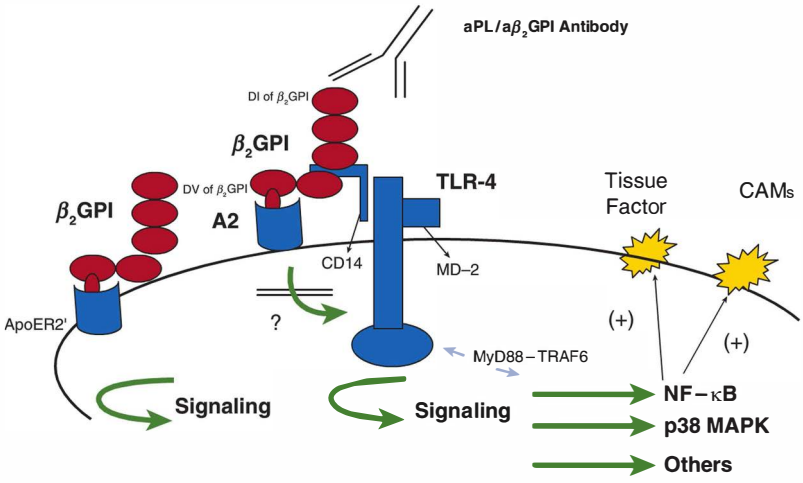

FIGURE 101.4 β_2GPI receptors on the endothelial cell membranes and their signaling pathways. Anti-β_2GPI/β_2GPI complexes bind through domain V of β_2GPI to ApoER2 and annexin A2 (A2) to activate downstream signaling pathways and activate p38 mitogen-activated protein kinase and NF-κB, leading to the upregulation of tissue factor and cellular adhesion molecules and a proinflammatory/prothrombotic phenotype. Note: annexin A2 does not have a transmembrane domain; therefore other membrane proteins such as TLR-4 and ApoER2 may act as accessory molecules. (Modified from Romay-Penabad Z, Montiel-Manzano MG, Shilagard T, et al. Annexin A2 is involved in antiphospholipid antibody-mediated pathogenic effects in vitro and in vivo. *Blood* 2009;114:3074–3083.)

Insights into the Pathogenesis of Pregnancy Complications in APS

Although there has been some controversy whether the pregnancy complications of APS are attributable to increased coagulation, a significant body of evidence supports this concept. Prothrombin activation fragment F1.2, a marker for thrombin generation, is increased in pregnant patients with aPL antibodies and a previous history of pregnancy losses, compared to control healthy aPL antibody-negative pregnant women.[110] Histologic abnormalities occur in many, but not all, placentas of APS patients.[111] Evaluation of placentas from aPL-positive women revealed that about half of women with aPL antibodies but without a prior history of fetal loss had evidence for uteroplacental vascular pathology, about half had evidence of thrombotic occlusion, and about one-third had chronic villitis and/or decidual plasma cell infiltrates.[112,113] These events may be due to the effects of aPL antibodies on placental annexin A5, by the triggering of tissue factor expression by aPL antibodies, and as described above by complement activation.

aPL antibodies have been implicated in mechanisms that do not involve thrombotic or inflammatory pathways. The antibodies can directly target the maternal decidua and affect the expression of integrins and cadherins interfering with decidual adhesion and invasion.[114] aPL antibodies were found to impair endometrial differentiation and reduce expression of complement regulatory proteins (DAF/CD55).[115] The antibodies may impact upon endometrial endothelial cell angiogenesis by reducing vascular endothelial growth factor (VEGF) and matrix metalloproteinases as well as NF-κB DNA–binding activity.[116] aPL antibodies may be involved in defective placentation; they were found to bind to trophoblast monolayers and reduce heparin-binding epidermal growth factor, which is important for blastocyte implantation, in placental tissue.[117]

Genetic Aspects of the APS Disease Process

Genetic factors are likely to be important determinants of susceptibility to development of aPL antibodies and APS. Several cases of familial APS have been described.[118,119] One study of seven families with 30 individuals, who met consensus criteria for APS, concluded that the inheritance pattern of aPL antibodies appeared to be autosomal dominant.[120] In other studies, genes in the major histocompatibility complex (MHC) have been associated with autoimmune disorders including specific MHC antigens. In patients with SLE, HLA-DPB1 alleles have been associated with anti-β_2GPI.[121]

Investigators have begun to apply genomic studies to identify specific pathogenic mechanisms. A recent genomic study done on peripheral blood mononuclear cells of aPL antibody-positive patients reported a gene-expression pattern that appeared to correlate with a predisposition toward developing thrombosis[122]. Some of the genes that were associated with APS encoded proteins are known to be involved in thrombosis—for example, apolipoprotein E (ApoE), coagulation factor X, and thromboxane–while others had no known connection to prothrombotic mechanisms.

CLINICAL MANIFESTATIONS OF THE ANTIPHOSPHOLIPID SYNDROME

Systemic Vascular Thrombosis

Although patients may present with venous and/or arterial thromboembolism in virtually any portion of the vasculature, the majority tend to have venous thromboembolic events. In one study, 59% of patients had thrombi limited to the venous circulation, 28% had solely arterial thrombi, and 13% had both types of events.[123] Deep vein thrombosis (DVT) of the lower extremities was the most common finding, occurring in about half of the patients; other sites of venous thrombotic events included pulmonary embolism, thoracic veins (superior vena cava, subclavian vein, or jugular vein), and abdominal or pelvic veins.[123] As in patients without APS, thrombosis may occur spontaneously or in the presence of risk factors such as estrogen hormone replacement therapy, oral contraceptives, pregnancy, the postpartum state,[124,125] vascular stasis, surgery, or trauma. Some patients with venous thrombosis—but generally not with arterial thrombosis[126]—also have concurrent hereditary thrombophilic conditions.[126–129] The most significant risk factor for a future thromboembolic event is having a clinical history of a thromboembolic event. The risk of recurrence increases to approximately 30% in patients with a first episode of venous thromboembolism (VTE) and aCL antibodies during 4 years of observation from the initial event.[130] The risk of recurrence and death appears to be increased in patients who have increased levels of antibodies[130,131] and with the presence of an LA. Antibodies against β_2GPI domain I significantly increase the risk of thrombosis, compared to antibodies and/or LA that are domain I independent.[39]

Catastrophic Antiphospholipid Syndrome

Rare patients develop a *catastrophic* form of APS, with widespread vascular occlusions and a high mortality (Table 101.3).[132] An inciting cause, such as surgery or infection, is suspected in about half of the patients. CAPS is defined by severe multiorgan ischemia/infarction, usually with concurrent microvascular thrombosis. Patients can present with massive VTE, along with respiratory failure due to acute respiratory distress syndrome and diffuse alveolar hemorrhage, stroke, abnormal liver enzymes, renal impairment, adrenal insufficiency, and cutaneous infarction. For recent information on the clinical characteristics of CAPS, the interested reader is referred to (http://www.med.ub.es/mimmun/forum/caps.htm) "The Registry of the European Forum on Antiphospholipid Antibodies for Patients with CAPS." At the time of writing, this registry included 280 patients of whom 72% were females, with a mean age of 37 (range 11 to 60); 46% had primary APS—that is, without other autoimmune disorders—and 40% had SLE. In about half of the patients, CAPS was the initial presentation for APS or thrombosis. Seventy percent of the patients had noninflammatory thrombotic microangiopathy as a main pathologic finding. In contrast to APS, which usually manifests as thrombosis in a large vein or artery, CAPS patients also had a susceptibility to intra-abdominal thrombotic complications affecting the kidneys, adrenal glands, splenic, intestinal, and mesenteric or pancreatic vasculature. Dermatologic abnormalities such as livedo reticularis, purpura, and necrosis occur in about half of CAPS patients. Finally, CAPS patients were more likely to have evidence of infarction at unusual sites—for example, testicular/ovarian infarction, prostate necrosis, acalculous cholecystitis, bone marrow infarction, esophageal rupture, gastric ulceration, colonic ulcerations, thrombotic pancreatitis, and adrenal infarction.[133] Although the mortality of the disorder is high, patients who recover from CAPS rarely experience a recurrence.

Pediatric Antiphospholipid Syndrome

APS is increasingly recognized to be a significant cause of thrombosis in children[134] and, as with adults, diverse clinical features are common. A European registry recently reviewed the initial 121 registered cases of pediatric APS and found thrombotic manifestations similar to those experienced by adults. Differences between primary and secondary APS were noted in the pediatric registry, with the primary APS patients being younger and having a higher frequency of arterial thrombotic events and the secondary APS patients being older and having a higher frequency of venous thrombotic events.[135] CAPS appears to be much less common in children than in adults.[136]

Organ Systems Targeted in APS

Reproductive Manifestations

The prevalence of aPL antibodies among general obstetric populations is 5% or less, and most of these aPL antibody-positive patients are asymptomatic.[137] Approximately 16% to 38% of obstetric patients with recurrent fetal losses (usually defined as three or more) have elevated aPL antibodies. Pregnant women with elevated aPL antibodies had significantly more obstetric complications than aPL antibody-negative pregnant women.[138–140] Women with obstetric APS typically present with a history of recurrent miscarriages, half of which occur in the first trimester. Pregnant patients with APS are also more prone to developing DVT during pregnancy or the puerperium. Rarely, pregnant patients develop CAPS.[141,142]

The best predictor for pregnancy loss in a patient who tests positive for aPL antibodies appears to be the clinical history of events including previous pregnancy loss, pregnancy complications attributable to placental insufficiency, or thrombosis, rather than the degree of laboratory abnormality.[131,143] A recent study showed that aPL antibody-positive women with an unexplained early loss prior to 10 weeks have a higher risk of complications in their second pregnancy.[144] Patients who have positivity of more than one assay—the so-called multipositivity—are more likely to have antepartum and postpartum DVTs[145] and an increased likelihood of poor neonatal outcome.[140]

Regarding the question whether aPL antibodies might contribute to early reproductive failure (i.e., infertility), there is a consensus that there is no relationship.[146] The Practice Committee of the American Society for Reproductive Medicine has stated that, "the assessment of aPL antibodies is not indicated among couples undergoing IVF, and therapy is not justified on the basis of existing data."[146] The reader should be aware that while this is a general consensus that is backed by evidence[147] and a practice guideline, the issue is not totally settled; there are some data contradicting this,[148] and some studies suggest that aPL antibodies may impair trophoblastic differentiation, proliferation, and migration and lead to recurrent implantation failure and infertility.[149–151]

Neurologic Manifestations

Stroke or transient ischemic attack (TIA) was the initial presentation in 30% of adults with APS in a large European cohort[152] and in 18% of Latin American adults with APS.[153] In the European cohort, stroke/TIA was the event that recurred most frequently and contributed to a significant proportion of deaths.[152] A multinational lupus cohort showed that aPL antibody-associated stroke accounted for 12% of deaths.[154] Stroke is also a frequent complication in CAPS; the European CAPS registry reported cerebral manifestations in 62% of patients, and these were responsible for 13% of deaths.[155]

The diagnosis of APS should be suspected when TIAs or strokes occur in younger patients, particularly when the usual risk factors such as hypertension, hypercholesterolemia, diabetes mellitus, and smoking are absent.[156] Case–control and prospective studies have shown strong associations between aPL antibody positivity or LA positivity and ischemic strokes in young adults,[157,158] with a remarkably high odds ratio (OR) of 43 for positive LA tests and ischemic strokes in this population.[158] Younger patients with stroke were also more likely to have venous occlusion,[159] with 7% of children in a multinational childhood registry presenting with cerebral sinus venous thrombosis.[135]

There are some conflicting data regarding the relative significance of the various aPL assays in stroke. The first prospective analysis by the AntiPhospholipid Antibody Stroke Study (APASS) group reported an association between elevated levels of aCL antibodies and risk for stroke but not for other thromboembolic events.[160] Patients who tested positive for both aCL and LA showed a trend to developing more thromboocclusive events than patients who tested negative for both (32% vs. 24%, $P = 0.07$).[160] However, the same group later reported that elevated aCL antibodies were not significantly associated, but rather that positive LA and elevated antibodies against β_2GPI were the most significant risk factors for stroke.[161] In the Risk of Arterial Thrombosis In relation to Oral contraceptives (RATIO) study, women with LA positivity and other modifiable risk factors such as smoking or use of oral contraceptives had an increased risk for ischemic strokes.[158] The presence of cardiac valvular lesions is also a significant risk factor for stroke in APS patients,[162] and this together with the high prevalence of cardiac valvular abnormalities in APS (see *Cardiovascular manifestations*) is the reason why clinicians should consider echocardiography in patients with APS.

Other aPL antibody-associated neurologic abnormalities include dementia, which is usually attributable to multiple infarcts, and also manifestations not usually attributable to thrombosis such as migraines, seizures, chorea, Guillain-Barrè syndrome, transient global amnesia, peripheral neuropathy, and orthostatic hypotension.[163] In the pediatric APS registry, migraines (7%), chorea (4%), and epilepsy (3%) were the most common nonthrombotic neurologic manifestations.[135]

Recurrent seizures are more prevalent in SLE patients with persistently elevated aCL antibodies—compared to those without elevated aCL antibodies or with antibodies that are occasionally elevated—and may be associated with ischemic changes.[164] aPL antibody positivity has also been associated with cognitive impairment in SLE, especially in the areas of attention, psychomotor speed, and executive abilities.[164,165]

The diagnosis of multiple sclerosis in patients with aPL antibodies can be problematic since elevated aCL antibodies occur frequently in patients diagnosed with multiple sclerosis, and these appear to be independent of any risk for thrombosis or stroke.[166] However, it has been proposed that aPL antibodies may themselves cause demyelination by directly damaging white matter tracts and basal ganglia structures and thereby account for multiple sclerosis-like features and movement disorders.[167]

Cardiovascular Manifestations

aPL antibodies have been associated with increased susceptibility to coronary artery disease,[168] particularly premature atherosclerosis.[169,170] aPL antibodies appear to be a risk factor for adverse outcomes following all coronary revascularization procedures, interventional and surgical,[168] and for restenosis after percutaneous transluminal coronary angioplasty.[171,172]

The LA was the aPL laboratory parameter that correlated best with myocardial occlusion in a large multicenter population-based case–control study—the RATIO study, mentioned above—with an OR of 5, which increased to 22 in women who used oral contraceptives and to 34 in women who smoked.[158] In that study, elevated anti-β_2GPI antibodies correlated with a mild increase in stroke but not with myocardial infarction. Antiprothrombin and aCL antibodies did not correlate with an increased risk of arterial thrombosis,[158] although antiprothrombin antibodies correlated with increased risk of myocardial infarction in middle-aged men.

Peripheral vascular disease has also been associated with the presence of elevated aPL antibodies. Approximately one-third of patients with peripheral arterial disease undergoing bypass grafting procedures had elevated aPL antibody levels that were mostly aCL antibodies.[173] In that study, aPL-positive patients did not have an increased risk for reocclusion compared to the aPL antibody negatives; however, both groups received anticoagulant therapy.

About 35% of patients with the primary APS have cardiac valvular abnormalities detectable by echocardiography.[174] Conversely, about 20% of patients with cardiac valvular diseases have elevated aPL antibodies compared to about 10% of matched controls.[175] Valvular abnormalities were reported in about half of patients with the combination of SLE and aPL antibodies; these abnormalities include leaflet thickening, vegetations, regurgitation, and stenosis.[176] The mitral valve is mainly affected, followed by the aortic valve.[177] In a prospective follow-up of 89 patients with severe, nonspecific valvular heart disease, thromboembolic events were significantly more frequent in the aPL antibody-positive group than in the aPL antibody-negative group; however, the presence of aPL antibodies was not an independent risk factor for thromboembolic events.[178] There was one dissenting study that did not find a relationship between increased aCL antibodies and valvular abnormalities in patients with SLE.[179]

Pulmonary Manifestations

aPL antibodies have been described in patients with pulmonary hypertension.[180] A multiinstitutional study of 687 patients with chronic thromboembolic pulmonary hypertension reported that aPL antibodies were a significant risk factor.[181] In one prospective trial of 38 consecutive patients with precapillary pulmonary hypertension, approximately 30% had aPL antibodies with various phospholipid specificities.[182]

APS patients may also bleed into the acinar portion of the lung and develop diffuse alveolar hemorrhage. Biopsies of those cases reveal microvascular thrombosis, septal thickening due to edema, neutrophilic septal infiltrates, and extravasation of red blood cells into the alveolar spaces. Since acute diffuse alveolar hemorrhage can occur in anticoagulated APS patients, it is thought that the lesions may be due to vasculitis rather than thrombosis.[183]

Hepatic and Other Gastrointestinal Manifestations

The liver is often affected in APS, mainly via occlusion of hepatic and biliary blood vessels.[184] aPL antibody levels are also frequently elevated in patients with a variety of chronic liver diseases. In a prospective study of patients with liver disease, approximately half of patients with alcoholic liver disease and one-third of patients with chronic hepatitis C virus had elevated aPL antibody levels. The frequency was even higher in patients with severe cirrhosis.[185] The aPL antibodies seen in viral hepatitis are usually cofactor independent.[22] Hepatitis C is an exception in that some patients present with "true" autoimmune aPL antibodies; the most common features reported were intra-abdominal thrombosis and myocardial infarction.[186]

Other gastrointestinal manifestations of APS include esophageal necrosis with perforation, intestinal ischemia and infarction, pancreatitis, and colonic ulceration. Primary biliary cirrhosis,[187] acute acalculous cholecystitis with gallbladder necrosis,[188,189] and giant gastric ulceration have been associated with APS.[190] APS has been reported in patients with mesenteric inflammatory venoocclusive disease[191] and with mesenteric and portal venous obstruction.[192]

Renal Abnormalities

Patients with APS may present with vasoocclusive manifestations such as renal artery stenosis and/or thrombosis, renal infarction, and renal vein thrombosis and with nonthrombotic manifestations, such as glomerulonephritis.[193,194] An entity named "APS nephropathy" has been described, which consists of a vasoocclusive disease of small-size intrarenal vessels and features fibrous intimal hyperplasia, focal cortical atrophy, and thrombotic microangiopathy.[195] Two forms of this vascular nephropathy, acute and chronic, have been described. The acute form resembles other thrombotic microangiopathies, such as hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. The chronic form is often clinically silent and consists of a vasoocclusive process that develops at all levels of the renal vasculature, from the main renal artery, its branches, to arterioles, to glomerular capillaries, and renal veins.

Several nonthrombotic types of renal lesions have been identified in APS patients. A review of 29 consecutive renal biopsies from patients with primary APS described 20 cases of APS nephropathy and identified nine cases with other distinct pathologic features;[194] these included membranous nephropathy, minimal-change disease/focal segmental glomerulonephritis, mesangial C3 nephropathy, and pauciimmune crescentic glomerulonephritis.

Skin Manifestations

Skin manifestations can be the first sign of APS in some patients.[196] The cutaneous manifestations of APS have recently been reviewed.[197,198] Livedo reticularis is relatively common, occurring in 24% of a series of 1,000 aPL patients,[193] and occasionally presents in a necrosing form.[199] It is usually widespread and can localize on nonadjacent areas on limbs, trunk, and buttocks. The prevalence is higher in APS that is associated with SLE compared to primary APS, in women compared to men, and in patients with high levels of aCL antibodies. Livedo reticularis may be associated with other manifestations of APS such as cerebral or ocular ischemic arterial events (OR 10.8; 95% CI 5.2 to 22.5), seizures (OR 6.5; 95% CI 2.6 to 16), arterial events (OR 6; 95% CI 2.9 to 12.6), heart valve abnormalities detected

on echocardiography (OR 7.3; 95% CI 3.6 to 14.7), and arterial systemic hypertension (>160/90 mm Hg) (OR 2.9; 95% CI 1.5 to 5.7).[200]

Skin ulcerations associated with skin necrosis are a common presenting feature of APS, occurring in 4% of cases.[200] Necrotizing vasculitis, livedoid vasculitis, thrombophlebitis, cutaneous ulceration and necrosis, erythematous macules, purpura, ecchymoses, painful skin nodules, subungual splinter hemorrhages, anetoderma (macular atrophy), discoid lupus erythematosus, and cutaneous T-cell lymphoma have all been reported.

Retinal Abnormalities

The diagnosis of APS retinopathy should be suspected in patients with diffuse retinal vasoocclusion, particularly when characterized by involvement of arteries and veins, neovascularization at presentation, and symptoms of systemic rheumatologic disease.[201] Elevated aPL antibody levels were present in 5% to 33% of patients with retinal vein occlusion.[202,203] Cilioretinal artery occlusion,[204] optic neuropathy,[205] and severe vasoocclusive retinopathy[206] have been described in patients with APS.

Other Organ Systems

Acute adrenal failure secondary to bilateral infarction of the adrenal glands has been reported as the first manifestation of primary APS.[207] Adrenal hemorrhage has been reported.[208] aPL antibodies have been associated with osteonecrosis.[209,210] Sudden acute sensorineural hearing loss in patients with SLE or lupus-like syndromes has been described as a manifestation of APS.[211]

Thrombocytopenia and Bleeding in APS

Thrombocytopenia occurs in a large fraction of patients with APS but is rarely significant enough to cause bleeding complications or to affect anticoagulant therapy.[212,213] Most cases appear to be immune mediated. According to one study, the majority of patients with APS and thrombocytopenia had antibodies against the platelet membrane glycoproteins, GPIIb/IIIa and/or GPIb/IX complexes.[214] However, in another study, no correlation was found between the presence of antibodies against platelet GPIIb/IIIa, GPIb/IX, and thrombocytopenia, and the eluted platelet antibodies did not have any LA activity.[215] Conversely, aPL antibodies and antibodies against platelet membrane glycoproteins were present simultaneously in about 70% of patients with immune-mediated thrombocytopenia (ITP).[216] In a prospective cohort study, the 5-year, thrombosis-free survival of aPL antibody-positive ITP patients was significantly less than aPL antibody negatives at 39% and 98%, respectively;[217] this also indicates that thrombocytopenia itself is not protective against thrombosis in these patients.

When patients with APS exhibit a bleeding tendency, the presence of a concurrent coagulopathy must be considered. Acquired hypoprothrombinemia has been reported with severe bleeding.[218,219] This diagnosis may be missed when abnormal coagulation screening tests are attributed only to the LA effect; therefore the plasma prothrombin level should be checked when the prothrombin time is prolonged. Other causes of bleeding in the setting of APS include acquired thrombocytopathies, thrombocytopenia (see above), acquired inhibitors against specific coagulation factors, such as factor VIII, and the acquired von Willebrand syndrome (AvWS). The mechanism for AVWS in autoimmunity has not been established, and this deficiency of vWF is rarely associated with a demonstrable inhibitor.[220]

LABORATORY DIAGNOSIS

Two classes of assays are used for the detection of aPL antibodies: (a) coagulation assays, in which LAs are detected by the inhibition of phospholipid-dependent coagulation reactions, and (b) immunoassays, in which aPL antibodies against phospholipids and protein cofactors are detected most commonly by enzyme-linked immunosorbent assay (ELISA).

aCL IgG and IgM assays are the most sensitive, but least specific assays; anti-β_2GPI IgG and IgM assays are more specific but less sensitive, and LA assays, of which the dilute Russell Viper Venom Time (dRVVT) is the most common, are the least sensitive but the most specific.[220a]

Lupus Anticoagulants

The LA phenomenon is one of the most intriguing aspects of APS.[221,222] There are several forms of the LA test, all of which are intended to report aPL antibody-mediated inhibition of phospholipid-dependent blood coagulation reactions.[223] These include modifications of the activated partial thromboplastin time (aPTT) test with LA-sensitive and LA-insensitive reagents, the kaolin clotting time (KCT), the dRVVT, the tissue thromboplastin inhibition time, the hexagonal phase array test, and the platelet neutralization procedure. The results of LA tests can be so variable that even specialized laboratories may disagree on the results.[224]

Despite these limitations, the presence of the LA activity is more predictive and more specific for the occurrence of thrombosis or pregnancy loss than the aCL ELISA assays, both in lupus patients[225] and in others. In a systematic literature review, 12 of 12 studies showed significant associations between LA and thrombosis, with ORs ranging from 5.7 to 9.4,[226] while only 15 of 28 studies showed significant associations between aCL antibodies and thrombosis. In the APASS study,[160] positivity for both LA and aCL antibodies, but not for aCL antibodies alone, predicted a higher risk for recurrent thromboocclusive events in patients with first ischemic stroke. In the RATIO study,[158] the presence of LA was a major risk factor for arterial thrombotic events in young women including an OR 5.3 for myocardial infarction and 43.1 for ischemic stroke, up to 22 and 201, respectively, for women on oral contraceptives, and 34 and 87, respectively, for cigarette smokers. There was no increased risk of myocardial infarction with anti-β_2GPI antibody positivity and only a mild increased risk (OR 2.3) for ischemic stroke. Neither aCL antibodies nor antiprothrombin antibodies increased the risk of myocardial infarction or stroke.[158]

The Antiphospholipid Antibodies Subcommittee of the International Society of Thrombosis and Hemostasis has prioritized appropriateness of testing for LA into the following categories:[227]

- *Low appropriateness* includes older patients with venous or arterial thromboembolism.
- *Moderate appropriateness* includes asymptomatic patients with an incidentally found prolonged aPTT and patients with recurrent spontaneous early pregnancy loss or provoked VTE.
- *High appropriateness* includes patients with unprovoked and unexplained VTE, arterial thrombosis in young patients (<50 years of age), thrombosis at unusual sites, late pregnancy loss, and any thrombosis or pregnancy morbidity in patients with autoimmune diseases.

Detailed specific guidelines have been proposed for standardizing all of the aspects of LA testing from blood collection

through centrifugation, preservation, test performance, and interpretation.[228] Two different LA tests based on different assay principles are required. The dRVVT is specific for detecting LA in patients at high risk of thrombosis.[229] aPTT testing with silica as an activator and low phospholipid content is the second test of choice.[230,231] Kaolin or ellagic acid are not recommended as activators, nor are the dilute prothrombin time assays based on snake venoms such as Ecarin and Textarin, and KCT.[228]

Assays Used for the Detection of Antiphospholipid Antibodies

Dilute Russell Viper Venom Time

The dRVVT uses Russell viper venom in a system containing limiting quantities of diluted rabbit brain phospholipid. Russell viper venom directly activates coagulation factor X, leading to the formation of a fibrin clot. LA prolongs dRVVT by interfering with assembly of the prothrombinase complex, and the prolongation is reversed by adding excess phospholipid. Anticoagulant therapy with heparin, warfarin, or direct thrombin inhibitors can yield falsely abnormal test results (Table 101.5).

Activated Partial Thromboplastin Time Tests

Prolongation of the aPTT detects some LAs, and prolonged aPTT in otherwise healthy individuals is most frequently due to an LA.[232] When the aPTT is prolonged and not "correctable" by mixture with normal plasma, an LA should be suspected, especially if the patient does not have bleeding symptoms. The LA needs to be differentiated from inhibitors of specific coagulation factors and from anticoagulants such as heparin. The clinician should check whether the aPTT normalizes when an LA-insensitive aPTT reagent is used, when the assay is performed with hexagonal phase array phospholipids, or when the assay is performed using frozen washed platelets as the source of phospholipid, a procedure referred to as the *platelet neutralization procedure*. The clinician should be aware that in rare patients, both types of anticoagulants—that is, LA and specific coagulation factor inhibitors–may coexist and yield a confusing laboratory picture.

Anticardiolipin Antibody Immunoassays

The aCL immunoassay was initially developed to quantify the biologic false-positive syphilis test.[6] In the aCL ELISA, the amount of binding of IgG- and IgM-aCL is expressed in IgG phospholipid units (GPL) or IgM phospholipid units (MPL) units, one unit representing the cardiolipin-binding activity of 1 μg/mL of affinity-purified aPL antibodies from reference sera. Correlation of aCL antibody levels determined in reference sera by different laboratories has been problematic, particularly when aCL antibodies are measured using different commercial ELISA kits.[233]

Most patients with APS are identified by elevated levels of aCL antibodies, a test with high sensitivity but poor specificity, especially in asymptomatic patients. There is an interesting seasonal variability, with more healthy people having increased aPL antibodies in the winter than in the summer months.[234]

High levels of aCL antibodies are associated with increased risk of venous thrombosis, whereas any elevated level is associated with myocardial infarction or stroke. During a 10-year follow-up of patients with elevated levels of aCL antibodies, approximately 50% of patients who presented with the antibodies but without clinical manifestations of APS subsequently developed APS.[235] Women with IgM antibodies, IgG aCL antibody titer <20 IgG binding units, and no LA do not appear to be at risk for APS.[236] In contrast, women with an IgG aCL antibody titer >20 binding units or a positive LA were more likely to develop complications.[236] A meta-analysis on aPL antibodies in women with recurrent fetal losses that reviewed 25 studies[237] showed significant correlation with the presence of increased aCL IgG; however, the highest OR was seen with the LA.

With respect to stroke, elevated levels of aCL antibodies of IgG or IgM isotype were reported to be significant risk factors.[238] aPL antibodies also are an independent risk factor for stroke in young women.[21]

Anti-β_2GPI Antibody Immunoassay

β_2GPI is the major antigenic target for aPL antibodies.[239] Although β_2GPI antibodies are usually present in conjunction with abnormal aCL and antiphosphatidylserine antibodies, some patients with APS present solely with antibodies to β_2GPI.[240,241] Despite their reported higher specificity for APS (98%), β_2GPI antibodies alone cannot be relied upon for the diagnosis because of their low sensitivity (40% to 50%) and interlaboratory variability,[242,243] and concurrent testing for both antibodies and LA is advised.

In a systematic literature review, 34 of 60 studies, of which none were prospective, showed significant associations between anti-β_2GPI antibodies and thrombosis.[244] Of the 10 studies that included a multivariate analysis, only two confirmed that IgG anti-β_2GPI antibodies were independent risk factors for venous thrombosis.

Multipositivity for aPL Tests and Clinical Risk

Strong positivity for more than one of the aPL assays correlates with a significant increased risk for clinical events. Multipositivity for aPL antibodies was associated with antenatal and postnatal DVTs,[145] a higher probability of poor neonatal outcome,[140] and a cumulative incidence of recurrent thromboembolism of 44.2% after 10 years.[245]

Overall, in patients with thromboembolic events and/or pregnancy morbidities, the data indicate that triple-positive patients (LA positive, aCL IgG or IgM positive, and anti-β_2GPI IgG or IgM positive) should be considered an especially high-risk population.[246]

Annexin A5 Resistance Assay

The annexin A5 resistance (A5R) assay and the others described below are not included in the consensus investigational criteria for diagnosing APS. This is the first functional test that was designed to identify a specific pathogenic mechanism—the aPL antibody-mediated disruption of annexin A5 crystallization on phospholipid surfaces. The failure of annexin A5 to sufficiently prolong coagulation times because of the presence of aPL antibodies is referred to as "A5R." A study of 96 patients demonstrated significantly lower values in APS patients with a history of thrombosis than in aPL antibody-positive patients with no thrombosis history, aPL antibody-negative patients with a thrombosis history, or healthy controls (FIGURE 101.5).[247]

Antidomain I of β_2GPI Immunoassay

This nonconsensus test measures IgG antibodies against domain I of β_2GPI. A multicenter study of 442 patients, who tested positive for anti-β_2GPI antibodies, reported that the detection of

Table 101.5

Assays that detect aPL antibodies

Assay	Test Type	Description	Results	Limitations
dRVVT	Sensitive test for detecting inhibition of phospholipid-dependent coagulation	Uses snake venom that activates factor X and limiting quantity of phospholipid, complete panel requires confirmation with mixing of test plasma with normal plasma and with neutralization with excess phospholipid	Interpretative result—positive or negative—based on ratio of clotting time results in the absence and presence of excess phospholipid. Significant shortening of clotting time by excess phospholipid is referred to as "confirmatory test"	Potential false-positives in patients who are anticoagulated or have other coagulation abnormalities
aPTT	PTT panel for detecting LA	Compares results with LA-sensitive aPTT reagent versus LA-insensitive aPTT reagent, correction with hexagonal phase array phospholipids, or platelet neutralization procedure	Interpretative result—positive or negative, based on difference between the two aPTT results	Potential false-positives or false-negatives in patients who are anticoagulated or have other coagulation abnormalities
aCL antibody IgG and IgM	Immunoassays done by ELISA or fluorescent bead assays	Cardiolipin is the target antigen, but requires source of β_2GPI for APS specificity	GPL or MPL units	Potential false-positives with some infectious diseases, and with polyclonal hypergammaglobulinemias, and issues with precision and interlaboratory agreement
Anti-β_2GPI IgG and IgM	Immunoassays done by ELISA or fluorescent bead assays	β_2GPI as the target antigen	GPL or MPL units	Potential false-positives with some infectious diseases, with polyclonal hypergammaglobulinemias, and issues with precision and interlaboratory agreement
Other Assays				
A5R	Coagulation-based assay	Annexin A5 is added to prolong coagulation time. Failure to sufficiently prolong coagulation time by annexin A5 in the presence of aPL antibodies indicates resistance	Expressed as ratio of coagulation times in the presence and absence of annexin A5	Under current investigation

Table 101.5

Assays that detect aPL antibodies (*Continued*)

Antidomain I of β_2GPI IgG	Immunoassay done by ELISA	Identifies IgG antibodies against a specific amino acid sequence, G40-R30, within domain I of β_2GPI	OD units	Under current investigation
Other immunoassays Antiprothrombin antibody	Immunoassay done by ELISA	Identifies antibodies to target antigen	GPL or MPL units	Under current investigation
Antiphosphatidylserine antibody immunoassay				
IgA antibodies to cardiolipin and β_2-GPI			Arbitrary units	

specific antidomain I IgG antibodies more strongly correlated with thrombosis and obstetric complications than when using the standard anti-β_2GPI antibody assays. Antidomain I IgG antibodies were present in plasma of 55% of patients, of which 83% had a history of thrombosis (OR 3.5) and 57% had pregnancy complications (OR 2.4).[57]

Antiprothrombin Antibody Immunoassay

Prothrombin is considered the second major target for aPL antibodies after β_2GPI. In a systematic literature review, 17 of 46 studies showed significant associations between antiprothrombin antibodies and thrombosis.[244] Of the eight studies that included a multivariate analysis, two confirmed that antiprothrombin antibodies were independent risk factors for thrombosis, and three other studies showed that antiprothrombin antibodies added to the risk borne by LA or aCL antibodies. Overall, there was no association found between antiprothrombin antibodies and risk of thrombosis.

However, in a possible improvement over the standard antiprothrombin assay, a new nonconsensus test for antibodies against the phosphatidylserine–prothrombin complex (aPS/PT) was closely associated with APS and LA,[248] and IgG aPS/PT antibodies were highly prevalent in APS patients compared to patients with other diseases with an OR of 12.8.[249]

Antiphosphatidylserine Antibody Immunoassay

It was hypothesized that immunoassays for antibodies against phosphatidylserine, which is exposed on syncytialized cells, apoptotic cells, and activated platelets, may be more relevant pathophysiologically than those that use cardiolipin, which is normally present in mitochondrial membranes. Experimental animal models indicate that antiphosphatidylserine antibodies are pathogenic to the trophoblast, and there is a relationship between antiphosphatidylserine antibodies and pregnancy complications,[148,250–252] and in arterial thrombosis antiphosphatidylserine antibodies have been shown to correlate more specifically with APS than aCL antibodies.[253,254] However, recent studies have shown no relationship between antiphosphatidylserine antibodies and pregnancy complications.[255–258]

IgA Antibodies to Cardiolipin and β_2-glycoprotein I

There have been case reports of patients with elevated IgA aCL antibodies with APS, but the prevalence of true positivity to IgA aCL antibodies is extremely low.[259] The international consensus statement on APS did not include aPL antibodies of IgA isotype (either aCL or anti-β_2GPI) in the consensus laboratory criteria for APS classification based on the opinion that these autoantibodies lack specificity and do not add to the diagnostic value of testing for the other aCL and anti-β_2GPI isotypes.[14,260,261] There are, however, some data that suggest that IgA anti-β_2GPI antibodies may be significant. A recent retrospective case–control study identified records of 56 patients with elevated IgA anti-β_2GPI, but normal results for all of the other aPL laboratory parameters, and matched them with aPL-negative controls.[262] About half of the cases had SLE; interestingly, the investigators found a significant increase in thromboembolic events that was restricted to the IgA-positive patients who also had SLE.[262]

TREATMENT OF PATIENTS WITH ANTIPHOSPHOLIPID ANTIBODIES

Thrombosis

Patients with a venous thrombotic event and confirmed positive aPL antibodies should generally be treated with warfarin to a target INR of 2.0 to 3.0.[263,264] There is controversy about whether the same treatment applies to arterial thrombosis or whether a higher intensity of INR > 3.0 should be used.[265] There is a general agreement that patients with spontaneous or recurrent thrombosis should be treated long-term, but there is uncertainty on duration of anticoagulant treatment of patients with provoked—for example, trauma, surgery, stasis, airplane travel,

tahir99-VRG & vip.persianss.ir

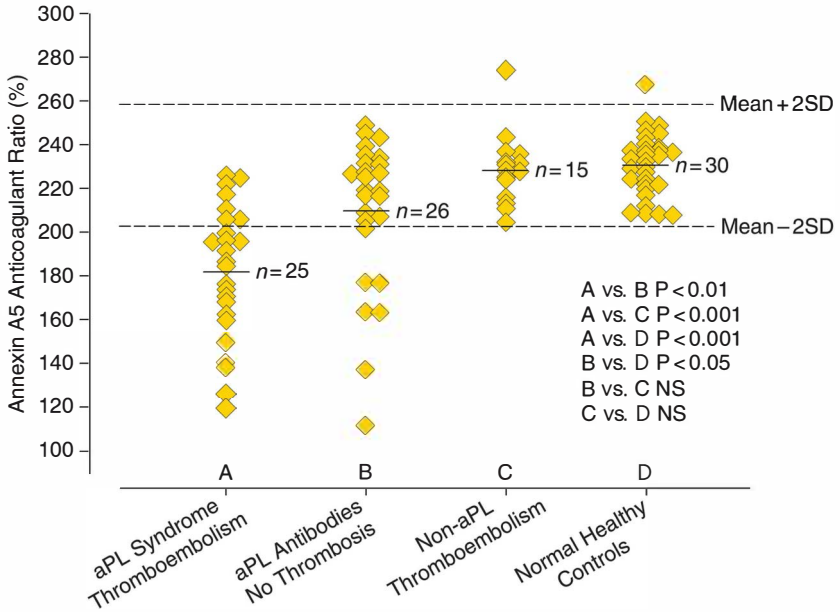

FIGURE 101.5 Reduction of annexin A5 anticoagulant effect—"A5R"—in plasmas from patients with APS. The mean annexin A5 anticoagulant ratio for the APS with thromboembolism group (*A*) was significantly decreased compared to the aPL antibody-positive patients who did not have a history for thrombosis (*B*), the aPL antibody-negative thromboembolism group (*C*), and the healthy control group (*D*). The mean ratio for the plasmas from the aPL antibody-positive patients who did not have a history for thrombosis (*B*) also was significantly reduced compared with the healthy control group (*D*). *Broken lines* indicate values included within mean ± 2SD of normal healthy controls. (From Rand JH, Wu XX, Lapinski R, et al. Detection of antibody-mediated reduction of annexin A5 anticoagulant activity in plasmas of patients with the antiphospholipid syndrome. *Blood* 2004;104:2783.)

pregnancy, or estrogens—or single thrombotic events. The last American College of Chest Physicians (ACCP) Evidence-Based Clinical Practice Guidelines made a Grade 1A recommendation for long-term anticoagulant therapy for all VTE patients—that is, not limited to APS–with a first unprovoked event without an increased risk for bleeding and who could achieve good anticoagulant monitoring.[266]

Stroke

There is controversy about the appropriate antithrombotic treatment of APS-associated stroke. A fair summary of the current views is that most hematologists and rheumatologists treat APS stroke no differently from other thrombotic manifestations of APS—that is, with anticoagulant therapy—whereas neurologists feel that evidence supports treatment with aspirin. The APASS study concluded that treating with aspirin (325 mg) alone is equivalent to anticoagulation but without the hemorrhagic risks.[160] Guidelines issued in 2006 from the American Heart Association/American Stroke Association stated that antiplatelet therapy is reasonable for APS cerebrovascular events and specified anticoagulant therapy for patients who also had APS manifestations in other organ systems.[267] The ACCP Guidelines made a Grade 1A recommendation for treatment of all noncardioembolic strokes or TIAs with aspirin over anticoagulation but qualified that there is disagreement about specific populations that included APS.[268]

Pregnancy Complications

Women with recurrent pregnancy losses or other pregnancy complications attributable to APS should be treated with a prophylactic dose of heparin along with aspirin 81 mg daily.[269] Although most clinical studies were done with unfractionated heparin (UFH) (at a usual dose of 5,000 units subcutaneously q12h), most clinicians treat with low molecular weight heparins because of the pharmacokinetic advantages and the hope of reducing adverse effects associated with UFH. About a month prior to the estimated delivery date, patients are usually switched to UFH, which is withheld when labor begins or, for induced or cesarean section deliveries, about 24 hours prior to delivery.[270,271] Anticoagulation is then resumed for about 6 weeks because of the increased risk of VTE during the puerperium.[270]

Catastrophic Antiphospholipid Syndrome

As described above (see Section "Clinical Manifestations of the Antiphospholipid Syndrome"), CAPS is a devastating disorder that continues to have a high mortality of around 50%.[272] In view of this and the lack of sufficient response to conventional anticoagulant therapy, these patients need to be aggressively treated. The main causes of death are stroke (27.2%), followed by cardiac involvement (19.8%) and infection (19.8%).[273] According to the CAPS Registry,[274] anticoagulation plus corticosteroids was the most common therapy used, followed by anticoagulation plus corticosteroids

tahir99-VRG & vip.persianss.ir

plus plasma exchange and/or intravenous IgG (IVIG). The highest recovery rate was obtained by the combination of anticoagulation, corticosteroids, and plasma exchange (78%), followed by a combination of anticoagulation, corticosteroids, plasma exchange, and/or IVIG (69%). The higher rate of the use of the last combination of treatment seems to be the main explanation for the significant reduction in mortality rate to 30% in CAPS.

Asymptomatic Antiphospholipid Antibody-Positive Patients

In general, otherwise healthy and asymptomatic patients who are found to have abnormal aPL laboratory tests should not be treated with prophylactic anticoagulation. Although there is not yet evidence on this, in our opinion anticoagulant therapy may be considered for rare asymptomatic patients who may be at extraordinarily high risk for future thromboembolism. These would include individuals with convincing strong family histories for thromboembolic complications of APS who themselves manifest significant laboratory abnormalities, patients with SLE who have significant multipositive aPL laboratory abnormalities, and patients who have additional significant risk factors for thrombosis (e.g., severe valvular heart disease).[178] A study of nearly 100 patients showed no benefit from treating asymptomatic aPL antibody-positive patients with aspirin.[275] However, in asymptomatic aPL antibody-positive patients with SLE, primary prophylaxis with aspirin and hydroxychloroquine (HCQ) appeared to reduce the frequency of thrombotic events.[276] The utility of HCQ for treating APS will need to be established in randomized, controlled trials.

Although there is no evidence from clinical trials that prophylactic treatment with aspirin benefits asymptomatic aPL antibody-positive patients, some authors recommend this approach in persistently aPL antibody-positive patients, in aPL antibody-positive patients with SLE, and in patients with obstetric APS.[277] During periods of increased thrombotic risk (surgery and/or prolonged immobilization), heparin prophylaxis is warranted, but the optimal type and duration of treatment is still unknown. American Society of Hematology evidence-based guidelines stress the importance of individual assessment of thrombotic risk in aPL antibody-positive patients and that reversible thrombotic risk factors should also be addressed.[278]

Unproven Treatments

Hydroxychloroquine

HCQ, a synthetic antimalarial drug, has several anti-inflammatory and antithrombotic effects.[279–281] Recently, HCQ was shown to inhibit the formation of anti-β_2GPI IgG–β_2GPI complexes[282] and to reverse the aPL antibody-mediated disruption of annexin A5 crystallization.[283] In a cohort of SLE patients, HCQ treatment was associated with a decreased risk of thrombosis,[284] and a cross-sectional study indicated that HCQ was protective against thrombosis in asymptomatic aPL antibody-positive patients.[285] Randomized, controlled trials will be needed to confirm whether this drug is useful for treating APS or asymptomatic individuals who are considered to be at high risk for recurrence.

Statins

A clinical trial is currently underway investigating the use of fluvastatin in APS patients (ClinicalTrials.gov Identifier: NCT00674297). In a preliminary analysis of nine APS patients treated with fluvastatin, seven out of nine patients showed significant decreases in proinflammatory/prothrombotic markers such as VEGF, soluble tissue factor, and TNF-α serum titers.[286]

Rituximab

Limited case reports have shown rituximab, an anti-CD20 chimeric monoclonal antibody, to be effective in treating thrombocytopenia and hemolytic anemia in aPL antibody-positive patients. It has not yet been established whether rituximab is effective against aPL antibody-mediated thrombosis. An open-label, phase IIa, pilot study is currently underway to evaluate the safety and effectiveness of rituximab in aPL antibody-positive patients with anticoagulant resistant manifestations such as persistent thrombocytopenia, autoimmune hemolytic anemia, cardiac valve disease, chronic skin ulcers, aPL nephropathy, and/or cognitive dysfunction (ClinicalTrials.gov Identifier: NCT00537290).

CHAPTER

102

Myeloproliferative Neoplasms and Thrombohemorrhagic Complications

AYALEW TEFFERI

The term "myeloproliferative disorder" (MPD) was first introduced by Dameshek[1] in 1951 to emphasize the clinicopathologic interrelationship between essential thrombocythemia (ET), polycythemia vera (PV), primary myelofibrosis (PMF), chronic myeloid leukemia (CML), and erythroleukemia (di Guglielmo's syndrome). Between 1967 and 1981, Fialkow et al. showed that the "MPDs" were also biologically interrelated on the basis of being clonal stem cell disorders with involvement of both myeloid and lymphoid lineage.[2–9] In the interim, several other myeloid malignancies have been described and shown to display clinicopathologic as well as biologic attributes that are similar to those of Dameshek's "MPD." Furthermore, there is now plenty of evidence to consider MPDs as myeloid malignancies and the name has accordingly been changed to "myeloproliferative neoplasms (MPNs)."

The World Health Organization (WHO) system recognizes five categories of myeloid malignancies including acute myeloid leukemia (AML), myelodysplastic syndromes (MDSs), MPNs, MDS/MPN overlap, and *PDGFR*/*FGFR1*-rearranged myeloid/lymphoid neoplasm with eosinophilia (Table 102.1).[10] "*BCR-ABL1*-negative MPN" is an operational subcategory of MPN that includes PV, ET, and PMF.[11] All three disorders are characterized by stem cell–derived clonal myeloproliferation and the presence of somatic mutations involving primarily *JAK2* and to a lesser extent *MPL*, *LNK*, *CBL*, *TET2*, *ASXL1*, *IDH*, *IKZF1*, *EZH2*, *DNMT3A*, *TP53*, or *SF3B1* mutations.[12–15,16,17] None of these mutations appear to garner the disease specificity or pathogenetic relevance otherwise displayed by *BCR-ABL1*, in CML.[12]

EPIDEMIOLOGY

Incidence figures for ET, PV, and PMF vary across studies but a population-based report from Olmsted county, Minnesota, USA provided estimates of 2.5, 1.9, and 1.5/100,000, respectively.[18,19] The corresponding figures for median age at diagnosis were 72, 67, and 70 years. All three *BCR-ABL1*-negative MPNs are rare in children and there is a slight male predominance in PMF and female predominance in ET.[20–22] A higher disease incidence involving all three MPNs has been suggested in persons of Jewish ancestry.[23–27] In general, there is no hard evidence that links any of these MPNs with environmental toxins.

Clinical Features

Most patients with ET are currently diagnosed incidentally and in an asymptomatic state.[28] However, symptoms and signs of disease are usually present when either PV or PMF is diagnosed.[29,30] Thrombohemorrhagic manifestations are the most frequent life threatening events in both PV and ET, and include microvascular disturbances (headache, lightheadedness, visual symptoms, palpitations, atypical chest pain, acral paresthesias, erythromelalgia), thrombotic episodes (stroke, transient ischemic attacks, retinal vein occlusion, cerebrovascular vein thrombosis, myocardial infarctions, angina pectoris, pulmonary embolism, abdominal large vein thrombosis, extremity deep vein thrombosis, digital ischemia, gangrene), and bleeding complications (central nervous system, retinal, mucosal, gingival, gastrointestinal, retroperitoneal, cutaneous, deep tissue, post-surgical, aspirin induced).[28,31–33] Bleeding in both PV and ET is exacerbated by the use of aspirin and other nonsteroidal antiinflammatory drugs.

Microvascular symptoms, especially erythromelalgia, are the result of small vessel platelet–endothelium interaction with associated inflammation and transient thrombotic occlusion.[34] Erythromelalgia represents acral erythema, warmth, and pain (FIGURE 102.1).[35] Young women with ET may present with recurrent first trimester miscarriages.[36] Newly diagnosed or untreated patients with PV might display plethora (a red and congested facial complexion), palmar erythema, and sausage-shaped distention of retinal veins. They might also experience symptoms of hyperviscosity that include head fullness, dizziness, flushing, visual disturbances, tinnitus, epistaxis, dyspnea, and increased blood pressure.[37–39] Nonvascular symptoms in PV include pruritus and constitutional symptoms including fatigue, malaise, and night sweats. PV-associated pruritus occurs in more than 50% of patients and is usually exacerbated by taking a bath.[40] Other symptoms and signs of PV include gout, splenomegaly, and early satiety.

The typical clinical presentation in PMF includes progressive anemia, severe constitutional symptoms, and marked splenomegaly.[30] Hepatosplenomegaly in PMF is secondary to extramedullary hematopoiesis (EMH). EMH in PMF may also occur in nonhepatosplenic tissue including lymph nodes, pleura (effusion), peritoneum (ascites), lung (interstitial process), and the paraspinal and epidural spaces (spinal cord and nerve

Table 102.1

WHO classification of myeloid malignancies

1. Acute myeloid leukemia (AML) and related precursor neoplasms[a]
2. Myeloproliferative neoplasms (MPNs)
2.1. Classic MPN
2.1.1. Chronic myelogenous leukemia, *BCR-ABL1* positive (CML)
2.1.2. Polycythemia vera (PV)
2.1.3. Primary myelofibrosis (PMF)
2.1.4. Essential thrombocythemia (ET)
2.2. Nonclassic MPN
2.2.1. Chronic neutrophilic leukemia (CNL)
2.2.2. Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
2.2.3. Mastocytosis
2.2.4. Myeloproliferative neoplasm, unclassifiable (MPN-U)
3. Myelodysplastic syndromes (MDSs)
3.1. Refractory cytopenia[b] with unilineage dysplasia (RCUD)
3.1.1. Refractory anemia (ring sideroblasts <15% of erythroid precursors)
3.1.2. Refractory neutropenia
3.1.3. Refractory thrombocytopenia
3.2. Refractory anemia with ring sideroblasts (RARS; dysplasia limited to erythroid lineage and ring sideroblasts ≥15% of bone marrow erythroid precursors)
3.3. Refractory cytopenia with multilineage dysplasia (RCMD; ring sideroblast count does not matter)
3.4. Refractory anemia with excess blasts (RAEB)
3.4.1. RAEB-1 (2%–4% circulating *or* 5%–9% marrow blasts)
3.4.2. RAEB-2 (5%–19% circulating *or* 10%–19% marrow blasts *or* Auer rods present)
3.5. MDS associated with isolated del(5q)
3.6. MDS, unclassifiable
4. MDS/MPN
4.1. Chronic myelomonocytic leukemia (CMML)
4.2. Atypical chronic myeloid leukemia, *BCR-ABL1* negative
4.3. Juvenile myelomonocytic leukemia (JMML)
4.4. MDS/MPN, unclassifiable
4.4.1. Provisional entity: Refractory anemia with ring sideroblasts associated with marked thrombocytosis (RARS-T)
5. Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*,[c] *PDGFRB*,[c] or *FGFR1*[c]
5.1. Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement
5.2. Myeloid neoplasms with *PDGFRB* rearrangement
5.3. Myeloid and lymphoid neoplasms with *FGFR1* abnormalities

[a]AML-related precursor neoplasms include "therapy-related MDS" and "myeloid sarcoma."
[b]Either mono- or bicytopenia: hemoglobin level < 10 g/dL, absolute neutrophil count < 1.8×10^9/L, or platelet count < 100×10^9/L. However, higher blood counts do not exclude the diagnosis in the presence of unequivocal histologic/cytogenetic evidence for MDS.
[c]Genetic rearrangements involving platelet-derived growth factor receptor α/β (*PDGFRA*/*PDGFRB*) or fibroblast growth factor receptor 1 (*FGFR1*).

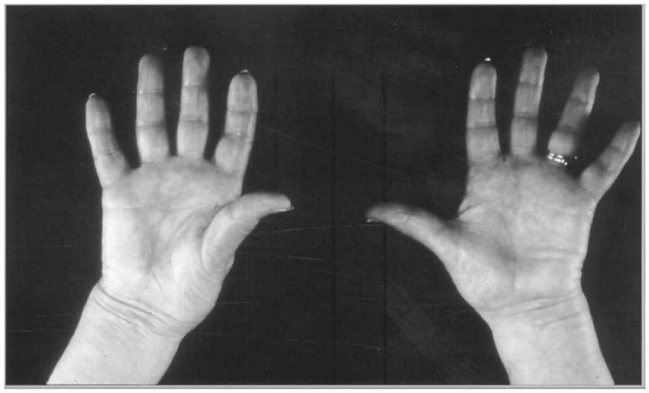

FIGURE 102.1 Erythromelalgia represents painful, erythematous discoloration of the hands or toes associated with warmth and burning sensation.

root compression). Constitutional symptoms in PMF include profound fatigue, weight loss, night sweats, and low-grade fever. Weight loss in PMF consists of mostly muscle mass wasting. Other disease manifestations include peripheral edema, diarrhea, early satiety, portal hypertension, and splenic infarcts.[41,42]

PATHOGENESIS

MPNs Are Clonal Stem Cell Diseases with Recurrent Somatic Mutations

As early as the 1970s and 1980s, the use of glucose-6-phosphate dehydrogenase (G-6-PD) isoenzyme analysis has suggested that patients with MPN including ET,[9] PV,[4] and PMF[7] have clonal hematopoiesis that originates at the stem cell level and may involve both myeloid and B lymphoid lineage.[43] This early observation has been supported by more recent investigations using X-linked DNA[44,45] and transcript[46] analysis in informative females. The disease-causing events in *BCR-ABL1*-negative MPN remain elusive. Beginning in 2005, several somatic mutations involving primarily *JAK2* and to a lesser extent *MPL*, *LNK*, *CBL*, *TET2*, *ASXL1*, *IDH*, *IKZF1*, *EZH2*, *DNMT3A*, *TP53*, or *SF3B1* have been described.[12–15,16,17] However, none of these mutations appear to garner the disease specificity or pathogenetic relevance otherwise displayed by *BCR-ABL1*, in CML.[12] Among the aforementioned mutations, *JAK2* and *MPL* have been more closely associated with MPN.

*JAK2*V617F results from a somatic G to T mutation involving *JAK2* exon 14, which leads to nucleotide change at position 1849 and the substitution of valine by phenylalanine at codon 617.[47] The mutation affects the JH2 domain and is believed to derail its kinase-regulatory activity. *JAK2*V617F-mediated transformation is believed to require co-expression of type 1 cytokine receptor and leads to STAT5/3 activation.[48–51] Also, *JAK2*V617F might have an epigenetic effect through nuclear translocation of the mutant molecule and direct phosphorylation of histone H3.[50] *JAK2*V617F induces PV-like phenotype in mouse transplantation models[52] and this observation has been further confirmed by a recent report of an inducible *JAK2*V617F knock-in mouse model where both heterozygous and homozygous mutation expression induced PV-like disease, with the latter causing a more aggressive phenotype with myelofibrosis (MF).[53] Such experimental data along with the fact that virtually all patients with PV carry a *JAK2* mutation[54] suggest a cause–effect relationship with erythrocytosis.[55–59] *JAK2*V617F homozygosity is infrequent in ET and its frequent occurrence in PV has been ascribed to mitotic recombination, possibly facilitated by *JAK2*V617F-induced genetic instability.[60]

*JAK2*V617F-positive MPN has been associated with older age at diagnosis (ET and PMF), higher hemoglobin level (ET and PMF), leukocytosis (ET and PMF), and lower platelet count (ET).[61] A higher mutant allele burden has been associated with pruritus (PV and PMF), higher hemoglobin level (PV), leukocytosis (PV, ET, and PMF), and larger spleen size (PV, ET, and PMF).[62–66] However, the mere presence of *JAK2*V617F or increased mutant allele burden does not appear to affect survival or leukemic transformation.[66–72] *JAK2*V617F allele burden increases with time in PV and PMF,[63,65,73] but not in ET.[66] Current evidence is not conclusive with regard to the relationship between *JAK2*V617F and thrombosis.[65–68,74–76] *JAK2* exon 12 mutations are relatively specific to *JAK2*V617F-negative PV.[55] *JAK2* exon 12 mutation–positive PV patients are often heterozygous for the mutation and are characterized by predominantly erythroid myelopoiesis, subnormal serum erythropoietin (Epo) level, and younger age at diagnosis.[55,77,78] The clinical course of these patients appears to be similar to that of patients with *JAK2*V617F-positive PV.[56,78,79]

MPL (Myeloproliferative Leukemia Virus oncogene) is located on chromosome 1p34. Gain-of-function germline *MPL* mutations have been associated with familial thrombocytosis (S505N) that is, interestingly, associated with an MPN-phenotype including splenomegaly, MF, and an increased risk of thrombosis.[80] An *MPL* single nucleotide polymorphism (G1238T) that results in a K39N substitution is found in approximately 7% of African Americans and is associated with higher platelet counts.[81] Somatic *MPL* mutations are rare and their occurrence is largely limited to patients with MPN. *MPL*W515L results from a G to T transition at nucleotide 1,544 (exon 10) resulting in a tryptophan to leucine substitution at codon 515. *MPL*W515L was first described in patients with *JAK2*V617F-negative PMF and induces a PMF-like disease with thrombocytosis in mice.[82] Subsequently, *MPL*W515K and other exon 10 *MPL* mutations (e.g., *MPL*W515S and *MPL*S505N) were described in ET and PMF with mutational frequencies that range from 3% to 15%.[82–87]

MPL-mutated ET has been associated with older age, lower hemoglobin level, higher platelet count, microvascular symptoms, and a higher risk of post-diagnosis arterial thrombosis.[87,88] The presence of *MPL* mutation did not appear to affect survival, fibrotic, or leukemic transformation.[87] *MPL*-mutated PMF has been associated with the female gender, older age, lower hemoglobin level, and a higher likelihood of becoming transfusion-dependent.[86] MPL mutations do not affect survival or leukemic transformation in PMF.[89]

MPNs Are Associated with Bone Marrow Stromal Reaction

Bone marrow histology in MPN, primarily in PMF,[90,91] but also to some extent in both PV[92,93] and ET,[94–96] displays excess collagen fibrosis, new bone formation, and angiogenesis.[95,97–101] Bone marrow fibroblasts in MPN are polyclonal and participate in the altered cellular as well as extracellular concentrations of various

tahir99-VRG & vip.persianss.ir

fibrogenic and angiogenic cytokines.[102–105] The latter are believed to derive from clonal megakaryocytes and/or monocytes and include platelet-derived growth factor (PDGF), transforming growth factor-β, basic fibroblast growth factor, and vascular endothelial growth factor. The current assumption is that these as well as other cytokines mediate the bone marrow stromal reaction in MPN.[102–104] Furthermore, increased tissue levels of pathogenetic cytokines might be promoted by an altered interaction between megakaryocytes and neutrophils that is promoted by increased expression of P-selectin by the former.[106] Similarly, neutrophil-derived elastase and other enzymes might contribute to the abnormal peripheral blood egress of myeloid progenitors in PMF.[107,108]

MPNs Are Associated with Endogenous Myeloid Colony Growth

Endogenous (spontaneous, growth factor-independent) *in vitro* erythroid or megakaryocyte colony formation is not seen in either normal subjects or reactive myeloproliferation.[109] Epo-independent erythroid proliferation is primarily seen in PV,[110–112] but is also seen in a proportion of patients with ET[113–116] or PMF.[114,117] Furthermore, endogenous colony growth is also manifested by granulocyte[118] and megakaryocyte[119] progenitors. Such growth factor-independence has not been attributed to mutations in ligand receptor[120,121] or receptor-associated signal transducer molecules.[122]

In Vitro Myeloid Growth in MPN is Associated with Growth Factor Hypersensitivity

Growth factor hypersensitivity under *in vitro* conditions has been demonstrated for both PV and ET. Erythroid cells in PV are hypersensitive to a variety of cytokines including insulin-like growth factor (IGF-1),[123] stem cell factor,[124] granulocyte–monocyte colony-stimulating factor,[125] interleukin-3 (IL-3),[126,127] and Tpo.[128] A similar growth factor hypersensitivity to IL-3[129] or Tpo[130] has also been suggested in ET. The consistently observed IGF-1 hypersensitivity of erythroid cells in PV has been attributed to alterations in IGF-1 binding proteins.[131,132] The receptors for both Epo[120,133,134] and Tpo[121,135] have been examined in patients with MPN and found to be intact.

MPNs Are Associated with Decreased Megakaryocyte/Platelet Mpl Expression

Decreased megakaryocyte/platelet Mpl expression was first reported in ET[136] and subsequently in PV[137] and other MPNs.[138,139] In ET, the decreased surface expression of Mpl has been associated with reduced *c-Mpl* transcription.[136,140] In PV, the particular defect was traced to a post-translational hypoglycosylation of the Mpl protein with derailment of membrane localization.[141]

Pathogenesis of Bleeding Diathesis in MPN

Platelet morphology in MPN is variable and includes both small and giant forms.[142] These platelets are often hypogranular, and on electron microscopy display decreased granular contents involving both δ (serotonin, adenine nucleotides) and α (PDGF, β-thromboglobulin, platelet factor 4) specific storage granules.[143–148] This acquired storage pool deficiency as well as altered surface expression of hemostatic molecules is believed to contribute to the prohemorrhagic platelet defects in MPN.

In vitro observed hemostatic abnormalities in MPN include poor platelet aggregation in response to various platelet agonists (i.e., thrombin, ADP, epinephrine, collagen, thromboxane A_2 (TXA_2), platelet-activating factor),[149–152] abnormally low intra-platelet levels of adenine nucleotides and serotonin,[153] reduced platelet factor X-activating activity,[154] defective platelet lipid peroxidation,[155] impaired binding to fibrinogen as a result of decreased glycoprotein IIb/IIIa expression,[156] decreased adrenergic receptor expression that could explain the often observed absent epinephrine response and mechanistically involve impaired signal transduction,[157,158] and acquired von Willebrand syndrome (AvWS).[159] Similarly, quantitative radiolabeled as well as flow cytometric studies in PV and ET have revealed decreased expression of platelet glycoprotein receptors Ib and IIb/IIIa.[156,160,161]

AvWS occurs in more than a third of the patients with MPN and has been associated with a bleeding diathesis.[162,163] Several investigators have established a relationship between the platelet count and loss of large von Willebrand factor (vWF) multimers in plasma of MPN patients.[164–166] The finding that large vWF multimers in plasma decrease progressively at increasing platelet counts of $>1{,}000 \times 10^9$/L is in agreement with epidemiologic studies in ET showing an increased bleeding risk when the platelet count exceeds this level.[31,167–169] The functional deficiency of MPN-associated acquired von Willebrand disease (AvWD) may not be apparent when measuring vWF:Ag and FVIII levels alone, as these are typically maintained within the normal range.[159,170]

The assays used to assess vWF function (collagen binding activity [VWF:CBA] or ristocetin cofactor activity [vWF:RCoA]) reveal that vWF function declines relative to the vWF:Ag with increasing platelet counts.[171–173] This phenomenon is not restricted to MPN, but has also been described among patients with reactive thrombocytosis (RT).[164] Therefore, the observed loss of large multimers in ET and PV is likely an effect of the absolute platelet number, rather than an effect of dysfunctional clonal platelets. Further evidence of the importance of platelet number is provided by the observed resolution of the clinical bleeding complications and the AvWD in ET and PV patients following platelet cytoreduction with myelosuppressive therapy or platelet pheresis.[159,164,170,172] Similarly, resolution of RT also restores the large multimers and, as a result, vWF function among affected patients.[164]

Studies of patients with ET and PV have demonstrated that the reduction in the levels of large vWF multimers is the result of increased turnover *in vivo*.[172] Increased clearance of large vWF multimers in MPN has been proposed by some investigators to be the result of enhanced binding to platelets. However, the binding of vWF to single platelets from patients with either ET or RT was not shown to be different from that of normal controls.[174] Instead, enhanced proteolytic degradation of vWF is the more likely mechanism.[159,175–178] Regardless, the relationship between extreme thrombocytosis and decreased large vWF multimers suggests a key role for the number of circulating platelets in mediating this process.[164] Platelet in excess may facilitate the interaction between platelet surface receptor GPIb and vWF,

tahir99-VRG & vip.persianss.ir

thus inducing the appropriate conformational changes in vWF that allows ADAMTS 13 to gain access to its cleavage site.

Pathogenesis of Thrombotic Diathesis in MPN

Thrombosis is often multifactorial in etiology. MPNs have an inherent predisposition to thrombosis driven by the underlying clonal proliferation, and this risk may be escalated in association with thrombogenic stimuli that contribute to thrombosis in the general population. As such, the role of hereditary and acquired cardiovascular and thrombophilic risk factors has been studied in relation to their contribution to MPN-related vascular complications.

In regards to PV, hematocrit level is the major determinant of thrombosis and the most effective treatment strategy in this regard has been phlebotomy.[179] The relationship between thrombosis, hematocrit level, and *in vitro* parameters of blood viscosity and tissue perfusion is complex. For example, although hematocrit has been shown to be the major determinant of whole blood viscosity *in vitro*,[180] flow dynamics in blood vessels is different than that predicted by *in vitro* experiments and, in addition, the strong relationship between hematocrit and oxygen transport substantially influences *in vivo* blood viscosity.[180] For example, *in vivo*, increased hematocrit level is associated with decreased cerebral blood flow rate[181] not because of the change in viscosity but that of arterial oxygen content.[182] At low shear rates, which is comparable to flow in large veins, the endothelial displacement of platelets, leukocytes, and other proteins from axial migration of red cells might enhance thrombogenic interaction between endothelial cells and platelets.[183] At high shear rates, which is comparable to flow in arterioles and other small vessels, red cell-derived platelet aggregants, such as ADP, might contribute to thrombosis.

Although the reduction in hematocrit level by phlebotomy addresses the above mentioned potentially detrimental, hematocrit-associated conditions,[183,184] it does not abolish the risk of thrombosis in PV. Therefore, factors other than hematocrit (platelets, leukocytes, endothelial cells, coagulation proteins) might contribute to thrombosis risk in both PV and other MPNs. In this regard, potentially thrombogenic, qualitative cell defects have been described and include a diminished response of platelet adenylate cyclase to prostaglandin D2 (a physiologic inhibitor of platelet aggregation),[185] an increased baseline platelet production of TXA_2 (a platelet aggregant),[186,187] and abnormal *in vivo* activation of leukocytes,[188] endothelial cells,[188,189] and platelets.[187,189] Furthermore, previous reports of widespread activation in coagulation proteins,[188] reduced levels of physiologic anticoagulants (ATIII, proteins C and S),[190,191] and decreased fibrinolytic activity[192] that may be partly secondary to increased plasma levels of plasminogen activator inhibitor-1[193] suggest a baseline prothrombotic state in these disorders.

Spontaneous platelet activation in MPN has been demonstrated by measurement of plasma and urinary levels of arachidonate metabolites (TX B_2 and α-granule proteins [PDGF, β-thromboglobulin, platelet factor 4]), and accounts for the noted acquired storage pool disorder.[144–147] Additional evidence comes from the assessment of platelet surface membrane expression of markers of platelet activation (with monoclonal antibodies to P selectin and the activated fibrinogen receptor, GPIIb/IIIa) by flow cytometry.[161] It is possible that this abnormal activation state may be in part due to MPN-specific defects in arachidonic acid metabolism, which result in abnormal and sustained spontaneous TXA_2 generation in PV and ET.[187,194,195] This observed endogenous TXA_2 generation in PV and ET was found to be almost completely suppressible with low-dose aspirin.[187,195] Clinically, this effect has been shown to correlate with resolution of microvascular thrombosis.[34,196] The pathogenesis of the enhanced TXA_2 production in MPN is unknown, but may involve preferential shunting of arachidonate to the cyclooxygenase pathway because of concurrent lipoxygenase deficiency.[194] However, earlier studies suggested that MPN patients with lipoxygenase deficiency might display a hemorrhagic rather than thrombotic phenotype.[194]

DIAGNOSIS AND LABORATORY INVESTIGATION

Essential Thrombocythemia

According to the 2008 WHO system (Table 102.2),[10] a working diagnosis of ET is considered in the presence of persistent non-RT and after the diagnostic exclusion of CML, PV, MDS, and PMF (including "prefibrotic" PMF). Accordingly, one has to first entertain the possibility of RT from various causes (Table 102.3) during the initial evaluation of all such patients. In this regard, patient history and physical examination are crucial and often adequate to answer the specific question. Additional help is readily available from routine laboratory tests, including serum ferritin (to consider the possibility of iron deficiency), peripheral blood smear (to look for Howell-Jolly bodies and other markers of hyposplenism), and C-reactive protein or similar acute phase reactants (to consider the possibility of occult inflammation or malignancy).[197] In addition, rare cases of hereditary thrombocytosis (activating mutation of *MPL* or *TPO*) have been described, and must be kept in mind while evaluating a patient with either life-long history of thrombocytosis or a family history of the same.[12] If neither patient history nor the aforementioned laboratory tests suggest RT, *JAK2*V617F mutation screening is indicated and its presence confirms the presence of an underlying MPN, but its absence does not rule out the possibility since up to 40% of patients with ET might be *JAK2*V617F-negative.[198] It is also important to note that other *JAK2*V617F-positive MPN (or MDS/MPN) can mimic ET in their presentation; these include prefibrotic PMF[199] and refractory anemia with ring sideroblasts with marked thrombocytosis (RARS-T).[200] Therefore, bone marrow examination is often necessary to make an accurate morphologic diagnosis of ET and distinguish it from other myeloid neoplasms, especially from prefibrotic PMF; megakaryocytes in ET are large and mature-appearing whereas those in prefibrotic PMF display abnormal maturation with hyperchromatic and irregularly folded nuclei (FIGURE 102.2).[201] A recent large international study confirmed the prognostic relevance of distinguishing ET from prefibrotic PMF.[202] In the absence of *JAK2*V617F, the possibility of CML is readily addressed by *BCR-ABL1* mutation screening, but it is also to be noted that megakaryocytes in CML (small and hypolobulated) are easily distinguished from those of ET (FIGURE 102.3).[203]

Polycythemia Vera

The diagnosis of PV should be suspected in the presence of either an increased hemoglobin level (Hb >18 gm/dL in a male white or the corresponding level in the opposite sex or in the

Table 102.2

WHO diagnostic criteria for PV, ET, and PMF

	2008 WHO Diagnostic Criteria		
	Polycythemia Vera[a]	**Essential Thrombocythemia**[a]	**Primary Myelofibrosis**[a]
Major criteria	**1** Hgb > 18.5 g/dL (men) > 16.5 g/dL (women) *or*[b]	**1** Platelet count ≥ 450 × 10^9/L	**1** Megakaryocyte proliferation and atypia[c] accompanied by either reticulin and/or collagen fibrosis, *or*[d]
	2 Presence of *JAK2*V617F or *JAK2* exon 12 mutation	**2** Megakaryocyte proliferation with large and mature morphology.	**2** Not meeting WHO criteria for CML, PV, MDS, or other myeloid neoplasm
		3 Not meeting WHO criteria for CML, PV, PMF, MDS, or other myeloid neoplasm	**3** Demonstration of *JAK2*V617F or other clonal marker *or* no evidence of reactive marrow fibrosis
		4 Demonstration of *JAK2*V617F or other clonal marker *or* no evidence of RT	
Minor criteria	**1** BM trilineage myeloproliferation		**1** Leukoerythroblastosis
	2 Subnormal serum Epo level		**2** Increased serum LDH level
	3 EEC growth		**3** Anemia
			4 Palpable splenomegaly

[a]PV diagnosis requires meeting either both major criteria and one minor criterion *or* the first major criterion and two minor criteria. ET diagnosis requires meeting all four major criteria. PMF diagnosis requires meeting all three major criteria and two minor criteria.
[b]*Or* Hgb or Hct >99th percentile of reference range for age, sex, or altitude of residence *or* RCM >25% above mean normal predicted *or* Hgb > 17 g/dL (men)/ >15 g/dL (women) if associated with a sustained increase of ≥2 g/dL from baseline that can not be attributed to correction of iron deficiency.
[c]Small to large megakaryocytes with aberrant nuclear/cytoplasmic ratio and hyperchromatic and irregularly folded nuclei and dense clustering.
[d]Or In the absence of reticulin fibrosis, the megakaryocyte changes must be accompanied by increased marrow cellularity, granulocytic proliferation and often decreased erythropoiesis (i.e., prefibrotic PMF).
BM, bone marrow; Hgb, hemoglobin; Hct, hematocrit; Epo, erythropoietin; EEC, endogenous erythroid colony; WHO, World Health Organization; CML, chronic myelogenous leukemia; PV, polycythemia vera; PMF, primary myelofibrosis; MDSs, myelodysplastic syndromes; LDH, lactate dehydrogenase.

presence of a different ethnic origin) or a PV-associated clinical feature (pruritus, erythromelalgia, splenomegaly, splanchnic vein thrombosis, increased leukocytosis or thrombocytosis). In the absence of the above scenario, a repeat complete blood count (CBC) in 3 months is all that is needed. Otherwise, one should further pursue the diagnosis of PV.

As is the case with ET, PV is currently diagnosed according to the WHO system (Table 102.2).[10] Other causes of polycythemia include secondary (usually Epo-mediated) and apparent (spurious or relative) polycythemia. Traditionally, this was accomplished through the Polycythemia Vera Study Group (PVSG) criteria, which required the demonstration of an elevated red cell mass (RCM).[204] At present, we seldom use either the PVSG criteria or RCM measurement and instead depend on the clinical presentation, *JAK2*V617F mutation screening, serum Epo level, and bone marrow histology in order to make a working diagnosis of PV.

FIGURE 102.3 provides a practical diagnostic algorithm for PV and other MPNs. The laboratory detection of *JAK2*V617F is highly sensitive (97% sensitivity), and virtually 100% specific for distinguishing PV from other causes of increased hematocrit.[205,206] The possibility of false positive or false negative mutation test result is effectively addressed by the concomitant measurement of serum Epo level, which is expected to be subnormal in more than 85% of patients with PV.[207] A subnormal serum Epo level in the absence of *JAK2*V617F mandates additional mutational analysis for *JAK2* exon 12 mutation in order to capture some of the approximately 3% of PV patients who are *JAK2*V617F negative.[56] Bone marrow examination is not essential for the diagnosis of PV, because patients who otherwise fulfill the diagnostic criteria for PV are labeled as having PV even if they display substantial bone marrow fibrosis (Table 102.2).[77]

Primary Myelofibrosis

The first clue to the diagnosis of PMF is a myelophthisic peripheral smear (the presence of nucleated red blood cells, granulocyte precursors, and teardrop-shaped erythrocytes). However, it should be noted that a myelophthisic smear may also be associated with either another myeloid malignancy with bone marrow fibrosis or a nonfibrotic bone marrow infiltrating process, including metastatic cancer, granulomatous infection, and lymphoma. Therefore, a careful morphologic evaluation of the bone marrow is necessary before making the diagnosis of PMF, and cytogenetic tests and fluorescence in situ hybridization (FISH)

Table 102.3

Causes of thrombocytosis

Primary Thrombocytosis	Reactive Thrombocytosis
• Essential thrombocythemia	• Infection
• Polycythemia vera	• Tissue damage
• Myelofibrosis with myeloid metaplasia (overt)	• Chronic inflammation
• Myelofibrosis with myeloid metaplasia (cellular phase)	• Malignancy • Rebound thrombocytosis
• Chronic myeloid leukemia	• Renal disorders
• Myelodysplastic syndrome	• Hemolytic anemia
• Acute leukemia	• Post-splenectomy • Blood loss

for bcr/abl should always be done to rule out fibrotic CML. Similarly, it is important to know that both MDS and other myeloid entities can be accompanied by bone marrow fibrosis, and the input from an experienced clinical pathologist is essential to distinguish these disorders from PMF.

Typical PMF is characterized by the presence of dysplastic megakaryocytic hyperplasia, collagen and reticulin fibrosis, osteosclerosis, and intra-sinusoidal hematopoiesis. In prefibrotic PMF, the degree of bone marrow fibrosis may be minimal, but

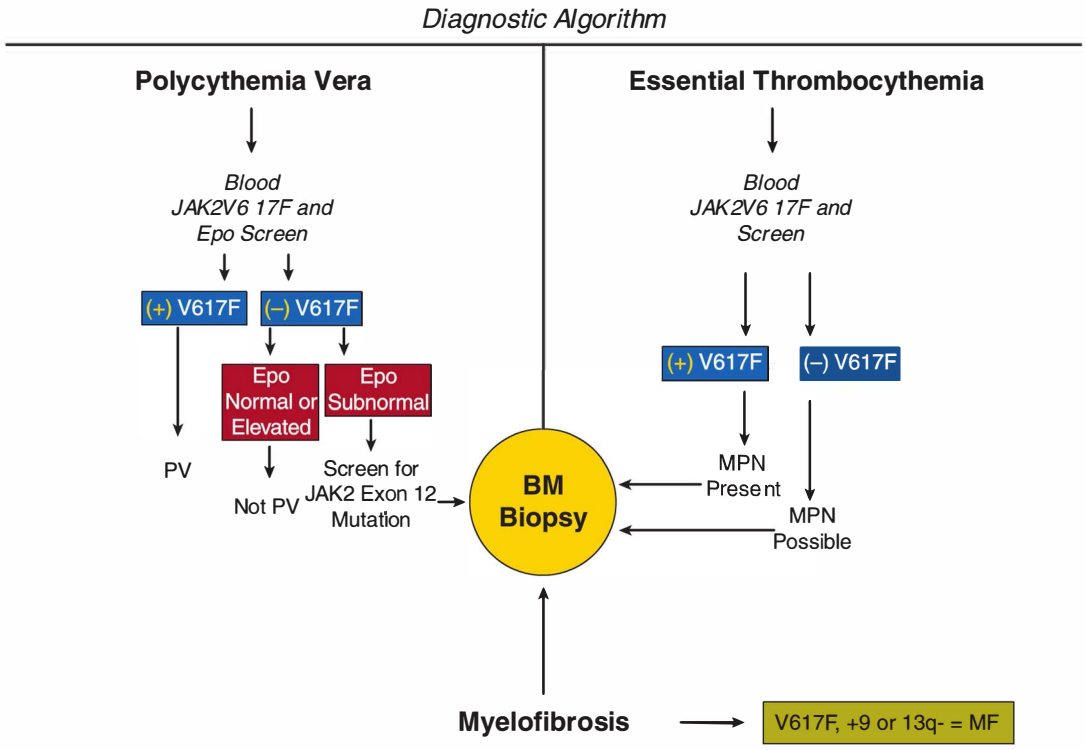

FIGURE 102.3 A practical algorithm for the diagnosis of polycythemia vera (PV), ET, and PMF. BM, bone marrow; MPN, myeloproliferative neoplasm.

splenomegaly, myelophthisis, and increased lactate dehydrogenase are often present. Recurrent cytogenetic abnormalities are seen in approximately a third of chemotherapy naïve patients with PMF.[208] The diagnosis of post-PV or post-ET MF should adhere to criteria recently published by the International Working Group for MPN Research and Treatment (Table 102.3).[209]

Coagulation and Platelet Function Tests in Myeloproliferative Disorders

Routine coagulation studies, including activated partial thromboplastin time (APTT), prothrombin time (PT), thrombin time (TT), and fibrinogen, are generally normal in both PV and ET. Although AvWS is associated with MPN, unlike the case with congenital vWD, the condition is usually associated with normal factor VIII levels, and thus will not be detected on the basis of a prolonged APTT.[170] Despite evidence of platelet dysfunction in ET and PV, as assessed by platelet aggregation studies, a prolonged bleeding time is seen only in a minority of cases (range, 7% to 26%).[31,210–212] Prolonged bleeding time in MPN has been attributed to an underlying defect in primary hemostasis (primary platelet dysfunction or AvWD), which is exacerbated by aspirin therapy.[213]

Platelet aggregation studies are frequently abnormal in MPN (demonstrating either or both hypo- and hyperfunction).[31,214,215] In general, platelet hypofunction (decreased aggregation with one or more agonists) is the predominant finding.[169] The most commonly reported abnormalities include decreased primary and secondary aggregation patterns to either epinephrine or ADP and decreased response to collagen, in descending order of frequency, with generally normal responses to arachidonic acid.[169] In a review of several studies in MPN patients, decreased aggregation responses to one, two, or all of these agonists were noted in 57%, 39%, and 37%, respectively.[210] Unlike the commonly encountered aspirin-type release defect in which the primary wave in response to epinephrine is maintained, but no secondary wave is obtained, complete absence of response to epinephrine is characteristic of MPN.[210]

Spontaneous platelet aggregation is another characteristic finding in MPN, but has not been correlated with clinical bleeding or thrombosis.[31,214] The possibility that whole blood-based platelet aggregation tests might provide a better clinical correlation has been touted, but remains to be confirmed by additional studies.[216]

ACQUIRED AND HEREDITARY THROMBOPHILIA AND MPN

The contribution of well-established risk factors of cardiovascular disease (hypertension, smoking, hypercholesterolemia, diabetes mellitus) have been assessed in MPN by multiple studies with some conflicting results, possibly reflecting the size of the studies and number of patients with the risk markers of interest included. On multivariate (hypertension, smoking, hypercholesterolemia, diabetes) analysis, one large retrospective study of ET patients (n = 148) demonstrated only the independent contribution of hypercholesterolemia, and another (n = 132), the independent association with smoking only.[28,217] The latter finding had been shown in an earlier, smaller (n = 46) study.[218] However, other large retrospective cohort studies including these variables could not confirm these associations.[31,212,219,220]

Over the last two decades there has been a vast expansion in knowledge of hereditary and acquired conditions contributing to thrombosis.[221] These include the congenital deficiencies of natural anticoagulants (antithrombin III, protein C, and protein S), genetic mutations (factor V Leiden, prothrombin G20210A, and MTHFR mutations), and acquired conditions (anticardiolipin antibodies and/or lupus anticoagulants). Several recent studies have explored the contribution of these to the occurrence of thrombotic events in MPN. Two prospective studies evaluated ET patients to determine the allele frequencies of factor V Leiden, prothrombin G20210A, and MTHFR mutations among those with and without thrombotic complications.[222,223] No significant correlation was found in either study, although both were limited by sample size (n = 43 and n = 42), respectively.

A more recent larger, yet retrospective study of 304 patients with PV (n = 178) and ET (n = 126), demonstrated a significant difference in the prevalence of the factor V Leiden mutation in patients with (16%), compared to those without (3%), a history of venous thrombotic events.[224] No such relationship was seen with regards to arterial thrombosis, as would be expected with this mutation.[225] This study did not investigate the other common thrombophilic polymorphisms (prothrombin G20210A, MTHFR) or acquired states (antiphospholipid syndrome), known to effect the phenotypic expression of prothrombotic disease.[224]

Several studies have confirmed the presence of elevated homocysteine levels among patients with MPN.[226–228] Elevated homocysteine levels may be hereditary (homozygosity for MTHFR mutation) or acquired (folic acid, vitamin B_{12} or B_6 deficiencies, renal failure), and is a recognized risk factor for both arterial and venous thrombotic disease.[229] However, no association with the homozygosity for the MTHFR mutation could be confirmed in these studies, leading investigators to postulate (and in study confirm) that the acquired increase in homocysteine may be the result of vitamin B deficiencies, possibly related to the persistent hyperproliferative hematopoiesis of these disorders. With regards to clinical impact of these observations, an association with arterial thrombotic disease was demonstrated by only one of the aforementioned studies,[226] but not the others.[227,228]

Antiphospholipid antibodies as measured either by a clot-bases assay [lupus anticoagulant] or ELISA are established risk factors for both arterial and venous thrombotic disease.[230] Several investigators have reported an increased prevalence of antiphospholipid antibodies in ET.[231,232] One of these studies suggested an association between the observed antiphospholipid antibodies and thrombosis.[231] However, the small sample sizes of patients included and lack of follow-up testing to confirm persistence (and thus significance) of the detected antibodies precludes any firm conclusions be made of these findings.

PROGNOSIS AND TREATMENT IN POLYCYTHEMIA VERA AND ESSENTIAL THROMBOCYTHEMIA

Survival in WHO-defined ET is near-normal[202] and median survival in contemporary PV is approximately 14 years.[233] Risk factors for shortened survival in ET and PV include history of thrombosis, leukocytosis, and advanced age.[202,233] Leukocytosis has also been associated with leukemic[233] and *JAK2*V617F allele burden with fibrotic[234] transformation in PV.[234] Current treatment for PV or ET is based on risk of thrombosis and designed

Table 102.4

Risk stratification in PV and ET and risk-adapted therapy

Risk Categories	Essential Thrombocythemia	Polycythemia Vera	Management During Pregnancy
Low-risk without extreme thrombocytosis (age < 60 y *and* no thrombosis history)	Low-dose aspirin	Low-dose aspirin + phlebotomy	Low-dose aspirin + phlebotomy if PV
Low-risk with extreme thrombocytosis (platelets > 1,000 × 10^9/L)	Low-dose aspirin *provided* ristocetin cofactor activity >30%	Low-dose aspirin *provided* ristocetin cofactor activity >30% + phlebotomy	Low-dose aspirin *provided* ristocetin cofactor activity >30% + phlebotomy if PV
High-risk (age ≥ 60 y *and/or* presence of thrombosis history)	Low-dose aspirin + hydroxyurea	Low-dose aspirin + phlebotomy + hydroxyurea	Low-dose aspirin + phlebotomy if PV + IFN-α
High-risk disease that is refractory or intolerant to hydroxyurea	Low-dose aspirin + IFN-α (age < 65 y) or busulfan (age ≥ 65 y)	Low-dose aspirin + phlebotomy + IFN-α (age < 65 y) or busulfan (age ≥ 65 y)	Low-dose aspirin + phlebotomy if PV + IFN-α

to prevent thrombotic and hemorrhagic complications.[235] Age ≥60 years and history of thrombosis are the two risk factors used to classify patients with PV or ET into low (0 risk factors) and high (1 or 2 risk factors) risk groups (Table 102.4).[233,236–238]

Controlled studies have confirmed the antithrombotic value of low-dose aspirin in PV[239] and hydroxyurea in ET.[240] The European collaboration study on low-dose aspirin in polycythemia[239] enrolled 518 patients with PV in a double-blind randomized trial to low-dose aspirin (100 mg daily) or placebo. Treatment with aspirin did not increase the incidence of major bleeding but instead reduced the risk of combined endpoints for "nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes" and "nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular causes."[241] Cortelazzo et al.[240] randomized 114 mostly high-risk ET patients to receive hydroxyurea ($n = 56$) or not ($n = 58$). After 27 months of follow-up, the incidences of thrombotic complications were 3.6% for hydroxyurea and 24% for no hydroxyurea.

Aspirin therapy is also considered to be adequate, and potentially useful in preventing complications during pregnancy, especially in *JAK2*V617F-positive cases.[242–244] First-trimester spontaneous miscarriage rate in ET or PV (>30%)[36,245,246] is significantly higher than the 15% rate expected in the control population and does not appear to be influenced by specific treatment.[36] Late obstetric complications as well as maternal thrombohemorrhagic events are relatively infrequent and platelet count usually decreases substantially during the second and third trimesters.[247] The use of aspirin in both PV and ET requires caution, especially in the presence of extreme thrombocytosis (platelet count >1,000 × 10^9/L), which promotes the development of AvWS.

No other drug therapy has been shown to be superior to hydroxyurea in the management of high-risk patients with ET or PV. In a randomized ET trial comparing hydroxyurea to anagrelide,[248] 809 high-risk patients were given low-dose aspirin plus either anagrelide or hydroxyurea. Hydroxyurea was better in terms of reducing the risk of arterial thrombosis, major bleeding, and fibrotic progression. Anagrelide performed better in preventing venous thrombosis. Similarly, in a nonrandomized study by the PVSG, treatment with hydroxyurea was associated with a lower incidence of early thrombosis compared to a historical cohort treated with phlebotomy alone (6.6% vs. 14% at 2 years), and the incidence of AML in patients treated with hydroxyurea, compared to a historical control treated with either chlorambucil or radiophosphorus, was significantly lower (5.9% vs. 10.6% vs. 8.3%, respectively, in the first 11 years of treatment).[249] Other studies have confirmed the low incidence of AML in PV patients treated with hydroxyurea (1% to 5.6%).[250–252]

Several drugs are available for use in hydroxyurea-refractory patients with ET or PV, including anagrelide, interferon-alpha (IFN-α), busulfan, pipobroman, and P32. The leukemogenic potential of P32 is now well established whereas pipobroman was recently similarly implicated.[253] In contrast, favorable outcome has been reported in single arm studies using oral busulfan.[254,255] In 65 busulfan-treated patients with PV followed between 1962 and 1983, median survival was 19 years in patients whose disease was diagnosed before age 60 years.[254] Only two patients (3.5%) treated with busulfan alone developed acute leukemia. A similar percentage (3%) developed the complication in another study involving ET patients.[256] The safety and efficacy of busulfan treatment in ET was recently underlined by a long-term study of 36 patients above 60 years of age[257]; no instances of AML or other malignancies were documented after a median follow-up of 72 months.

IFN-α therapy has been shown to control erythrocytosis, thrombocytosis, splenomegaly, and pruritus in the majority patients with PV or ET.[258] Two recent studies of pegylated INF-α (~90 μg SC weekly) in PV and ET reported hematologic remissions of approximately 80% accompanied by decrease in *JAK2*V617F allele burden (complete molecular remission rate of 5% to 10%).[259,260] In one of the two studies,[259] 77 cases were evaluable after a median follow up of 21 months, and 76% and 70% of patients with ET or PV, respectively, achieved a complete hematologic remission, mostly in the first 3 months; side effects

were recorded in 96% of the patients, and 22% had discontinued treatment.

Despite the availability of effective antithrombotic therapy in ET and PV, thrombotic events persist; in a recent international study of 891 patients with WHO-defined ET followed for a median of 6.2 years,[261] the rate of fatal and nonfatal thrombotic events was 1.9% patient-years, nonfatal arterial events 1.2% patient-years, and venous events 0.6% patient-years. In the same study, analysis that included 180 patients with prefibrotic PMF revealed that major bleeding during follow-up occurred in 6% of patients with WHO-ET and 12% of those with PMF, at a rate of 0.79% and 1.39% patients per year, respectively.[262] Predictors of bleeding included diagnosis of PMF, leukocytosis, previous hemorrhage, and aspirin therapy. The analysis restricted to patients with WHO-ET confirmed previous hemorrhage and aspirin as independent risk factors.

PROGNOSIS AND TREATMENT IN MYELOFIBROSIS

Current prognostication in PMF is based on the Dynamic International Prognostic Scoring System (DIPSS)-plus system (Table 102.5).[263] DIPSS-plus utilizes eight independent predictors of inferior survival: age >65 years, hemoglobin <10 g/dL, leukocyte count $>25 \times 10^9$/L, circulating blasts ≥1% and presence of constitutional symptoms, unfavorable karyotype (i.e., complex karyotype or sole or two abnormalities that include +8, −7/7q-, i(17q), inv(3), −5/5q-, 12p- or 11q23 rearrangement), red cell transfusion need, and platelet count $<100 \times 10^9$/L. The four DIPSS-plus risk categories based on the aforementioned eight risk factors are low (no risk factors), intermediate-1 (one risk factor), intermediate-2 (two or three risk factors), and high (four or more risk factors) with respective median survivals of 15.4, 6.5, 2.9, and 1.3 years.[263]

There is no evidence to support the value of specific therapy in asymptomatic patients with low or intermediate-1 risk disease (Table 102.5). MF-associated anemia is usually treated with androgens, prednisone, danazol, thalidomide ± prednisone, or lenalidomide ± prednisone.[264] Erythropoiesis stimulating agents are not used because they are ineffective in transfusion-dependent patients and could exacerbate splenomegaly. Response rates to each one of the aforementioned drugs are in the vicinity of 15% to 25%, and response durations average about 1 to 2 years. Lenalidomide works best in the presence of del(5q31). First-line therapy for MF-associated splenomegaly is hydroxyurea, which is effective in reducing spleen size by half in approximately 40% of patients. Both thalidomide and lenalidomide might improve splenomegaly and thrombocytopenia in some patients.

PMF patients with high or intermediate-2 risk disease should be considered for investigational drug therapy or allogeneic stem cell transplant (ASCT).[264] In considering ASCT, one should be acutely aware of the risks involved. In one of the largest studies of ASCT in PMF,[265] 5-year disease-free survival and treatment-related mortality were 33% and 35% for matched related and 27% and 50% for unrelated transplants, respectively. Of note, outcome did not appear to be favorably affected by reduced intensity conditioning. Several experimental drugs are currently being evaluated in MF and other related MPNs. So far, pomalidomide and JAK inhibitor ATP mimetics have shown the most promise. Pomalidomide is a second generation immunomodulatory drug, and in a phase-2 randomized study, 25% of patients with anemia responded to the drug used alone (2 mg/d) or in combination with prednisone (0.5 or 2 mg/d).[266] JAK2 inhibitor ATP mimetics that are currently in clinical trials include ruxolitinib (recently FDA approved), SAR302503, CYT387, lestaurtinib, SB1518, AZD1480, BMS911543, LY2784544, and XL019 (*clinicalTrials.gov*).

Ruxolitinib is a JAK1/JAK2 inhibitor. In a phase-1/2 study,[267] adverse events included thrombocytopenia, anemia, and a "cytokine rebound reaction" upon drug discontinuation, characterized by acute relapse of symptoms and splenomegaly.[268] Among all evaluable patients, 44% experienced ≥50% decrease in palpable spleen size. Improvement in constitutional symptoms (fatigue, pruritus, abdominal discomfort, early satiety, night sweats, and exercise tolerance) and weight gain were seen in the majority of patients. A major reduction in proinflammatory cytokines was documented and coincided with improvement in constitutional symptoms. These results were confirmed by two randomized studies comparing ruxolitinib with either placebo or best supportive care.

The aforementioned palliative effect of ruxolitinib on splenomegaly and constitutional symptoms is shared by other JAK inhibitors. SAR302503 therapy was associated with

Table 102.5

Risk stratification and risk-adapted therapy in PMF

DIPSS-Plus[42] Risk Groups PMF	Median Survival	Management PMF
Low-risk (*No risk factors*[a])	~15.4 y	Observation or conventional drugs[b]
Intermediate-1 risk (*1 risk factor*[a])	~6.5 y	Observation or conventional drugs[b] or experimental drugs
Intermediate-2 risk (*2 or 3 risk factors*[a])	~2.9 y	Allo-SCT *or* experimental drugs
High-risk (*≥4 risk factors*[a])	~1.3 y	Allo-SCT *or* experimental drugs

[a]DIPSS-plus[42] uses eight risk factors for inferior survival: age > 65 y, hemoglobin < 10 g/dL, leukocyte count > 25×10^9/L, circulating blasts ≥ 1%, presence of constitutional symptoms, presence of unfavorable karyotype, platelet count < 100×10^9/L and presence of red cell transfusion need. Please note that a transfusion-dependent patient automatically has two risk factors because of transfusion need (one risk point) and hemoglobin < 10 g/dL (one risk point).
[b]Androgen preparations or thalidomide with prednisone for anemia; hydroxyurea for symptomatic splenomegaly.
DIPSS, Dynamic International Prognostic Scoring System.[42]

gastrointestinal symptoms, but drug withdrawal syndrome was less frequent. Interestingly, 39% of patients with a baseline *JAK2*V617F allele burden of >20% experienced a ≥50% decrease in mutant allele burden. CYT387 therapy was less likely to cause anemia but was associated with grade 1 peripheral neuropathy in a third of the patients. In the absence of experimental drug therapy opportunities and in nontransplant candidates, hydroxyurea-refractory splenomegaly is managed by splenectomy or splenic irradiation. Nonhepatosplenic EMH is effectively treated with low-dose radiotherapy.

MANAGEMENT AND PREVENTION OF THROMBOHEMORRHAGIC COMPLICATIONS

Platelet count reduction to below 1 million/μL is the most effective means of controlling symptomatic, MPN-associated AvWS, and this is best accomplished by the use of cytoreductive chemotherapy.[159,165,213] The main drug of choice in this regard is hydroxyurea.[240] Platelet apheresis for MPD-associated AvWS is indicated when extreme thrombocytosis is accompanied by an urgent need to acutely reduce the platelet count.[159,165,213] The procedure has often been employed in the setting of postsplenectomy thrombocytosis because of the associated high risk of hemostatic morbidity.[213,269] Because the beneficial effect of platelet pheresis is generally brief and repeated procedures are often required, it is recommended that cytoreductive therapy be initiated as soon as possible to provide long-term control of the platelet count.

Desmopressin, during the treatment of MPN-associated AvWS, has been shown to increase both vWF:Ag and function.[159,165,176,213] However, due to the increased vWF proteolysis observed in association with MPN-associated thrombocytosis, the half-life of functional vWF is decreased, rendering the administration of desmopressin generally of limited value. Furthermore, in view of reports of thrombotic complications (stroke and myocardial infarction) among patients with increased thrombotic risk (elderly, cardiovascular disease) treated with desmopressin, administration of this agent to patients with MPN may not be prudent.[270,271] Similar problems may arise from the administration of vWF-containing plasma products (such as cryoprecipitate or vWF-containing concentrates).[213]

To minimize aspirin-associated bleeding diathesis in MPN, low-dose aspirin (75 to 100 mg/d) is administered with or after a meal and concurrent therapy with a proton-pump inhibitor is considered for patients with gastric symptoms.[272] In the presence of extreme thrombocytosis (platelet count >1,000 × 10^9/L), it is recommended that clinically significant AvWS be ruled out before the institution of aspirin therapy. If aspirin therapy is indicated in the particular instance, cytoreduction is necessary to reduce the platelet count to below 800 × 10^9/L, which usually corrects the AvWS, before instituting aspirin therapy.

Thrombotic episodes in patients with MPN are managed in the usual manner with standard dose and schedule of systemic anticoagulant therapy. However, systemic anticoagulation alone is not sufficient, and myelosuppressive therapy should be instituted to further reduce the risk of recurrent thrombosis in patients with either PV or ET.[273] Because of the potential for increased bleeding risk, especially in patients with MPN,[274] long-term warfarin therapy requires close monitoring of both the international normalized ratio, in view of potential drug interactions and dietary influences, and the platelet count to avoid overlooking inadvertent thrombocytopenia due to excessive myelosuppression. The use of aspirin in combination with oral anticoagulant therapy increases the risk of bleeding. However, no studies have been performed addressing the combined use of these agents in MPN.

Patients with MPN have a higher risk of morbidity and mortality when undergoing surgical procedures. These risks are substantially increased in the setting of splenectomy, a procedure often performed in for management of symptomatic splenomegaly due to portal vein thrombosis in MPN.[275–277] Splenectomy in MF typically leads to extreme thrombocytosis postprocedure in the absence of appropriate platelet suppression. In one series of 223 patients undergoing splenectomy for MF, postoperative thrombocytosis developed in 49 patients (22%) and 9 (18%) died as a result of either thrombosis (6 patients) or gastrointestinal bleeding (3 patients).[275] Therefore, MPN patients undergoing surgery should first have their disease well controlled (i.e., hematocrit level below 45% and platelet count below 400 × 10^9/L), and the prophylactic use of hydroxyurea should be considered before splenectomy.

Daily platelet counts should be performed in the immediate postoperative period. Aspirin therapy should be withheld for at least 1 week before elective surgery as well as when elective anticoagulation is required perioperatively. Although there are no prospective studies describing the efficacy of prophylactic anticoagulation for patients with MPN, such therapy might be instituted in view of the increased risk of postoperative thrombosis, for patients without known contraindications. However, such patients must be followed closely for the development of hemorrhage. Aspirin can be restarted 24 hours after surgery if no excessive bleeding has occurred or is anticipated by the surgeon. Aspirin can also be restarted 24 hours after stopping heparin prophylaxis in cases where this is prescribed.

CONCLUSIONS

Low-dose aspirin (40 to 100 mg/d) is the cornerstone of therapy in most low-risk patients with PV or ET, provided there are no major contraindications. In PV, phlebotomy is required to keep the hematocrit <45% but a higher target (50%) might be acceptable in aspirin-treated patients. Pregnant patients or women of childbearing potential are managed in the same general manner. In the presence of extreme thrombocytosis, screening for ristocetin cofactor activity is advised and consideration be given to withhold aspirin therapy if the result shows <30% activity. High-risk patients with PV or ET should receive hydroxyurea in order to minimize their risk of thrombosis. The dose of hydroxyurea is titrated to keep platelet count in the normal range. PV or ET patients who are either intolerant or resistant to hydroxyurea are effectively managed by INF-α (pegylated preparations preferred) or busulfan. I no longer use anagrelide for the treatment of PV or ET because of its reported association with increased risk of arterial thrombosis, major bleeding, and fibrotic progression.[248]

Low or intermediate-1 risk asymptomatic patients with PMF can be observed without any therapeutic intervention. Specific therapy is considered only in the presence of symptoms. First-line drugs of choice for anemia include thalidomide + prednisone, an androgen preparation, or danazol. I use lenalidomide in the presence of del(5q) or in case of treatment failure with thalidomide, danazol, or androgens. First-line drug of choice for symptomatic splenomegaly is hydroxyurea. Considering the lack of effective drug therapy in PMF, the risk of transplant-related

complications might be justified in those patients in whom median survival is expected to be <5 years. Nontransplant candidates are best managed with experimental drug therapy.[278–281] I have yet to be satisfied by the value of any currently available JAK inhibitor and strongly advise patients to continue participating in clinical trials.

CHAPTER

103

Thrombotic and Hemorrhagic Complications Associated with Stem Cell Transplantation

YONA NADIR AND BENJAMIN BRENNER

Thrombotic and hemorrhagic complications are common in stem cell transplantation (SCT) recipients. Endothelial cell (EC) injury is a dominant contributing factor to the hemostatic impairments related to administration of chemotherapy[1] and growth factors,[1] use of intravenous catheters, and graft-versus-host reaction.[2] As bone marrow endothelial progenitor cells are one of the sources for endothelial regeneration, the ability to repair the endothelial damage during SCT is limited. Profound thrombocytopenia is another major contributor to bleeding manifestations. Refractoriness or severe reactions to platelet transfusions, common in patients previously exposed to blood product transfusions during chemotherapy, predispose them to life-threatening bleeding events. A number of alterations in procoagulant, anticoagulant, and, to a lesser extent, fibrinolytic factors have been described. They include prohemorrhagic reduction of factor VII and factor X, as well as tissue-type plasminogen activator (t-PA) increase, simultaneous to prothrombotic decrease of protein C, antithrombin, and plasminogen and increase of fibrinogen, von Willebrand factor (vWF), and plasminogen activator inhibitor (PAI-1).[3–9] Major changes in the coagulation system have been established to be predisposing risk factors for hemostatic complications in SCT patients.

In a retrospective analysis of 364 allogeneic and 83 autologous transplants, 83% of patients presented with at least one hemostatic complication as early as the start of conditioning therapy and throughout a 4- to 10-year follow-up.[10] Thromboembolic events, hepatic venoocclusive disease (VOD), and thrombotic microangiopathy (TMA) were most frequently observed in allogeneic transplant recipients, with an incidence of 15%, 4.7%, and 14.6%, respectively, leading to an increased overall mortality.[10] The majority of bleeding episodes occurred within the first 4 weeks after transplantation and were relatively mild. However, 27% of the patients hemorrhaged severely, mostly in the gastrointestinal tract and intracranial, doubling the overall mortality of SCT recipients. Bleeding was strongly associated with prolonged thrombocytopenia and graft-versus-host disease (GVHD).[10]

This chapter deals primarily with thrombotic and hemorrhagic conditions that are specific for SCT. Bleeding resulting from thrombocytopenia and venous thrombosis (e.g., deep vein thrombosis, pulmonary emboli) occurs in SCT patients as well as in many other medical conditions where patients are hospitalized and are not specific. The chapter is organized into two sections (thrombotic and hemorrhagic), each of which considers two special complications. Etiology and treatment of the complications are summarized in Table 103.1.

THROMBOTIC COMPLICATIONS

Site-Specific Microcirculation Thrombosis

The two most common thrombotic manifestations related to SCT, VOD, and TMA are characterized by microcirculation thrombosis. The endothelium synthesizes both anticoagulants and procoagulants. On the anticoagulant side, ECs express tissue factor pathway inhibitor (TFPI), heparan sulfate, thrombomodulin (TM), endothelial protein C receptor (EPCR), t-PA,[11,12,13] ecto-ADPase, prostacyclin, and nitric oxide (NO). On the procoagulant side, ECs synthesize PAI-1, vWF, protease-activated receptors, and tissue factor. Importantly, endothelial derived anticoagulant and procoagulant molecules are not expressed uniformly in the vasculature. For example, TFPI is predominantly expressed in the capillary endothelium, EPCR in large veins and arteries, endothelial NO synthase on the arterial side of the circulation, vWF prevails in veins, and TM in blood vessels of every caliber in all organs apart from the brain.[14–16] These data suggest that ECs originating from different sites of the vascular tree employ site-specific formulas of procoagulants and anticoagulants to balance local hemostasis.[11]

Hepatic Venoocclusive Disease

VOD is the most common and important regimen-related toxicity experienced after allogeneic and autologous SCT and is characterized by painful hepatomegaly, jaundice, ascites, fluid retention, and weight gain,[17,18,19,20] with onset typically prior to day 35 after stem cell reinfusion.[17,18,19,20] VOD develops in 1% to 22% of patients after SCT and ranges in severity from a mild, reversible disease to a severe syndrome associated with multiorgan failure and death.[18] The incidence and severity of VOD can be influenced by differences in patient characteristics, conditioning regimens, and source of graft, with allogeneic transplantation conferring a threefold increase in risk compared to autologous transplantation.[21,22]

Pathogenesis

Hepatic sinusoidal ECs, which comprise 50% of hepatic nonparenchymal cells, are discontinuous. They possess large (100 to 200 nm) membrane-bound, nondiaphragmed cytoplasmic holes or fenestrae, occupying 6% to 8% of the endothelial surface,[23] and also display gaps and lack an organized basement membrane. The lack of basement membrane generates a space between sinusoidal ECs and hepatocytes called the space of Disse. The sinusoidal endothelium functions as a selective sieve. The fenestrae act as a dynamic filter for fluids, solutes, and particles, allowing

passage of small particles (up to medium-sized chylomicrons) from blood to hepatocytes via the space of Disse. Although the fenestrae are not large enough to accommodate leukocyte transmigration, they do allow cytoplasmic extensions from such cells to penetrate and "touch" the underlying matrix, stellate cells, and hepatocytes. Blood flow velocity in the sinusoids has been estimated to be 400 to 450 μm/s, compared with 500 to 1,000 μm/s in "true capillaries," thus prolonging interactions between blood and sinusoidal ECs and promoting filtration.[23]

Sinusoidal obstructive syndrome, also known as hepatic VOD, occurs most commonly in response to conditioning regimens (chemotherapy with or without irradiation) used in bone marrow transplantation. The first lesions appear in the sinusoids. Experimental models suggest that exposure to toxins results in swelling and rounding up of sinusoidal ECs, especially in the centrilobular area that has the poorest oxygenation, and is relatively more sensitive to ischemic injury, after which red blood cells enter the space of Disse.[24] Here, blood flow essentially dissects the sinusoidal endothelial lining away from the underlying parenchymal cells, resulting in embolization of sinusoidal ECs and occlusion of the downstream venous vessel (FIGURE 103.1A–C).[24] Subsequent changes include deposition of fibrin within sinusoids and veins, fibroblast cell proliferation, and collagen accumulation in the extracellular matrix (FIGURE 103.1D).[25,26,27] As the process of venous microthrombosis, ischemia, and fibrosis advances, widespread zonal disruption leads to portal hypertension, hepatorenal syndrome, multiorgan failure, and death.[28]

Injury to sinusoidal ECs caused by high-dose alkylating agents appears to be the primary event in the pathogenesis of VOD.[29–31] Detoxification of these chemotherapy agents in the liver is mainly mediated by cytochrome P450 and glutathione-*S*-transferase enzymes, which are present at high concentrations within the centrilobular area.[32] Depletion of glutathione stores predisposes hepatocytes to necrosis, whereas addition of glutathione mono-8-diester protects hepatocytes from high-dose alkylator injury.[33,34]

Several endothelial injury markers and adhesion molecules are upregulated in patients with VOD, including plasma TM, P- and E-selectins, TFPI, soluble tissue factor, and PAI-1.[9,35] *In vitro* studies show that endothelial PAI-1 production is triggered by cytokine transforming growth factor beta (TGF-β) released from activated platelets.[36] Elevated pretransplant plasma levels of TGF-β have been associated with the development of hepatic VOD.[37] Additionally, proinflammatory cytokines could also contribute to the initial endothelial injury, and increased tumor necrosis factor (TNF-α), interleukin (IL)-6, IL-8, and IL-1β are correlated with the jaundice, renal dysfunction, and pulmonary disease of SCT.[4,38]

The role of thrombophilic factors in the pathogenesis of thrombotic complications in SCT is unclear. In a small retrospective study, the prothrombin gene 20210 G-A mutation was found to be a predisposing factor for VOD,[39] and a prospective study in children revealed a strong association between factor V Leiden mutation and VOD.[40] More studies are warranted to confirm the association between thrombophilia and VOD.

Therapy

The most established practice in VOD prevention has been the use of pharmacokinetics to monitor chemotherapeutic drug levels to minimize hepatic injury. Prophylactic administration of ursodeoxycholic acid, a hydrophilic water-soluble bile acid, has been studied in randomized placebo-controlled trials, some showing a statistically significant benefit in patients predicted to be at a high risk of VOD.[41–43] However, a large phase III study failed to demonstrate significant benefit of this approach.[44] The role of heparin anticoagulation, alone or in combination with other agents, in VOD prophylaxis has been assessed in only one randomized study, which reported a beneficial effect of low-dose continuous heparin infusion.[45] Low molecular weight heparin is relatively safe and may have some impact on VOD prevention,[46–49] but well-designed studies are needed to confirm these results.

There is no approved therapy for established hepatic VOD. Current approaches focus on supportive care and on anticoagulant or fibrinolytic drugs,[45,46,50–52] based on pathologic findings of hepatic venules or sinusoids obliteration by fibrin.[18,26,27] The major disadvantage of exposure to heparin or recombinant t-PA is the high risk of life-threatening bleeding in patients with concurrent thrombocytopenia. The lack of response to platelet transfusions due to portal hypertension, splenic sequestration, and antiplatelet antibodies hampers effective management.[51,53]

Defibrotide, a single-stranded polydeoxyribonucleotide that exerts antithrombotic activity by binding to vascular endothelium, has shown promising results in VOD management.[54–56] Defibrotide upregulates the endothelial release of prostacyclin (PG I_2), prostaglandin E_2, TM, and t-PA,[57–59] and decreases thrombin generation, tissue factor expression, PAI-1 release, and endothelin activity.[57,60] Defibrotide exerts no significant effect on systemic coagulation,[61] but it has antiangiogenic potential in ECs and in an animal model.[62] Preclinical studies have demonstrated profibrinolytic effects and inhibition of fibrin deposition, with selective activity in

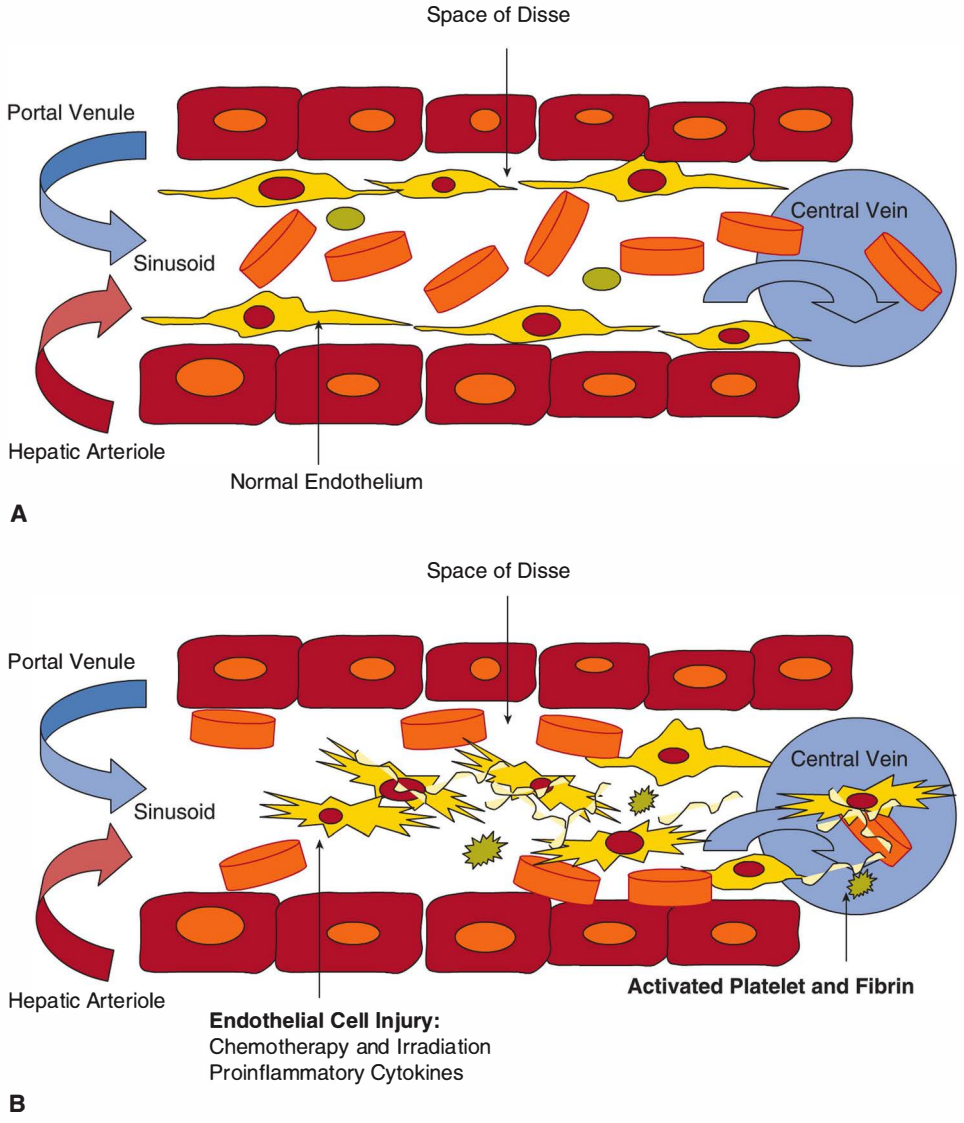

FIGURE 103.1 Mechanism of VOD. **A:** Normal blood flow in hepatic sinusoid. No basement membrane is present. **B:** Damaged ECs torn away from the sinusoid. Red blood cells enter the potential space of Disse and aggravate EC separation. Damaged ECs and the exposure of the subendothelial space activate platelets and the coagulation system to form fibrin.

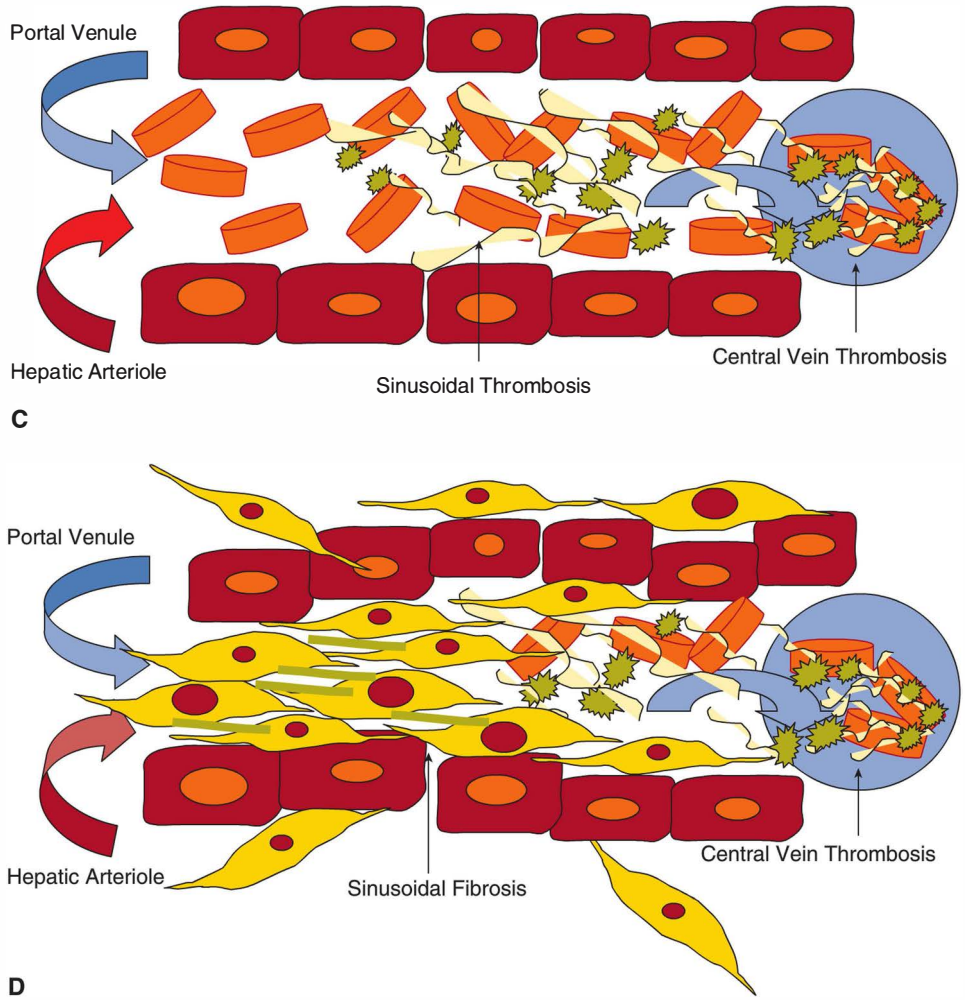

FIGURE 103.1 *(Continued)* **C:** The formed thrombus obstructs the sinusoid and central vein. **D:** Secondary changes of fibroblasts invasion and collagen deposition resulting in sinusoidal fibrosis.

small vessels.[63] Initial clinical reports of defibrotide for severe VOD recorded complete resolution in 36% to 42% of patients, with most individuals surviving beyond day 100.[54,55,64] In a recent randomized phase II dose-finding trial in adult and pediatric patients, defibrotide 25 mg/kg/d was selected for forthcoming phase III trials.[65] Preemptive antithrombin replacement and combined antithrombin/defibrotide therapy allowed excellent remission and survival rates in a prospective case series study of pediatric SCT patients.[66] In another report on 58 adults undergoing SCT, no patient developed VOD following the use of defibrotide prophylaxis (without concurrent heparin).[67] Cappelli et al.[68] reported on 57 children with beta thalassemia at a very high risk for developing VOD (liver fibrosis, iron overload, hepatitis C virus infections, busulfan-based conditioning), and only one patient developed VOD, after discontinuation of defibrotide 6 days prior to VOD onset. To date, no phase III randomized studies have been published on the use of defibrotide as prophylaxis or treatment of VOD.

Transplantation-related Thrombotic Microangiopathy

Transplantation-related TMA is a devastating complication occurring following SCT. The incidence of TMA after allogeneic and autologous transplantation is 0.5% to 15% and 0.1% to 0.25%, respectively.[10,69,70] Diagnosis is based principally on the presence of thrombocytopenia and microangiopathic hemolytic anemia in the absence of an alternative clinically apparent etiology.[71,72] Similar to idiopathic thrombotic thrombocytopenia purpura (TTP), transplantation-related TMA is associated with renal dysfunction and neurologic complications.[72] However, since both thrombocytopenia and fragmentation of red blood cells are extremely common after SCT, and renal dysfunction and neurologic complications can occur secondary to a diverse range of etiologies, definitive diagnosis of transplantation-related TMA is often uncertain.[73,74] Transplantation-related TMA can be attributed to extensive prior therapy, GVHD, reactivation of cytomegalovirus (CMV), and drugs (cyclosporine-A, tacrolimus).[70,75,76] Cyclosporine A is widely used as an immunosuppressive agent and is the most commonly reported cause of drug-induced TMA,[77] not only in bone marrow transplantation, but also in 3% to 5% of renal transplant recipients.[78] Chemotherapy-induced TMA is rare, reported in association with mitomycin-C,[79] cisplatin, alone or with bleomycin,[80] and gemcitabine.[81] These drugs are not routinely used in SCT chemotherapy protocols. Although transplantation-related TMA is associated with a shorter survival due to multifactorial causes, the exact prognosis is difficult to assess.[82]

Pathogenesis

Posttransplant TMA is not associated with severe vWF-cleaving protease deficiency, and the elevated vWF antigen found in these patients is more likely the result of diffuse endothelial injury (FIGURE 103.2A–C).[70,83] Cyclosporine-A is cytotoxic to cultured ECs at concentrations similar to the peak plasma levels achieved *in vivo*.[84] During episodes of cyclosporine-A–induced microangiopathy, plasma levels of vWF and endothelin are elevated,[85] as well as those of prostacyclin and thromboxane A_2 released by ECs.[84]

In patients with transplant-related TMA who received tacrolimus, a rise in serum levels of endothelin and several cytokines (IL-10, IL-12, TNF-α, interferon-γ) occurs, consistent with EC injury and cytokine-induced expression of adhesion molecules.[86] In addition, cyclosporine-A enhances platelet aggregation and platelet thromboxane A_2 release. Platelet hyperaggregability in renal allograft patients on long-term cyclosporine-A therapy reverts toward normal following the replacement of the drug with azathioprine.[87]

Therapy

Optimal management of transplantation-related TMA is currently not clear. Certainly, any suspected offending drug should be discontinued. Because of clinical similarity to idiopathic TTP, treatment-related TMA has been managed with plasma exchange, albeit with limited efficacy and relatively low response rates of <20% to 50% compared with idiopathic TTP (80%).[71,74,88] Other modalities of treatment, such as defibrotide or immunoglobulin G, have been attempted with variable success.[89,90]

HEMORRHAGIC COMPLICATIONS

Diffuse Alveolar Hemorrhage

Respiratory insufficiency associated with lung injury, both infectious and noninfectious, is a major cause of death in SCT patients. In a retrospective cohort study, medical and autopsy records of 71 autologous or allogeneic SCT recipients with

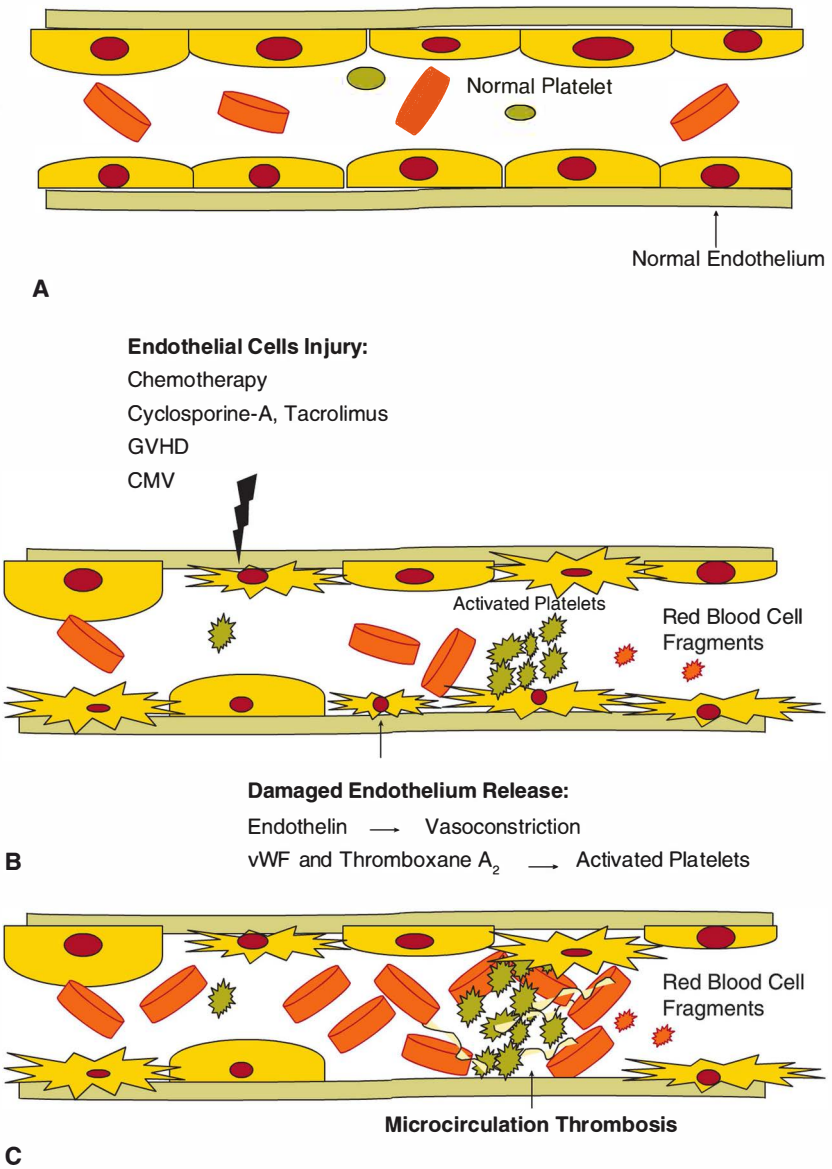

FIGURE 103.2 Endothelial damage in transplantation-related TMA. **A:** Normal blood flow in a capillary. **B:** Mechanism of endothelial damage involves drugs, GVHD, and CMV infection. Damaged ECs release endothelin, vWF, and thromboxane A_2, resulting in vasoconstriction and platelet activation. **C:** Capillary occlusion with a thrombus.

pulmonary complications found an infectious cause of death in 27 (37%) patients.[91] Noninfectious causes included diffuse alveolar damage, amyloidosis, leukemia/lymphoma, bronchitis obliterans, bronchiolitis obliterans, pulmonary alveolar proteinosis, acute organizing pneumonia, and aspiration pneumonia. Hemostatic problems were identified in 21% of the patients, including alveolar hemorrhage in 14% and pulmonary embolism in 7%.[91]

The reported incidence of diffuse alveolar hemorrhage (DAH) varies from 1% to 21% in autologous and from 2% to 17% in allogeneic SCT patients, suggesting that the type of transplantation does not play a major role in this pathology.[92–96] DAH can present with hypoxemia, pulmonary infiltrates, and progressive bloody alveolar lavage. A documented associated infectious cause occurred in 50% to 60% of the patients.[97] The probability of a 60-day survival from the onset of hemorrhage was 16% for the DAH and 32% for the infection-associated alveolar hemorrhage group.[97] Allogeneic SCT using reduced-intensity conditioning (RIC) has lower morbidity and mortality compared to transplantation using myeloablative conditioning (MAC), although alveolar hemorrhage occurs in 18/206 (8%) and 85/1112 (7%, $P = 0.56$), respectively, indicating that reduction in the intensity of a preparative regimen does not prevent transplantation-related DAH.[98] White blood cell (WBC) recovery and renal insufficiency, but not prolonged prothrombin time, partial thromboplastin time, or low platelets counts, are associated with DAH;[99,100] although most patients have thrombocytopenia, the condition is not corrected with platelet transfusion.[100]

Pathogenesis

Autopsies of SCT recipients with acute hemorrhagic pulmonary edema show intraalveolar and, to a lesser extent, interstitial collections of edema, fibrin, and erythrocytes, without hyaline membranes, pneumocyte changes, interstitial mononuclear cell infiltration, and fibrosis.[101] Thus, although the clinical presentation is hemorrhagic, autopsy findings imply a thrombotic etiology (FIGURE 103.3A,B). The incidence of DAH is high in SCT recipients with acute GVHD.[102] In addition to toxicity of the GVHD therapy, antigen-specific injury of endothelium may be a contributing factor to the development of DAH.[103] Mice receiving bone marrow T lymphocytes develop alveolitis, characterized by alveolar hemorrhage, increased alveolar leukocytes, platelet microthrombi, and damage to endothelial and epithelial cells during the acute phase of the graft-versus-host reaction.[2] The use of dimethyl sulfoxide (DMSO)

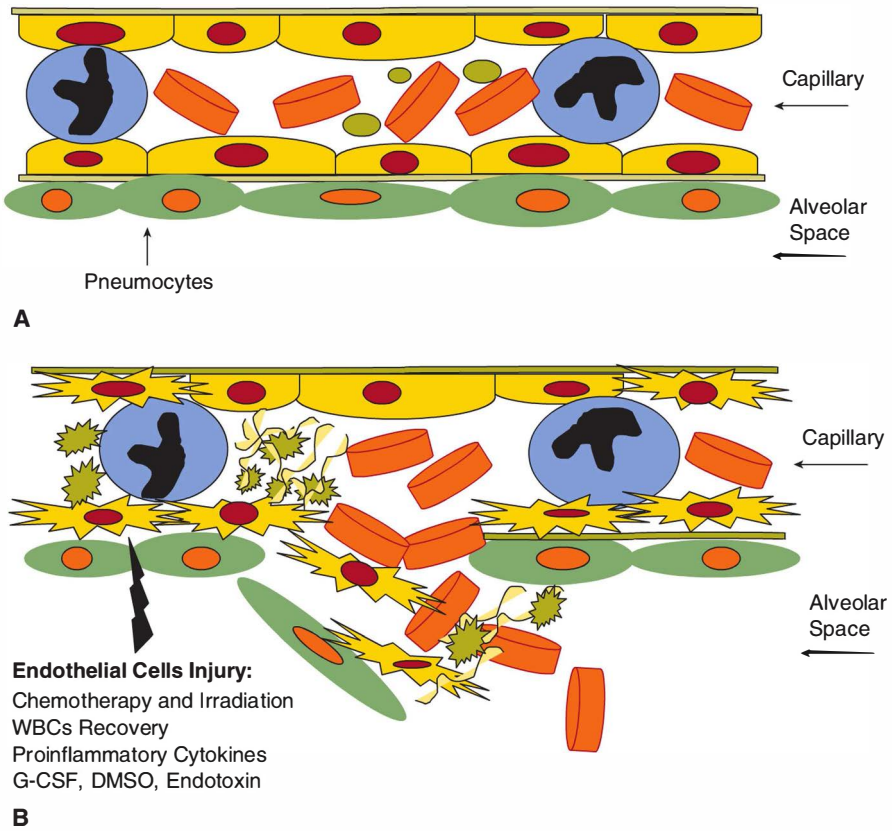

FIGURE 103.3 Proposed mechanism of DAH. **A:** Normal capillary and alveolar space. Pulmonary capillary bed has small diameter, hardly enabling WBC passage. **B:** Alveolar capillary EC injury is the primary insult. WBC recovery exacerbates the thrombotic potential due to the large diameter of neutrophils and tissue factor exposure during inflammation, infection, and G-CSF treatment. Injured endothelium activates platelets and coagulation factors to form fibrin. The thrombotic capillary rupture and red blood cells enter the alveolar space resulting in alveolar hemorrhage.

for cryopreservation of blood stem cells has been implicated in causing damage to the alveolar endothelial lining, thereby leading to the development of DAH,[95,104] and hematopoietic growth factors may also play a role in worsening the alveolar damage and capillary leakage by increasing neutrophil infiltration into the lungs.[105,106] It is speculated that damage to alveolar capillary endothelial membranes begins during preparative chemotherapy or total body irradiation, resulting in release of inflammatory mediators,[107] a response that may be amplified after the release of endotoxin into circulation from an inflamed gastrointestinal tract.[107]

Although alveolar capillary ECs do not express vWF,[108] they produce and secrete the clotting factor VIII that may enhance local coagulation.[109] Alveolar capillary blood contains an increased concentration of neutrophils and other leukocytes compared with large vessels, due to the structure of the pulmonary capillary bed, the diameter of spherical leukocytes, and their poor deformability compared with erythrocytes.[110] While capillary diameter in most organs is about 10 μm, it is about 8 μm in the pulmonary bed, enforcing deformability of granulocytes and monocytes which are 10 to 17 μm in diameter.[110] DAH typically occurs in parallel to WBC recovery,[99,100] and most contributing factors involve an inflammatory process. Impaired ability of WBCs to transmigrate lung ECs, as was shown in the mice model of DAH,[2] together with endothelial damage, may engender local alveolar capillary endothelial thrombosis resulting in endothelial damage and hemorrhage (FIGURE 103.3B). Although no supporting clinical data are available, this suggested obstructive and thrombotic damage may be potentially treated with regular preventive inhalation of heparin. Heparins are capable of transmigrating thin alveolar cells and reaching the alveolar capillary ECs. The ability of heparins to interfere with WBC rolling and adhesion to ECs[111] may prevent the alveolar endothelial sequestration.

Therapy

There are no prospective, randomized trials that address treatment of DAH in SCT recipients. Given that the pathogenesis of DAH is considered to be an inflammatory response and based on anecdotal experience and retrospective studies, SCT recipients with DAH are treated with systemic corticosteroids.[93,95,107,112] Fresh frozen plasma transfusion and plasmapheresis have been tried in one study with inconclusive results.[113] Paucity of reports on the off-label use of recombinant factor VIIa (rFVIIa) in SCT recipients with DAH precludes drawing definitive conclusions regarding the efficacy of this therapy.[114,115] In a phase II multicenter trial in SCT patients with major bleeding, a total dose of 280 to 1,120 μg/kg rFVIIa was used,[116] with regimens 40, 80, or 160 μg/d administered in seven successive doses every 6 hours for 36 hours. In this study, 7 patients out of 100 suffered from DAH, 6 thromboembolic events were observed in the treated group, and the trial did not show a significant benefit of rFVIIa in the setting of SCT-related severe bleeding.[116] The use of antifibrinolytic agents, such as tranexamic acid and aprotinin, is not well documented. Solomonov et al.[117] reported on six patients with significant hemoptysis, two of whom bled during bronchoscopy biopsy and four with spontaneous bleeding, treated successfully with local tranexamic acid without adverse events.

Hemorrhagic Cystitis

Hemorrhagic cystitis occurs as microscopic hematuria (grade I), or as gross hematuria, with clots and urinary tract obstruction (grades II to IV) in 5% to 40% of SCT recipients and causes significant morbidity and mortality. It occurs during or following SCT. Its incidence is twofold to threefold higher in allogeneic than autologous transplantation.[118,119]

Pathogenesis

Histologic analyses reveal mucosal bladder alterations such as edema, necrosis, and hemorrhage (FIGURE 103.4A,B).[120] Acute GVHD, the use of alkylating agents, and irradiation as part of conditioning regimen as well as viral reactivation have been implicated in the pathogenesis of hemorrhagic cystitis.[119,121] Reactivation of viral infection (BK virus, adenovirus, and herpes simplex viruses) has been associated with late-onset (>2 weeks posttransplant) hemorrhagic cystitis.[119,122,123] A recent study demonstrated that hemorrhagic cystitis was less common in patients with related donors than in those with unrelated donors and was less frequent in patients receiving a RIC regimen, compared to those exposed to MAC.[124]

Therapy

Various palliative treatments, including hydration, hyperbaric oxygen, antiviral antibiotic, estrogen, selective embolization of the internal iliac arteries, intravesicle instillation of materials as alum, silver nitrate, and formalin, showed variable success in alleviating symptoms.[123,125–128] A multicenter randomized trial in SCT patients with major bleeding[116] included 26 individuals with intractable hemorrhagic cystitis, which was not controlled with rFVIIa treatment.[116] A trial of four patients with SCT-related severe hemorrhagic cystitis treated with rFVIIa (150 to 1,200 μg/kg) was effective without thrombotic events.[129]

CONCLUSIONS

Hemostatic complications are common in allogeneic as well as autologous SCT patients, and there is an overlap in contributing factors. Due to the possibility that DAH could also be a thrombotic event, the three typical hemostatic complications in SCT, namely, VOD, TMA, and DAH, may be manifestations of thrombosis in the microcirculation. Hemorrhagic cystitis is likely to be a primary epithelial injury. ECs line the vascular bed, and each vascular bed has unique structural and functional properties, and therefore, understanding of these properties may hold important clues to site-specific diagnostics and therapeutics. Better understanding of the unique endothelial changes in each thrombotic condition would promote advanced treatment strategies. Hemostatic complications are known to cause high morbidity and mortality in SCT patients. The use of more intensive

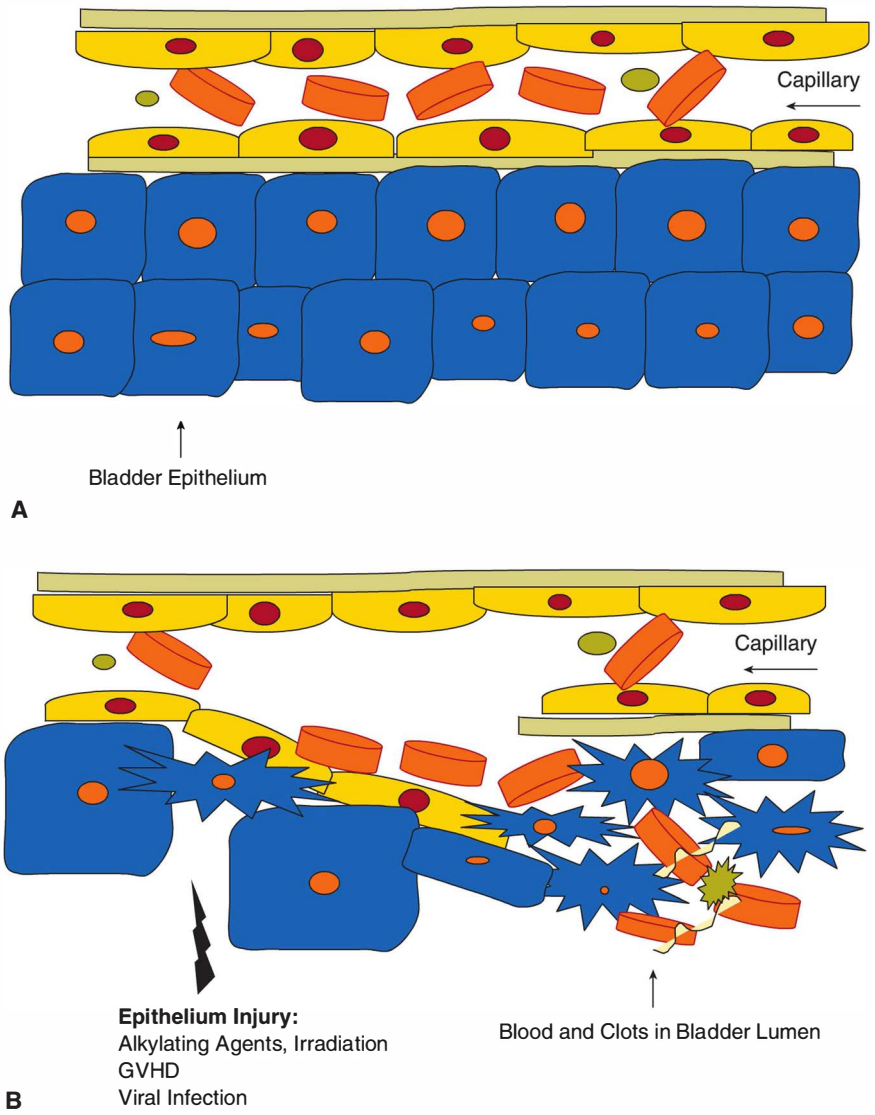

FIGURE 103.4 Epithelial damage in hemorrhagic cystitis. **A:** Normal bladder epithelium. **B:** Epithelial injury resulting in mucosal bladder alterations such as edema, necrosis, and hemorrhage.

conditioning regimens and mismatched donors increase the incidence of bleeding and thrombosis. Given that the ability of treating patients with severe thrombocytopenia, frequently refractory to platelets transfusions, is currently limited, the search for hemostatic agents that do not significantly interfere with coagulation system, such as defibrotide, is essential.

CHAPTER 104

Overview of Therapeutic Agents Used in Thrombotic Disorders

SAM SCHULMAN AND VICTOR J. MARDER

In this section, the many recent developments in drug and device therapy for venous or arterial thromboembolism are presented together with reviews of the biochemistry, pharmacology, mechanism of action, and side effects of the various agents. Thrombolytic therapy has gone through many modifications regarding both agents and regimens over the past 40 years from the initial infusions of streptokinase or urokinase. An important reason for the many attempts to improve this kind of therapy has been the wish to reduce the risk of bleeding and to simplify the treatment. Conversely, the drive to improve treatment with antiplatelet agents during the past 30 years has mainly been related to a desire to improve efficacy. Among the anticoagulants, vitamin K antagonists (VKAs) and unfractionated or low molecular weight heparins have dominated the clinical stage until the last decade. Recently, an unprecedented number of new anticoagulants have been taken to phase II and III clinical trials, and the standard therapy is about to undergo a shift in paradigm. Finally, vena cava filters have been refined to enhance retrieval after they have served their purpose, and sophisticated catheters for local injection of thrombolytic agents in combination with mechanical clot disruption are for the first time investigated in randomized control trials.

This introduction to the section focuses on some therapeutic dilemmas that will continue to haunt the clinicians for the foreseeable time, despite improvements of the therapeutic agents.

ANTICOAGULANTS AND COMPLIANCE

The VKAs are very effective—as long as they are taken as ordered and the proportional time in therapeutic range (TTR) is high. Even in well-conducted randomized clinical trials, about 30% of the time is spent outside of the therapeutic range.[1,2] Many countries have difficulties keeping an average TTR above 50% due to their therapeutic traditions. The new orally available anticoagulant agents may improve the efficacy by reducing the risk of nontherapeutic levels related to drug–drug or drug–food interactions. Poor compliance from the patients will, however, continue to result in treatment failures. An attempt to solve this problem was seen with the development of a very long-acting, more negatively charged derivative of the pentasaccharide fondaparinux. Idraparinux, with a half-life of 80 hours, was designed to be injected once a week, but with the actual experiences from phase III clinical trials and a half-life after multiple injections of 60 days,[3] it might have been suitable for even less frequent administration. This could have been a helpful solution for the poorly compliant patients employing relatively inexpensive support from medical staff.

The favorable results from treatment of deep vein thrombosis (DVT) in phase II,[4] were replicated with the selected dose of 2.5 mg idraparinux also in phase III in patients with DVT.[5] Nevertheless, the same dose was inferior regarding efficacy in the treatment of pulmonary embolism (PE),[5] and, conversely, it caused an increased risk of bleeding, particularly intracranial bleeding, compared to warfarin in patients with atrial fibrillation[6] (Table 104.1). The trial program of idraparinux has been discontinued, but the dilemma of how to best manage poor compliance will be highlighted with the introduction of new oral anticoagulants without the need for routine laboratory monitoring.

Furthermore, this lesson has taught us that results from trials in DVT cannot be directly extrapolated to other types of patients not only to those with atrial fibrillation but also to the very closely related condition PE. Although often thought of as one and the same disease, PE and DVT are probably best described as different expressions of a disease—with discrepancies regarding clinical picture, short-term prognosis in case of missed diagnosis,[7] location of recurrence,[8] and case fatality of recurrences.[9]

With respect to the issue of compliance, the use of the new, nonmonitored anticoagulants will require imaginative steps to ensure adherence. Otherwise, the promising results from clinical trials[2,10] (EINSTEIN) will not be replicated in the real-world setting. The solutions may include clinical follow-up with unannounced point-of-care screening test, for example with activated partial thromboplastin time for oral thrombin inhibitors. It would be of interest to develop a test that identifies activation of coagulation over prolonged periods, corresponding to the HbA1c for diabetes. Another option is the use of "intelligent" drug packaging that records removal of tablets and alarms when a dose is missed.[11]

Finally, in terms of new development of glycosaminoglycans—our oldest clinically used anticoagulant—the most recent agent currently in phase III trials is a hemisynthetic heparin with a molecular weight of only 2,000 to 3,000 Da (semuloparin, AVE5026), which makes it almost a pure factor Xa inhibitor.[12] Whether it can be adapted for oral administration, in view of its low molecular weight, is unclear, but previous attempts with longer glycosaminoglycans have only had limited success.[13,14] The glycosaminoglycans are reviewed in

Table 104.1

Example of discrepant results with the same drugs (warfarin with therapeutic range, INR 2–3, vs. idraparinux 2.5 mg daily) for different indications

	Idraparinux (%)	Warfarin (%)	Hazard Ratio (95% CI)	Interpretation
Efficacy				
DVT: Recurrence	3.7	3.7	1.01 (0.66–1.55)	Noninferior
PE: Recurrence	4.0	2.0	2.09 (1.22–3.57)	Inferior
Atrial fibrillation: Stroke, systemic embolism	0.9	1.3	0.71 (0.39–1.30)	Noninferior
Bleeding				
DVT: Major	0.8	1.2	NA	Noninferior, $P = 0.35$
PE: Major	1.1	2.1	NA	Borderline superior, $P = 0.05$
Atrial fibrillation: Intracranial	1.1	0.4	2.58 (1.18–5.63)	Inferior
Death				
DVT	2.3	2.0	NA	Noninferior, $P = 0.61$
PE	5.1	2.9	NA	Inferior, $P = 0.006$
Atrial fibrillation	3.2	2.9	NA	Noninferior, $P = 0.49$

CI, confidence interval; NA, not available.

detail regarding their pharmacology and mechanism of action in Chapter 105.

DURATION OF ANTICOAGULATION AFTER VENOUS THROMBOEMBOLISM

For most of the indications for anticoagulant treatment, until now mainly with VKAs, the duration is minimally disputed. Thus, 1 to 3 months is considered sufficient after cardioversion for atrial fibrillation, 3 months after anterior myocardial infarction and/or left-ventricle thrombus, ablation therapy for atrial fibrillation with low risk for stroke, and (if at all) after bioprosthetic valve replacement or postoperative transient atrial fibrillation. Indefinite treatment duration is chosen for patients with mechanical heart valves or atrial fibrillation with risk factors for stroke. The situation is different for venous thromboembolism (VTE) for the following reasons: (a) the risk of recurrence seems to remain indefinitely, albeit with some decrease over time, (b) the balance between recurrence without treatment and bleeding with treatment is tight for many patients with suboptimal control of the anticoagulation, (c) the individual risk of recurrence varies widely depending on the presence or absence of a large number of known risk factors, and (d) despite more randomized trials than for any other indication no clear answer has emerged.

For a minority of patients—those with a distal DVT provoked by temporary risk factors such as surgery or trauma—6 weeks of therapy seems sufficient.[15,16] At the other end of the spectrum are the patients with unprovoked and recurrent VTE, or thromboembolism associated with noncurable cancer or with serious thrombophilia (deficiency of antithrombin or combinations of defects). The vast majority of patients with VTE fall between these groups. Since several studies on the duration of treatment showed that the risk of recurrence after unprovoked VTE was 10% during the 1st year after stopping anticoagulation, irrespective of the treatment duration being 3, 6, 12, or 24 months, it has been suggested that the choice should be between 3 months and indefinite duration.[17] This dichotomous decision should be influenced by the risk of bleeding and the quality of anticoagulant management provided.

Common risk factors for recurrence are male sex,[18] cancer,[19] proximal location of the DVT,[20] and elevated level of factor VIII[21] or of D-dimers.[22] Absence of most of these risk factors as well as of the relatively common mutations, factor V Leiden, and prothrombin G20210A is not very helpful in the prediction of thrombosis-free survival,[23] but a negative D-dimer has a negative predictive value of 93% and a likelihood ratio associated with the absence of pos D-dimer, LR(–) was 0.58. Therefore, if an additional and objective decision support is needed, the use of this risk factor is probably the most cost-effective. A negative D-dimer after anticoagulant treatment for 3 to 6 months with subsequent discontinuation and a repeat negative D-dimer 1 month later predicts an annual risk of recurrence of 3.5%.[24] This risk is for most patients and physicians acceptably low in comparison with an annual risk of major bleeding on anticoagulation of about 2% per year and the inconvenience

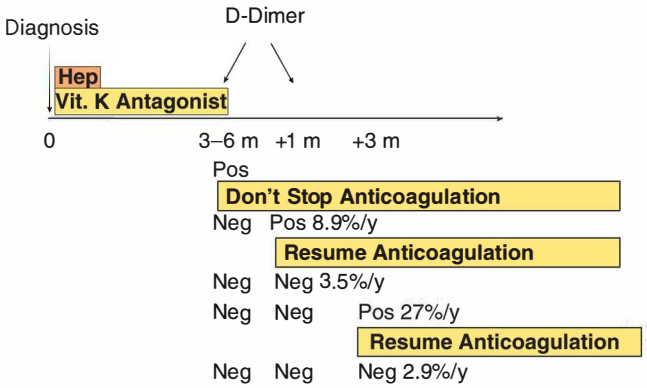

FIGURE 104.1 The use of D-dimer to predict risk of recurrent VTE. Rates (in %) show risk of recurrence during 1 year.

of treatment. With a third negative D-dimer, 3 months after stopping anticoagulation, some additional narrowing of the risk for recurrence is possible[25] (FIGURE 104.1).

A somewhat more sophisticated decision algorithm includes the sex of the patient and the location of the VTE, as presented in the Vienna model.[26] A cumulative recurrence rate for 12 months and for 60 months is obtained, and then the physician must decide what risk is acceptable. The data regarding the influence of the location of the VTE are, however, controversial since a large Canadian study demonstrated higher risk for recurrence after DVT than after PE,[20] which is in contrast to the Vienna model rule.[26]

Finally, the decision can be individualized according to a combination of risk factors for thrombosis and for bleeding and by also taking into account patient preferences (FIGURE 104.2).[27] This requires the physician to spend some time with the patient to obtain a good medical history and to discuss the options and understand the preferences of the patient.

With the introduction of new oral anticoagulants, such as dabigatran, rivaroxaban, or apixaban, the decision process may

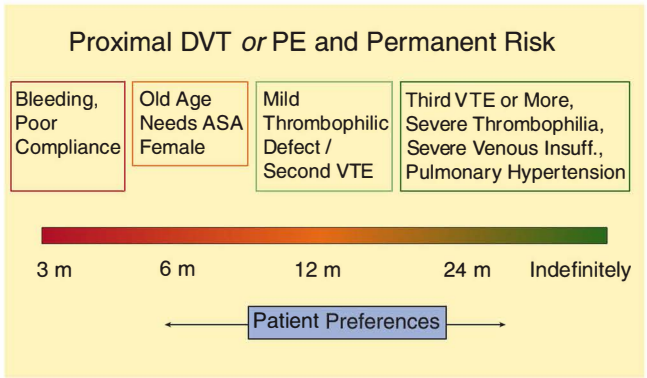

FIGURE 104.2 Individual decision tool for duration of anticoagulation after unprovoked VTE. ASA, acetylsalicylic acid; PE, pulmonary embolism; DVT, deep vein thrombosis. (From Schulman S, Ogren M. New concepts in optimal management of anticoagulant therapy for extended treatment of venous thromboembolism. *Thromb Haemost* 2006;96:258–266.)

change with a preference for long-term treatment. This prediction is based on the eliminated need for frequent laboratory monitoring, dose adjustments, and limitations regarding diet and use of interacting drugs as well as possibly lower risk of bleeding compared to warfarin.[10]

The biochemistry and pharmacology of VKAs are described in Chapter 106, whereas the duration of secondary prophylaxis after VTE is discussed further in Chapter 87. The above-mentioned new anticoagulants are presented in more detail in Chapter 110.

COMBINATIONS OF ANTIPLATELET AGENTS AND VITAMIN K ANTAGONISTS—"TRIPLE THERAPY"

Whereas some thromboembolic conditions are more effectively prevented or treated with anticoagulants, others require antiplatelet agent(s). The former include VTE, stroke prophylaxis in atrial fibrillation or mechanical heart valves. Conversely, for patients with coronary stents, stroke prophylaxis in carotid stenosis, or secondary prophylaxis after acute coronary syndromes (ACSs), platelet inhibition seems to be the most effective strategy. The situation becomes complex when a patient has concomitant conditions from both of these groups. Typical scenarios are (a) a patient with atrial fibrillation, already receiving stroke prophylaxis with a VKA, and then due to ACS managed with percutaneous coronary intervention (PCI) and stent insertion or (b) anterior myocardial infarction with development of left-ventricle aneurysm and thrombus but also treated with primary PCI and insertion of a stent.

Combinations with an increasing number of antithrombotic agents augment inevitably the risk of bleeding. In a registry study on more than 400,000 patients, the risks for bleeding with different agents and combinations were compared (Table 104.2).[28] The risk of bleeding requiring hospitalization in patients with triple therapy was 12.0% per year, which reasonably corresponds to the 1st year since hardly any patients receive this combination longer than that. The risk of bleeding is usually highest initially, partly due to proximity to invasive procedures and partly because patients with a high risk of bleeding will manifest the complication early and are thereafter weeded out. A meta-analysis of observational studies on triple therapy demonstrated a pooled bleeding rate of 2.2% during the 1st month.[29] With these two studies, it is plausible that the risk of major bleeding on triple therapy is 2% the 1st month and thereafter 1% per month. With aspirin + clopidogrel, the annual rate of bleeding is one-third of that on triple therapy.

The annual risk of stroke risk in patients with atrial fibrillation and a mean $CHADS_2$ score[30] of 2.0 is 5.5% for patients on aspirin + clopidogrel versus 3.7% for those continuing previous therapy with warfarin (relative risk 1.50), as shown in the ACTIVE W trial.[1] The annual risk of stroke without prophylaxis according to the $CHADS_2$ risk stratification is 1.9 for score 0, 2.8 for 1, 4.0 for 2, 5.9 for 3, 8.5 for 4, 12.5 for 5, and 18.2 for 6.[30] Warfarin reduces this risk by 67%. The bleeding risk increases also with the $CHADS_2$ score but not as much as the stroke risk. In an Italian study, the high $CHADS_2$ scores were a risk factor, independent of age and associated with approximately a doubling of the bleeding rate.[31] From this information, the excess risk of bleeding with triple therapy versus aspirin + clopidogrel and the excess risk of ischemic stroke with aspirin + clopidogrel versus triple therapy can be calculated for different $CHADS_2$ scores (FIGURES 104.3 and 104.4). The excess risk of

Table 104.2

Annual risks and adjusted hazard ratios for bleeding requiring hospitalization on antithrombotic therapy in patients with myocardial infarction

	Annual Incidence (%)	Adjusted Hazard Ratio	95% Confidence Interval	Number Needed to Harm
One Drug				
Aspirin	2.6	Reference		Reference
Clopidogrel	4.6	1.33	1.11–1.59	115.7
VKA	4.3	1.23	0.94–1.61	165.9
Two Drugs				
Aspirin + clopidogrel	3.7	1.47	1.28–1.69	81.2
Aspirin + VKA	5.7	1.84	1.51–2.23	45.4
Clopidogrel + VKA	12.3	3.52	2.42–5.11	15.2
Three Drugs				
Aspirin + clopidogrel + VKA	12.0	4.05	3.08–5.33	12.5

Adapted from Sørensen R, Hansen ML, Abildstrom SZ, et al. Risk of bleeding in patients with acute myocardial infarction treated with different combinations of aspirin, clopidogrel, and vitamin K antagonists in Denmark: a retrospective analysis of nationwide registry data. *Lancet* 2009;374:1967–1974.

bleeding is always higher than the excess risk of ischemic stroke, for any duration of therapy and for any $CHADS_2$ score. The excess bleeding risk with triple therapy is so much higher than the excess stroke risk with aspirin + clopidogrel for the low $CHADS_2$ scores that it seems unreasonable to recommend triple therapy. This is the case even if only 20% to 25% of the major bleedings are intracranial. However, for the high $CHADS_2$ scores and with drug-eluting stents, requiring 6 to 12 months of aspirin + clopidogrel, it may be justified to add warfarin, if most of the excess bleedings are gastrointestinal.

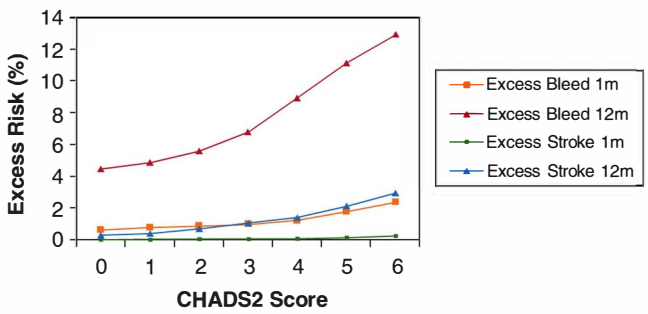

FIGURE 104.3 Excess risk of bleeding with triple therapy (aspirin + clopidogrel + warfarin) versus aspirin + clopidogrel compared to excess risk of stroke with aspirin +clopidogrel versus triple therapy for patients with atrial fibrillation and different risk levels for stroke according to $CHADS_2$ score. (Adapted from Gage BF, Waterman AD, Shannon W, et al. Validation of clinical classification schemes for predicting stroke: results from the National Registry of Atrial Fibrillation. *JAMA* 2001;285:2864–2870.) Results are shown for 1 month of therapy (*bare metal stent*) and for 12 months (*drug-eluting stent*). See text for further explanation.

Aspirin and clopidogrel have drawbacks with interindividual differences in efficacy and lacking a reliable laboratory method to predict the clinical response. New antiplatelet agents such as the direct-acting ADP-receptor $P2Y_{12}$-inhibitor ticagrelor seem to be more predictable than clopidogrel and may change the scenario for complex patients.[32] Bleeding complications on anticoagulant treatment are discussed in more detail in Chapter 107 and the old and new antiplatelet drugs are described in Chapter 111.

Several new drugs for humans have their origin in the animal kingdom or sometimes from the most primitive organisms (streptokinase from streptococci). Refined derivatives of animal proteins may prove very useful with improved risk: benefit ratio. One example is bivalirudin,[33] developed from the salivary protein hirudin from the medicinal leech. Procoagulant proteins from animals are useful as components in coagulation assays. These topics are dealt with in Chapter 113.

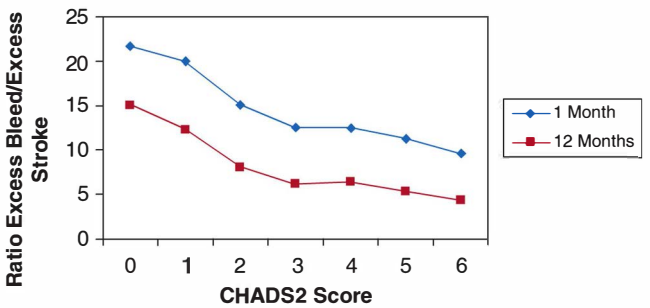

FIGURE 104.4 Ratio of risk of excess bleeding (with triple therapy) to risk of excess stroke (with aspirin + clopidogrel), based on results in FIGURE 104.3.

Despite all advances in drug therapy, there are sometimes important contraindications to the use of anticoagulants, treatment failures, or large limb- or life-threatening thrombi. In those situations, mechanical devices or mechanical thrombus removal may be required, as described in Chapter 114.

CHAPTER

105 Pharmacology and Mode of Action of Heparin and Glycosaminoglycans

MEYER MICHEL SAMAMA, JEANINE M. WALENGA, EVI KALODIKI, AND JAWED FAREED

Heparin belongs to a class of linear acidic polysaccharides known as glycosaminoglycans (GAGs). Unfractionated heparin (UFH) came into clinical use in the 1930s, making extracorporeal circulation and cardiovascular surgery possible. Despite its discovery almost 100 years ago, heparin is still a life-saving compound, crucial for procedures such as treatment of deep venous thrombosis (DVT), pulmonary embolism (PE), and acute coronary syndrome (ACS), as well as for anticoagulation in surgery, interventional cardiology, and hemodialysis.

Low molecular weight heparins (LMWHs) are depolymerized heparin derivatives developed in the 1980s, with pharmacologic profiles distinct from UFH.[1] Other heparin-related GAGs (heparinoids) of clinical interest include heparan sulfate, dermatan sulfate, chondroitin sulfate, and heparinoids.

There have been major developments recently for new anticoagulant drugs including advancements in new oral anticoagulants. However, heparins continue to be widely used as a clinical anticoagulant.

UNFRACTIONATED HEPARIN

History of the Discovery of Heparin

Jay McLean[2] discovered heparin in 1916 by serendipity. He was at that time a medical student in the physiology laboratory of William Henry Howell at Johns Hopkins University Hospital in Baltimore, working on dog liver in search of a procoagulant substance, not an anticoagulant.[3,4,5]

The first publication was authored by McLean[2] without the name of Howell, who was skeptical that a real anticoagulant had been discovered. Yet Howell made McLean fight the rest of his life for recognition that the great discovery of heparin was in fact McLean's.

Howell[6] gave the term heparin (Greek for liver "hepar") to the anticoagulant material discovered by McLean. Finally in 1963, 6 years after McLean's death, the New York Academy of Medicine presented to Johns Hopkins a plaque in recognition of McLean's work.[4,7]

Several researchers worked on the purification of heparin including Charles Best.[8] The story of heparin also includes a history of the discovery of its primary mechanism of anticoagulant activity through binding to the endogenous protease inhibitor antithrombin (AT),[9,10] as outlined (see also Chapter 18):

- 1895: Discovery of thrombin inhibition by AT[11]
- 1916: Discovery of heparin (McLean)[2]
- 1935: Heparin active only in the presence of heparin cofactor (Brinkhous)[9]
- 1950: Confirmation of AT as heparin cofactor (Seegers' group and others)[12,13]
- 1968: Isolation of AT (Abildgaard)[10]
- 1973: Procedure to obtain large amounts of AT (Rosenberg)[14]
- 1976: AT-binding site separation of active and inactive heparin[15]
- 1980: Heparin oligosaccharides with only anti–factor Xa (anti-FXa) activity (Lindahl; Choay)[13,16]

The ultimate proof of AT as a cofactor for the anticoagulant activity of heparin was provided by a specific pentasaccharide sequence[17] and its subsequent chemical synthesis,[16,18] which became the pharmaceutical compound fondaparinux.

Chemistry of Heparin

Heparin is a heterogeneous natural polysaccharide (FIGURE 105.1), the complexity of which makes its study of pharmacologic characteristics difficult.[19,20]UFH is a biologic product isolated from mammalian tissues, most commonly porcine intestinal mucosa or bovine lung. Heparin is synthesized in these tissues by mast cells as part of a high molecular weight (MW) proteoglycan (MW 750,000–1,000,000 Dalton [Da]), which consists of a center core protein composed of 20 to 25 residues each of glycine and serine.[21] There are 15 carbohydrate chains[22] (MW 40,000 to 300,000 Da) attached to the core peptide via a galactosyl–galactosyl–xylosyl trisaccharide sequence.[23–25] These chains are polymers of disaccharide repeats that are highly sulfated and therefore negative in charge. Polysaccharide chain elongation and a series of modification reactions of the polymer occur in the final synthesis step.[26,27]

The GAGs attached to the proteoglycan central core protein include chondroitin sulfate, heparan sulfate, and heparin.[28] Chondroitin sulfate is composed of repeats of glucuronic acid and D-acetyl galactosamine with sulfate groups in the 4 or 6 position of the galactosamine. Its sulfate/carboxylate ratio is equal to 1.0; its sulfur content is ≥5%. Dermatan sulfate is a copolymer composed of repeated iduronic acid and D-galactosamine. It has anti–factor IIa anticoagulant activity.

Heparan sulfate consists of repeats of glucuronic or iduronic acid and *N*-acetylglucosamine. Total sulfate content and sulfate/carbohydrate ratios differ between GAG types, which play a role in the biologic processes of tissue physiology,[29] particularly cell adhesion, cell migration, and cell differentiation, as well as in coagulation, fibrinolysis, and inflammation.[28]

Four enzymatic modifications of the polysaccharide backbone occur following its synthesis. The majority of the *N*-acetyl groups on the glucosamine residues are removed,[30] and the *N*-deacetylated glucosamines are subsequently sulfated. In the next step, D-glucuronic acid residues are epimerized to L-iduronic acid units by uronosyl C-5 epimerase.[31,32] During the epimerization process, most iduronic acids are 2-O sulfated.

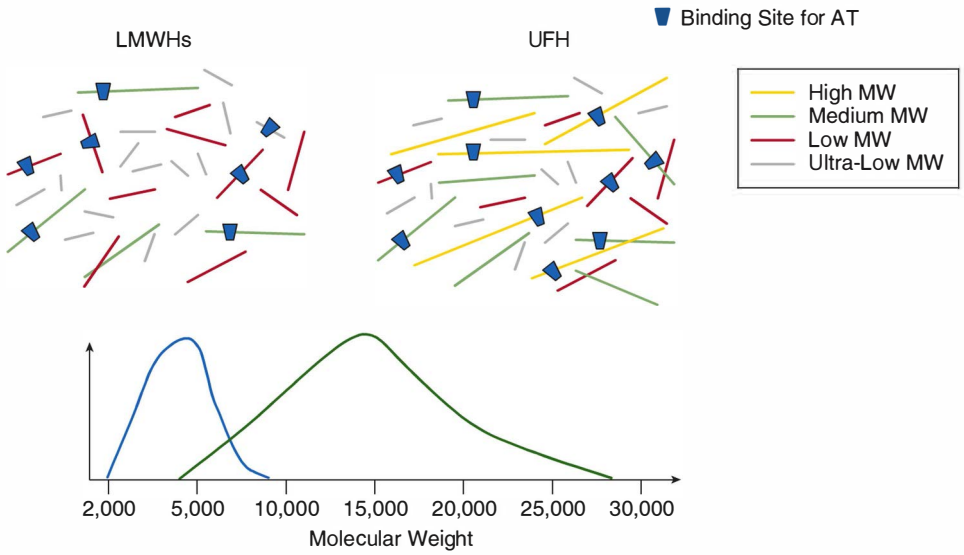

FIGURE 105.1 Characteristics of UFH and LMWHs (Source Material = Porcine Intestinal Mucosa Heparin).

Finally, 3-O and 6-O sulfate groups are added onto the glucosamine units. *N*-sulfation allows more efficient O-sulfation to occur.[22]

Heparin consists of a mixture of GAG chains that are made of disaccharide subunits and possess a reducing end and a nonreducing end (FIGURE 105.2). The heparin backbone is composed of alternating sugar units of α-D-glucosamine (*N*-sulfated, or *N*-acetylated, O-sulfated) and O-sulfated uronic acids (α-L-iduronic acid or β-D-glucuronic acid).[33] It is the linear pattern of the disaccharide units and the placement of specific disaccharide units within a certain chain length that impart the various and heterogeneous biologic activities of heparin. The most notable illustration of the heterogeneous sulfation pattern is the presence of a particular 3-O sulfate group required for specific interaction of heparin with AT.[34] This 3-O sulfate group is present on only a small percentage of heparin chains.

The mean MW of UFH is around 12,000 to 15,000 Da, with individual polysaccharide heparin chains varying in MW from 3,000 to 30,000 Da (FIGURE 105.1).[19,35]

Models for Evaluation of Anticoagulant Activity of Heparin

The Wessler model of human serum-induced thrombosis (1959), based on the teachings of Virchow,[36] was a commonly used model to determine whether heparin fractions and LMWHs possessed an anticoagulant effect. In this model, an intravenous (IV) serum injection is followed by ligation of an isolated segment of the jugular vein.[37] After a 10- or 20-minute period, a full red cell-fibrin thrombus forms in controls, but clot formation is inhibited in the presence of an anticoagulant. Variations of this thrombosis model utilize thromboplastin, activated prothrombin complex concentrate,

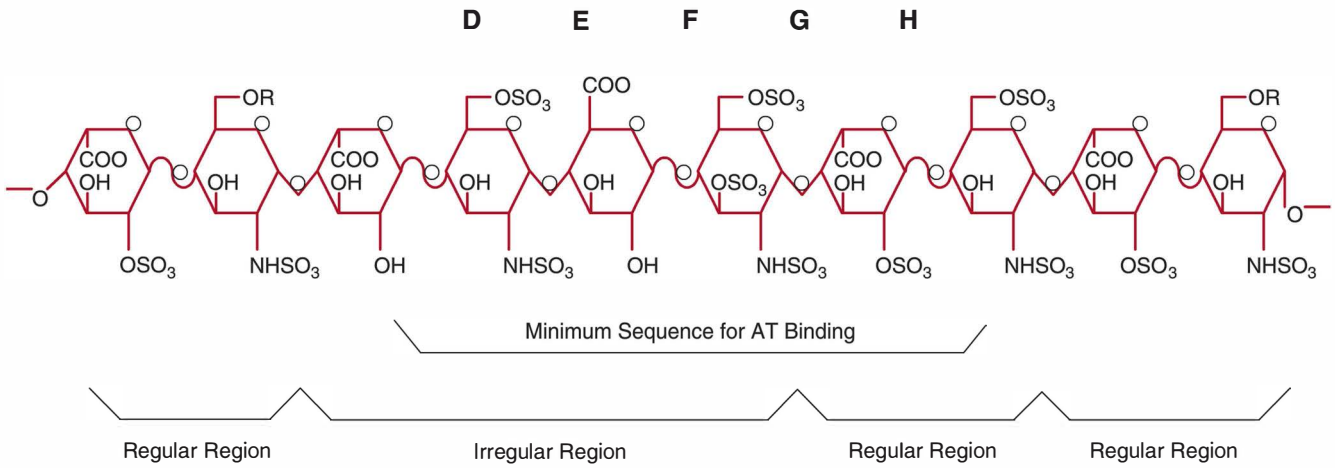

FIGURE 105.2 Heparin chains are a mixture of heterogeneous saccharide unit sequences. An example of the linkage of the disaccharide subunits of heparin is shown. The specific pentasaccharide with high affinity binding to AT is represented by the DEFGH sequence.

or factor Xa as the thrombogenic stimulus.[38] Vena cava ligation using a steel coil, collagen, or kaolin has also been used.[39] These methods are reproducible and allow for the evaluation of the antithrombotic activity of pharmaceutical preparations.[40,41]

Investigations of the anticoagulant activity of heparin and LMWHs in the arterial system were largely performed in a model of vessel wall damage-induced thrombosis using chemical damage ($FeCl_3$), mechanical crushing, or electrical stimulation.[42,43] The Folts model using stenosis and compression injury of the right common carotid artery in the rabbit was another popular model.[44,45]

Mechanisms of the Anticoagulant Action of Heparin

The anticoagulant effect of heparin is primarily attributed to inhibition of the serine protease coagulation factors mediated through heparin binding to these plasma proteins.[46] The most important anticoagulant activities are the inhibition of the coagulation factors thrombin (factor IIa) and factor Xa by heparin bound to AT.

Heparin has a polycomponent anticoagulant mechanism inhibiting numerous coagulation factors, inhibiting platelet function, and enhancing the antithrombotic functions of vascular endothelium as well as fibrinolysis. In addition, by inhibiting thrombin, heparin affects thrombin-mediated coagulation mechanisms involving factor V, factor VIII, protein C, and thrombin activatable fibrinolytic inhibitor (TAFI). It also releases tissue factor pathway inhibitor (TFPI),[1,47] inhibits the release of P-selectin (an adhesion molecule that in the presence of tissue factor and microparticles modulates the interaction between thrombosis and inflammation),[48,49] impairs vascular barrier properties, and attenuates nitric oxide-mediated vasodilatation during dynamic changes in blood flow.[50]

Antithrombin

The primary mechanism of heparin is through association with AT, a 55,000-Da single-chain glycoprotein, with a plasma concentration of 2 to 3 μM.[51–53,54] Heparin binding produces an allosteric modification of AT, which promotes stable complexes, exposing the arginine-385 residue of AT, allowing for interaction with the serine-active site of coagulation enzymes.[14,54,55,56]

In the presence of heparin, inhibition of coagulation is accelerated 300 to 2,000-fold more than by AT alone.[14,57–59] Some of the higher MW heparin chains possess two binding sites for AT (FIGURE 105.3).[60] The longer heparin chains (i.e., chains of >18 saccharide units; >5,400 Da) bind both AT and the activated coagulation factor, whereas the shorter heparin chains (e.g., pentasaccharide; 1,727 Da) bind only AT.[61–63] Single-site binding of short heparin chains to AT is sufficient to inhibit factor Xa (anti-FXa activity), whereas a second binding site on the higher MW heparin chains is required for the binding and inhibition of thrombin (anti-FIIa activity), FXIIa, FIXa, kallikrein, etc. Thrombin is 10-fold more sensitive to inhibition than factor Xa.

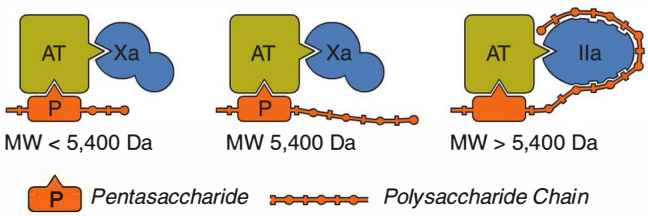

FIGURE 105.3 Schematic representation of the interaction of heparin, AT, FXa, and thrombin.

Structure-activity studies have identified a unique minimum saccharide sequence that binds with high affinity to AT (FIGURE 105.2), causing inhibition of FXa but not thrombin.[41] Heparin chains that lack this particular pentasaccharide sequence have minimal anticoagulant activity.[34]

Heparin-bound AT weakly inhibits coagulation factors IXa, XIa, and XIIa, as well as the enzymes trypsin, plasmin, and kallikrein,[61,64] and requires high concentrations of AT (~5 units). A weak inhibitory activity of this complex toward factor VIIa has been described, but the mechanism is unknown.[65]

Heparin Cofactor II

Heparin cofactor II (HCII) is a second plasma inhibitor (MW 60,000 Da) that binds heparin and inhibits thrombin by forming a 1:1 stoichiometric complex with the enzyme. Thrombin interacts with the active site of HCII on the C-terminus and forms a covalent bond.[64] The reaction of HCII and heparin is charge and chain length dependent, but independent of the pentasaccharide sequence.[18]

Whereas the activation of AT is dependent upon a specific sequence in the heparin chain, HCII can be activated by a wide variety of agents, including heparin, heparan sulfate, dermatan sulfate, pentosan polysulfate, and dextran sulfate.[66–68] Agents with relatively little sulfation such as chondroitin 4-O- or 6-O-sulfate, keratan sulfate, and hyaluronic acid do not activate HCII.[69] High and low AT affinity fractions of heparin equally activate HCII if charge density is equal.[70]

Tissue Factor Pathway Inhibitor

TFPI (MW 42,000 Da) is a coagulation protease inhibitor synthesized in the vascular endothelium,[71,72] the largest pool of which is bound to the endothelial cell surface.[47,73,74] Also found in plasma and platelets,[75] TFPI has three Kunitz domains linked in tandem between a negatively charged amino terminus and a positively charged carboxy terminus.[76] TFPI simultaneously binds to and inhibits the factor VIIa–tissue factor complex and FXa via two of its Kunitz domains.

Heparin displaces TFPI bound to endogenous GAGs on the surface of the endothelium.[77–79,80,81] Repeated heparin administration releases TFPI showing no diminishing releasability with TFPI levels reaching 2- to 10-fold over baseline.[77] LMWHs have a variable effect on TFPI release.[82] Neutralization of heparin by protamine sulfate results in a dramatic decrease in the plasma TFPI level.[83,84] The anticoagulant activity of TFPI can be detected by the prothrombin time (PT), the activated partial thromboplastin time (aPTT), and clot-based anti-FXa assays.[85–87]

Other Anticoagulation Properties of Heparin

Platelets

Heparin is a weak platelet agonist, but is also a potent inhibitor of platelet activation induced by thrombin, the LMWHs less so.[88] A weak or no response occurs with very low MW heparins (<3,000 Da), having almost no reactivity on ADP, collagen, epinephrine, and thrombin-induced platelet aggregation. Heparin also binds to and inhibits von Willebrand factor

(vWF), the clinical implication being a reduction of thrombotic risk in general and control of platelet–endothelium interactions in specific.[89] The weaker antiplatelet effect of LMWHs also is associated with a lower bleeding risk, along with a lesser antithrombotic effect than for UFH. The role of low affinity material which does not contain the binding site of AT is not well documented.[90–93]

Fibrinolysis

A weak profibrinolytic effect has been described,[94] but this was not clearly related to the MW of heparin.[95,96] Heparin regulates tissue plasminogen activator and plasminogen activator inhibitor release from endothelial cells, and the anti–FIIa activity of heparin induces a reduced activation of TAFI that facilitates fibrinolysis.[97,98] An increase in the porosity of the fibrin network has been demonstrated.[99] At comparable anti-FXa *in vitro* concentrations, LMWHs exhibit different profibrinolytic activities.[100] The clinical significance of these results remains to be established.

Nonanticoagulant Properties of Heparin

In addition to the heterogeneous mixture of saccharide chains, heparin also contains three functional groups that occupy multiple sites on its individual saccharide units: $-OSO_3^-$, $-NHSO_3^-$, and $-COO^-$.[19,28] This structural diversity induces a diverse range of nonanticoagulant properties. Only 20% to 30% of GAG components produce anticoagulant activity by binding AT, the other 70% to 80% exhibit multiple biologic actions that are only partially understood.[29,101]

Heparin and heparan sulfate are found on cell surfaces, in the extracellular matrix, and in intracellular granules. These GAGs can interact with a large number of proteins and biologic activities of cell proliferation, inflammation, angiogenesis, viral infectivity,[102] and cell function.[103]

Heparin-binding Proteins

Heparin-binding proteins can be divided into 1) proteins that enhance the anticoagulant activity such as AT and HCII found in blood and released by heparin such as TFPI and lipase and 2) proteins that inhibit the anticoagulant activity of heparin such as PF4, histidine-rich glycoprotein (HRG), protamine, and vitronectin.[28,104–106,107] Some of these interactions are dependent on the MW of the heparin molecules, while others require calcium ions.[106]

There are different types of heparin binding.[22,107,108] The first type relates to a specific saccharide sequence of heparin, present on only one-third of the heparin chains, the second is covalent bonding, and the third depends on charge density and chain length.

Histidine-rich Glycoprotein

HRG belongs to the group of proteins that neutralize heparin anticoagulant activity.[109,110] It has an MW of 75,000 Da, has a plasma concentration of approximately 100 mg/L, and binds to heparin and LMWHs. However, only the long-chain fragments of heparin have both anti-FXa and anti–FIIa activities completely neutralized.[106,111] The antiheparin action of HRG requires calcium.[109]

Vitronectin

Vitronectin, also called complement S protein, is present in the plasma (about 400 mg/L) and in the extracellular matrix. Binding of vitronectin to UFH or LMWHs is associated with neutralization of the anticoagulant activity, but this antiheparin effect is of minor importance.[112]

Vascular Cells

The direct interaction of endothelial cells with heparin depends on the MW of the heparin.[113] Once attached, heparin molecules lose their anticoagulant effect and are internalized. Heparin also binds to smooth muscle cells, which could play a role in atherosclerosis.[114,115] LMWHs and pentasaccharide have the same beneficial activity against atherosclerosis.[116] Heparin interacts with endothelial cell growth factors, which results in an enhanced mitogenic activity at the vascular cell lining.[117]

Platelet Factor 4

Heparin bound to PF4 produces an immunogenic response that can lead to the potential life-threatening disorder of heparin-induced thrombocytopenia (HIT)[118–121] (Chapter 108).

Lipases

Lipoprotein lipase and hepatic lipase are two critical enzymes in lipid and lipoprotein metabolism.[122,123] They are released after an IV injection of heparin or LMWH. Repeated injections of heparin or LMWH do not exhaust the release.[124] Elevated levels cause a lipid-clearing lipolytic effect on the blood that is less for LMWHs than for heparin.[125] Lipase release is associated with an anti-FXa activity that is not neutralized by protamine or PF4.[126,127]

Anti-inflammatory Effect

Heparin has anti-inflammatory actions, for example, in inflammatory bowel disease[128,129] and ulcerative colitis.[130] Removal of the 2-0, 3-0 sulfate groups of heparin reduces its anticoagulant activity without impacting its anti-inflammatory effect.[131] Heparin inhibits the release of P-selectin from platelets and endothelial cells and also binds to P-selectin and L-selectin and CD11b/CD18 expressed on leukocytes.[132] Heparin also binds to components of the complement cascade, reducing activation, a process that may account for the reduced early phase of the asthmatic reaction with inhaled heparin, and for protection of the heart from ischemic reperfusion injury.[133–135] Heparin binding to cytokines inhibits the recruitment of neutrophils and reduces proinflammatory cytokine levels, thereby producing immunomodulating and anti-inflammatory actions.[134–136]

Antineoplastic Effect

A link between improved survival and heparin treatment was suggested by Lebeau[137] in cancer patients receiving heparin or LMWH for the prevention or treatment of venous thromboembolism (VTE),[137] an observation that launched fundamental research and clinical trials.[138–141] In both animal studies and clinical trials, heparin has an antiproliferative property, whereby it inhibits cell growth, cell adhesion, cellular microparticle formation, smooth muscle cell proliferation, and tumor growth.[133,142–145,146,147] Fondaparinux is inactive in these respects.[138,139] Heparin has been postulated to have an antimetastatic effect due to a decrease in neoangiogenesis, possibly mediated by binding to vascular endothelial growth factors, cytokines, and adhesion molecules. Heparin could inhibit metastasis by interference with P- and L-selectin–moderated cell–cell interactions. Other mechanisms have been attributed to the modulation of the angiogenic activity of fibroblast growth factor by heparin[140–145,146,147,148] or by nonanticoagulant components that inhibit cancer growth.[149]

Pharmacokinetics of Heparin

Heparin (sodium or calcium salt) is administered either by IV bolus injection followed by continuous infusion or by subcutaneous (SC) injection. Upon entering the blood stream, heparin binds to a variety of plasma proteins, thereby lowering its bioavailability and producing a variable anticoagulant response.[150] Major binding proteins include HRG, PF4, fibronectin, vitronectin, and vWF.[106,111,151–153] Heparin chains of varying MW exhibit different binding capacities reflected in varying pharmacokinetic behavior, with shorter heparin chains exhibiting a higher and more reliable bioavailability and slower clearance than larger chains.

Heparin exhibits complex pharmacokinetics, and its anticoagulant effect is not linearly related to the dose.[35,154–156] The half-life of heparin's anticoagulant activity is approximately 1 hour at therapeutic doses;[157] it increases from 30 minutes following an IV bolus dose of 25 U/kg to 150 minutes following a dose of 400 U/kg.[158]

Heparin is cleared by two mechanisms. The rapid, saturable phase of elimination is due to receptor-mediated internalization of heparin by endothelial cells and macrophages,[158–160] while a slower, nonsaturable renal mechanism is also operative.[161–163] Accumulation of UFH is modest in severe renal deficiency in contrast to LMWH.

Alternative Routes of Heparin Administration

Attempts have been made to give heparin via oral, sublingual, rectal, nasal, pulmonary, topical, and transdermal routes of administration.

Intrapulmonary or Intranasal

Animal studies demonstrated that heparin is efficiently, rapidly, and reproducibly delivered through the lungs.[164,165] In a limited study, 16 VTE patients were treated with intrapulmonary heparin without adverse effects.[166] The intrapulmonary dose of LMWH needed to produce the same anti-FXa level and TFPI release as obtained with SC administration is about 10-fold higher as shown in healthy volunteers.[167]

Topical

Heparin and other GAGs have been shown to enhance the healing process when applied to the surface of an ulcer.[168,169] The mechanism may be through proteinases, which digest necrotic tissue, and the release of growth factors that accelerate granulation and epithelialization.

Oral

Oral heparin formulations have been developed, the prototype being a diamine salt that showed the importance of charge neutralization for transport across the gastrointestinal epithelium.[170,171] Heparin carriers with the highest bioavailability were chitosan/peg-alginate microspheres of heparin with 70% release,[172] nanoparticles with a blend of polyester and polycationic polymethacrylate with 51% to 59% release,[171] and sodium *N*-(8[2-hydroxybenzoyl]amino) caprylate (SNAC) with 38% release.[173] Other absorption enhancers are abrasol, gelucire, and thiolated polymers in combination with reduced glutathione, biodegradable (poly-epsilon-caprolactone and poly-lactic-co-glycolic acid) and nonbiodegradable polycationic polymers. While preclinical and clinical studies suggested that the heparin–SNAC combination facilitated higher absorption of heparin, the clinical development has stalled.[174,175]

Contamination of Heparin

In early 2008, the US Federal Drug Administration recalled several batches of heparin due to the increased incidence of adverse reactions and death.[176] Fatal hypotension from anaphylactoid-type reactions following heparin administration was responsible for over 149 deaths worldwide.[177] Researchers identified a heparin-like semisynthetic contaminant, which was oversulfated chondroitin sulfate (OSCS), in significant amounts (5% to 30%) that appeared to be an intentional adulteration of therapeutic heparin.[177] Varying degrees of high MW dermatan sulfate and heparan sulfate were also detected.[176,178,179] Because LMWHs are produced from UFH, OSCS was also found in various batches of LMWHs.[177,180]

Potency Designation and Standardization of Heparin

The heparin contamination issue that occurred in 2007 to 2008 led the United States Pharmacopeia (USP) to rewrite the heparin monograph in 2009. Simultaneous with the changes to the monograph, the USP instituted a new heparin reference standard, with the intent to harmonize the US heparin unit with the European Pharmacopeial Commission heparin unit based on International Standard for heparin issued by the World Health Organization.

LOW MOLECULAR WEIGHT HEPARINS

Differences Between LMWHs and UFH

The LMWHs are prepared by controlled depolymerization from porcine mucosa-derived heparin (FIGURE 105.1). The LMWHs have approximately one-third the MW of the parent material (MW 3,000 to 10,000 Da) with a mean MW around 5,000 Da (Table 105.1).[181] The different depolymerization processes also cause partial desulfation, reduction in charge density, and other changes in the heparin saccharide chains (Table 105.2).

Table 105.1

Biochemical and pharmacologic characteristics of UFH and LMWH

	UFH	LMWHs
Mean MW (Da)	15,000	5,000
Anti-FXa/anti–FIIa ratio	1	2–7
Bioavailability at small doses	Poor	Very good
Binding to endothelium	Yes	Low
Dose-dependent clearance	Yes	No
Affinity for plasma protein binding	High	Low
Neutralization by protamine	Yes	Partial
Heparin-induced thrombocytopenia	Rare	Very rare
Osteoporosis	Rare	Very rare

Table 105.2

Characteristics of LMWHs

Depolymerization Method	MW (Da)	Anti-FXa (U/mg)	Anti-FIIa (U/mg)	Ratio
Alkaline depolymerization				
• Enoxaparin	4,034	105	27	3.9
Heparinase depolymerization				
• Tinzaparin	4,500	83	45	1.8
Nitrous acid				
• Nadroparin	4,279	95	27	3.5
• Reviparin	4,395	130	40	3.3
• Dalteparin	5,663	130	58	2.2
• Certoparin	4,959	88	32	2.8
Peroxidative cleavage				
• Parnaparin	3,190	88	30	2.9
• Ardeparin	6,000	100	30	2.0

Impact of manufacturing processes.
Different manufacturing processes produce different LMWH products.

The LMWHs are similar to UFH in their biologic properties yet, because of their lower MW, certain of their biologic properties differ.[181,182] Only heparin molecules that contain at least 18 saccharides (corresponding to a MW of ~5,400 Da) simultaneously bind to AT and thrombin, which is required for the inactivation of thrombin by the heparin–AT complex. Smaller heparin molecules are only able to bind to AT and catalyze the inactivation of FXa.[182] By definition, the ratio of anti-FXa activity to anti–FIIa activity for UFH is 1, whereas the ratio for the originally developed LMWHs ranges from two to four.[181] Newer LMWHs have ratios up to 7.

The LMWHs in experimental models of venous thrombosis are active antithrombotic agents.[183] The increased specificity for anti-FXa activity with LMWHs seems to result in the inhibition of thrombosis with a reduced risk of bleeding.[158,181] Reduced molecular size also decreases nonspecific binding of LMWHs to plasma proteins.[184] Specifically, LMWHs exhibit less interaction with PF4, resulting in a reduced risk of HIT.[185,186]

The pharmacologic differences between LMWHs and UFH result in several practical advantages for LMWHs. First, the bioavailability following SC administration is much higher with LMWHs.[35,187] As a consequence of reduced binding to cells and plasma proteins, LMWHs have a longer half-life, 3 to 6 hours, with more predictable anticoagulation.[187] These properties permit convenient once-daily or twice-daily SC administration without the need for routine monitoring or dose adjustments[187] (Tables 105.3 and 105.4). After SC administration, circulating anti-FXa activity is not detectable in samples collected 12 hours after the administration of prophylactic doses of LMWHs.[182]

Distinct Biochemical and Biologic Properties of Different LMWHs

Commercial LMWH preparations are derived from heparin using a number of different depolymerization processes to cleave the longer saccharide chains (Table 105.2). Each manufacturer uses a distinct chemical (β-elimination, nitrous acid, oxidative cleavage), enzymatic (β elimination), or physicochemical (γ irradiation) process; thus specific LMWH products differ substantially from one another in their physical structure, biologic properties, and pharmacologic properties.[181,184,187,188]

Although the average MW of LMWHs is similar, the proportion of the different saccharide chain lengths differs within each LMWH, and the end-residue alterations of the heparin fragments are specific to the depolymerization method.[189] Some LMWHs are characterized by the presence of a sulfated pentose at the reducing end of the molecule or double bonds at the reducing terminus.[181,188] Although enoxaparin and tinzaparin are derived via β-elimination reactions, only enoxaparin contains specific 1,6-anhydromanno and 1,6-anhydrogluco groups at the reducing end.[190]

Studies comparing different LMWHs using standard analytical methods have demonstrated considerable biochemical differences between the different products.[181,191–193] The anti-FXa

Table 105.3

Clinical Indications for UFH

1. Prophylaxis of VTE[251,252]
2. Treatment of VTE[251,252]
3. Prophylaxis and treatment of atrial fibrillation with systemic embolization
4. Treatment of acute and chronic consumptive coagulopathies (disseminated intravascular coagulation)
5. Prevention of clotting in cardiac surgery
6. Prevention of clotting in hemodialysis procedures
7. As an anticoagulant in:
   i. blood transfusions
   ii. blood samples for laboratory purposes

Table 105.4

Clinical Indications for LMWHs

1. For VTE prophylaxis:
   After total hip and knee replacement surgery[253]
   After abdominal surgery[254]
   In high-risk medical patients[255]
2. For the treatment of VTE
3. For long-term prophylaxis against VTE in pregnant women[256]
4. For long-term secondary prophylaxis after VTE in cancer[146]
5. For treatment of unstable angina[257]
6. In thrombolytic therapy
7. For treatment of superficial thrombophlebitis[258]

activities ranged from 80 to 160 international units (IU)/mg, and the anti-FXa:anti–FIIa ratios ranged from 2:1 to 8:1.[193] The HCII affinity, thrombin generation inhibition, PF4 and protamine neutralization, cellular interactions, and release of mediators from the vascular endothelium also vary from product to product.[184,194]

The clearance half-life is not dose dependent in contrast to UFH.[195] The LMWHs are cleared by the kidney, and their biologic half-life is prolonged in patients with renal failure.[196,197] Bioaccumulation of LMWHs at prophylactic doses can be observed in patients with various degrees of impaired renal function and weight extremes, more pronounced for some LMWHs.[198–200] Pharmacologic studies have demonstrated significant differences among the various LMWHs.[184,201,202,203] Differences in efficacy and hemorrhagic risk have also been demonstrated with different LMWHs,[35] suggesting that LMWHs are not clinically interchangeable.

Generic/Biosimilar LMWHs

Several biosimilar LMWHs have been developed and are available worldwide. The biosimilar LMWHs have a similar average MW and anti-FXa potency as their branded counterpart, but biologic and pharmacologic behaviors have not been proven to be the same.[204–209]

SYNTHETIC HEPARIN PENTASACCHARIDE AND ITS DERIVATIVES

Fondaparinux

Fondaparinux (MW 1,727 Da) was the first of a new class of antithrombotic agents distinct from LMWHs and UFH.[210] It is a chemically synthetic pentasaccharide mimicking the active site of heparin that binds to AT, exhibiting only factor Xa inhibitory activity leading to an inhibition of thrombin generation.[18] There is nearly complete bioavailability by the SC route, rapid onset of action, a prolonged half-life in both IV and SC dosing regimens, and it is renally excreted.[211]

While fondaparinux was more effective than enoxaparin in reducing asymptomatic DVT in orthopedic surgery patients, hemorrhagic complications were either comparable to or more frequent than those for the LMWH.[211] Fondaparinux has been used in a limited number of cases with HIT, since it has a low cross-reactivity with heparin antibodies.[212] However, there have also been very rare cases of HIT reported where fondaparinux was implicated.[213]

Idraparinux and Idrabiotaparinux

A long half-life of fondaparinux derivative, idraparinux (1,729 Da), has been obtained by incorporating an additional 3-O-sulfate group in the glucose moiety at the reducing end of the fondaparinux molecule and additional methyl groups.[190,214] This alteration in the chemical structure causes a significantly stronger binding to AT, increased potency to inactivate factor Xa via AT, and increased half-life of elimination (120 to 200 hours), allowing for a weekly rather than a daily SC administration. The complete pharmacokinetic profile is complex and not well understood. After weekly SC administration of 2.5 mg idraparinux over 12 weeks, the elimination half-life increased to about 600 hours, and in clinical trials the elimination half-life was about 60 days after reaching steady state.[215] In clinical application, idraparinux showed a higher risk of PE recurrence compared to warfarin.[216,217] In patients with atrial fibrillation, idraparinux was equivalent to warfarin in terms of efficacy but caused more bleeding.[218] A biotinylated form of idraparinux/idrabiotaparinux (1,853 Da) can be specifically neutralized by the IV administration of avidin.[219] The biotin arm does not interfere with the AT-dependent inhibition of FXa.

DANAPAROID AND RELATED HEPARINOIDS

Danaparoid has been in clinical use for more than 20 years for the prevention and treatment of thrombosis, during pregnancy (does not cross the placenta and is not excreted in breast milk) and hemodialysis.[220] Danaparoid is a mixture of low MW GAG components that result from the manufacture of UFH, mainly comprising heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%), obtained without further depolymerization. Danaparoid has a mean MW of 5,500 Da, half-life approximately 18 hours, and biologic and pharmacokinetic profiles distinct from UFH and LMWH.

Danaparoid has a weaker anti-FXa activity than LMWH, but multiple other biologic targets of danaparoid exert profound effects on cellular responses (anti-inflammatory[221] and antiulcer) and protease regulation by mechanisms other than those mediated by AT and HCII. Despite the sustained anticoagulant activity, the risk of bleeding with danaparoid is low (except in cardiopulmonary bypass where major bleeding can occur).

Due to low cross-reactivity with heparin antibodies, danaparoid has been used to treat patients with HIT.[220] Potential other clinical uses include anticoagulation for percutaneous coronary intervention and treatment of ACS, leg ulcers, cancer, sepsis, and acute ischemic stroke.[222]

Other Heparinoids

Dermatan sulfate has been developed for the prophylaxis of venous thrombosis. Other heparinoids include heparan sulfate and sulfaminoheparosan derivatives derived from bacterial cell wall, but none of these drugs are in clinical use.[223]

LABORATORY MONITORING OF HEPARIN ANTICOAGULANTS

Heparin

The laboratory monitoring of heparin reduces the risk of bleeding and decreases the rate of thrombotic recurrences,[224,225] the therapeutic range of aPTT in patients receiving IV infusion being 1.5 to 2.5 times control.[226] The variability of aPTT to heparin is dependent on the reagent,[227,228] which can be selected with more sensitivity to heparin based on their lipid composition and the concentration of phospholipids.[229]

In an effort to standardize heparin monitoring, the therapeutic range of 1.5 to 2.5 times aPTT control was considered by the American College of Chest Physician (ACCP) as equivalent to 0.2 to 0.4 U/mL heparin by protamine titration or 0.35 to 0.70 U/mL by anti-FXa assay.[20,229] However, the concentration of heparin associated with an aPTT ratio of 1.5 to 2.5 also varies significantly with different reagents.[20,230,231] Since the aPTT ratio and the anti-FXa activity may be discrepant in a given patient, it is recommended by the ACCP that the dose in patients with heparin resistance, who require unusually high doses of heparin to achieve a therapeutic aPTT ratio, should be adjusted on the basis of anti-FXa levels rather than on the aPTT results.[20,232,233] In some groups of patients, often in intensive care units, an unusually low dose of heparin is sufficient to achieve a therapeutic aPTT ratio. The increased response to heparin could be due to congenital or acquired contact factor deficiency.[234] In these patients, monitoring heparin with a chromogenic anti-FXa assay would be a useful alternative.

Low Molecular Weight Heparins

Routine monitoring of LMWHs given at prophylactic doses is not required, but may be used in special clinical situations such as obesity, renal insufficiency, long-term treatment in pregnant women, and pediatric patients.[20] At prophylactic doses, the PT and aPTT are not significantly prolonged by LMWHs. Therapeutic doses prolong the aPTT, although to variable degree with different reagents.[227,228] The test recommended for laboratory monitoring of LMWHs is a chromogenic assay measuring anti-FXa activity,[225,235] the results being expressed in IU of anti-FXa, using a LMWH reference preparation for assay calibration.[225,236,237]

Fondaparinux

Routine monitoring is not required due to predictable pharmacokinetics. A chromogenic anti-FXa measurement can be used, with fondaparinux as the assay calibrator, the results then reported as fondaparinux concentration (μg/mL) and not in IU as for heparin.[238] The aPTT is not affected by fondaparinux.

Danaparoid

Routine monitoring is not required; if desired, the chromogenic anti-FXa measurement can be used with danaparoid as the calibrator.[239] The aPTT is not affected by danaparoid.

SIDE EFFECTS OF HEPARIN THERAPY

The most common side effect of heparin therapy is hemorrhage, which can range from minor to life threatening and is related to the total administered dose and the degree of prolongation of the aPTT rather than the route of administration. Fondaparinux and LMWHs have a lower bleeding risk. Although bleeding can be attributed to thrombin inhibition, the effect of these drugs on vascular endothelium and platelets also contribute to the bleeding. HIT occurs in 0.1% to 5% of patients treated with heparin[118] (see Chapter 108). A rare but potentially lethal acute "anaphylactic" reaction to heparin can also occur.[182] Heparin therapy is also associated with transient elevations in serum transaminase levels, which is likely not of clinical importance. Prolonged exposure to heparin can result in osteoporosis, and skin reactions, eosinophilia, alopecia, and hyperkalemia are rare complications.[182] Multiple anticoagulants, antiplatelet drugs, and thrombolytic drugs have an additive, even synergistic effect, and nonanticoagulant agents can affect the anticoagulant effects of heparin.

NEUTRALIZATION OF HEPARINS

The anticoagulant and bleeding effects of heparin are reversed with IV protamine sulfate and protamine chloride. Protamine is associated with hemodynamic effects, can cause severe hypotension if administered too rapidly,[240] and may also activate the complement system causing pulmonary vasoconstriction, pulmonary hypertension, and peripheral vascular collapse.[241] While protamine effectively neutralizes heparin, it has limited value in the neutralization of LMWHs,[242] only partially reversing the anti-FXa activity.[243] Protamine does not reverse the anticoagulant effect of fondaparinux. Several approaches have been unsuccessful as an antagonist for heparin and LMWHs, including recombinant PF4 and heparinase-1; a salicylamide derivative, PMX-60056, is under development.[244]

FUTURE HEPARIN-DERIVED DRUGS

UltraLow Molecular Weight Heparins

Recently, several newer depolymerized heparin-based agents have been developed, which mimic the anticoagulant and antithrombotic effects of heparin. These include the ultra-LMWHs such as AVE-5026 (semuloparin; enriched in AT-binding oligosaccharides) and bemiparin.[245,246] Several approaches to modify heparin have been used to obtain selective therapeutic agents, including hypersulfation, desulfation, oxidation; agents that have been clinically tested include Astenose, Vasoflux, and M-118, but none is available for clinical use.[247–249]

Heparin Mimicking Oligosaccharides

The elucidation of the mechanism of heparin's anticoagulant action led to the development of synthetic drugs, beginning with the development of the heparin pentasaccharide obtained by *de novo* chemical synthesis[250] followed by idraparinux.[214] Other additions to this class of agents are compounds constructed of a pentasaccharide analogue conjugated via a spacer to a specific thrombin inhibitor group derivative that provides thrombin inhibitory activity.[16,190] EP-42675 uses a specific thrombin

inhibitor that can inhibit both fibrin-bound and fluid-phase thrombin. A biotinylated form, EP-217609, which can be neutralized by avidin, has also been prepared with the same biologic activities.[190]

ACKNOWLEDGMENT

The authors acknowledge the contribution of Walter Jeske, PhD, for his scientific and editorial review of this chapter and the contribution of Alexander Bridoux, PhD, on the oral heparin section.

Vitamin K Antagonists: Biochemistry, Pharmacology, and Management

NIRMISH SHAH, THOMAS L. ORTEL, AND SAM SCHULMAN

INTRODUCTION/HISTORY

Vitamin K antagonists (VKAs) are currently the most common oral anticoagulants used worldwide. The discovery of VKAs began in 1921 to 1922, with initial investigations into bleeding cattle that had eaten improperly cured hay from the sweet clovers *Melilotus alba* and *Melilotus officinalis*. These cattle were given the diagnosis of sweet clover disease and found to have an increased prothrombin time (PT).[1] In 1939, crystals of the anticoagulant were isolated and the structure was subsequently identified as 3,3′-methylenebis(4-hydroxycoumarin), a conjugation of two molecules of 4-hydroxycoumarin with a methylene bridge. In addition, this dicumarol anticoagulant was found to be counteracted by vitamin K.[2] Although the anticoagulant effect was not understood until the 1970s, efforts then focused on development of coumarin-type compounds.[3] The development and synthesis of these compounds eventually led to patents for both dicumarol and WARF 42, which were held by the Wisconsin Alumni Research Foundation (WARF). WARF 42 was later renamed as warfarin and was initially used as a rodenticide due to its relative nontoxic effects to humans and domestic animals.[4] All coumarin derivatives have a central 4-hydroxycoumarin with a substituent in the 3-position and an asymmetric carbon atom resulting in enantiomers. The anticoagulant effect of both dicoumarol and warfarin quickly became a significant weapon in the arsenal of the cardiac specialist and has remained so to this day. VKA are now used worldwide to treat patients with thrombosis or an increased risk for thrombosis. This chapter reviews the biochemistry and pharmacology of VKA, as well as issues related to the management of patients treated with VKA.

BIOCHEMISTRY

Mechanism of Action

Effect on Coagulation Factor Synthesis/Degradation

Vitamin K is a cofactor for the posttranslational γ-carboxylation of glutamate residues to γ-carboxyglutamates on the *N*-terminal regions of vitamin K–dependent proteins. The anticoagulant effect of VKA is due to interference of the cyclic conversion of vitamin K and its 2,3-epoxide, which blocks the regeneration of the reduced form of vitamin K (FIGURE 106.1A). The VKAs interfere by inhibiting the enzyme vitamin K epoxide reductase, subunit 1 (VKOR*C1*). The reduced form of vitamin K (KH_2) is responsible for the carboxylation of glutamic residues on the procoagulant forms of factors II, VII, IX, and X. By inhibiting vitamin K conversion, coumarins cause hepatic production of partially carboxylated and decarboxylated proteins with reduced procoagulant activity, resulting in their observed anticoagulant effect.[5,6]

Conformational changes in coagulation proteins occur as a result of carboxylation and in the presence of calcium. These conformational changes are important to promoting binding to cofactors on phospholipid surfaces and procoagulant activity.[7,8] It should be noted that VKAs also inhibit carboxylation of the regulatory anticoagulant proteins C, S, and Z, which can lead to an increased procoagulant risk in certain clinical settings.

The oxidation of vitamin KH_2 to vitamin K epoxide also requires molecular oxygen and carbon dioxide. Vitamin K epoxide is subsequently recycled to vitamin KH_2 through two reductase steps. The first step reduces vitamin K epoxide to vitamin K_1 (common in natural food) and is sensitive to VKAs.[9–11] The second step reduces vitamin K_1 to vitamin KH_2 and is relatively insensitive to VKA (FIGURE 106.1A).

The use of VKAs reduces availability of vitamin KH_2, which subsequently leads to decreased γ-carboxylation of the vitamin K–dependent coagulant proteins. Whereas normally about 10 glutamic acid residues on the vitamin K–dependent factors are carboxylated, only approximately seven residues undergo this posttranslational change at a therapeutic level of VKAs.[12,13] The effect of VKAs can be counteracted by vitamin K_1 administered therapeutically or from ingestion in food. The counteraction is effectively due to the second reductase step, which is relatively insensitive to VKAs. In fact, the use of large doses of vitamin K_1 will lead to warfarin resistance for up to a week or longer, due to its accumulation in the liver.

Procoagulant Effect

VKAs also have the potential to have a procoagulant effect in addition to their anticoagulant effect. This is due to inhibition of carboxylation of anticoagulant proteins C and S. This rare occurrence leads to complications such as skin necrosis and is discussed in detail below.

PHARMACOLOGY

Pharmacodynamics/Pharmacokinetics

Although there are several oral VKAs, warfarin is currently the most common form in clinical use. It has a high bioavailability due to its water solubility and is rapidly absorbed from the stomach and duodenum.[14,15] In addition, it has maximal blood concentrations in healthy volunteers within 90 minutes of oral administration.[16] Warfarin will circulate in plasma bound to 98% to 99% to proteins, primarily to albumin, and accordingly only a minor fraction of the drug is biologically active. The drug

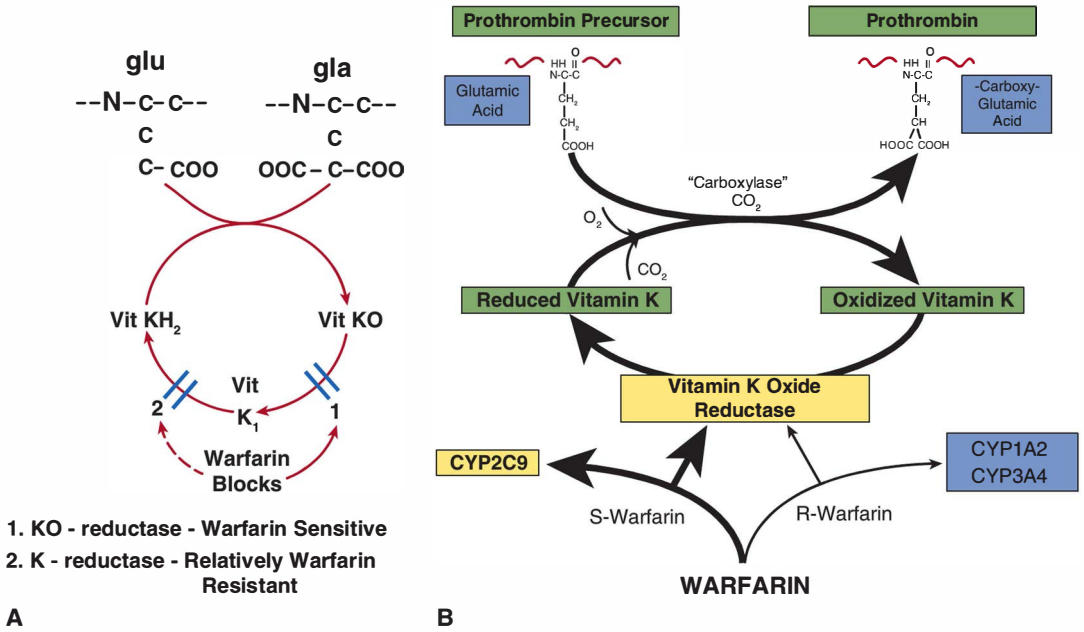

FIGURE 106.1 **A,B**: Metabolism of vitamin K and warfarin. (From Hirsh J, Dalen J, Guyatt G. The sixth [2000] ACCP guidelines for antithrombotic therapy for prevention and treatment of thrombosis. American College of Chest Physicians. *Chest* 2001;119:1S–2S; Ansell J, Hirsh J, Hylek E, et al. Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* 2008;133:160S–198S.)

will then accumulate in the liver, specifically in the microsomes.[17] Warfarin is a racemic mixture of S and R enantiomers, which are present in almost equal proportions. Warfarin has a half-life of 36 to 42 hours, which is the result of different metabolism rates of the two enantiomers. The R enantiomer is less potent, is metabolized primarily by two microsomal cytochrome enzymes (CYP1A2 and CYP3A4) to 6- and 8-hydroxywarfarin, and has a half-life of 45 hours. The S enantiomer is 2.7 to 3.8 times more potent than the R enantiomer, is metabolized primarily by the CYP2C9 enzyme of the P450 system to 7-hydroxywarfarin, and has a half-life of 29 hours (FIGURE 106.1B).[18] The inactive hydroxywarfarins are excreted renally.

Although warfarin is the most common VKA used, acenocoumarol, phenprocoumon, indanedione derivatives (phenindione), and rodenticides are occasionally encountered. Similar to warfarin, acenocoumarol and phenprocoumon are both composed of a racemic mixture of R- and S-isomers with different stereochemical characteristics. Although R-acenocoumarol has an elimination half-life of 9 hours, the less potent S-acenocoumarol has an elimination half-life of 0.5 hours.[19] The longer acting phenprocoumon has an elimination half-life of 5.5 days, with the S-phenprocoumon isomer 1.5 to 2.5 times more potent than R-phenprocoumon.[20] The most commonly used superwarfarin rodenticide is brodifacoum, a 4-hydroxycoumarin, which has higher lipid solubility and an elimination half-life of 16 to 36 days.[21] Patients with accidental ingestion or overdoses of brodifacoum should be administered vitamin K daily for an extended period due to the long half-life.[22]

Alterations in Pharmacodynamics/ Pharmacokinetics

Drugs, diet, and various disease states influence the pharmacokinetic properties of warfarin. Therefore, monitoring should occur more frequently in patients with any changes to medications or illness. The response to warfarin is also affected by multiple drugs, which lead to alterations in absorption or metabolic clearance. In addition, recently identified genetic polymorphisms can also influence the response to warfarin and should be considered in treatment protocols. Finally, anticoagulant effect may also vary based on the result of inaccurate laboratory testing, patient noncompliance, and miscommunication between patient and physician.

Pharmacokinetics of Interactions

Displacement of Warfarin from Protein-Binding Sites

Warfarin is bound to albumin at binding site I and may theoretically be displaced by compounds that are primarily albumin bound (phenylbutazone, azapropazone). Displacement may then acutely increase the effects of warfarin.[23] This effect, however, seems to be transient since the rate of elimination also increases, and it is rarely of clinical importance.[24]

Induction/Inhibition of Metabolism

Multiple drugs reduce gastrointestinal absorption of warfarin and influence pharmacokinetics. Other drugs potentiate warfarin effect by decreasing warfarin clearance through stereoselective or nonselective pathways.[25–27] Either the S-isomer or R-isomer is selectively influenced by stereoselective interactions. The influence on the S-isomer of warfarin metabolism is clinically important.[26,27] Examples of stereoselective inhibition of the S-isomer include phenylbutazone, sulfinpyrazone, metronidazole, and trimethoprim-sulfamethoxazole.[28]

Hepatic dysfunction impairs synthesis of vitamin K–dependent factors and potentiates the response to warfarin.[29] Fever or hyperthyroidism may also increase warfarin response by inducing a hypermetabolic state and increasing catabolism of vitamin K–dependent coagulation factors.[30,31]

Diet

The intake of dietary vitamin K will change daily and is an important cause of intraindividual variability over time. Vitamin K is primarily found in high amounts in foods such as green leafy vegetables and certain vegetable oils. Foods low in content can also become clinically important when ingested in large amounts. Patients need to be advised which foods contain vitamin K, as well as the variations in the international normalized ratio (INR) that can occur with warfarin use in the setting of vitamin K deficiency. The information should aim at avoiding very large amounts of these foods but make sure the patient understands that a moderate intake of vitamin K is beneficial. Reduced dietary vitamin K may arise in poor nutritional states, fat malabsorption, and sick patients treated with antibiotics and intravenous fluids without vitamin K supplementation (Table 106.1).

Genetics

Allelic variants in either CYP2C9 or VKOR*C1* are found in more than two-thirds of the White population and up to 90% of East Asians[32,33] (see Table 106.2). Individuals with certain polymorphisms of these genes will usually require a lower dose of warfarin to maintain a therapeutic INR, as well as need a longer time to achieve a stable dose.[33,34]

The first gene identified to influence the effects of warfarin was CYP2C9, which encodes for a cytochrome P450 2C9 hepatic microsomal enzyme. Certain polymorphisms in this gene lead to an alteration in the pharmacokinetics of warfarin. The most common CYP2C9 variant alleles are designated 2C9*2 and 2C9*3 and lead to decreased metabolism of the S-warfarin, especially in those individuals who are homozygous for these mutations.[35] More recently, mutations in genes encoding for the enzyme VKOR*C1* have been identified to lead to variable sensitivity to inhibition by warfarin, affecting the pharmacokinetics and dosing.

Rarely, patients may have a mutation affecting the factor IX propeptide that leads to a selective reduction in factor IX. This leads to a decreased factor IX level without prolonging the PT and may increase risk of bleeding.[36] These mutations are estimated to affect <1.5% of the population and are phenotypically silent except when the patient is receiving warfarin therapy.

Carriers of these variant alleles are at increased risk of bleeding complications, especially at the initiation of therapy. Several studies have investigated the utility of pharmacogenetic-guided strategies for the dosing of warfarin, reviewed under *Genetic Guidance* below.

Drug Interactions

There are numerous drugs that alter the pharmacodynamics of warfarin by either inhibiting synthesis or increasing clearance of vitamin K–dependent factors (see Table 106.1). For example, second- and third-generation cephalosporins,[37] erythromycin,[38] and some anabolic steroids[39] augment the effects of warfarin; thyroxine increases metabolism of coagulation factors[40]; sulfonamides as well as broad-spectrum antibiotics augment the warfarin effect by eliminating bacterial flora and aggravating vitamin K deficiency[41]; and amiodarone inhibits the metabolic clearance of both the S and R enantiomer of warfarin and potentiates the warfarin effect. Following medication changes for a patient, increased monitoring is usually required to determine the potential effect on the INR and warfarin dosing.

Dietary Supplement Interactions

A common difficulty of health care providers is the use of nutritional supplements and herbal products by patients on warfarin therapy. Most physicians do not ask about the use of these products, and patients rarely divulge this information. However, survey data would suggest that as many as 12% of the general public have used a herbal preparation or supplement within the prior year.[42] Difficulty arises from little to no standardization of the contents of these products, and interactions are not well studied. Ginkgo, ginger, and coenzyme Q10 were not shown to have an effect on warfarin.[24,43] Ginseng, however, was shown to reduce the effect of warfarin.[44] As expected, products containing vitamin K, such as green tea, also reduce warfarin effect. Table 106.1 details dietary supplement interactions with warfarin by level of supporting evidence.

MANAGEMENT

Warfarin Initiation

Commercially available warfarin has a half-life of approximately 36 hours; however, treatment for 4 to 5 days is usually required to stably reduce the vitamin K–dependent coagulation proteins to achieve a therapeutic INR. This is due to the >2 day half-life of factor X and prothrombin, despite the shorter half-lives of factors VII and IX (FIGURE 106.2). In addition, the therapeutic effects of warfarin seem to be primarily mitigated by decreased levels of factors X and II.[45] This has been the rationale for using heparin or low molecular weight heparin (LMWH) in the initial treatment period to provide an effective anticoagulant until a therapeutic warfarin effect can be achieved.[46] Treatment with warfarin should be overlapped with heparin or LMWH for at least 2 days following a therapeutic INR on two consecutive measurements 24 hours apart. This allows further reduction of factors X and II.[45]

Studies have evaluated the effect of an initial "loading" dose (e.g., ≥10 mg) of warfarin, which shortens the time to reach the therapeutic range (TTR). This may be of benefit for outpatients, who have to overlap with heparin/LMWH, and was evaluated as safe in two large case series.[47,48] Loading doses lead to a more rapid decrease in factor VII and protein C levels, as well as theoretically an increased risk of warfarin skin necrosis, and should be avoided in generally ill, hospitalized patients.[49,50]

Further attempts have also been made to supplement with oral vitamin K, at a dose corresponding to usual dietary intake, to improve stability of control of anticoagulation with warfarin. Supplementation seemed to decrease the variability of and increase the time of INR within the TTR.[51–53] This has so far not translated into a lower risk of clinical events, and larger studies will be needed to determine any clinical benefit.

It is usually recommended to begin warfarin therapy with an average maintenance dose of 5 mg, due to this dose resulting in an INR of >2.0 in 4 to 5 days with less excessive anticoagulation.[45] There are situations in which this standard dose may not be appropriate. A lower dose may be appropriate in elderly patients; in patients with impaired nutrition, liver disease, or congestive heart failure; and in patients at high risk for bleeding. For example, a patient who is undergoing heart valve replacement may begin with an initial dose of 2 to 3 mg[54] and in elderly a nomogram starting with 4 mg daily and using the INR directly as predictor led to a correct decision on the maintenance dose in 88% of the patients.[55]

Table 106.1

Level of evidence for drug, food, and dietary supplement interactions with warfarin

Level of Causation	Anti-Infectives	Cardiovascular	Analgesics, Anti-Inflammatories, and Immunologics	CNS Drugs	GI Drugs and Food	Herbal Supplements	Other Drugs

Warfarin Discontinuation

Discontinuation of warfarin will remove inhibition of vitamin K–dependent coagulation proteins and lead to a gradual normalization of INR. The rate of decrease of an INR is influenced by factors including liver dysfunction and age, with average time to normalization of 96 hours.[56] For patients on chronic anticoagulation with warfarin, elective procedures require either discontinuation of warfarin or bridging therapy (see below). Current guidelines by the American College of Chest Physicians (ACCP) suggest that if the annual risk of thromboembolism is low, warfarin therapy may be held for 4 to 5 days prior to the procedure and reinitiated shortly thereafter.[45]

Temporary discontinuation of warfarin is also recommended for nonbleeding patients with a supratherapeutic INR. Once the INR is at the therapeutic level, warfarin can be resumed with more frequent monitoring. Bleeding patients with supratherapeutic INRs require additional interventions in addition to discontinuation of warfarin (see below). Discontinuation of warfarin at the end of planned therapy can be abrupt, since several trials have failed to show any benefit of a tapered regimen.[57–61]

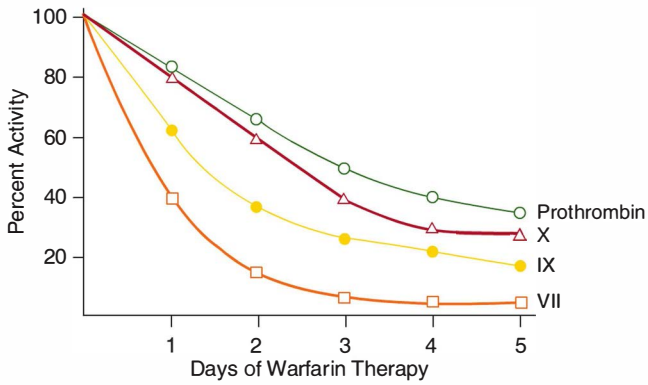

FIGURE 106.2 Effects of warfarin therapy on the plasma vitamin K–dependent procoagulant proteins. Administration of 5 to 10 mg daily of warfarin results in inhibition of synthesis of functional vitamin K–dependent proteins. The coagulant activity of these proteins in plasma declines as a function of their half-life. Half-lives of factors VII, IX, and X and prothrombin are 6, 24, and 40 and 60 hours, respectively. Although 1 to 2 days of warfarin prolongs the PT assay (because of the rapid decrease in factor VII concentration), therapeutic anticoagulation requires at least 4 to 5 days. (Data from O'Reilly RA. The pharmacodynamics of the oral anticoagulant drugs. *Prog Hemost Thromb* 1974;2:175–213; reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. *Clinical pharmacology: basic principles in therapeutics*, 3rd ed. New York: McGraw-Hill, 1992:524–599, with permission; from Wintrobe MM, Greer JP. *Wintrobe's clinical hematology*, 12th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins, 2009:1488, Ref. 178.)

Monitoring

The most useful assay to monitor therapy with warfarin is the PT assay, which measures three vitamin K–dependent coagulation proteins (factors VII, X, and prothrombin). Factor VII has a half-life of 4 to 6 hours; therefore, factor VII levels often decrease significantly following only 1 day of warfarin therapy. This may lead to a prolonged PT value, but, due to the longer half-lives of the other vitamin K–dependent coagulation proteins, therapeutic anticoagulation usually takes 4 to 5 days.[62]

The PT is performed by adding calcium and thromboplastin to citrated plasma. Thromboplastins vary in their response to reduced levels of the vitamin K–dependent coagulation factors. PT monitoring of warfarin treatment is not standardized when expressed in seconds, as a simple ratio of the patient's plasma value to that of plasma of a healthy control subject, or as a percentage of diluted normal plasma.[45] To standardize PT assays among different laboratories, an international reference thromboplastin preparation and calibration model was adopted by the World Health Organization (WHO) in 1982. To determine the responsiveness of each thromboplastin reagent, all commercial thromboplastin reagents are calibrated against the primary WHO reference preparation. These results are used to calculate the relative sensitivity of the unknown preparation compared to the WHO standard providing an international sensitivity index (ISI).[63] Once a particular thromboplastin is adjusted for the ISI, an INR is defined as the PT ratio that would be obtained if the WHO standard thromboplastin had been used. The calculation of the INR is determined by $INR = (PT\ ratio)^{ISI}$

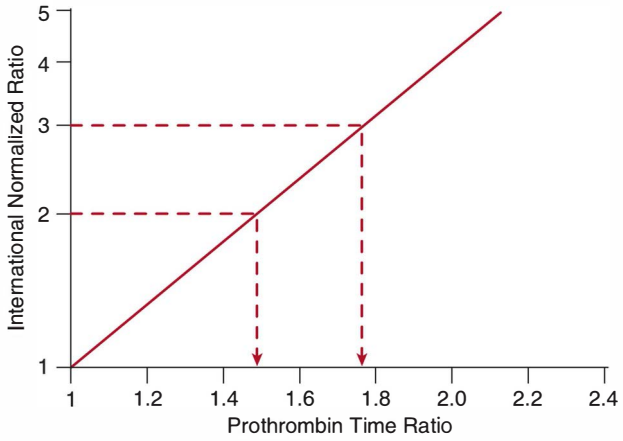

FIGURE 106.3 Relationship between PT ratio on warfarin therapy and the corresponding INR. The slope of the line represents the ISI value of the particular thromboplastin preparation used in the laboratory's PT assay. In this example, for low-intensity warfarin therapy (INR 2.0 to 3.0), a PT ratio between 1.50 and 1.75 would be required. Thromboplastins with higher ISI values would have slopes greater than that shown and would be less sensitive reagents for the PT assay, whereas thromboplastins with lower ISI values would have slopes less than that shown (more sensitive reagents). (From Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. *Clinical pharmacology: basic principles in therapeutics*, 3rd ed. New York: McGraw-Hill, 1992:524–599, with permission; from Wintrobe MM, Greer JP. *Wintrobe's clinical hematology*, 12th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins, 2009:1490.)

(FIGURE 106.3).[64] With the wide use of the standardized INR, several of its limitations have become apparent (Table 106.3). These include decreased precision when insensitive thromboplastins are used; there is an incorrect assignment of an ISI value by the manufacturer; a different reagent–instrument combination is used than that recommended by the manufacturer; and if an incorrect control PT value is used.[45]

Recommendations by the ACCP are for standard-intensity warfarin therapy (INR 2.0 to 3.0) for all indications except prosthetic mechanical heart valves and prophylaxis against recurrent myocardial infarction (MI) for which a higher intensity warfarin therapy (INR 2.5 to 3.5) is suggested.[45]

Frequency of Monitoring

Many factors influence the response to warfarin, and as a result, the dose required to achieve a therapeutic dose will vary over time. Therefore, warfarin dosing is adjusted in response to ongoing PT measurements to maximize the proportion of time in the TTR. Appropriate anticoagulation is important because (a) subtherapeutic anticoagulation (particularly INR < 1.5) increases the risk of thromboembolism; (b) supratherapeutic anticoagulation (particularly INR > 5.0) increases the risk of bleeding; and (c) poor anticoagulation control leads to an increased burden of anticoagulation therapy and discourages patients and health care providers from continuing warfarin therapy when indicated.[65] In a systematic review, the TTR was 56.7% in community practices compared to 66.4% in randomized trials.[66]

For hospitalized patients, although INR monitoring is usually daily, frequency is often guided by the attempt to keep patients therapeutic. Once a therapeutic INR has been obtained for two consecutive days, it is often recommended to subsequently monitor two to three times weekly for 1 to 2 weeks, then less often depending on the stability of the INR.[45]

As an outpatient, initial therapy is often monitored every few days until a stable dose is achieved and then frequency is often monitored at reduced intervals. It is suggested, however, that more frequent monitoring may lead to an increased TTR.[67] For example, patient self-testing, in which patients have unlimited access to testing, seems to increase TTR,[68] although the benefit of more frequent testing begins to decrease once testing occurs more frequently than several times per week.

The optimal frequency will ultimately be influenced by patient compliance, changes in diet, interactions with medications, as well as fluctuations in comorbid conditions. In addition, physician dose adjustment decisions will also lead to variability in obtaining a therapeutic effect. To assist health care providers in decisions of warfarin dosing adjustments, there are several predictive models being used to reduce the frequency of testing while keeping patients therapeutic. The current ACCP guidelines recommend that patients receiving a stable dose of oral anticoagulation should be monitored no less than every 4 weeks.[45] A randomized trial comparing 4 versus 12 weeks interval for very stable patients indicated that the frequency can be decreased without compromising the TTR.[69]

Management of Nontherapeutic INR

The management of patients with nontherapeutic INRs is variable due to few studies comparing the various options. Changes in INR may occur due to multiple causes including (a) inaccurate INR testing; (b) inconsistent vitamin K intake; (c) changes in vitamin K or warfarin absorption; (d) changes in warfarin metabolism; (e) changes in vitamin K–dependent coagulation factor synthesis or metabolism; (f) influence of additional medications being taken; or (g) noncompliance.[45]

Patients with nontherapeutic INRs will require omitting or adjustment of the warfarin dose. If the INR is near the TTR, then adjustments of 5% to 20% based on the cumulative weekly dose and increases monitoring is usually accepted as an appropriate management plan. Due to a low absolute daily bleeding risk when the INR is minimally elevated (e.g., INR between 2.5 and 5.0), many health care providers will make no change to dose and initiate more frequent monitoring. In otherwise stable patients with an occasional INR minimally above or below the TTR, no change at all versus a single-day dose adjustment resulted in a similar proportion back in the range after 2 weeks.[70]

When the INR is elevated between 5.0 and 9.0, it is recommended to hold warfarin for 1 day or more, reduce the weekly dose, and monitor more frequently. Patients at increased risk of bleeding (intermediate to high risk) may receive vitamin K (1 to 2.5 mg) orally in addition to discontinuation of therapy.[71] Patients requiring urgent procedures and more rapid reversal may consider receiving vitamin K (≤5 mg) orally and expect a reduction with 24 hours. If the INR is still elevated, then an additional dose of oral vitamin K (1 to 2 mg) is indicated. More recent studies have revealed that vitamin K may not be as beneficial, with recent evidence that vitamin K supplementation for an INR 4.5 to 10.0 did not reduce bleeding events in

Table 106.3

Causes of incorrect INR results

Problem	Description
1. Incorrect PT ratio from erroneous PT determination due to: pretest variables (sampling and blood collection problems) Incorrect normal value	Trisodium-citrate concentration, storage time, storage temperature, evacuated tube effects, inadequate sample, variations in manual technique From nonuse of MNPT, error in MNPT due to (a) unrepresentative selection; (b) technical faults (see above); (c) nonuse of geometric mean
2. Incorrect ISI of local thromboplastin reagent/test system from lack of reliability of the ISI result provided by the manufacturer	Incorrect choice of international reference preparation; poor distribution of coumarin test samples across treatment range; inadequate numbers of test samples in ISI calibration; incorrect transformation of PT ratio of test plasmas to INR
3. Drift of ISI since original calibration	
4. Instrument (coagulometer) effects on INR at local site	
5. Lupus anticoagulant effects on some thromboplastin reagents	
6. Lack of reliability of the INR system when used at the onset of warfarin therapy and for screening for a coagulopathy in patients with liver disease	
7. Relative lack of reliability of INR > 4.5 as these values excluded from ISI calibrations	
8. Sample carryover in INR determination[181]	

MNPT, mean normal prothrombin time; ISI, international sensitivity index.
Modified from Ansell J, Hirsh J, Hylek E, et al. Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* 2008;133:160S–198S.

these patients.[72] The use of vitamin K in nonbleeding patients, therefore, should be considered but is not required.

For bleeding patients, rapid correction of the INR requires fresh-frozen plasma (FFP) or prothrombin complex concentrates (PCCs), containing FII, IX, X with or without FVII, as well as protein C and protein S. Although FFP will replace vitamin K–dependent factors and reverse an elevated INR, it is not the optimal product to use in this situation. Due to the amount of FFP needed for rapid reversal, PCCs should be considered.[73] In addition, although recombinant factor VIIa (rFVIIa) is not approved, there is evidence supporting its use to reverse supratherapeutic INR results to normal.[74–76] Table 106.4 outlines recommendations by the ACCP for management of an elevated INR or of bleeding patients receiving warfarin. See also under *Hemorrhage*, below.

Periprocedure Management or "Bridging"

Bridging is the use of shorter acting anticoagulation for elective procedures and surgery. The risk of thromboembolism, risk of bleeding, and the type of procedure should all be considered when evaluating patients on chronic VKA therapy for bridge therapy. Patients are initially classified as low, intermediate, or high risk for thromboembolism. For patients at low risk of thromboembolism, simply discontinuing warfarin prior to surgery without a bridge can be considered.

Patients requiring long-term warfarin treatment, who have an intermediate to high risk of thromboembolism, will require bridging therapy for procedures or elective surgery. It is recommended to discontinue warfarin 4 to 5 days prior to surgery and begin heparin or LMWH prior to the procedure. LMWH has the advantage of being administered safely in an outpatient setting,[77] and this approach is more cost-effective than the use of heparin as an inpatient.[78] Twice-daily dosing of LMWH should be used, and the final preoperative dose should be administered 24 hours prior to the procedure. This should decrease the incidence of bleeding during the procedure; however, there is a residual anticoagulant effect at the time of surgery that may be important in cases at high risk of bleeding.[79] Postoperatively, LMWH and warfarin may be reinitiated when the risk of bleeding is judged to be minimal.

There are several procedures that are not high-risk procedures for thromboembolism, but may have increased risk for serious bleeding with aggressive anticoagulation. Procedures such as prostate and kidney biopsy, pacemaker or defibrillator implantation, and resection of colonic polyps, especially sessile polyps and polyps larger than 2 cm in diameter, should also be taken into consideration when developing a bridge therapy plan.[80]

ACCP Guidelines

The most current ACCP guidelines review consensus recommendations for the treatment and monitoring of VKAs. Although these guidelines are referenced in this chapter, for full

Table 106.4

Management of excessive INRs or of bleeding in patients on VKAs

Condition[a]	Intervention
INR > TTR but <5.0; no significant bleeding	Lower dose or omit dose; monitor more frequently, and resume at lower dose when INR therapeutic; if only minimally above TTR, no dose reduction may be required
INR ≥ 5.0, but <10.0; no significant bleeding	Omit next 1–2 doses, monitor more frequently, and resume at lower dose when INR in TTR In addition, give vitamin K (1–2.5 mg orally), if at increased risk of bleeding. If more rapid reversal is required because the patient requires urgent surgery, vitamin K (2–5 mg) can be given intravenously with the expectation that a reduction of the INR will occur in 6–12 h. If the INR is still high, additional vitamin K_1 (1–2 mg orally) can be given
INR > 10.0; no significant bleeding	Hold warfarin therapy and give vitamin K_1 (2.5–5 mg orally) with the expectation that the INR will be reduced substantially in 24–48 h. Monitor more frequently and use additional vitamin K if necessary. Resume therapy at lower dose when INR therapeutic
Serious bleeding at any elevation of INR	Hold warfarin therapy and give vitamin K (10 mg by slow IV infusion), supplemented with PCC, FFP, or rFVIIa depending on the urgency of the situation; vitamin K can be repeated every 12 h
Life-threatening bleeding	Hold warfarin therapy and give PCC or rFVIIa supplemented with vitamin K (10 mg by slow IV infusion); repeat if necessary depending on INR
Administration of vitamin K	In patients with mild to moderately elevated INRs without major bleeding, we recommend that when vitamin K is to be given, it be administered orally rather than SC

[a]If continuing warfarin therapy is indicated after high doses of vitamin K_1, then heparin or LMWH can be given until the effects of vitamin K_1 have been reversed and the patient becomes responsive to warfarin therapy. It should be noted that INR values >4.5 are less reliable than values in or near the therapeutic range. Thus, these guidelines represent an approximate guide for high INRs.
Modified from Ansell J, Hirsh J, Hylek E, ET AL. Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* 2008;133:160S–198S.

detailed recommendations the guidelines should be reviewed[45] or any future edition replacing this.

IMPROVING CONTROL

Due to the increased risk of complication when patients are not in the therapeutic INR range, it is necessary to closely monitor treatment with VKAs. To improve anticoagulation control, monitoring has commonly involved anticoagulation clinics, self-testing strategies, and computer guidance for dose adjustments. More recently, the use of algorithms have been used following genetic testing to guide initiation of warfarin, but these have not been shown to be cost-effective for the typical patient with nonvalvular atrial fibrillation.[81]

Education

The amount of education that a patient and family receive has been reported to correlate with the results in patient knowledge tests. However, there is no solid evidence for a reduction of clinically important adverse events. Nevertheless, patients should be involved in warfarin education programs, which has recently been recommended to be a part of oral anticoagulation management plan.[45] Education includes both written and verbal information, as well as potential interactions with food and drugs.

Anticoagulation Clinics

History

The narrow therapeutic index of VKAs, numerous medication and dietary interactions, and genetic and physiologic variations in metabolism have led to the development of specialized health care services dedicated to maximizing the effectiveness and safety of oral anticoagulation. The first organized effort to use a coordinated network of services specifically dedicated to managing oral anticoagulant therapy was developed in the Netherlands, using a model from Utrecht in 1949.[82] The underlying philosophy was that only adequately maintained therapy is of value to the patient, which requires considerable effort and dedication and cannot be offered if the staff is continually changing. This fundamental concept for the management of anticoagulant therapy is still critical for optimal efficacy and safety, even as new anticoagulants are being introduced for patient management.

Nonrandomized, observational studies of either routine medical care or an anticoagulation management service (AMS) beginning in the 1980s demonstrated lower observed rates

of hemorrhage (7.6% vs. 2.8% per patient-year of therapy, respectively) and thrombosis (8.1% vs. 2.6% per patient-year of therapy) for patients followed in an AMS.[64] These observations were subsequently confirmed in several studies that used a before-and-after trial design.[83–86] Four prospective, randomized trials comparing routine medical care to an AMS have been reported.[87,88,89,90] None of the studies demonstrated a significant difference in major hemorrhage or thromboembolism, although the study by Wilson et al.[88] did show an increased frequency of INR results within the target TTR (82% vs. 76%, $P = 0.034$) and a decrease in high-risk INR values, defined as being <1.5 or >5.0 (30% vs. 40%, $P = 0.005$), favoring the AMS model.

Although the literature comparing routine medical care with the AMS model is not as robust as would be preferred, the results are almost always consistent, indicating that care provided through an AMS is associated with better outcomes and more stable therapy than by routine medical care. The current recommendation from the ACCP concerning this issue is that health care providers who manage oral anticoagulation therapy "…do so in a systematic and coordinated fashion, incorporating patient education, systematic INR testing, tracking, follow-up, and good patient communication of results and dosing decisions as occurs in an AMS (Grade 1B)."[45]

Personnel and Infrastructure

A variety of different structures exist for anticoagulation services. Clinics may be primarily composed of pharmacists,[83,85,91] integrated provider groups,[92,93] telephone-based services,[94,95] or, more recently, internet-based connections.[96,97] These providers benefit from specialized training, and national certification for anticoagulation providers is available through the Anticoagulation Forum, a multidisciplinary nonprofit organization of health care professionals who manage patients on antithrombotic therapy (http://www.acforum.org).

A point-of-care (POC) instrument for determination of the INR with capillary blood obtained by a finger stick can enhance the interaction with the patient by providing immediate feedback with the laboratory result. These monitors measure a thromboplastin-mediated clotting time from capillary whole blood or from a nonanticoagulated venous whole blood sample, converting the result to a PT and/or an INR.[98] Numerous studies have reported on the accuracy and precision of these instruments and on their suitability for monitoring anticoagulant therapy.[98–101] Limitations of these instruments have been described, however, including greater differences compared to a standard, plasma-based methodology as the INR results increase above the TTR,[102] incorrect calibration of the ISI, inability to calculate a mean normal PT, and inaccuracies in certain patients with antiphospholipid antibodies.[103]

Optimal management of oral anticoagulant therapy also depends on a robust data management software package to track patients' INR results, dosing adjustments, nonanticoagulant medication changes, and any complications encountered. In addition to simple data management, a variety of computer programs have been described that provide recommendations concerning anticoagulant dosage and timing for follow-up testing.[104–106] Recently, two of these computer-assisted oral anticoagulant dosage programs were evaluated in large, multicenter, randomized clinical trials comparing management by the software program with manual dosage by experienced medical staff.[107,108] Importantly, these two studies were the first to compare clinical outcomes (hemorrhagic and thromboembolic events) in addition to therapeutic control of the INR. One study, using the DAWN AC program, found that clinical events were almost identical between the computer-assisted dosing group and the experienced manual dosage group.[108] The second study, using the PARMA 5 program, found a nonsignificant reduction in clinical events in the computer-assisted group, and this reduction was significant in the subset of patients with deep vein thrombosis/pulmonary embolism ($P = 0.005$).[107] A subsequent cost-effectiveness analysis of both studies revealed that the computer-assisted dosage strategy was less expensive than manual dosage, indicating that investment in this technology was cost-effective.[109]

The Future of Anticoagulation Management Services

With the development of novel oral anticoagulant agents that do not need routine laboratory monitoring, there has been some concern about the future of these effective management services. More likely, there will be an evolution in their services to more broadly assist in the management of patients who may be on a variety of antithrombotic agents. When AMSs can take a leadership role, patient and provider education concerning antithrombotic therapy will continue to be critical. Certain patients will not be eligible for new antithrombotic agents for various medical reasons (e.g., patients with prosthetic cardiac valves, patients with renal failure, etc.) and will likely be continued on warfarin therapy. The cost of the newer therapies may also be prohibitive for many patients. Although routine laboratory management is not required for the new therapies, expertise in evaluating and managing patients with thrombotic complications or hemorrhagic events can be provided through the AMS, particularly those with an integrated group of providers (including physicians, physician extenders, and pharmacists). Perioperative management and management of patients on combined anticoagulant and antiplatelet regimens would also benefit from an AMS model. Consequently, the AMS will evolve from providing supervision of a single therapeutic agent to one that provides essential expertise for managing patients on a variety of antithrombotic therapies.

Self-Testing/Management

Several studies have demonstrated that more frequent testing of the INR, up to once or twice a week, can lead to an increased time in the TTR.[110] Patient self-testing using a POC monitor to measure the PT from a finger stick sample of capillary whole blood makes this frequency of testing feasible, and several meters are currently available for patients to use. Patient self-testing refers to the patient performing their own PT, but decision making about adjustments to the warfarin dose and time of next INR test requires interaction with a health care provider. In contrast, patient self-management refers to the patient performing their own PT as well as making adjustments in their warfarin dose and determining when to recheck their PT. These two strategies are described in further detail below.

The first reports of patients performing their own PT testing using a POC meter appeared in 1989.[111,112] In the study from White et al.,[111] patients who were randomized to using a portable PT monitor and calling in their results to their provider for management were subtherapeutic significantly less frequently than patients randomized to follow-up in the anticoagulation clinic ($P < 0.001$). In the study from Ansell et al.,[112] a total of

16 patients were given a portable PT instrument and structured guidelines concerning how to adjust their warfarin dose based on the test result. No clinical complications were encountered with either study, but both enrolled a small number of patients.

Since these initial reports, several randomized, controlled clinical trials have confirmed that patient self-testing can be reliably used to manage a patient's oral anticoagulant therapy.[113] In addition, novel approaches have been developed to simplify the therapeutic adjustments of patients using home INR monitors. Ryan et al.[96] demonstrated that an internet-based, direct-to-patient expert system could be used to effectively manage patients using INR self-testing with home monitors. More recently, Matchar et al.[114] described the results of The Home INR Study (THINRS) trial, which used an interactive voice-response reporting system across the telephone with Web-based local monitoring of INR results. For the THINRS study, it was found that approximately four out of five patients who underwent training to perform self-testing demonstrated competency with the home INR device. Factors associated with failure to perform self-testing included age, prior stroke, poor cognition, and poor manual dexterity.[115]

Following the initial report from Ansell et al. in 1989, self-management of warfarin using a home INR monitor and an algorithm to self-adjust oral anticoagulant dosing has been shown to be safe and efficacious in several prospective, randomized clinical trials.[116–118] A recent Cochrane review summarized results from 18 clinical trials investigating self-monitoring of oral anticoagulant therapy, of which 12 investigated patients performing self-management in addition to self-testing. They found that patients performing self-management had significant reductions in thromboembolic events (relative risk [RR] 0.47, 95% confidence interval [CI] 0.31 to 0.70) and all-cause mortality (RR 0.55, 95% CI 0.36 to 0.84), but no reduction was observed with major hemorrhage (RR 1.12, 95% CI 0.78 to 1.61).[119] Although most studies also report an improved quality of INR control, defined by the TTR, this has not been observed in all studies of patient self-management.[116]

The adoption of patient self-testing and/or self-management as a strategy to manage chronic oral anticoagulant therapy with VKAs is extremely variable in different countries. In the United States, this approach is rarely used, with common barriers to adoption including the cost of the instrument and/or test strips, concern that self-testing might lead to self-management, and loss of clinic revenue.[120] In contrast, self-management of oral anticoagulant therapy using a structured training approach is widely used in Germany and other European countries, particularly in patients receiving mechanical heart valves.[118,121,122]

Genetic Guidance

The use of pharmacogenetic guidance for the dosing of warfarin has been promising, but it has had few studies to support recommendations for testing in all patients. The presence of polymorphisms of the genes encoding CYP2C9 and VKOR*C1* has been found to need lower doses of warfarin at initiation and required a longer time to achieving a stable dose.[123] Based on these findings, the Federal Drug Administration (FDA) recommended a label change to describe the reported effects of CYP2C9 and VKOR*C1* on dose adjustment (FDA press release 2007). The increased risk of hemorrhage associated with overanticoagulation has led to recent investigations of individualized treatment algorithms for determining the dosage of warfarin at initiation.

Millican et al. recently attempted to develop an algorithm based on evaluation of warfarin treatment and genotyping in patients undergoing knee or hip surgery. They suggested warfarin initiation as per previous recommendations, however also suggested that genotype be determined. Further refinement of the dose would then occur with the third dose of warfarin to allow time for results of an offsite genotyping.[124] The group has subsequently developed an interactive and free Web site that is accessible to clinicians.

Current efforts are focused on definitively proving that genotyping will lead to improved safety and efficacy. Four randomized controlled trials with a total of 544 patients have been performed to compare the advantages of genotyping.[125–128] They have not been able to demonstrate any advantage regarding clinical outcomes.[34] There are currently no recommendations, however, for the use of genotyping and algorithms utilizing evaluation of genotyping to guide therapy with warfarin. Table 106.5 gives an overview of the arguments for and against genotype-guided dosing of VKAs.

The Future of Vitamin K Antagonists

The past decade has brought forward in clinical trials a dozen new oral anticoagulants without need for frequent laboratory monitoring or dose adjustments (Chapter 110). Some of these

Table 106.5

Advantages and drawbacks with pharmacogenetic-guided dosing of VKAs

Pros	Cons
Identifies patients who need ≤21 mg warfarin per week and may have high risk of bleeding	Systematic review of randomized controlled trials failed to show a reduction of risk of bleeding[34]
Identifies patients who need ≥49 mg warfarin per week	All trials were underpowered
Genotype predicts up to 50% of interindividual dose variability	Intervention arm differed in each trial
Possibly more rapid achievement of stable dose	Algorithm including sex, age, and body weight also has predictive value
May reduce cost by shortening concomitant parenteral therapy	Incurs additional analysis costs

agents have already achieved registration in many countries for the indication "prophylaxis against venous thromboembolism after major orthopedic surgery" and for "stroke prophylaxis in atrial fibrillation." At the time of writing, the oral thrombin inhibitor dabigatran is gaining part of the market from warfarin. Many patients starting on oral anticoagulant therapy prefer a more convenient drug to a drug that initially will require intensive monitoring. There is, however, a substantial proportion of patients on warfarin with very stable INR levels and monitoring only once per month, which is not perceived as an inconvenience. Studies indicate that they might be safely managed with even less frequent monitoring.[69,129] The management of major bleeding on VKAs is well defined, whereas at this point there is no available antidote against dabigatran. Even though the risk of intracranial bleeding is reduced by 60% with dabigatran,[130] some patients and physicians prefer the VKA with its antidote (PCC and vitamin K). Disturbing gastrointestinal adverse effects occur in 5% to 10% of the patients on dabigatran, whereas intolerable side effects from VKAs are very rare and some patients have asked to be switched back to warfarin. Patients with mechanical valves have not been studied yet on the new agents, and severe renal dysfunction seems to be a contraindication for several of these anticoagulants. The most complex issue is the reimbursement. Warfarin is one of the most inexpensive drugs. Conversely, its management incurs significant direct and indirect costs,[131] which correspond to the drug cost of dabigatran but involve different sources of funding.

It therefore seems likely that VKAs will continue to be used for at least a decade ahead (a) by patients with very stable INRs, (b) by patients with mechanical heart valves and possibly other less common indications, and (c) wherever there is restricted funding for drugs.

WARFARIN COMPLICATIONS

The situation with an asymptomatic high INR has been described above under "management on nontherapeutic INR."

Hemorrhage

Hemorrhagic complications to anticoagulant therapy are discussed in detail in Chapter 107. The risk of bleeding increases sharply with the INR (FIGURE 106.4).[132] Patients who have hemorrhage during treatment with VKAs will need rapid reversal following discontinuation of the VKAs. Patients should receive intravenous vitamin K and replacement of coagulation factors. There have been several attempts to determine ideal dosing of oral vitamin K for warfarin-associated coagulopathy. Several randomized controlled trials as well as a recent meta-analysis have found that the use of low-dose oral vitamin K leads to a reduction in an excessively elevated INR without lowering it into a subtherapeutic range.[71,133,134] The intravenous form of vitamin K has effects more rapidly than oral or subcutaneous forms and causes a progressive reduction of the INR starting from 2 hours.[135,136] In addition, normalization of the INR usually occurs within 24 hours following a sufficiently large dose of vitamin K with normal hepatic function.[137] There are reports that intravenous vitamin K causes anaphylactoid reactions in 3:100,000,[138] and therefore it is recommended to inject slowly. Subcutaneous injection of vitamin K leads to a slower and less predictable reduction of INR than intravenous injection[139] and should be avoided.

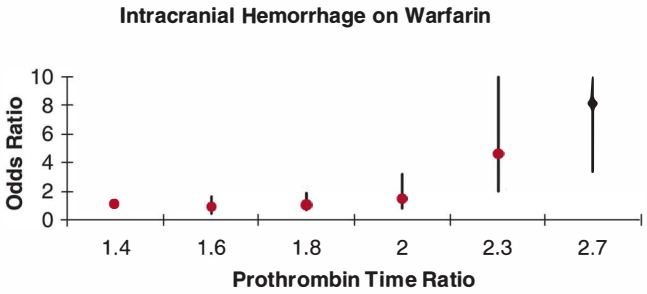

FIGURE 106.4 Relationship between PT and risk for intracranial hemorrhage. (Adapted from Hylek EM, Singer DE. Risk factors for intracranial hemorrhage in outpatients taking warfarin. *Ann Intern Med* 1994;120:897–902.)

The use of coagulation factor replacement products are additionally needed to rapidly reverse the coagulopathy. FFP is commonly given at a dose of 15 mL/kg, although a standard dose has not been determined. Limitations to the use of FFP include (a) administration of a large volume, which may be an issue for patients with volume overload; (b) the usual dose of FFP is insufficient to normalize factor IX levels; (iii) therapy is delayed because being a frozen product it requires a thawing process; and (iv) FFP has a small risk of transfusion-transmitted infections.[137]

Alternative products available for hemorrhage or rapid reversal of VKA-associated coagulopathy include PCCs and rFVIIa. PCCs include factors II, IX, X, various levels of VII, as well as anticoagulant proteins C and S. PCCs seem to be more effective at rapidly correcting a supratherapeutic INR. Makris et al.[140] found that a complete correction of the INR to normal was achieved within 15 minutes in nearly all patients treated with PCCs (25 to 50 U/kg) versus no patients achieving correction of their INR when treated with FFP. Although there are several different PCCs, no direct comparison has been made between them, and currently there is no standard dose. Increased usage of PCCs has been limited by the fear of a risk of thrombotic complications such as stroke, MI, and deep-vein thrombosis. A recent literature review revealed seven patients with evidence of thrombosis among 460 patients treated with PCCs in 14 separate studies.[141] There are, however, also thrombotic complications when VKAs are interrupted without PCCs, for example, for elective surgery.

rFVIIa appeared to be effective in rapidly correcting supratherapeutic INRs in patients with central nervous system bleeds, as shown in a study with 13 patients.[75] However, due to its risk of thrombosis and lack of clinical evidence for its use, there have been limited recommendations for its use. Should rFVIIa be used, close monitoring of coagulopathy and bleeding should occur due to its short half-life of approximately 60 minutes.

Skin Necrosis/Limb Gangrene

The use of VKAs may uncommonly cause nonhemorrhagic complications such as skin necrosis or limb gangrene. Although not well understood, reports of potential mechanisms include thrombosis, hypersensitivity, hemorrhage, factor

VII deficiency, protein C and S deficiency, and direct toxic effects of warfarin.[142] The effect seems to involve the venules and capillaries of subcutaneous fat or massive venous outflow obstruction, leading to skin necrosis and limb gangrene respectively.[45] These complications usually occur between the 3rd and 8th day of VKA therapy.

Warfarin-induced skin necrosis usually presents with pain, edema, and erythematous changes to the skin. Over the initial 24 hours, petechiae develop and eventually hemorrhagic bullae signal significant necrosis of the skin.[143] Once skin necrosis develops, there is no specific treatment that has been shown to affect outcome,[144] and nearly half of the patients will require surgical intervention.[143] The discontinuation of warfarin and administration of vitamin K, however, usually limits further development. The development of skin necrosis also does not preclude further use of VKA; however, most recommendations include a slow initiation and additional treatment with LMWH.[145] In a small study, the use of prostacyclin did seem to be beneficial in treating patients with skin necrosis.[146] Warfarin-induced skin necrosis is discussed in detail in Chapter 109.

Cutaneous Manifestations—Purple Toe Syndrome

Another rare complication of VKAs is "purple toe syndrome" and may develop several weeks after initiation. Initial reports described patients with bilateral purple discoloration of the feet on the plantar surface and postulated to be due to the direct toxic effect of warfarin on capillaries and venules.[147] More recently, histopathologic examination seems to indicate cholesterol embolization as a possible etiology.[148] No specific recommendations beyond discontinuation of warfarin have been recommended for this uncommon complication.

Other Cutaneous Manifestations

Rashes that are very itchy and are maculopapular,[149] vesicular, or urticarial[150] have been described with onset weeks to months after the start of anticoagulation with coumarin derivatives. The reactions seem to be at least as often a result from the coloring of the tablet as from the drug itself, and the first action should be to try another strength or white warfarin tablets. If that does not alleviate the problem, a switch to another VKA may be attempted. Phenindione occasionally causes severe hypersensitivity reactions.[151]

Other Complications of Warfarin

Warfarin has been reported to cause eosinophilic pleurisy[152] or vasculitis.[153] Toxic hepatitis[154] and intrahepatic jaundice[155] are very rare complications from warfarin therapy.

Alopecia occurs in <1% of patients on warfarin[156] and may be alleviated by switching to another VKA. There is also a report of two patients, whose alopecia was treated successfully with ubidecarenone 30 mg/day.[157]

Warfarin also has an effect on bone mineral density possibly via a reduction of the vitamin K–dependent osteocalcin.[158] In a retrospective study of hospital records, it was found that males on long-term warfarin had an increased risk of osteoporotic fractures (OR 1.63, 95% CI 1.26 to 2.10).[159] Conversely, warfarin can cause unwanted valvular and vascular calcification via hypocarboxylation of the vitamin K–dependent matrix Gla protein, which seems to play a role for inhibition of calcification.[160]

Yet another vitamin K–dependent protein, growth arrest-specific gene 6 protein stimulates mesangial proliferation in glomerular kidney disease.[161] However, in this situation, warfarin—and actually at lower than therapeutic doses—may provide a benefit.[162]

Pregnancy and Lactation

VKAs readily cross the placenta and produce characteristic embryopathy, central nervous system abnormalities, and fetal bleeding. The first reported case of multiple congenital abnormalities in a mother ingesting coumarin was published in 1966.[163] Subsequently, Shaul and Hall summarized the abnormalities in 11 patients exposed to warfarin during gestation. The abnormalities most typically seen included nasal hypoplasia, stippled epiphyses, eye anomalies, and developmental delay.[164] Retrospective reviews initially noted the incidence of warfarin embryopathy to be approximately 8% in infants exposed between week 6 and 9 of gestation.[165] A prospective study of 63 women with prosthetic valves, however, reported that 28.6% of all infants exposed to warfarin between week 6 and 12 of gestation developed congenital abnormalities.[166] Importantly, warfarin embryopathy was not found in the 19 patients in whom heparin was substituted for warfarin between weeks 6 and 12.[166] Neurologic abnormalities have been reported in 3% of liveborn infants exposed to coumarin derivatives. Abnormalities often seen include mental retardation, blindness, spasticity, and seizures.[165] Finally, an expected high incidence of fetal hemorrhage and death is seen in pregnant women on warfarin. Animal studies suggest significant numbers of stillborn fetuses and widespread hemorrhage, although a prospective analysis by Hirsh et al.[167] reported no fetal or neonatal complications when VKAs were discontinued after 37 weeks of gestation and replaced with heparin.

As described above, the literature suggests a strong association between maternal warfarin use and adverse effects to the fetus. Women who conceive while taking VKAs should be advised to discontinue their use prior to 6 weeks of gestation, if feasible. The use of unfractionated heparin (UFH) or LMWH would be useful alternatives. For patients with mechanical valves or at high risk for thrombosis, it is suggested to use either adjusted-dose LMWH or UFH twice daily throughout pregnancy or until the 13th week with substitution to warfarin thereafter. Warfarin would then be continued only until 2 to 4 weeks prior to delivery to avoid an anticoagulated fetus at birth.[168,169] Finally, patients with high-risk mechanical valves (e.g., older generation valves, history of thromboembolism) are suggested to continue using VKA rather than heparin.

There are few studies evaluating the safety of VKAs in lactating women. Warfarin is polar, nonlipophilic, and highly protein bound.[170] There have been two relevant studies, which reveal no evidence of warfarin within breast milk and that it does not induce an anticoagulant effect in the breastfed infant.[171,172] Therefore, the use of warfarin in lactating mothers is regarded as safe.

Warfarin Resistance

Requirement for extremely high doses of VKAs to achieve a therapeutic INR is a rare phenomenon (<0.1%).[173] There are several possible mechanisms for this. An absorption defect has been

described for cases with resistance to warfarin or dicoumarol.[174] Another explanation has been identified with mutations in the target protein VKOR*C1*,[175] which also seems to be behind the selection of warfarin-resistant rodents.[176]

Increased elimination via duplication of the CYP2C9 gene has also been described.[177] Before hereditary defects are investigated, it is crucial to review acquired causes such as poor compliance, high intake of vitamin K in any form, other dietary habits, and concomitant medication with rifampicin, carbamazepine, etc., as well as malabsorption disorders. An algorithm for investigation of patients with a daily requirement of >15 mg of warfarin has been published.[177]

CHAPTER

107 Hemorrhagic Complications of Anticoagulation

SAM SCHULMAN AND MARK A. CROWTHER

Bleeding is the most common complication of anticoagulant therapy. The spectrum is from seemingly harmless subcutaneous ecchymoses, albeit cosmetically disturbing for some individuals, to severely disabling intracerebral hemorrhages and fatal bleeding. Parenteral anticoagulants, for example, unfractionated heparin (UFH) or low molecular weight heparin (LMWH), may cause serious hemorrhage despite careful monitoring or predictable plasma levels, respectively, because of the underlying illness and invasive procedures performed in the hospital. Vitamin K antagonist (VKA) therapy is in many patients difficult to control, and excessive anticoagulation increases dramatically the risk of bleeding. New anticoagulants with more predictable pharmacokinetics and a minimum of drug–drug and drug–food interactions may have a lower risk of bleeding. However, a substantial number of bleeding events occur without provoking risk factors and while patients are within the therapeutic range—these events are impossible to avoid during anticoagulant therapy. It is therefore also crucial to be familiar with the reversal of anticoagulants and management of hemorrhage.

DEFINITIONS

Comparison of incidences of bleeding between clinical studies is hampered by the plethora of definitions for serious or major bleeding. Some of the most used or well-reasoned classifications and their criteria are provided in Table 107.1.[1–5] Many studies have, however, used their own definition or a "modified" version of any of those in Table 107.1.[1]

The International Society on Thrombosis and Haemostasis (ISTH) definition of major bleeding for nonsurgical patients[2] is supported by the European Medicines Agency,[3] and many contemporary clinical trials have chosen this definition. A criterion for major bleeding that has been used in several clinical trials on prophylaxis against venous thromboembolism (VTE) after major orthopedic surgery is the bleeding index of at least 2. This index is the sum of the number of red cell and whole blood units transfused plus the difference between pre- and postbleeding hemoglobin (in g/dL).

The number of major bleedings is often compared with the number of thromboembolic events to evaluate the net benefit of a treatment. It is then necessary to analyze the proportion of different types of major bleeding events, since an intracranial hemorrhage has about the same clinical burden as an ischemic stroke, whereas a gastrointestinal bleeding usually has far less severe consequences. In many large trials, the greatest proportion of major hemorrhages were indeed gastrointestinal.[8]

INCIDENCE OF ANTICOAGULATION-ASSOCIATED BLEEDING

Vitamin K Antagonists

The risk of bleeding complications in randomized control trials (RCTs) is lower than that seen in routine clinical practice since the study population is selected and patients with risk of bleeding are usually excluded. Paradoxically, the risk of bleeding reported in observational studies is often lower than in RCTs. This could be due to recall bias in retrospective studies, missed events in registry studies, or a result of studying a VKA-experienced cohort. Conversely, RCTs may demonstrate a high incidence of bleeding if they are pivotal registration trials, where all events are carefully captured, and if a large proportion of patients are VKA naïve.[4]

The largest RCTs on VKA therapy have been performed in patients with *atrial fibrillation*. In Table 107.2, the annualized incidence of fatal, intracranial, and major bleeding on VKA is shown for RCTs versus placebo, aspirin + clopidogrel, and dabigatran as well as for observational studies of an inception cohort and of VKA-experienced patients. The annual incidences of intracranial bleeding and of major hemorrhage range from 0.3% to 1.7% and from 1.3% to 4.7%, respectively.[4–9]. Detailed information on incidence of bleeding for each RCT can be found in the guidelines of the American College of Chest Physician.[10]

In a pooled analysis of five studies on VKA versus placebo the attributable risk of major bleeding or of intracranial hemorrhage for VKA was 0.3% and 0.2% per year, respectively.[6]

In a meta-analysis of 33 RCTs and prospective cohort studies with 10,757 patients treated with VKAs for VTE for an average of 5 months, the annualized risk of fatal, intracranial, and major bleeding was 1.3%, 1.15%, and 7.2%, respectively.[11] It should be noted that these patients are all VKA naïve and the risk of bleeding is highest shortly after start of therapy. For the subpopulation with duration of anticoagulation longer than 3 months, the annualized incidence of fatal, intracranial, and major bleeding for the period after 3 months was 0.6%, 0.6%, and 2.7%, respectively.[11]

In nine RCTs on VKA versus combined VKA–antiplatelet therapy for patients with *mechanical prosthetic heart valves*, there were 59 major bleeding events in the VKA-alone arm during a total of 1,926 patient-years, corresponding to an annualized risk of 3.1%.[12] Three of these studies aimed for a therapeutic international normalized ratio (INR) of 3.0 to 4.5, and the risk includes nonfatal intra- and extracranial major bleeding.

Whenever VKA is combined with other antithrombotic agents, the risk of bleeding increases. The annual risk of bleeding requiring hospitalization was in a large registry study 4.3% on VKA, 5.7% with aspirin added, and 12% with aspirin and clopidogrel added[13] (Table 104.2, Chapter 104).

Table 107.1

Commonly used and/or well-reasoned classifications for major or severe bleeding in nonsurgical and surgical patients

Nonsurgical Patients

TIMI Major Bleeding[149]	GUSTO Severe Bleeding[150]	ISTH Major Bleeding[2]
Intracranial bleeding ≥5 g/dL decrease in Hgb ≥15% decrease in Hct	*At least one of*: Intracranial bleeding Bleeding causing hemodynamic compromise	*At least one of*: Fatal bleeding Bleeding in critical organ Bleeding with either of (a) ≥2 g/dL decrease in Hgb or (b) transfusion of ≥2 units of whole blood or red cells

Surgical Patients

ISTF—Adjudicated Serious Bleeding[151]	ISTH Major Bleeding (Surgical)[152]
At least one of:	*At least one of*:
Fatal bleeding	Fatal bleeding
Intracranial bleeding	Bleeding in critical organ
Retroperitoneal bleeding	Extrasurgical site bleeding with either of:
Bleeding causing treatment cessation	(a) ≥2 g/dL decrease in Hgb or (b) transfusion of ≥2 U of whole blood or red cells
Bleeding causing reoperation	Complicated hemarthrosis Surgical site bleeding requiring second intervention Surgical site bleeding with (a) ≥2 g/dL decrease in Hgb or (b) transfusion of ≥2 U of whole blood or red cells *AND* that, as assessed by the surgeon, is either (c) unexpected and prolonged or (d) causing hemodynamic instability

TIMI, thrombolysis in myocardial infarction; GUSTO, global utilization of streptokinase and tPA for occluded coronary arteries; ISTH, International Society on Thrombosis and Haemostasis; ISTF, International Surgical Thrombosis Forum.

Unfractionated Heparin

The administration of UFH should be by continuous infusion or subcutaneous injections, since the risk of bleeding is increased with intermittent intravenous injections.[10] The risk of bleeding depends very much on the indication for treatment. In patients with acute myocardial infarction, there is a high risk due to invasive procedures, frontloaded thrombolysis, and concomitant (frequently multiagent) antiplatelet therapy. The frequent use of revascularization procedures in non–ST-elevation acute coronary syndromes probably explains the high risk of major bleeding seen in this setting (Table 107.3).[14] Patients with ischemic stroke have a risk of hemorrhagic stroke transformation,[15] whereas those treated for VTE are less susceptible unless they have underlying cancer.

Low Molecular Weight Heparin

Whereas UFH is almost exclusively given for short durations, LMWH is, due to the possibility of once-daily administration without monitoring, sometimes used for many months, particularly during pregnancy or in patients with VTE and cancer. The risk of bleeding for different indications and durations of treatment is shown in Table 107.4.[14,15,16,17,18] In comparison with UFH, LMWH resulted in more bleeding in acute coronary syndromes, and the difference was statistically significant in ST-elevation myocardial infarction, although this was outweighed by better efficacy for LMWH.[14] In acute stroke and in pulmonary embolism, there was a nonsignificant decrease of risk of major hemorrhage with LMWH compared to UFH,[15] whereas in short-term treatment of deep vein thrombosis LMWH resulted in significantly fewer major bleedings.[17]

Fondaparinux

The pentasaccharide fondaparinux is almost exclusively used for durations up to approximately 10 days, both in prevention and treatment of thromboembolism. The risks of major bleeding during treatment for cardiac or for venous indications are presented in Table 107.5.[19–22]

Dabigatran

The orally available direct thrombin inhibitor, dabigatran etexilate, was evaluated in a study with 18,000 patients versus warfarin and was given as either 110 mg b.i.d. or 150 mg b.i.d. for a mean of 2 years.[7] The annualized risk for major bleeding was 2.7% and 3.1%, respectively, and for intracranial bleeding it was 0.2% and 0.3%, respectively. The risk of intracranial

Table 107.2

Annual risk (in %) for different types of hemorrhages with VKA therapy in studies with various designs

Study/Year	Design	Fatal	Intracranial	Major Bleed
Atrial Fibrillation				
Atrial fibrillation Investigators/1994[6]	Pooled analysis of RCTs; warfarin vs. control	NA	0.3	1.3
SPAF III/1996[5]	RCT; vs. low, fixed dose VKA plus aspirin	NA	0.5	2.1
ACTIVE W/2006[4]	RCT; vs. aspirin plus clopidogrel; 23% of patients VKA naïve	0.26	0.36	2.21
RE-LY/2009[7]	RCT; vs. dabigatran; 50% of patients VKA naïve	NA	0.74	3.36
Hylek/2007[9]	Inception cohort; elderly	0.8	1.7	4.7
Go/2003[8]	ATRIA cohort, retro and prospective	NA	0.5	1.5
VTE				
Linkins/2003[11]	Meta-analysis, RCTs, and prospective cohorts	1.3	1.15	7.2
Linkins/2003[11]	Same, but 1st 3 mo excluded	0.6	0.6	2.7
Akl/2008[16]	Meta-analysis, four RCTs, VTE and cancer, 3–6 mo	NA	NA	1.9
Mechanical Heart Valves				
Little/2003[12]	Meta-analysis of RCTs	NA	NA	3.1

bleeding was for both dose levels significantly lower than for patients randomized to warfarin (0.7%).

Parenteral Direct Thrombin Inhibitors

Several parenteral, direct thrombin inhibitors (argatroban, bivalirudin, and lepirudin) are used for limited indications and often with small populations studied.[10]

Table 107.3

Risk for major hemorrhage with UFH according to indication

Study/Year	Design; Duration	Intracranial	Major Bleed
Acute Coronary Syndromes, ST-Elevation			
Murphy/2007[14]	Meta-analysis, six RCTs; 30 d	NA	1.8%[a]
Acute Coronary Syndromes, Non–ST-Elevation			
Murphy/2007[14]	Meta-analysis, six RCTs; 30 d	NA	5.4%[a]
Acute Ischemic Stroke			
Sandercock/2008[15]	Meta-analysis, eight RCTs; 10 d	1.1%[b]	0.1%[c]
Acute VTE			
Quinlan/2004[18]	Meta-analysis, 12 RCTs, pulmonary embolism; 7 d	NA	2.3%
Erkens/2010[17]	Meta-analysis, 8 RCTs, deep vein thrombosis; 7 d	NA	2.1%

[a]Includes intracranial bleeding but not fatal bleeding.
[b]Symptomatic bleeding; for any—including asymptomatic hemorrhagic transformation—the risk was 2.6%.
[c]Extracranial, nonfatal bleeding.

Table 107.4

Risk for major hemorrhage with LMWH according to indication

Study/Year	Design; Duration	Intracranial	Major Bleed
Acute Coronary Syndromes, ST-Elevation			
Murphy/2007[14]	Meta-analysis, six RCTs; 30 d	NA	2.6%[a]
Acute Coronary Syndromes, Non–ST-Elevation			
Murphy/2007[14]	Meta-analysis, six RCTs; 30 d	NA	6.3%[a]
Acute Ischemic Stroke			
Sandercock/2008[15]	Meta-analysis, four RCTs; 10 d	0.7%[b]	0.6%[c]
Acute VTE, Short-Term			
Quinlan/2004[18]	Meta-analysis, 12 RCTs, pulmonary embolism; 7 d	NA	1.4%
Erkens/2010[17]	Meta-analysis, eight RCTs, deep vein thrombosis; 7 d	NA	1.0%
VTE, Long-Term			
Akl/2008[16]	Meta-analysis, four RCTs, patients with cancer, 3–6 mo	NA	6.4%[d]

[a]Includes intracranial bleeding but not fatal bleeding.
[b]Symptomatic bleeding; for any—including asymptomatic hemorrhagic transformation—the risk was 1.7%.
[c]Extracranial, nonfatal bleeding.
[d]Annualized risk was 2.0%.

Argatroban has been studied in treatment after stroke, and the incidence of intracranial bleeding was 3.4% or 5.1% with a bolus dose of 100 μg/kg followed by continuous infusion at 1 or 3 mg/kg/min, respectively, compared to 0% with placebo.[23] In three trials including patients with myocardial infarction after initial thrombolytic therapy, the risk of bleeding was similar[24] or lower[25,26] with argatroban compared to UFH. In a pooled analysis of two cohort studies with argatroban for patients with heparin-induced thrombocytopenia (HIT), the incidence of major bleeding was 6% compared to 7% in historical controls for whom heparin was stopped and sometimes replaced with VKA.[27] Argatroban is eliminated by hepatic metabolism, and the dose has to be reduced in case of liver impairment or a drug with alternative route of elimination chosen.

Bivalirudin was compared with UFH in patients with ST-elevation myocardial infarction in the HERO-2 trial and was associated with a trend to more severe bleeding and intracranial bleeding events.[28] Conversely, after percutaneous coronary interventions, bivalirudin has consistently resulted in only about half the number of major bleeding events as with UFH (~3% vs. 6%).[29,30]

Lepirudin as anticoagulant after thrombolysis in myocardial infarction resulted in a similar risk of major or intracranial bleeding as UFH.[31] In patients with acute coronary syndrome

Table 107.5

Risk for major hemorrhage with fondaparinux according to indication

Study/Year	Design	Fatal	Intracranial	Major Bleed
Acute Coronary Syndromes, ST-Elevation				
OASIS 6/2006[21]	RCT, 9 d	0.6%	0.2%	1.8%[a]
Acute Coronary Syndromes, Non–ST-Elevation				
OASIS 5/2006[22]	RCT, 9 d	NA	NA	2.2%
	Same, 30 d	NA	NA	3.1%
Acute VTE, Short-Term				
MATISSE PE/2003[20]	RCTs, pulmonary embolism, 7 d	0.1%	NA	1.3%
MATISSE DVT/2004[19]	RCTs, deep vein thrombosis, 7 d	0.2%	NA	1.1%

[a]Fatal and intracranial hemorrhages are included in this result. Severe bleeding according to modified TIMI definition occurred in 1.0%.

without thrombolysis, lepirudin was, however, associated with a higher incidence of major bleeding than UFH.[32] In patients with HIT treatment, lepirudin appears in indirect or historical comparisons to give more major bleeding (10% to 14%)[33,34] than with argatroban (6%),[27] danaparoid (2.5%),[33] or controls (8.5%).[34] Both bivalirudin and lepirudin are eliminated renally and are contraindicated in severe kidney disease.

Rivaroxaban

Several direct and orally available factor Xa inhibitors are under development. Rivaroxaban was, in a phase III RCT for patients with deep vein thrombosis, associated with a similar risk of major bleeding and fatal bleeding as LMWH and VKA (0.8% vs. 1.2% and 0.1% vs. 0.3%, respectively).[35] The same was true in a study on 14,000 patients with atrial fibrillation with major hemorrhage in 3.6% per 100 patient-years with rivaroxaban versus 3.45% with warfarin.[36]

RISK FACTORS FOR BLEEDING

The risk factors for bleeding can be classified as drug related and patient related. Drug-related risk factors may result in excessive drug levels—every known antithrombotic agent has a dose–bleeding relationship, although this curve may be more or less steep for different drugs.

Drug-Related Risk Factors

The risk of bleeding with overly intensive treatment has been best documented with VKAs. The risk of intracranial bleeding doubles with each increase of approximately 1 in the INR.[37] The risk for major bleeding on warfarin doubles when the treatment range is above INR 3.0 compared to when it is INR 2.0 to 3.0.[38–41] Patients with myocardial infarction, treated with UFH in a large trial, had an increase of the risk of bleeding of 7% for every 10-second additional prolongation of the activated partial thromboplastin time (APTT).[42] Increased bleeding with higher doses have also been reported for lepirudin,[43] argatroban,[25] and dabigatran.[7]

High variability in the drug level will inevitably result in frequent periods of excessive anticoagulation. The VKAs are most susceptible to such variations due to a multitude of interactions with other drugs and with food and a narrow therapeutic range. The variability is a risk factor that is independent of the mean INR.[5,44,45] Furthermore, "time in therapeutic range" (TTR) is closely related to hemorrhagic as well as thromboembolic complications.[46] Nevertheless, a patient that has INR results consistently a few decimal points above the upper limit of the therapeutic range and accordingly a very low TTR has probably a lower risk of bleeding than another patient with alternating low and high INR results and a modest TTR. Therefore, a method that estimates both the variability of INR and the time spent in range probably provides the best estimate of risk for complications.[47]

The management of anticoagulation with VKA needs to be meticulous and delivered by experienced staff to minimize the complication rate. A systematic review of 67 studies with more than 50,000 patients monitored by specialized anticoagulation clinics (68%), community practices (24%), or in clinical trials (7%) demonstrated that the study setting had the greatest influence on TTR, which was lowest in community practices.[48] Dosing decision support with manual algorithms[49,50] or computer software[51] can effectively improve the quality of anticoagulant management.

Concomitant medications can result in increased risk of bleeding with VKAs either via direct interacting effects on the pharmacokinetics of VKA and resulting high INRs (see Chapter 106) or by exerting inhibition on other components in the hemostatic system, typically on the platelets (nonsteroid anti-inflammatory drugs, serotonin reuptake inhibitors, aspirin, glycoprotein IIb/IIIa, or $P2Y_{12}$ receptor inhibitors) (Table 104.2, Chapter 104; Table 106.1, Chapter 106). Multiple inhibitions of the hemostatic system or concomitant thrombolysis and increased bleeding have also been described for other drugs, for example, UFH.[52–55]

A frequently described interaction is between VKA and paracetamol (acetaminophen), resulting in increased INR,[56–58] which has been associated with increased risk for gastrointestinal bleeding requiring hospitalization.[59] Nonsteroid anti-inflammatory drugs increase the risk of upper gastrointestinal bleeding 3.6 times compared to a matched nontreated population and with VKA added the risk is 8 to 11 times the expected.[59,60]

Patient-Related Risk Factors

Age is an independent risk factor for bleeding on treatment with VKA[61–64] and UFH,[65,66] but it is more controversial whether female sex is such a risk factor for either of these drugs.[66–68] In recent large trials with new anticoagulants in atrial fibrillation, there was no apparent difference in risk of bleeding between males and females,[36,69,70] supporting the notion of play of small numbers in the above-mentioned older studies.

Genetic variants that influence the effect of VKAs and may cause increased risk of bleeding can involve the metabolism (microsomal enzyme CYP2C9*2 or *3) and the target protein (C1173T polymorphism of vitamin K epoxide reductase complex 1 [VKOR*C1*])[71] or result in dysfunction of hemostatic components such as platelets (A1A1 variant of glycoprotein IIb/IIIa)[72] or factor IX (drastic decrease on VKA, unnoticed with prothrombin time).[73] However, the influence of genetic polymorphisms on warfarin response, expressed as bleeding complications, remains controversial. Whereas on one hand observational studies have indicated strong associations between polymorphisms in CYP2C9 or VKOR*C1* and dose requirements and also an association between a low maintenance dose and the risk of bleeding,[74,75] randomized trials on pharmacogenetic dosing have not demonstrated a reduction of clinical adverse events[76] (see also Chapter 106).

A history of previous bleeding may be a risk factor for recurrent bleeding on VKAs.[77,78,79] Comorbid diseases are frequently reported as risk factors for bleeding on VKAs[10] and include hypertension, cerebrovascular disease, ischemic stroke, serious heart disease, diabetes, alcoholism, liver disease, malignancy, and renal insufficiency. Chronic kidney disease is obviously also a risk factor for bleeding with drugs that are dependent on renal elimination (LMWH,[80] pentasaccharides,[81] lepirudin,[43] and dabigatran[82]), and a glomerular filtration rate of <30 mL/min is usually considered a contraindication for their use. However, increased risk of bleeding in chronic kidney disease has been observed with UFH[83] as well. A body weight of <50 kg was in a registry study associated with increased risk of bleeding with an

odds ratio of 2.2 (95% CI 1.2 to 4.0) compared to 50 to 100 kg.[84] This was partly, but not entirely, explained by the use of excessive doses of anticoagulants or by other comorbidities.

Finally, temporal proximity to trauma or invasive procedures has been reported as a determinant of bleeding for several anticoagulants.[22,85–89]

CLINICAL PREDICTION RULES FOR BLEEDING

A logical step after identification of risk factors for bleeding is the derivation of the proportional importance of independent risk factors into a formula that subsequently is used prospectively in another cohort for validation of the predictive value. Several clinical prediction rules have been published,[77,90–94] and they are summarized in Table 107.6. These tools are for patients starting treatment with VKAs, but some of these are difficult to memorize due to many components and complicated point systems. Furthermore, it is challenging enough for a clinician to stratify the patient according to risk for stroke, and to simultaneously stratify each patient for risk of thromboembolism and for bleeding complications is unrealistic. A systematic review of the bleeding risk rules has been performed,[95] and the outpatient bleeding risk index (OBRI)[77] had the best level of evidence in view of prospective validation by different investigators and in different populations. None of the tools would, however, have a "strong" ability to predict whether a major bleeding will occur or not during treatment with VKAs. Nevertheless, for patients where the assessment of thromboembolic risk leaves the physician uncertain about the optimal choice of prophylaxis, a subsequent analysis of the bleeding risk may be decisive.

PROGNOSIS AFTER BLEEDING

In an analysis of patients with acute coronary syndromes, recruited for two large RCTs, Eikelboom et al.[96] found that a major bleeding was associated with a high risk of death within 30 days but to a much lesser extent after that time period (hazard ratio 5.37; 95% CI 3.97 to 7.26 and 1.54; 95% CI 1.01 to 2.36, respectively). The risk was higher if the bleeding had been major rather than minor. The same association was identified in populations treated with fondaparinux to prevent VTE with 8.6% risk of death by 30 days compared to 1.7% when no major bleeding had occurred.[97]

There are obviously several plausible and perhaps all of them contributing reasons for this association, including that major bleeding is more likely to occur in patients with comorbidities (see above), the fact that antithrombotic treatment usually is stopped after a hemorrhage with subsequent increase in the risk of thromboembolism, the potential for hypovolemia and hypoxemia causing myocardial damage, and possible harmful effects of blood transfusions.[98]

MANAGEMENT OF BLEEDING COMPLICATIONS IN ANTICOAGULATED PATIENTS

Localization of Bleeding

As discussed, bleeding is the most frequent and important complication of anticoagulant therapy. The clinical burden of bleeding is generally underestimated—in a systematic review the case fatality rate for bleeding was 9.7% in patients enrolled in large RCTs.[11] Although minor bleeding is inconvenient and potentially disruptive for patients, it generally does not have an adverse outcome. Thus, ecchymoses, epistaxis, and menorrhagia may be very bothersome for patients, albeit rarely resulting in clinically important outcomes. Chronic blood loss will, however, eventually cause iron deficiency anemia. Major bleeding is generally gastrointestinal, genitourinary, or intracranial. Gastrointestinal bleeding may occur from any location within the gastrointestinal tract and may be an indicator of underlying pathology "unmasked" by the anticoagulant. Thus, 50% to 75% of patients presenting with evidence of gastrointestinal bleeding will have a detectable underlying lesion on endoscopic evaluation.[99] Similarly, genitourinary bleeding is generally an indicator of underlying pathology, irrespective of the patient being anticoagulated or not and requiring investigation if renal tract infection has been ruled out. In a prospective study, 81% of individuals with microscopic hematuria had identifiable genitourinary disease.[100] Women treated with VKAs reported menorrhagia in 70.8% compared to 44.2% before therapy.[101] VKAs did, however, not increase the incidence of hematuria in those studies.[100,101]

Intracerebral bleeding may be subdural (usually occurring as a result of traumatic injury), subarachnoid (rarely a complication of anticoagulant therapy), or parenchymal. Subdural hematoma will usually present with chronic and progressive symptomatology associated with slow expansion and compression. Rarely, rapid enlargement may cause a drastically deteriorating neurologic course due to tentorial herniation. Intracerebral hematoma will usually present with a sudden, oftentimes catastrophic, deterioration in neurologic function associated with focal neurologic findings, which may progress rapidly to unconsciousness and death due to raised intracranial pressure.

General Approach to Management

In all cases, management of bleeding requires an organized approach to reduce morbidity and potential mortality.[102] For all major bleedings, the anticoagulant medication should be stopped. Intubation, ventilation, and administration of inotropic drugs and volume substitution may be required during the initial stabilization or while investigations are carried out. Acute resuscitation of a critically ill patient with anticoagulant-associated bleeding will require prompt and thorough evaluation by an interventional or surgical expert. The source of bleeding should be identified and interventions proposed to halt the bleeding. This will require either a surgical, radiologic, or endoscopic intervention. Clinically important bleeding is rarely rectified by medical therapy alone. Local therapies to treat bleeding (such as cauterization of a gastrointestinal lesion or surgical resection of bleeding lesions) can result in immediate cessation of bleeding. More aggressive treatments such as embolization of briskly bleeding vessels may be lifesaving in selected circumstances. Prompt administration of an antidote (if available) should occur in all patients with major or life-threatening hemorrhage. In many patients, empiric therapy with an antidote may antecede imaging. For example, acute neurologic deterioration in a patient with previously normal neurologic function in the setting of administration of a thrombolytic agent is likely to be due to hemorrhage; in this setting, it is more appropriate

Table 107.6

Published bleeding risk prediction tools for patients starting on VKAs

Acronym or First Author	Indication for VKA	N (Derivation/ Validation)	Components and Scoring	Scores and Bleeding Risk		
				Low	Intermediate	High
OBRI[77]	Mixed	556/264	Age ≥ 65, previous stroke, GI bleed <2 wk ago, ≥1 of (recent myocardial infarction, hematocrit <30%, creatinine >1.5 mg/dL, diabetes mellitus) (1 p each)	0	1–2	3–4
Kuijer[90] (simplified score)	VTE	241/780	Age ≥ 60 (1.6 p), female (1.3 p), malignancy (2.2 p)	0	1–3	>3
HEMORR^{2}HAGES[91]	Atrial fibrillation	3,138 patient-y	Hepatic or renal disease, ethanol abuse, malignancy, age > 75, ↓ platelet count or function, hypertension, anemia, genetic factors, fall risk, previous stroke/TIA (1 p each), previous bleed (2 p)	0–1	2–3	4
Shireman[92]	Atrial fibrillation	19,875/6,470	Age ≥ 70 (0.49 p), female (0.32 p), remote bleed (0.58 p), recent bleed (0.62 p), alcohol/drug abuse (0.71 p), diabetes (0.27 p), anemia (0.86 p), antiplatelet Rx (0.32 p)	≤1.07	1.08–2.18	≥2.19
RIETE[93]	VTE	13,057/6,572	Recent bleeding (2 p); creatinine >1.2 mg/dL, anemia (1.5 p each), cancer, symptomatic PE, age > 75 (1 p each)	0	1–4	>4
HAS-BLED[94]	Atrial fibrillation	3.978/not done	Hypertension, abnormal liver function, abnormal kidney function, stroke, previous bleeding, labile INRs, age > 65, alcohol abuse, drugs affecting platelet function (1 p each)	NA	NA	NA

to provide agents to reverse the thrombolytic agent than it is to send the patient for imaging since the delay that such imaging implies will probably result in worsening outcomes or death.

Transfusion Therapy

Transfusion of blood components should be undertaken to address identified coagulation factor defects or to replace red blood cells, platelets, or coagulation factors reduced due to dilutional coagulopathy. Transfusions should not be ordered without adequate clinical basis; they may cause an unrealistic expectation of efficacy, carry the potential for harm, and will delay needed treatments. Thus, for example, the administration of fresh frozen plasma (FFP) or prothrombin complex concentrates (PCCs) to patients with UFH- or LMWH-associated bleeding is inappropriate as antidote, and FFP is potentially dangerous for volume overload.[103,104] However, administration of FFP or PCCs to a patient who has received VKAs is very appropriate. Red blood cells should be administered based on assessments of the hemoglobin value, interpreted in light of the amount of bleeding. FFP and platelets should be administered based on laboratory evaluations of coagulation parameters except in the setting of profuse bleeding where FFP may be administered at an initial dose of 10 to 15 mL/kg.[105]

Nonspecific Agents

A number of nonspecific prohemostatic agents are available. These include deamino-D-arginine vasopressin (DDAVP), antifibrinolytics, and estrogens. These agents should be considered in patients with major or life-threatening bleeding, although their efficacy in patients with antithrombotic therapy–induced bleeding has generally not been studied and they may be associated with complications including thrombosis. Recombinant activated factor VII (rfVIIa) has been widely promulgated as an effective agent for the reversal of a variety of anticoagulants,[106,107] and it is indeed able to generate a thrombin burst on the surface of platelets even in the setting of severe coagulopathy.[108] However, use of rfVIIa is largely based on animal models, impact on surrogate markers in healthy volunteers, and occasional case reports in patients who are receiving multiple interventions in the setting of acute bleeding. Given its cost and potential for thromboembolic complications,[109] it should only be entertained in patients with life-threatening bleeding who have not responded to other interventions.

MANAGEMENT OF BLEEDING ON SPECIFIC AGENTS

The principles are summarized in Table 107.7.

Vitamin K Antagonists

Warfarin, acenocoumarol, and phenprocoumon are the three commonly used oral VKAs (although others are available in some jurisdictions). The initial management of a patient with major or life-threatening bleeding receiving VKAs should adhere to the first principles outlined previously. In critical situations, rapid reversal of the INR is of the utmost importance; this should precede imaging to determine the source of bleeding. Traditionally, FFP was the agent of choice for reversal of VKAs. FFP is slow to obtain, is associated with the potential for fluid overload,[110] may not be virally inactivated, and requires a group and screen unless AB plasma is used. Furthermore, the volume of FFP required to normalize the INR is very large and, in many settings, impractical. Usual FFP transfusions (e.g., 4 to 6 U) will not normalize the INR in the bulk of patients.[104] Estimates of the volume of FFP required to restore vitamin K–dependent coagulation factors and normalize the INR are as high as 35 mL/kg,[111] a dose far in excess of what is practical to administer to a bleeding patient. PCCs are now available in many jurisdictions. Generally, the so-called three-factor PCCs have adequate levels of coagulation factors II, IX, and X and reduced levels of VII. As a result, when administered to patients who have received warfarin, they may not normalize the INR.[112] However, the coadministration of a three factor PCCs with a small dose of FFP or rfVIIa can rapidly correct the INR.[112] The four-factor PCCs have adequate levels of coagulation factors II, VII, IX, and X. As a result, when administered in appropriate doses, they can rapidly correct the INR to normal.[113] Advantages of PCCs include the ability to rapidly reconstitute them from a lyophilized powder, viral inactivation, a small volume of administration allowing rapid infusion, and a lack of a need for cross-match. In general, they are somewhat more expensive than FFP (300 U resource costs for PCCs, 500 IU, vs. 176.5 U resource costs for one bag of FFP), but their ability to rapidly correct the INR results in better cost-effectiveness for PCCs.[114] Currently, there are a number of three- and four-factor PCCs available or under evaluation in many jurisdictions. Their composition regarding contents of the four coagulation factors—protein C, protein S, antithrombin, and heparin—differ somewhat, but there are no comparisons to demonstrate whether this has clinical implications.[115] Clinicians are advised to contact their transfusion medicine service to better understand what is available in their area. The required dose of PCCs can be calculated from the current and the desired INR and the body weight[116] or appreciated according to a simplified algorithm (Table 107.8).

When reversing oral VKAs, it is critically important to remember to administer supplemental vitamin K. In the setting of major or life-threatening bleeding, this is best administered in doses of 5 to 10 mg given by slow intravenous infusion. Vitamin K has been reported to cause anaphylaxis at an incidence of 3 per 100,000

Table 107.7

Efficacy of different antidotes for the antithrombotic agents[a]

	Vitamin K	Plasma	PCC	rfVIIa	APCC	Protamine	DDAVP	Platelets
VKA	+++ very slow	+	+++	++				
UFH				+		+++		
Low molecular weight heparin				++		++		
Direct thrombin inhibitors					?			
Fondaparinux				++				
Direct factor Xa inhibitors			++					
Aspirin							++	++
Clopidogrel, Prasugrel							++	+++
Ticagrelor								–

[a]+++ indicates very good effect; ++ indicates effect shown in human volunteers or in clinical situations under certain conditions; + indicates some effect, other alternatives preferred; ? indicates effect in animal model or single case reports; – indicates no expected effect.
PCC, prothrombin complex concentrate; rfVIIa, recombinant-activated factor VII; APCC, activated prothrombin complex concentrate; DDAVP, deamino-D-arginine vasopressin.

Table 107.8

A simplified nomogram for estimation of dose of PCC for reversal of VKAs

Dosing for Target INR:	~1.5	<1.2
Current INR	Dose	Dose
2–3	20 IU/kg	30 IU/kg
3–6	30 IU/kg	40 IU/kg
>6	40 IU/kg	50 IU/kg

intravenous doses (95% CI, 0.04 to 11).[117,118] Failure to administer vitamin K may result in "rebound" anticoagulation on the day following admission due to diminution of the activity of transfused coagulation factors in the setting of a persistent effect of the VKAs (particularly with warfarin and phenprocoumon that have longer half-life than acenocoumarol). Vitamin K at doses of 1 to 2 mg, administered orally, are effective treatments for excessive anticoagulation without bleeding, or in the setting of minor bleeding where a short period of reduction or normalization of the INR is deemed necessary. However, low-dose oral vitamin K has been shown to not reduce bleeding in asymptomatic patients with excessively prolonged INR values.[119] If the INR is markedly prolonged (e.g., >10.0), the administration of a small oral dose of vitamin K (e.g., 2.5 mg) is generally recommended.[46,120]

Unfractionated and Low Molecular Weight Heparin

Heparin is a complex macromolecular biologic agent that produces the majority of its anticoagulant effect through an antithrombin-dependent catalytic action on serine proteases that are active in coagulation, including factors IIa, Xa, VIIa, VIIIa, Xia, and XIIa. Chemical or physical depolymerization of heparin produces LMWH, which (due to reduced nonspecific binding) has more predictable pharmacokinetics. UFH and LMWH can be given in prophylactic doses (for the prevention of thrombosis) or therapeutic doses (for its treatment). Although bleeding may complicate lower dose heparin therapy, it is predominately a complication of higher doses. Very large doses of UFH, associated with a high risk of major bleeding, are used in procedures such as cardiopulmonary bypass, extracorporeal membrane oxygenation, and in other settings with intense prothrombotic stimuli or where a surface is in contact with the blood.

UFH can be completely reversed with protamine sulphate, which inhibits heparin through a covalent interaction. One mg of protamine reverses about 100 U of heparin activity. When judging the dose of protamine sulphate, the amount of heparin in the circulation should be estimated, assuming a half-life of infused drug of 30 to 60 minutes. The effectiveness of protamine can be assessed using an APTT, activated clotting time, or thrombin clotting time (TCT); full neutralization should result in normalization of these tests. When UFH is given by subcutaneous injection or in very large doses, its half-life may exceed that of protamine; in such cases "rebound" anticoagulation may be seen and additional doses of protamine may be required.[121] Care should be taken with protamine; it is a fish-derived protein and may cause allergic reactions in selected groups of patients, including those with an allergy to iodine. Rapid administration is associated with hypotension and a systemic inflammatory state—thus the infusion should be at a moderate rate, and slowed or stopped if these complications are seen.

Protamine partially reverses the effect of LMWHs—it reverses all of their anti-IIa effect and a variable proportion of their anti-Xa effect.[122,123] The degree of reversal appears to correlate *in vivo* with the average chain length and charge of the LMWH with products such as tinzaparin being more reversible than enoxaparin.[123] However, the clinical impact of these differences is unknown.

In addition to the administration of protamine, those measures discussed in the introduction should be instituted. As the half-life of heparin is short (UFH 0.5 to 2 hours, LMWH ~5 hours), its effect will wane rapidly—thus with mild or moderate bleeding simple heparin withdrawal may be all that is required.

A variety of heparinases[124] and synthetic heparin-binding agents such as concatemeric peptides[125] and platelet factor 4[126] have been evaluated in clinical trials—none are approved or commercially available.

There is no evidence that fibrinolytic inhibitors of PCCs, are effective for the reversal of heparin-associated bleeding.

The amount of LMWH present may be determined using an anti-Xa heparin level. Although there are concerns about the reliability of this test, any detectable level indicates the presence of drug. Serial anti-Xa levels may be useful in the case of intentional overdose or to monitor for residual or excessive anticoagulant effect in patients with renal insufficiency.

Thrombin Inhibitors

Until recently, direct thrombin inhibitors were exclusively parenteral and used in limited clinical circumstances. Thrombin inhibitors available include argatroban, the hirudins, and hirudin derivatives such as bivalirudin. Recently, dabigatran was approved for the prevention of cerebrovascular events in patients with atrial fibrillation. Other approved or sought indications include orthopedic prophylaxis and the prevention of recurrent thrombosis in patients with acute deep vein thrombosis or pulmonary embolism. With the advent of these medications, thrombin inhibitors are likely to become commonly used.

There are no antidotes for the anticoagulant effect of the thrombin inhibitors. Management of major or life-threatening hemorrhage is contingent on the basic principles previously outlined: withdrawal of the agent, investigations to identify and treat the bleeding source, lifesaving therapy, and transfusion to treat identified cytopenias or coagulopathies.

Argatroban has a half-life of <1 hour after intravenous administration, and thus its effect wanes quickly with withdrawal. Argatroban is not renally excreted; thus, it can be used in patients with severe renal insufficiency. Argatroban is very dependent on normal hepatic function, and its half-life will be markedly prolonged in patients with hepatic dysfunction. The INR is markedly prolonged during treatment with argatroban. Concomitant treatment with warfarin should start at the expected daily dose without any loading dose. The argatroban infusion at doses up to 2 μg/kg/min is discontinued when INR is >4, and it should then be checked again after 4 to 6 hours. If the repeat INR is below 2.0, the argatroban infusion should be resumed.

Hirudins are renally excreted, in part. Their half-lives are markedly prolonged in the setting of renal failure. Bivalirudin is cleared in part by autocatalysis. As a result, it is less affected than the other parenteral direct thrombin inhibitors by organ dysfunction. It has a very short circulating half-life of about 25 minutes.

Dabigatran is 80% excreted by the kidneys.[127] After oral administration, it has a half-life of approximately 15 hours, becoming prolonged in patients with renal insufficiency. Dabigatran is only 25% to 35% protein bound[128] and thus may be removed by dialysis. Unabsorbed drug may be cleared by oral charcoal administration and gastric lavage.[129] Dialysis, oral charcoal administration, and gastric lavage may be particularly useful in the case of intentional overdose where dabigatran may be present in the gastrointestinal tract and circulation in much higher than normal levels.[129]

It is unclear whether "prohemostatic" agents such as PCC, rfVIIa, fibrinolytic inhibitors, or DDAVP are able to mitigate bleeding complications due to thrombin inhibitors. Small studies in animals and in normal volunteers suggest that *ex vivo* markers of activity (such as coagulation tests) may be normalized with PCCs or rfVIIa.[129] Conversely, rfVIIa failed to reverse the effect of another oral thrombin inhibitor, melagatran, in volunteers.[130] Activated prothrombin complex concentrate (APCC) at a dose of 50 U/kg effectively stopped bleeding in an animal model with melagatran.[131] There is no evidence of the efficacy of these agents in bleeding patients. In the case of major or life-threatening bleeding, any of these agents may be considered, keeping in mind the lack of evidence for their efficacy and their potential to cause side effects including thrombosis.

There are no commonly available quantitative assays for any of the direct thrombin inhibitors. These agents variably prolong the INR, the APTT, and other coagulation tests such as the ecarin clotting time.[129] TCT using 2 U thrombin/mL of reagent is very sensitive to the presence of direct thrombin inhibitors. As a result, a normal TCT rules out the presence of any of these agents.

Indirect Factor Xa Inhibitors

Fondaparinux is a parenteral antithrombin-dependent inhibitor of coagulation factor Xa. After subcutaneous administration, it has a half-life of 17 to 21 hours. It is dependent on renal function for clearance, and its half-life is markedly prolonged in patients with severe renal insufficiency. Protamine is ineffective for the reversal of fondaparinux. When bleeding occurs, standard management (previously outlined) should be invoked. There is no evidence that transfusion therapy effectively reduces the activity of fondaparinux. Small studies in animals and healthy volunteers suggest that rfVIIa can ameliorate the anticoagulant effect of fondaparinux, and there are case reports supporting the efficacy of 30 to 90 μg/kg rfVIIa to control bleeding associated with fondaparinux or the long-acting pentasaccharides idraparinux.[132–135]

Fondaparinux levels can be determined using an anti-Xa heparin level. For quantification, the assay should use a fondaparinux standard, although in emergency situations an LMWH standard could be used realizing that the resultant levels will inaccurately convey the quantity of fondaparinux but should accurately reflect the presence or absence of the medication.

Direct Factor Xa Inhibitors

Rivaroxaban is available in many countries, and apixaban has been approved for prophylaxis against VTE after orthopedic surgery in the European Union at the time of writing. Additional agents (including edoxaban and betrixaban) are currently in the late stage of clinical evaluation. The direct inhibitors of factor Xa are oral agents. They are dependent to a greater or lesser extent on normal renal function for excretion. After oral administration, they are rapidly absorbed and have relatively short half-lives (<12 hours).

With major bleeding, patients should receive standard management (previously outlined). If a dose has been taken recently or in the case of intentional overdose, elimination from the gastrointestinal tract with gastric lavage and oral administration of charcoal might be considered. Rivaroxaban is highly protein bound and thus is not amenable to dialysis.[136] It might be removed by hemoperfusion, but this has not been studied. The use of rfVIIa is recommended for bleeding; however, there is no clinical evidence to support its effectiveness.[137] *Ex vivo* studies suggest that PCCs may be able to reverse the effective rivaroxaban. This effect, if it actually exists, is probably due to the fact that rivaroxaban is a stoichiometric inhibitor of factor Xa—administering PCCs presumably "floods" the circulation with factor X that binds to and inactivates rivaroxaban.[138]

Prothrombin time and anti-Xa show a linear response to rivaroxaban levels, but the tests are assay dependant. Standard calibrators for rivaroxaban are available and should be used to develop assay-specific calibration curves.

Antiplatelet Drugs

Bleeding complications commonly occur in patients taking antiplatelet agents. The risk of hemorrhage is increased by the use of multiple agents particularly when in concert with an anticoagulant such as warfarin.[139]

In general terms, there are no specific antidotes for the antithrombotic effect of any of the antiplatelet agents. Treatment is further complicated by the observation that most agents produced sustained inhibition of platelet activity, with the degree of inhibition depending on the type of agent. Recently, a number of short-acting agents and/or reversible agents have been evaluated,[140,141] although it is likely that their use will be limited given the widespread acceptance and relative inexpensiveness of agents such as aspirin and clopidogrel.

There are no easily available assays, which accurately reflect the degree of inhibition of platelet activity. As a result, treatment of bleeding should be undertaken with the assumption that an antiplatelet effect is present if, based on an estimation of half-life, it is likely that drug effect will still be present. It is important to remember that the platelet inhibitory half-life of aspirin and clopidogrel considerably exceeds their pharmacokinetic half-life due to their irreversible impact on platelet function (in the case of aspirin) or the presence of a metabolite with an extended half-life (clopidogrel).

In the setting of major or life-threatening bleeding, the general approach to managing hemorrhage (previously outlined) should be implemented. Use of nonspecific prohemostatic agents (such as DDAVP) has been evaluated in small experiments in normal volunteers or in animals, but there is little evidence to guide practice in patients with hemorrhage.[142] In

truly life-threatening hemorrhage or in patients requiring time-limited interventions, transfusion of platelets may provide enhanced prothrombotic activity particularly if the drug has been removed from the circulation while the patient's native platelets continue to be inhibited.[143] For example, the antithrombotic effect of aspirin persists well beyond its pharmacologic half-life due to irreversible inhibition of the cyclooxygenase enzyme. Transfusion of normally functional platelets should reconstitute some degree of platelet function if administered after the clearance of all of the aspirin from the circulation. Ticagrelor binds reversibly to the ADP receptor and can therefore inhibit freshly transfused platelets to the same extent. Further details on the management of antiplatelet agents are provided in Chapter 111.

MANAGEMENT OF ANTICOAGULATION AFTER MAJOR BLEEDING

Patient with a VKA-associated major bleeding have to be evaluated carefully for (a) resumption of anticoagulation and (b) the optimal timing, in case resumption is deemed having a greater benefit than risk. The most difficult constellation is the patient with a clear indication for anticoagulation (mechanical valve or atrial fibrillation with a previous ischemic stroke) and an intracranial bleeding. In a decision analysis using a Markov model, stratified for the location of an intracerebral hemorrhage being lobar or deep hemispheric, Eckman et al.[144] found that for lobar bleeding withholding future anticoagulation resulted in improved quality-adjusted life expectancy. Conversely, for deep hemispheric hemorrhage and a high risk of stroke, resumption of anticoagulation was preferred. Majeed et al.[145] performed a retrospective study of 234 patients with warfarin-associated intracranial hemorrhage, out of whom 59 resumed anticoagulation. By estimation of the rates of the two main adverse events—recurrent intracranial bleeding and ischemic stroke—in relation to different time points of resumed anticoagulation, it was demonstrated that the optimal resumption point for VKAs is 10 to 30 weeks after the index bleeding. Prophylaxis against VTE should, however, be started already after 2 to 4 days with low-dose subcutaneous heparin or LMWH.[146,147]

The most common major hemorrhagic complication on VKA, gastrointestinal bleeding, is more tolerable, even in case of recurrence. Half of these bleeding are from the upper part of the gastrointestinal tract, usually caused by an ulcer and the early mortality is about 4%.[148] Recurrent bleeding, including life-threatening events, are not uncommon.[78] It is probably optimal to delay resumption of anticoagulation until healing of an ulcer has been demonstrated by repeat endoscopy, although this has not been proven in any appropriately designed study.

SUMMARY

Antithrombotic agents are highly effective for the prevention and treatment of a variety of prothrombotic disorders. Complications of their use largely consist of bleeding. As novel agents are introduced, management becomes more complex. The lack of antidotes and a proliferation of agents with variable half-lives, pharmacologic effects, and dosing increases the likelihood of errors leading to excessive anticoagulant effect. Management of hemorrhage should consist predominantly of a withdrawal of the agent, evaluation of the source of bleeding, disruption of the source of bleeding, administration of an antidote (if one exists), administration of nonspecific prohemostatic agents, and heroic interventions (when required) including the use of dialysis or hemoperfusion. In most cases, symptomatic management and the passage of time will lead to elimination of the anticoagulant effect of these agents and cessation of bleeding.

CHAPTER

108 Heparin-Induced Thrombocytopenia

THEODORE E. WARKENTIN AND ANDREAS GREINACHER

Heparin-induced thrombocytopenia (HIT) is an immune-mediated adverse drug reaction caused by heparin-dependent, platelet-activating immunoglobulin (Ig) G antibodies that recognize complexes of platelet factor 4 (PF4) bound to heparin.[1–3] HIT represents a strong, independent risk factor for venous and arterial thrombosis.[4]

HIT typically causes thrombosis in large veins and arteries; platelet-rich, intra-arterial "white thrombi" were first described in 1958.[5,6,7] However, HIT is also a risk factor for microvascular thrombosis in certain situations, such as in coumarin treatment of deep vein thrombosis (DVT) (i.e., coumarin-associated venous limb gangrene [see Chapter 109]) or severe HIT-associated disseminated intravascular coagulation (DIC).[8,9,10]

Thrombosis typically occurs in anti-PF4/heparin antibody-positive patients who develop significant declines in platelet count,[11,12,13,14] pointing to clinically relevant consequences of *in vivo* platelet activation induced by these antibodies. A central role for *in vivo* thrombin generation in HIT[8] provides a rationale for the use of anticoagulants that inhibit thrombin or its generation.[15]

DEFINITION AND TERMINOLOGY

HIT can be defined as any clinical event best explained by platelet-activating anti-PF4/heparin antibodies ("HIT antibodies") in a patient who is receiving, or who has recently received, heparin (or another polyanion implicated in this syndrome).[1] Thrombocytopenia is the most common event in HIT and occurs in at least 90% of the patients, depending on the definition of thrombocytopenia. A high proportion (50% to 75%) of patients with HIT develop thrombosis.

A consensus report[15] recommended that the term *heparin-induced thrombocytopenia* should be used to refer to the antibody-mediated disorder. Therefore, HIT can be considered a *clinicopathologic* syndrome in which the diagnosis can be made accurately when one or more *clinical* events (e.g., thrombocytopenia, thrombosis, necrotizing skin lesions at heparin injection sites, acute systemic [anaphylactoid] reactions, decompensated DIC) occur together with laboratory detection of the *pathologic* HIT antibodies. In contrast, it is recommended that the term *nonimmune heparin-associated thrombocytopenia* (HAT) should be used to describe thrombocytopenia occurring during heparin use that is not associated with HIT antibodies. Often, nonimmune HAT is due to a comorbid disorder (e.g., perioperative hemodilution), although a direct platelet-activating effect of heparin that is not mediated by antibody may occur in some patients.[16] Unlike the situation in HIT, the causative role of heparin in nonimmune HAT in a given patient cannot readily be ascertained.

PATHOGENESIS

FIGURE 108.1 summarizes the pathogenesis of HIT.[17] The central concept is the formation of heparin-dependent IgG that activates platelets via their FcγIIa receptors.[18] It remains controversial—although in our view unlikely—whether IgA and IgM antibodies evince pathogenicity.[19–21,22] The target antigen is a complex of heparin and the positively charged platelet α-granule protein, PF4,[23,24–26] a member of the CXC subfamily of chemokines. HIT antibodies are directed against one or more sites on PF4 that have been conformationally altered by binding to negatively charged heparin.[27–29,30] This model is consistent with reports that other highly sulfated, nonheparin carbohydrates such as pentosan polysulfate[31] and polysulfated chondroitin sulfate[32] can trigger HIT. This possibly triggered additional adverse effects by oversulfated chondroitin sulfate within "contaminated" heparin.[33] It may also explain why low molecular weight heparin (LMWH) is less likely to trigger HIT,[11,12] as only heparin molecules of at least 12 saccharides in length bind PF4 in such a way as to induce a large number of neoepitopes required for clinical breakthrough of HIT.[34] Rarely, a disorder mimicking HIT on clinical and serologic grounds can occur in the absence of preceding heparin exposure ("spontaneous HIT"); reported cases have featured preceding inflammatory events such as surgery or infection.[35–37] This indicates that the immune reaction to PF4/polyanion complexes can also be induced by endogeneous factors, a feature relevant to understanding the temporal features of antibody formation. Moreover, many HIT-positive sera[38,39]—but especially those obtained from patients whose HIT begins[40] or worsens after stopping heparin—are able to activate platelets *in vitro* even in the absence of pharmacologic heparin, a phenomenon consistent with "autoimmune-like" features.

Anti-PF4/heparin seroconversion has certain atypical features[41,42]: Antibodies are formed relatively quickly—approximately 4 days (median) after even a first-time immunizing heparin exposure, and without evidence for more rapid formation with previous heparin exposure or even with previous HIT.[43] Anti-PF4/heparin antibodies of any of the three major Ig classes can develop and in any combination, in the frequency IgG > IgA > IgM.[41,42] Moreover, when IgM antibodies are formed, these are detectable simultaneously with IgG and/or IgA, that is, there is no IgM precedence (as would be expected in a "classic" immune response). This indicates that the immune response induced by heparin is a secondary, rather than a primary, immune response; PF4 complexed to polyanions on bacterial surfaces might be the "preimmunizing" trigger.[44]

Several factors contribute to the prothrombotic nature of HIT (FIGURE 108.1): (a) the potent platelet-activating

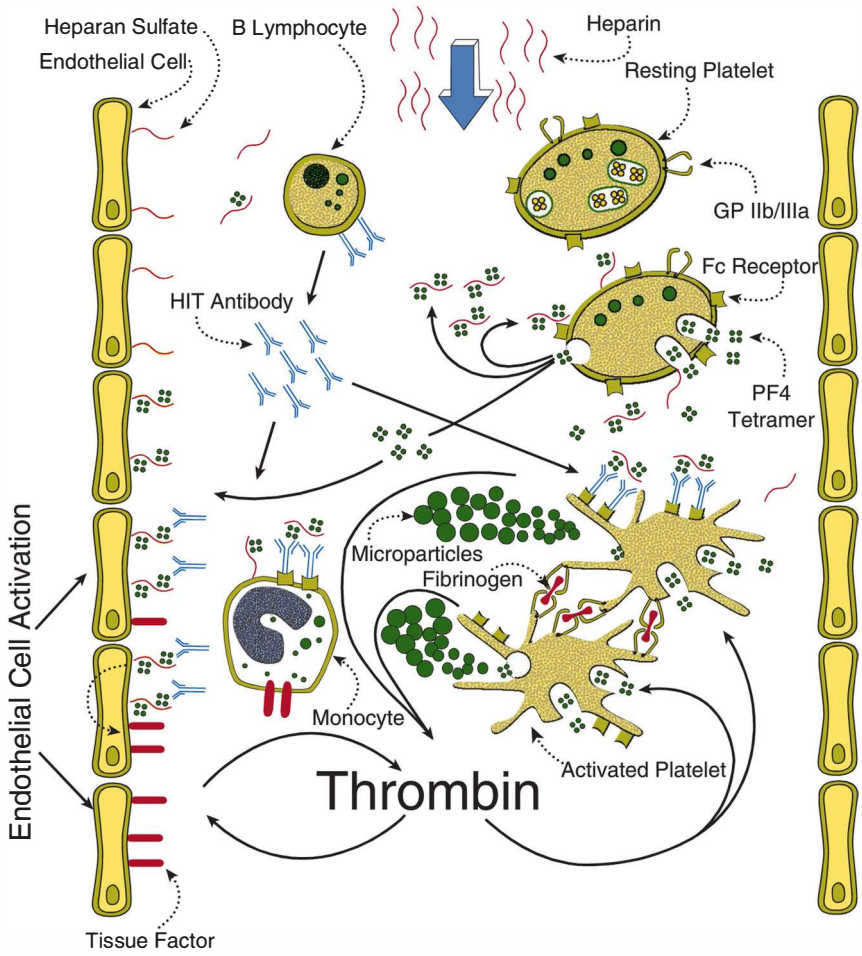

FIGURE 108.1 Pathogenesis of HIT. Heparin produces mild platelet activation, resulting in the release of PF4 from platelet α-granules and in the formation of immunogenic PF4/heparin complexes. B lymphocytes generate IgG that recognize the PF4/heparin complexes; the Fc "*tails*" of the IgG bind to platelet FcγII receptors, resulting in Fc receptor clustering and consequent strong platelet activation. Platelet aggregation is mediated by glycoprotein (GP) IIb/IIIa. Platelet-derived microparticles that accelerate thrombin generation are produced. The HIT antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to tissue factor expression on endothelium. HIT antibodies also can activate monocytes. In all, increased thrombin generation results can explain some of the unusual clinical manifestations of HIT (e.g., venous limb gangrene and DIC) and provide a rationale for treatment that reduces thrombin generation. (From Greinacher A, Warkentin TE. Treatment of heparin-induced thrombocytopenia: an overview. In: Warkentin TE, Greinacher A, eds. *Heparin-induced thrombocytopenia*, 4th ed. New York: Informa Healthcare USA, 2007:283–317.)

properties of the HIT antibodies, which also generate procoagulant, platelet-derived microparticles[45,46]; (b) pancellular activation (either directly or indirectly by HIT antibodies),[47,48] manifesting as tissue factor expression on endothelium[25,48,49] and monocytes,[50,51] and possibly platelet–leukocyte complex formation[52]; and (c) neutralization of the heparin anticoagulant effects by PF4. Collectively, these factors result in increased thrombin generation in HIT.[8,53,54]

Women are more likely than men to develop HIT (~ twofold increase by odds ratio).[55] However, no HLA association or other genetic risk factor has been identified.[56] Although the platelets bearing FcγIIa receptors of the His131 phenotype (~70% of the population) are more readily activated by HIT antibodies of IgG1 subclass (the predominant subclass in HIT),[57,58] no clear association between HIT and Fc receptor genotype has been established.[59,60] A strong, albeit indirect, argument against a genetic risk factor is the surprising observation that even patients with a previous history of HIT do not usually regenerate HIT antibodies upon repeat heparin exposure.[43,61]

RISK FACTORS FOR HIT

The frequency of HIT is variable and is influenced by the type of patient population (major surgery or trauma > minor surgery > medical > obstetrical), sex (female > male), the type of heparin used (bovine unfractionated heparin [UFH] > porcine UFH > porcine LMWH > fondaparinux), duration of heparin therapy (the risk increases until ~10 to 14 days of heparin administration), and, possibly, the timing of the first

dose of anticoagulant in relation to surgery (postoperative > preoperative) and body mass index (BMI) (high BMI > low BMI).[55,62–64] A stoichiometric model of optimally immunizing PF4:heparin ratios has been proposed to explain some of these observations.[64,65]

A relatively high frequency (~5%) of HIT occurs in postoperative orthopedic surgery patients receiving prophylactic-dose UFH for up to 14 days.[11,12,66] The frequency is even higher (8% to 10%) in postcardiac surgery patients who receive therapeutic-dose UFH after implantation of a ventricular assist device.[67–69] In contrast, HIT was not observed in several large studies in which LMWH was administered for many weeks during pregnancy.[70–72] The frequency of HIT occurrence is estimated to be about 1% in patients receiving UFH for treatment of venous thromboembolism[62] and, perhaps, for prevention of thrombosis in medical patients,[73] and approximately 0.1% to 0.5% in postoperative patients receiving LMWH[62]; case reports suggest a small risk of HIT (probably <0.01%) with fondaparinux thromboprophylaxis after surgery.[74–76] However, it might be that in these cases the antibodies (albeit triggered by fondaparinux) show the autoantibody-like behavior described above. Given the decreasing use of UFH after orthopedic surgery, one common scenario for HIT today is antithrombotic prophylaxis with UFH following cardiac surgery (risk: ~1% if UFH is given for >1 week).[77]

Patient-dependent risk factors influence the type of HIT-associated thrombotic event. For example, venous thrombosis occurs in at least half of postorthopedic surgery patients who develop HIT, with relatively few arterial thrombi observed.[11,12,66] In contrast, arterial thrombosis occurs at least as often as venous thrombosis in patients with HIT after cardiac surgery, suggesting a predisposing role for atherosclerosis.[62,78,79] Risk of limb amputation is greater in patients who develop HIT in the setting of peripheral vascular surgery.[80] Patients with a central venous catheter who develop HIT have about a 10% chance of developing symptomatic upper limb DVT at the catheter site, reflecting the interaction of localized vessel injury with the systemic hypercoagulability of HIT.[81]

CLINICAL PRESENTATION

HIT is a distinct immunohematologic syndrome that usually can be distinguished on clinical grounds from IgG-mediated thrombocytopenia caused by drugs such as quinine/quinidine or sulfa antibiotics.[82–84]

Thrombocytopenia

The thrombocytopenia is usually mild to moderate in severity (median platelet count nadir, ~50 to 60 × 10^9/L)[1,9,82–84] (see FIGURE 108.2). The platelet count is <20 × 10^9/L in only 5% to 10% of patients with HIT; in contrast, severe thrombocytopenia typically occurs in patients with immune thrombocytopenia caused by other drugs.[84–86] Petechiae and ecchymoses are usually absent even in patients with HIT who have severe thrombocytopenia. Thrombosis is common in HIT, irrespective of the severity of the thrombocytopenia, and can occur in patients with a decreased platelet count that may not necessarily be lower than 150 × 10^9/L[1,12] (see FIGURE 108.3), although the risk and severity of thrombosis increase with the degree of thrombocytopenia, whether expressed in absolute or proportional terms.[12,13,14,80,87,88] In postoperative patients, a proportional fall in platelet count (≥50%) between postoperative days 4 and 14 is more sensitive (and similarly specific) for HIT than the conventional definition of thrombocytopenia (platelet count fall to <150 × 10^9/L). Identifying the postoperative platelet count peak as the appropriate "baseline," together with regular platelet count monitoring (particularly in patients receiving UFH after a major surgery), is important for being able to recognize a HIT-associated decrease in platelet count when a thrombotic event occurs (FIGURE 108.3).[12,83,87,88]

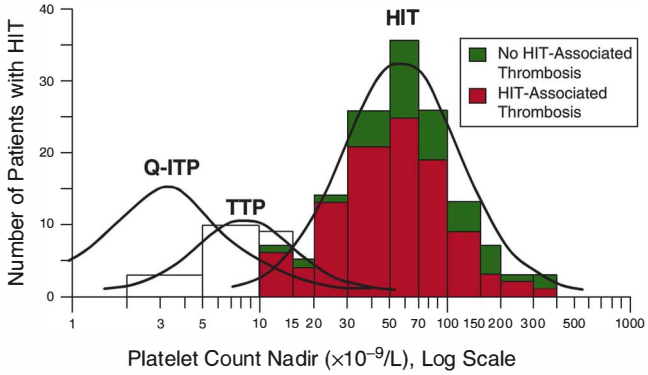

FIGURE 108.2 Platelet count nadirs in HIT, quinine-induced immune thrombocytopenic purpura (Q-ITP), and thrombotic thrombocytopenic purpura (TTP) with absent ADAMTS-13 activity. The majority of patients with HIT have HIT-associated thrombosis, and the risk of thrombosis is substantial irrespective of the severity of the thrombocytopenia. Data on TTP were kindly provided by James N. George, MD. (From Warkentin TE. Think of HIT. *Hematology Am Soc Hematol Educ Program* 2006:404–414, with permission.)

Timing

Patients with HIT typically develop a platelet count fall that begins between days 5 and 10 of heparin treatment (1st day of heparin use [especially intraoperative or early postoperative heparin] = day 0).[9,43,89] Sometimes, thrombocytopenia can begin earlier in patients who have been exposed previously to heparin. In general, this is observed only in patients whose previous heparin exposure is recent (within the past 3 months), in which case an immediate recurrence of thrombocytopenia can occur on reexposure to heparin.[43,89] A true anamnestic immune response, in which previous heparin exposure predisposes to a greater probability of forming more avid (higher-titer, higher-affinity) antibodies, is *not* a feature of HIT. Sometimes, HIT can begin several days after all heparin has been stopped (delayed-onset HIT) or progress despite stopping heparin.[40,90–92,93] This clinical picture is characterized by high-titer HIT antibodies that can activate platelets even in the absence of heparin.[40]

Prospective studies indicate a characteristic "timeline" of anti-PF4/heparin seroconversion and development of clinically evident HIT: Antibodies first become detectable at day 4, the platelet count begins to fall at day 6, thrombocytopenia (≥50% platelet count fall) is manifest at day 8, and thrombosis occurs at day 10 (days all expressed as median values). However, while the timing of the immune response and the associated platelet

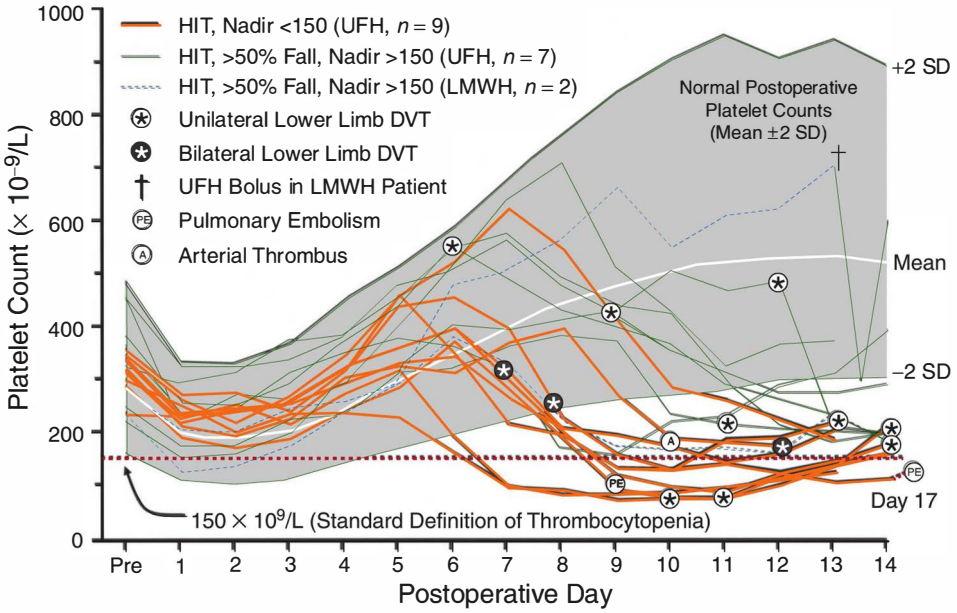

FIGURE 108.3 Characteristic timing, severity, and prothrombotic nature of HIT. The *shaded area* indicates the mean (±2 standard deviation [SD]) platelet count range in the reference population without HIT. There is an immediate postoperative decrease in the platelet count (maximal, days 1 to 3), followed by a rise to levels greater than baseline (maximal, days 11 to 14). Antithrombotic prophylaxis with subcutaneous UFH (7,500 U twice daily) or the LMWH, enoxaparin (30 mg twice daily), was begun usually on postoperative day 1. Eighteen patients developed HIT (50% or greater fall in the platelet count from the postoperative peak), with nine evincing a platelet count nadir <150 × 10^9/L and nine a platelet count nadir >150 × 10^9/L. The *symbols* indicate thrombotic events, 18 of which occurred in 13 of the 18 patients with HIT. One patient who received enoxaparin developed an abrupt platelet count fall when given a 5,000 U bolus of UFH (†). (Created from figures in Warkentin TE, Levine MN, Hirsh J, et al. Heparin-induced thrombocytopenia in patients treated with low-molecular-weight heparin or unfractionated heparin. *N Engl J Med* 1995;332:1330–1335; Warkentin TE, Roberts RS, Hirsh J, et al. An improved definition of immune heparin-induced thrombocytopenia in postoperative orthopedic patients. *Arch Intern Med* 2003;163:2518–2524.)

count fall is rather uniform, for thrombotic events, the onset ranges widely, sometimes occurring even before the fall in platelet count is readily apparent, or up to several weeks later.[14,83,88]

Complications

Table 108.1 lists various complications of HIT by frequency. The strong association between HIT and thrombosis means that this diagnosis should be considered when a patient develops thrombosis or other potential HIT-associated sequelae in association with a falling platelet count during, or shortly after stopping, heparin therapy (FIGURE 108.3).

Venous thrombosis is the most common complication of HIT and includes DVT and pulmonary embolism.[1,11,12,13,94] Abdominal or flank pain suggests adrenal hemorrhagic necrosis, which can lead to shock secondary to acute adrenal failure if bilateral. This complication results from adrenal vein thrombosis.[9] Headache and acute neurologic sequelae suggest dural sinus (cerebral venous) thrombosis.[91,92] Splanchnic vein thrombosis (e.g., mesenteric vein thrombosis) is a rare complication of HIT.

Arterial thrombosis is relatively common in HIT and most often involves large limb arteries, resulting in acute arterial occlusion with absent pulses.[8,94,95] Thrombotic stroke, myocardial infarction, or mesenteric artery thrombosis occurs less often.[9,94]

Limb ischemia or gangrene can be categorized as limb ischemia with and without palpable or Doppler-identifiable pulses (see FIGURE 108.4).[5,8,95] Absent pulses suggests that the acute limb ischemia is caused by large artery occlusion by platelet-rich "white clots." In contrast, severe limb ischemia with pulses present indicates microvascular thrombosis in HIT and is most commonly caused by treatment of DVT using warfarin (coumarin) (see Chapter 109).[8,96–98] The laboratory hallmark of coumarin-associated venous limb ischemia is a supratherapeutic international normalized ratio (INR) (usually >3.5), which is a surrogate marker for severe protein C depletion (in parallel with a severe reduction of factor VII) complicating coumarin therapy for HIT-associated DVT (see Chapter 109). Rarely, venous limb ischemia or necrosis is associated with decompensated DIC in HIT in the absence of coumarin therapy, with or without associated DVT,[9,10] possibly because of acquired natural anticoagulant depletion.

Classic (nonacral) coumarin-induced skin necrosis has been reported in patients with HIT,[8,98,99] but this is less common than venous limb gangrene (see Chapter 109).

Table 108.1

Complications of HIT

Venous Thrombosis	Arterial Thrombosis	Miscellaneous
DVT (50%)	Aortoiliac thrombosis (acute limb ischemia) (5%–15%)	Heparin-induced necrotizing skin lesions (small minority of sensitized patients receiving subcutaneous heparin injections)
Pulmonary embolism (25%)	Acute thrombotic cerebrovascular accident (5%–10%)	Acute systemic reactions postintravenous heparin bolus (≈25% of sensitized patients who receive a heparin bolus)
Warfarin-induced venous limb gangrene (≈10% of HIT patients with DVT treated with warfarin)	Myocardial infarction (3%–5%)	Adrenal hemorrhagic infarction (1%–3%)—manifestation of adrenal vein thrombosis
Rare: cerebral sinus thrombosis (<3%); splanchnic vein thrombosis (e.g., mesenteric or portal vein thrombosis) (<3%)	Rare: thrombosis of upper limb, renal, mesenteric, spinal, other arteries (<3%)	Rare: DIC with hypofibrinogenemia and microvascular thrombosis (<3%)

Estimated frequencies of the various complications of HIT are taken from several series of patients with serologic support of the diagnosis of HIT.
HIT, heparin-induced thrombocytopenia; DVT, deep vein thrombosis; DIC, disseminated intravascular coagulation.

Heparin-induced skin lesions are dermal reactions noted within 24 hours of subcutaneous heparin injection that begin 5 or more days after heparin initiation.[100,101] These lesions are associated with HIT antibodies. Interestingly, only about one-fourth of patients who develop skin lesions together with HIT antibodies develop thrombocytopenia, but those with heparin-induced skin lesions and thrombocytopenia are at particularly high risk for arterial limb thrombosis.[102] The antibodies found in patients with necrotizing skin lesions are indistinguishable from those associated with other manifestations of HIT.

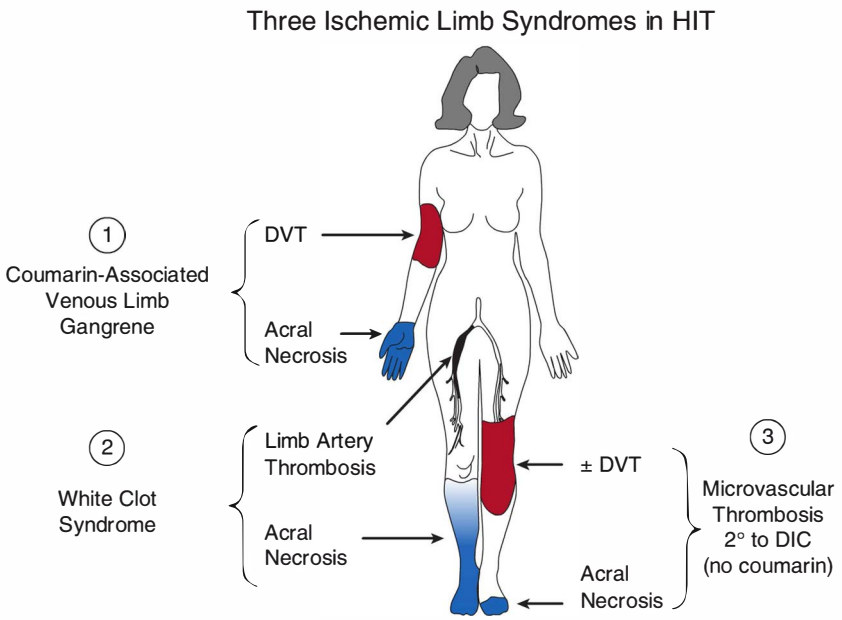

FIGURE 108.4 Three ischemic limb syndromes in HIT. The two most common causes of limb loss in HIT are coumarin-induced venous limb gangrene (microvascular thrombosis in a limb affected by DVT) and white clot syndrome (occlusion of large limb arteries by platelet-rich white clots). Rarely, microvascular thrombosis (with or without associated DVT) is associated with limb ischemia in the absence of coumarin use. DIC, disseminated intravascular coagulation. (Modified from Warkentin TE. Heparin-induced thrombocytopenia: IgG-mediated platelet activation, platelet microparticle generation, and altered procoagulant/anticoagulant balance in the pathogenesis of thrombosis and venous limb gangrene complicating heparin-induced thrombocytopenia. *Transfus Med Rev* 1996;10:249–258.)

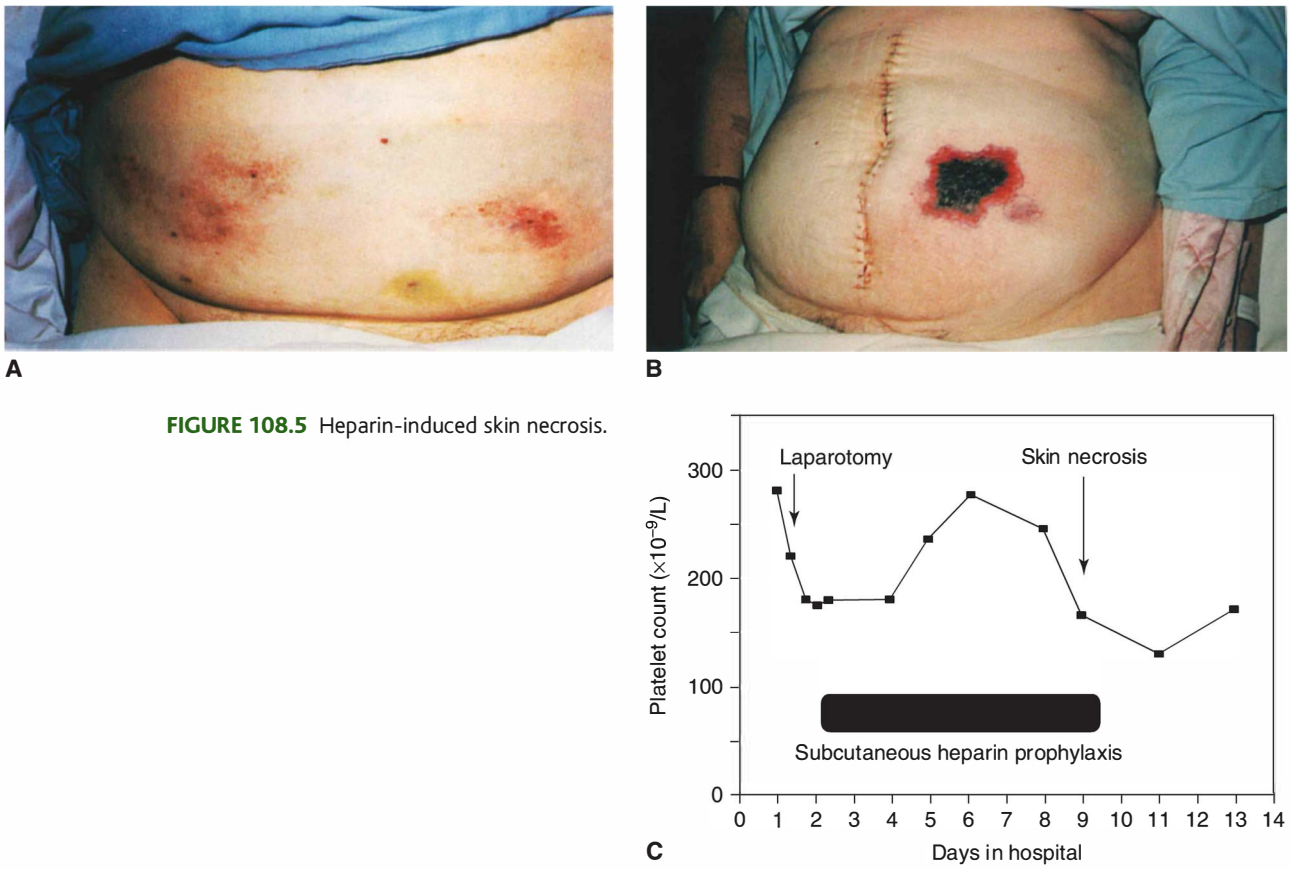

FIGURE 108.5 Heparin-induced skin necrosis.

Two types of skin lesions are described: painful, red plaques and frank skin necrosis (see FIGURE 108.5). Whereas the former can represent delayed-type hypersensitivity reactions with coincidental anti-PF4/heparin seroconversion,[103,104] the latter (necrotizing) reactions appear to be specific for HIT. Close clinical observation and monitoring of platelet count should be performed for several days after stopping heparin injections in patients with skin lesions because thrombocytopenia and thrombosis can begin several days later.[102]

Acute anaphylactoid reactions (*acute systemic reactions*) refer to a variety of systemic symptoms and signs that begin within 5 to 30 minutes of receiving an intravenous heparin bolus—or less often, following subcutaneous injection—and are accompanied by an abrupt decrease in platelet count.[9,105–107] Clinical features are inflammatory (i.e., fever, chills, and flushing), cardiopulmonary (i.e., hypertension, tachycardia, dyspnea or tachypnea, and cardiac or respiratory arrest), neurologic (i.e., transient global amnesia and pounding headache), and gastrointestinal (i.e., watery diarrhea). These differ from the anaphylactic reactions induced by heparin contaminants such as oversulfated chondroitin sulfate.[33,107]

Decompensated DIC refers to an elevated INR and/or activated partial thromboplastin time (aPTT); reduced concentration of fibrinogen; presence of red cell fragments and/or circulating normoblasts; or other laboratory features of severe DIC. Although increased thrombin generation is a universal feature of HIT (as shown by increased levels of thrombin–antithrombin complexes),[8] only 10% to 15% of the patients evince one or more of these features of decompensated DIC. These patients are at an unusually high risk for developing multiple thrombi and/or microvascular thrombosis.

SCORING SYSTEMS

Scoring systems have been developed for use in diagnosis of HIT, to evaluate new laboratory tests for HIT antibodies, or to estimate the pretest probability of HIT.[108–110,111,112,113] Table 108.2 shows the 4Ts scoring system; depending on the clinical setting in which the 4Ts is used, the likelihood of HIT ranges from <2% (low score), to 10% to 30% (intermediate score), to 50% to 70% (high score).[111] Thus, the main utility of the 4Ts is in predicting a low likelihood of HIT when the score is low (≤3 points), that is, a high negative predictive value.[111] A recent scoring system developed using broad expert opinion, the HIT Expert Probability Score, exhibited favorable operating characteristics but requires prospective validation.[113]

LABORATORY TESTING

Both platelet activation and PF4-dependent antigen assays are useful to support the diagnosis of HIT.[114–116] In general, the more abnormal the test result, for example, higher optical density (OD) in the enzyme (-linked) immuno(sorbent) assay (EIA or ELISA), the greater the likelihood that the patient has HIT.[117–119] HIT antibodies are usually detectable in patient serum or plasma only for a few weeks or months,[43] and therefore, acute serum or plasma should be tested.

Table 108.2

Estimating the pretest probability of HIT: 4Ts scoring system

	Points (0, 1, or 2 for Each of 4 Categories: Maximum Possible Score = 8)[a]		
	2	**1**	**0**
*T*hrombocytopenia (acute)	>50% platelet fall (nadir ≥ 20 × 10^9/L)	30%–50% platelet fall (or >50% fall due to surgery) or nadir 10–19 × 10^9/L	<30% platelet fall or nadir <10 × 10^9/L
*T*iming[b] of platelet count fall, thrombosis, or other sequelae (1st day of immunizing heparin course = day 0)	Clear onset between days 5 and 10 or ≤1 d (if heparin exposure within the past 30 d)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts) or ≤1 d (heparin exposure within the past 31–100 d) or platelet fall after day 10	Platelet count fall ≤4 d without recent preceding heparin exposure
*T*hrombosis or other sequelae (e.g., skin lesions, ASR)	New thrombosis; skin necrosis[c]; ASR after IV heparin bolus	Progressive or recurrent thrombosis; suspected thrombosis (not yet proven); asymptomatic upper limb DVT)	None
o*T*her causes of thrombocytopenia not evident	No explanation (besides HIT) for platelet count fall is evident.	Possible other cause is evident.	Definite other cause is present.

Note: The score can increase or decrease as additional information is obtained and as the thrombocytopenia evolves.
[a]Pretest probability score: 6–8 = high; 4–5 = intermediate; 0–3 = low.
[b]First day of immunizing heparin exposure is considered day 0; the day the platelet count *begins* to fall for any given episode of thrombocytopenia is considered the day of onset of thrombocytopenia (it generally takes 1–3 more days until an arbitrary threshold that defines thrombocytopenia is passed). In general, giving heparin during or soon after surgery is most likely to induce immunization, and this scenario (when applicable) should be primarily evaluated.
[c]At site(s) of heparin injections.
ASR, acute systemic reaction (i.e., anaphylactoid reaction); DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; IV, intravenous.
Modified from Warkentin TE. Clinical picture of heparin-induced thrombocytopenia. In: Warkentin TE, Greinacher A, eds. *Heparin-induced thrombocytopenia*. New York: Informa Healthcare USA, 2007:21–66.

Activation Assays

Activation assays exploit the platelet-activating properties of the HIT–IgG antibodies. The characteristic profile of HIT sera is the activation of normal donor platelets using therapeutic heparin concentrations (optimal at 0.1 to 0.3 U/mL) and the inhibition of activation of normal donor platelets at supratherapeutic heparin concentrations (10 to 100 U/mL).[120,121] As noted earlier, many HIT sera also induce considerable platelet activation in the absence of heparin (i.e., buffer control), a feature associated with delayed-onset or worsening of HIT despite stopping heparin.[40] Washed platelets that have been resuspended in divalent cation-containing buffer—with "washing" performed in the presence of apyrase (an enzyme that preserves platelet reactivity to adenosine diphosphate—an important potentiator of HIT antibody-induced platelet activation[122])—respond optimally to HIT antibodies. These features have been incorporated into two "gold standard" assays, the platelet serotonin release assay (SRA)[120,123] and the heparin-induced platelet activation (HIPA) test.[124] In one study, a positive SRA was strongly associated with thrombocytopenia that began on day 5 or later of heparin treatment (odds ratio 78, 95% CI 12 to 819, $P < 0.001$).[11]

Methods to improve quality control in the detection of HIT antibodies include using an Fcγ receptor (FcγRIIa)-blocking monoclonal antibody to ascertain inhibition of platelet activation by HIT serum[18] and testing a panel of negative, weak, and strong HIT control sera to confirm that the test platelets selected are adequate to detect HIT antibodies of varying reactivity.[123] When performed by experienced laboratories, the sensitivity and specificity of washed platelet assays for HIT are >95%[114]; in approximately 2% of sera, however, the serum induces platelet activation at all concentrations of heparin, and the result is "indeterminate" for presence of HIT antibodies.[125]

Conventional platelet aggregation assays using normal donor platelets suspended in citrated plasma have a relatively low sensitivity for HIT (50% to 80%)[126] and are no longer widely used. Specificity also is lower because heparin can produce nonspecific activation of platelets under these test conditions.

Antigen Assays

Table 108.3 summarizes commercially available antigen assays.[21,23,34,108,116,126–137] These can be divided into PF4-dependent EIAs (polyspecific and IgG-specific) and various particle-based immunoassays.

Antigen assays using the EIA technique have been developed using the PF4/heparin (or PF4/polyanion) target antigen.[21,23,34,116,126,127] Potentially, false-negative EIA results could arise if HIT antibodies recognize chemokines other than PF4 (e.g., interleukin-8 and neutrophil-activating peptide-2).[138,139] However, these antigens are rarely implicated (<1% of HIT patients); indeed, for >99% of sera that cause a clear positive result in a platelet activation assay, anti-PF4/heparin antibodies are readily detectable. Although the PF4/heparin EIA is more sensitive than the SRA or HIPA for detecting PF4-/heparin-dependent antibodies, this may not be an advantage because more clinically insignificant antibodies are detected,[127,140]

Table 108.3

Commercially available PF4-dependent immunoassays

Assay	PF4 Source	Polyanion	Ig Classes Detected
Enzyme Immunoassays			
Asserachrom HPIA	Recombinant	Heparin	Polyspecific (IgG/A/M)
PF4 enhanced	Platelets	PVS	Polyspecific (IgG/A/M)
PF4 IgG	Platelets	PVS	IgG
Zymutest HIA	Platelet lysate	Heparin (bound to protamine)	Polyspecific (IgG/A/M) IgG or IgA or IgM (individually)
Particle-Based Immunoassays			
PaGIA	Platelets	Heparin	Polyspecific (IgG/A/M)
PIFA	Platelets	Heparin	Polyspecific (IgG/A/M)
HemosIL HIT-$Ab_{(PF4-H)}$	Platelets	PVS	Polyspecific (IgG/A/M)
Chemiluminesent-Based Immunoassays			
HemosIL AcuStar HIT-$IgG_{(PF4-H)}$	Platelets	PVS	IgG
HemosIL AcuStar HIT-$Ab_{(PF4-H)}$	Platelets	PVS	Polyspecific (IgG/A/M)

resulting in a lower specificity for clinical HIT.[117] The nonspecific nature of the negatively charged coantigen of HIT is illustrated by the development of an antigen assay using PF4 complexed to polyvinylsulfonate (PVS), a negatively charged material devoid of both carbohydrate and sulfate groups.[34] Despite the absence of heparin, this assay has high sensitivity for detecting HIT antibodies. A high heparin "confirmatory" step—inhibition of reactivity by >50% at high heparin concentrations—has been suggested to increase diagnostic specificity; this maneuver has some utility for weakly reacting sera (positive but OD < 1.0 U), but for stronger reacting sera (OD > 1.0), lack of inhibition does not rule out the presence of platelet-activating antibodies.[141–144]

There are two types of rapid, particle-based assays. The "particle gel immunoassay" (PaGIA),[132–134] which utilizes gel centrifugation technology (used in blood banks), has operating characteristics (sensitivity–specificity trade-offs) intermediate between the commercial EIA and a washed platelet activation assay[127,128,133]; one study[134] suggested that the utility of this test is enhanced by interpreting the assay results quantitatively (rather than simply as positive or negative). Unlike the very high sensitivity (~99%) of the EIAs, approximately 5% of HIT sera test negative in the PaGIA (i.e., ~95% sensitivity).[127,128] The second assay, particle immunofiltration assay (PIFA), however, showed very poor operating characteristics in two laboratories and cannot be recommended for the diagnosis of HIT.[135]

Two automated assays have recently been introduced in Europe.[136,137] One assay is based on the agglutination of latex particles coated with a monoclonal antibody specific for PF4/polyanion complexes. In the presence of anti-PF4/heparin antibodies in the patient plasma and added PF4/PVS complexes, agglutination by the monoclonal antibody is inhibited. The degree of agglutination is inversely proportional to the concentration of antibodies in the sample and is determined by measuring the decrease of transmitted light caused by the aggregates. The other assay is based on chemiluminescence. A potential advantage of this latter assay is the much wider range of reactivities, which may yield additional information, for example, potential association of very high antibody titers and thrombotic complications. These automated assays could allow for greater standardization of interlaboratory results, compared with other assays.

Iceberg Model and Interpretation of HIT Assays

The "iceberg" model (FIGURE 108.6) provides a framework for interpreting HIT antibody test results.[7,62,145] Among the totality of the anti-PF4/heparin immune response, only the "tip" of the iceberg extending above the waterline—constituting platelet-activating antibodies of IgG class—is potentially capable of causing HIT. Thus, whereas washed platelet activation assays and PF4-dependent EIAs (whether IgG-specific or not) have similar high sensitivity for HIT, diagnostic specificity increases as: EIA-IgG/A/M < EIA-IgG < washed platelet activation assay.

Results of HIT antibody tests must be interpreted in the appropriate clinical context of pretest probability.[117,146] Relying on a positive EIA alone to diagnose HIT risks overdiagnosis: Only approximately half of the patients who have a positive EIA test result actually have HIT.[147] The magnitude of the positive EIA test result provides useful diagnostic information. For example, predictivity of a positive polyspecific EIA for the presence of platelet-activating antibodies ranges from approximately 5% (for weakly positive results with OD 0.40 to 1.0 U) to 90% for strong-positive results (>2.0 U).[118,119] However, simply using a higher cutoff (e.g., 1.0 OD units) will result in some false-negative results. Laboratories should report the results of antigen tests at least semiquantitatively (negative, weak, intermediate, strong) to allow an estimate of the likelihood of platelet-activating antibodies being present. In the case of an intermediate pretest score of HIT (e.g., 4Ts score of 4 to 5),

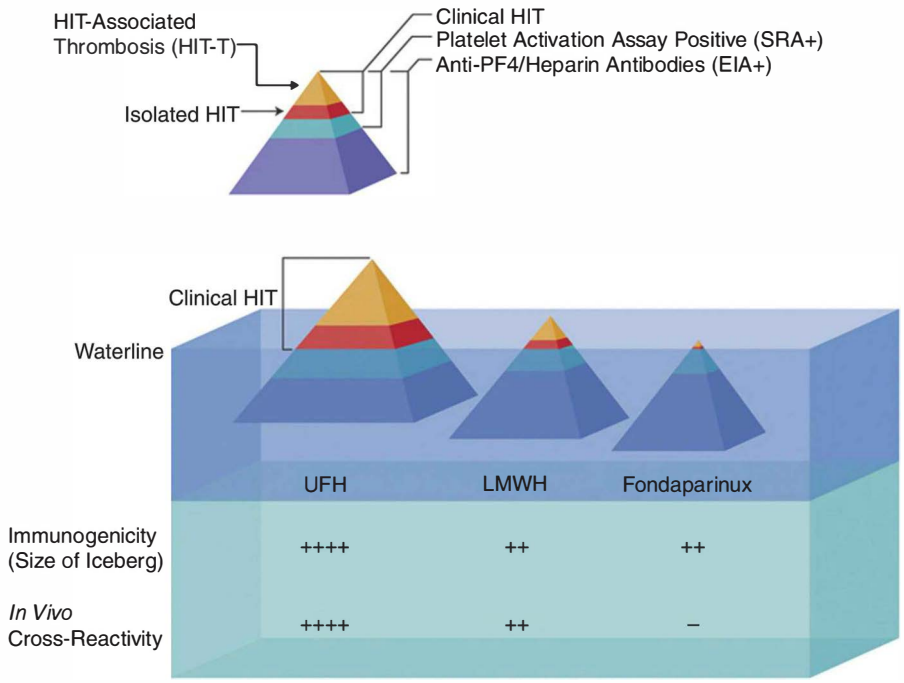

FIGURE 108.6 The relationship among the clinical expression of HIT (thrombocytopenia with or without thrombosis), the type of heparin used, and the antibodies that cause HIT. This can be conceptualized as an "iceberg." The visible component of the iceberg (*the portion above the waterline*) represents clinically evident features of HIT, such as thrombocytopenia and/or thrombosis. The mass of the iceberg corresponds to the entire spectrum of anti-PF4/heparin antibodies generated. Some of these antibodies will be biologically active (platelet-activating), and others will be non–platelet-activating, which may make them unlikely to cause clinical consequences. The type of heparin given to the patient determines the overall size of the iceberg, with UFH being the largest (most immunogenic) and LMWH and fondaparinux having less immunogenicity. Also illustrated in this figure is the *in vivo* cross-reactivity. UFH forms antibodies that are readily recognized by HIT antibodies. In contrast, fondaparinux forms poorly recognized antigens. LMWH is intermediate. (From Kelton JG, Warkentin TE. Heparin-induced thrombocytopenia: a historical perspective. *Blood* 2008;112:2607–2616.)

it makes a great difference, whether the test is weakly positive (0.5 to 1.0 OD units) or very strong (OD >2.0 U), with only the latter positive result representing a likely HIT scenario (~5% vs. >90%, respectively).

The presence of anti-PF4/heparin antibodies but without platelet-activating properties (i.e., negative washed platelet activation assay) does not appear to indicate the presence of HIT, based upon clinical comparisons with antibody-negative and activation assay–positive controls.[147] Adverse prognosis associated with anti-PF4/heparin antibodies, but in the absence of clinical HIT, has been observed in some[148–155] but not all studies.[156,157] One possibility for the potential association of nonactivating anti-PF4/heparin antibodies with adverse outcomes is that inflammation could potentiate generation of these antibodies.[158] In so, inflammation itself could be the key factor for adverse prognosis.

TREATMENT

Table 108.4 lists consensus conference treatment recommendations for HIT.[159] Although it is recommended that heparin be discontinued when a patient is strongly suspected (or confirmed) as having HIT, the risk for subsequent thrombosis postheparin discontinuation ranges from 25% to 50% in patients with serologically confirmed HIT.[1,79,94,160] Further, the risk of sudden thrombotic death is about 5%.[1,94,160] The lack of benefit of stopping heparin is further illustrated by the nature of "delayed-onset HIT": In such patients, thrombocytopenia begins and intensifies, with the development of thrombosis, while no heparin is being given.[40,90–92,93] Furthermore, microvascular thrombotic complications of HIT typically occur only *after* all heparin has been stopped.[8] One explanation for this is the anticoagulant activity of heparin, which protects against part of the prothrombotic effects of HIT. However, the half-life of the anticoagulant activity of heparin is shorter (1 to 2 hours) than that of the non–antithrombin-binding heparin molecules (up to 24 hours),[161] which can still form antigenic complexes with PF4. Therefore, when HIT is strongly suspected or confirmed, heparin should be substituted by a rapidly acting, alternative anticoagulant, such as a direct thrombin inhibitor (DTI) (e.g., lepirudin, argatroban, or bivalirudin) or factor Xa inhibitor (e.g., danaparoid or fondaparinux), generally in therapeutic doses, until the platelet count has recovered.[159,162,163] In addition, to rule out DVT, duplex ultrasound examination of the lower limbs should be performed prior to discharge in patients strongly suspected or confirmed as having HIT.[159]

Table 108.4

Treatment of HIT: recommendations[a] of the eighth ACCP conference on antithrombotic and thrombolytic therapy: evidence-based guidelines, 2008

Treatment Strategy	Recommendation
Nonheparin anticoagulants for HIT	For patients with strongly suspected (or confirmed) HIT, whether or not complicated by thrombosis, we recommend the use of an alternative, nonheparin anticoagulant (danaparoid [grade 1B], lepirudin [grade 1C], argatroban [grade 1C], fondaparinux [grade 2C], bivalirudin [grade 2C]) over the further use of UFH or LMWH therapy or initiation/continuation of a VKA (grade 1B).
Screening for DVT	For patients with strongly suspected or confirmed HIT, whether or not there is clinical evidence of lower limb DVT, we recommend routine ultrasonography of the lower limb veins for investigation of DVT over not performing routine ultrasonography (grade 1C).
Management of nonheparin anticoagulant–VKA overlap	For patients with strongly suspected or confirmed HIT, we recommend *against* the use of VKA (coumarin) therapy until after the platelet count has substantially recovered (i.e., usually to at least 150×10^9/L) over starting VKA therapy at a lower platelet count (grade 1B); that VKA therapy be started only with low, maintenance doses (maximum, 5 mg of warfarin or 6 mg of phenprocoumon) rather than with higher initial doses (grade 1B); and that the nonheparin anticoagulant (e.g., lepirudin, argatroban, danaparoid) be continued until the platelet count has reached a stable plateau, the INR has reached the intended target, and after a minimum overlap of at least 5 days between nonheparin anticoagulation and VKA therapy rather than a shorter overlap (grade 1B).
Reversal of VKA anticoagulation	For patients receiving a VKA at the time of diagnosis of HIT, we recommend the use of vitamin K (10 mg PO or 5 to 10 mg IV) (grade 1C).
LMWH for HIT	For patients with strongly suspected HIT, whether or not complicated by thrombosis, we recommend against the use of LMWH (grade 1B).
Prophylactic platelet transfusions for HIT	For patients with strongly suspected or confirmed HIT who do not have active bleeding, we suggest that prophylactic platelet transfusions should not be given (grade 2C).

[a]Grading of recommendations: Recommendations are ranked as grade 1 (strong recommendation) and grade 2 (weak recommendation). Methodologic strengths of supporting evidence are ranked as grade 1B (strong recommendation, moderate-quality evidence); grade 1C (strong recommendation, low or very low-quality evidence); and grade 2C (weak recommendation, low or very low-quality evidence).
HIT, heparin-induced thrombocytopenia; DVT, deep vein thrombosis; INR, international normalized ratio; IV, intravenous; UFH, unfractionated heparin; LMWH, low molecular weight heparin; VKA, vitamin K antagonist (e.g., warfarin).
From Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines [8th edition]. *Chest* 2008;133(Suppl):340S–380S.

Two DTIs, lepirudin and argatroban, are approved for management of HIT in the United States. Both agents have relative advantages and disadvantages. Careful drug selection, dosing, and monitoring are important because neither agent has a specific antidote.

Recombinant Hirudin

Lepirudin (Refludan) is a recombinant hirudin (r-hirudin) derivative that inhibits thrombin via a high-affinity, irreversible, noncovalent interaction.[10,164–167] The *C*-terminal region of this 65-amino acid polypeptide (6,980 Da) binds to thrombin's fibrinogen-binding site (exosite 1), and a highly packed hydrophobic region near the *N*-terminus (produced by three disulfide bridges) binds to the apolar region of thrombin, thereby blocking the active (catalytic) site of thrombin. Its anticoagulant effect is usually monitored with the aPTT. Lepirudin is renally eliminated, and greatly reduced dosing is required in patients with renal failure. Antihirudin antibodies are commonly generated in patients treated with lepirudin; in a minority of patients, this can lead paradoxically to a greater anticoagulant effect of lepirudin[168] due to an immune complex–mediated prolonged half-life of active agent. It is advisable to avoid the initial intravenous bolus[159] to minimize the risk of postbolus anaphylaxis[169] and to reduce the risk of overdosing.[170–173] Lepirudin is approved in the United States and in the European Union to treat HIT complicated by thrombosis, but the potential for bleeding has prevented approval for other indications, such as acute coronary syndrome. Table 108.5 lists consensus conference dosing recommendations (which are lower than the manufacturer's recommendations given in the package insert).

Desirudin (US trademark, Iprivask; EU trademark, Revasc) is another r-hirudin, which is effective for thrombosis prophylaxis after hip replacement surgery[174] and is approved for this (non-HIT) indication in the United States and the European Union (and additionally approved for knee replacement surgery in the European Union); the dose (normal renal function) is 15 mg every 12 hours by subcutaneous injection. It has the potential to be used for thrombosis prophylaxis in patients who cannot receive heparin.[175] Its pharmacologic characteristics are very similar to lepirudin, including risk of rapid accumulation in renal insufficiency and induction of antibodies.[176]

Table 108.5

Lepirudin for treatment of HIT

Standard protocol: *HIT with thrombosis*: ± initial bolus, 0.2 to 0.4 mg/kg IV; followed by IV infusion at 0.05 to 0.10 mg/kg/h (target aPTT, 1.5–2.0 × baseline), aPTT adjusted 4 h later and at 4-h intervals until steady state is reached and 4 h after any dose adjustment; increase rate by 20% and decrease by 50% if aPTT below or above target range, respectively. *HIT without thrombosis*: no initial bolus; initial infusion rate, 0.05 to 0.10 mg/kg/h, adjusted by aPTT as in the preceding text.

Other Dosing Considerations	Rationale
Laboratory tests to determine standard curve of plasma lepirudin (using normal plasma "spiked" with lepirudin) to aPTT, including low- and high-therapeutic lepirudin levels (0.6–1.4 μg/mL)[83]	Because different aPTT reagents show flattening of the lepirudin–aPTT curve at different lepirudin concentrations, the standard curve is used to determine the lepirudin level beyond which accurate assessment by aPTT is no longer possible.
Avoid the initial bolus dose, beginning with infusion alone (unless severe thrombosis is present)	Safety enhanced by minimizing risk of postbolus anaphylaxis, with only minor delay (~6 h) in achieving therapeutic anticoagulation
In elderly patients (>60 y), even with normal creatinine levels, begin with lower infusion rate (0.05 mg/kg/h)	Renal function declines with age and may be underestimated by serum creatinine levels; overdosing can occur at 0.15 mg/kg/h (with or without bolus).
Repeat aPTT monitoring at 4-h intervals until steady state is obtained.	Steady state may not be reached at 4 h, especially if any renal dysfunction is present.
Monitor aPTT daily while on lepirudin	Antihirudin antibodies can affect lepirudin clearance (either increase or decrease aPTT).

Dose Adjustments in Renal Insufficiency

Serum Creatinine mg/dL (μmol/L)	Initial IV Infusion Rate (then Adjust by aPTT)
1.0–1.6 (90–140)	0.05 mg/kg/h
1.6–4.5 (141–400)	0.01 mg/kg/h
>4.5 (>400)	0.005 mg/kg/h

HIT, heparin-induced thrombocytopenia; IV, intravenous; aPTT, activated partial thromboplastin time.
Modified from, with dosing guidelines from, Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines [8th Edition]. *Chest* 2008;133(6 Suppl):340S–380S.

Argatroban

Argatroban (non-US trademark, Novastan) is a synthetic, small-molecule DTI (527 Da) derivative of arginine.[177,178] Argatroban inhibits thrombin at therapeutically relevant concentrations. The anticoagulant effect is monitored using the aPTT (usual target: 1.5 to 3.0 times baseline, maximum 100 seconds). Unlike lepirudin, however, argatroban is predominantly metabolized by the liver and, therefore, may be safer in patients with renal failure. Argatroban prolongs the INR to a greater extent than does bivalirudin or lepirudin,[179] complicating the monitoring of overlapping warfarin anticoagulation.

Argatroban is approved in the United States, Canada, and several countries within Europe for treatment of HIT with or without associated thrombosis[177] and also for anticoagulation during percutaneous coronary intervention (PCI) in patients with, or at risk for, HIT.[177,180]

Bivalirudin

Bivalirudin (Angiomax) is a 20-amino acid (2,180 Da) analog of hirudin comprising two subunits: the *C*-terminal dodecapeptide of hirudin and a thrombin active site–binding *N*-terminal tetrapeptide (D-Phe1–Pro2–Arg3–Pro4) bridged by four glycine "spacers."[164,181–184] As with hirudin, the *C*-terminus moiety binds to the fibrinogen recognition site of thrombin (exosite 1). This "designer molecule" has several theoretical advantages over hirudin,[183] including (a) predominant nonrenal elimination (80% of its degradation is by plasma proteases), (b) a shorter half-life (25 vs. >80 minutes), (c) reduced or absent immunogenicity, and (d) minimal prolongation of the INR (greater than lepirudin, but less than argatroban). Unlike r-hirudin, thrombin inhibition is reversible. Favorable results of "off-label" use of bivalirudin for HIT have been reported in uncontrolled studies,[183,185] with initial dosing of 0.15 mg/kg/h and aPTT monitoring (target aPTT 1.5- to 2.5-fold greater than baseline). Bivalirudin has undergone evaluation for both "on-pump" and "off-pump" cardiac surgery in patients with HIT or with anti-PF4/heparin antibodies.[77,183,186–188] It is widely used in the United States for PCIs and is the anticoagulant of choice in patients with HIT, or a history of HIT, requiring coronary interventions.

Direct Thrombin Inhibitor–Coumarin Overlap

The risk of warfarin-associated venous limb gangrene (discussed in Chapter 109) remains when warfarin is prematurely started and/or when the DTI is prematurely discontinued in a

patient with HIT-associated venous thrombosis and ongoing thrombocytopenia.[97,98] Therefore, it is prudent to delay commencing warfarin until the platelet count has substantially recovered (preferably, to >150 × 10^9/L) and any clinically manifest thrombosis is improving. Further, there should be at least a 5-day overlap between the DTI and warfarin (with target INR levels achieved for at least the last 2 days), and the DTI should not be stopped until the platelet count has reached a stable plateau. If warfarin has already been initiated when HIT is recognized, vitamin K should be given for two reasons: (a) to reduce the risk of warfarin-induced microvascular thrombosis and (b) to avoid underdosing of DTI because warfarin also prolongs the aPTT.[159,189]

Confounding of aPTT Monitoring in HIT-Associated Coagulopathy

The observation that aPTT prolongation by warfarin confounds subsequent dosing and aPTT-based monitoring of DTI therapy raises the issue whether HIT-associated coagulopathy itself can confound DTI therapy. Indeed, there are reports of frequent dose interruptions and reductions—associated with progressive limb necrosis—in patients who had baseline (pre-DTI) aPTT prolongation due to HIT-associated consumptive coagulopathy.[10,93] In theory, the use of drug levels could avoid this problem,[190] but these assays are not widely available.

AT-Dependent, Factor Xa Inhibition

Table 108.6 summarizes advantages and disadvantages of indirect (AT-dependent) factor Xa inhibitors (danaparoid, fondaparinux) with DTIs.[93]

Danaparoid sodium (Orgaran) is a mixture of anticoagulant glycosaminoglycans (e.g., low-sulfated heparan sulfate, dermatan sulfate) with predominant anti–factor Xa activity; the anti-Xa/anti-IIa ratio is 22:1.[191,192] Approximately 10% to 40% of HIT sera will show some degree of *in vitro* cross-reactivity for danaparoid. However, *in vitro* cross-reactivity is usually not of clinical significance,[193] and treatment should not be delayed to perform *in vitro* cross-reactivity studies. Indeed, a unique property of danaparoid is that high therapeutic concentrations *inhibit* HIT antibody–induced platelet activation.[194] Anticoagulant monitoring of danaparoid is performed by measuring anti–factor Xa activity. However, monitoring is not usually required because the anticoagulant effect is largely predictable when administered on a weight-adjusted basis, and the likelihood of obtaining therapeutic anticoagulant levels is high using an empirically derived standard treatment protocol that begins with intravenous bolus administration. Danaparoid can accumulate in renal failure; therefore, the maintenance dose should be reduced in these cases by approximately 30%, and anti–factor Xa activity should be closely monitored. No antidote for danaparoid exists. Danaparoid's long half-life and lack of effect on the INR generally make for a smooth transition to warfarin monotherapy, suggesting that the risk of iatrogenic venous limb gangrene

Table 108.6

A comparison of two classes of anticoagulant used to treat HIT

	Indirect AT-Dependent Factor Xa Inhibitors: Danaparoid, Fondaparinux	Direct AT-Independent Thrombin Inhibitors: r-Hirudin, Argatroban, Bivalirudin
Half-life	√ Long (> 16 h): avoids potential for rebound hypercoagulability	SHORT (<2 h): potential for rebound hypercoagulability. Half-life of lepirudin and bivalirudin depends on renal function; half-life of argatroban depends on liver perfusion/function.
Dosing	√ Both prophylactic- and therapeutic-dose regimens[a]	Prophylactic-dose regimens are not well established.
Monitoring	√ Direct (anti-Xa levels): accurate drug levels obtained	Indirect (aPTT): risk for DTI underdosing due to aPTT elevation for non-DTI factors
Effect on INR	√ No significant effect: thus, simplifies overlap with warfarin	Increases INR: argatroban > bivalirudin > r-hirudin; complicates warfarin overlap
Protein C pathway	√ No significant effect	Thrombin inhibition could impair activation of protein C pathway.
Reversibility of action	√ Irreversible inhibition (AT forms covalent bond with factor Xa)	Irreversible inhibition only with r-hirudin
Platelet activation	√ Danaparoid inhibits platelet activation by HIT antibodies	No effect
Drug clearance	Predominantly renal	Variable (see half-life [above] and text)

Legend: "√", that is, check mark, indicates positive feature in comparison of drug classes.
[a]Although therapeutic dosing is recommended for HIT, availability of prophylactic-dose regimens increases flexibility when managing potential non-HIT situations.
Modified from Warkentin TE. Agents for the treatment of heparin-induced thrombocytopenia. *Hematol Oncol Clin North Am* 2010;24:755–775.

during overlapping therapy with danaparoid and coumarin is very low (in contrast to DTI–warfarin overlap). Danaparoid is the only therapy for HIT evaluated in a randomized clinical trial (vs. the antiplatelet agent, dextran-70).[195] A retrospective comparison with ancrod (defibrinogenating snake venom) and/or coumarin therapy showed significantly fewer thrombotic events with danaparoid, and with less bleeding.[196] Danaparoid is not available in the United States.

Fondaparinux (Arixtra) is a synthetic, sulfated pentasaccharide that catalyzes antithrombin-mediated inactivation of factor Xa. It only rarely cross-reacts with HIT antibodies[197,198] and, theoretically, should be effective in patients with HIT. Indeed, recent experience[199–203] supports the thesis[93,204] that fondaparinux is an effective anticoagulant for treatment of HIT (Table 108.7). Its long half-life and renal elimination, however, require careful dosing and monitoring if used in critically ill patients.

New Oral Anticoagulants

The new oral anticoagulants, dabigatran (thrombin inhibitor) and rivaroxaban and apixaban (FXa inhibitors), cannot induce HIT, as they have a different molecular structure than heparin.[205] Although no experience with these agents in acute HIT exists, they are an option for patients with a history of HIT who require anticoagulation.

PROGNOSIS

Many patients with HIT present with life- or limb-threatening thrombosis,[79,94] and thus even "effective" anticoagulation may not prevent long-term sequelae (e.g., disabling stroke, limb amputation). Despite stopping heparin, as many as 40% to 50% of the patients with "isolated HIT" develop thrombosis.[1,79,94] Limb amputation occurred in approximately 5% of patients with HIT-associated thrombosis treated with danaparoid, fondaparinux, or lepirudin, and 10% to 15% of patients treated with argatroban.[159,160] The mortality rate is 15% to 25%, but deaths often reflect comorbidities rather than thrombotic death.[159,160]

Table 108.8 lists treatment outcomes of lepirudin and argatroban, assessed in prospective cohort studies (with historic controls), as well as that of danaparoid, which was compared against dextran-70 in a randomized controlled trial.[160,206,207,208–210] All three agents appeared to prevent thrombosis in HIT, although an impact on overall mortality and limb loss is less clear.

PREVENTION OF HEPARIN-INDUCED THROMBOCYTOPENIA AND ITS COMPLICATIONS

HIT is a potentially preventable adverse drug reaction: The frequency of HIT with LMWH thromboprophylaxis is approximately one-tenth that observed with UFH[55,211] and is likely lower still with fondaparinux.[76,212]

The recent emphasis on substituting heparin with an alternative anticoagulant even in patients with isolated HIT suggests an important role for platelet count monitoring for HIT. Consensus conferences[114,159] have adopted the view that the most frequent monitoring (at least every other day) should be performed in situations in which HIT is common (>1%), such as in postoperative patients receiving antithrombotic prophylaxis with UFH or treatment of thrombosis with UFH. Less frequent monitoring (two or three times per week) is appropriate if HIT occurs at a frequency of 1/100 to 1/1,000, such as in medical and surgical patients receiving prophylaxis with UFH and LMWH, respectively. Routine monitoring is not recommended in circumstances in which HIT is rare (<1/1,000 in

Table 108.7

[a]Dose per day administered by subcutaneous injection (10 and 5 mg if the patient weighted >100 and <50 kg, respectively).
[b]The single patient without thrombosis received 2.5mg daily by subcutaneous injection.
[c]One patient with popliteal artery thrombosis and failed thrombectomy required amputation; however, the ischemic limb necrosis was judged to have been present before fondaparinux therapy.
[d]All 10 patients without HIT-T nevertheless had preceding thrombosis that led to the heparin therapy that triggered HIT.
[e]The mean platelet count nadir excludes two patients with myeloproliferative disease whose HIT-associated platelet count declines resulted in relative, rather than absolute, thrombocytopenia.
[f]The mean OD was significantly greater (2.0 U) in the 14 patients with HIT-T.
[g]One patient had limb amputation before commencing fondaparinux.
[h]An IgG-specific EIA was used; all 16 patients also tested strongly positive in the serotonin-release assay (mean percent serotonin-release, 91%).
[i]7.5 mg was the median initial dose; however, some patients received initial dosing of 2.5, 5, 10 or 15 mg/d.
[j]One patient had limb amputation because of ischemic limb necrosis established prior to initiation of fondaparinux.
[k]Mean OD value excludes one result with very high OD value (>7.50 U); the 3 patients with OD values <2.00 tested positive in the serotonin-release assay.
EIA, enzyme-immunoassay; HIT-T, HIT-associated thrombosis; N.A., not available; OD, optical density.

Table 108.8

HIT treatment outcomes

Study, Year (Reference)	Regimen	n	Mean Days of Alternative Anticoagulant	% HIT Antibody Positive	New Thrombosis Rate (RRR)[a]	Amputation Rate (RRR)[a]	Composite Endpoint (RRR)[a]	Major Bleed (% per Day Alternative Anticoagulant Given)[b]
HIT-Associated Thrombosis								
HAT-1/2, 2000 (206)	Lep 0.4 mg/kg bolus + 0.15 mg/kg/h	113	13.3	100%	10.1 (63%)	6.5% (38%)	21.3% (55%)	1.4%

[a]RRR (relative risk reduction, expressed as percent) compared with historical controls (not shown) or, for danaparoid vs. dextran study,[195] RCT controls (not shown).
[b]Calculated by dividing major bleed rate by the number of mean days of alternative anticoagulant given.
[c]Median (data provided by Dr. Harry Magnani, Organon NV).
[d]34/37 (91.9%) patients tested were positive for HIT antibodies (4 patients did not undergo testing).
[e]Data limited to on-treatment observation period.
[f]Data limited to on-treatment observation period + 1 day.
Arg, argatroban; DMP, drug monitoring program (postmarketing study); Danap, danaparoid; HAT, heparin-associated thrombocytopenia (prospective lepirudin study); Lep, lepirudin; NA, not available; RCT, randomized controlled trial; RRR, relative risk reduction.
Modified from Warkentin TE, Poncz M, Cines DB. Heparin-induced thrombocytopenia. In: Young NS, Gerson SL, High KA, eds. *Clinical hematology*. Philadelphia, PA: Elsevier/Mosby, 2006:887--899. Some data pertaining to a published trial[195] obtained from Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines [8th edition]. *Chest* 2008;133(Suppl):340S–380S.

medical or obstetrical patients receiving LMWH). Nevertheless, HIT is frequently recognized only after a new thrombosis has occurred, even when frequent platelet count monitoring is performed,[1,11,12] and there is no proof that frequent platelet count monitoring will prevent HIT-associated thrombosis.

Physicians should suspect HIT in any patient who develops new or progressive thrombosis during or within several days after stopping heparin therapy. In 10% to 15% of the patients with HIT, the platelet count nadir is >150 × 10^9/L (FIGURE 108.2), although usually a proportional platelet count decline of at least 50% had occurred (FIGURE 108.3). Heparin should be discontinued and an alternative management strategy instituted in any patient in whom HIT is the most likely diagnosis, even prior to obtaining diagnostic laboratory results.

Although the frequency of HIT, HIT-associated thrombosis, and HIT–IgG seroconversion is lower in patients treated with LMWH than in those treated with UFH (e.g., ~90% lower in patients receiving heparin >5 days after a major orthopedic surgery),[11,12,62,211] LMWH should not be used to treat HIT,[159] because HIT antibodies frequently activate platelets strongly in the presence of LMWH.[11,213]

HEPARIN REEXPOSURE

Table 108.9 lists treatment recommendations of the American College of Chest Physicians (ACCP) in special situations such as heparin reexposure in patients with previous HIT and PCI.[159] For patients with a previous history of HIT who have

Table 108.9

Treatment of HIT: special patient populations; recommendations of the eighth ACCP conference on antithrombotic and thrombolytic therapy: evidence-based guidelines, 2008

Clinical Situation	Recommendation (Grade of Recommendations[a])
Patients with previous HIT undergoing cardiac or vascular surgery	For patients with a history of HIT who are HIT antibody negative and require cardiac surgery, we recommend the use of UFH over a nonheparin anticoagulant (grade 1B). For patients with a history of HIT who are antibody positive by PF4-dependent EIA but antibody negative by washed platelet activation assay, we recommend the use of UFH over a nonheparin anticoagulant. Remark: Preoperative and postoperative anticoagulation, if indicated, should be given with a nonheparin anticoagulant.
Patients with acute HIT undergoing cardiac surgery	For patients with acute HIT (thrombocytopenic, HIT antibody positive) who require cardiac surgery, we recommend one of the following alternative anticoagulant approaches (in descending order of preference): delaying surgery (if possible) until HIT has resolved and antibodies are negative or weakly positive (grade 1B); using bivalirudin for intraoperative anticoagulation during cardiopulmonary bypass (if techniques of cardiac surgery and anesthesiology have been adapted to the unique features of bivalirudin pharmacology) (grade 1B) or during "off-pump" cardiac surgery (grade 1B); using lepirudin for intraoperative anticoagulation (if ECT is available and the patient has normal renal function and is judged to be at low risk for postcardiac surgery renal dysfunction) (grade 2C); using UFH plus the antiplatelet agent epoprostenol (if ECT monitoring is not available or renal insufficiency precludes lepirudin use) (grade 2C); using UFH plus the antiplatelet agent, tirofiban (grade 2C); or using danaparoid for intraoperative anticoagulation for off-pump coronary artery bypass surgery (grade 2C) over performing the surgery with UFH when platelet-activating anti-PF4/heparin antibodies are known to be present in a patient with acute or recent HIT (grade 2C).
Patients with subacute HIT undergoing cardiac surgery	For patients with subacute HIT (platelet count recovery, but continuing HIT antibody positive), we recommend delaying surgery (if possible) until HIT antibodies (washed platelet activation assay) are negative and then using heparin over using a nonheparin anticoagulant (grade 1C). If surgery cannot be delayed, we suggest the use of a nonheparin anticoagulant over the use of UFH (grade 2C).
PCI	For patients with strongly suspected (or confirmed) acute HIT who require cardiac catheterization or PCI, we recommend a nonheparin anticoagulant bivalirudin (grade 1B), argatroban (grade 1C), lepirudin (grade 1C), or danaparoid (grade 1C) over UFH or LMWH (grade 1B). For patients with preious HIT (who are antibody negative) who require cardiac catheterization or PCI, we suggest the use of a nonheparin anticoagulant over UFH or LMWH (grade 2C).

[a]See footnote of Table 114.3 for grading of recommendations.
HIT, heparin-induced thrombocytopenia; LMWH, low molecular weight heparin; UFH, unfractionated heparin; ECT, ecarin clotting time; EIA, enzyme immunoassay; PCI, percutaneous coronary interventions; PF4, platelet factor 4.
From Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th edition). *Chest* 2008;133(Suppl):340S–380S.

an important indication for heparin, such as cardiac or vascular surgery, the recommended approach is to use heparin, provided that HIT antibodies are undetectable.[159] This is because HIT antibodies are transient[43] and usually decline to nondetectable levels (by SRA) within a few weeks following an episode of HIT, although the antigen assay may persist at low-positive levels for a somewhat longer period. In patients who require urgent surgery, for example, heart transplantation, it is acceptable to wait until platelet-activating antibodies become undetectable and to reexpose the patient to heparin even while the antigen assay is still positive.[214] Furthermore, HIT does not exhibit features of a typical anamnestic response: upon heparin reexposure, HIT antibodies are usually not regenerated,[61] or if regenerated do not form more rapidly than *de novo* HIT (i.e., minimum of 5 days),[43] thereby safely permitting at least a brief intraoperative reexposure to heparin. Usually, alternative nonheparin anticoagulants are used for preoperative and postoperative anticoagulation in this setting. Patients with recent HIT, whose platelet count has recovered but who still have detectable platelet-activating antibodies (subacute HIT), should be considered to be at risk for developing rapid-onset HIT upon heparin reexposure.[159,214] Alternative anticoagulant approaches for patients in whom heparin is not judged appropriately (because of acute or very recent HIT with residual antibodies) are listed in Table 108.9.[159]

Two recent studies[215,216] describing reintroduction of LMWH or UFH for hemodialysis—following disappearance of HIT antibodies—reported successful hemodialysis and lack of HIT recurrence.

ACKNOWLEDGMENTS

Studies described in this chapter were supported by the Heart and Stroke Foundation of Ontario grants #A2449, #T2967, #B3763, #T4502, #T5207, #T6157, and #T6590 (from 1993 to 2012). Dr. Warkentin was supported by a research fellowship (1988–1991) and a research scholarship (1993–1998) from the Heart and Stroke Foundation of Canada. Other studies described in this chapter were supported by the Deutsche Forschungsgemeinschaft (GR 1096/2-1, GR 1096/2-2, GR 1096/2-3, GR 1096/2-4; Graduiertenkolleg GRK-840); the German Federal Ministry for Education and Research (CAN04/006; NBL3 program, reference 01-ZZ0403; Zentrum für Innovationskompetenz Humorale Immunreaktionen bei Herz-Kreislauf Erkrankungen ZIK-HIKE 03Z2CK1, ZIK-HIKE 03Z2CI1); the Land Mecklenburg-Vorpommern Exzellenzinitiative (Projekt 0500320 FOP; UG 07-064, HWP 303.18, HWP-324-PV-ZIK-3); the Fellows-Programms "Life Sciences" des Alfried Krupp Wissenschaftskollegs Greifswald and Alfried Krupp von Bohlen and Halbach-Stiftung; the Forschungsverbund Molekulare Medizin of the Ernst-Moritz-Arndt-University Greifswald (FOMM 130, FOMM 03-08, FOMM 04-01, FOMM 05-02, FOMM 2007-06, FOMM-2008-02, FOMM 2009-04, FOMM 2010-06); and the Department of Cardiovascular Medicine of the Medical School of the Ernst-Moritz-Arndt University, Greifswald (FOKM 02-105, FOKM 04-102, FOKM 06-05, FOKM 06-07, FOKM 2009-08, FOKM).

CHAPTER

109 Coumarin-Induced Skin Necrosis and Venous Limb Gangrene

THEODORE E. WARKENTIN

Thrombotic events that result from coumarin administration are incongruous but well-documented complications of anticoagulant therapy. The key role of coumarin (vitamin K antagonist) in causing thrombosis and necrosis is by the depletion of one or both vitamin K–dependent natural anticoagulants, protein C, and protein S. In this chapter, *coumarin-induced necrosis* denotes both (central) skin necrosis and (acral) venous limb gangrene syndromes. *Coumarin-induced skin necrosis* (CISN) was first recognized by Verhagen,[1] who described 13 cases in 1954, noting features such as its female predominance, characteristic localization of lesions, and typical onset within a few days of initiating coumarin. CISN is characterized by infarction and necrosis of the skin and underlying subcutaneous tissues.[2,3] A distinct though related syndrome, *coumarin-induced venous limb gangrene*, is linked to warfarin treatment of acute deep vein thrombosis (DVT) complicating certain hypercoagulability disorders, most notably immune heparin-induced thrombocytopenia (HIT) and adenocarcinoma.[4–6,7–11]

COUMARINS

The *coumarins* are a group of naturally occurring lactones that are produced by a number of plants and microbes. Ironically, the least complex member, *coumarin* (1,2-benzopyrone), has no anticoagulant action despite its synonymous designation for those chemically related molecules that possess anticoagulant activity.[12] Warfarin (Coumadin), a 4-hydroxycoumarin derivative, is the most widely used oral anticoagulant in North America and worldwide.[2] Therefore, most instances of CISN in North America are warfarin induced. However, the syndrome can be caused by other coumarin congeners (e.g., phenprocoumon, acenocoumarol, and nicoumalone), as well as by the rarely used phenindione group of oral anticoagulants.[13,14] Phenprocoumon (Marcumar) is widely used in continental Europe. Because its half-life is longer than that of warfarin (6 vs. 1.5 days), relatively large loading doses are often given; however, whether these differences result in a lesser or greater frequency of CISN, compared with warfarin, is unknown. The coumarins interfere with vitamin K epoxide reductase,[15] producing post-translational modifications of four procoagulant and two anticoagulant vitamin K–dependent factors[16] (see Chapter 106).

PATHOGENESIS

Several observations suggest that the fundamental pathobiology of coumarin necrosis is a transient disturbance in procoagulant/anticoagulant balance that leads to microthrombosis in susceptible tissue sites. First, coumarin necrosis has a characteristic temporal profile, usually occurring within 1 week of initiating oral anticoagulant therapy.[5,6,7,9,17,18,19,20] During this interval, functional levels of protein C decline much more quickly than the major procoagulant factor, prothrombin,[21,22] because of differences in their half-lives[16] (see Table 109.1); given that prothrombin inhibits the ability of activated protein C to inactivate factor Va,[23] this early discrepancy in prothrombin versus protein C concentrations—(low-)normal and very low, respectively—can impair the protein C anticoagulant system. Second, the pathology is that of non-inflammatory, small-vessel thrombosis affecting the dermal and subcutaneous postcapillary venules and small veins.[5,19] This is consistent with the role of the protein C anticoagulant pathway in preventing thrombosis of these small vessels.[24] Third, a relatively high proportion of patients with CISN (although not with venous limb gangrene) have a hereditary abnormality of the protein C anticoagulant pathway, which predisposes such patients to further, potentially dangerous reductions in protein C during the first few days of oral anticoagulant treatment. Fourth, the clinical and pathologic appearance of CISN resembles that of neonatal purpura fulminans caused by severe congenital protein C deficiency.[25] Fifth, skin necrosis can be a feature of acquired deficiency of protein C or protein S due to infection, autoimmunity, or the antiphospholipid syndrome[26–28] or functional inhibition of protein C or protein S by antiphospholipid antibodies.[29,30] Sixth, coumarin necrosis (particularly venous limb gangrene) is associated with markedly increased thrombin generation.[4–6,31]

COUMARIN-INDUCED SKIN NECROSIS

CISN refers to *central* (nonacral) necrosis of skin and subcutaneous tissues (see FIGURE 109.1) (4); it occurs more often in women (3:1 ratio), with mean age being 50 to 55 years, and most commonly involves sites with substantial underlying fatty tissues, such as the breast, anterior abdomen, buttocks, hips, thighs, and calves and less commonly, the flank, back, penis (ischemic priapism, necrosis), legs, arms, and face (e.g., cheeks, nose, eyelids, pinnae).[3,13,17,18,19,20,32–39] Multiple (sometimes symmetric) lesions are observed in about one-third of patients. CISN is rare (estimated frequency, 0.01% to 0.1%).[3,18]

The typical temporal onset between 3 and 6 days of oral anticoagulant therapy occurs in 90% of patients,[13,17,18,19,20,40] although late onset after weeks or months has been reported.[41–43] Localized pain, induration, and erythema progress over hours to central purplish black skin discoloration, usually with blistering, and ultimately evolving to well-demarcated, full-thickness necrosis of the skin and subdermal tissues (see FIGURE 109.2). With or without surgical debridement, there usually is a permanent region of depressed skin that reflects the loss of underlying tissues. The necrotic skin also presents the real possibility of secondary fatal sepsis.[40,42,44]

Table 109.1

Half-lives of the vitamin K–dependent procoagulant and anticoagulant factors

Procoagulant Factors	Half-Life, h	Anticoagulant Factors	Half-Life, h
Factor II (prothrombin)	60	Protein C	9
Factor X	40	Protein S	60
Factor IX	24		
Factor VII	4–6		

There are six vitamin K–dependent hemostatic factors: four with procoagulant activity and two with anticoagulant activity. Treatment with coumarin anticoagulants reduces functional levels of these factors. The paradoxic procoagulant effect of warfarin can be explained by the different half-lives[16] of these factors following the onset of action of coumarin—the time to a therapeutically significant reduction of the major procoagulant factor, prothrombin (half-life, ~60 h), is much longer than the time to a clinically important reduction in the major anticoagulant factor, protein C (half-life, ~9 h). Thus, within the first several days of coumarin anticoagulation, and under certain clinical circumstances (see text), there can arise a transient, but clinically important, disturbance in procoagulant—anticoagulant balance.

The earliest stages of CISN can resemble subcutaneous hemorrhage. Incipient skin necrosis is suggested by (a) recent initiation of coumarin, (b) typical location of lesions, (c) absence of trauma, and (d) an international normalized ratio (INR) that is within (in 33% to 60% of patients) or above the therapeutic range.[17,18] CISN that occurs when the INR is within the therapeutic range suggests that the patient has a preexisting abnormality of the protein C natural anticoagulant pathway, as noted in four family members with hereditary protein S deficiency.[45] In contrast, when warfarin-induced venous limb gangrene complicates disorders associated with disseminated intravascular coagulation (DIC), such as HIT or adenocarcinoma, there typically is a *supra*therapeutic INR (>3.5). This reflects the special susceptibility of factor VII and protein C to severe depletion during coumarin therapy in DIC. In such patients, congenital abnormalities of the protein C natural anticoagulant pathway are usually not present.[5,6,10,44]

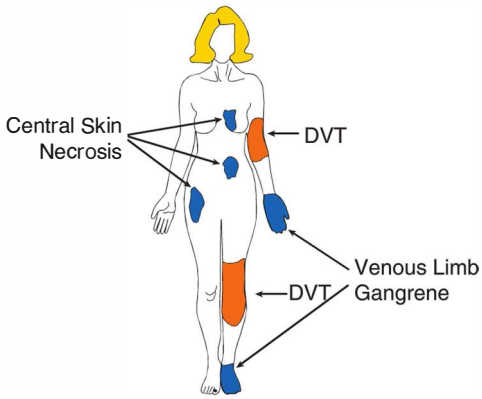

FIGURE 109.1 Two syndromes of coumarin-induced necrosis. (a) CISN and (b) coumarin-induced venous limb gangrene. CISN most often affects the breast, abdomen, thigh, buttock, and calf and often is symmetrical; it is usually associated with congenital or acquired abnormalities in the protein C natural anticoagulant pathway. In contrast, venous limb gangrene occurs in patients with DIC associated with immune HIT or adenocarcinoma. This syndrome is characterized by microvascular thrombosis in a limb affected by DVT that leads to acral ischemic necrosis. (Reprinted with modifications from Warkentin TE. Heparin-induced thrombocytopenia: IgG-mediated platelet activation, platelet microparticle generation, and altered procoagulant/anticoagulant balance in the pathogenesis of thrombosis and venous limb gangrene complicating heparin-induced thrombocytopenia. *Transfus Med Rev* 1996;10:249–258, with permission.)

FIGURE 109.2 Coumarin-induced skin necrosis. Breast necrosis necessitating bilateral mastectomies occurred during the use of warfarin to treat pulmonary embolism complicating HIT. Follow-up studies showed no congenital deficiency in protein C, protein S, or antithrombin. Factor V_{Leiden} and the prothrombin G→A20210 variant were not present. (Reprinted from Warkentin TE, Sikov WM, Lillicrap DP. Multicentric warfarin-induced skin necrosis complicating heparin-induced thrombocytopenia. *Am J Hematol* 1999;62:44–48, with permission.)

Often, multiple risk factors can be identified in individual patients (see Table 109.2).[5,6,7–10,31,32–34,40,44,45,46–64,65,66,67,68,69,70,71,72–76] An example is the concurrence of postpartum DVT, antiphospholipid syndrome, "loading doses" of warfarin, and premature discontinuation of heparin in one patient[50]; another is the concurrence of pulmonary embolism, factor V_{Leiden}, "loading doses" of warfarin, and premature discontinuation of heparin in another.[46]

Abnormalities of the protein C natural anticoagulant pathway are a relatively common finding in patients with CISN. Indeed, congenital deficiency of protein C was the first hemostatic abnormality identified in some patients with CISN (although reports do not always distinguish hereditary deficiency from the reversible reduction expected in a patient receiving coumarin).[68,69,70] Congenital deficiency of protein S[45,48,49,51,52,64,71] and of antithrombin[74] also has been observed, as has been the presence of factor V_{Leiden},[46,49,53,63,72,73] a common mutation that renders factor V less susceptible to proteolytic degradation by activated protein C. Most patients with CISN have acute DVT (rather than a nonthrombotic indication such as atrial fibrillation)[55] as their indication for oral anticoagulants,[3] suggesting

Table 109.2

Multifactorial nature of coumarin necrosis

Local Risk Factors
Sites of increased subcutaneous fat[a] (e.g., breast, abdomen, thigh, calf; obesity is common; lesions often are symmetric, e.g., bilateral thighs)[40,44,45,46–51]
DVT[a,b;40,44,47–50,52,53] and/or pulmonary embolism[46]
Peripheral vasospasm, for example, Raynaud phenomenon[54,55]
Coumarin Pharmacokinetics (Often Resulting in Supratherapeutic INR)
"Loading doses" of warfarin[a;40,44,46–51,53,56]
Drugs enhancing pharmacologic effect of warfarin, for example, antibiotics[57–59]
Hepatic dysfunction (including congestive heart failure)[59,60]
Vitamin K deficiency[61,62]
Premature discontinuation of heparin or low molecular weight heparin (or DTI) during coumarin overlap[c;40,44,46,47,50,54,63,64,65]
Cytochrome P-450 mutations (CYP2C9*2, CYP2CP9*3) affecting coumarin pharmacokinetics[d;66,67]
Disorders Associated with DIC[e]
Heparin-induced thrombocytopenia[a;5,31,49,52,54,65]
Adenocarcinoma[a;6,7–10,47,54]
Congenital or Acquired Hypercoagulability Disorders
Abnormalities of the protein C natural anticoagulant pathway
Congenital protein C deficiency[a;32–34,53,68,69,70]
Congenital or acquired protein S deficiency[a;45,48,49,51,52,64,71]
Factor V_{Leiden} (heterozygous or homozygous)[a;46,49,53,63,72,73]
Antiphospholipid syndrome[50]
Miscellaneous
Postpartum state[a;49–52]
Antithrombin deficiency[d;74,75]
Prothrombin gene mutation G20210A[d;76]
Hyperhomocysteinemia (methyltetrahydrofolate reductase C677T polymorphism)[d;48]
HIV infection with active tuberculosis[40]
The multifactorial nature of coumarin necrosis is illustrated by four or more risk factors in many patients.[46–54]

[a]Common association with coumarin necrosis that is likely of pathogenetic significance.
[b]DVT also predisposes to subtending acral limb necrosis, that is, venous limb gangrene.
[c]Early protein C depletion is more likely to be clinically significant if heparin is prematurely discontinued during heparin–coumarin overlap for treatment of thrombosis.
[d]Theoretical risk factor for coumarin necrosis that is not established.
[e]DIC predisposes more strongly to venous limb gangrene than to CISN.
INR, international normalized ratio; DTI, direct thrombin inhibitor; DIC, disseminated intravascular coagulations.

that associated clinical factors (perhaps thrombin generation related to an acute thrombus) are relevant in CISN pathogenesis.

COUMARIN-INDUCED VENOUS LIMB GANGRENE

A form of coumarin necrosis known as *venous limb gangrene* affects acral tissues such as toes/feet/legs or fingers/hands/arms (see FIGURES 109.1 and 109.3A–C)[4,5]; ischemic necrosis starts at the most distal part of the extremity and progresses proximally.[77] Tissue necrosis occurs in the limb with acute DVT, sometimes with a discernible prodrome of phlegmasia cerulea dolens[5,44,77–79] (see FIGURE 109.3D). Manifestations of acral tissue necrosis range from sloughing of skin of the toes or fingers that does not require amputation to extensive gangrene that requires below-the-knee or even above-the-knee amputation. In contrast, necrosis in CISN is limited to skin and subcutaneous tissues.

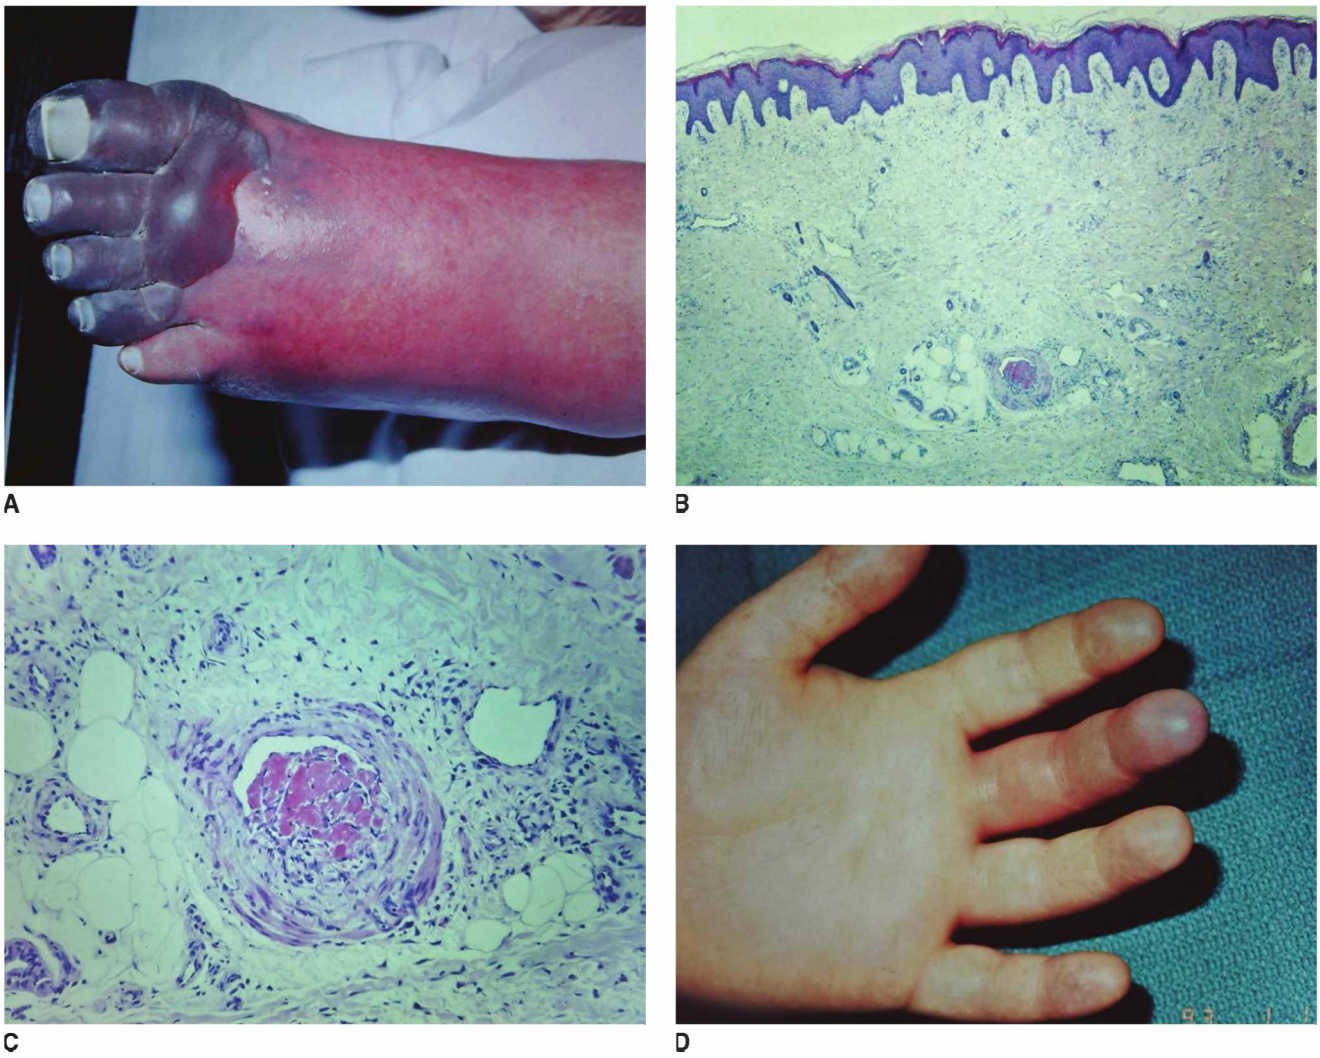

FIGURE 109.3 **A:** Warfarin-induced venous limb gangrene complicating HIT. **B:** An occluding thrombus can be seen in a subcutaneous venule (original magnification, ×40). **C:** High-power view (original magnification, ×100) of the subcutaneous venule from part **(B)**. **D:** Warfarin-associated phlegmasia cerulea dolens complicating HIT. (Photograph from patient 4, reported previously.[5]) (FIGURE 109.3A–C: From Warkentin TE, Elavathil LJ, Hayward CPM, et al. The pathogenesis of venous limb gangrene associated with heparin-induced thrombocytopenia. *Ann Intern Med* 1997;127:804–812, with permission.)

Two hypercoagulability disorders have been linked to coumarin-induced venous limb gangrene: immune HIT[5,11,31,44] and DIC associated with adenocarcinoma.[6,7–11,47,54,79,80] Occasionally, CISN and venous limb gangrene occur in the same patient.[5,31,78,79]

Clinical and laboratory data support a pathogenic role for coumarin in the pathogenesis of venous limb gangrene complicating HIT. First, a case–control study[5] of patients with HIT observed a higher frequency of warfarin use coinciding with the onset of venous limb gangrene than in control patients with limb ischemia secondary to arterial thrombosis (8 of 8 vs. 3 of 10; $P = 0.004$). Additional analysis showed that patients with HIT, DVT, and venous limb gangrene had a significantly greater median INR (5.8 vs. 3.1; $P < 0.001$) than control patients with HIT who had DVT and who were also treated with warfarin but did not develop limb gangrene.

Laboratory studies corroborated an important role for warfarin in the pathogenesis of venous limb gangrene (see FIGURE 109.4A,B). Compared with controls, plasma from patients with venous limb gangrene had a higher ratio of thrombin–antithrombin complex (a marker of *in vivo* thrombin generation) to protein C activity during warfarin treatment (FIGURE 109.4B, bottom). Analysis of individual cases showed that the onset of venous limb gangrene coincided with a fall in protein C activity to very low levels (FIGURE 109.4A, bottom). No hereditable abnormalities in the protein C anticoagulant pathway were seen in any patient. Thrombosis of subcutaneous venules characteristic of this syndrome is consistent with the role of the protein C anticoagulant pathway to downregulate thrombin generated in the microvasculature.[19,24] The normal INR values before initiation of warfarin therapy, as well as normal (or elevated) levels of factors V and VIII during warfarin treatment, rule out DIC as the sole explanation for the elevated INR values.[6]

Venous limb gangrene usually presents as a characteristic clinical triad[4–6]: (a) an acute DVT involving the limb

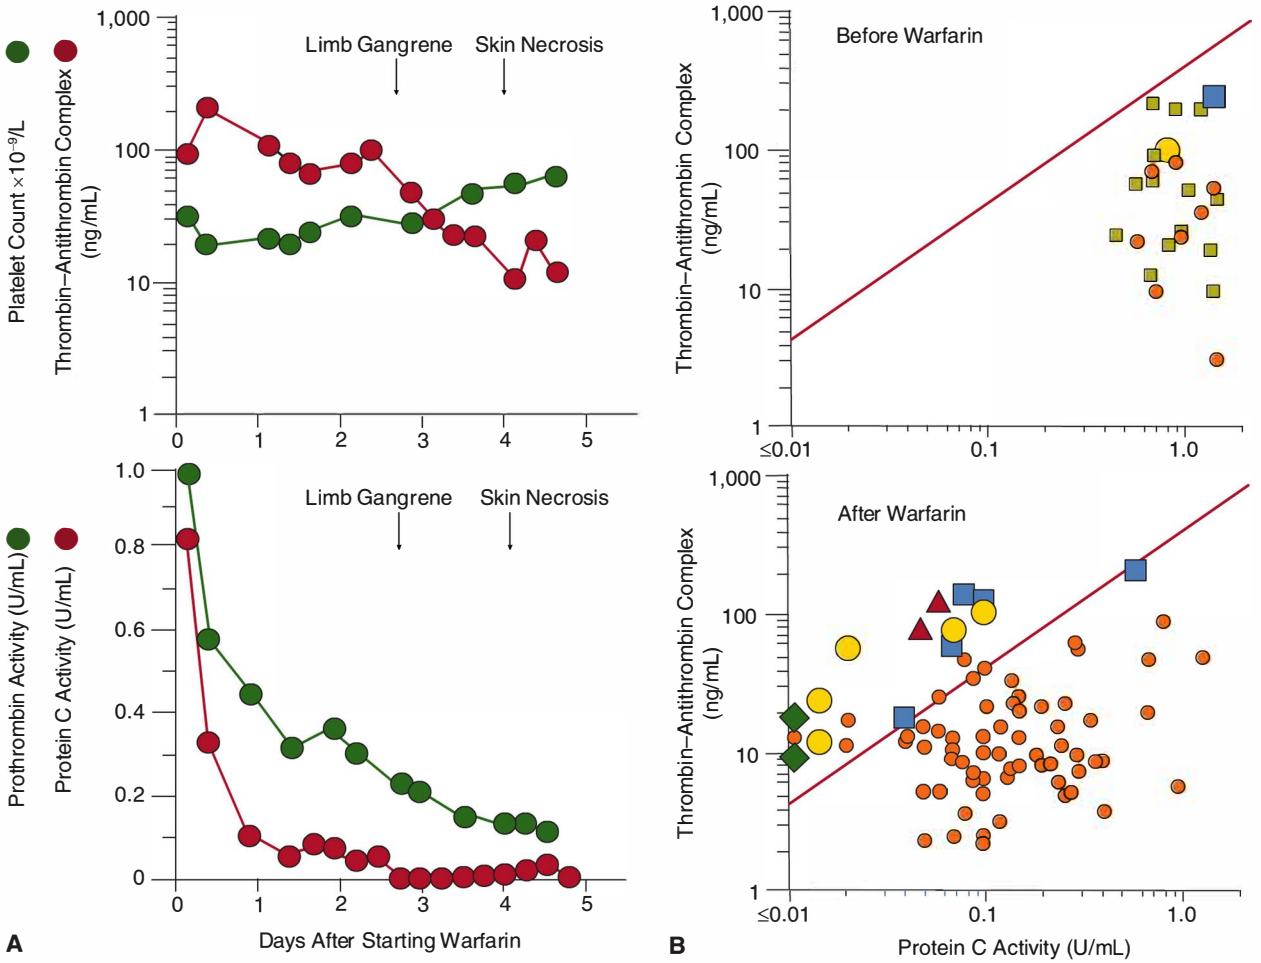

FIGURE 109.4 Coumarin-induced venous limb gangrene: a disturbance in procoagulant–anticoagulant balance. **A:** Hemostatic markers in relation to clinical course in a patient with warfarin-induced venous limb gangrene. Venous limb gangrene and central skin necrosis occurred when warfarin was given during acute HIT; the INR rose to a supratherapeutic value, 7.2 (not shown). **Top:** Platelet counts and thrombin–antithrombin complexes. **Bottom:** Prothrombin activity and protein C activity. **B:** Thrombin–antithrombin complexes compared with protein C activity in patients with HIT. Each data point represents thrombin–antithrombin complexes and protein C activity per single treatment day per patient. In both panels, *large symbols* represent patients who developed venous limb gangrene (n = 3) or cerulea phlegmasia dolens (n = 1). The *diagonal line* indicates an arbitrary ratio of thrombin–antithrombin complex to protein C of 40. **Top:** Results obtained when HIT was first diagnosed and before warfarin therapy began for two patients (*large symbols*) who developed venous limb gangrene or severe venous ischemia and for eight patients (*small orange circles*) who subsequently received warfarin for DVT without developing venous limb gangrene. For comparison, results obtained when HIT was diagnosed in 15 patients (*small olive squares*) without clinically suspected DVT who did not subsequently receive warfarin are shown. **Bottom:** Results in 16 patients who were receiving warfarin for HIT, including four patients (*large symbols*) who developed venous limb gangrene or phlegmasia cerulea dolens and 12 patients (*small orange circles*) (nine of whom had DVT) who received warfarin without developing venous limb gangrene. More than one data point is shown for patients from whom plasma samples were available on more than 1 day of warfarin treatment. (Reprinted with modifications from Warkentin TE, Elavathil LJ, Hayward CPM, et al. The pathogenesis of venous limb gangrene associated with heparin-induced thrombocytopenia. *Ann Intern Med* 1997;127:804–812, with permission.)

subsequently affected by necrosis, (b) a supratherapeutic INR, and (c) thrombocytopenia associated with a procoagulant disorder such as HIT or adenocarcinoma. FIGURE 109.5 summarizes the pathogenesis of warfarin-induced venous limb gangrene in relation to this clinical triad.

Typically, acral necrosis occurs in a limb with a concurrent symptomatic *acute DVT*. In the study of venous limb gangrene complicating HIT,[5] this complication occurred in 10 limbs (among 8 patients). Symptomatic lower limb DVT was present in all 10 limbs within the previous week; necrosis did not occur in upper or contralateral lower limbs unaffected by DVT. These observations suggest a role for large vein thrombosis in predisposing to ipsilateral involvement of small veins and venules, either by direct extension of thrombosis from large to

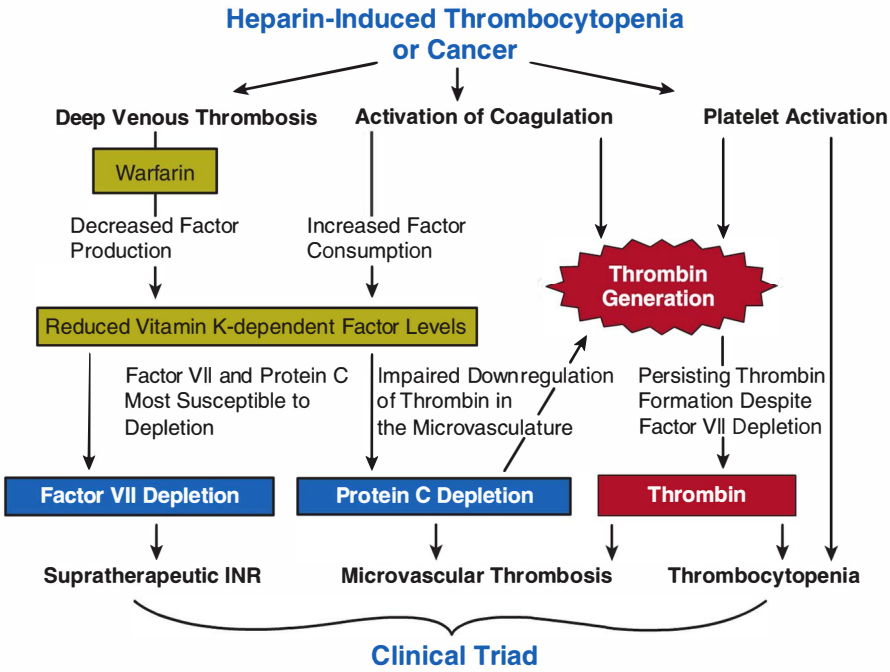

FIGURE 109.5 Proposed pathogenesis of coumarin-induced venous limb gangrene complicating either immune HIT or adenocarcinoma. INR, international normalized ratio. (From Warkentin TE. Venous limb gangrene during warfarin treatment of cancer-associated deep venous thrombosis. *Ann Intern Med* 2001;135:589–593, with permission.)

progressively smaller veins or by venous stasis predisposing to microvascular thrombosis.

An *elevated INR* is the laboratory hallmark of this syndrome. Patients with venous limb gangrene typically have an INR that is at least 3.5.[4–6,7,44,47,49,54,65,80] The high INR is a surrogate marker for severe protein C depletion that reflects parallel depletion in factor VII[6] (see FIGURE 109.6).

Increased thrombin generation and platelet activation, clinically manifesting as thrombocytopenia, are characteristic of coumarin-induced venous limb gangrene.[5,6] Platelet activation by HIT antibodies produces a marked platelet procoagulant response, as shown by *in vitro* and *in vivo* generation of procoagulant, platelet-derived microparticles,[81,82] leading to increased thrombin generation in patients with HIT, with the potential for impaired procoagulant–anticoagulant balance during coumarin treatment.

Table 109.3 lists the reasons why physicians may not recognize the role of coumarin in contributing to venous limb gangrene.[5,77] Clinicians should suspect oral anticoagulation as the explanation for progressive acral ischemia when an otherwise typical DVT worsens in association with a rise in the INR to above 3.5, especially if the patient has thrombocytopenia suggestive of HIT or DIC.[4–6]

Warfarin-induced digital necrosis affecting multiple digits occurred in a patient with adenocarcinoma, HIT, and Raynaud phenomenon; the absence of DVT in three limbs affected by digital ischemia and necrosis suggested that vasospasm predisposed to this unusual presentation of multiple digital gangrene.[54] Raynaud phenomenon was also a feature of warfarin-associated multiple digital necrosis in a patient with protein S deficiency.[55]

TREATMENT

Vitamin K may reverse incipient CISN or phlegmasia cerulea dolens if given in the earliest stages of the disease.[5,44,83] Often, however, the diagnosis is not made until extensive microthrombosis has occurred and necrosis is inevitable. It is not known whether vitamin K, plasma, protein C,[84–86] or activated protein C concentrates alter the natural history at this point. Amputation or skin grafting is required in about half of the patients with coumarin necrosis.

In the original report of CISN by Verhagen,[1] the coumarin was usually continued despite the occurrence of tissue necrosis, and it was the author's view that tissue injury nevertheless did not progress beyond the level at which it was already clinically apparent. An alternative view is that intravenous vitamin K and effective parenteral anticoagulation are important in avoiding progressive macrothrombosis and microthrombosis in a patient with coumarin-associated phlegmasia or venous limb gangrene complicating HIT or cancer. The reasoning is that unlike the transient disturbance of procoagulant–anticoagulant balance seen in some patients with CISN, ongoing consumption of the vitamin K–dependent factors can persist if the underlying hypercoagulability state is uncontrolled. Anticoagulation involves either heparin (or low molecular weight heparin) for cancer-associated DIC, or a nonheparin anticoagulant (e.g., lepirudin, argatroban, danaparoid), if HIT is the diagnosis. A relevant issue is that ongoing vitamin K antagonism tends to prolong the activated partial thromboplastin time (aPTT), thereby confounding the monitoring and dosing of heparin or a direct thrombin inhibitor, underscoring the importance of giving vitamin K, preferably by the intravenous route.[87,88,89]

PREVENTION

A cautious approach to further use of coumarin anticoagulants in acute HIT or DIC secondary to malignancy should be adopted. Warfarin should be started only in patients with acute HIT who are adequately anticoagulated with a nonheparin anticoagulant, and only after the platelet count has recovered

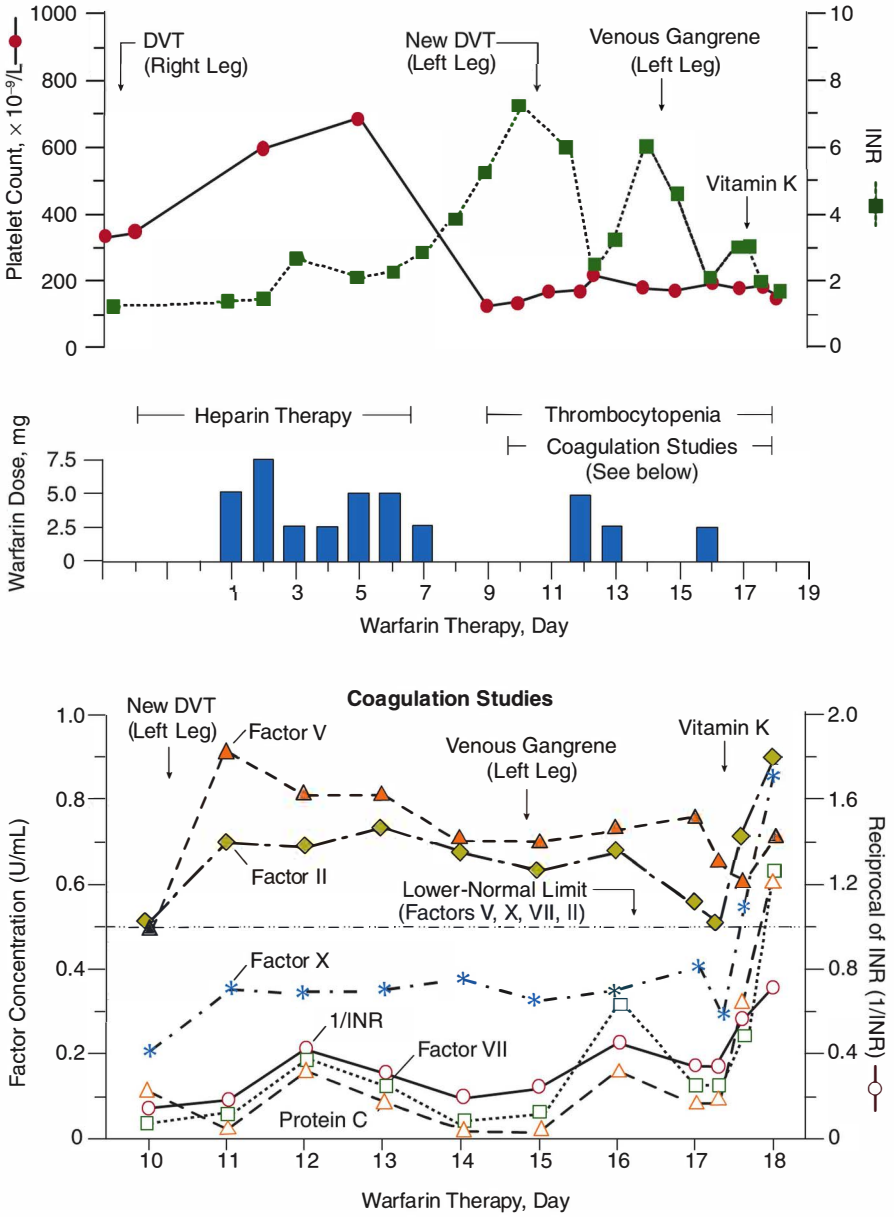

FIGURE 109.6 Top: Cancer-associated venous limb gangrene: serial platelet counts and international normalized ratio (INR) values in relation to heparin and warfarin treatments. The abrupt increase in the INR and decrease in the platelet counts on discontinuation of heparin therapy are consistent with the increase in the consumption of coagulation factors and platelets in this patient with cancer-associated DIC resistant to warfarin. **Bottom:** Plasma factor studies. Eleven plasma samples obtained between days 10 and 18 of warfarin treatment were studied. Vitamin K, 5 mg intravenously, was given where indicated. Of the four coagulation factors that affect the INR (factors II, V, VII, and X), only factor VII levels explained the variability in the reciprocal of the INR: 1/INR = 0.178 + 0.974 (factor VII level) (r^2 = 0.883, P < 0.001). Protein C activity showed a near-identity relationship with factor VII: (protein C level) = −0.01 + 0.94 (factor VII level). The following coagulation factor levels (not shown in the figure) were normal: factor VIII, factor IX, factor XI, factor XII, free protein S, fibrinogen, and antithrombin activity. (From Warkentin TE. Venous limb gangrene during warfarin treatment of cancer-associated deep venous thrombosis. *Ann Intern Med* 2001;135:589–593, with permission.)

to more than 150 × 10^9/L[88,89] (see Chapter 108). FIGURE 109.7 illustrates the danger of initiating warfarin in a patient with DIC and thrombocytopenia associated with HIT; even though concomitant lepirudin was given, when the INR reached 5.5 and lepirudin was stopped, progression to venous limb gangrene rapidly ensued. Low molecular weight heparin rather than warfarin should be considered for patients with cancer-associated DVT[80,90] who have laboratory evidence for DIC.

Routinely avoiding loading doses of oral anticoagulants may reduce the frequency of coumarin necrosis. A maximum of 5 mg for the first dose (even less in case of an elderly patient) is appropriate.[91,92] Harrison et al.[21] performed a randomized controlled trial

Table 109.3

Reasons why venous limb gangrene is often not recognized as being caused by warfarin or other oral anticoagulants

1. Limb necrosis primarily blamed on associated illness alone (e.g., HIT, malignancy) rather than on warfarin
2. DVT usually precedes use of warfarin
3. Classic *clinical* features of CISN are usually lacking (i.e., central skin necrosis involving breast, abdomen, or thigh is usually not present)
4. Classic *laboratory* features of CISN are usually lacking (i.e., congenital abnormality of the protein C anticoagulant pathway usually is not found)

HIT, heparin-induced thrombocytopenia; DVT, deep vein thrombosis; CISN, coumarin-induced skin necrosis.

comparing 5 versus 10 mg warfarin as an initial "loading" dose for typical patients undergoing initial warfarin anticoagulation. The group that received the lower dose of warfarin had significantly higher levels of protein C at 36 and 60 hours after initiation of warfarin and was less likely to have early excess anticoagulation (as measured by the INR). Therefore, there may be an advantage of using the lower dose (avoidance of protein C deficiency and an associated disturbance in procoagulant/anticoagulant balance).[21,93]

The manufacturer of Coumadin advocates avoiding loading doses: "Routine use of loading doses is not recommended as this may increase hemorrhagic and other complications and does not offer more rapid protection against clot formation. .... [T]he initial dose of Coumadin is usually 2 to 5 mg per day. Modify this dose based on consideration of patient-specific clinical factors. Consider lower initiation doses for elderly and/or debilitated patients."[94] An important reason to avoid loading doses of warfarin, although it is safe in most patients, is because it is unsafe in the *minority* of patients who have one or more risk

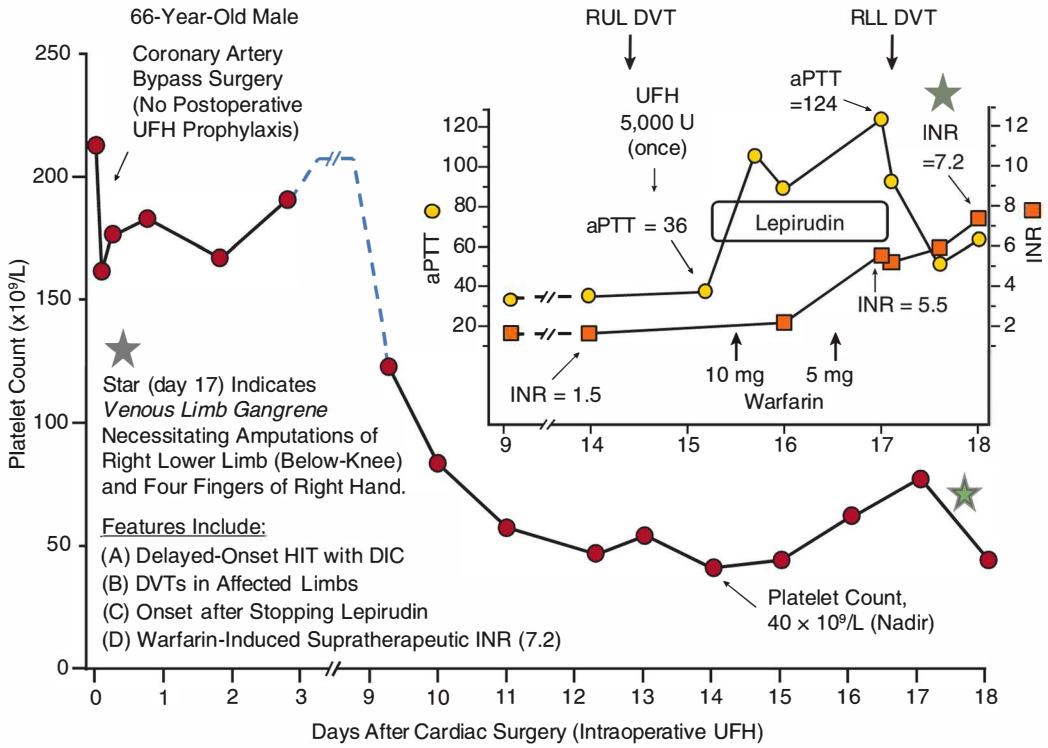

FIGURE 109.7 Patient with delayed-onset HIT, DIC, and venous limb gangrene during overlapping treatment with lepirudin and warfarin. The patient was readmitted to hospital on postoperative day 9 following cardiac surgery because of sternal wound complications. DIC was indicated by elevated INR (1.5) and aPTT (36 s), low fibrinogen (1.5 g/L), and elevated lactate dehydrogenase and reticulocyte counts. On day 14, symptomatic right upper-limb DVT (brachial and basilic veins) occurred, and one subcutaneous dose of UFH was given. An anti-PF4/polyanion enzyme immunoassay was "strongly positive," and thus lepirudin (0.4 mg/kg bolus followed by 0.20 mg/kg/h) was administered. Unfortunately, two doses of warfarin (10 and 5 mg) also were given, in spite of persisting thrombocytopenia (platelet count ~40 × 10^9/L). On day 17, the aPTT of 124 seconds and INR of 5.5 prompted discontinuation of lepirudin; within hours, the patient developed explosive symptoms and signs of right lower-limb DVT (common/superficial femoral and popliteal veins) with rapid progression to venous limb gangrene of the right upper and lower limbs. Other risk factors for venous limb gangrene identified in this patient included heterozygous factor V_{Leiden} status and intravenous ciprofloxacin and amoxicillin (potentiation of warfarin effect). aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; RLL, right lower limb; RUL, right upper limb; U, units; UFH, unfractionated heparin.

factors for coumarin necrosis, the presence of which is generally unknown when warfarin is commenced.[91]

REPEAT USE OF COUMARIN

For patients with a history of CISN or venous limb gangrene, it is acceptable to reintroduce oral anticoagulants with appropriate precautions.[5,50,74] This is because coumarin necrosis is often related to dynamic and transient clinical and biochemical factors that may not exist later. It is prudent to start with low doses of warfarin (e.g., 1 to 2 mg/d for 3 to 4 days), gradually increasing the INR into the target range over 1 to 2 weeks. However, even higher initial doses (2 to 5 mg/d) are reported to be safe.[95] Unless HIT is suspected, combined treatment with therapeutic dose heparin is recommended[96] as thrombin inhibition theoretically reduces the risk of coumarin necrosis. Plasma or protein C concentrates have been given to some patients with known congenital protein C deficiency during initiation of warfarin.[97–99] The risk of recurrence of necrosis despite using any of these precautions is unknown, but likely is low.

COUMARIN-ASSOCIATED "PURPLE TOE" AND CHOLESTEROL EMBOLISM SYNDROMES

Use of oral anticoagulants may contribute to the development of "purple" or "blue" toes (or, rarely, fingers)[100] in patients with severe atherosclerosis. This syndrome was first described by Feder and Auerbach,[101] who reported six patients who developed blue-purple discoloration of the feet, especially the plantar surfaces and sides of the first two toes, that began 3 to 8 weeks after starting a coumarin. Other clinical features included pain and tenderness of the toes, blanching on moderate pressure, and persistence of these features despite stopping oral anticoagulation. Because these patients were male with peripheral vascular disease, it was suggested that "purple toe syndrome" could be explained by cholesterol microembolization,[102,103] a concept that is gaining acceptance.[104,105]

Classically, cholesterol (or atheromatous) embolism syndrome is characterized by a variety of peripheral ischemic signs (livedo reticularis, "blue" toes, focal digital necrosis); renal failure may also occur.[103,106,107] Pedal pulses are usually palpable, consistent with the histopathologic findings of biconvex clefts in small arteries and arterioles indicative of preceding microembolism of cholesterol crystals. Although advanced atherosclerosis is conspicuous, there is often a history of recent vascular injury (e.g., cardiac surgery, arteriography)[103] or of disruption of adherent thrombus (e.g., postthrombolytic therapy).[108]

Only about 20% to 50% of patients who are clinically diagnosed with cholesterol embolism syndrome are receiving anticoagulants.[109,110] Theoretically, coumarins could cause or exacerbate this syndrome by contributing to a gradual loss over weeks of a protective fibrin layer overlying an ulcerated atherosclerotic plaque, facilitating cholesterol microembolization.[111] Fibrin dissolution could also explain the occurrence of this syndrome following thrombolysis.[108] However, any causal role for coumarin or other anticoagulants is speculative. Therefore, the physician must balance the risks of stopping warfarin with the uncertain potential for improvement. Although resolution of cholesterol embolism syndrome might seem improbable, there are well-documented reports of clinical improvement or resolution after stopping warfarin,[107] and even subsequent recurrence of purple toes with resumption of coumarin.[112]

MISCELLANEOUS CUTANEOUS EFFECTS OF ORAL ANTICOAGULANTS

In addition to ecchymotic purpura related to the anticoagulant effects of warfarin and other oral anticoagulants, a few patients may develop macular, papular, vesicular, or urticarial lesions, presumably of an allergic origin.[113,114] Alopecia of varying severity in relation to oral anticoagulation has also been described. Use of a different oral anticoagulant agent may permit further anticoagulation with resolution of these adverse effects.

Calcific uremic arteriopathy (or arteriolopathy), also known as *calciphylaxis*, occurs in patients with chronic renal failure and hyperparathyroidism and is characterized by painful, well-demarcated purpuric plaques and nodules with surrounding livedo reticularis.[115,116,117,118–120] As with CISN, involved skin often overlies adipose tissues, and therefore thigh and abdomen are involved more often than acral locations.[118] Histologic features include medial calcification of small- and medium-sized arteries, with intimal proliferation and endovascular fibrosis.[118] Reduced protein C activity (with normal protein C antigen levels) has been described.[115] Some patients develop this complication while receiving warfarin and may benefit from substituting oral anticoagulation by low molecular weight heparin.[116,119,120]

CHAPTER

110 New Antithrombotic Drugs

JEFFREY I. WEITZ AND PETER L. GROSS

Currently available antithrombotic drugs include (a) antiplatelet agents, which inhibit platelet activation or aggregation, (b) anticoagulants, which attenuate fibrin formation, and (c) fibrinolytic agents, which degrade the fibrin component of thrombi by catalyzing the generation of plasmin (FIGURE 110.1). Because arterial thrombi consist of platelet aggregates held together by small amounts of fibrin,[1] strategies to prevent or treat arterial thrombosis focus mainly on drugs that block platelet function, but may include anticoagulants to prevent fibrin deposition. Anticoagulants are the treatment of choice for prevention of cardioembolic events in patients with atrial fibrillation or mechanical heart valves. Anticoagulants also are the drugs of choice for their prevention and treatment of venous thromboembolism (VTE) because venous thrombi are composed mainly of fibrin.[1]

Fibrinolytic therapy is used in selected patients with arterial or venous thrombosis. When percutaneous intervention is not feasible, systemic fibrinolytic therapy is often administered to patients with acute myocardial infarction (MI) or selected patients with ischemic stroke to rapidly restore antegrade flow in occluded arteries. Patients with massive pulmonary embolism (PE) may also benefit from systemic or catheter-directed fibrinolytic therapy. Although systemic fibrinolytic therapy is ineffective for treatment of patients with extensive deep vein thrombosis (DVT) involving the iliac and/or femoral veins, catheter-directed fibrinolysis, often in conjunction with mechanical methods of thrombus disruption, may be of benefit in some patients.[2]

Focusing on new antithrombotic agents, this chapter (a) identifies the limitations of current antithrombotic drugs, (b) describes the new antiplatelet and anticoagulant drugs in more advanced stages of development, focusing on their mechanism of action and the results of clinical trials, and (c) provides clinical perspective on the unmet needs in antithrombotic therapy for prevention and treatment of venous and arterial thrombosis. Fibrinolytic drugs are discussed in Chapter 112.

LIMITATIONS OF CURRENT ANTITHROMBOTIC DRUGS

New antithrombotic drugs have been developed to overcome the limitations of existing agents. Most of the advances have been in the area of antiplatelet drugs and anticoagulants. The development of new fibrinolytic agents has lagged behind.

Currently available oral antiplatelet agents include aspirin, clopidogrel, prasugrel, and ticagrelor. The efficacy of aspirin and clopidogrel has established cyclooxygenase-1 (COX-1), a key enzyme in thromboxane A_2 synthesis, and $P2Y_{12}$, the major ADP receptor on platelets, as important targets for antiplatelet drugs. On its own, clopidogrel has been shown to be only marginally more effective than aspirin.[3] The combination of aspirin plus clopidogrel is superior to aspirin alone in patients at high risk for cardiovascular events,[4–7] but combination therapy is associated with a significant risk of bleeding and has yielded disappointing results in patients with stable cardiovascular disease.[8,9] Although the combination of aspirin plus dipyridamole is superior to aspirin alone for secondary prevention in patients with cerebrovascular disease,[10] the efficacy of this combination is similar to that of clopidogrel.[11]

The limitations of existing antiplatelet drugs reflect, at least in part, their capacity to attenuate only a single pathway of platelet activation. Because platelets can be activated via multiple pathways, the potential for bypassing the inhibitory effects of these drugs remains high when there is a potent stimulus for platelet activation. Consequently, it is not surprising that breakthrough cardiovascular events occur, and these should not necessarily be labeled as simple treatment failures.

Another factor that may contribute to breakthrough cardiovascular events is individual variability in the response to antiplatelet drugs. Such variability may reflect poor compliance, pharmacogenetic factors, increased platelet turnover, drug interactions, baseline and residual platelet hyper-reactivity, as well as other factors.[12,13] Decreased responsiveness to aspirin and/or clopidogrel is common in patients with acute coronary syndrome (ACS), particularly those with diabetes.[14] In patients undergoing percutaneous coronary intervention (PCI), a reduced biologic response to aspirin plus clopidogrel has been associated with a poorer outcome. The decreased response may reflect, at least in part, limited metabolic activation of clopidogrel[13] in patients with reduced function variants of the *CYP2C19* gene (see Chapter 111).

Although prasugrel also requires biotransformation to active metabolites, variants of the *CYP2C19* gene do not appear to influence outcomes in prasugrel-treated patients.[15,16] These findings have prompted some experts to recommend tailored antiplatelet therapy based on periprocedural platelet function or genetic testing.[17,18] However, the value of this approach has not been established, and, in one study, doubling the clopidogrel dose in patients with increased platelet reactivity did not improve outcome.[19] Instead, the limitations of existing antiplatelet agents has prompted the development of newer and more potent drugs, some directed against proven targets involved in platelet activation and others against new targets. These agents include novel inhibitors of the thromboxane A_2 receptor, new $P2Y_{12}$ antagonists, and inhibitors of protease activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

On the anticoagulant front, attention has focused on the development of new oral agents to replace vitamin K antagonists (VKA).[20] Rivaroxaban, a direct factor Xa inhibitor, and

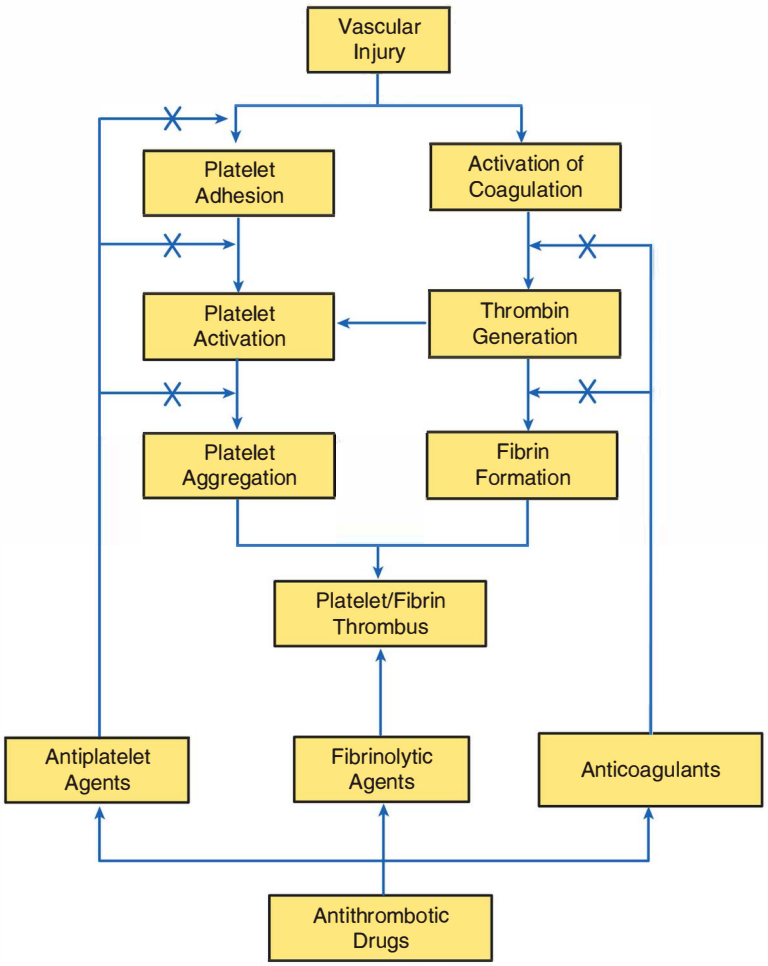

FIGURE 110.1 Targets of new antithrombotic drugs. Thrombosis occurs at sites of vascular injury by coordinated processes that result in platelet activation and activation of the coagulation system. Formation of the platelet plug represents the first step in hemostasis. Subsequent thrombin generation amplifies the platelet response because thrombin is a potent platelet agonist. Thrombin also converts fibrinogen to fibrin, and the fibrin strands stabilize the platelet aggregates, thereby forming a platelet/fibrin thrombus. Given the importance of platelets and fibrin in thrombogenesis, new antithrombotic agents target these components. New antiplatelet strategies focus on blocking platelet adhesion, activation, or aggregation. Novel anticoagulants, which target various coagulation enzymes, are geared at inhibiting thrombin generation or thrombin activity. Finally, fibrinolytic agents digest the fibrin component of the thrombus, thereby causing thrombus dissolution.

dabigatran etexilate, a direct thrombin inhibitor, have been licensed in many countries for short-term thromboprophylaxis after elective hip or knee arthroplasty, and dabigatran etexilate and rivaroxaban have been licensed in the United States, Canada, and Europe for stroke prevention in patients with atrial fibrillation. The pharmacologic properties of these agents are compared in Table 110.1.

PLATELET INHIBITORS

Inhibitors of Platelet Adhesion

The interaction of platelets with subendothelial adhesive proteins exposed at sites of vascular injury promotes platelet signaling pathways that trigger platelet activation and adhesion. Consequently, strategies aimed at blocking platelet adhesion represent a novel antithrombotic approach. The targets for these inhibitors include von Willebrand factor (vWF), glycoprotein (GP) Ib/V/IX, GPVI, GPIa/IIa, collagen, or intracellular signaling molecules that are triggered by platelet adhesion (FIGURE 110.2).

vWF Inhibitors

Because vWF serves as the molecular glue that tethers platelets to the damaged vessel wall, vWF is an attractive target for agents that block platelet adhesion. Strategies to target vWF include (a) aurintricarboxylic acid, a heterogeneous mixture of polycarboxylic and polyaromatic polymers that bind vWF and prevent its interaction with GPIb,[21,22] (b) genetically engineered vWF fragments encompassing the GPIb-binding site, which compete with intact vWF for receptor binding,[23] and (c) monoclonal antibodies or oligonucleotide aptamers directed against the A1 domain of vWF, which block the interaction of vWF with GPIb.[24–27] ARC1779, a DNA aptamer consisting of 40 nucleotides directed against the A1 domain of vWF, is the only one of these agents to be evaluated in humans. Polyethylene glycol was attached to the aptamer to extend its half-life. ARC1779 was well tolerated in a phase I study in healthy volunteers and has shown promise in the treatment of patients with thrombotic thrombocytopenic purpura.[27]

GPIb/V/IX Inhibitors

The interaction of vWF with GPIb/V/IX is an early and pivotal step in platelet adhesion. Thus, thrombus formation is abolished in GPIb-knockout mice.[28] In contrast, when vWF is knocked out, thrombus formation is only modestly attenuated, presumably because other adhesive ligands substitute for vWF and mediate platelet adhesion. Strategies to target GPIb/V/IX include (a) monoclonal antibodies directed against GPIb, (b) GPIb-binding proteins isolated from the venom of *Bothrops jararaca* or *Crotalus atrox*, which compete with vWF for GPIb binding, and (c) R9alpha557, a palmitylated, cell-permeable peptide

Table 110.1

Comparison of the pharmacologic properties of the new oral anticoagulants that are licensed or in the most advanced stages of clinical development

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	Thrombin	Factor Xa	Factor Xa	Factor Xa
Molecular weight	628	436	460	548

CYP metabolism (%)	None	32	15	<4
P-gp transport	Yes	Yes	Yes	Yes
Renal excretion (%)	80	66[a]	25	35
Drug interactions	Potent P-gp inhibitors and inducers[b]	Potent inhibitors and inducers of P-gp and CYP3A4[b]	Potent inhibitors and inducers of CYP3A4[b]	Potent inhibitors and inducers of P-gp
Antidote[c]	Fab fragment	Factor Xa	Factor Xa	Factor Xa

[a]One-half of renally cleared rivaroxaban is excreted as unchanged drug and one-half as inactive metabolites.
[b]Potent inhibitors of P-gp include quinidine, amiodarone, and verapamil. Potent inhibitors of both P-gp and CYP3A4 include azole antifungals (e.g., ketoconazole), protease inhibitors (e.g., ritonavir), and macrolide antibodies (e.g., clarithromycin). Potent CYP3A4 inhibitors include azole antifungals, macrolide antibiotics, and protease inhibitors. Potent inducer of both P-gp and CYP3A4 is rifampicin.
[c]Neither of these antidotes has been tested in humans.
bid, twice daily; od, once daily; CYP, cytochrome P450; P-gp, P-glycoprotein efflux transporter.

corresponding to the 557 to 569 segment of the cytoplasmic tail of GPIb that attenuates receptor signaling.[29] None of these strategies has been evaluated in humans.

GPVI Inhibitors

As a collagen receptor, GPVI plays an important part in the adhesion of platelets at sites of vascular damage. Mice deficient in GPVI exhibit reduced thrombus formation in response to ferric chloride–induced arterial injury, which exposes collagen.[30] In contrast, thrombus formation in response to laser injury, which does not expose collagen, is minimally affected.[30] Strategies to inhibit GPVI include (a) monoclonal antibodies directed against the receptor,[31,32] (b) soluble GPVI or a chimeric molecule consisting of GPVI linked to the Fc domain of human immunoglobulin,[33–35] and (d) EXP3179, a losartan metabolite that blocks collagen-induced platelet aggregation and platelet adhesion at sites of arterial injury.[36] None of these strategies has been evaluated in humans.

GPIa/IIa Inhibitors

Like GPVI, GPIa/IIa also binds collagen, thereby facilitating platelet adhesion.[37] Although platelets from mice deficient in either of the GPIa/IIa subunits exhibit reduced aggregation in response to collagen, the mice have a normal bleeding time and thrombus formation in response to injury is minimally impaired.[38,39] Strategies to inhibit GPIa/IIa include (a) recombinant protein analogues of the collagen-binding site on the receptor[40] and (b) small molecule receptor inhibitors.[41] Neither strategy has been tested in humans.

Collagen Inhibitors

Anopheline antiplatelet protein, a protein isolated from the saliva of the *Anopheles stephensi* mosquito, binds collagen and inhibits its interaction with GPVI and GPIa/IIa.[42] Additional work is needed to determine the therapeutic potential of this protein or the usefulness of similar antiplatelet strategies.

Inhibitors of Intracellular Signaling

An alternative strategy to targeting platelet receptors or their ligands is to block the downstream signaling pathways that trigger platelet activation. Type Ia phosphoinositide 3-kinase (PI3K) is an intracellular signaling molecule whose activation in platelets is linked to GPIIb/IIIa under high shear conditions. TGX-221, an inhibitor of the β isoform of PI3K, decreases shear-dependent platelet adhesion *in vitro* and in animal models of arterial injury.[43–45] TGX-221 has not been tested in humans.

Inhibitors of Platelet Recruitment

Strategies to block platelet recruitment have targeted the thromboxane A_2 receptor, to which thromboxane A_2 and its endoperoxide precursors bind, $P2Y_{12}$, the most important ADP receptor, or PAR-1, the major thrombin receptor on platelets.

Thromboxane A_2 Receptor Antagonists

The thromboxane A_2 receptor is a G-protein–coupled receptor on platelets that is not only activated by thromboxane A_2, but also by its cyclic endoperoxide precursors. Thromboxane A_2 receptor

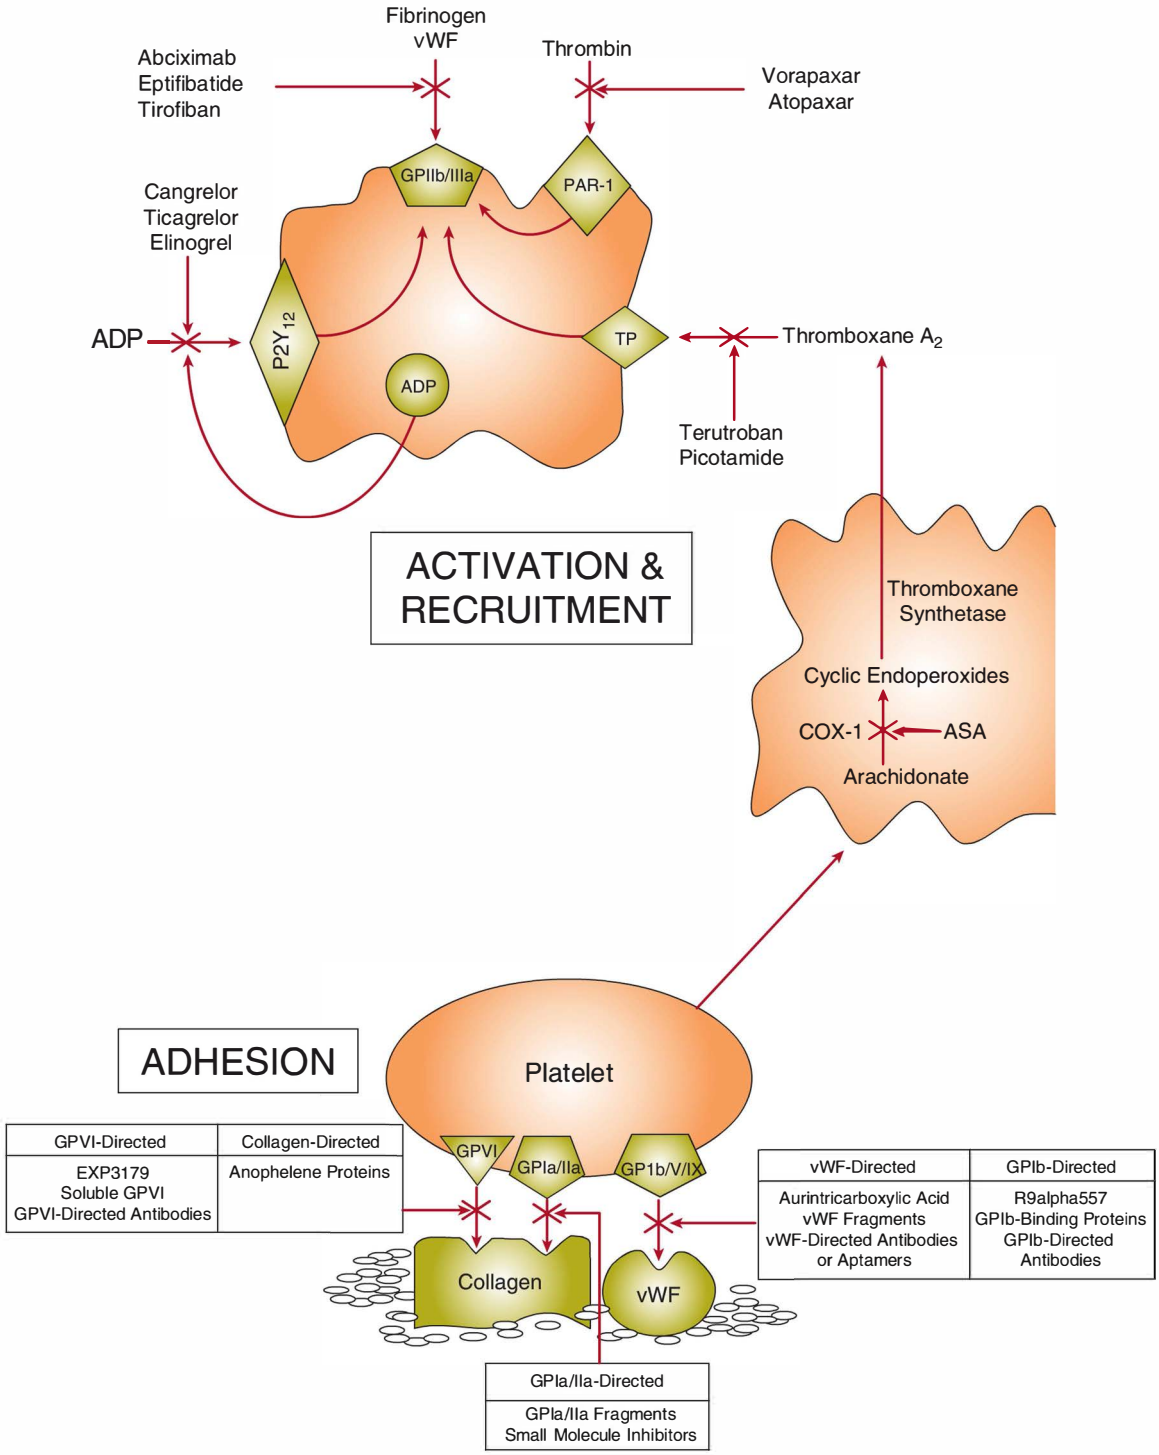

FIGURE 110.2 Sites of action of new antiplatelet drugs. Platelets adhere to subendothelial collagen via glycoprotein (GP) VI and GPIa/IIa, and to von Willebrand factor (vWF) via GPIb/V/IX, respectively (*top panel*). Adherent platelets become activated and release thromboxane A_2 and adenosine diphosphate (ADP), substances that activate adjacent platelets. By irreversibly inhibiting cyclooxygenase-1 (COX-1), aspirin blocks thromboxane A_2 synthesis. Thromboxane A_2 receptor (TP) antagonists attenuate platelet recruitment by preventing thromboxane A_2–mediated platelet activation. ADP induces platelet recruitment by binding to $P2Y_{12}$, the major ADP receptor on platelets, and triggering platelet activation. By binding to $P2Y_{12}$, cangrelor, ticagrelor, and elinogrel block ADP-induced platelet activation. Thrombin, the most potent platelet agonist, binds to, cleaves, and activates protease-activated receptor-1 (PAR-1) on the platelet surface. Vorapaxar and atopaxar inhibit PAR-1 activation, thereby blocking thrombin-induced platelet activation.

antagonists were developed, at least in part, to overcome the variable response to aspirin.[46] Although aspirin blocks thromboxane A_2 synthesis in most individuals, elevated urinary levels of its stable metabolite, thromboxane B_2, have been associated with an increased risk of cardiovascular events.[47,48] Elevated levels of urinary thromboxane B_2 may reflect incomplete blockade of COX-1 in platelets and/or the shuttling of endoperoxide intermediates to platelets from other cells. The thromboxane A_2 receptor antagonists include terutroban and picotamide.

Terutroban

A selective inhibitor of the thromboxane A_2 receptor on platelets, terutroban (previously known as S18886), is orally active.[49] Peak plasma concentrations are achieved within 1 to 2 hours of oral administration, and the drug has a half-life of 6 to 10 hours. Terutroban inhibits thromboxane A_2–induced platelet aggregation in a dose-dependent fashion with maximum inhibition obtained with drug levels above 10 ng/mL—a concentration that can be achieved with daily doses of 10 to 30 mg.[50]

In a phase II study, peripheral arterial disease (PAD) patients were randomized to terutroban, aspirin, or placebo. Terutroban produced dose-dependent inhibition of platelet aggregation in response to thromboxane, ADP, or collagen and was at least as potent as aspirin.[51] The phase III double-blind PERFORM trial compared terutroban (30 mg/day) with aspirin (100 mg/day) for secondary prevention in 19,119 patients with a recent history of ischemic stroke or transient ischemic attacks.[52,53,54] The trial was stopped early because the rate of the primary efficacy endpoint, a composite of fatal or nonfatal ischemic stroke, fatal or nonfatal MI, or other vascular death, was 11% in both groups, and there was a slight increase in the rate of minor bleeding with terutroban compared with aspirin (12% and 11%, respectively).

Picotamide

A derivative of methoxy-isophtalic acid, picotamide not only inhibits the thromboxane A_2 receptor, but also inhibits thromboxane synthetase at equivalent concentrations.[55] In contrast to aspirin, picotamide does not interfere with prostacyclin production. In a double-blind, placebo-controlled study in 2,304 patients with PAD, treatment with picotamide (300 mg bid) or placebo was administered for 18 months.[56] Endpoints of the study included major events (cardiovascular death, MI, stroke, or amputation) and minor events (unstable angina, transient ischemic attacks, hypertension, renal failure, or worsening of PAD symptoms). Although the intention-to-treat analysis revealed an 18.9% reduction in major plus minor events with picotamide, this difference was not statistically significant. However, the on-treatment analysis showed a 22.8% reduction in the same endpoints. Bleeding side effects were similar in the two groups. A *post hoc* subgroup analysis of the data from the 438 diabetic patients included in the study revealed a 45.2% reduction in major and minor endpoints with picotamide compared with placebo.[57] These findings prompted a randomized trial comparing picotamide (600 mg bid) with aspirin (320 mg/day) in 1,209 diabetic patients with PAD.[58] The primary efficacy endpoint was overall mortality, while the secondary endpoint was the composite of death and cardiovascular events. At 2 years, the overall mortality rates with picotamide and aspirin were 3.0% and 5.5%, respectively (relative risk [RR] 0.55, 95% confidence interval [CI] 0.31 to 0.98). Cardiovascular events occurred in 7.1% of patients given picotamide and 8.7% of those treated with aspirin. The difference in the combined endpoint of mortality plus cardiovascular events between the two groups did not reach statistical significance. Bleeding events were infrequent with both picotamide and aspirin (1.3% and 2.0%, respectively). Although these results are promising, additional studies are needed to establish the role of picotamide in diabetics with PAD.

$P2Y_{12}$ Antagonists

ADP receptors on the platelet surface include $P2Y_{12}$, $P2Y_1$, and $P2X_1$. The most important of these is $P2Y_{12}$, which is the target of the thienopyridines: ticlopidine, clopidogrel, and prasugrel. However, $P2Y_1$ also contributes to ADP-induced platelet activation, and maximal ADP-induced platelet activation requires activation of both receptors. The third receptor, $P2X_1$, serves as an adenosine triphosphate (ATP)-gated calcium channel.

Building on the proven benefit of the thienopyridines, $P2Y_{12}$ is the target for several new antiplatelet agents. In contrast to the thienopyridines, these new drugs do not require metabolic activation. Instead, they are active compounds that bind directly and reversibly to $P2Y_{12}$. With no requirement for metabolic activation, the direct $P2Y_{12}$ antagonists have a more rapid onset of action and produce a more potent and predictable level of receptor blockade that is unaffected by the genetic polymorphisms that influence thienopyridine absorption and/or metabolic activation. In addition, because their interaction with $P2Y_{12}$ is reversible, direct $P2Y_{12}$ antagonists have a more rapid offset of action than the thienopyridines, which bind $P2Y_{12}$ in an irreversible fashion. The agents in most advanced stages of development include cangrelor, ticagrelor, and elinogrel (Table 110.2).

Cangrelor

An ATP analogue, cangrelor is a direct competitive inhibitor of $P2Y_{12}$.[58] The drug is only active when administered intravenously, and it produces almost immediate and dose-proportional inhibition of ADP-induced platelet aggregation. Cangrelor is rapidly inactivated by dephosphorylation and has a half-life of 3 to 5 minutes. Upon cessation of therapy, therefore, there is recovery of platelet function within 60 minutes.[58,59]

The interaction of cangrelor with $P2Y_{12}$ prevents the binding of the active metabolites of clopidogrel or prasugrel. This phenomenon complicates the transitioning of patients from cangrelor to clopidogrel or other thienopyridines, which can only exert their inhibitory effects once cangrelor dissociates from $P2Y_{12}$.

Cangrelor has been evaluated in a two-part phase II trial in patients undergoing PCI.[60] For part one, patients were randomized to an 18- to 24-hour infusion of cangrelor or placebo in addition to aspirin plus heparin. In the second part, patients were randomized to intravenous cangrelor or abciximab prior to PCI. In both parts, the primary endpoint, the combination of major and minor bleeding, was not different between cangrelor and the control groups (placebo or abciximab). The 30-day composite of adverse cardiac events (death, MI, or unplanned repeat coronary intervention) was also not significantly different in the two groups.

Building on these phase II data, cangrelor was investigated in two double-blind phase III trials. In the CHAMPION-PCI trial, 8,877 patients scheduled for PCI were randomized to receive intravenous cangrelor (30 μg/kg bolus followed by

Table 110.2

Pharmacologic characteristics of direct-acting reversible $P2Y_{12}$ inhibitors

Characteristic	Cangrelor	Ticagrelor	Elinogrel
Molecular weight	776	523	562
Route of administration	Intravenous	Oral	Intravenous or oral
Site of action	ADP-binding site	Site distinct from ADP-binding site	ADP-binding site
Type of inhibition	Competitive	Noncompetitive	Competitive
Time to peak activity	30 min	2 h	20 min and 12 h for intravenous and oral formulation, respectively
Frequency of oral administration	Inactive orally	Twice daily	Twice daily
Half-life	3–5 min	6–12 h	Not reported
Metabolism	Dephosphorylation	*O*-deethylation and oxidation	None
Elimination	Extrarenal	30% renal; 70% feces	40% renal; 60% feces
Time to recovery of platelet function	60 min	3–5 d	Not reported
Stage of development	Phase III	Completed phase III; approved in United States, Europe and Canada	Phase II

an infusion of 4 μg/kg/min) or placebo starting 30 minutes prior to PCI and continuing for at least 2 hours after completion of the procedure.[61] All patients received aspirin. The primary efficacy endpoint, a composite of all-cause mortality, MI, or ischemia-driven revascularization within 48 hours of PCI, occurred in 7.5% of those randomized to cangrelor and 7.1% of those given placebo (hazard ratio [HR] 1.05, 95% CI 0.88 to 1.24, $P = 0.59$). Rates of major bleeding were similar with cangrelor or clopidogrel (3.6% and 2.9%, respectively; $P = 0.06$), but rates of minor bleeding were higher with cangrelor (17.6% and 15.2%, respectively; $P = 0.003$).

In the CHAMPION PLATFORM trial, 5,362 patients with non–ST-elevation MI or unstable angina with at least one coronary lesion amenable to PCI were randomized to receive cangrelor (in the same regimen used in the CHAMPION-PCI trial) or placebo at the time of PCI.[62] The primary efficacy endpoint, which was the same as that used in CHAMPION-PCI, occurred in 7.0% of those given cangrelor and in 8.0% of patients randomized to placebo (HR 0.87, 95% CI 0.71 to 1.07, $P = 0.17$). Major bleeding was more frequent with cangrelor than with placebo (5.5% and 3.5%, respectively; $P < 0.001$). Based on the negative results of these two trials, more work is needed to determine the role of cangrelor in ACS patients undergoing PCI.

Ticagrelor

An orally active agent belonging to the cyclopentyl-triazolopyrimidine class, ticagrelor acts as a direct inhibitor of $P2Y_{12}$.[63] Ticagrelor binds to the receptor at a location distinct from the ADP-binding site and blocks ADP-mediated receptor activation in a noncompetitive fashion, likely through an allosteric mechanism. Because it does not require metabolic activation, ticagrelor has a rapid onset of action and achieves a level of inhibition of ADP-induced platelet aggregation within 30 minutes that exceeds that obtained with a 300 or 600-mg loading dose of clopidogrel.[64] The peak inhibitory effect of ticagrelor is seen about 2 hours after a loading dose of ticagrelor of 180 mg or a maintenance dose of 90 mg twice daily.

When compared with clopidogrel in 200 aspirin-treated patients with atherosclerosis, ticagrelor, at doses of 100 or 200 mg twice daily, or 400 mg once daily, produced more rapid and more potent inhibition of ADP-induced platelet aggregation.[65] The DISPERSE 2 study compared ticagrelor (90 or 180 mg twice daily) with clopidogrel (75 mg once daily) in 990 patients with non–ST-segment elevation ACS.[66] All patients received aspirin. The primary endpoint, a combination of major and minor bleeding, occurred in 10.2% of patients given either dose of ticagrelor and in 9.2% of those treated with clopidogrel.

In the phase III PLATO trial, ticagrelor (180-mg loading dose followed by 90 mg twice daily) was compared with clopidogrel in 18,624 ACS patients.[67] At 12 months, the primary efficacy endpoint—a composite of cardiovascular death, MI, or stroke—occurred in 9.8% of patients treated with ticagrelor and in 11.7% of those given clopidogrel (HR 0.84, 95% CI 0.77 to 0.92, $P < 0.001$). The rates of the individual efficacy components and of bleeding complications are summarized in Table 110.3.

An invasive strategy was planned for 72% of the 18,624 patients entered in the PLATO trial. In this subset, the primary composite endpoint occurred in 9.0% of patients randomized to ticagrelor and in 10.7% of those given clopidogrel (HR 0.84, 95% CI 0.75 to 0.94, $P = 0.0025$). Rates of major bleeding were similar with ticagrelor and clopidogrel (11.6% and 16.5%, respectively; $P = 0.88$).

PLATO-STEMI focused on the 7,544 patients with ST-elevation MI who were scheduled to undergo primary PCI.[68] Of these, 75% received a stent. In this subset, definite stent thrombosis occurred in 1.6% of patients taking ticagrelor and in 2.4% of those given clopidogrel (HR 0.60, 95% CI 0.45 to 0.95, $P = 0.03$). Other endpoints are summarized in Table 110.3. Outcomes in the 1,899 patients in

Table 110.3

Summary of the results of the PLATO trial comparing ticagrelor with clopidogrel

Endpoint	Ticagrelor (180 mg Then 90 mg Twice Daily)	Clopidogrel (300–600 mg Then 75 mg Daily)	P Value
Primary endpoint (cardiovascular mortality, MI, or stroke)			
PLATO	9.8% (HR 0.84, 95% CI 0.77–0.92)	11.7%	<0.001
PLATO-STEMI	9.4% (HR 0.84, 95% CI 0.75–1.01)	10.8%	0.07
PLATO-CABG	10.6% (HR 0.84, 95% CI 0.60–1.16)	13.1%	0.29
MI

PLATO-STEMI	4.7%	5.8%	0.03
Cardiovascular mortality			
PLATO	4.0%	5.1%	0.001
PLATO-STEMI	4.1%	9.7%	<0.01
PLATO-CABG	4.1%	7.9%	<0.01
All-cause mortality			
PLATO	4.5%	5.9%	<0.001
PLATO-STEMI	5.0%	6.1%	0.05
PLATO-CABG	4.7%	9.7%	<0.01
Stroke			
PLATO	1.5%	1.3%	0.22
PLATO-STEMI			
Major bleeding			
PLATO	11.6%	11.2%	0.43
PLATO-STEMI	9.0%	9.2%	0.76
Major bleeding not associated with CABG			
PLATO	4.5%	3.8%	0.03
Fatal intracranial bleeding			
PLATO	0.1%	0.01%	0.02

Overall, PLATO enrolled 18,625 patients with acute coronary syndromes. PLATO-STEMI included those 7,544 patients with ST-elevation MI who were scheduled to undergo primary PCI. PLATO-CABG included those 1,889 patients who underwent coronary artery bypass graft surgery postrandomization.

the PLATO trial who underwent coronary artery bypass grafting (CABG) surgery postrandomization were reported in PLATO-CABG.[69] The rates of cardiovascular death and of all-cause mortality were reduced with ticagrelor (Table 110.3), but there was no difference in MI or stroke and no reduction in CABG-related bleeding.

Side effects of ticagrelor include dyspnea, which is usually mild and dose related,[70] asymptomatic bradycardia with ventricular pauses,[67] and a modest increase in the levels of uric acid. The mechanisms responsible for these side effects are unclear. One possible explanation relates to the capacity of ticagrelor to inhibit adenosine reuptake by erythrocytes, thereby increasing circulating levels of adenosine. In addition to explaining the dyspnea and the bradycardia, the resultant adenosine-induced vasodilatation and increased myocardial perfusion could also endow ticagrelor with beneficial effects that are independent of $P2Y_{12}$ blockade.

Elinogrel

A reversible $P2Y_{12}$ inhibitor available in both intravenous and oral formulations, elinogrel is a competitive inhibitor of $P2Y_{12}$ that blocks ADP binding to the receptor.[71] Consequently, the drug inhibits platelet aggregation in response to low concentrations of ADP, but its inhibitory effects can be overcome with higher ADP concentrations. This phenomenon may endow elinogrel with a more favorable risk–benefit profile if ADP concentrations are higher with hemostatic plug formation than with intravascular thrombosis.

In the phase II INNOVATE-PCI study, 652 patients scheduled for nonurgent PCI were randomized to clopidogrel (300 to 600 mg load followed by 75 mg daily) or elinogrel (80 mg intravenous bolus followed by oral dosing of 50, 100, or 150 mg twice daily).[72] The Data Safety Monitoring Board recommended discontinuation of the 50 mg oral dose and suggested increasing the intravenous dose to 120 mg. The study was not powered for

efficacy, but patients given elinogrel exhibited greater platelet inhibition than those treated with clopidogrel.

Dyspnea occurred more frequently with elinogrel than with clopidogrel. Abnormal liver function tests also were more common with elinogrel, but the abnormalities appeared to resolve over time, even if the drug was continued.[72,73] The plans for phase III evaluation of elinogrel are not available.

PAR-1 Antagonists

PAR-1 belongs to a family of G-protein–coupled receptors that are activated by proteolytic cleavage.[74] Human platelets express PAR-1 and PAR-4, both of which can be activated by thrombin to induce platelet secretion and aggregation. Although activation of either receptor can cause platelet aggregation independently of the other, PAR-1 and PAR-4 act synergistically to induce platelet activation. However, the affinity of PAR-1 for thrombin is 40-fold higher than that of PAR-4. Consequently, PAR-1 is activated by relatively low concentrations of thrombin, whereas PAR-4 activation requires higher thrombin concentrations. Therefore, PAR-1 is considered to be the major thrombin receptor on human platelets.[74]

PAR-1 also is found on endothelial cells, smooth muscle cells, fibroblasts, and cardiac myocytes.[74] Thrombin-mediated activation of PAR-1 on these cells may contribute to the proliferative and proinflammatory effects of thrombin. Therefore, it is possible that PAR-1 antagonism will not only attenuate arterial thrombosis, but may also modulate other thrombin-mediated processes, including restenosis. Two orally active PAR-1 antagonists are under investigation—vorapaxar and atopaxar (Table 110.4).

Vorapaxar

A synthetic tricyclic 3-phenylpyridine analogue of himbacine, an alkaloid isolated from the bark of Australian magnolia trees that is used in several natural products, vorapaxar is a potent and specific competitive inhibitor of PAR-1.[75] The drug has excellent oral bioavailability and produces dose-dependent inhibition of thrombin- or thrombin receptor agonist peptide (TRAP)-induced platelet aggregation. Vorapaxar does not affect platelet aggregation in response to other agonists nor does it affect thrombin-mediated conversion of fibrinogen to fibrin. Vorapaxar has a half-life of 126 to 269 hours and inhibits TRAP-induced platelet aggregation for up to 4 weeks. Although the binding of vorapaxar to PAR-1 is reversible, dissociation of the drug from the receptor is slow, which may explain the long half-life. Vorapaxar is metabolized by CYP3A4.[74]

Table 110.4

PAR-1 antagonists: comparison of the features of vorapaxar and atopaxar

Feature	Vorapaxar	Atopaxar
Molecular weight	591	608
Onset of action (h)	2	3.5
Half-life (h)	250	23
Route of elimination	Feces	Feces
Metabolism	CYP3A4	CYP3A4
Stage of development	Phase III	Phase II

In phase I studies, vorapaxar did not appear to prolong the bleeding time when administered to healthy volunteers.[76] A phase II study in 1,031 patients scheduled for coronary angiography and possible PCI randomized patients to vorapaxar (at loading doses of 10, 20, or 40 mg) or placebo in a 3:1 ratio.[77] A total of 573 patients underwent PCI, all of whom received aspirin, clopidogrel, and an anticoagulant (either heparin or bivalirudin). Those randomized to vorapaxar received maintenance therapy at doses of 0.5, 1.0, or 2.5 mg once daily for 2 months. The primary outcome, a combination of thrombolysis in myocardial infarction (TIMI) major and minor bleeding, occurred in 3.3% of the patients randomized to placebo and in 2.8% of those given vorapaxar. Although underpowered for efficacy, the composite of death, major adverse coronary events, or stroke occurred in 8.6% of patients randomized to placebo and in 6.2% of those given vorapaxar.

The safety of vorapaxar was also evaluated in two small studies in Japanese patients. In the first, 117 patients undergoing PCI were randomized to vorapaxar for 60 days (either 20 or 40-mg loading dose, followed by 1 or 2.5 mg daily thereafter) or placebo in addition to standard-of-care antithrombotic therapy.[78] No differences were observed in the rate of the primary safety endpoint (TIMI major and minor bleeding), but compared with placebo, vorapaxar reduced the rate of nonfatal MI (42.9% and 16.9%, respectively; $P = 0.013$). In the second study, which included 90 patients with a recent history of ischemic stroke,[79] vorapaxar (1 or 2.5 mg daily) or placebo was administered for 60 days. All patients received aspirin. Event rates were low, and vorapaxar appeared to be safe in this setting.

Building on these phase II results, vorapaxar underwent phase III evaluation in two large clinical trials—TRA-CER[80] and TRA2P-TIMI 50.[81] TRA-CER compared vorapaxar with placebo on top of standard-of-care treatment with aspirin and/or clopidogrel in 12,944 patients with non–ST-elevation ACS. Follow-up in the trial was terminated early because of safety concerns. After a median follow-up of 502 days, the rates of the primary efficacy outcome (a composite of cardiovascular death, MI, stroke, hospitalization for recurrent ischemia, or urgent coronary revascularization) in the vorapaxar and placebo groups were 18.5% and 19.9% (HR 0.92, 95% CI 0.85 to 1.01, $P = 0.07$). The composite of cardiovascular death, MI, or stroke was lower with vorapaxar than with placebo occurred in 14.7% and 16.4%, respectively (HR 0.89, 95% CI 0.81 to 0.98, $P = 0.02$). Rates of moderate and severe bleeding with vorapaxar and placebo were 7.2% and 5.2% (HR 1.35, 95% CI 1.16 to 1.58, $P < 0.001$). There was more intracranial bleeding with vorapaxar than with placebo (1.1% and 0.2%). Thus, addition of vorapaxar to standard therapy did not reduce the composite primary efficacy endpoint but significantly increased the risk of bleeding.

TRA2P-TIMI 50 was a randomized double-blind trial that compared vorapaxar (2.5 mg daily) with placebo on top of standard antiplatelet therapy in 26,449 patients with a history of MI, stroke, or PAD. The primary efficacy endpoint was the composite of cardiovascular death, MI, or stroke. After safety review, vorapaxar was discontinued early in patients with a stroke prior to entry or during the course of the trial because of excess bleeding. At 3 years, the primary efficacy endpoint occurred in 9.3% of patients in the vorapaxar group and in 10.5% of those in the placebo group (HR 0.87, 95% CI 0.80 to 0.94). Moderate or severe bleeding was more frequent in the vorapaxar group (4.2% and 2.5%, respectively) and

there was an increase in intracranial hemorrhage with vorapaxar compared with placebo (1.0% and 0.5%, respectively). Therefore, the role of vorapaxar as add-on therapy is uncertain.

Atopaxar

A reversible PAR-1 antagonist, atopaxar is a small molecule that binds PAR-1 with high affinity and blocks thrombin and TRAP-induced platelet aggregation.[74] Because atopaxar inhibits TRAP binding to PAR-1, it is likely that the drug interacts with PAR-1 at or near the tethered ligand-binding site. Atopaxar exhibits good oral bioavailability and is rapidly absorbed. Maximal platelet inhibition is achieved within 3 to 5 hours of dosing and the half-life is about 23 hours. Like vorapaxar, atopaxar does not appear to prolong the bleeding time when administered to healthy volunteers.[74]

In the first of the phase II J-LANCELOT trials, 241 patients with ACS were given atopaxar (loading dose of 400 mg followed by either placebo or atopaxar 50, 100, or 200 mg daily thereafter) for 12 weeks.[82] Over 95% of the patients were also taking aspirin and clopidogrel. In the second trial, 263 patients with coronary artery disease were randomized to placebo or the same doses of atopaxar for 24 weeks.[75] All patients were taking aspirin, and about 40% were also receiving clopidogrel. The primary endpoint in these studies was bleeding events. There was a trend toward more bleeding with increasing doses of atopaxar. The combination of major plus minor bleeding and minimal bleeding requiring medical attention was similar with placebo and atopaxar (6.6% and 5.0%, respectively, in the first study and 1.5% in both groups in the second study). The studies were underpowered for efficacy, but at trough levels, atopaxar produced a mean of over 90% inhibition of TRAP-induced platelet aggregation with the 100 or 200 mg doses and 20% to 60% inhibition with the 50 mg dose.[75]

The clinical development plan for atopaxar is uncertain. Increased transaminase levels were noted in up to 15% of patients receiving atopaxar.[82] It is currently unclear whether these abnormalities are drug related. In addition, prolongation of the QTc interval was seen with higher doses of atopaxar.[82] More studies are needed to determine the clinical significance of these findings.

Inhibitors of Platelet Aggregation

Because the final common pathway of platelet aggregation in response to all agonists involves conformational activation of GPIIb/IIIa, considerable attention focused on development of GPIIb/IIIa antagonists.[83,84] Three parenteral agents, abciximab, eptifibatide, and tirofiban, are of proven efficacy in patients undergoing PCI and in some patients with ACS with maximum benefit seen in those with high-risk features (e.g., elevated troponin levels or diabetes mellitus) and those managed with PCI.[85] However, the use of these parenteral agents has declined with the introduction of more potent oral antiplatelet agents.

Although oral GPIIb/IIIa inhibitors, such as xemilofiban, orbofiban, and sibrafiban, were developed, these agents were associated with an excess of major bleeding in phase III trials, and they produced no significant clinical benefit, even in high-risk patients. Furthermore, a meta-analysis of four trials found an increase in all-cause mortality with their use.[86] Potential mechanisms to explain these findings include suboptimal inhibition of platelet aggregation, partial platelet agonist activity at trough concentrations, lack of responsiveness in patients with certain genetic polymorphisms, and enhancement of cardiac myocyte apoptosis.[87] Based on these disappointing results, further development of this class of drugs has stopped.

NEW ANTICOAGULANTS

Anticoagulants can inhibit the initiation or propagation of coagulation, or by targeting thrombin, they can attenuate fibrin formation (FIGURE 110.3). Drugs that target the tissue factor/factor VIIa complex block the initiation of coagulation, while those that inhibit factor IXa or factor Xa, or their cofactors, factors VIIIa and Va, block the propagation of coagulation. New anticoagulants can be further subclassified as direct or indirect inhibitors. Direct inhibitors bind directly to the target enzyme and block substrate interactions. In contrast, indirect inhibitors exert their anticoagulant effects by binding to naturally occurring plasma cofactors, such as antithrombin or heparin cofactor II, thereby accelerating their interaction with clotting enzymes.

Inhibitors of Initiation of Coagulation

Drugs that target the factor VIIa/tissue factor complex inhibit the initiation of coagulation. Only parenteral agents in this category have reached phase II or III clinical testing. These include

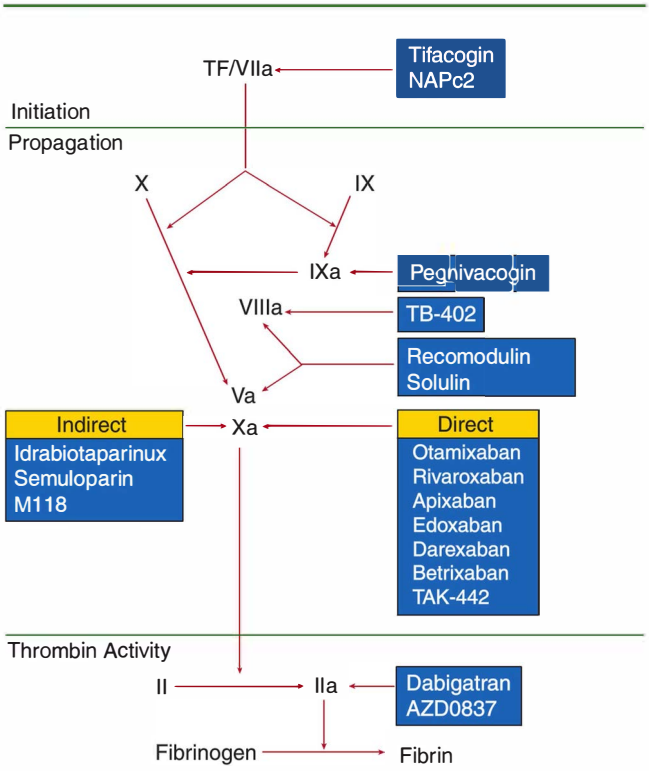

FIGURE 110.3 Targets of the new anticoagulants. Coagulation is initiated by the tissue factor/factor VIIa (TF/VIIa) complex, which activates factors IX and X (IX and X, respectively). The process is propagated by activated factors IX and X (IXa and Xa, respectively) which, together with their cofactors, activated factors VIIIa and Va (VIIIa and Va, respectively), assemble on the surface of activated platelets to form intrinsic tenase and prothrombinase, respectively. Intrinsic tenase activates factor X, whereas prothrombinase converts prothrombin (II) to thrombin (IIa). In the final step, IIa converts fibrinogen to fibrin. The targets for the new anticoagulants are indicated by the *arrows*.

tifacogin, which is a recombinant form of tissue factory pathway inhibitor, recombinant nematode anticoagulant peptide (NAPc2), and active site–inhibited factor VIIa (factor VIIai).

Tifacogin

A recombinant form of tissue factory pathway inhibitor expressed in *Saccharomyces cerevisiae*, tifacogin has been evaluated in patients with sepsis. The drug has a half-life of minutes, which necessitates intravenous infusion, and is cleared by the liver. In a phase II trial,[88] 210 sepsis patients were randomized to receive tifacogin (25 or 50 mg/kg/h) or placebo for 4 days. Tifacogin produced a 20% relative reduction in 28-day mortality. Major bleeding occurred in 9% of patients treated with tifacogin and in 6% of those given placebo, a difference that was not statistically significant. In a phase III trial that compared tifacogin with placebo in 1,754 severe sepsis patients,[89] 28-day mortality was similar with tifacogin and placebo (34.2% and 33.9%, respectively), while the rate of bleeding was significantly higher with tifacogin (6.5% and 4.8%, respectively). A *post hoc* subgroup analysis suggested a benefit of tifacogin in the 780 patients with severe community-acquired pneumonia; in this subset, 28-day mortality was 28% and 33% with tifacogin and placebo, respectively.[90] Differences in mortality were greater in patients with more severe disease who did not receive adjunctive heparin. Based on this analysis, a phase III double-blind trial compared two doses of tifacogin with placebo in about 2,100 patients with severe community-acquired pneumonia (www.clinicaltrials.gov NCT00084071). Although enrollment was completed in 2008, the results of this trial have not been reported.

NAPc2

An 85–amino acid polypeptide originally isolated from the canine hookworm, *Ancylostoma caninum*,[91] recombinant NAPc2 is expressed in yeast. NAPc2 binds to a noncatalytic site on factor X or factor Xa.[92] Once bound to factor Xa, the NAPc2/factor Xa complex inhibits tissue factor–bound factor VIIa. Because it binds factor X with high affinity, NAPc2 has a half-life of approximately 50 hours after subcutaneous injection.[93] Consequently, the drug can be given on alternate days.

Initial clinical trials with NAPc2 focused on venous thromboprophylaxis. In a phase II dose-finding study,[94] 293 patients undergoing elective knee arthroplasty were given subcutaneous NAPc2 on the day of surgery and every 2nd day thereafter to a maximum of four doses. The best results were observed with an NAPc2 dose of 3.0 μg/kg administered 1 hour after surgery. With this dose, the rate of venographically detected DVT in the operated leg was 12%, while the rate of proximal DVT was 1%. Major bleeding occurred in 2% of patients. Compared with historical controls, NAPc2 appears to have efficacy and safety similar to those of low molecular weight heparin (LMWH). However, prospective randomized trials are needed to confirm these findings.

In the next series of phase II studies, NAPc2 was evaluated in patients with ACS and in those undergoing elective PCI. Addition of NAPc2 to usual antithrombotic therapy reduced levels of prothrombin fragment 1.2 (F1.2) in a dose-dependent fashion without increasing the risk of bleeding.[95,96] Despite these promising results, the disease focus then shifted from thrombosis to cancer. A phase II study examining the feasibility of twice-weekly subcutaneous NAPc2 as an adjunct to chemotherapy in patients with metastatic colon cancer was suspended (www.clinicaltrials.gov: NCT0043573), but the results have not been reported and development of NAPc2 has stopped.

Factor VIIai

With its active site irreversibly inhibited, factor VIIai competes with factor VIIa for tissue factor binding, thereby attenuating the initiation of coagulation. Based on promising results in animal models of thrombosis,[97,98] factor VIIai, given in doses of 50 to 400 mg/kg with or without adjunctive heparin, was compared with heparin alone in 491 patients undergoing elective PCI.[99] Factor VIIai produced no significant reduction in the primary endpoint, a composite of death, MI, need for urgent revascularization, abrupt vessel closure, or bailout use of GPIIb/IIIa antagonists. Because of these disappointing results, factor VIIai has not been developed further.

Inhibitors of Propagation of Coagulation

Factor IXa Inhibitors

Both parenteral and oral factor IXa inhibitors have been developed (Table 110.5). The parenteral agents include factor IX–directed monoclonal antibodies and pegnivacogin, a factor IXa–directed aptamer. Development of TTP889, the only oral factor IXa inhibitor, has been halted.

Factor IX–directed antibodies. Several monoclonal antibodies directed against various factor IX epitopes have been developed. Of these, SB 249417, a humanized mouse monoclonal antibody directed against the Gla-domain of factor IX, has undergone the most extensive investigation. The antibody exhibited antithrombotic activity comparable to that of enoxaparin in a rat arterial thrombosis model but produced less prolongation of the activated partial thromboplastin time (aPTT).[100] In a rat model of thromboembolic stroke, the antibody reduced infarct volumes and neurologic deficits to a greater extent than tissue-type plasminogen activator.[101]

SB249417 has undergone limited evaluation in humans. In a phase I study in 26 human volunteers, a 50-minute infusion of antibody prolonged the aPTT in a dose-dependent fashion.[102] Although these early results were promising, development of the antibody was stopped.

Pegnivacogin. A specific factor IXa–directed RNA aptamer, pegnivacogin, which was previously known as RB006, was isolated from a library of 104 nucleic acid species.[103] Pegnivacogin binds to both factor IX and factor IXa with high affinity and not only inhibits factor IXa activity, but also blocks the activation of factor IX by the factor VIIa–tissue factor complex, but not by factor XIa. As such, pegnivacogin prolongs the aPTT in a dose-dependent fashion, but has no effect on the prothrombin time. A unique feature of pegnivacogin is that its anticoagulant activity can be rapidly reversed with a complementary aptamer, anivamersen (previously known as RB007). Anivamersen exerts its inhibitory effect by binding to pegnivacogin and releasing it from factor IX or factor IXa.

In a phase I study, pegnivacogin and anivamersen were evaluated in 85 healthy volunteers.[104] At doses of 30 to 60 mg, pegnivacogin produced dose-dependent prolongation of the aPTT and activated clotting time; both tests were rapidly restored to baseline levels with intravenous anivamersen.

Two early phase II studies evaluated the safety and tolerability of pegnivacogin and anivamersen in patients with coronary artery disease.[105,106] In the first, 50 patients taking aspirin

Phase III studies with semuloparin for VTE prophylaxis

Study	n	Comparator (Dose and Interval)	Prophylaxis (Days)	Total VTE or All-Cause Death Semuloparin vs. Comparator OR (95% CI)	Clinically Relevant Bleeding[a] Semuloparin vs. Comparator OR (95% CI)
SAVE-KNEE	1,150	Enoxaparin (30 mg bid)	7–10	24.5% vs. 28.1%	2.6% vs. 1.8%
				0.83 (0.60–1.14)	1.50 (0.67–3.49)
SAVE-HIP1	2,326	Enoxaparin (40 mg od)	7–10	6.3% vs. 11.1%	1% vs. 2.2%
				0.54 (0.38–0.76)	0.48 (0.23–0.94)
SAVE-HIP2	1,003	Enoxaparin (40 mg od)	7–10	17.7% vs. 22%	2% vs. 0.8%
				0.77 (0.53–1.12)	2.59 (0.83–9.57)
Meta-analysis	4,479	Enoxaparin	7–10	13.4% vs. 17.6%	1.7% vs. 1.8%
				0.70 (0.58–0.85)	0.95 (0.60–1.50)
SAVE-HIP3	509	Placebo	19–23	3.9% vs. 18.6%	0.6% vs. 0%
				0.18 (0.07–0.45)	NA
SAVE-ABDO	4,414	Enoxaparin (40 mg od)	7–10	6.3% vs. 5.5%	1.2% vs. 1.2%
				1.16 (0.84–1.59)	NA
SAVE-ONCO	3,212	Placebo	Variable, at least 90	1.2% vs. 3.4%	2.8% vs. 2.0%
				0.36 (0.21–0.60)	NA

SAVE-KNEE, elective knee replacement surgery; SAVE-HIP1, total hip replacement surgery; SAVE-HIP2, hip fracture surgery; meta-analysis, meta-analysis of three studies (SAVE-KNEE, SAVE-HIP1, and SAVE-HIP-2); SAVE-HIP3, hip fracture surgery (extended prophylaxis); SAVE-ABDO, major abdominal surgery; SAVE-ONCO, medical patients undergoing chemotherapy; bid, twice daily; od, once daily; VTE, venous thromboembolism; OR, odds ratio; CI, confidence interval; NA, not available.
[a]Clinically relevant bleeding is major bleeding plus clinically relevant nonmajor bleeding.

and/or clopidogrel received an intravenous bolus of pegnivacogin at doses of 15, 30, 50, or 75 mg. Subsequent administration of anivamersen (30, 60, 100, or 150 mg) rapidly restored the aPTT to baseline levels.[105] In the second study, 24 patients undergoing nonurgent PCI were randomized in a 5:1 ratio to receive pegnivacogin or heparin with immediate or delayed reversal of pegnivacogin after the procedure.[106] All procedures were successful, and both reversal strategies enabled successful sheath removal.

In the phase II RADAR study, 640 ACS patients were randomly allocated to receive open-label pegnivacogin or heparin in a 4:1 ratio prior to cardiac catheterization. Patients given pegnivacogin then received various doses of anivamersen at the end of the procedure. Doses of anivamersen that produced at least 50% reversal were associated with rates of major plus minor bleeding similar or lower than that with heparin. The plans for phase III investigation of pegnivacogin have not yet been disclosed.

TTP889. An orally active partial inhibitor of factor IXa, TTP889 exhibited antithrombotic activity in rat and porcine arteriovenous shunt models. A small phase I study showed a predictable pharmacokinetic profile after single- or multiple-dose administration and a half-life of about 20 hours. In a phase II study, 261 patients undergoing surgery for hip fracture were given conventional anticoagulant prophylaxis for 1 week and were then randomized to receive once-daily oral TTP889 (300 mg) or placebo for 3 weeks at which point bilateral venography was performed.[107] The primary efficacy outcome was VTE, which occurred in 32.1% of patients randomized to TTP889 and in 28.2% of those given placebo ($P = 0.58$). There were no major bleeding events and only two clinically relevant nonmajor bleeds with TTP889. Because of the negative results, development of TTP889 was halted.

Factor Xa Inhibitors

New factor Xa inhibitors include agents that block factor Xa indirectly or directly (FIGURE 110.4). Indirect inhibitors are given parenterally and act by catalyzing factor Xa inhibition by antithrombin. In contrast, direct factor Xa inhibitors bind directly to the active site of factor Xa, thereby blocking its interaction with its substrates. New direct factor Xa inhibitors include otamixaban, which is given intravenously, and a number of orally active drugs. Unlike the heparin/antithrombin complex, which has limited capacity to inhibit factor Xa incorporated into the prothrombinase complex,[108,109] direct factor Xa inhibitors inhibit both free and platelet-bound factor Xa.[110,111] This property may endow these agents with an advantage over indirect factor Xa inhibitors.

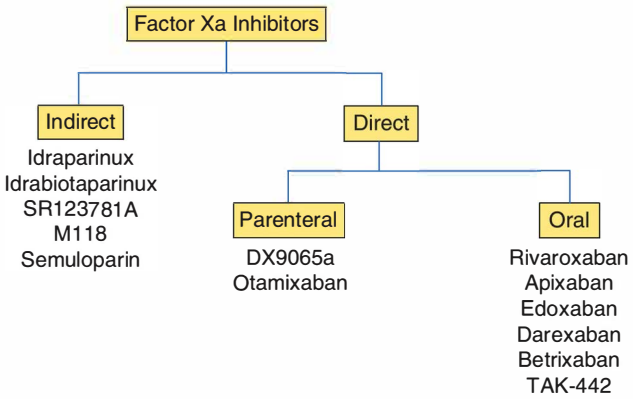

FIGURE 110.4 Classification of the new factor Xa inhibitors. The new factor Xa inhibitors exert their anticoagulant activity indirectly or directly. Indirect inhibitors bind to antithrombin and accelerate the rate at which it inhibits factor Xa. In contrast, direct factor Xa inhibitors, which include parenteral and oral agents, bind directly to factor Xa and prevent it from activating prothrombin.

Indirect Factor Xa Inhibitors

The prototype for most of the new indirect factor Xa inhibitors is fondaparinux, a first-generation synthetic analog of the antithrombin-binding pentasaccharide found in heparin or LMWH. Three of the newer indirect factor Xa inhibitors, idraparinux, idrabiotaparinux, and SR123781A, are second- and third-generation variants of fondaparinux, whereas M118 and semuloparin are LMWH derivatives.

Idraparinux. A hypermethylated derivative of fondaparinux, idraparinux binds antithrombin with such high affinity that its plasma half-life of 80 hours is similar to that of antithrombin.[112] Because of its long half-life, idraparinux can be given subcutaneously on a once-weekly basis. In a phase II dose-finding trial, idraparinux was compared with warfarin in 659 patients with proximal DVT.[113] Patients given the lowest dose of idraparinux, 2.5 mg, had less bleeding than those randomized to warfarin ($P = 0.029$), and this dose was chosen for further trials.

The phase III van Gogh DVT and PE trials[114] randomized 2,904 patients with acute symptomatic DVT and 2,215 patients with PE to either a 3- or 6-month course of once-weekly subcutaneous idraparinux or to conventional therapy with LMWH or heparin followed by a VKA with the dose adjusted to achieve an international normalized ratio (INR) of 2 to 3. In the DVT patients, the rate of recurrent VTE at 3 months was similar in the idraparinux and conventionally treated groups (2.9% and 3.0%, respectively). Clinically relevant bleeds were less common with idraparinux than with conventional treatment (4.5% and 7.0%, respectively; $P = 0.004$). In the PE patients, idraparinux was less effective than conventional therapy at 3 months, with recurrent VTE occurring in 3.4% and 1.6%, respectively. Clinically relevant bleeding events occurred in 5.8% and 8.2%, respectively. Based on the results of these trials, idraparinux appeared to have an acceptable safety profile compared with warfarin. The discordant efficacy results in the DVT and PE trials highlight the importance of adequate levels of anticoagulation for initial PE treatment because the majority of the recurrences occurred early.

The efficacy of long-term idraparinux was evaluated in the van Gogh extension study.[115] In this trial, 1,215 patients who had completed 6 months of initial treatment of DVT or PE with either idraparinux or a VKA were randomized to an additional 6 months of treatment with either once-weekly subcutaneous idraparinux or with placebo. Compared with placebo, idraparinux produced a 72.9% relative reduction in the risk of recurrent VTE ($P = 0.002$). Major bleeding occurred in 3.7% of those given idraparinux, including three fatal intracranial bleeds versus no major bleeds in the placebo group.

In the phase III AMADEUS trial, idraparinux (2.5 mg once weekly) was compared with warfarin (dose-adjusted to achieve an INR of 2 to 3) for stroke prevention in patients with atrial fibrillation.[116] Although the plan was to randomize 5,940 such patients to treatment for 18 months, the trial was stopped after randomization of only 4,576 patients and a mean follow-up of 10.7 months because of an excess of clinically relevant bleeding with idraparinux (19.7 and 11.3/100 patient years, respectively; $P < 0.0001$), including an excess of intracranial bleeding with idraparinux compared with warfarin (1.1 and 0.4/100 patient years, respectively; $P = 0.014$). There were 18 cases of thromboembolism with idraparinux and 27 cases with warfarin (0.9 and 1.3/100 patient years, respectively; HR 0.71, 95% CI 0.39 to 1.30), a result that met the prespecified noninferiority criterion (noninferiority $P = 0.007$).

The results of these studies suggested that although idraparinux was effective, it caused excessive bleeding. Consequently, the development of idraparinux was halted and attention shifted to idrabiotaparinux.

Idrabiotaparinux. A biotinylated form of idraparinux previously known as SSR126517E, idrabiotaparinux exhibits the same pharmacokinetic and pharmacodynamic profile as idraparinux. Like idraparinux, idrabiotaparinux is given subcutaneously on a once-weekly basis. The only difference between the drugs is that the anticoagulant activity of idrabiotaparinux can be neutralized by intravenous administration of avidin. A protein derived from egg white, avidin binds the biotin moiety of idrabiotaparinux with high affinity, thereby forming a 1:1 stoichiometric complex that is rapidly cleared by the kidneys.

In the phase III EQUINOX trial, 757 patients with DVT were randomized to receive equimolar doses of once-weekly subcutaneous idrabiotaparinux or idraparinux (3 and 2.5 mg, respectively) for 6 months.[117] Recurrent VTE occurred in 2.3% and 3.2% of patients given idrabiotaparinux and idraparinux, respectively, while clinically relevant bleeding occurred in 5.2% and 7.3%, respectively ($P = 0.29$). Both agents inhibited factor Xa to a similar extent. Reversibility of idrabiotaparinux was demonstrated in a study in 41 healthy males[118] and in 55 patients with DVT at the end of their planned treatment in the EQUINOX trial. Avidin was well tolerated and reduced the anti-Xa activity by 66% to 97%.

The phase III CASSIOPEA trial compared 3 or 6 months of subcutaneous idrabiotaparinux (3 mg once weekly) with conventional anticoagulant therapy for prevention of recurrent VTE in 3,200 patients with acute PE. At 3 months, the rates of recurrent VTE with idrabiotaparinux and warfarin were 2.1% and 2.7%, respectively, and there was less clinically relevant bleeding with idrabiotaparinux than with warfarin (4.5% and 6.6%, respectively; $P < 0.001$).

The phase III BOREALIS-AF trial, which compared idrabiotaparinux with warfarin for stroke prevention in patients with atrial fibrillation, was stopped early, but the results are not available. With only the EQUINOX and CASSIOPEA trial results to support its use, it is likely that the role of idrabiotaparinux will be limited.

SR123781A. A synthetic hexadecasaccharide, SR123781A is composed of the antithrombin-binding synthetic pentasaccharide plus a thrombin-binding sulfated tetrasaccharide joined together by a central nonsulfated heptasaccharide. SR123781A binds antithrombin with high affinity.[119] In addition to catalyzing factor Xa inhibition by antithrombin, SR123781A is long enough to bridge antithrombin to thrombin, thereby enhancing thrombin inhibition. Like heparin, therefore, SR123781A catalyzes the inhibition of both factor Xa and thrombin.[119] Unlike heparin, however, SR123781A does not bind platelet factor 4 (PF4) or fibrin.[120,121]

SR123781A exhibits almost complete bioavailability after subcutaneous administration and produces a dose proportional increase in anti–factor Xa activity and the aPTT. The drug is cleared by the kidneys.

Subcutaneous SR123781A, at doses of 0.25 to 4 mg once daily, was compared with enoxaparin (40 mg once daily) in 1,023 patients undergoing elective hip arthroplasty.[122] SR123781A reduced the rate of VTE dose dependently, and the rates of VTE with the 2.0 and 4.0 mg doses (7.0% and 4.4%, respectively) were similar to that with enoxaparin (8.7%). Major bleeding occurred in 0.6% and 5.8% of patients given the 2.0 and 4.0 mg doses of SR123781A, respectively, and in 0.6% of those given enoxaparin. A phase II study comparing two different doses of SR123781A with heparin plus a GPIIb/IIIa antagonist in 180 patients with ACS undergoing PCI has been completed, but the results have not been reported.

M118. Obtained by depolymerization of heparin, M118 is a novel LMWH that has a mean molecular weight of 6,500 and an anti–factor Xa to antifactor IIa ratio of 4:1.[123] The drug has a subcutaneous bioavailability of about 70% and a half-life of about 1 hour after intravenous administration and 2 to 3 hours after subcutaneous delivery. The anticoagulant activity is reversed with protamine sulfate and can be monitored using the aPTT.

In the phase II EMINENCE study, 503 patients undergoing PCI were randomized to receive either intravenous M118 or 70 U/kg of heparin.[124] The primary endpoint (a composite of death, MI, stroke, thrombocytopenia, catheter thrombus, bailout use of a GPIIb/IIIa antagonist, or any bleeding up to 20 days) occurred in 31.1% of patients given heparin and in 22.7%, 28.3%, and 30.1% of those randomized to 50, 75, or 110 U/kg of M118, respectively. The rates of adverse events were similar across all study groups.[124] These early results require further confirmation.

Semuloparin. An ultra-LMWH, semuloparin is synthesized from heparin by selective and controlled depolymerization. With a mean molecular weight of 2,000 to 3,000, most of the semuloparin molecules are too short to bridge antithrombin to thrombin. Consequently, semuloparin has high anti–factor Xa activity and minimal activity against thrombin. The drug is administered subcutaneously and exhibits 98% bioavailability. Peak plasma levels are achieved 3 hours after subcutaneous injection and the half-life is 16 to 20 hours, which enables once-daily administration. Excretion of the drug is primarily via the kidneys.

In phase III trials, semuloparin has been evaluated for postoperative thromboprophylaxis after hip or knee arthroplasty or after surgery for hip fracture and for VTE prevention after major abdominal surgery (Table 110.5). Enoxaparin was the comparator in all of these studies. The primary efficacy endpoint in these studies was the composite of VTE and all-cause mortality. Semuloparin also has been compared with placebo for VTE prevention in patients receiving chemotherapy for treatment of cancer. A trial comparing semuloparin with enoxaparin for thromboprophylaxis in hospitalized, medically ill patients was stopped early because of a change in priorities (www.clinicaltrials.gov: NCT00714597).

A meta-analysis of the results of the SAVE-HIP1, SAVE-HIP2 and SAVE-KNEE trials demonstrated an almost one-third reduction in VTE and all-cause mortality with semuloparin compared with enoxaparin (OR 0.70, 95% CI 0.58 to 0.85, $P = 0.0003$); rates of major or clinically relevant nonmajor bleeding were 1.7% and 1.8%, respectively (OR 0.95, 95% CI 0.60 to 1.50).[125] In the SAVE-HIP3 trial, 509 patients undergoing surgery for hip fracture received semuloparin for 7 to 10 days and 469 patients were then randomized in a 2:1 fashion to either continued semuloparin or to placebo for an additional 19 to 23 days.[126] In 332 patients with evaluable venograms, the primary efficacy endpoint occurred in 3.9% of those randomized to extended semuloparin and in 18.6% of those given placebo (OR 0.18, 95% CI 0.07 to 0.45, $P < 0.001$). The rates of major bleeding and clinically relevant nonmajor bleeding with semuloparin in this trial were both 0.3%; there were no bleeding events with placebo.

In the SAVE-ABDO trial, semuloparin (20 mg once daily started 8 hours after surgery) was compared with enoxaparin (40 mg once daily started 12 to 24 hours after surgery) in 4,413 patients undergoing major abdominal surgery.[127] Both treatments were administered for 7 to 10 days. Though it was originally conceived as a superiority trial, there was revision to a noninferiority design after an interim analysis. In the 3,030 patients with evaluable venograms, the primary efficacy endpoint occurred in 6.3% of those randomized to semuloparin and in 5.5% of those given enoxaparin (OR 1.16, 95% CI 0.84 to 1.59), a difference that failed to meet the prespecified noninferiority margin of 1.25. The rates of major VTE (proximal DVT or PE) or all-cause mortality were 2.2% and 2.3%, respectively. Major bleeding occurred in 2.9% and 4.5%, respectively, while the rates of clinically relevant nonmajor bleeding were 1.2% in both groups.

The SAVE-ONCO trial compared semuloparin (20 mg once daily) with placebo in over 3,000 patients with cancer who were receiving chemotherapy (www.clinicaltrials.gov: NCT00694382). Semuloparin reduced the risk of symptomatic VTE or VTE-related death by 64% (from 3.4% to 1.2%, respectively) without producing a significant increase in bleeding (1.1% and 1.2%, respectively).

Overall, the results with semuloparin have been positive, but the need for a new injectable anticoagulant in the orthopedic setting is limited given the availability of the new oral anticoagulants. Although the SAVE-ONCO trial findings are interesting, the disappointing results of the SAVE-ABDO trial suggest that the 20 mg once-daily dose of semuloparin is not appropriate for all thromboprophylactic indications.

Direct Factor Xa Inhibitors

Direct factor Xa inhibitors include parenteral agents, such as DX-9065a and otamixaban, as well as several orally active drugs (FIGURE 110.4). All of the direct factor Xa inhibitors are small molecules that reversibly block the active site of factor

Xa. The large number of oral factor Xa inhibitors highlights the continued focus on development of oral anticoagulants that can replace VKA, such as warfarin.

DX-9065a. A synthetic nonpeptidic direct factor Xa inhibitor, DX-9065a is administered parentally, has a dose-dependent half-life of 40 minutes to 5 hours, and is cleared by the kidneys.[128–130] DX-9065a was evaluated in patients with non–ST-elevation ACS and in patients undergoing PCI. In the ACS trial, 402 patients were randomized to weight-adjusted heparin or to low- or high-dose DX-9065a.[131] The primary efficacy endpoint, a composite of death, MI, urgent revascularization, or ischemia, occurred in 33.6%, 34.3%, and 31.3% of patients, respectively. Major bleeding occurred in 3.3% of those randomized to heparin and in <1% of those who received DX-9065a. In the PCI trial, 175 patients were randomized to open-label DX-9065a or to heparin in one of four sequential phases.[132] Although thrombotic events were rare in all phases of the study, enrolment in the phase evaluating the lowest dose of DX-9065 was stopped because of catheter thrombosis. Major bleeding events were uncommon, and there was no apparent dose response. Although promising, DX-9065a has not undergone further clinical evaluation.

Otamixaban. A parenteral direct factor Xa inhibitor, otamixaban has a rapid onset of action, produces a predictable anticoagulant effect, has a short half-life, and <25% of the drug is cleared by the kidneys.[133,134] These features render otamixaban as a potential candidate to replace heparin in patients with ACS and those undergoing PCI. This possibility was evaluated in two phase II dose-finding trials.

The SEPIA-PCI trial compared five different doses of otamixaban with heparin in 947 patients undergoing nonurgent PCI.[135] The primary outcomes were change in blood levels of F1.2 and anti–factor Xa activity. The highest dose of otamixaban produced greater suppression of F1.2 than heparin. Otamixaban increased bleeding in a dose-dependent fashion, and there was more bleeding with the two highest otamixaban doses than with heparin. Rates of ischemic events were similar across treatment groups.

The SEPIA-ACS-1-TIMI 42 trial compared five different doses of otamixaban with the combination of heparin plus eptifibatide for the prevention of major cardiovascular events in 3,241 patients with non–ST-elevation ACS.[136] All patients received aspirin and clopidogrel and 62.7% underwent PCI. Although the rates of the primary efficacy outcome, a composite of death, MI, urgent revascularization, or bailout GPIIb/IIIa antagonist use at 7 days, were not significantly different across the five doses of otamixaban or compared with heparin plus eptifibatide, rates were numerically lowest with the two intermediate doses of otamixaban. The rates of thrombotic complications were numerically higher with all doses of otamixaban than with heparin plus eptifibatide. Otamixaban was associated with a significant dose-dependent increase in the primary safety outcome, TIMI major or minor bleeding, but bleeding rates with intermediate doses of otamixaban were similar to those with heparin plus eptifibatide. On the basis of these results, a phase III trial of the same design has been initiated (www.clinicaltrials.gov: NCT01076764).

Apixaban. An oral direct factor Xa inhibitor, apixaban is an active drug with an oral bioavailability of about 50%. Apixaban inhibits both free and clot-associated factor Xa activity.[137] In healthy males, levels of apixaban in plasma peak about 3 hours after oral administration, and the drug is cleared with a terminal plasma half-life of 8 to 14 hours.[138] Apixaban is eliminated via multiple pathways, including oxidative metabolism, renal, and intestinal routes. Potent inhibitors of CYP3A4, such as ketoconazole or ritonavir, are contraindicated because they increase plasma drug concentrations.

Prevention of VTE. Apixaban has been evaluated in three phase III randomized controlled trials—two in patients undergoing knee arthroplasty (n = 6,252) and one in patients undergoing hip arthroplasty (n = 5,407). All three trials used the same apixaban dose regimen of 2.5 mg twice daily starting 12 to 24 hours after surgery, which was administered for 10 to 14 days in patients undergoing knee arthroplasty and for 35 days in those undergoing hip arthroplasty. The primary efficacy endpoint in all of the trials was total VTE and all-cause mortality. In the ADVANCE-1 trial, apixaban was similarly effective to enoxaparin 30 mg twice daily (9.0% and 8.8%, respectively; RR 1.02, 95% CI 0.78 to 1.32) in patients undergoing knee arthroplasty, although the prespecified statistical criteria for noninferiority were not met.[139] In the ADVANCE-2 trial, apixaban was superior to enoxaparin 40 mg once daily (15.1% and 24.4%, respectively; RR 0.62, 95% CI 0.51 to 0.78, $P < 0.0001$).[140] Patients undergoing hip arthroplasty were randomized to apixaban or enoxaparin (40 mg once daily) in the ADVANCE-3 trial,[141] where apixaban was superior to enoxaparin (1.4% and 3.9%, respectively; RR 0.36, 95% CI 0.22 to 0.54, $P < 0.001$). Rates of major or clinically relevant nonmajor bleeding were numerically lower with apixaban than with enoxaparin in all three trials, but the differences only reached statistical significance in the ADVANCE-1 trial.

Apixaban was evaluated for thromboprophylaxis in 6,528 medically ill patients in the ADOPT trial,[142] which compared a 30-day regimen of apixaban (2.5 mg twice daily) with enoxaparin (40 mg once daily, given for 6 to 14 days). At 30 days, the primary efficacy outcome (a composite of symptomatic VTE, asymptomatic proximal DVT detected by routine ultrasonography, or VTE-related mortality) occurred in 2.71% of patients given apixaban and in 3.06% of those treated with enoxaparin (RR 0.87, 95% CI 0.62 to 1.23). By day 30, rates of major bleeding in the apixaban and enoxaparin groups were 0.47% and 0.19%, respectively (RR 2.58, 95% CI 1.02 to 7.24, P = 0.04). Therefore, extended thromboprophylaxis with apixaban was not superior to a shorter course with enoxaparin, and there was more bleeding with apixaban.

Treatment of VTE. The phase III multicenter, double-blind, randomized AMPLIFY trial is comparing apixaban (10 mg twice daily for 1 week followed by 5 mg twice daily thereafter) with conventional anticoagulant therapy (heparin or LMWH followed by dose-adjusted warfarin) for treatment of patients with acute VTE. The phase III multicenter, double-blind, randomized AMPLIFY-EXT trial is comparing apixaban (at doses of either 2.5 or 5 mg twice daily) with placebo for prevention of recurrent VTE in patients who have completed a minimum of a 6-month course of anticoagulation therapy for a first episode of VTE (www.clinicaltrials.gov: NCT00633893 and NCT00643201, respectively).

Stroke prevention in atrial fibrillation. The AVERROES trial, which compared apixaban with aspirin, is discussed in Chapter 92. The multicenter, double-blind, randomized phase III ARISTOTLE trial[143] compared apixaban (5 mg twice daily) with warfarin (dose adjusted to achieve an INR of 2.0 to 3.0) in 18,201 atrial fibrillation patients with at least one additional risk factor for stroke. Compared with warfarin, treatment with apixaban reduced stroke or systemic embolism from 1.60% to

1.27% (RR 0.79, 95% CI 0.66 to 0.95). Rates of major bleeding were lower with apixaban than with warfarin (2.13% and 3.09%, respectively; RR 0.69, 95% CI 0.60 to 0.80).[143]

Acute coronary syndromes. In the phase II APPRAISE study, varying doses of apixaban (2.5 mg twice daily, 10 mg once daily, 10 mg twice daily, or 20 mg once daily) were compared with placebo in 1,715 patients with recent ST-elevation or non–ST-elevation ACS.[144] Nearly all patients received aspirin and 76% also received clopidogrel. The primary outcome was bleeding. Recruitment into the two higher dose arms of apixaban was stopped early because of excess bleeding. Compared with placebo, apixaban (2.5 mg twice daily or 10 mg once daily) increased bleeding in a dose-dependent fashion. There was a trend for fewer ischemic events in patients given apixaban, a phenomenon that was attenuated in those taking aspirin plus clopidogrel compared with those receiving aspirin alone.

The multicenter, double-blind, randomized, phase III APPRAISE-2 trial compared apixaban (5 mg twice daily) with placebo as adjuncts to antiplatelet therapy with aspirin with or without a thienopyridine. The trial was stopped early after recruitment of 7,392 patients because of excess bleeding (including intracranial bleeding) with apixaban and no compensatory reduction in ischemic events. Thus, the primary efficacy outcome, a composite of cardiovascular death, MI, or ischemic stroke, occurred in 7.5% of patients given apixaban and in 7.9% of those assigned to placebo, whereas major bleeding occurred in 1.3% and 0.5%, respectively (HR 2.59, 95% CI 1.50 to 4.46, $P = 0.001$).[145]

Rivaroxaban. Rivaroxaban is an active compound with 80% oral bioavailability. Plasma levels of rivaroxaban peak 2 to 3 hours after administration and the terminal half-life is 7 to 11 hours.[146,147] One-third of the administered drug is cleared as unchanged active drug by the kidneys, one-third is metabolized by the liver via CYP3A4-dependent and independent pathways and then excreted in feces, and one-third is metabolized to inactive metabolites, which are then excreted by the kidneys. The pharmacokinetic and pharmacodynamic profile of rivaroxaban is predictable and dose dependent and is not influenced by age, gender, or body weight. Potent inhibitors of both CYP3A4 and P-glycoprotein (P-gp), such as ketoconazole or ritonavir, are contraindicated because they increase plasma drug concentrations.

Prevention of VTE. Rivaroxaban has been approved in the European Union, USA, Canada, and several other countries for the prevention of VTE in adult patients undergoing hip or knee arthroplasty, and the results of the studies are reviewed in Chapter 86.

The MAGELLAN trial compared extended prophylaxis with oral rivaroxaban (10 mg once daily for 35 days) with short-term prophylaxis with subcutaneous enoxaparin (40 mg once daily for 10 days) in 8,101 hospitalized, medically ill patients.[148] The primary efficacy outcome, VTE and VTE-related mortality at 35 days, occurred in 4.4% of patients given rivaroxaban and in 5.7% of those treated with enoxaparin (HR 0.77, 95% CI 0.62 to 0.96). However, there was more major plus clinically relevant bleeding with rivaroxaban than with enoxaparin (5.3% and 2.1%, respectively).

Treatment of VTE. In the phase III, open-label EINSTEIN-DVT trial, 3,449 patients with acute, symptomatic DVT were randomized to treatment with rivaroxaban (15 mg twice daily for 21 days, followed by 20 mg once daily) or conventional therapy (enoxaparin followed by a VKA) for 3, 6, or 12 months based on the treating physician's assessment at baseline.[149] Rivaroxaban was noninferior to conventional treatment for the prevention of recurrent VTE, which occurred in 2.1% and 3.0% of patients, respectively (HR 0.68, 95% CI 0.44 to 1.04). Major or clinically relevant nonmajor bleeding, the primary safety endpoint, occurred in 8.1% of patients in both groups, while major bleeding occurred in 0.8% and 1.0% of patients given rivaroxaban and conventional treatment, respectively. The rates of all-cause mortality were similar in both treatment groups (2.2% and 2.9%, respectively). The EINSTEIN PE trial, which compared the same rivaroxaban regimen with conventional anticoagulant treatment in 4832 patients with PE, showed similar rates of recurrent venous thromboembolism (2.1% and 1.8%, respectively; HR 1.12, 95% CI 0.75 to 1.07). Rates of major or clinically relevant nonmajor bleeding were 10.3% and 11.4% in the rivaroxaban and standard therapy groups, but there was significantly less major bleeding with rivaroxaban (1.1% and 2.2%, respectively).

The EINSTEIN EXT trial randomized 1,196 patients who had completed a 6- or 12-month course of anticoagulant therapy with rivaroxaban or a VKA for a first episode of VTE to either rivaroxaban (20 mg once daily) or placebo for an additional 6 or 12 months.[149] Compared with placebo, rivaroxaban reduced the risk of recurrent VTE from 7.1% to 1.3% (HR 0.18, 95% CI 0.09 to 0.39, $P < 0.001$). Major or clinically relevant nonmajor bleeding occurred in 5.4% and 1.4%, respectively ($P < 0.001$).

Stroke prevention in atrial fibrillation. As reviewed in Chapter 92, the ROCKET-AF trial compared rivaroxaban with dose-adjusted warfarin. Rates of stroke or systemic embolism with rivaroxaban and warfarin were 2.1% and 2.4%, respectively, and rates of major bleeding were 3.6% and 3.5%, respectively.[150] Rivaroxaban has now been licensed in the United States, Europe and Canada for this indication.

Acute coronary syndromes. In a phase II study, varying doses and regimens of rivaroxaban (5 to 20 mg once daily, or the same total daily doses given twice daily) were compared with placebo in 3,491 patients who were stabilized after ACS.[151] The primary outcome, clinically significant bleeding, increased in a dose-dependent fashion with rivaroxaban compared with placebo. Rates of the primary efficacy endpoint, a composite of death, MI, stroke, or severe recurrent ischemia requiring revascularization with rivaroxaban and placebo were 5.6% and 7.0%, respectively. The rate of the secondary efficacy endpoint, a composite of death, MI, or stroke, was reduced with rivaroxaban compared with placebo (3.9% and 5.5%, respectively; HR 0.69, 95% CI 0.50 to 0.96, $P = 0.027$).

The phase III, ATLAS ACS TIMI 51 trial compared rivaroxaban (at doses of 2.5 or 5 mg twice daily) with placebo as adjuncts to aspirin with or without a thienopyridine for prevention of recurrent ischemic events in 15,526 patients with a recent ACS.[152] Rivaroxaban significantly reduced the primary efficacy outcome (a composite of cardiovascular death, MI, or stroke) compared with placebo, with respective rates of 8.9% and 10.7% (HR 0.84, 95% CI 0.74 to 0.96, $P = 0.008$). Both the 2.5 and the 5 mg doses of rivaroxaban significantly reduced the primary efficacy endpoint compared with placebo (9.1%, 8.8%, and 10.7%, respectively) and the 2.5 mg dose reduced the rates of death from cardiovascular causes (2.7% and 4.1%, $P = 0.002$) and from any cause (2.9% and 4.5%, $P = 0.002$). Compared with placebo, rivaroxaban increased the rates of major bleeding (2.1% and 0.6%, $P < 0.001$) and intracranial hemorrhage (0.3% and 0.2%, $P = 0.009$). There were fewer fatal bleeds with the 2.5 mg dose of rivaroxaban than with the 5 mg dose (0.1% and 0.4%, $P = 0.04$). Therefore, the 2.5 mg twice-daily dose regimen of rivaroxaban reduces mortality in patients with ACS, but increases the risk of major and intracranial bleeding.

Edoxaban. Formerly known as DU-176b, edoxaban is an active drug with an oral bioavailability of at least 50%. Edoxaban is rapidly absorbed from the gastrointestinal tract such that plasma concentrations peak 1 to 2 hours after dosing. Elimination follows a biphasic pattern and the terminal elimination half-life is approximately 8 to 10 hours.[153] There is a dual mechanism of elimination; approximately 35% of the total administered oral dose is excreted via the kidneys, while the remainder is eliminated in the feces.[153]

Prevention of VTE. Oral edoxaban (30 mg once daily) was compared with subcutaneous enoxaparin (20 mg twice daily) in two double-blind phase III trials conducted in Japan. Overall, edoxaban was more effective for VTE prevention and was not associated with more bleeding. On the basis of these studies, edoxaban has been licensed in Japan for this indication.

Treatment of VTE. The phase III double-blind HOKUSAI trial is comparing edoxaban 60 mg once daily (reduced to 30 mg once daily in selected patients) with warfarin (dose adjusted to achieve an INR of 2 to 3). Patients are randomized to edoxaban or warfarin after they have completed an initial course of therapy with heparin or LMWH for at least 5 days. Study drug is administered for 3, 6, or 12 months depending on whether the VTE is provoked or unprovoked (www.clinicaltrials.gov: NCT00986154).

Stroke prevention in atrial fibrillation. In a phase II trial, edoxaban (at doses of 30 or 60 once daily or 30 or 60 mg twice daily) was compared with warfarin in 1,146 patients with atrial fibrillation. The rates of the primary endpoint, the composite of major plus clinically relevant nonmajor bleeding, were significantly higher in the groups randomized to 30 or 60 mg of edoxaban twice daily than the rate in patients given warfarin (7.8%, 10.6%, and 3.2%, respectively). In contrast, the rates with 30 or 60 mg of edoxaban once daily were similar to that with warfarin (3.0% and 3.8%, respectively).[154] Based on these data, the phase III double-blind ENGAGE-AF-TIMI 48 trial is comparing two doses of edoxaban (30 or 60 mg once daily with dose adjustments for renal impairment, low body weight or use of potent P-gp inhibitors) with warfarin (INR of 2 to 3) for stroke prevention in 21,500 patients with atrial fibrillation.[155] Enrollment into the trial has been completed, and patients are now being followed in this event-driven trial.

Darexaban. Formerly known as YM150, darexaban has high oral bioavailability and drug levels peak about 2 hours after oral drug administration. The half-life of darexaban is 14 to 18 hours; consequently, the drug is given once daily. Darexaban has a dual mechanism of elimination; one-half is eliminated via the kidneys and the remainder in the feces.

Prevention of VTE. Darexaban was first evaluated in 174 patients undergoing elective hip arthroplasty.[156] At once-daily doses of 3, 10, 30, or 60 mg, darexaban produced a statistically significant dose response for efficacy. No major bleeds were reported, and there was no dose–response trend for clinically relevant nonmajor bleeding. In a second phase II dose-finding study, 1,017 patients undergoing elective hip arthroplasty were randomized to once-daily oral darexaban (at doses of 5, 10, 30, 60, or 120 mg) or to subcutaneous enoxaparin (40 mg once daily starting 12 hours prior to surgery) for 5 weeks. The primary efficacy endpoint, a composite of VTE or all-cause mortality, occurred in 18.9% of patients given enoxaparin. Darexaban reduced the rate of VTE in a dose-dependent fashion and the rates in the 30, 60, and 120 mg dose groups were 19.3%, 13.3%, and 14.5%, respectively. There was one major bleed with the 60 mg dose of darexaban and one with enoxaparin.

Stroke prevention in atrial fibrillation. In a phase II dose-finding study, once-daily darexaban was compared with warfarin in 448 patients with atrial fibrillation. The warfarin dose was adjusted to achieve an INR of 2.0 to 3.0 for those up to an age 69 years and an INR of 1.6 to 2.6 for those aged 70 years or older. Recruitment into the 240 mg darexaban dose arm was stopped early because of excess bleeding. Rates of major or clinically relevant nonmajor bleeding with the 30, 60, and 120 mg doses of darexaban were 2.2%, 2.2%, and 3.2%, respectively, while the rate was 2.1% with warfarin.

Acute coronary syndrome. In the phase II RUBY-1 study, 1,279 patients with recent ACS were randomized to receive one of six dosage regimens of darexaban or placebo in addition to antiplatelet therapy.[157] The primary outcome of the study, major or clinically relevant nonmajor bleeding, was higher with all doses of darexaban than with placebo (pooled HR 2.27, 95% CI 1.13 to 4.60). There was no apparent decrease in the rate of recurrent ischemic events with any of the regimens. Because of these results and the lack of a clear advantage of darexaban over other oral factor Xa inhibitors, development of darexaban has been halted.

Betrixaban. With oral bioavailability of 47% and a half-life of 19 hours, betrixaban is reported to exhibit minimal renal excretion. Betrixaban had antithrombotic activity in animal models and was well tolerated in humans in a phase I trial that included 64 subjects.[158]

Prevention of VTE. In the phase II EXPERT trial, oral betrixaban, at doses of 15 or 40 mg twice daily, was compared with subcutaneous enoxaparin (30 mg twice daily) for thromboprophylaxis in 215 patients undergoing elective knee arthroplasty.[159] Randomization was done in a 2:2:1 fashion and treatment was given for 10 to 14 days. VTE occurred in 20% and 15% of patients given 15 or 40 mg of betrixaban, respectively, and in 10% of those given enoxaparin. There were no major bleeds in the 171 patients given betrixaban versus, one in the 43 patients given enoxaparin.

Stroke prevention in atrial fibrillation. In the phase II, EXPLORE-Xa study, oral betrixaban was compared with warfarin (INR of 2 to 3) in 506 patients with atrial fibrillation. Major or clinically relevant nonmajor bleeding occurred in 1, 5, and 4 patients in the groups of patients given 40, 60, or 80 mg of betrixaban, respectively, and in 4 of those given warfarin. Betrixaban is now undergoing phase III evaluation for extended thromboprophylaxis in medically ill patients.

TAK-442. With good oral bioavailability, TAK-442 produced a predictable and dose-proportional level of anticoagulation in healthy volunteers. Plasma concentrations peaked 1 to 2 hours after oral administration and the elimination half-life was 9 to 13 hours.[158] In a phase II dose-finding study, oral TAK-442 (in doses of 40 or 80 mg once daily or 10, 20, 40, or 80 mg twice daily) was compared with subcutaneous enoxaparin (30 mg twice daily) in 1,038 patients undergoing knee arthroplasty.[160] Both treatments were given for 10 to 14 days. The primary efficacy endpoint was composite of total VTE and all-cause mortality, while the primary safety endpoint was major bleeding. Recruitment into the TAK-442 10 and 20 mg twice-daily arms of the study was stopped early because the rates of the primary efficacy endpoint were higher than that with enoxaparin (39.0%, 38.4%, and 22.0%, respectively). The primary efficacy endpoint occurred in 23.5%, 21.4%, 26.8%, and 14.3% of those receiving TAK-442 40 mg once daily, 40 mg twice daily, 80 mg once daily, or 80 mg twice daily, respectively. Rates of major

bleeding were low and the rates of major plus clinically relevant nonmajor bleeding were similar across all treatment groups.[159]

A phase II dose-finding study compared varying doses and regimens of TAK-442 with placebo in ACS patients, most of whom were also taking aspirin and clopidogrel (www.clinicaltrials.gov: NCT00677053). Although the study has been completed, the results have not been reported.

LY-517717. With oral bioavailability of 25% to 82%, LY-517717 has a half-life of about 25 hours and is given once daily.[158] LY-517717 was evaluated in a phase II noninferiority study that randomized 511 patients undergoing hip or knee arthroplasty to one of six doses of LY-517717 (25, 50, 75, 100, 125, or 150 mg started 6 to 8 hours after wound closure) or to once-daily subcutaneous enoxaparin (40 mg) started the evening before surgery.[161] Both treatments were administered for a total of 6 to 10 doses. Randomization to the three lower doses of LY-517717 was stopped early due to lack of efficacy. The three higher doses of LY-517717 had efficacy similar to that of enoxaparin (17.1% to 24.0% and 22.2%, respectively). Adjudicated major bleeding events were uncommon in all study arms. Although promising, further development of LY-517717 has been halted.

Inhibitors of Factors Va and/or VIIIa

Factor Va and, to a lesser extent, factor VIIIa are the targets of activated protein C (APC). APC acts as an anticoagulant by proteolytically degrading and inactivating factors Va and VIIIa, key cofactors in thrombin generation (FIGURE 110.5). Factors Va and VIIIa are directly inhibited by drotrecogin alfa (activated), a recombinant form of APC. Recomodulin, previously known as ART-123, is a recombinant analogue of the extracellular domain of thrombomodulin that binds thrombin and enhances its capacity to activate protein C. TB-402 is a factor VIIIa–directed monoclonal antibody.

Drotrecogin alfa (activated). A recombinant form of APC, drotrecogin is licensed for treatment of patients with severe sepsis. Approval for this indication was based on a trial comparing drotrecogin with placebo in 1,690 patients with severe sepsis.[162] The phase III trial and postapproval trials are discussed in Chapter 123.

Recomodulin. A recombinant analogue of the extracellular domain of thrombomodulin,[163] recomodulin binds thrombin and converts it from a procoagulant enzyme into a potent activator of protein C. Recomodulin has nearly 100% bioavailability after subcutaneous administration and a half-life of 2 to 3 days. In a phase IIa dose-ranging study in patients undergoing elective hip arthroplasty, the primary endpoint (a composite of venographically detected DVT and symptomatic PE) occurred in 4.3% of the 94 patients given lower dose recomodulin and in none of the 99 patients receiving the higher dose.[164] Major bleeding occurred in 1.6% and 5.7% of patients receiving low- or high-dose recomodulin, respectively. In a double-blind study, recomodulin was compared with placebo in 750 patients with sepsis associated with disseminated intravascular coagulation. Although the study has been completed, the results are not available.

TB-402. A human IgG_4 monoclonal antibody that partially inhibits factor VIIIa, TB-402 was generated by introducing a point mutation into the gene encoding MAB-LE2E9, a factor VIII–directed monoclonal antibody.[165,166] TB-402 does not affect the interaction of factor VIII with vWF, but it inhibits

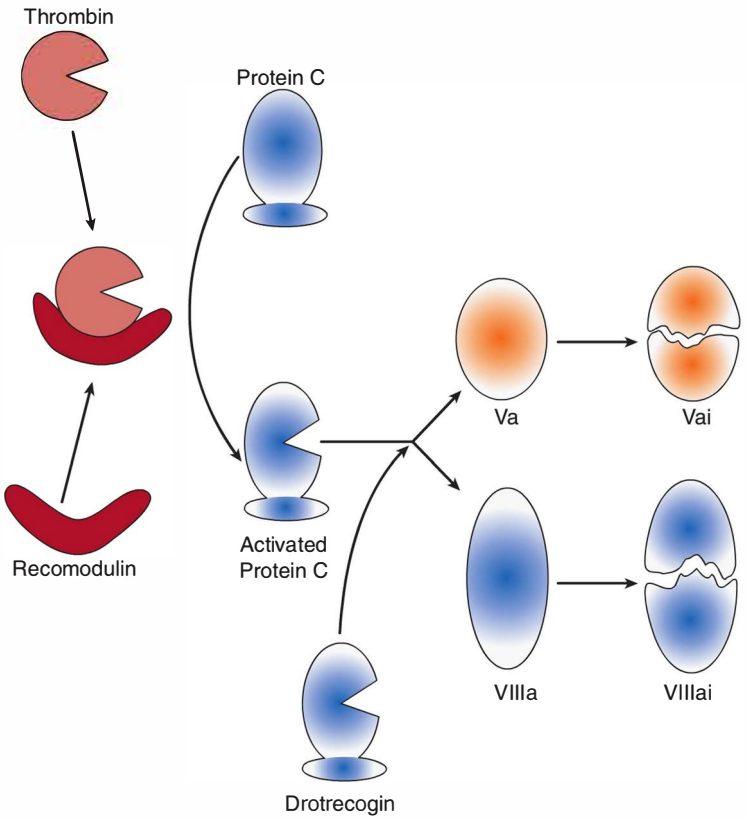

FIGURE 110.5 Inhibitors of factors Va and VIIIa. Recomodulin and solulin, which are analogues of the extracellular domain of thrombomodulin, bind thrombin and alter its substrate specificity such that it becomes a potent activator of protein C. Activated protein C (APC) acts as an anticoagulant by degrading factors Va and VIIIa, key cofactors in coagulation, into inactive fragments (Vai and VIIIai, respectively). Drotrecogin, a recombinant analogue of APC, bypasses the need for activation of endogenous protein C and directly inactivates factors Va and VIIIa.

factor VIII activity by about 40%.[167] The antibody has a half-life of about 3 weeks, which may enable prolonged VTE prophylaxis with a single dose.

In a phase I study in healthy volunteers, increasing doses of TB-402 decreased factor VIII activity to plateau levels that were one-third to two-thirds lower than baseline.[167] The aPTT was correspondingly prolonged and remained so for at least 4 weeks, consistent with the long half-life. In a phase II study, a single dose of intravenous TB-402 was compared with enoxaparin in 316 patients undergoing knee arthroplasty.[168] All patients received a 40 mg subcutaneous dose of enoxaparin 12 hours prior to surgery; they were then randomized to receive either TB-402 or enoxaparin 18 to 24 hours after the procedure. The primary outcome, major or clinically relevant nonmajor bleeding, occurred in 3.8% of patients given enoxaparin and in 4.0%, 5.4%, and 8.0% of those given TB-402, 0.3, 0.6, and 1.2 mg/kg, respectively. The primary efficacy outcome, total VTE, occurred in 39.0% of the patients given enoxaparin and in 16.7%, 23.9%, and 24.1% of those receiving TB-402 at doses of 0.3, 0.6, and 1.2 mg/kg, respectively. Thus, there was no dose–response trend for efficacy with TB-402, but there was a dose-dependent increase in bleeding. At a dose of 0.3 mg/kg, TB-402 appeared to have efficacy and safety similar to that of enoxaparin. Additional studies are needed to confirm these findings.

Inhibitors of Thrombin

Thrombin is a logical target for new anticoagulants because in addition to converting fibrinogen to fibrin, thrombin also amplifies its own generation by activating factors V, VIII, and XI and serves as a potent platelet agonist. Thrombin can be inhibited indirectly or directly. Indirect inhibitors that are specific for thrombin act by catalyzing heparin cofactor II. In contrast, direct thrombin inhibitors bind to the enzyme and block its interaction with substrates.

Direct thrombin inhibitors have properties that give them potential mechanistic advantages over indirect inhibitors.[169,170] First, because direct thrombin inhibitors do not bind to plasma proteins, they produce a more predictable anticoagulant response. Second, unlike heparin, direct thrombin inhibitors do not bind to PF4. Consequently, the anticoagulant activity of direct thrombin inhibitors is unaffected by the large quantities of PF4 released in the vicinity of platelet-rich thrombi. Finally, direct thrombin inhibitors inactivate fibrin-bound thrombin, as well as fluid-phase thrombin.

Flovagatran and pegmusirudin are parenteral direct thrombin inhibitors that have undergone phase II evaluation; since neither agent has advanced to phase III, they will not be discussed further. There are three new oral thrombin inhibitors; odiparcil, an indirect inhibitor whose development has been halted, and dabigatran etexilate and AZD0837, which are oral direct thrombin inhibitors.

Dabigatran etexilate. A prodrug of dabigatran, dabigatran etexilate has an oral bioavailability of about 6%.[170] After oral administration, dabigatran etexilate is rapidly and completely converted by esterases to dabigatran. Plasma levels of dabigatran peak 2 hours after drug administration. Dabigatran has a half-life of 14 to 17 hours, which permits once-daily or twice-daily administration. The elimination of dabigatran occurs predominantly via the kidneys, with approximately 80% of the drug excreted unchanged in the urine. Dabigatran exhibits predictable pharmacokinetics and pharmacodynamics with little effect of food. Drug–drug interactions are limited; potent P-gp inhibitors, such as ketoconazole, are contraindicated.[170]

Prevention of VTE. As discussed in Chapter 86, dabigatran has been evaluated for VTE prevention in four phase III randomized controlled trials in patients undergoing hip arthroplasty (n = 5,549) or knee arthroplasty (n = 4,691). Based on the results of these trials, dabigatran has been licensed in many countries, but not the United States, for short-term thromboprophylaxis after elective hip or knee arthroplasty.

Treatment of VTE. In the phase III, double-blind RE-COVER trial, 2,539 patients with acute VTE were randomized to treatment with dabigatran etexilate (150 mg twice daily) or warfarin (INR of 2 to 3) for 6 months after an initial course of therapy with a parenteral anticoagulant for at least 5 days.[171] Dabigatran was noninferior to warfarin for the prevention of recurrent VTE or VTE-related mortality (HR 1.10, 95% CI 0.65 to 1.84). The rate of major bleeding was 1.6% with dabigatran and 1.9% with warfarin (HR 0.82, 95% CI 0.45 to 1.48). A second phase III trial with the same design is underway (RE-COVER-2; www.clinicaltrials.gov: NCT00680186). Other phase III trials compared dabigatran etexilate with placebo for the long-term secondary prevention of recurrent VTE in patients who have completed a course of anticoagulant treatment with a VKA or dabigatran for 6 to 18 months (RE-SONATE; www.clinicaltrials.gov: NCT00558259), or dabigatran with warfarin in patients who have completed a 3- to 12-month course of anticoagulant therapy for acute VTE (RE-MEDY; www.clinicaltrials.gov: NCT00329238).

Stroke prevention in atrial fibrillation. Based on the results of the RELY trial, which is reviewed in Chapter 92, dabigatran etexilate is licensed as an alternative to warfarin for stroke prevention in patients with atrial fibrillation in the United States, Europe, and Canada.

Acute coronary syndromes. Although a phase II dose-finding study in ACS patients has been completed,[172] a phase III trial has yet to be initiated for this indication.

AZD0837. A follow-up to ximelagatran, AZD0837 is a prodrug, which undergoes rapid metabolism by CYP isoenzymes, including CYP2C9, CYP2C19, and CYP3A4, to AR-H69927, an intermediate that is then converted to AR-H067637, a selective and reversible direct inhibitor of thrombin.[167] The half-life of AR-H067637 is 9 to 14 hours in healthy subjects and AZD0837 and its metabolites are excreted in the urine and the feces. The oral bioavailability of AZD0837 is in the range of 22% to 55%, and drug levels in plasma peak about 1.5 hours after oral drug administration. Both immediate release and extended release formulations of AZD0837 have been developed.[173] The extended release form has the potential for once-daily administration. In a phase II study, the immediate release formulation of AZD0837 (in doses of 150 or 350 mg twice daily) was compared with warfarin (dose-adjusted to achieve an INR of 2 to 3) in 250 patients with atrial fibrillation.[173] Total bleeding events were reported in 6 patients receiving the 150 mg dose of AZD0837, in 15 patients given the 350 mg dose, and in 8 of those treated with warfarin. Elevations in alanine aminotransferase levels were infrequent and the rates were similar with AZD0837 and warfarin.

The extended release formulation has been evaluated in two phase II studies. The first compared the extended release formulation of AZD0837 (150, 300, and 450 mg once daily and 200 mg twice daily) with warfarin in 955 patients with atrial fibrillation.[174] Total bleeding events were similar or lower with

all doses of AZD0837 than with warfarin (5.3% to 14.7% and 14.5%, respectively).

The second phase II study compared the extended release formulation of AZD0837 (150 or 300 mg once daily) with standard therapy (consisting of either nothing, aspirin, or clopidogrel), in 131 patients with atrial fibrillation who were unwilling or unable to take a VKA.[175] Treatment was given for a median duration of 6 weeks. There were no major bleeds.

Side effects of AZD0837 include dyspepsia, diarrhea, and nausea and a reversible elevation in the serum creatinine level that appears to be the result of decreased inhibition of the tubular secretion of creatinine.[176] Despite the promising clinical results with AZD0837, phase III trials have not been initiated.

CONCLUSIONS AND FUTURE DIRECTIONS

The last decade has seen an explosion of new antithrombotic drugs enter the clinical arena. Several of these agents have already been licensed. On the antiplatelet front, ticagrelor was recently approved in Europe and Canada. Following on the heels of prasugrel, the benefit-to-risk profile of ticagrelor appears to be more favorable. But will prasugrel or ticagrelor replace clopidogrel? Compared with clopidogrel, both prasugrel and ticagrelor reduce the risk of stent thrombosis in patients undergoing PCI, but the risk of this complication is low and may be reduced even further with double-dose clopidogrel. In addition to lowering the risk of stent thrombosis in PCI patients, however, ticagrelor also is associated with reduced mortality compared with clopidogrel. This is an important finding; whether it reflects greater ADP receptor inhibition or a $P2Y_{12}$-independent phenomenon remains to be established.

PAR-1 is a promising target because its inhibition does interfere with platelet adhesion or activation in response to collagen. The efficacy and safety of PAR-1 inhibitors when added on top of aspirin and clopidogrel remain to be established. The recent discontinuation of vorapaxar in stroke patients entered in the TRA2P-TIMI 50 trial highlights the potential for bleeding with triple antiplatelet therapy. Safety will be even more of a concern for add-on therapy if there is a shift from clopidogrel to more potent ADP receptor antagonists.

Perhaps the greatest advance has been in the area of new oral anticoagulants. Rivaroxaban, dabigatran, and apixaban have been licensed in many countries as alternatives to LMWH or fondaparinux for thromboprophylaxis after knee or hip arthroplasty. Although these agents streamline out-of-hospital prophylaxis by eliminating the need for daily injections, these drugs were designed for longer term use as alternatives to VKA. The elusive goal of developing oral anticoagulants that can be administered in fixed doses without the need for routine coagulation monitoring has finally been realized with the recent licensing of dabigatran and rivaroxaban as alternatives to warfarin for stroke prevention in patients with atrial fibrillation. Apixaban and other oral factor Xa inhibitors are likely to follow for this and other indications. Therefore, we are on the verge of a new era of oral anticoagulation therapy as we move from VKA to fixed dose unmonitored treatments.

CHAPTER

111 Antiplatelet Therapy

CARLO PATRONO

As reviewed in other chapters, platelet activation and aggregation play a key role in atherothrombosis.[1] Antiplatelet drugs target enzymes or receptors involved in the platelet synthesis of important agonists (e.g., thromboxane [TX] A_2) or in mediating their activating/amplifying effects, respectively (FIGURE 111.1).[2,3] Because of the multifactorial nature of atherothrombosis, antiplatelet drugs can only avoid a fraction (typically, one-quarter to one-third) of major vascular complications. This protective effect against the occurrence of a first (primary prevention) or recurrent (secondary prevention) myocardial infarction or ischemic stroke cannot be dissociated from enhanced risk of bleeding complications, because of the important role played by the same drug targets in primary hemostasis. Moreover, antiplatelet therapy should be viewed within the context of a multifactorial approach to cardiovascular prevention that includes lifestyle modifications as well as other pharmacologic interventions.

This chapter reviews the pharmacologic basis and clinical evidence supporting the efficacy and safety of antiplatelet drugs for the treatment and prevention of atherothrombosis.

ASPIRIN

Aspirin (acetylsalicylic acid) was originally developed by the Bayer Company as an analgesic, antipyretic, and antiinflammatory agent at the end of the 19th century, and represented the prototypic nonsteroidal anti-inflammatory drug (NSAID). Following the discovery of its mechanism of action and characterization of its unique pharmacodynamic properties in inhibiting platelet function (reviewed in Ref.4), aspirin was developed as an antiplatelet agent during the past 30 years, a process largely driven by the medical–scientific community (reviewed in Ref.5).

Pharmacokinetics and Pharmacodynamics

Aspirin is rapidly absorbed in the stomach and upper intestine. Peak plasma levels occur 30 to 40 minutes after oral intake, and maximal inhibition of platelet function is achieved by 1 hour.[2] In contrast, it can take up to 3 to 4 hours to reach peak plasma levels after the oral administration of enteric-coated aspirin. The oral bioavailability of regular aspirin tablets is approximately 50% over a wide range of doses,[6] because of deacetylation of the drug during passage through the liver (first-pass effect). However, substantial variability has been reported in the oral bioavailability of enteric-coated aspirin formulations.[7] Poor absorption from the higher pH environment of the small intestine and lower bioavailability of some enteric-coated aspirin preparations may result in inadequate platelet inhibition, particularly in heavier subjects.[7]

The plasma concentration of aspirin decays with a half-life of 15 to 20 minutes.[2] Despite the rapid clearance of the intact drug moiety from the circulation, aspirin induces a long-lasting functional defect in human platelets. This appears to be primarily, if not exclusively, due to permanent inactivation by aspirin of a key enzyme in platelet arachidonate metabolism (FIGURE 111.2). This enzyme, prostaglandin (PG) H-synthase 1, is responsible for the formation of PGH_2, the precursor of TXA_2. In human platelets, TXA_2 provides a mechanism for amplifying the activation signal by being synthesized and released in response to various platelet agonists (e.g., collagen, adenosine diphosphate [ADP], platelet-activating factor, thrombin) and, in turn, inducing irreversible aggregation.[1]

Aspirin selectively acetylates the hydroxyl group of a single serine residue at position 529 (Ser^{529}) within the polypeptide chain of platelet PGH-synthase 1. This enzyme exhibits two distinct catalytic activities: a bis-oxygenase (cyclooxygenase [COX]) involved in formation of PGG_2 and a hydroperoxidase (HOX) allowing a net two-electron reduction in the 15-hydroperoxyl group of PGG_2, thus yielding PGH_2 (FIGURE 111.2). An inducible form of PGH-synthase has been identified and termed PGH-synthase 2 or COX-2.[8] While newly formed platelets can express both COX-1 and COX-2,[9] mature platelets primarily display COX-1 activity. As a consequence of *O*-acetylation of Ser^{529} by aspirin, the COX activity of the enzyme is lost permanently, whereas the HOX activity is not affected. The highly hydrophobic environment of the COX-1 channel stabilizes the aspirin-modified serine side chain against hydrolysis. As a result of this permanent modification of the enzyme, COX activity can only resume through new protein synthesis (occurring within a few hours in nucleated cells) or cell turnover (occurring at a daily rate of 10% to 12% in the case of human platelets).[2] Aspirin is equally potent in acetylating COX-1 and COX-2, when tested *in vitro*.[10] However, its unique mechanism of action and unusual pharmacokinetic features[6] (short half-life and presystemic encounter with the platelet target in the portal blood prior to first-pass liver metabolism) allow selective, cumulative inhibition of platelet COX-1 at low doses while substantially sparing endothelial COX-2.[2] Whereas the effect of aspirin on COX-1–dependent TXA_2 production is saturable at daily doses as low as 30 mg,[11] its inhibitory effect on COX-2–derived PGI_2 production is dose dependent up to daily doses of 650 to 1,300 mg.[12]

The strikingly nonlinear relationship between inactivation of platelet COX-1 and inhibition of TXA_2-dependent platelet function by low-dose aspirin (i.e., relatively limited inhibition of platelet function between 0% and 95% inhibition of COX-1; exponential increase in platelet inhibition between 97% and 100% COX-1 inactivation)[13,14] has important clinical implications: (a) a substantial loss of platelet inhibition is associated

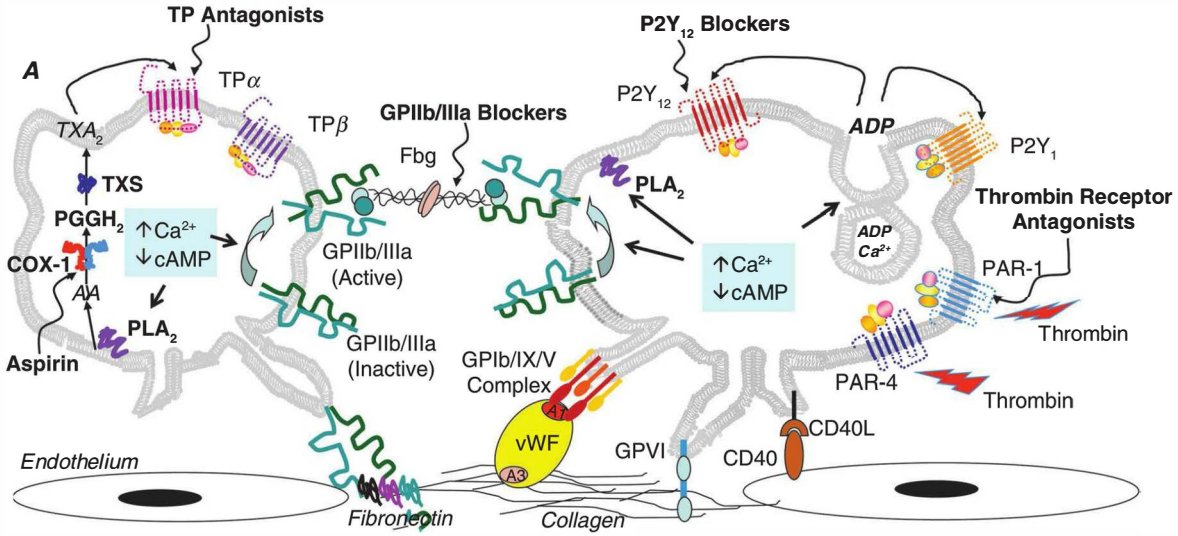

FIGURE 111.1 Platelet activation and aggregation: agonists, receptors, and site of action of antiplatelet drugs. The activation, adhesion, and aggregation of platelets are triggered by several agonists interacting with specific receptors on the platelet membrane. The GPIb/IX/V complex plays an essential role in the initial phase of platelet–vessel wall interaction that finally converges to GPIIb/IIIa activation. vWF binds to GPIb and collagen, while the subendothelial collagen binds to GPIa/IIa and GPVI as well. Platelet activation by agonists results in the decrease in cAMP and/or increase in intracellular Ca^{2+}, leading to the inside-out change in the ligand-binding properties of GPIIb/IIIa, which conformationally switches to a high-affinity state for adhesive proteins such as fibrinogen, vWF, fibronectin, and vitronectin. Fibrinogen-mediated bridging of adjacent platelets via activated GPIIb/IIIa is the final mediator of aggregation. This response is amplified by further release of ADP and TXA_2 and degranulation, which induce additional platelet activation/recruitment, changes in morphology and aggregation stability via outside-in signaling events mediated by activated GPIIb/IIIa. Antiplatelet drugs target enzymes (e.g., COX-1) or receptors (e.g., $P2Y_{12}$) involved in the platelet synthesis of endogenous agonists (e.g., TXA_2) or in mediating their activating/amplifying effects, respectively. ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; TX, thromboxane; TP, thromboxane receptor; PKC, protein kinase C; PAR, protease-activated receptor; TXS, thromboxane synthase; PGH_2, prostaglandin H_2; COX, cyclooxygenase; AA, arachidonic acid; PLA_2, phospholipase A_2; GP, glycoprotein; vWF, von Willebrand factor; CD40L, CD40 ligand; Fbg, fibrinogen.

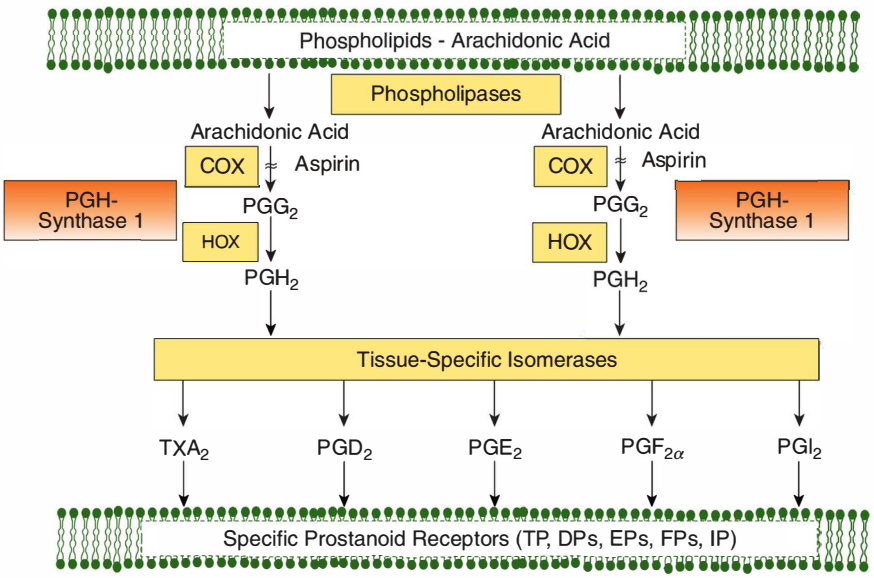

FIGURE 111.2 Arachidonic acid metabolism through the PG H-synthase pathways. Arachidonic acid, a 20-carbon fatty acid containing four double bonds, is liberated from the *sn*2 position in membrane phospholipids by several forms of phospholipase A_2, which are activated by diverse stimuli. Arachidonic acid is converted by cytosolic PGH-synthases, which have both COX and HOX activity, to the unstable intermediate PGH_2. The synthases are colloquially termed COXs and exist in two forms, COX-1 and COX-2. Aspirin inhibits both COX-1 and COX-2. PGH_2 is converted by tissue-specific isomerases to multiple prostanoids. These bioactive lipids activate specific cell-membrane receptors of the superfamily of G-protein–coupled receptors. TP denotes the TXA_2 receptor, DP the PGD_2 receptor, EP the PGE_2 receptor, FP the $PGF_{2\alpha}$ receptor, and IP the PGI_2 receptor.

with less than maximal inactivation of COX-1; (b) recovery of platelet function is disproportionately rapid upon drug withdrawal; and (c) the requirement for virtually complete and persistent inhibition of platelet COX-1 cannot be met by most traditional NSAIDs, allowing their COX-2–dependent cardiotoxicity to be unmasked.[15]

Efficacy and Safety

A very large database of randomized clinical trials (RCTs) now offers the most compelling evidence that prevention of myocardial infarction and ischemic stroke by aspirin is largely due to permanent inactivation of platelet COX-1.[2,5] These studies, which tested the efficacy and safety of the drug when given at daily doses ranging from as low as 30 mg to as high as 1,500 mg, have established two important facts. First, the antithrombotic effect of aspirin is saturable at doses in the range of 50 to 100 mg, as would be expected from human studies of platelet COX-1 inactivation.[11] Second, despite a half-life of approximately 20 minutes in the human circulation, the antithrombotic effect of aspirin is observed with a dosing interval of 24 to 48 hours, reflecting the permanent nature of platelet COX-1 inactivation and the duration of TXA_2 suppression following oral dosing in human.[11] Other mechanisms of action that have been suggested to contribute to the antithrombotic effect of aspirin, such as a direct anti-inflammatory effect of the drug, are incompatible with these unique properties, because they require higher doses and shorter dosing interval.[2]

Aspirin's unique feature in inhibiting platelet COX-1—its ability to inactivate the enzyme permanently through a short-lived active moiety—is ideally suited to its role as an antiplatelet drug, because it limits the extent and duration of extraplatelet effects of the drug, including the inhibition of PGI_2.[12] Moreover, the cumulative nature of platelet COX-1 acetylation by repeated low doses of aspirin[11] explains the clinical efficacy of doses as low as 30 to 50 mg daily,[2] the predictable high-grade inhibition of platelet TXA_2 biosynthesis,[14] and the persistence of the drug's effect.[2] These features, in turn, may limit the consequences of less-than-ideal compliance in a real world setting.

Permanent inactivation of platelet COX-1 by aspirin may lead to the prevention of atherothrombosis as well as to excess bleeding. At least two distinct COX-1–dependent mechanisms contribute to the increased risk of upper gastrointestinal (GI) bleeding associated with aspirin exposure: inhibition of TXA_2-mediated platelet function and impairment of PGE_2-mediated cytoprotection in the GI mucosa.[2] Whereas the former effect is dose independent for daily doses >30 mg, the latter effect is clearly dose dependent.[2] Inhibition of platelet function is largely responsible for the twofold increase in the risk of upper GI bleeding associated with daily doses of aspirin in the range of 75 to 100 mg, inasmuch as a similar relative risk (RR) is associated with other antiplatelet agents (e.g., clopidogrel) that do not act on COX and therefore do not affect PGE_2-mediated cytoprotection.[16] Inhibition of COX-1–dependent cytoprotection of the GI mucosa amplifies the risk of bleeding/perforation by causing new mucosal lesions or aggravating existing ones and is associated with a RR of four to six at the higher, analgesic, or anti-inflammatory doses of aspirin.[2]

The hypothesis that both the reduction in atherothrombotic complications and the increase in bleeding events are primarily due to inhibition of platelet TXA_2 biosynthesis is supported by the recent finding that a highly selective TXA_2 receptor (TP) antagonist, terutroban, and low-dose (100 mg daily) aspirin were associated with virtually identical rates of recurrent vascular events and major bleeds in an RCT of over 19,000 patients with a recent stroke.[17] The possibility that aspirin may exert "pleiotropic" effects at low doses is not incompatible with a single mechanism of action, that is, inactivation of platelet COX-1, explaining antithrombotic, anti-inflammatory, and antiproliferative effects of the drug. In fact, there may be "pleiotropic" consequences of platelet inhibition by low-dose aspirin, resulting from reduced release of platelet-active prostanoids, inflammatory cytokines, and growth factors.[1] The recent reports[18,19] of long-term reduction in the risk of colorectal (and other) cancer and death associated with low-dose aspirin in RCTs using as low as 75 mg daily are consistent with this hypothesis.[20]

Assessing the benefit/risk profile of aspirin requires an estimation of the absolute risk of the individual patient for atherothrombotic and hemorrhagic complications. In individuals at low risk for vascular occlusion (e.g., <1% per year), a very small absolute benefit may be offset by exposure of very large numbers of healthy subjects to undue serious bleeding complications (see Balance of Benefits and Risks). As the risk of experiencing a major vascular event increases, so does the absolute benefit of antiplatelet prophylaxis with aspirin (FIGURE 111.3), and, above a certain threshold, benefit clearly outweighs risk of bleeding (Table 111.1).[2,5]

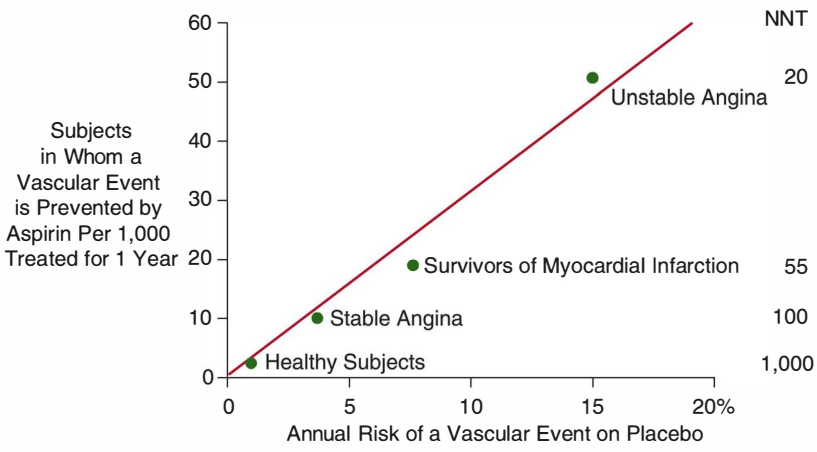

FIGURE 111.3 The risk of vascular complications is the major determinant of the absolute benefit of antiplatelet therapy. Data are plotted from placebo-controlled aspirin trials in different clinical settings. For each category of patients, the abscissa denotes the absolute risk of experiencing a major vascular event as recorded in the placebo arm of the trial(s). The absolute benefit of antiplatelet treatment is reported on the ordinate as the number of subjects in whom an important vascular event (nonfatal MI, nonfatal stroke, or vascular death) is actually prevented by treating 1,000 subjects with aspirin for 1 year. Numbers needed to treat (NNT) are also reported for each clinical setting.

Table 111.1

Benefit/risk ratio of antiplatelet prophylaxis with aspirin in different settings

Clinical Setting	Benefit[a]	Risk[b]	Benefit/Risk Ratio
	Number of Patients in Whom a Major Vascular Event is Avoided per 1,000/y	Number of Patients in Whom a Major GI Bleeding Event is Caused per 1,000/y	
Men and women at low cardiovascular risk	1–2	1–2	1
Essential hypertension	1–2	1–2	1
Chronic stable angina	10	1–2	5–10
Prior stroke or TIA	10	1–2	5–10
Prior myocardial infarction	15	1–2	7.5–15
Unstable angina	50	1–2	25–50

[a]Benefits are calculated from randomized trial data reviewed in Refs. 2, and 5 and depicted in FIGURE 111.3.
[b]Risks of upper GI bleeding are estimated from a background rate of 1 event per 1,000 per year in the general population of nonusers and a RR of 2.0 to 3.0 associated with aspirin prophylaxis. Such an estimate assumes comparability of other risk factors for upper GI bleeding, such as age and concomitant use of NSAIDs, and may actually underestimate the absolute risk in an elderly population exposed to "primary" prevention. The absolute excess of major extracranial bleeding complications in the "primary" prevention trials reviewed in Ref. 39 ranged between 0.2 and 2.0 per 1,000 patient-years.
Modified from Patrono C, Baigent C, Hirsh J, et al. Antiplatelet drugs: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* 2008;133:199S–233S.

The efficacy and safety of aspirin has been evaluated in numerous placebo-controlled RCTs of patients at variable risk of atherothrombotic complications, from asymptomatic low-risk individuals to patients presenting with an acute myocardial infarction or an acute ischemic stroke[2,5]; trials have extended from as short as a few weeks' duration to as long as 10 years. In the Second International Study of Infarct Survival,[21] a single tablet of aspirin (162.5 mg) started within 24 hours of the onset of symptoms of a suspected myocardial infarction and continued daily for 5 weeks produced highly significant reductions in the risk of vascular mortality (by 23%), nonfatal reinfarction (by 49%), and nonfatal stroke (by 46%). There was no increase in hemorrhagic stroke or GI bleeding in the aspirin-treated patients and only a small increase in minor bleeding.[21] Treatment of 1,000 patients with suspected acute myocardial infarction with aspirin for 5 weeks will result in approximately 40 patients in whom a vascular event is prevented,[22] with a proportional odds reduction of 30%. Two separate trials with a similar protocol, the International Stroke Trial[23] and the Chinese Acute Stroke Trial,[24] tested the efficacy and safety of early aspirin use in acute ischemic stroke. Approximately 40,000 patients were randomized within 48 hours of the onset of symptoms to 2 to 4 weeks of daily aspirin therapy (300 and 160 mg, respectively) or placebo. An overview of the results of both trials suggests an absolute benefit of nine fewer deaths or nonfatal strokes per 1,000 patients in the 1st month of aspirin therapy.[22] The proportional odds reduction in fatal or nonfatal vascular events was only 10% in this setting. Although the background risk of hemorrhagic stroke was threefold higher in the Chinese Acute Stroke Trial than in the International Stroke Trial, the absolute increase in this risk associated with early use of aspirin was similar in the two studies (excess 2 per 1,000 patients).[23,24]

Balance of Benefits and Risks

Long-term aspirin therapy confers conclusive net benefit on the risk of subsequent myocardial infarction, stroke, or vascular death among subjects at high risk of vascular complications. These include patients with chronic stable angina,[25] patients with prior myocardial infarction,[22] patients with unstable angina,[26–29] and patients with transient ischemic attack (TIA) or minor stroke[30–35] as well as other high-risk categories.[22] The proportional effects of long-term aspirin therapy on vascular events in these different clinical settings showed substantial heterogeneity, ranging from no statistically significant benefits in patients with peripheral vascular disease[36] to approximately 50% risk reduction in patients with unstable angina.[22] In terms of absolute benefit, these protective effects of aspirin translate into avoidance of a major vascular event in 50 per 1,000 patients with unstable angina treated for 6 months and in 36 per 1,000 patients with prior myocardial infarction, stroke, or TIA treated for approximately 30 months.[22]

For patients with different manifestations of ischemic heart or brain disease, a consensus exists in defining a rather narrow range of recommended daily doses (i.e., 75 to 160 mg) for the prevention of atherothrombotic complications.[37,38] This is supported by separate trial data in patients randomized to treatment with low-dose aspirin or placebo as well as by an overview of all antiplatelet trials showing no obvious dose dependence, from indirect comparisons, for the protective effects of aspirin.[22] There is no convincing evidence that the dose requirement for the antithrombotic effect of aspirin varies in different clinical settings.[2]

Among most high-risk patient groups, the expected number avoiding a serious vascular event by using aspirin substantially exceeds the number experiencing a major bleed (Table 111.1). However, it is unclear whether aspirin might benefit people who, although asymptomatic, are at low to intermediate risk of serious vascular events. The question of whether aspirin is effective and safe for the primary prevention of vascular events has been addressed in a meta-analysis of six randomized trials.[39] It is interesting to compare the effects of low-dose aspirin in primary prevention with the well-known benefits in secondary prevention.[39] In the six primary prevention trials among 95,000 low-risk individuals, with a mean follow-up of 6.9 years, aspirin allocation yielded a 12% RR reduction in serious vascular events,

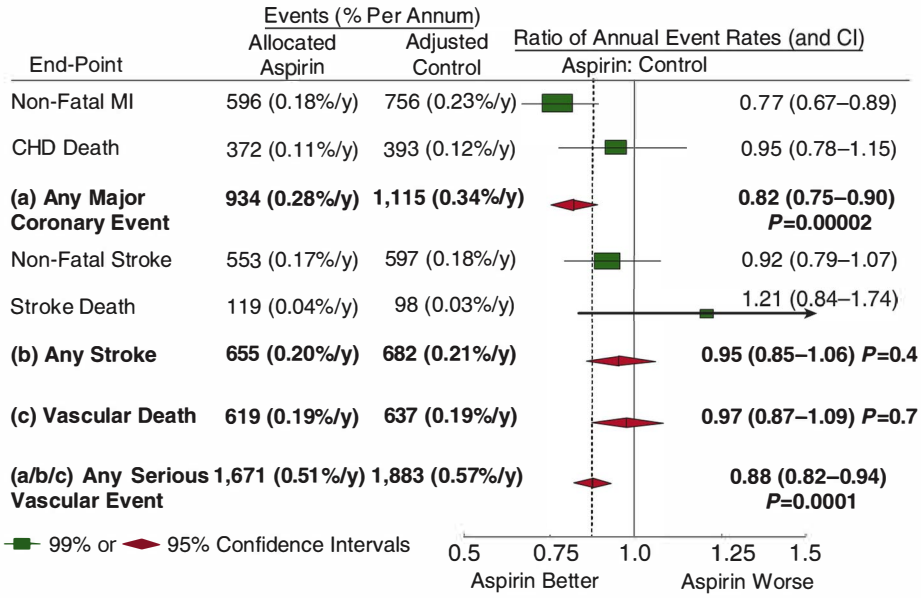

FIGURE 111.4 Serious vascular events in primary prevention trials—proportional effects of aspirin allocation. Actual numbers for aspirin-allocated trial participants, and adjusted numbers for control-allocated trial participants, are presented, together with the corresponding mean yearly event rate (*in parentheses*). Rate ratios for all trials are indicated by *squares* and the 99% CIs by *horizontal lines*. Subtotals and the 95% CIs are represented by *diamonds*. *Squares* or *diamonds* to the left of the *solid line* indicate benefit. MI, myocardial infarction; CHD, coronary heart disease. (Modified from ATT Collaboration. Aspirin in the primary and secondary prevention of vascular disease: collaborative meta-analysis of individual participant data from randomised trials. *Lancet* 2009;373:1849–1860.)

from an annual rate of 0.57% to 0.51% (FIGURE 111.4). This effect was mainly due to a reduction in nonfatal myocardial infarction, from 0.23% to 0.18% per year. The net effect on stroke was not significant (from 0.21% to 0.20% per year), reflecting a small reduction in presumed ischemic stroke and counterbalancing effects on hemorrhagic stroke and other stroke.[39] There was no significant reduction in vascular mortality (from 0.19% to 0.19% per year). Aspirin allocation increased GI (or other extracranial) bleeds by about half, from 0.07% to 0.1% per year.[39]

In 16 long-term, secondary prevention trials in 17,000 high-risk patients with prior myocardial infarction, or prior stroke or TIA, with a mean follow-up of 2.5 years, aspirin allocation yielded 19% fewer serious vascular events (from 8.2% to 6.7% per year), with similar proportional reductions in coronary events (20% RR reduction) and ischemic stroke (22% RR reduction), but a nonsignificant increase in hemorrhagic stroke.[39] Although the 19% proportional reduction in serious vascular events was only slightly higher than that observed in primary prevention, the absolute benefit of aspirin was 25 times larger in secondary prevention (15 vs. 0.6 fewer vascular events per 1,000 per year).[39] In both primary and secondary prevention trials, the proportional reductions in serious vascular events appeared similar for men and women and for older and younger people.[39] In the primary prevention studies, the risks of serious vascular events and of major extracranial bleeds were predicted by the same independent risk factors (age, male gender, diabetes mellitus, current smoking, blood pressure, and body mass index), so those at higher risk of vascular complications also had a high risk of bleeding.[39]

While for secondary prevention the net benefits of adding aspirin to other preventive measures (e.g., statin) would substantially exceed the bleeding hazards, irrespective of age and gender, in people without preexisting vascular disease the benefits of adding long-term aspirin would be of similar magnitude as the hazards.[39] However, the recent reports[18,19] of additional long-term effects of low-dose aspirin on the risk of death due to cancer, recorded in patients participating in both primary and secondary cardiovascular prevention trials, may lead to reconsidering the benefit/risk profile of the drug in people without preexisting vascular disease.

A low ankle brachial index (ABI) is a relatively simple measure of peripheral atherosclerosis and predicts cardiovascular events and mortality.[40] The Aspirin for Asymptomatic Atherosclerosis trial[41] aimed to determine whether screening the general population for a low ABI could identify a higher-risk group who might benefit from antiplatelet therapy. Its largely negative findings in 3,350 men and women with a low ABI (≤0.95), after a mean follow-up of 8.2 years, are most likely due to lack of statistical power possibly amplified by relatively poor compliance.[42]

CLOPIDOGREL AND OTHER P2Y$_{12}$ BLOCKERS

Ticlopidine, clopidogrel, and prasugrel are structurally related thienopyridines with platelet inhibitory properties. These drugs selectively inhibit ADP-induced platelet aggregation, with no direct effects on the metabolism of arachidonic acid.[43] Thienopyridines also can inhibit platelet aggregation induced by collagen and thrombin, but these inhibitory effects are abolished by increasing the agonist concentration and, therefore, likely reflect blockade of ADP-mediated amplification of the response to other agonists.[43]

Pharmacokinetics and Pharmacodynamics

Thienopyridines inhibit ADP-dependent platelet function by irreversible modification of platelet P2Y$_{12}$[44] through short-lived

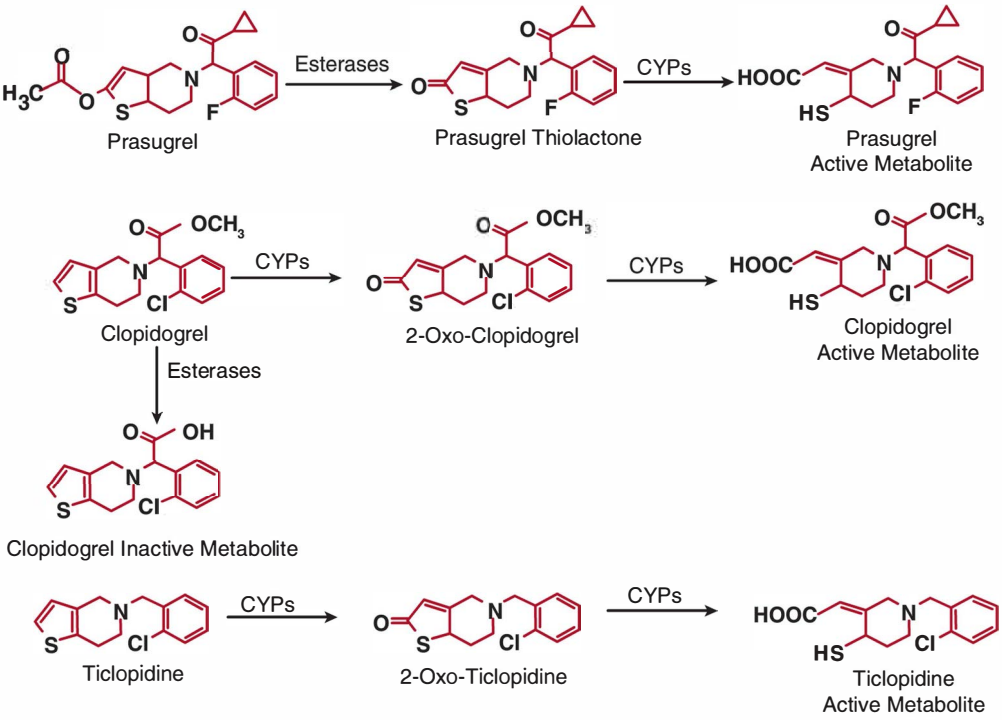

FIGURE 111.5 Pathways of thienopyridine metabolism. Metabolic activation of prasugrel, clopidogrel, and ticlopidine by the liver cytochrome P450 (CYP) system to form thiol-containing AMs is illustrated. The latter are responsible for the antiplatelet effects of thienopyridines.

active metabolites (AMs) generated by liver cytochrome P450 (CYP) isozymes[45] (FIGURE 111.5). Although conceptually analogous to aspirin in terms of pharmacokinetic/pharmacodynamic dissociation (short half-life, long duration of action), the inhibition of ADP-dependent platelet function by clopidogrel is less predictable than the inhibition of TXA_2-dependent platelet function by aspirin. Insufficient availability of the AM of clopidogrel at conventional therapeutic doses results in incomplete inactivation of platelet $P2Y_{12}$.[46] However, because of the linear relationship between $P2Y_{12}$ inactivation and inhibition of ADP-dependent platelet function, even incomplete inactivation of the drug target may result in a measurable clinical effect. Genetic variations of the liver enzymes responsible for the metabolism of clopidogrel as well as drug–drug interactions (e.g., with proton pump inhibitors [PPIs]) are important determinants of the highly variable circulating levels of its AM. These, in turn, are associated with variable inhibition of ADP-induced platelet aggregation and variable clinical response to clopidogrel treatment[47,48] (FIGURE 111.6).

Efficacy and Safety of Clopidogrel as Monotherapy

Clopidogrel has undergone an unusual clinical development, with limited phase 2 studies and a single large phase 3 trial (CAPRIE, in over 19,000 patients) to test its efficacy and safety at 75 mg daily compared with aspirin at 325 mg daily in three groups of patients enrolled because of a recent myocardial infarction, recent ischemic stroke, or symptomatic peripheral arterial disease (PAD).[49] Clopidogrel was slightly more effective than aspirin (annual rate of major vascular events: 5.3% vs. 5.8%, RR reduction 8.7%, 95% CI 0.3 to 16.5), and there was some suggestion from a marginally significant ($P = 0.042$) heterogeneity test that clopidogrel might be particularly effective at preventing vascular events in patients with symptomatic PAD (RR reduction = 24% [$P = 0.0028$] in PAD patients vs. RR reduction = 7%, [$P = 0.26$] in stroke patients and an RR increase of 4% [$P = 0.66$] in coronary patients).[49] In CAPRIE, the frequency of severe rash was significantly higher with clopidogrel than with aspirin (absolute excess ~1 to 2 per 1,000), as was the frequency of diarrhea, thus reproducing the characteristic side effects of ticlopidine. No excess neutropenia was associated with clopidogrel, but the frequency of this serious complication was extremely low (0.05%) in this trial.[49] Rates of any bleeding complication and of intracranial hemorrhage were similar for aspirin and clopidogrel, with an absolute excess of severe GI bleeds of approximately 2 per 1,000 for aspirin versus clopidogrel.[49]

DUAL ANTIPLATELET THERAPY

The complementary mechanism of action of clopidogrel and aspirin has led to testing the efficacy and safety of their combination in several high-risk settings.[50–53] The RR reduction of major vascular events associated with the combination of clopidogrel and aspirin, as compared with aspirin alone, was relatively modest in the absence of percutaneous coronary intervention (PCI) and stenting. The additional benefit of dual antiplatelet therapy versus aspirin alone[50–53] was only a fraction of the benefit achieved by aspirin versus placebo in a similar clinical setting (FIGURE 111.7), raising the possibility that the role of ADP in atherothrombosis may have been underestimated on the basis of clopidogrel trials, because of incomplete and variable blockade of ADP-induced platelet aggregation by the drug.[1]

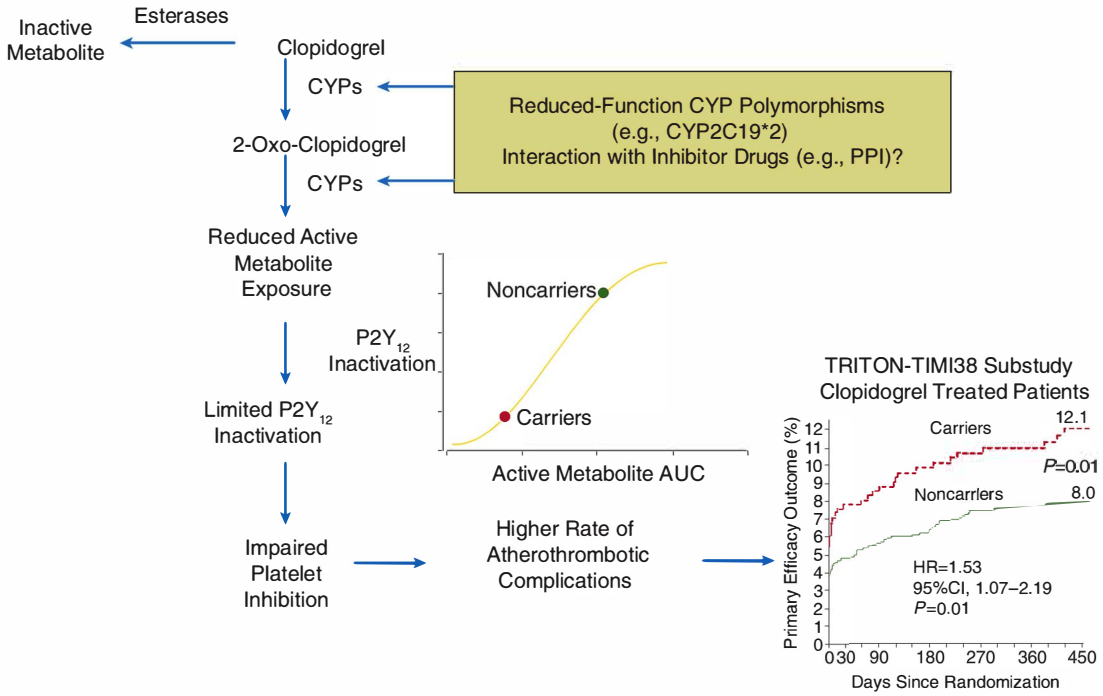

FIGURE 111.6 Mechanisms underlying the interindividual variability in response to clopidogrel. Both pharmacogenetic (e.g., reduced-function polymorphisms of cytochrome P450 [CYP] isozymes) and pharmacokinetic (e.g., drug interactions with inhibitors of CYP isozymes, such as some PPIs) mechanisms may be responsible for reduced conversion of clopidogrel to its AM. The resulting incomplete inactivation of platelet $P2Y_{12}$ is associated with impaired inhibition of ADP-dependent platelet aggregation. In a pharmacogenetic substudy of the TRITON-TIMI 38 trial,[48] clopidogrel-treated carriers of the reduced-function CYP2C19*2 allele had lower levels of the AM of clopidogrel, diminished platelet inhibition, and a higher rate of major cardiovascular events than did clopidogrel-treated noncarriers.

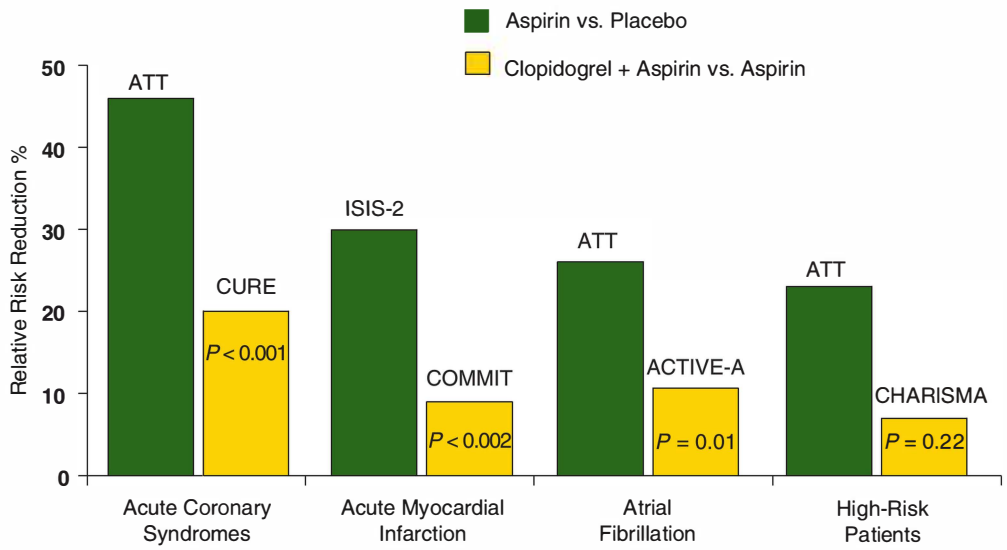

FIGURE 111.7 Additional benefit of dual antiplatelet therapy with aspirin and clopidogrel versus aspirin alone in high-risk settings. RR reductions for the combined endpoint of major vascular events are represented. Data are from individual RCTs and from a meta-analysis of trials of aspirin in high-risk patients. ATT denotes Antithrombotic Trialists' Collaboration,[22] CURE Clopidogrel in Unstable Angina to Prevent Recurrent Events,[50] ISIS-2 Second International Study of Infarct Survival,[21] COMMIT Clopidogrel and Metoprolol in Myocardial Infarction Trial,[51] ACTIVE Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events,[53] and CHARISMA Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance.[52]

In the CURE study,[50] blockade of both platelet COX-1 with aspirin and of platelet $P2Y_{12}$ with clopidogrel produced additive effects in patients with acute coronary syndromes without ST-segment elevation (NSTE-ACS), by reducing the rate of the first primary outcome (a composite of cardiovascular death, nonfatal myocardial infarction, or stroke) from 11.4% to 9.3% (RR 0.80, 95% CI 0.72 to 0.90) as compared to aspirin alone, with no evidence of attenuation of the additional benefit over up to 12 months of treatment.[50] As would be expected from more aggressive antiplatelet therapy, there were significantly more patients with major bleeding complications in the aspirin plus clopidogrel group than in the aspirin alone group (3.7% vs. 2.7%, RR 1.38, 95% CI 1.13 to 1.67).[50]

The clinical benefit of dual antiplatelet therapy versus aspirin alone has been confirmed in patients undergoing PCI,[54] in those presenting with acute myocardial infarction with ST-segment elevation (STEMI) within 12[55] to 24 hours[51] after the onset of symptoms, and in patients with nonvalvular atrial fibrillation.[53] In the Clopidogrel and Metoprolol Myocardial Infarction Trial (COMMIT),[51] 45,852 Chinese patients with suspected acute myocardial infarction were studied. Primary PCI was an exclusion criterion, and 55% of the patients received fibrinolytic therapy before or after randomization. Addition of 75 mg/day of clopidogrel to 162 mg/day of aspirin reduced mortality and major vascular events in the hospital by 9% (95% CI 3% to 14%), corresponding to nine fewer events per 1,000 patients treated for about 2 weeks. Overall in this trial, when all transfused, fatal, or cerebral bleeds were considered together, there was no significant excess risk associated with the use of clopidogrel during the scheduled treatment period (0.58% clopidogrel plus aspirin vs. 0.55% aspirin alone; $P = 0.59$), nor was there any excess of major bleeds in patients >70 years of age or in those given fibrinolytic therapy before randomization.[51] Clopidogrel was, however, associated with a small, but significant, excess of 4.7 reported minor bleeds per 1,000 patients treated. Taking major and minor bleeds together, there was no apparent trend with respect to age in the excess risk.[51] Factors that may have contributed to the remarkable safety of dual antiplatelet therapy in the COMMIT trial include the lack of a loading dose of clopidogrel, the uniform use of 162 mg of aspirin, the short duration of treatment with clopidogrel (on average 2 weeks), and the small proportion of elderly patients that received fibrinolytic therapy. In the CLARITY trial, 3,491 STEMI patients <76 years of age received standard fibrinolytic therapy and aspirin and were randomized to a loading dose of clopidogrel 300 mg followed by 75 mg daily or placebo up to and including the day of angiography or day of discharge if no angiography was performed.[55] The mean duration of study treatment was around 3 days. Clopidogrel was associated with higher coronary patency rates at angiography and fewer ischemic complications without a significant increase in major bleeding complications or intracranial hemorrhage. Although long-term treatment with aspirin and clopidogrel for 1 year after STEMI is recommended by various guidelines, irrespective of the acute reperfusion treatment, long-term studies have not been performed in this regard.[43]

At present, there is no sound evidence for defining the optimal duration of dual antiplatelet therapy after drug-eluting stent (DES) placement with current recommendations ranging between 3 and 12 months, depending on the DES type.[56] Several randomized studies, such as OPTIDUAL (Optimal Duration of Dual Antiplatelet Therapy After Drug-Eluting Stent Implantation) and ISAR-SAFE (Safety and Efficacy of Six Months Dual Antiplatelet Therapy After Drug-Eluting Stenting), are currently investigating this issue. Until the results of these studies are available, the potential benefit of extended dual antiplatelet therapy needs to be weighed against the excess risk of major bleeding.

In the ACTIVE-A trial of patients with nonvalvular atrial fibrillation who had an increased risk of stroke and for whom therapy with a vitamin K antagonist was considered unsuitable, dual antiplatelet therapy reduced the risk of major vascular events from 7.6% to 6.8% per year (RR 0.89, 95% CI 0.81 to 0.98) versus aspirin alone (recommended dose, 75 to 100 mg/day).[53] This additional benefit was primarily due to a reduction in the risk of stroke. There was, however, a significant increase in the risk of major bleeding (from 1.3% to 2.0% per year), including a doubling of intracranial bleeding (from 0.2% to 0.4% per year).[53]

In contrast to the consistent finding of a favorable benefit/risk profile of dual antiplatelet therapy in ACS patients[50,51,55] and those undergoing PCI,[54] the same strategy has not proven more effective when compared to clopidogrel alone in patients after a recent ischemic stroke or TIA,[57] or when compared to aspirin alone in patients at high risk for atherothrombotic events.[52] Major bleeding was increased by dual antiplatelet therapy in both MATCH[57] and CHARISMA.[52] In patients with previous stroke or TIA, intensified platelet inhibition seems to be associated with disproportionately increased bleeding risk.[57]

PRASUGREL

Prasugrel is a novel thienopyridine antiplatelet agent. Like ticlopidine and clopidogrel, prasugrel is a prodrug that is inactive *in vitro*.[58] The three compounds are converted to thiol-containing AMs through a corresponding thiolactone[59] (FIGURE 111.5). However, whereas ticlopidine and clopidogrel are metabolized to their thiolactones in the liver by CYP isozymes, prasugrel is converted to its thiolactone via hydrolysis by carboxylesterase 2 during absorption[59] (FIGURE 111.5). Prasugrel thiolactone is efficiently converted to its AM by the liver with a less rigorous dependence on specific CYP isozymes than ticlopidine or clopidogrel. The AM of prasugrel binds specifically and irreversibly to the platelet $P2Y_{12}$ receptor and inhibits ADP-induced platelet aggregation with the same potency as the AM of clopidogrel[58] (FIGURE 111.8). While equimolar concentrations of the AMs of clopidogrel and prasugrel resulted in similar levels of platelet inhibition *in vitro*, the markedly different amounts of each metabolite generated *in vivo* following a loading dose of clopidogrel (300 mg) or prasugrel (60 mg) resulted in approximately 10-fold greater exposure to the latter as compared to the former[58] (FIGURE 111.8). This observation provides a pharmacokinetic basis for the faster, more profound, and less variable inhibition of platelet function observed with prasugrel as compared to clopidogrel in healthy subjects as well as in patients with ischemic heart disease.[46,58] In contrast to clopidogrel, the lack of drug interaction potential and the absence of CYP2C19 genetic effect resulted in a predictable antiplatelet response to prasugrel.[58] This, in turn, helps explain the superior clinical efficacy and enhanced bleeding liability of prasugrel versus clopidogrel in ACS patients undergoing PCI, as established by the TRITON-TIMI 38 trial.[60]

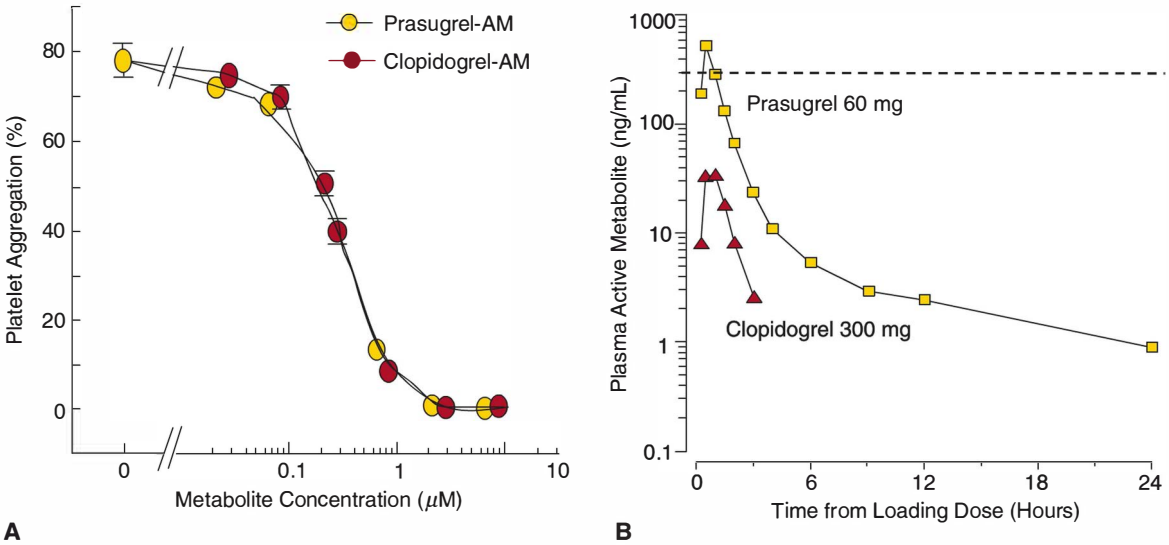

FIGURE 111.8 *In vitro* pharmacodynamics and *in vivo* pharmacokinetics of clopidogrel and prasugrel AMs. **Panel A** illustrates the effects of prasugrel and clopidogrel AM on human platelet aggregation induced by ADP (10 μM). **Panel B** depicts plasma active metabolite concentrations following prasugrel and clopidogrel loading doses. The *broken horizontal line* corresponds to a 1 μM concentration of the active metabolite that is required for profound suppression of ADP-induced platelet aggregation. (Modified from Sugidachi et al. *J Thromb Haemost* 2007;5:1545–1551; Jakubowski et al. *Cardiovasc Drug Rev* 2007;25:357–374.)

REVERSIBLE $P2Y_{12}$ ANTAGONISTS

Three direct and reversible $P2Y_{12}$ antagonists, cangrelor (an intravenous agent), ticagrelor (an oral agent), and elinogrel (available both as an intravenous and as oral agent) are associated with rapid onset and offset of platelet inhibition.[58] Unlike the thienopyridines, they do not require metabolic activation by the liver. Detailed molecular studies of ticagrelor have demonstrated that this selective $P2Y_{12}$ inhibitor displays apparent noncompetitive antagonism toward ADP-induced receptor activation, suggesting the existence of more than one ligand-binding site on $P2Y_{12}$.[61] Ticagrelor is rapidly absorbed and undergoes enzymatic transformation to at least one AM.[58] Peak plasma concentrations of ticagrelor and maximum platelet inhibition are achieved within 1 to 3 hours after dosing. The plasma half-life of ticagrelor is 6 to 13 hours, which dictates a twice-daily regimen of administration.[58]

The full potential of dual antiplatelet therapy with low-dose aspirin and a $P2Y_{12}$ inhibitor in ACS has been unmasked by two recently completed superiority trials of prasugrel and ticagrelor versus clopidogrel, the TRITON-TIMI 38[60] and PLATO[62] studies, respectively. Both trials met their primary endpoint by demonstrating that the 12-month rate of major vascular events can be further reduced by 16% to 19% over clopidogrel with a $P2Y_{12}$ blocker that achieves faster, more profound, and less variable inhibition of ADP-dependent platelet function than clopidogrel[60,62] (FIGURE 111.9). However, important differences between the two trials are worth noting. While the benefit of prasugrel versus clopidogrel was largely confined to a reduction in nonfatal myocardial infarction,[60] the incremental benefit of ticagrelor translated into a statistically significant reduction in vascular as well as total mortality.[62] Moreover, $P2Y_{12}$ blockade with prasugrel was associated with statistically significant increases in both fatal and nonfatal major bleeds,[60] while the effects of ticagrelor were largely confined to nonfatal spontaneous (i.e., non coronary artery bypass graft [CABG]-related) bleeds.[62] In TRITON-TIMI 38, three subgroups of prasugrel-treated patients appeared to be particularly prone to major bleeding complications: the elderly, the underweight, and patients with prior cerebrovascular ischemia.[60] Regardless of the mechanism(s), the increase in death due to hemorrhagic complications of prasugrel treatment may have masked any benefit of the drug on deaths due to vascular causes. The overall safety profiles of the two novel antiplatelet agents displayed additional individual features, with prasugrel being associated with an increase in the diagnosis of colonic neoplasms (13 vs. 4, $P = 0.03$),[60] while ticagrelor caused more frequent episodes of dyspnea, ventricular pauses, and creatinine increases than clopidogrel.[62]

Based on the TRITON-TIMI 38 results, prasugrel has been approved by both the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for the reduction of thrombotic cardiovascular events in ACS patients who undergo PCI. A black-boxed warning underscores the increased bleeding risk for patients 75 years of age or older and for patients undergoing urgent CABG. Because of the high probability of a false-positive finding, the imbalance in newly diagnosed cancers is described in the adverse reactions section of the label for prasugrel but is not emphasized as a warning.[63] However, the sponsors have a postmarketing requirement by the FDA to collect baseline and subsequent data on cancer in a large, ongoing clinical trial.[63] The New Drug Application for ticagrelor has been recently approved by EMA and FDA.

INTERINDIVIDUAL VARIABILITY IN RESPONSE TO ANTIPLATELET DRUGS

The term "aspirin resistance" has been introduced some 20 years ago to designate less-than-expected inhibition of platelet aggregation in response to standard doses of the drug.[64,65] Similarly,

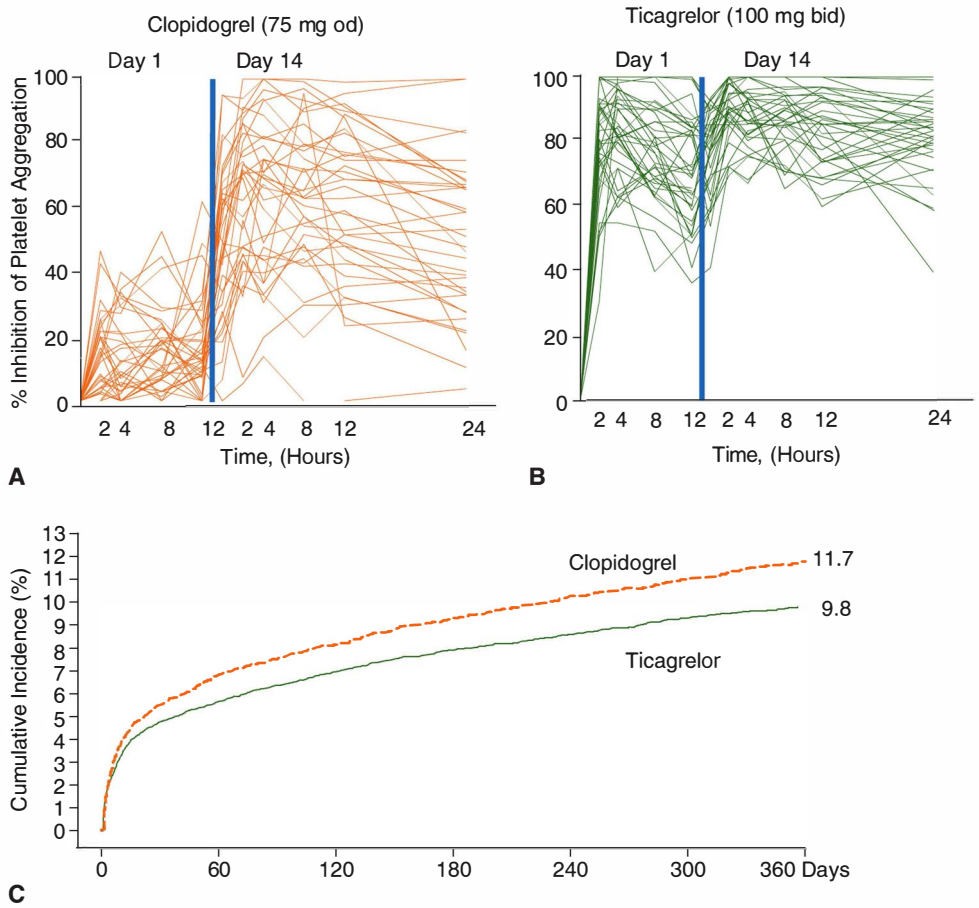

FIGURE 111.9 Pharmacodynamics of clopidogrel and ticagrelor and clinical efficacy in acute coronary syndromes. **Panels A** and **B** illustrate the effects of clopidogrel and ticagrelor, respectively, on ADP-induced platelet aggregation measured *ex vivo* on the 1st day and after 2 weeks of oral dosing. **Panel C** depicts the Kaplan-Meier curves of major vascular events in patients with acute coronary syndromes randomized to clopidogrel or ticagrelor in the PLATO trial. (Modified from Husted et al. *Eur Heart J* 2006;27:1038–1047; Wallentin et al. *N Engl J Med* 2009;361:1045–1057.)

the concept of "clopidogrel resistance" has emerged during the past 10 years based on similar functional measurements.[65,66] Moreover, because these abnormal measurements of platelet aggregation in aspirin- and/or clopidogrel-treated patients have been associated with enhanced risk of atherothrombotic events in a large series of small observational studies and their meta-analyses,[67,68] the same practical corollaries of drug resistance to chemotherapy have evolved as a natural consequence of this clinical paradigm. However, in contrast to antibiotic resistance, there is no agreement on the most appropriate test(s) to diagnose "resistance" to aspirin or clopidogrel. Moreover, there is no randomized clinical evidence that changing antiplatelet therapy in light of such diagnosis is a more effective strategy than maintaining standard therapy.

Aspirin, ticlopidine, clopidogrel, and prasugrel are characterized by individual pharmacokinetic features that may explain the delivery of variable amounts of the active moiety of the drug to its site(s) of action in different individuals. This provides a pharmacokinetic basis for interindividual variability in pharmacologic response. Inadequate bioavailability of intact acetylsalicylic acid or thiol-containing AMs of thienopyridines, because of galenic or genetic reasons, may be sufficient to explain a reduced antiplatelet effect in some individuals without the need for invoking "resistance" of the drug target. This is particularly true for clopidogrel because of its pharmacokinetics that is both unecologic (most of the administered prodrug is wasted) and risky (its metabolic activation is critically dependent on a single CYP).

There seems to be relatively limited room for pharmacodynamic variability in response to aspirin or thienopyridines, with the notable exception of a pharmacodynamic interaction between some reversible COX-1 inhibitors (e.g., ibuprofen and naproxen) and low-dose aspirin.[69,70] These NSAIDs have a higher affinity for and can displace aspirin from Arg-120, a common docking site inside the COX-1 channel, which aspirin has to anchor to in order to acetylate Ser-529.[2] Concomitant treatment with some readily available over-the-counter NSAIDs may limit the cardioprotective effects of low-dose aspirin (as recently outlined by the FDA in a statement for patients and health care professionals), and contribute, together with nonadherence,[71] to many reports of so-called aspirin "resistance."

Based on a pharmacodynamic analysis of the variability in response to aspirin and $P2Y_{12}$ blockers, there seems to be no solid grounds for the practice of phenotyping patients as being

"resistant" or "nonresponders" to these drugs based on a single measurement of platelet function, performed at a variable time point after dosing, and using a largely arbitrary threshold value of response. Moreover, unless the primary mechanism underlying a repeated finding of less-than-expected inhibition of platelet function at a standardized time point (e.g., 24 hours after a witnessed administration) is characterized in the individual patient, changing his/her antiplatelet therapy will represent a purely empirical exercise. Thus, while changing the daily dose of the drug is unlikely to overcome incomplete $P2Y_{12}$ blockade in clopidogrel-treated patients with inadequate metabolic activation of the prodrug, switching to a different thienopyridine (e.g., prasugrel) or reversible $P2Y_{12}$ blocker (e.g., ticagrelor) may effectively address the problem. On the other hand, increasing the daily dose of aspirin or switching from clopidogrel to prasugrel is unlikely to overcome faster renewal of the drug target because of altered platelet production, a problem likely requiring a change in the dosing interval of these irreversible antiplatelet agents or the administration of a reversible inhibitor.

In conclusion, studies of "aspirin resistance" have led to revisiting the clinical pharmacology of platelet COX-1 inhibition in health[14] and disease.[72,73] Serum TXB_2 remains the gold standard test of response to aspirin, and its measurements have clearly indicated noncompliance as well as a pharmacodynamic interaction with other NSAIDs as the main causes of incomplete COX-1 inhibition.[43] The perspective of tailoring aspirin therapy to the individual patient seems unnecessary, except perhaps for changing the pharmaceutical formulation (plain vs. enteric-coated) and/or the dosing interval of aspirin administration where inadequate systemic bioavailability of the drug and/or accelerated renewal of the drug target can be identified as being responsible for less-than-complete inhibition of platelet COX-1. Studies of "clopidogrel resistance," as well as the clinical development of prasugrel and ticagrelor, have been instrumental in characterizing the main determinants of the interindividual variability in response to $P2Y_{12}$ blockers. Pharmacogenetic assessment of clopidogrel response has led to regulatory warning action that requires careful consideration.[74,75] Ideally, tailoring $P2Y_{12}$ blockade to the individual patient would require integrating pharmacokinetic/pharmacodynamic assessment with pharmacogenetics, inasmuch as the therapeutic options might change depending whether inadequate receptor blockade results from a pharmacokinetic interaction with concomitant therapy (e.g., PPI or statin) or reflects genetically determined, poor metabolic activation of the prodrug.

ANTIPLATELET THERAPY: UNCERTAINTIES AND AREAS WHERE WE NEED NEW TRIALS

Although the benefits of low-dose aspirin, clopidogrel, or both are clear among patients with symptomatic vascular disease, the benefit/risk profile of the same preventive strategy is substantially uncertain in low-risk individuals with no clinically apparent vascular disease. The decision to prescribe low-dose aspirin in a person with no history of vascular disease must rely on an individual judgment that the likely benefits of aspirin will exceed any risks. On the basis of the available evidence from a meta-analysis of six primary prevention trials,[39] low-dose aspirin therapy for 4 to 10 years prevents nonfatal myocardial infarction by one-quarter, but it has no clear protective effects against ischemic stroke or vascular death. Therefore, assessing the benefits and risks of low-dose aspirin requires balancing any absolute reduction in nonfatal myocardial infarction (1 to 3 per 1,000 treated for 1 year) against an increased risk of major GI bleeding (1 to 2 per 1,000) and hemorrhagic stroke (0.1 to 0.2 per 1,000).

To maximize the absolute size of benefit versus hazard in primary prevention, most current guidelines[76,77] recommend that aspirin be given to those with coronary risk exceeding a particular threshold. These guidelines implicitly assume, however, either that the absolute risk of bleeding remains approximately constant irrespective of coronary risk or that it depends solely on age. These widely held assumptions have been challenged by the recent Antithrombotic Trialists' meta-analysis of individual participant data from primary prevention trials of antiplatelet prophylaxis,[39] demonstrating that the major risk factors for coronary events, with the notable exception of hypercholesterolemia, are also risk factors for bleeding. As a result, even for people at increased risk of coronary events (i.e., 5-year risk > 10%), the absolute benefit and hazard of adding aspirin to a statin-based primary prevention regimen are likely to be evenly balanced.

A nonfatal stroke or heart attack is more likely to result in long-term disability than is a nonfatal GI (or other extracranial) bleed, but in primary prevention the net absolute reduction in disabling or fatal occlusive events is likely to be small, and at least partially offset by a small increase in serious intracranial and extracranial bleeds.[39] Thus, although it might cost little to add aspirin to any other drugs that are being used for the primary prevention of vascular disease, the additional effectiveness against fatal or disabling outcomes has not been reliably demonstrated for men or women of any age who do not yet have any relevant disease (and, if effectiveness is uncertain then detailed estimates of cost-effectiveness are of limited relevance). Hence, although the currently available trial results could well help inform personally appropriate judgments by individuals about their own use of long-term aspirin, they do not seem to justify general guidelines advocating the routine use of aspirin in all apparently healthy individuals above a moderate level of coronary risk.[39] As noted above, this perspective on primary antiplatelet prophylaxis with low-dose aspirin for cardioprotection may need reevaluation if the recent reports on cancer prevention[18,19] provide the basis for regulatory approval of a new indication.

Further primary prevention trials of aspirin are currently ongoing, with the aim of recruiting people at relatively high cardiovascular risk (expected annual rate of major vascular events ≥ 2%), because of diabetes mellitus (ASCEND and ACCEPT-D), advanced age (ASPREE), or a cluster of risk factors that do not include diabetes (ARRIVE). Although a subgroup analysis of the six primary prevention trials is consistent with some net benefit of aspirin in adults with diabetes but no known vascular disease,[39] the evidence from placebo-controlled trials that recruited only patients with diabetes has been inconclusive.[78] While the unpromising results of these trials may well reflect their relatively limited sample size, it is also conceivable that low-dose aspirin is less effective in people with diabetes because of abnormalities in platelet regeneration potentially limiting the duration of the antiplatelet effect of a standard once-daily regimen of the drug.[79]

Since vascular disease rates rise exponentially above 60 years, and since demographic changes will result in large increases in the elderly population in the coming years, the potential for prevention in this group is substantial. However, the balance of

risk and benefit is uncertain in older individuals (in whom the bleeding risks also increase) because the amount of randomized evidence in those aged 70 or over is limited (around 10% of the primary prevention trial population).[39] Further randomized trials among elderly individuals (e.g., ASPREE) would therefore help to strengthen the evidence in this important group.

Despite virtually complete blockade of platelet COX-1 with low-dose aspirin and $P2Y_{12}$ with prasugrel or ticagrelor, the rate of major vascular events occurring during the 1st year after ACS continues to be unacceptably high, that is, around 10%[60,62] (FIGURE 111.9). The mechanisms underlying these events may include the participation of other pathways of platelet activation (e.g., thrombin-PAR-1) uninhibited by aspirin and $P2Y_{12}$ blockers. Triple antiplatelet therapy with low-dose aspirin, clopidogrel, and vorapaxar, a PAR-1 antagonist, has been tested in ACS patients with limited success,[80] and additional studies are clearly needed to characterize novel drug targets.

Finally, it should be emphasized that tailoring antiplatelet therapy in the individual patient based on his/her genotype and functional response to different $P2Y_{12}$ blockers represents a realistic scenario and may soon become standard of care if ongoing trials establish the efficacy and safety of such a strategy.

CHAPTER

112 Foundations of Thrombolytic Therapy

VICTOR J. MARDER AND DAPHNE B. STEWART

Thrombolytic therapy represents a conjoint approach to vascular reperfusion, based primarily on the use of fibrinolytic agents delivered systemically or directly into the offending thrombus and complemented by anticoagulation, antiplatelet, and mechanical strategies. Theoretically, any major thrombosed vessel that is the cause of clinically significant disease is amenable to this therapeutic approach, and the decision to utilize thrombolytic therapy requires an informed choice between the potential for clinical benefit and the risk for serious complication. In actuality, thrombolytic therapy represents the acute phase of a prolonged antithrombotic management plan, and the decision about the benefit-to-risk ratio relates to this usually brief but aggressive approach to vascular occlusion.[1,2,3,4–6,7,8,9,10,11–17] This review describes the properties of thrombolytic agents, the physiopathology of thrombolysis and bleeding complications, and the effects of treatment on blood coagulation and fibrinolytic parameters.

THROMBOLYTIC AGENTS

Mode of Action

All of the currently used thrombolytic agents are plasminogen activators (PAs) that induce plasmin action on fibrin contained within a thrombus and an associated state of plasma fibrinogenolysis (lytic state) (FIGURE 112.1). Degradation of fibrin produces the beneficial effect of reducing thrombus size (thrombolysis), but at the same time, PAs may lyse hemostatic plugs at sites of vascular injury[4] and cause bleeding. Susceptible plasma substrates such as fibrinogen are degraded to varying degrees, contributing to a hypocoagulable lytic state. Rethrombosis of the vessel may follow initial reperfusion, generally as a result of a persistent local vascular lesion. The relation of the biologic actions of thrombolysis, altered vascular integrity, rethrombosis, and the plasma lytic state determine the effectiveness and safety of thrombolytic treatment (Table 112.1).

Thrombolytic Agents

Plasminogen Activators

Six PAs have been approved by the US Food and Drug Administration (FDA) for use in major thrombotic diseases, namely, streptokinase (SK),[18] urokinase (UK),[19,20] alteplase (t-PA),[21,22] anistreplase (anisoylated plasminogen streptokinase [APSAC]),[23] reteplase,[24] and tenecteplase (TNK-t-PA),[25] although UK is no longer available in the United States, and anistreplase is rarely utilized (Table 112.2). Certain PAs are considered relatively fibrin selective (e.g., rt-PA and derivatives, staphylokinase, UK) and digest clot with less systemic plasminogen activation, while nonfibrin selective agents (e.g., SK, APSAC) activate systemic and fibrin-bound plasminogen relatively indiscriminately.[26,27]

The t-PA molecule contains four domains, an NH_2-terminal region which is homologous with the finger domains of fibronectin, an epidermal growth factor (EGF) domain, two kringle regions that are homologous with those of plasminogen, and a serine protease domain. Fibrin binding is mediated by the finger and kringle 2 domains, *in vivo* clearance is regulated by the finger and growth factor domains and by the carbohydrate side chains, and plasminogen activator inhibitor-1(PAI-1) inhibition occurs via interaction with the positively charged amino acid sequence at position 296 to 304.[21,22,27]

Tissue-type PA variants have been synthesized by recombinant DNA technology in attempts to attain improved properties such as greater activity and fibrin specificity, prolonged half-life, or an attenuated lytic state (FIGURE 112.2). Reteplase is a single-chain nonglycosylated deletion variant consisting only of the kringle 2 and the proteinase domain of human rt-PA and has a prolonged half-life (15 minutes) that allows for administration in a double bolus regimen.[28] Tenecteplase[25] is altered at three t-PA amino acid sites, conferring resistance to inhibition by PAI-1[29] and a prolonged half-life, allowing administration as a single bolus injection.[30] Lanoteplase (nPA) has a deletion of the finger and EGF domains and the carbohydrate at amino acid 117, resulting in a very prolonged half-life.[31] Vampire bat salivary PA is 70% homologous to t-PA, differing in that it has one kringle domain rather than two,[32,33] conferring greater fibrin specificity. A recombinant version of the protein, desmoteplase, has been tested in a phase III trial of acute ischemic stroke.[34]

UK is secreted as a 54-kDa single-chain molecule (scuPA; pro-UK)[35,36] and converted to a two-chain form (tcuPA) by proteolytic cleavage.[37] It contains an NH_2-terminal growth factor domain, a protease domain, and one kringle structure homologous to those of plasminogen and t-PA. In the presence of a fibrin clot, scuPA, but not tcuPA, induces fibrin-specific clot lysis.[38–41]

Staphylokinase (Sak) is a PA produced by *Staphylococcus aureus* strains that forms a 1:1 stoichiometric complex with plasmin that activates thrombus-bound plasminogen.[42,43] As with SK, Sak is immunogenic, and patients may develop neutralizing antibodies.[44]

The major distinctions between PAs relate to their origin (antigenicity), half-life, potential for inducing a lytic state, and hemorrhagic potential (Table 112.3). PAs that are derived from a human protein (UK, alteplase, reteplase, saruplase, tenecteplase, lanoteplase) are minimally or nonantigenic, whereas those from a bacterial species, whether purified from the *Streptococcus* as SK, complexed with human plasminogen as anistreplase, or prepared

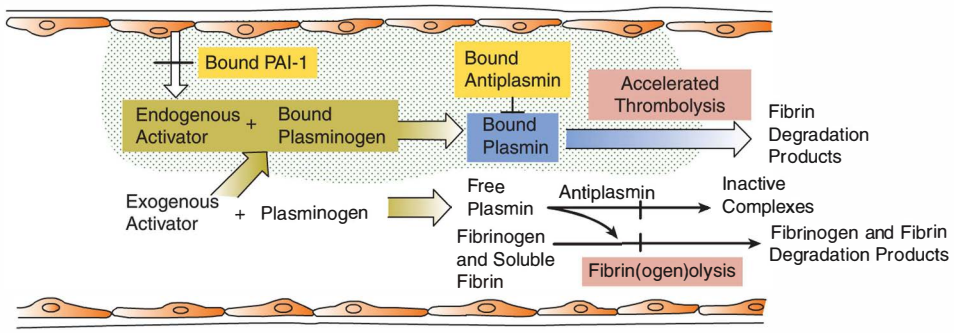

FIGURE 112.1 Molecular interactions of physiologic and therapeutic thrombolysis. Therapeutic administration of plasminogen activator accelerates thrombolysis. Free plasmin in the blood exceeds the capacity of antiplasmin to neutralize the protease activity, resulting in fibrinogen degradation and the so-called plasma proteolytic state. PAI-1, plasminogen activator inhibitor-1.

by recombinant technology from *Staphylococci* as Sak,[45] can induce antibody formation and an allergic response. Modified recombinant forms of Sak and SK with lessened antigenicity and retained thrombolytic potency have been developed.[46,47]

The half-life of each PA determines whether it can be administered as a bolus injection, short infusion, or continuous infusion. The most suitable agents for bolus injections are anistreplase (half-life, ~40 minutes),[48] reteplase,[49] tenecteplase,[50] and lanoteplase,[51] and the least suitable is alteplase (half-life, 5 minutes),[52] which best utilizes a continuous infusion for therapy. Clinical results suggest that some of the newer agents will have less of a plasma lytic state, for example, tenecteplase,[53] but to date, all PAs are associated with a significant bleeding risk. The rate of bleeding is roughly equivalent for all agents, except for the higher rate of intracranial hemorrhage (ICH) with t-PA[54] or t-PA mutant derivatives,[49,55] relative to results using SK. The anticipation of greater safety with a new PA, based on biochemical studies, must be considered cautiously, because no PA has yet been shown to be free of hemorrhagic risk.

Recombinant forms of UK,[35] saruplase (pro-UK, scu-PA),[36] Sak,[37] and BAT-PA[33] (from the salivary gland of *Desmodus rotundus*), chimerics of t-PA and pro-UK,[56] and bifunctional agents composed of antifibrin or antiplatelet antibodies complexed to PA[57] are at various stages of clinical testing. Desmoteplase has marked homology with rt-PA and a much longer half-life of 21 minutes,[58] but it showed no clinical benefit and increased ICH (3.5% to 4.5%) in acute stroke patients at 3 to 9 hours after symptom onset.[34] A recombinant plasminogen that is activated by thrombin, rather than by a PA, has been developed as an agent that would work only at sites of fresh thrombus formation.[59] It has an injection half-life of >4 hours, and early studies have not shown increased ICH.[60,61]

Direct-Acting Thrombolytics

An old agent has recently been revisited as a therapeutic thrombolytic: the direct-acting thrombolytic enzyme plasmin.[62,63,64] The potential for safety is based upon regional administration of the agent by catheter. PAs are administered in sufficient concentration that the inhibitory capacity of PAI-1 is overwhelmed, so they lyse hemostatic plugs and cause hemorrhagic complications, even after local (catheter) delivery (FIGURE 112.3, middle-left and bottom-left panels). In contradistinction, plasmin is rapidly and irreversibly neutralized by α_2-antiplasmin,[65] so it lacks thrombolytic activity upon systemic infusion (FIGURE 112.3, middle right). However, plasmin binds to and dissolves thrombus when administered by catheter, and, after thrombolysis, plasmin would be quickly neutralized by α_2-antiplasmin, thereby preventing its circulation to sites of vascular injury, and avoiding bleeding

Table 112.1

Principal biologic effects of thrombolysis therapy

Clinical Result	Process	Cellular and Biochemical Events
Therapeutic	Thrombolysis	Degradation of fibrin and disruption of platelets in the thrombus, restoration of blood flow
Side effect	Systemic lytic state	Plasma fibrinogenolysis and derangement of platelet function
Complications	Bleeding	Degradation of fibrin in hemostatic plugs and of matrix in abnormal vessels, plus blood hypocoagulability
	Rethrombosis	Persistent local vascular lesions plus permissive status of blood coagulation

Table 112.2

Food and drug administration approvals of PA

Agent	Clinical Indication	FDA-Approved Regimen	Common Usage
SK (Streptase)	Acute MI	IV or IC	Used primarily by IV route
	PE	IV over 12 h	Effective given for shorter courses, even 2 h
	DVT	IV for up to 36 h	Shorter infusions safer, for example, over 18 h
	PAO	IV	IV route not as effective as regionally
	Thrombosed arteriovenous cannulae	Local installation	
Reteplase (Retavase)	Acute MI	Two bolus injections 30 min apart	Approved, 1999
	PAO	Not approved	Usage "off-label" regionally
Alteplase (Activase)	Acute MI	3 h or 90 min	Accelerated dosage used most often
	Acute ischemic stroke	90 mg over 1 h	Limited usage, as must be applied within 3 h of onset
	PE	100 mg/2 h	UK over 2 h, equal efficacy
Anistreplase (Eminase)	Acute MI	30 U over 2–5 min	Infrequently used
Tenecteplase (TNKase)	Acute MI	Single bolus, weight adjusted	Approved, 2000
UK (Abbokinase)	PE	12-h IV infusion	Agent not currently available
	Acute MI	Intracoronary only	Agent not currently available
	Thrombosed central line or shunt	5,000 U in 1 mL	Agent not currently available

PE, pulmonary embolism; IV, intravenous; MI, myocardial infarction; PAO, peripheral arterial occlusion; DVT, deep-vein thrombosis; IC, intracoronary.

that could result from hemostatic plug degradation.[66,67] Animal studies support this hypothesis, showing that more than six-fold the therapeutic dose of plasmin does not induce bleeding, whereas t-PA causes bleeding at the therapeutic dose, and even at dosages as low as 25% of the optimal therapeutic amount.[68] Thrombolysis under conditions of limited plasminogen content (restricted blood flow) is superior following plasmin compared with t-PA.[66] Plasmin is safe and efficacious in preclinical models of cerebral artery occlusion,[69] has been assessed in patients with thrombosed hemodialysis shunts,[70] and is currently in clinical trial in patients with peripheral arterial or graft occlusion (NCT 00418483)[71] and acute ischemic stroke (NCT 01014975).[72]

Other direct-acting thrombolytic agents are shown schematically in FIGURE 112.4.[63] A truncated plasmin, "miniplasmin," consists of the plasmin serine protease domain and kringle 5[73,74] and is inhibited by α_2-antiplasmin 100 times slower than is plasmin; thus its principal inhibitor is α_2-macroglobulin.[75,76] Miniplasmin has shown efficacy in a canine femoral artery thrombolysis model[77] and in the middle cerebral artery ligation stroke model in mouse and hamster,[78] but there are no reports of this agent in human clinical trial.[63] Microplasmin is produced chemically by cleavage of the kringle domains from the serine protease domain[79] or by recombinant technology.[80] Microplasmin does not bind to fibrin and is inhibited by α_2-antiplasmin 100 times slower than is plasmin.[81] Microplasmin showed rapid thrombolysis but no clinical benefit in patients with peripheral arterial or graft occlusion,[82] and trials in ischemic stroke have been curtailed after a phase II study[83]; studies in vitreoretinal disease have shown positive results.[84] Delta-plasmin is a recombinant molecule composed of plasmin kringle 1 spliced to the serine protease domain; it retains the same fibrin-binding capacity and fibrinolytic effect as plasmin and is likewise rapidly inhibited by α_2-antiplasmin.[85] Delta-plasmin has a similar safety profile as full-length plasmin in a preclinical model of bleeding[86] but has not yet been assessed in clinical trials.

A recombinant derivative of fibrolase (alfimeprase), isolated from the venom of the Southern copperhead snake, degrades fibrinogen and fibrin and is inhibited relatively slowly by α_2-macroglublin.[87] Alfimeprase showed promise in an early trial[88] in patients with peripheral arterial or graft occlusion, but results from a subsequent study were not better than placebo, and release of bradykinin from low molecular weight kininogen caused hypotension in some recipients.[89]

ADJUNCTIVE AGENTS AND APPROACHES

Inadequate response to PA therapy occurs if a thrombosed vessel does not manifest full reperfusion or if reocclusion quickly follows initial success. Generally, t-PA and recombinant derivatives have potent thrombolytic activity and achieve early vascular patency with relatively mild effects on blood coagulation, but are utilized along with anticoagulants to counteract any ongoing procoagulant state. PAs such as SK elicit a greater effect on plasma coagulation factors and reperfuse vessels more gradually but tend to maintain an anticoagulant state. Acknowledging that early and persistent patency is a principal objective of treatment, considerable effort has been directed to adjunctive management with antiplatelet agents and antithrombins.

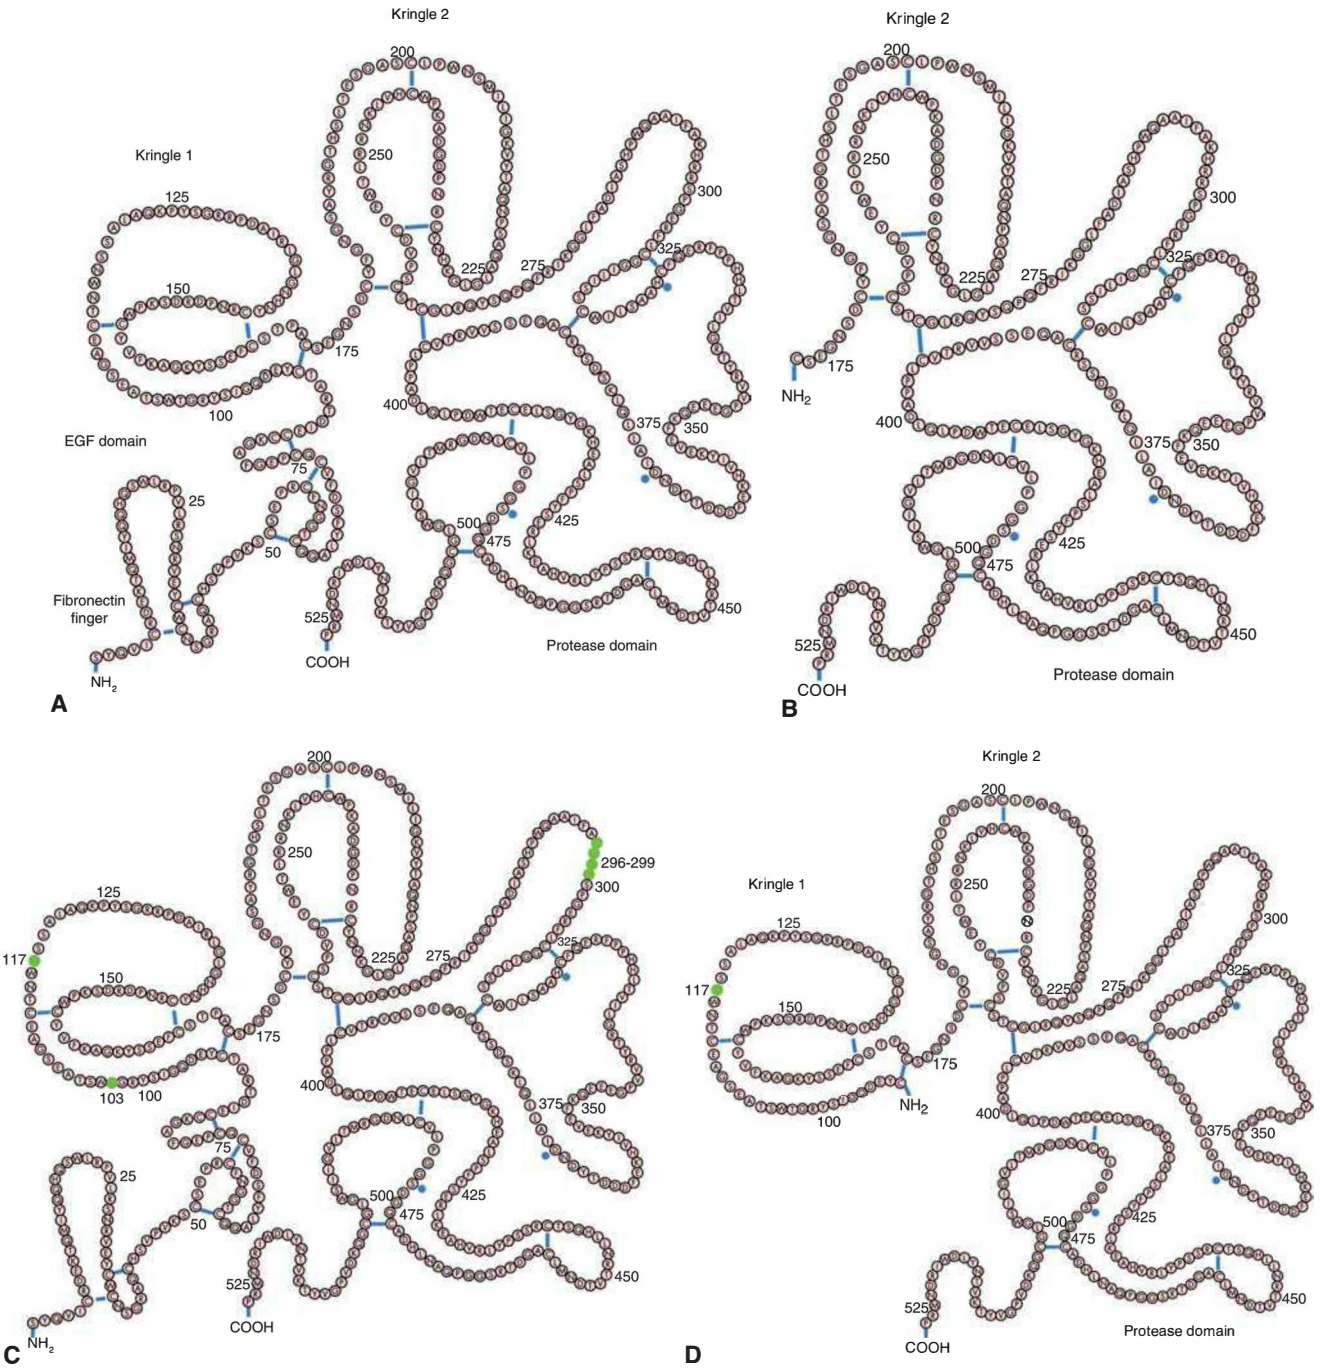

FIGURE 112.2 Schematic representation of t-PA and three mutant derivatives synthesized by recombinant technology. **Panel A** shows t-PA (alteplase), **panel B** shows reteplase, **panel C** shows TNK (tenecteplase), **panel D** shows lanoteplase. Antiplatelet Function Approaches

Aspirin

The first definitive demonstration of antiplatelet efficacy in the treatment of an acute thrombotic event was with the use of a simple aspirin regimen of 160 mg/day for 30 days to decrease mortality after acute myocardial infarction (AMI) (Second International Study of Infarct Survival, ISIS-2).[90] In patients treated within 6 hours, aspirin reduced the 35-day mortality by 23%, equal to the reduction achieved by SK alone, and both agents together had an additive effect amounting to a 39% relative risk reduction compared to patients who received neither SK nor aspirin. Clopidogrel, an oral antiplatelet agent that blocks platelet activation and aggregation by inhibiting the

$P2Y_{12}$ adenosine diphosphate receptor, was randomly added to a fibrinolytic and aspirin regimen versus placebo and showed a 36% reduction in the rate of death or recurrent ischemia and represents the current standard of care.[91]

Glycoprotein IIb/IIa Inhibitors

Effective GP IIb/IIIa inhibition can be achieved by the monoclonal antibody 7E3 (Abciximab [Centocor Inc., Malvern, PA]) and by small molecule inhibitors, which effectively block fibrinogen binding to platelets and prevent the cascade of biochemical events leading to aggregation.[92–101] These agents are effective in preventing adverse outcomes after unstable angina and angioplasty,[102,103] and appropriate dosing of concomitant anticoagulant therapy prevents the excessive bleeding associated with these procedures.[104] The rationale for combining GP IIb/IIIa inhibition with fibrinolytic therapy would be that passivation of arterial wall by a long-acting or bound GP IIb/IIIa inhibitor could prevent vascular reocclusion, especially that which follows t-PA therapy.[105] Early angiographic patency studies showed that abciximab combined with low-dose PA led to higher rates of full recanalization (thrombolysis in myocardial infarction [TIMI] 3 flow), with one trial showing a higher rate of bleeding using the combination.[106,107] Concern for greater bleeding risk led to large trials comparing reduced doses of PA combined with a GP IIb/IIIa inhibitor. In the Assessment of the Safety and Efficacy of a New Thrombolytic Regimen (ASSENT)-3 mortality trial, reduced-dose tenecteplase plus abciximab and low-dose unfractionated heparin (UFH) showed similar mortality rates compared with tenecteplase plus low molecular weight heparin (LMWH) or UFH,[108] although the combination was associated with significantly higher rates of major bleeding and requirement for transfusion in patients older than 65 years. The GUSTO-V trial showed no difference in mortality between low-dose reteplase plus abciximab versus standard reteplase, but there was a higher rate of ICH in patients older than 75 years of age in the combination therapy group.[109] Meta-analysis shows no benefit of adding abciximab to fibrinolytic regimens,[110] and the 8th Conference of the American College of Chest Physicians (ACCP) guidelines recommend against the combination.[111]

Several phase II trials in patients with ischemic stroke have looked to the combination of attenuated-dose PA and GPIIb/IIIa antagonists in order to increase vascular patency and lower the risk for ICH. The CLEAR trial[112] randomized 94 patients to low-dose alteplase (0.3 to 0.45 mg/kg) plus eptifibatide (75 μg/kg bolus, then 0.75 μg/kg/min infusion for 2 hours), versus standard intravenous alteplase (0.9 mg/kg). The primary safety endpoint was rate of ICH, and there was no suggestion of more bleeding in the combination arm, although efficacy analysis suggested slight superiority of standard-dose alteplase.

Anticoagulants

Heparin

UFH was included in fibrinolytic regimens, and the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) study[113] documented that early intravenous heparin is no more effective than delayed subcutaneous heparin in patient survival at 30 days after AMI following fibrinolysis with SK or alteplase. Analysis of 21 small randomized trials demonstrated improved survival (11.4% vs. 14.9% in-hospital mortality following treatment with a fibrinolytic agent plus heparin versus placebo).[114] However, the large trials that combined fibrinolytic therapy with aspirin and heparin or placebo showed the benefit of adding heparin was minimal (in-hospital mortality 6.8% vs. 7.3%).[115] Coronary artery patency studies show that intravenous heparin, in addition to SK or APSAC (plus adequate aspirin), does not increase vascular patency[116,117] over fibrinolytics alone, but does increase bleeding complications.[117] The rate of ICH is 0.92% to 2.8% with accelerated t-PA regimens combined with intravenous heparin at 5,000 units bolus followed by 1,300 U/h, but are reported to be lower (0.7% to 1.16%) using a reduced heparin infusion rate of 1,000 U/h.[118]

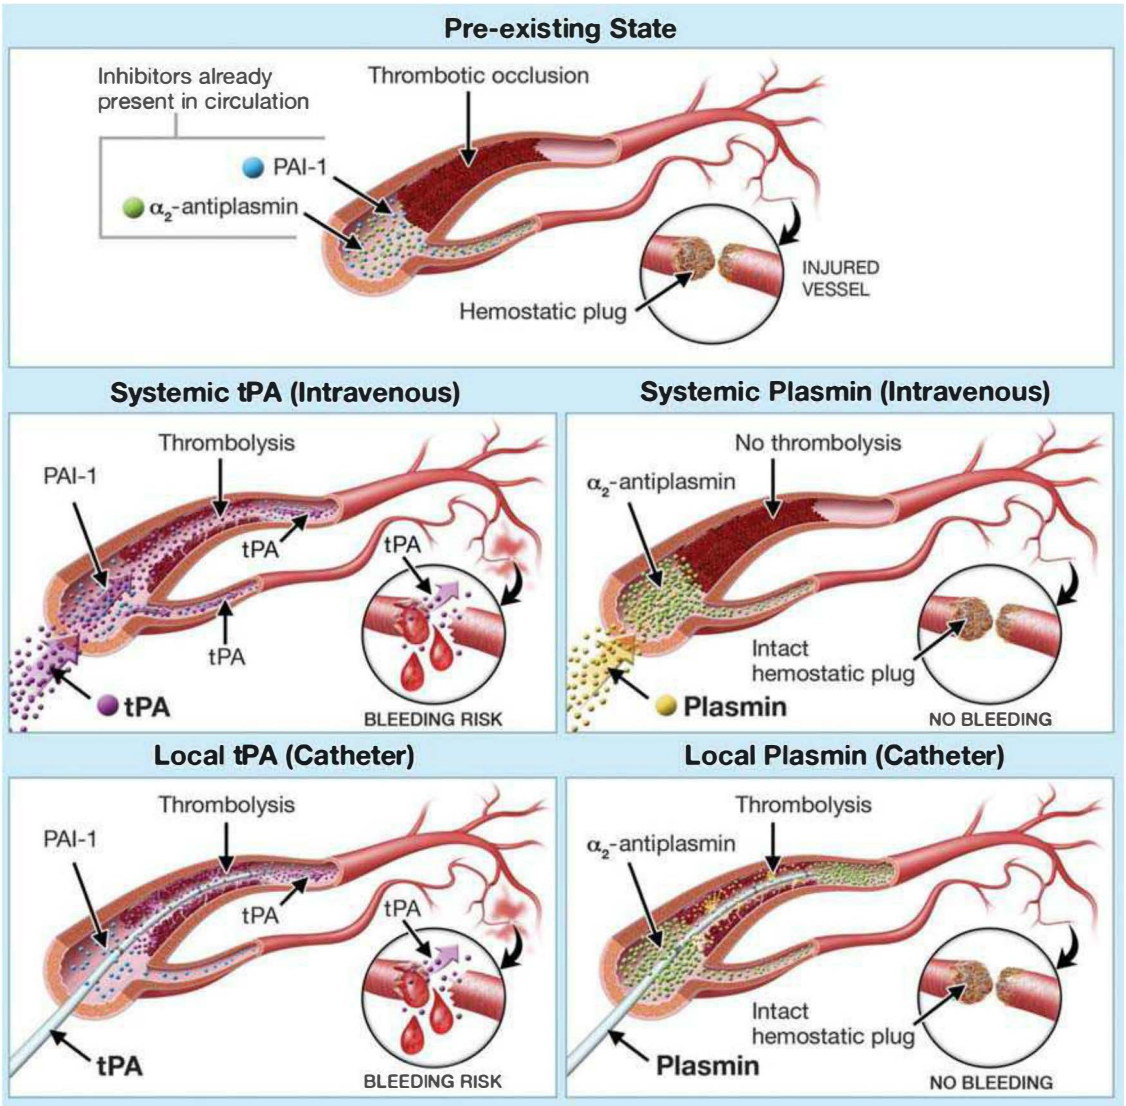

FIGURE 112.3 Modes of action of plasmin and t-PA on vascular thrombi and hemostatic plugs at vascular injury sites, after intravenous or catheter administration. (Reproduced from Marder VJ. Historical perspective and future direction of thrombolysis research: the re-discovery of plasmin. *J Thromb Haemost* 2011;9(Suppl 1):364–373, as modified from Marder VJ, Novokhatny V. Direct fibrinolytic agents: biochemical attributes, preclinical foundation and clinical potential. *J Thromb Haemost* 2010;8:433–444.) **Top panel**: Thrombus occludes an artery or vein and a hemostatic plug is present at a site of vascular injury. Inhibitors of plasmin (α_2-antiplasmin) and of t-PA (PAI-1) in the circulation are shown as *green* and *blue spheres*, respectively. **Middle panels**: Systemic delivery of t-PA exceeds the inhibitory capacity of PAI-1, allowing it to reach and dissolve thrombus; t-PA also reaches and dissolves hemostatic plugs, which can result in bleeding. Plasmin delivered systemically is safe but ineffective, as it is neutralized by α_2-antiplasmin. **Bottom panels**: Catheter delivery of t-PA is effective for dissolving thrombi, but t-PA enters the circulation despite its "local" administration and can cause bleeding. Catheter delivery of plasmin induces thrombolysis. Plasmin that enters the circulation after thrombolysis is rapidly neutralized by α_2-antiplasmin, thus preventing lysis of hemostatic plugs and avoiding hemorrhage.

The benefit of UFH depends on ASA use and dosage: when the dosage of aspirin is 160 mg/day or more, the addition of heparin produces little or no improvement of patency,[119–121] but with 80 mg/day or less of aspirin, heparin exerts a markedly improved vascular patency.[122,123] In spite of these trials, the recommendation of the ACCP is to use weight-adjusted heparin with t-PA and also suggests weight-adjusted intravenous or subcutaneous UFH with SK.[111]

Low Molecular Weight Heparin

The ASSENT-3 PLUS trial,[93] which assessed LMWH versus UFH in combination with tenecteplase, favored LMWH in the composite efficacy endpoint (mortality, reinfarction, ischemia) offset by a higher rate of ICH for LMWH. The ExTRACT-TIMI 25 trial randomized more than 20,000 patients with acute MI treated with thrombolytic therapy to enoxaparin versus UFH,

NAME	SCHEMATIC	MASS (kDa)	FIBRIN BINDING	INHIBITOR
Plasmin		82	Yes	Very fast (α2-antiplasmin)
Mini-plasmin		37	Yes	Fast (α2-macro-globulin)
Micro-plasmin		26-29	No	Fast (α2-macro-globulin)
Delta-plasmin		37	Yes	Very fast (α2-antiplasmin)
Alfimeprase		23	No	Fast (α2-macro-globulin)

FIGURE 112.4 Direct-acting thrombolytics. (Modified from Marder VJ, Novokhatny V. Direct fibrinolytic agents: biochemical attributes, preclinical foundation and clinical potential. *J Thromb Haemost* 2010;8:433–444.) SP, serine protease; K, kringle; MP, metalloprotease. *Small circles* on kringles represent lysine-binding sites. Diamonds represent carbohydrate, which are present only on plasmin. The likely main inhibitor of microplasmin is considered to be α_2-macroglobulin, given the absence of kringles.

and the results showed improvement in the net composite endpoint (30-day death, nonfatal MI, major bleeding) after enoxaparin treatment (11% vs. 12.8%).[124] Patients older than 75 years, or with impaired renal function, had increased bleeding complications. The current ACCP recommendation favors the use of enoxaparin over UFH in patients younger than 75 with preserved renal function.[111] The use of fondaparinux, an indirect thrombin inhibitor that selectively binds fXa, is not superior to UFH when combined with fibrin-specific PA therapy for the treatment of ST-elevation-MI.[125]

Antithrombin-Independent Anticoagulants (Hirudin and Related Agents)

Among the newer potential adjunctive agents, two groups have received the most attention: the hirudin family of small molecule inhibitors of thrombin and argatroban.[94–97] Pilot studies in patients with AMI showed encouraging increases in 90-minute patency rates with hirudin rather than with heparin,[126–128] but the relatively high dosages of anticoagulant resulted in unacceptable rates of ICH.[129–131] The advantages in the use of a direct thrombin inhibitor over indirect antithrombin include the inhibition of thrombin-mediated platelet activation and the capability of inactivating thrombin bound to fibrin derivatives. With a scaled-back dosage regimen of anticoagulant in patients receiving t-PA or SK along with aspirin, a large patient trial of 3,002 patients (TIMI-9B) showed no significant difference in clinical outcome using heparin or hirudin.[132] A patency study of 412 patients showed significantly greater TIMI-3 patency at 90 minutes (48% vs. 35%) and less bleeding using Hirulog (bivalirudin) rather than heparin after SK therapy.[133] More emphatically, retrospective analysis of the GUSTO-IIb trial[134] showed that hirudin had a dramatic mortality benefit over heparin in AMI in the patients treated with SK but not in the patients treated with t-PA. It is possible that the relatively high 90-minute patency rate attained with t-PA plus heparin and aspirin approaches a maximal response, whereas the slower reperfusion that occurs with SK plus heparin and aspirin can be ameliorated by the more effective anticoagulant action of hirudin. A definitive study of 17,000 patients with AMI (Hirulog Early Reperfusion/Occlusion 2) assessed whether such increased coronary artery patency is translated to a lower mortality using Hirulog rather than heparin (plus aspirin) before SK therapy.[135] Despite a higher 90-minute patency rate compared with heparin, there was no difference in mortality, and a slight (insignificant) increase in ICH occurred with bivalirudin use. Hirudin or bivalirudin is indicated in combination with fibrinolytic therapy in patients with heparin-induced thrombocytopenia (see Chapter 108).

OTHER MODALITIES TO MAXIMIZE THERAPEUTIC EFFECT OF THROMBOLYTICS

Prehospital Administration of Agent

Since the Fibrinolytic Therapy Trialists collaborative study established the time to reperfusion as a crucial determinant of mortality benefit to any intervention in AMI,[7] efforts to deliver therapy as near to the onset of symptoms have been undertaken. Several trials of prehospital treatment with fibrinolytic therapy have demonstrated a shortened time to definitive therapy and trends toward decreased mortality. The Early Retavase-Thrombolysis in Myocardial Infarction 19 study showed delivery of bolus reteplase produced a decrease in time to initial treatment of 32 minutes.[136] The ASSENT-3 PLUS trial analyzed a prehospital strategy of delivering fibrinolytic therapy, showing 53% of patients were able to receive treatment within 2 hours of symptoms if delivered in the field.[137] When compared with percutaneous coronary intervention (PCI), prehospital fibrinolysis in patients with symptom onset of <2 to 3 hours had equivalent 30-day mortality.[138,139]

Plasminogen Supplementation

Because fibrinolysis depends on conversion of plasminogen to plasmin, the rate is determined at least in part by the plasminogen concentration incorporated into a clot.[140] The decrease in plasma plasminogen varies according to the type of PA that is administered, decreasing by 80% with SK,[141] by 50% to 75% with rt-PA,[141–143] and by 10% to 20% with Sak or TNK.[142,143] Enrichment of plasminogen enhances the thrombolytic rate

in vitro[144] and in animal models,[145] but despite the theoretical advantage of supplemental plasminogen administration, clear-cut clinical benefit has not been obtained.[146–148]

Ultrasound

Ultrasound has been applied to thrombolysis, alone by remote or direct application, and with or without targeted delivery of microbubbles.[149] Direct application by thin wire[150] is effective but less amenable for many thrombi, and appropriate conditions of frequency and energy must be utilized to disrupt and disintegrate clots.[151] Percutaneous, transvascular ultrasonic disruption of a femoral artery thrombus has been reported in animals[152,153] and patients.[154] Experiments suggest that transcutaneous ultrasound may induce thrombolysis when combined with systemic infusion of microbubbles, even in the absence of PA administration[152]; another potential mechanism of action may involve accelerated transport of plasminogen into the thrombus.[155] Ultrasound accelerates recanalization induced by systemic rt-PA in stroke patients.[156] The phase II CLOTBUST trial randomized patients with ischemic stroke to t-PA with or without continuous 2 MHz transcranial Doppler ultrasound, observing complete early recanalization or significant clinical recovery at 2 hours in 49% of treated patients versus 30% of controls ($P = 0.03$), but with no clinical difference at 24 hours and no difference in ICH (4.7% in both arms).[157] Optimism for improved results with better methodology is anticipated upon further work in this field,[158] which has even been applied with an intravascular device for effective lysis of dural sinus thrombosis, even in the face of preexisting subarachnoid and intraparenchymal hemorrhages.[159]

Catheter-Directed (Regional) Infusion

A recurrent issue concerns the administration of PA directly through a catheter onto or into a thrombus. The rationale for such regional therapy is compelling for arterial occlusions, because the thrombus is usually localized to a single vessel downstream from the catheter tip, and the catheter also provides a means for angiographic documentation of progress. Regional treatment of arterial thrombi does achieve better thrombolysis than systemic therapy, but activity of the PA is not restricted to the region in question. During the period of infusion, the lytic state may be comparable to that following systemic administration, and bleeding or ICH may complicate therapy.[160] Local therapy for venous thromboembolic disease achieves an impressive degree of vascular reperfusion,[161–163] although bleeding complications, including ICH, are not avoided.[164] Local intraarterial (IA) administration of fibrinolytics for the treatment of acute ischemic stroke has been studied in randomized trials.[165] Meta-analysis of five randomized trials of 395 patients treated with IA t-PA, UK, or pro-UK found an increased rate of complete recanalization (19% vs. 1.4%) versus controls as well as a doubling of beneficial neurologic outcomes.[166] There was an increased risk of symptomatic ICH with IA fibrinolysis, but no difference in overall mortality.[166] An approach of IV followed by IA delivery of rt-PA (IMS trials) is under assessment,[167] including a trial that combines IB/IA rt-PA with catheter-applied ultrasound.[168]

The main decision about regional treatment is the clinical exigency of the patient. For example, regional infusion into the coronary artery may dissolve clots more effectively, but systemic administration is more efficient for first-line treatment of patients with MI. Still, with maximization of effort such as has been applied to early angioplasty for AMI,[169] mechanical revascularization therapy rendered the use of local coronary artery delivery of thrombolytic agent obsolete.[170] Regional treatment of slower progressing illnesses such as peripheral arterial occlusion (PAO) and especially deep-vein thrombosis (DVT) and occluded central venous access devices is attractive. Catheter-directed therapy (CDT) for DVT applies multiple approaches to recanalize the thrombosed vessel, in addition to local PA infusion, including thrombectomy, thrombus disruption, angioplasty, and stent placement, an approach that has been termed "minimally invasive endovascular strategies."[171] Patency rates are high (up to 70%),[172,173] although a direct comparison with IV PA administration, which induces a 45% to 50% recanalization rate,[174] has never been performed. The CDT approach likely provides a better outcome in preventing the postphlebitic syndrome[175] and in managing difficult cases of DVT such as in the May-Thurner syndrome.[176] In the CaVenT study,[175] the 6-month iliofemoral patency rate was 66% using CDT versus 47% with conventional anticoagulant therapy ($P = 0.012$), and the 24-month incidence of the postphlebitic syndrome was 41% for CDT versus 56% for anticoagulant therapy ($P = 0.047$). Clinically relevant bleeding events occurred in 9% of patients, noted as an "acceptable" complication rate, but one that still merits careful attention to contraindications to such therapy.

Endovascular intervention in acute ischemic stroke, aiming to mechanically extract an occlusive thrombus, may be a useful adjunct ("rescue") following incomplete intravenous or IA thrombolysis.[177] In the RECANALISE trial, a prospective registry trial that compared outcomes using systemic t-PA versus systemic t-PA plus mechanical thrombectomy demonstrated improved functional outcome with the combined approach, with equivalent rates of ICH.[178] A multitude of novel retrieval or combined stent/retrieval devices has been manufactured and approved for clinical use in acute thromboembolic stroke. While high recanalization rates of 50% to 80% can be achieved, functional benefit is not universal, at least partly due to their use after delay of up to 8 hours after stroke onset.[166] Furthermore, despite high rates of recanalization, there is a 26% to 36% incidence of symptomatic ICH, and about one-third of cases end in death.[17] As for the treatment of PAO and DVT, CDT for stroke applies a multitude of recanalization approaches ("multimodal reperfusion therapy"),[179] including IA agent delivery,[165] clot retrieval,[177] ultrasound,[157] stent placement,[180] and mechanical disruption.

EFFECTS OF THROMBOLYTIC TREATMENT ON THE BLOOD

The lytic state is a general description of the effects of PA therapy in the circulation[181] (Table 112.4), beginning with a shortening of the euglobulin lysis time, a test that measures free activator. Laboratory parameters reflect the biochemical events that culminate in the degradation of plasma fibrinogen and a hypocoagulable state. The simplest definition of the lytic state is a decrease in plasma fibrinogen that is not due to laboratory artifact,[3] such as contamination of the sample with heparin. Platelet glycoprotein degradation may cause

Table 112.4

Development of the plasma proteolytic (lytic) state

Biochemical State	Laboratory Finding
Circulating plasminogen activator	Short euglobulin lysis time, platelet hyperreactivity
Plasminogen activation	Decreased plasminogen
Antiplasmin inhibits plasmin	Plasmin–antiplasmin complexes
Free plasmin	Increased chromogenic activity
Degradation of fibrinogen	Decreased clottable protein, increased D-dimer
Platelet dysfunction	Decreased platelet aggregation
Hypocoagulable state	Prolonged coagulation tests

decreased platelet aggregation with ADP or ristocetin,[182–184] sometimes following an initial hyperaggregability.[184] Patients may experience sequential hypercoagulability and hypocoagulability or even the simultaneous occurrence of these opposite influences, depending upon the phase of lytic state that exists.

Predictive Value of Laboratory Changes

Laboratory markers of hematologic events that occur after PA administration have potential relevance for predicting vascular events (Table 112.5). According to the concept that the actions of PAs in the blood and on the thrombus are separate events,[4] successful dissolution of the pathologic thrombus through fibrin degradation would not necessarily correlate with the extent of fibrinogenolysis (lytic state). Likewise, bleeding that would result from hemostatic plug disruption or vascular matrix degradation could occur independently of changes in blood hemostatic measurements.[3,4] An ongoing question is whether the degree of hypocoagulable state contributes to hemorrhagic events. Proponents of this thesis would state that a PA with fibrinogen-sparing properties causes less bleeding, because the induced hypocoagulability is minimized. Similar questions have been asked about the effect of blood changes on vascular reperfusion and reocclusion. The potential markers of bleeding could include any change in the lytic state, including a decrease in plasminogen, hypofibrinogenemia, increased D-dimer, and deranged platelet aggregation. Markers of vascular reperfusion as a surrogate of clinical recovery could potentially utilize lytic state markers, including changes in platelet function, or an increased D-dimer level (FIGURE 112.1).[185]

Bleeding Associated with Thrombolytic Therapy

Although patients who receive thrombolytic agents are at risk of bleeding, such complications are at best only weakly correlated with laboratory parameters of the lytic state. For example, UK or SK treatment of pulmonary embolism (PE) or DVT regularly induces a marked lytic state, but the degree of such changes in fibrinogen concentration, plasminogen, or euglobulin lysis time is not significantly different in patients with or without a hemorrhagic complication.[174,186] The direct comparison of t-PA and SK in the TIMI trial–phase I showed significantly lower fibrinogen values with SK than with t-PA, but the incidence of major and minor bleeding complications was the same with both treatments.[187] Furthermore, patients with ischemic (thrombotic) or hemorrhagic cerebrovascular accident (CVA) who were treated with t-PA had the same nadir concentration of fibrinogen.[188]

Table 112.5

Hematologic and vascular parameters of thrombolysis and potential for laboratory monitoring

Hematologic	Vascular	Potential Marker
Thrombolysis	Reperfusion	Hypofibrinogenemia, elevated D-dimer
Hemostatic plug or matrix disruption	Bleeding	Long bleeding time, hypofibrinogenemia
Hypercoagulable state	No reperfusion or occlusion	Increased prothrombin fragment 1+2, thrombin–antithrombin complexes, soluble fibrin
Hypocoagulable state	Late bleeding (with new injury)	Long bleeding time, persistent lytic state

Table 112.6

Rate of ICH in four studies of accelerated regimen alteplase (t-PA)

	GUSTO-I (1990–1993)		GUSTO-III (1995–1997)		COBALT		ASSENT-2	
	SK (17,804)	t-PA (9,039)	Reteplase (10,138)	t-PA (4,921)	Bolus t-PA (3,585)	t-PA (3,585)	Bolus tenecteplase (8,461)	t-PA (8,488)
Age <75 y	0.4	0.5	0.7	0.8	0.7	0.6	0.8	—
Age >75 y	1.2	2.5	2.5	1.7	3.6	2.6	1.7	2.6
Overall	0.5	0.7	0.9	0.9	1.1	0.8	0.93	0.94

GUSTO, Global Use of Strategies to Open Occluded Coronary Arteries; COBALT, Continuous Infusion Versus Double-Bolus Administration of Alteplase; ASSENT, Assessment of the Safety and Efficacy of a New Thrombolytic Regimen; SK, streptokinase; t-PA, tissue-type plasminogen activator.

The only predictive blood value for hemorrhagic complication during t-PA treatment is the plasma t-PA concentration (3.4 μg/mL in bleeders vs. 2.2 μg/mL; $P = 0.002$).[189] This suggests that t-PA has a direct effect on susceptible hemostatic plugs or vascular sites, more with higher concentrations, independent of changes in fibrinogen concentration. This effect helps to explain the higher rate of ICH with high therapeutic dosages of t-PA[190] and supports the concept that bleeding occurs independent of PA effect on blood coagulation, probably the result of action at sites of vascular injury or malformation.[4] A retrospective analysis of more than 40,000 patients in the GUSTO-I study found independent predictors of hemorrhage to be of older age, lighter body weight, female sex, and of African origin, rather than the degree of laboratory derangement.[191]

The template bleeding time is prolonged during thrombolytic therapy, either as a direct result of the PA or as a result of concomitant aspirin therapy, but there is no distinction in patients with or without hemorrhagic complication.[192] Thrombocytopenia of $<100^9$/L has been noted in 2.4% to 3.9% of patients undergoing coronary artery angioplasty and receiving abciximab, with approximately one-fourth of these patients having severe decreases of $<50^9$/L.[193] Thrombocytopenia was associated with more unfavorable outcomes, including bleeding episodes, and with lower baseline counts, increasing age, and decreased weight.

The occurrence of ICH with PA treatment is relatively infrequent but of great clinical importance in that more than 50% of patients have lethal outcomes or significant neurologic deficits. Although major hemorrhagic complications other than ICH are induced with approximately equal frequency by all of the PAs, the more potent agents such as t-PA have a consistently higher risk of inducing ICH. The reason is not clear; it is not likely to reflect the presence of a fresh hemostatic plug that is dissolved, but may be related to a vascular abnormality associated with amyloid deposition.[194] As with other bleeding complications, the degree of lytic state does not explain the event, as the fibrinogen level is the same in patients with ICH or with a thrombotic (ischemic) CVA.[188] Subcutaneous heparin added to aspirin during PA infusion increases the risk slightly (0.6% vs. 0.4%),[7] but the use of t-PA is the most important predictor,[54] along with age >65, weight <70 kg, hypertension on admission, and a prior history of transient ischemic attack or CVA.[190] A retrospective comparison of SK (41,000 patients), anistreplase (21,000 patients), and t-PA (41,000 patients) showed the incidence of ICH to be 0.2%, 0.6%, and 0.6%, respectively.[12] Recent observations of accelerated regimen t-PA versus SK, reteplase, or double bolus t-PA show an overall risk of approximately 0.8% for accelerated t-PA, with the risk in elderly patients (older than 75 years of age) being significantly higher (2.1%) (Table 112.6).[113,195,196]

Vascular Patency and Reocclusion

Laboratory results also do not predict vascular reperfusion or degree of patency. A reasonable hypothesis for noninvasive measurement of successful thrombolysis would be to measure plasma levels of crosslinked fibrin-degradation products (FDPs), but the data so far are not conclusive, with some showing high predictability for successful vascular reperfusion[197] whereas others fail to document such a correlation.[198] In the Urokinase Pulmonary Embolism Trial (UPET) study in which a large systemic dose of UK was administered, there was no correlation of laboratory results with decrease of embolus size,[186] and DVT trials also showed a lack of correlation of venographic change after PA therapy with degrees of alteration in fibrinogen, thrombin time, plasminogen, and FDP.[174] Even intracoronary administration of SK for treatment of AMI showed no difference in nadir plasma fibrinogen in patients who did or did not reperfuse,[199] and similar measurements in patients with AMI receiving t-PA also failed to show a correlation with posttreatment coronary artery patency.[189] Although there is no universal agreement, the data do suggest that changes in blood coagulation or fibrinolytic assays following PA administration do not directly reflect the degree of thrombus dissolution.

Prediction of coronary artery reocclusion in an individual patient is problematic, but trials using t-PA provide instructive information.[189] Among 55 patients with reocclusion, the depth of fibrinogen nadir was less (120 vs. 180 mg/dL) than in patients whose vessels stayed patent. The data suggest that a more profound lytic state protects against reocclusion and may partially explain the lower tendency for reocclusion with SK, UK, and anistreplase than with t-PA.[113,200,201]

Laboratory Monitoring

The major role for monitoring thrombolytic therapy with a PA would be to document that a given dose of agent has achieved a lytic state. There is no need to regulate the dose of PA based

Table 112.7
Absolute contraindications to fibrinolytic therapy

Risk	Condition
Intracranial bleeding	Hemorrhagic CVA, intracranial neoplasm, recent cranial surgery or trauma (within 10 d), uncontrolled severe hypertension
Massive hemorrhage	Major surgery of thorax or abdomen (within 10 d), prolonged cardiopulmonary resuscitation, current severe bleeding site

on laboratory markers, as these values neither improve the chance of thrombolysis nor decrease the risk of hemorrhagic complication. The exception to this rule is for therapy using direct thrombolytic agents such as plasmin, for which there is a direct relation of dose with plasma fibrinogen, and an apparent threshold of plasma fibrinogen above which hemostatic safety is anticipated.[48]

MANAGEMENT OF BLEEDING COMPLICATIONS

Prevention of Bleeding

The absolute contraindications to PA therapy are those that may result in ICH or massive, life-threatening hemorrhage (Table 112.7). Decisions about PA use must weigh the expected severity of a complication with the potential benefit of accelerated thrombolysis. Therefore, some patients with obvious life-threatening thrombotic disease, for example, massive PE with profound shock or a large anterior wall AMI, may warrant potentially life-saving thrombolytic therapy even in the face of "absolute" contraindications. On the other hand, patients with a relatively less threatening thrombotic disease such as DVT would reasonably not receive PA therapy if there is a relevant history that significantly increases the risk of ICH, for example, transient ischemic attack, prior thrombotic stroke, or current hypertension. The risk of major bleeding after recent surgery of the head, thorax, or abdomen is obvious, but some clinical situations are associated with an increased risk of symptomatic but not serious bleeding, for example, patients with superficial wounds, arteriotomy or venotomy, active menses, and minor surgical or biopsy procedures. Elderly patients have a higher risk of bleeding, especially ICH, but they also have a higher risk of death from AMI than do younger patients. Therefore, the survival benefit in patients older than 70 years is relatively more than in patients younger than 60 years (80 vs. 25 lives saved per 1,000 treated).[90,202]

Management of Acute Bleeding and Posttreatment Surgery

In patients who have life-threatening bleeding or sudden emergencies that require surgical intervention, normal hemostasis can quickly be reestablished by discontinuing PA infusion, replenishing plasma fibrinogen with either whole plasma or cryoprecipitate, and providing fresh platelets to correct a prolonged bleeding time (Table 112.8). If the PA is not yet cleared from the circulation, fibrinolytic activity can be neutralized by infusion of fibrinolytic inhibitor such as ε-aminocaproic acid.

There are cases of coronary artery bypass graft surgery after SK usage, indicating that the operation can be performed immediately,[203,204] but that such therapy may result in bleeding complications and the need for blood transfusion.[205] Such results are relevant for invasive procedures after t-PA treatment as well, even if performed after a delay of 12 and sometimes 24 hours.[206] In the TIMI-IIA study,[189] angioplasty performed immediately after stopping t-PA resulted in a considerably greater need for blood transfusion than if performed 18 to 48 hours later. The reason for bleeding, coincident with interventional procedures after t-PA, which is cleared quickly from the circulation, is that the nadir fibrinogen remains low for 24 hours.[189] Plasma fibrinogen concentrations are ultimately achieved by hepatic synthesis of fresh fibrinogen, a process that requires 24 to 36 hours to accomplish, irrespective of the PA that was administered.

In anticipation of invasive surgery immediately after PA treatment, it is reasonable to replenish fibrinogen with cryoprecipitate because essentially no normal fibrinogen is present during SK[207] or t-PA infusion[208] and to restore platelet function with fresh platelet transfusion for up to 24 hours after PA administration. In addition, antifibrinolytic therapy should be administered prophylactically if activator is still circulating, an expected situation for variable times after the infusion is stopped.[209] Once a patient is to be treated with a PA, unnecessary trauma to the

Table 112.8
Hypocoagulable state induced by PA

	During Treatment	Immediately After Treatment	6–36 h After Treatment
Plasma fibrinogen	Low	Nadir	Recovery
Need for cryoprecipitate	Yes	Yes	Variable
Bleeding time	Long	Variable	Normal[a]
Need for platelets	Yes	Yes	No
Circulating PA	Present	Variable	Absent
Need for antifibrinolytics	Yes	Yes	Variable

[a]Unless aspirin has been administered, in which case the potential for bleeding persists.

patient should be avoided. One should administer medication by mouth or intravenously, but not intramuscularly. Phlebotomy sites should be compressed for 5 to 10 minutes, unnecessary arteriotomy should be postponed or avoided, and rough manual manipulation of the patient should be minimized. The use of intravenous or subcutaneous heparin in addition to aspirin and a PA increases the risk of bleeding.[90,118]

Bleeding that occurs during PA infusion should be managed appropriately with blood replacement and, if necessary and possible, by discontinuing the PA treatment. If bleeding is to be controlled immediately, the PA must be neutralized by a fibrinolytic inhibitor, and cryoprecipitate and platelets should be transfused. Recent and unhealed vascular trauma sites are susceptible to bleeding for approximately 10 days. Depending upon their location, a bleeding complication can be unimportant (ecchymoses and hematuria), bothersome and requiring transfusion (duodenal ulcer and accessible surgical site), or life-threatening (thoracic or cranial surgery, recent or even remote stroke).

Other Side Effects and Complications

Termination of treatment may be necessitated by allergic or pyrogenic side effects, which could also be managed with corticosteroids, antihistamines or adrenergic agents for anaphylaxis, and antipyretics for fever. Allergic reactions are three to five times more frequent using bacterial derived products than rt-PA-type derivatives, but patients who receive t-PA may rarely manifest allergic reactions such as bronchospasm or angioneurotic edema.[210,211] A second side effect is hypotension, especially in patients with AMI, occurring in approximately 12% of patients exposed to SK or anistreplase and 7% of those exposed to t-PA, in comparison with only 1.5% of patients not exposed to a PA.[212] Hypotension occurred in a significant proportion of patients treated during clinical trial of alfimeprase, which is known to cause bradykinin release.[88]

Embolic phenomena of clinical importance are rare in patients with venous thromboembolic disease who receive PA treatment. In the UPET trial,[186] recurrent PE occurred in 15% of patients who received either UK or heparin. A venous thrombus breaking off to become a fatal pulmonary embolus is distinctly unusual and may have alternative explanations other than lysis of a vulnerable, free-floating thrombus. On the other hand, distal systemic embolization from a cardiac source during PA treatment, although unusual, does occur, and up to 20% of patients with PAO are affected by sudden new ischemia of the distal extremity.[213] In this circumstance, the best treatment approach is continued local instillation of PA, which usually succeeds in dissolving the new embolus. Rarely, systemic treatment with PA results in cholesterol crystal embolization, usually in the setting of extensive preexisting atherosclerotic disease.[214]

CHAPTER

113

Anticoagulant and Procoagulant Proteins in the Animal Kingdom

ANGELINA WEI LING TAN, SHIYANG KWONG, AND R. MANJUNATHA KINI

Blood circulation has a crucial role in the survival of vertebrate animals, including man. It transports oxygen and nutrients to every tissue and organ and carries waste products and carbon dioxide to be removed via the liver, kidneys, and lungs. It also has a vital role in defense against a wide range of pathogens by recruiting leukocytes and other immune cells to the appropriate site in case of a pathogen attack. Thus, any problem with the hemostatic system can lead to death or severe debility, and therefore, it is normally tightly regulated by a complex system of proteins and cells that prevent blood loss from injuries or major blockages by pathologic thrombi and emboli.

Various animals have developed mechanisms to target the hemostatic system and exploit this vulnerability for their own ends. In some species (e.g., snakes), such mechanisms are used to immobilize and kill the prey/victim, and these are also used as defensive strategies against attacks by larger animals. In others (e.g., leeches, or insects such as mosquitoes and ticks), they are used to provide a continuous supply of blood as food. In all these animals, the mechanisms have evolved to perfection over millions of years, in parallel with the development of their hosts, to allow their survival. Since many of the components present in venom and saliva target critical hemostatic pathways, they have been of great interest in basic research into the mechanisms of these pathways, as well as in potential therapeutic applications to modify disease. Over the last three to four decades, due to the efforts of scientists from various backgrounds including biology, protein chemistry, molecular biology, pharmacology, hematology, and structural biology, significant progress has been made in understanding the structure–function relationships, as well as the mechanism of action of a number of exogenous factors from various animals, that affect blood coagulation. These exogenous factors have contributed significantly to the development of research tools as well as providing new therapeutic agents. In this chapter, we describe anticoagulant and procoagulant proteins that have been reported from the animal kingdom. Their mode of inhibition or activation of the blood coagulation cascade together with their structure–function relationships is also discussed.

ANTICOAGULANTS

Anticoagulants may inhibit the blood coagulation cascade through either direct or indirect mechanisms. In nature, animals make use of anticoagulants to their advantage, to kill their prey or to feed off their hosts. As these anticoagulants evolved independently and for different purposes, they differ greatly in function and structure.

Anticoagulants from Snake Venoms

Snakes feed on a variety of animals, including snails, fishes, frogs, toads, lizards, chickens, mice, rats, and even other snakes. As they lack the ability to tear apart the flesh of their prey, they resort to swallowing them whole. Hence, the venoms of snakes have evolved as a complex mixture of pharmacologically active proteins and peptides that have the ability to incapacitate, immobilize, and even digest their prey. These molecules include neurotoxins, cardiotoxins, hemotoxins, and cytotoxins, which target crucial physiologic systems of the prey as well as a number of hydrolytic enzymes including phospholipases, proteinases, and nucleotidases. Hence, exposure to these toxins during a snake bite often leads to symptoms ranging from tissue damage and paralysis to hypotension and hemolysis. Over the years, numerous toxins that contain anticoagulant properties have been isolated and characterized. These proteins and glycoproteins have molecular masses ranging from 6 to 90 kDa and inhibit blood coagulation through a variety of mechanisms. They can be classified under enzymatic or nonenzymatic anticoagulant proteins. As not all of the mechanisms of these anticoagulant proteins are entirely well understood, further research of these proteins is essential to delineate their mechanism and structure–function relationships.

Anticoagulant Enzymes

Phospholipases A_2

Phospholipases A_2 (PLA_2) enzymes are esterolytic enzymes that specifically hydrolyze the *sn*-2 acyl bond of phospholipids, releasing lysophospholipids and fatty acids. Snake venoms are a rich source of these PLA_2 enzymes, and hundreds of them have been previously purified and characterized.[1,2] Approximately 13 kDa in size, they usually consist of 116 to 124 amino acid residues and have 6 to 7 disulphide bonds. Typically, the structure of PLA_2 enzymes comprises a core of three α-helices, a calcium-binding loop, and a β-wing composed of antiparallel β-sheets (FIGURE 113.1). Although they share this common scaffold with nontoxic mammalian enzymes, most snake venom PLA_2 enzymes are toxic and induce diverse pharmacologic effects, including cardiotoxic, myotoxic, neurotoxic, hemolytic, convulsive, anticoagulant, antiplatelet, and edema-inducing and tissue-damaging effects.[3,4] Based on their anticoagulant properties, PLA_2 enzymes have been classified into strongly, weakly, or nonanticoagulant enzymes.[5,6] Strongly anticoagulant PLA_2 enzymes inhibit blood coagulation below 2 μg/mL, whereas weakly anticoagulant enzymes inhibit between 3 and 10 μg/mL. Nonanticoagulant enzymes do not display anticoagulant activities even at 15 μg/mL. As many coagulation complexes

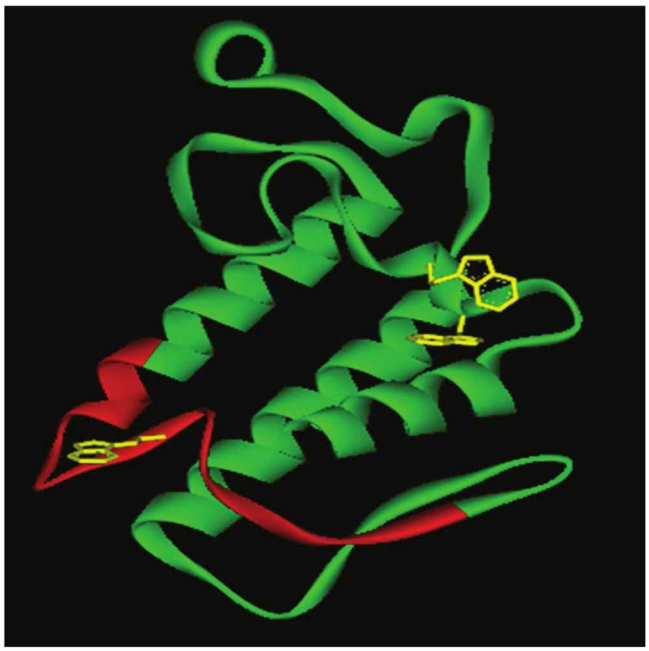

FIGURE 113.1 Three-dimensional structure of snake venom PLA_2. The ribbon model of *Naja naja* PLA_2 was generated from the PDB file #1POA. The predicted anticoagulant region is highlighted in *red*. Trp residues are shown in *yellow*. (Reprinted from Kini RM. Structure-function relationships and mechanism of anticoagulant phospholipase A_2 enzymes from snake venoms. *Toxicon* 2005;45(8):1147–1161, with permission.)

depend on phospholipids for their formation and function, it was thought that PLA_2 enzymes exhibit their anticoagulant function primarily through their ability to hydrolyze phospholipids. However, the results from the experiments to study the role of phospholipid hydrolysis in the anticoagulant effects of PLA_2 enzymes were contradictory. For example, several studies indicated that the enzymatic activity of PLA_2 enzymes is essential for their anticoagulant activities. (a) The modification of active site His48 by *p*-bromophenacyl bromide led to the loss of both enzymatic and anticoagulant activities. (b) The replacement of hydrolyzable phospholipids by nonhydrolyzable phospholipids led to loss of anticoagulant activities. (c) Longer times of incubation of PLA_2 enzymes with plasma led to increased phospholipid hydrolysis and clotting times. On the other hand, several other studies suggested that the enzymatic activity of PLA_2 enzymes is *not* essential for their anticoagulant activities. (a) The catalytic efficiency of anticoagulant PLA_2 enzymes did not correlate with their anticoagulant potency. (b) There is a lack of correlation between plasma lipid hydrolysis and anticoagulant effects of the PLA_2 enzymes. (c) The addition of antibodies to PLA_2-hydrolyzed phospholipids reversed the anticoagulant effects. (d) Chemical modifications have shown that the loss of enzymatic activity led to little effect on anticoagulant effects, and *vice versa* (for details, see review[7]). The controversies in the field were essentially due to two critical but wrong assumptions, namely, the anticoagulant mechanism of different PLA_2 enzymes is the same and the phospholipid requirements of different coagulation complexes are alike.

To resolve the controversies and decipher the mechanism of anticoagulant activity, three anticoagulant PLA_2 enzymes—CM-I, CM-II, and CM-IV from the venom of the black-necked spitting cobra (*Naja nigricollis*), were studied.[8] Based on their anticoagulant properties, CM-I and CM-II are classified as weakly anticoagulant enzymes, whereas CM-IV, which is at least 100-fold more potent than CM-I and CM-II, is classified as strongly anticoagulant enzyme.[9] As a first step, the coagulation complexes that are inhibited by these enzymes were identified using the "dissection approach" (see FIGURE 113.2), followed by their effects on reconstituted coagulation complexes. CM-IV was reported to inhibit the coagulation cascade at two different points—the extrinsic tenase complex as well as the prothrombinase complex.[10] Further studies have identified that while it inhibits the extrinsic tenase complex through a combination of enzymatic and nonenzymatic mechanisms, the inhibition of the prothrombinase complex, however, is independent of phospholipid hydrolysis.[11] This inhibition is achieved through competing with factor Va (FVa) in binding to factor Xa (FXa), hence blocking the formation of the prothrombinase complex. It forms a 1:1 complex with FXa, with a dissociation constant (K_d) of 500 nM.[12] On the other hand, CM-I and CM-II inhibits only at a single point in the coagulation cascade, at the extrinsic tenase complex, solely through enzymatic hydrolysis of phospholipids. Unlike CM-IV, CM-I and CM-II display no effect toward the prothrombinase complex.[13]

As mentioned previously, although PLA_2 enzymes possess similar folds and three-dimensional (3-D) structures, they display a vast array of biologic functions. This indicates that their structure–function relationships are subtle and complex. By a systematic analysis, the anticoagulation site was identified to be situated between residues 54 and 77 in strongly anticoagulant PLA_2 enzymes.[13] This predicted site was well supported by subsequent experiments.[9,14–16] This region is positively charged and is located on the surface of the molecule, thus accessible for interactions (FIGURE 113.1). This region contains four positively charged lysine residues that may play a role in intermolecular interactions.[9,16] In the case of protein CM-IV, a comparison of amino acid sequences with bovine FX, FV, prothrombin, and tissue factor (TF) revealed that half of CM-IV's anticoagulant region was homologous with the light chain of FVa and the other half with a section of TF.[11] These two sites are hypothesized to be responsible for targeting the prothrombinase and the extrinsic tenase complexes respectively.[17]

Metalloproteinases

Metalloproteinases are zinc-dependent endoproteolytic enzymes that cleave peptide bonds in the middle of the proteins. They form three different classes, P-I, P-II, and P-III, based on their domain structure and size.[18,19,20] The snake venom metalloproteinases exert digestive (of prey), hemorrhagic, procoagulant, anticoagulant, and antiplatelet effects.[18] Most snake venom metalloproteinases are α-fibrinogenases that selectively cleave the Aα chain of fibrinogen. They inhibit blood coagulation as they produce truncated fibrinogen, which is unable to form a fibrin clot as stable as the native fibrinogen. The structure–function relationships of these metalloproteinases with respect to their anticoagulant effects have not yet been studied.

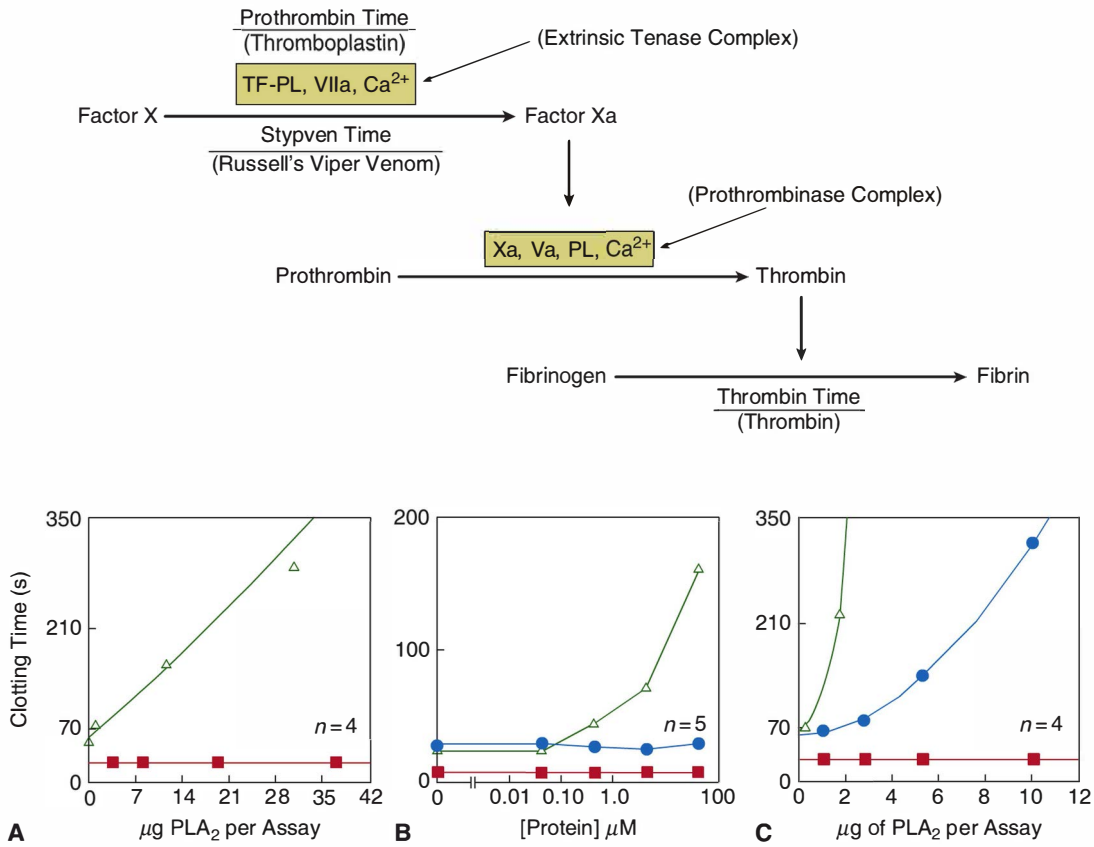

FIGURE 113.2 The dissection approach. This is a simple strategy designed to determine which particular step an anticoagulant is interfering with in the extrinsic coagulation pathway **(upper panel)**. It comprises three common clotting assays—prothrombin time, Stypven time, and thrombin time. The concept is if the cascade is initiated "upstream" from the point of inhibition, clotting times will be prolonged, whereas if initiated "downstream," clotting times will not be affected. In the example **(lower panels)**, the strongly anticoagulant CM-IV (*C*) prolonged the prothrombin time (Δ) and Stypven time (•), but not the thrombin time (❑). Hence, it can be concluded that CM-IV does not inhibit the conversion of fibrinogen to fibrin clot, but may affect either the prothrombinase complex alone or both the extrinsic tenase and prothrombinase complexes. In contrast, weakly anticoagulant CM-I (*A*) and a three-finger toxin, protein A (*B*) prolonged only the prothrombin time, but not the Stypven time and the thrombin time. These results suggest that these proteins affect only the extrinsic tenase complex but not the prothrombinase complex and the conversion of fibrinogen to fibrin clot. This strategy is applicable to any anticoagulant affecting the extrinsic coagulation cascade. (Reprinted from Kini RM, Banerjee Y. Dissection approach: a simple strategy for the identification of the step of action of anticoagulant agents in the blood coagulation cascade. *J Thromb Hemost* 2005;3:170–171, with permission.)

Serine Proteases

Protein C activators are the only serine proteases that indirectly inhibit coagulation. Under normal physiologic conditions, protein C is activated by thrombin and thrombomodulin to activated protein C (APC). APC exerts its anticoagulant activity by degrading FV/FVa and FVIII/FVIIIa. It also stimulates fibrinolysis by interacting with plasminogen activator inhibitor.[21] Protein C activators are approximately 36 to 40 kDa in molecular weight, and they activate protein C in the absence of Ca^{2+} with low salt concentrations.[22–24] A protein C activator isolated from the venom of *Agkistrodon contortrix contortrix* activates protein C through thrombomodulin-independent mechanisms.[22] The stretch of positively charged residues on its interfacial surface, together with three carbohydrate moieties surrounding the catalytic site, are pivotal in protein C recognition, binding, and activation.[25]

Nonenzymatic Anticoagulants

C-type Lectin-related Proteins

C-type lectins are calcium-dependent carbohydrate-binding proteins that agglutinate red blood cells. They usually exist as homodimers. On the other hand, C-type lectin-related proteins are usually heterodimers or oligomeric complexes of heterodimers, and they do not have lectin-like activity.[26,27,28] Anticoagulant C-type lectin-related proteins were one of the first few nonenzymatic proteins isolated and characterized from snake venoms.[17] From the venoms of the hundred-pace pit viper (*Deinagkistrodon acutus*) and Stejneger's bamboo viper (*Trimeresurus stejnegeri*), anticoagulant proteins that inhibit prothrombinase activation were isolated and purified.[29–32] Although they were shown to perform inhibition through nonenzymatic mechanism, details on their mechanism and structure–function relationships are still unclear. A specific FIX-binding protein

and FX-binding protein from the venoms of *Protobothrops flavoviridis* (formerly, *Trimeresurus flavoviridis*) and *D. acutus*, respectively, were isolated and characterized. Both are heterodimeric, with α- and β-chains, and both chains are structurally similar to C-type lectins. They were shown to bind and inhibit the coagulation factors FIX and FX respectively, with nanomolar and subnanomolar affinities. The dimeric interface created by domain swapping recognizes the Gla domain of FX and FIX.[33]

Another group of anticoagulant C-type lectin-related proteins interact specifically with thrombin/prothrombin. This includes bothrojaracin[34,35] from *Bothrops jararaca* and bothroalternin[36] from *Bothrops alternatus* venoms. Bothrojaracin inhibits thrombin directly through both exosite 1 and exosite 2, which accounts for its high affinity toward thrombin with a K_d of 0.6 nM. However, it does not bind to the active site of thrombin. Due to its binding to thrombin's exosite 1, it also inhibits FV activation by thrombin.[37] In prothrombin, bothrojaracin binds to partially exposed anion-binding exosite (pro-exosite 1) with a K_d of 175 nM, thus inhibiting the activation of prothrombin to thrombin.[38]

Three-finger Toxins

Three-finger toxins are a family of nonenzymatic proteins that are commonly found in the venom of snakes.[39] They range from 60 to 74 amino acid residues in length. Their structure is unique, with three β-stranded loops extending from a central core, which is held by four to five conserved disulphide bridges. This gives it an appearance of three extended fingers, hence its name. Despite the overall similarity in structure, three-finger toxins display a great diversity of biologic functions. Members of this family include α-neurotoxins,[40,41] κ-bungarotoxins,[42] muscarinic toxins,[43] fasciculins,[44] calciseptine,[45,46] cardiotoxins (cytotoxins),[47,48] dendroaspins,[49] and anticoagulant proteins.[50,51] An example of an anticoagulant three-finger toxin is the Hemextin AB complex, isolated from the ring-necked spitting cobra, *Hemachatus haemachatus*.[51] This complex consists of two subunits, Hemextin A and Hemextin B, and inhibits the extrinsic tenase complex with a K_i of 50 nM. Interestingly, subunit Hemextin B by itself does not display any anticoagulant effects, but instead synergistically enhances the anticoagulant effects of Hemextin A by forming a complex with it.[52]

Anticoagulants from Hematophagous Animals

In hematophagous organisms, blood meals from their hosts are crucial for survival. This process is not trivial as the hosts defend themselves by a variety of responses at the feeding site, which involves platelet activation and aggregation, local vasoconstriction, blood coagulation, and raising an immune response. To overcome such host responses, blood-feeding organisms produce a pharmacopeia of molecules in their saliva, from anticoagulants and platelet aggregation inhibitors to vasodilators, anti-inflammatory, and immunomodulatory molecules. The blood-feeding habit is found in several thousands of species in nature, and in arthropods alone blood-feeding habit has evolved at least 20 times independently, resulting in a vast molecular diversity of antihemostatic molecules. Thus, it is not uncommon to observe functional diversity among closely related proteins and functional convergence among structurally unrelated proteins. The saliva of these animals provides an excellent source of novel anticoagulant proteins and peptides, which differ in structure and mechanism of action. Based on this mechanism of action of the anticoagulants, they can be broadly classified into thrombin inhibitors, FXa inhibitors (FXaIs), extrinsic tenase complex inhibitors, and intrinsic tenase complex inhibitors.

Thrombin Inhibitors

There are several classes of thrombin inhibitors isolated from hematophagous animals (FIGURE 113.3). Each class of thrombin inhibitors shows distinct protein folds, and hence, they have evolved through convergent evolution. They also inhibit thrombin by different mechanisms.

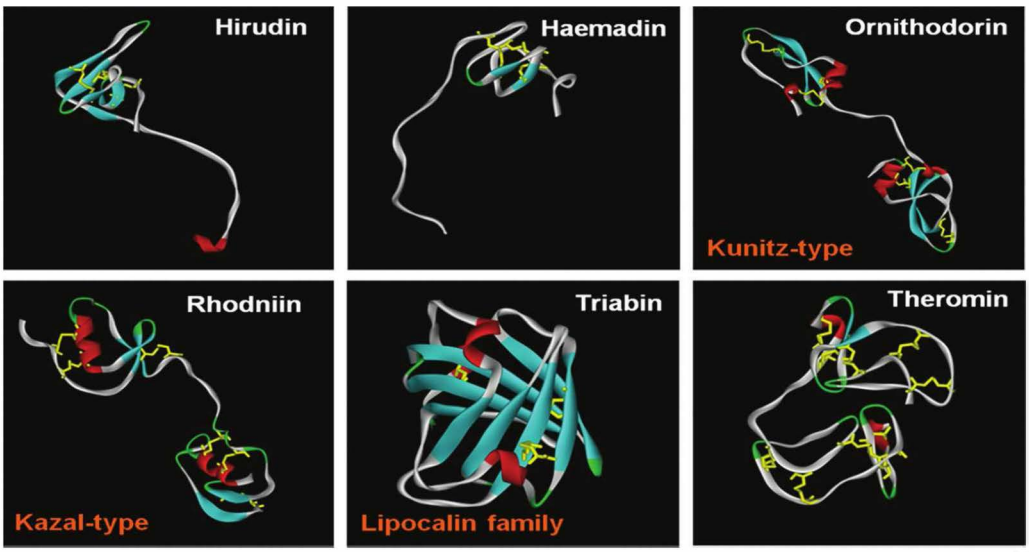

FIGURE 113.3 Structural diversity of thrombin inhibitors. Thrombin inhibitors have been isolated from a multitude of hematophagous animals. As the feeding habit of these animals evolved independently at least 20 times in over 15,000 species of arthropods in more than 400 genera, it is of no surprise that nature has produced such a wide array of thrombin inhibitors. As seen in the figure, although all six molecules inhibit thrombin, they come in different shapes and sizes, each binding to thrombin in their own unique ways. There are at least nine other structural classes of thrombin inhibitors whose 3-D structures are not yet known.

Hirudin

Hirudin, isolated from the medicinal leech, *Hirudo medicinalis*, is probably the most prominent and well-characterized thrombin inhibitor. Reported more than 100 years ago, hirudin is a 65-residue protein that is specific for thrombin, with a K_i of 22 fM.[53] A sulphated tyrosine (Tyr64) on hirudin has been identified to play a significant role in interactions with thrombin, which, when removed, results in a binding to thrombin 10 times weaker.[54] Hirudin's first three *N*-terminal residues bind to the hydrophobic pocket of thrombin's active site in a noncanonical form, through hydrogen bonds. The *C*-terminus on the other hand is rich in acidic residues and through specific electrostatic interactions binds to exosite-I of thrombin.[55–59] Thus, via these two interactions, hirudin inhibits specifically thrombin as a tight-binding inhibitor. Apart from hirudin, there have also been many inhibitors from other species of leeches that belong to this family of proteins that were subsequently isolated.[60,61]

Haemadin

Another molecule, haemadin, was also isolated from leeches. Found in *Haemadipsa sylvestris*, the Indian leech, haemadin is 57-amino acid residue in length, slightly smaller than hirudin.[62] It is a slow and tight-binding inhibitor of thrombin, with a K_i of 210 fM. Although haemadin's sequence similarity with hirudin is low, they share a common 3-D fold, where its globular *N*-terminal core is stabilized by three disulphide bridges with an extended *C*-terminal tail.[63] Like hirudin, the first three *N*-terminal residues bind to active site of thrombin in a noncanonical form. However, haemadin's acidic *C*-terminus binds to thrombin's exosite-II, instead of exosite-I as in the case of hirudin[63,64] (see FIGURE 113.4).

Kunitz-type Thrombin Inhibitors

The Kunitz-type inhibitors are a family of proteins belonging to the serine protease inhibitors.[65] They have a characteristic reactive-site loop, which binds and runs antiparallel to the enzyme active site residues. This type of inhibitors is commonly found in ticks. However, based on their sequences, there appears to be two different subclasses of these inhibitors, which originate from the two different families of tick—Ixodidae (hard ticks) and Argasidae (soft ticks). From the hard ticks, inhibitors that have been isolated include amblin from *Amblyomma hebraeum*,[66] boophilin from *Boophilus microplus*,[67] and haemalin from *Haemaphysalis longicornis*.[68] With two tandem Kunitz domains, these proteins generally have a lower affinity for thrombin as compared to those from the soft ticks (see below), with a K_i of 20 nM for amblin[66] and 1.8 nM for boophilin.[67] On the other hand, Kunitz-type inhibitors from soft ticks include ornithodorin from *Ornithodoros moubata*,[69] savignin from *Ornithodoros savignyi*,[70,71] and monobin from *Argas monolakensis*.[72] They are slow, tight-binding, and competitive inhibitors of thrombin, with a K_i of 4.89 pM for savignin[70] and 7 pM for monobin.[72]

Kazal-type Thrombin Inhibitors

Another common family of serine protease inhibitors are the Kazal-type inhibitors.[65] While the classical Kazal domains have the first two cysteine residues separated by seven to eight residues, the nonclassical Kazal domains has only one to two spacer residues. Generally, thrombin inhibitors belonging to this family of proteins contain tandem nonclassical Kazal domains and bind to thrombin in a slow, tight-binding, and competitive mode. In these inhibitors, the first domain binds to the active site of thrombin canonically while the second domain, together with interdomain linkers, binds to exosite-I. Examples of exogenous Kazal-type thrombin inhibitors include rhodniin from the triatomid bug, *Rhodnius prolixus*,[73,74] dipetalogastin from the blood-sucking bug, *Dipetalogaster maximus*,[75] and infestin from the assassin bug, *Triatoma infestans*.[76] Kinetically, the K_i values for rhodniin, dipetalogastin (domain 3 to 4), and infestin (domain 1 to 2) are 0.2,[73] 0.05,[75] and 25 pM,[76] respectively.

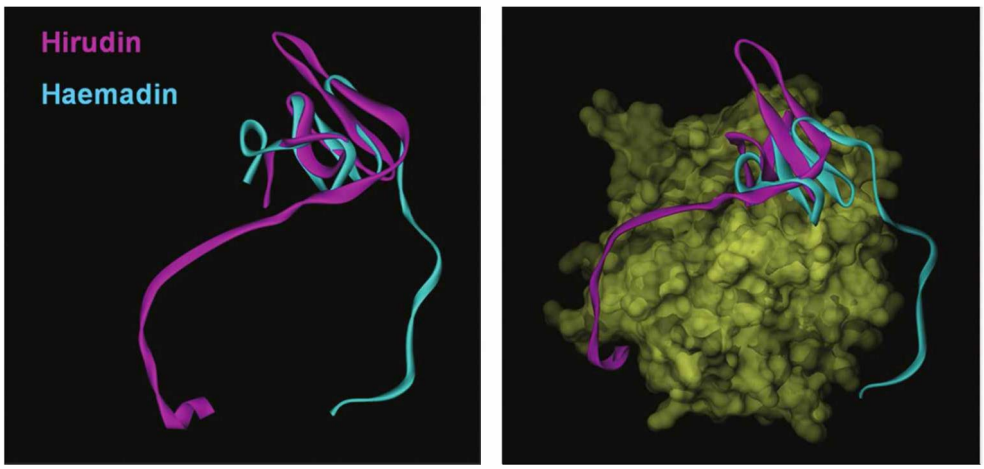

FIGURE 113.4 Identical fold but distinct mechanisms: hirudin versus haemadin. These two molecules are thrombin inhibitors isolated from the medicinal leech and the Indian leech, respectively. Although the two molecules display low sequence similarity, they share a common 3-D structure. Despite this, both molecules inhibit thrombin through distinct mechanisms. Hirudin targets thrombin's active site and exosite-I, whereas haemadin binds to the thrombin's active site and exosite-II. This is due to marked differences in haemadin's *C*-terminus where it lacks a sulphated tyrosine and complex formation with thrombin is independent of ionic strength, as in the case of hirudin. This classic example highlights how proteins of different amino acid sequences are able to have similar 3-D folds, while proteins of similar structures are able to bind and inhibit their target molecule through different mechanisms.

Variegin

Recently, a novel class of thrombin inhibitors have been identified from the tropical bont tick, *Amblyomma variegatum*. Named variegin, this fast and tight-binding thrombin inhibitor is one of the smallest thrombin inhibitors found in nature, with a length of only 32 residues.[77] Structurally, variegin is flexible as it lacks secondary structures. Despite this and its small size, variegin is highly specific to thrombin and binds with a K_i of 10.4 pM.[77] It does this by binding to thrombin's exosite-I with its *C*-terminus and the active site with its middle region. Its *N*-terminus is found to be responsible for its fast-binding kinetic properties. Interestingly, comparing structure and function, variegin resembles bivalirudin,[78] which is the product of a human-designed, bivalent thrombin inhibitor. It is fascinating to envisage the independent development of bivalirudin through rational drug design[78] and compare it with nature's own design of variegin through evolution and natural selection.

FXa Inhibitors

Kunitz-type FXa Inhibitors

Two anticoagulants, tick anticoagulant peptide (TAP)[79] and FXaI,[80] were isolated from the soft ticks *O. moubata* and *O. savignyi* respectively. These two inhibitors belong to the Kunitz-type FXaIs. Unlike the Kunitz-type thrombin inhibitors, TAP and FXaI contains only a single Kunitz domain with 60 and 56 amino acid residues, respectively. Both anticoagulants are slow, tight-binding, and competitive inhibitors of FXa.[79,81] TAP inhibits FXa through a noncanonical active site inhibition, where its first three *N*-terminal residues are in multiple contacts with the FXa active site and catalytic triad.[82] TAP also interacts with some of the residues on the Na^+-binding site and on the autolysis loop of FXa.[82]

Ascaris-type FXa Inhibitors

The Ascaris family of serine protease inhibitors is distinguished by 10 cysteine residues that form a unique disulphide pattern in a single domain.[83] Several Ascaris-type FXa-binding proteins have been reported from the hookworms *Ancylostoma caninum* (NAP5/6 and NAPc2/3/4)[84,85,86] and *Ancylostoma ceylonicum* (AceAP1).[87] While NAP5/6 and AceAP1 bind to the active site of FXa,[86,87] NAPc2/3/4 binds to an exosite.[84,86] As NAPc2/3/4 and AceAP1 exploit the binding of FXa to inhibit the FVIIa–TF complex, they are considered as extrinsic tenase complex inhibitors (see below for details). NAP5 inhibits FXa canonically at the active site, with a K_i of 43 pM.[86] Similar to TAP, it also interacts with the Na^+-binding site and autolysis loop of FXa.[88]

Antistasin-like FXa Inhibitors

Many leeches have anticoagulants that contain antistasin-like domain. This class of FXaIs includes antistasin,[89,90] ghilanten,[91] and therostasin.[92] Antistasin is a 119-amino acid protein that was isolated from the Mexican leech, *Haementeria officinalis*. It contains two tandem antistasin-like domains, which have 10 cysteines that form five intradomain disulphide bridges. Antistasin is a slow, tight-binding, and competitive inhibitor, with a K_i of 0.3 to 0.6 nM. Inhibition of the active site of FXa is achieved through the canonical reactive-site loop residing in the *N*-terminal domain.[93] In therostasin, although this canonical reactive-site loop and the domain signature are conserved, its overall sequence similarity with antistasin is low.[92] It is noted that therostasin is more potent than antistasin, with a K_i of 34 pM.

Serpin Family of FXa Inhibitors

Serpins are a superfamily of proteins (45 to 55 kDa) that undergo huge conformational changes and form a covalent complex with the target protease, thereby inhibiting it irreversibly.[94] An example of a FXaI that belongs to this class of proteins is found in the saliva of the yellow fever mosquito, *Aedes aegypti*. The crude salivary gland extract of female *A. aegypti* was found to inhibit the FXa active site reversibly and noncompetitively.[95] Fifty-four kilodalton in size, this protein, named as anticoagulant factor Xa (AFXa), contains posttranslational modifications (four *N*-linked glycosylation sites), which are likely to be important for its activity. However, as compared to typical serpins, AFXa has a shorter reactive-site loop and different hinge residues.

Extrinsic Tenase Complex Inhibitors

There are two main classes of extrinsic tenase complex inhibitors that have been isolated from hematophagous animals. Both classes act through a similar, but not identical, mechanism as the physiologic TF pathway inhibitor. The first class of inhibitors is the Kunitz-type inhibitors. Two such inhibitors have been isolated from the hard tick, *Ixodes scapularis*—ixolaris[96] and penthalaris.[97] Ixolaris, 15.7 kDa in size, has two tandem Kunitz domains. It was postulated that the second Kunitz domain binds first to FX/Xa, then followed by the FVIIa–TF complex via the first Kunitz domain.[96] Ixolaris binds to FX and FXa with affinities between 0.5 and 10 nM, but not at the FXa active site.[98] The surface amino acid residues of F X/Xa that are involved in the binding of ixolaris overlap largely with the heparin-binding proexosite/exosite.[98,99] This binding of ixolaris to FX and FXa impairs their interactions with FVIIIa and prothrombin, respectively.[98,99] Penthalaris, on the other hand, has five Kunitz domains, as compared to only two in ixolaris. Penthalaris inhibits the FVIIa–TF complex in the same way as ixolaris, making use of FX or FXa as a scaffold. The contribution of the three additional Kunitz domains of penthalaris to the interaction/function has yet to be elucidated.[97]

The second class of extrinsic tenase complex inhibitors is the Ascaris-type inhibitors, isolated from the hookworms *A. caninum*[84] and *A. ceylanicum*.[84,100] They are single-domain Ascaris-type inhibitors, such as NAPc2 and AceAP1. NAPc2 binds to the FXa heparin-binding exosite with its extended *C*-terminus, before binding to the FVIIa–TF complex.[101] In contrast, AceAP1 uses FXa as a scaffold by binding to both its active site and exosite and forms a quaternary complex with the FVIIa–TF complex.[84,100]

Intrinsic Tenase Complex Inhibitors

To date, nitrophorin-2 (or prolixin-s), isolated from *R. prolixus* (kissing bug), is the only intrinsic tenase complex inhibitor that has been identified from animals.[102] Approximately 20 kDa in molecular weight, it belongs to the lipocalin family. By targeting the Gla-domain of FIX/FIXa, nitrophorin-2 binds specifically to FIX/FIXa with a K_d of about 13 nM. This binding interferes with FIX activation (by both the FVIIa–TF complex and FXIa) and with FIXa activity in the intrinsic tenase complex.[103] The surfaces on nitrophorin-2 involved in FIX/FIXa binding have been suggested to be within its B-C and E-F strands as well as its *C*-terminus.[104]

PROCOAGULANTS

Procoagulants are agents that promote coagulation of blood. Often, these molecules either mimic the action of coagulation factors or activate them. Most procoagulant toxins characterized are proteinases, and majority of them are found in snake venoms. Until 1992, it was thought that only snake venoms had procoagulant activities.[105] This was due to difficulty in collecting venoms of other species, as their venoms were low in yield. However, with the progresses in technology, procoagulant toxins are also being isolated and characterized from spiders and scorpions. This section describes procoagulant toxins found in snakes and other venomous species.

Procoagulants from Snakes

In addition to the plethora of anticoagulant molecules, snake venoms are also a rich source of procoagulant toxins, many of which have been purified and characterized. These procoagulant toxins are serine proteases or metalloproteinases, and they promote blood clotting by activating zymogens, such as FX or prothrombin, to initiate blood clotting.

FX Activators

Venom toxins, which activate FX, are either metalloproteinases or serine proteases. These toxins can be found in venoms of snakes in the Viperidae, Crotalidae, and Elapidae families. The FX activator (RVV-X) from Russell's viper (*Daboia russelli*) venom[106] is a metalloproteinase with a mass of 93 kDa. Structurally, it consists of a heavy chain and two distinct light chains.[107] The heavy chain, which is the catalytic subunit, consists of a metalloproteinase, a disintegrin, and a cysteine-rich domain.[108] The light chains are homologous to C-type lectin-related proteins.[109] Functionally, RVV-X specifically cleaves the Arg52–Ile53 bond in the heavy chain of FX, and it requires Ca^{2+} for optimal activity. Several serine proteases that activate FX have also been isolated from the venoms of *Ophiophagus hannah*, *Bungarus fasciatus*, *Cerastes cerastes*, and *Cerastes vipera*.[110] However, the structural details of these serine proteases are not yet known.

Prothrombin Activators

A number of snake venoms possess prothrombin activators (PAs) in their venom. This group of toxins activates prothrombin to thrombin, which then causes fibrin formation. Based on their structure, cofactor requirements, and end products formed, snake venom PAs have been classified into four groups (Table 113.1, FIGURE 113.5).[111] Both group A and group B PAs are metalloproteinases, and they convert prothrombin to meizothrombin, which in turn is converted to thrombin through autoactivation. Their main difference lies in their cofactor requirements and structure. Group A PAs, such as ecarin from *Echis carinatus* venom,[112] function efficiently without any cofactor requirements and group B PAs, such as multiactivase from *Echis multisquamatus* venom, require Ca^{2+} for optimal activity.[113] The C-type lectin-related protein subunit confers the Ca^{2+} requirement to group B PAs. Group C and group D PAs are serine proteases, which are found exclusively in Australian elapid snakes, and they activate prothrombin to mature thrombin. Their main difference also lies in their cofactor requirements and structure. Group C PAs, such as pseutarin C from *Pseudonaja textilis* venom, require Ca^{2+} and negatively charged phospholipids but not FVa for maximal activity.[114] Group D PAs, such as trocarin D from *Tropidechis carinatus* venom, require Ca^{2+}, activated FV, and negatively charged phospholipids for their optimal activities.[115] Pseutarin C consists of two subunits, pseutarin C catalytic subunit and pseutarin C nonenzymatic subunit, which are structurally and functionally similar to FXa and FVa, respectively.[116–118] In contrast, group D PAs are structurally and functionally similar to FXa. Both these PAs activate prothrombin by targeting identical cleavage sites.[119,120] Thus, group C and group D PAs are similar to blood coagulation factors (FIGURE 113.5) and are probably evolved from coagulation factors by gene duplication.[121,122–124]

Procoagulants from Lonomia Caterpillar Venoms

Lonomia caterpillars are found in South America, and their venom found in the bristles affects mainly the coagulation system.[125] Victims get envenomed upon contact with the bristles. *Lonomia oblique* and *Lonomia achelous* venoms have procoagulant activities. Kelen et al.[126] were the first to examine the hemotoxic effect of *L. oblique* and found that its crude venom induces dose-dependent procoagulant activities, which increase in the presence of calcium. *Lonomia oblique* venom activates FX and prothrombin.[127] Subsequently, two serine proteases were isolated and characterized from the *L. oblique* venom: an FX activator termed as Losac (*L. obliqua* Stuart-factor activator) and Lopap (*L. obliqua* PA protease).[128,129] *Lonomia achelous* venom possesses procoagulant activities. Two PAs from this venom

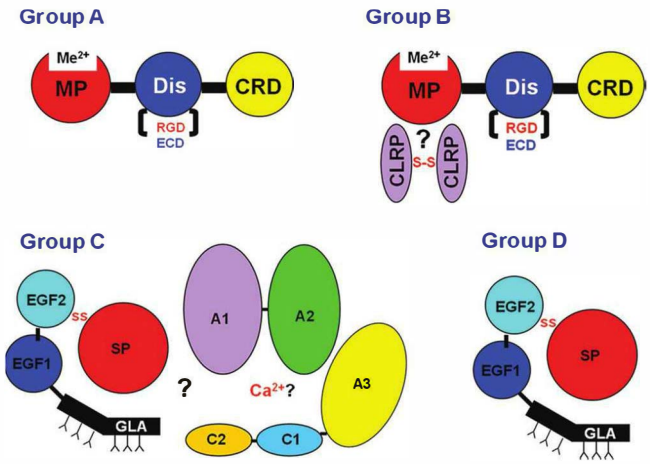

FIGURE 113.5 Schematic representation of snake venom PAs. Groups A and B PAs are metalloproteinases and are unrelated to blood coagulation factors. Group B PAs have a light chain made up of C-type lectin-related proteins. Individual domains are MP, metalloproteinase domain; Dis, disintegrin-like domain; CRD, Cys-rich domain; CLRP, C-type lectin-related protein domain. Groups C and D PAs are serine proteases. Group D PAs are structurally similar to FXa. They have a light chain containing Gla, EGF1, and EGF2 domains and a heavy chain containing serine protease domain. Group C PAs are structurally similar to FXa–FVa complex. The catalytic subunit is similar to FXa and group D PAs, whereas the nonenzymatic subunit is similar to FVa. Individual domains are Gla, γ-carboxyglutamic acid domain; EGF1 and EGF2, epidermal growth factor domains; SP, serine protease domain; A1, A2, A3, C1, and C2, respective domains of FVa.

Table 113.1

Classification of snake venom prothrombin activators

Group	Cofactor Requirements	Type of Proteinase	Product Formed	Estimated Size	Similar to Blood Coagulation Factors	Examples
A	None	Metalloproteinase	Meizothrombin	~47 kDa	None	Ecarin
B	Ca^{2+}	Metalloproteinase	Meizothrombin	Two subunits of ~25 and 60 kDa	None	Carinactivase, multactivase
C	Ca^{2+} *plus* phospholipids	Serine protease	Thrombin	Two subunits of ~60 and 220 kDa	"FXa–FVa" complex	Oscutarin, pseutarin C
D	Ca^{2+} *plus* phospholipids *plus* FVa	Serine protease	Thrombin	~60 kDa	FXa	Trocarin D, hopsarin D, notanarin D

were isolated and characterized[130]: Lonomin III, which directly activates prothrombin independently of the prothrombinase complex, and Lonomin IV, which has FXa-like activity.[130]

Procoagulants from Scorpion Venoms

Scorpion stings are a major threat to public health in many underdeveloped tropical countries, such as South India, the Middle East, and Latin America. The estimated annual number of scorpion stings is 1.2 million leading to 3,250 deaths.[131] Besides the painful local lesion of a scorpion sting, severe systemic complications have been also observed. Some of the hemotoxic symptoms include blood-stained tears and urine, intraperitoneal hemorrhage, and priapism.[132] The crude venom of *Palamneus gravimanus* has been shown to have procoagulant activities at low concentrations by significant shortening of the clotting time of recalcified plasma.[133] The crude venom was partially fractionated, and three fractions were shown to reduce recalcification time in plasma deficient of blood coagulation factors XII, IX, VIII, and VII, but not in those deficient of factors X, V, and prothrombin. It is concluded that the *P. gravimanus* venom promotes blood coagulation by activating blood coagulant FX.[133] Further characterization of these procoagulant factors is still needed.

Procoagulants from Spider Venoms

Venomous spiders use their toxins to immobilize their prey. Their venoms induce a variety of clinical symptoms related to hemorrhage, edema, hemolysis, inflammation, neurotoxicity, cytotoxicity, and platelet aggregation, and they interfere in plasma coagulation.[134] Although the majority of spider bites cause minor discomforts in humans, a few groups of spiders such as the Australian funnel web *Hadronyche* species may cause lethal bites.[135] Recently, a serine protease from the venom of *Hippasa agelenoides* was isolated.[136] This protease is 16,350 Da in mass and is termed Hag-protease. This enzyme is nonlethal but shows procoagulant properties when characterized with plasma recalcification times.[136] It reduces activated partial thromboplastin time and prothrombin time and hence targets the common pathway of the blood coagulation cascade.[137] It does not clot purified fibrinogen but is able to coagulate FX-deficient human plasma.[137] Thus it was concluded that this enzyme has FXa-like activity. In addition, Hag-protease induces aggregation of human platelets in platelet-rich plasmas at low concentrations but induces spontaneous clumping at high concentrations. This Hag-protease is similar to the group C and/or D snake venom PAs as it is a serine protease and has maximal activity in the presence of $CaCl_2$ and phospholipids. However, the lack of structural details and low molecular weight does not allow its grouping with them.

FUTURE PROSPECTS

Since ancient times, plants and animals have been exploited for medicinal purposes. A classic example is that of development of antimalarial drugs based on the alkaloid quinine from the barks of *Cinchona* trees. Only in the last couple of decades, scientists have developed drugs based on animal proteins. For example, angiotensin-converting enzyme inhibitors (Captopril, Enalapril family) were designed based on bradykinin-potentiating peptides isolated from Brazilian snake venom. Similarly, based on hirudin from medicinal leech, Hirulog or bivalirudin was

Snake Venom Proteins as Diagnostic Agents

Toxins from snake venoms that target hemostatic systems have greatly facilitated numerous routine assays for coagulation factors and the study of hemostasis in general. For instance, the venom of Russell's viper, *D. russelli*, is used in standard practice to assay the blood clotting factors V, VII, and X, as well as lupus anticoagulants. The venom contains a component that directly activates FX, turning FX into FXa, in the presence of calcium ions, FVa, and phospholipids. This complex then activates prothrombin, which will initiate the fibrin clot formation. As the clotting time, known as the Stypven time, is proportional to the concentration of FX, this assay is commonly used as a diagnostic test for FX deficiency in patients.

designed to inhibit thrombin. So far, a myriad of anticoagulants from other animals have been identified and characterized. With further development, some of these anticoagulants may potentially play a role in the treatment and prevention of thromboembolic diseases. On the other hand, procoagulants from animals have been used as diagnostic agents in the laboratory settings (Box 113.1). There is still a large number of anticoagulant and procoagulant compounds to be characterized. Thus, proteins from animal sources have a tremendous potential in developing new therapeutic agents, research tools, and diagnostic agents.[138]

CHAPTER

114 Mechanical Devices and Embolectomy

HERVÉ DECOUSUS, PATRICK MISMETTI, AND NICOLAS MENEVEAU

VENA CAVA FILTERS AND VENOUS THROMBOEMBOLISM

Interruption of the vena cava by filter insertion was initially suggested by Armand Trousseau in 1868, and these devices have been used since the 1970s to reduce the risk of pulmonary embolism (PE).[1,2] These devices have been used for the treatment of venous thromboembolism (VTE) either alone, in patients with a contraindication to anticoagulation, or in combination with conventional anticoagulation, especially in case of failure of the antithrombotic therapy. Inferior vena cava (IVC) filters could also be proposed as VTE prophylaxis in certain patient populations at high thromboembolic risk. Despite these rather limited indications and despite current guidelines, IVC filters are frequently used especially in North America with 49,000 insertions in the United States in 1999.[3,4] Forty-five percent of the filters are inserted for patients with deep vein thrombosis (DVT), 36% for those with PE, and 19% are used as primary prophylaxis.[3] An increasing proportion of all filter insertions are outside the recommendations of current guidelines.[5] The use of these devices has been extensively studied with more than 2,000 publications during the past 10 years. However, these publications are mainly case reports or retrospective cohorts. Several prospective cohort studies with a limited number of patients have been performed, and only two randomized clinical trials have been published[6,7]: the first comparing IVC filter plus anticoagulant therapy with anticoagulant therapy alone in patients with proximal DVT and no contraindication to anticoagulation[6] and the second comparing two types of IVC filters in patients requiring filters for different reasons.[7]

Different Types of Filters

Several types of IVC filters have been developed, and at least 10 variants of vena cava filters are currently in use in North America and Europe. The original filters were permanent, with no possibility of removal, such as the Greenfield (Boston Scientific, Boston, MA, USA), Bird's Nest (Cook, Bloomington, IN, USA), Venatech (B Braun, Boulogne, France), and Simon nitinol (Bard, Tempe, AZ, USA) filters (FIGURE 114.1).

One of the main complications of these filters is a twofold increase in DVT recurrences.[6,8] Due to this risk, the filter placement requires prolonged anticoagulation, and despite this, the rate of filter thrombosis, of new lower extremity DVT, and of new PE was 12%, 20%, and 5%, respectively.[9] This complication may occur late (≥3 months after filter insertion)[6] and could be avoided if the filter is retrieved, since the indications for IVC filters are mainly temporary. Accordingly, temporary filters were then developed, but they need a permanent venous access to be retrieved (Tempofilter II, B. Braun, Boulogne, France). This permanent venous access could be associated with septic complications, and this reduced the duration of IVC filter implantations. More recently, retrievable filters, such as the Gunther Tulip (Cook, Bloomington, IN, USA), Recovery (Bard, Tempe, AZ, USA), OptEase (Johnson and Johnson, Cordis Endovascular, Miami, FL, USA), and ALN (ALN Implants Chirurgicaux, France) filters, have been developed (FIGURE 114.2). These filters can be left in place indefinitely or retrieval can be performed several weeks and up to 1 year after insertion.[10]

Complications of IVC Filters

Before discussing their efficiency and potential indications, it seems important to note that apart from the thromboembolic complications mentioned above, the iatrogenic effects of these filters can be serious, and the incidence of these complications is not clearly established. Indeed the occurrence of adverse events after filter implantation is not negligible, as shown in several cohorts.[11] Moreover failures of filter removal can reach 12% in observational studies.[11]

These complications are listed in Table 114.1.

Recommendations for Use

As with all invasive procedures, insertion of a vena cava filter may be associated with a risk of serious adverse events,[3] justifying careful consideration of the benefit-to-risk ratio for all indications. Due to the limited data currently available regarding the benefit-to-risk ratio of these devices, their use even for validated indications should be restrictive.

The eighth edition of the American College of Chest Physicians (ACCP) guidelines published in 2008 recommends[12]

- For the use of IVC filters in patients with acute proximal lower extremity DVT, in whom anticoagulant therapy is not possible because of the risk of bleeding (grade 1C)
- Against the routine use of filter in addition to anticoagulants for most patients with PE and for patients with proximal DVT (grade 1A)
- Against the routine use of filter as primary prophylaxis in trauma patients (grade 1C) and in spinal cord injury (grade 1C)

Despite these recommendations, filters are increasingly prescribed especially in the United States either to prevent or to treat VTE.[13] This is probably due to potential indications that are insufficiently assessed. These potential indications correspond in particular to patients supposed to be at risk of VTE despite anticoagulant therapy and/or to be at high risk of bleeding while receiving anticoagulants.[4,13]

Recommended and Potential Indications of IVC Filters

Treatment of VTE

For this indication, there are considerable discrepancies between the United States and Europe in terms of frequency of use. Two North American cohorts showed that a filter[4,13,14] was inserted in about 15% of patients hospitalized for an episode of VTE compared with only 2% of patients in a similar cohort in Europe.[15]

In one of the North American cohorts,[4] three experts in the subject reviewed each of the indications for the filters, and only 50% of the indications were considered to comply with ACCP guidelines. The indications outside of the guidelines were essentially related to the perception of a high risk of bleeding or to a recurrence of VTE despite anticoagulant therapy.

Treatment of VTE in Patients with a High Risk of Bleeding

In patients presenting with a recent VTE episode and a contraindication for anticoagulant treatment, the risk of PE recurrence or PE-related death may reach 20%.[16,17] With this risk in mind, it is not ethically acceptable to perform a randomized trial to validate use of the filter.

There is, however, a European cohort study that supports this indication for the IVC filter. In a population of 17,368 VTE patients, the incidence of major hemorrhagic incidents was 2.3%, and the mortality rate for the patients who experienced bleeding was 33%. Among these patients with a hemorrhagic incident, a filter was inserted in 9% and multivariate analysis identified the filter as the only independent protective factor with a reduced risk of death after a hemorrhagic incident, with an odds ratio of 0.2 (95% confidence interval [CI], 0.1 to 0.6).[18]

These results would at first sight justify use of the vena cava filter in all VTE patients with a hemorrhagic incident contraindicating anticoagulant therapy. Indeed, when these hemorrhagic incidents are transient or curable, use of a retrievable filter is fully justified, provided that removal of the filter is effectively scheduled.

Treatment of VTE in Patients at a High Risk of Fatal PE

IVC filters could be used when the risk of death due to PE is high (>5% at 3 months) despite anticoagulation,[4] that is,

- In hemodynamically unstable patients with PE
- In patients at risk of recurrence of life-threatening PE, such as those with chronic pulmonary heart disease, especially if a surgical treatment if proposed

In these specific situations, indications for IVC filter placement are intuitive, and a randomized clinical trial is unrealistic and not feasible. In the absence of more convincing data, the indications are not discussed in the most recent guidelines.[12]

Treatment of VTE Recurrences Despite Anticoagulant Treatment

In VTE patients presenting with a recurrent PE in spite of optimal anticoagulant treatment, use of vena cava filters appears to be appropriate. However, there are no scientific data to support this indication. Moreover, it is necessary in this case to discuss the notion of optimal anticoagulant treatment.

For example, in studies in cancer patients with an episode of VTE, continued administration of low molecular weight

Table 114.1

Different types and rates of adverse events associated with filter implantation

Hematoma and infection related to filter insertion	4%–10%
Thrombosis at filter insertion site	2%–28%
Arteriovenous fistula at the insertion site	<1%
Filter tilt	6%
Filter migration	3%–69%
Acute perforation of vena cava	3%–25%
Filter thrombosis	5%–30%
Failure of filter removal	0%–12%
Mortality rate related to the filter insertion procedure	0.1%

Imberti D, Prisco D. Retrievable vena cava filters: key considerations. *Thromb Res* 2008;122(4):442–449

heparin for 3 to 6 months seemed to be more effective than vitamin K antagonists (VKAs), even when the international normalized ratio (INR) was optimally controlled.[19,20] Thus, for recurrent PE during VKA therapy with an INR between 2 and 3, it may be more appropriate to resume heparin treatment rather than to use a vena cava filter. It is likely that the arrival of the new anticoagulants will provide another alternative to VKAs and filters in this situation.

Treatment of VTE in Patients at High Risk of Recurrences Despite Anticoagulant Treatment

The only well-conducted randomized trial, the PREPIC study was designed for patients with this indication.[6] In this study, patients with a proximal DVT were randomly allocated to receive either anticoagulation with insertion of a filter or anticoagulant treatment alone. The filters assessed in this study were permanent versions. The results after 8 years of follow-up showed a significant reduction in the risk of PE (hazard ratio [HR] 0.37; 95% CI, 0.17 to 0.79; $P = 0.008$), but this beneficial effect was accompanied by a significant rise in the risk of DVT in the lower limbs (HR 1.57<; 95% CI, 1.02 to 2.27; $P = 0.042$) and notably with a 13% risk of filter thrombosis.[21] These contradictory results justify the fact that the guidelines do not recommend routine use of filters.[12]

The beneficial effects with respect to PE are evident essentially during the 1st 3 months of treatment, while the negative effects are observed mostly after the sixth month.[6] Therefore, a retrievable filter left in place for only 3 months could achieve the beneficial effects regarding PE while avoiding the extra risk of DVT recurrence. In addition, in order to optimize the beneficial effects of the filter, it could be inserted in patients with a higher risk of PE than in the PREPIC population. In fact, when recruited to the study, 38% of the PREPIC patients presented with DVT alone without any initial PE,[6] whereas the presence of an initial PE multiplies by five the risk of a fatal PE at 3 months compared to isolated DVT.[8,22]

With this in mind, a randomized study, PREPIC 2, is under way to assess the effect of a retrievable vena cava filter, systematically removed after 3 months in patients with an initial PE and thrombosis of the lower limbs, all of whom are treated with an anticoagulant agent (ClinicalTrials.gov identifier: NCT 00457158).

Optimal Duration of Anticoagulant Treatment in VTE Patients with an Inserted Filter

The insertion of a filter is associated with a doubling of recurrent of DVT.[6,21] Furthermore, full efficacy of vena cava filters is not guaranteed, with an estimated residual incidence of PE ranging from 0.5% to 6% despite filter insertion.[11] According to these data, the optimal duration of anticoagulant treatment should be discussed independently from the filter insertion and based on the current guidelines.[12]

Prevention of VTE in High-risk Situations

For this prophylactic indication, the ACCP guidelines[23] recommend against the routine use of IVC filters (grade 1C). There is no randomized comparative trial evaluating the systematic use of filters as primary prophylaxis after trauma or spinal cord injury. However, certain recommendations suggest that these filters may be used for the following indications in patients with a high thromboembolic risk.[24]

Prophylaxis of VTE in Trauma Patients

Filters present potential advantages in situations where there is a high risk of VTE and a simultaneous risk of hemorrhage, limiting the use of anticoagulant treatment even at prophylactic levels. With this hypothesis in mind, filters are in widespread use for patients at particular high risk for PE immediately after a traumatic injury including spinal cord injury, pelvic fracture, lower extremity fracture, venous repair, injury severity score >9 or >15, and history of VTE, coma (Glasgow coma scale <8). These indications are even supported by EAST guidelines.[24]

Prophylaxis of VTE in Bariatric Surgery

In spite of the recommendations against filters by the ACCP[23] and American Society of Hematology,[25] clinicians suggest the use of retrievable filters in bariatric surgery insofar as the efficacy of prophylactic anticoagulant treatments appears to be limited in obese patients, notably those with a BMI > 50 kg/m^2.[26] Accordingly, these filters are used today in about 50% of bariatric surgery cases in the United States.[25] Nevertheless, the efficacy of these filters along with the iatrogenic effects of the insertion and retrieval procedures is not well established, with up to 30% failures to retrieve and 15% cases of filter thrombosis.[27] Furthermore, the problem with insufficient prophylactic effect from low molecular weight heparin can most likely be obviated by a modest increase of the dose for this group of patients.[28]

Prophylaxis of VTE in Other Indications

Vena cava filters are also used in other situations with a high risk of thromboembolism, such as major orthopedic surgery (total hip or knee replacement).[29] Other indications such as cancer surgery have been studied.[30] However, in these indications, the noninvasive prophylactic measures are efficient and the benefit–risk ratio is well established, which is not at all true for vena cava filters.[23]

Filter Retrieval Procedures in Prophylactic Situations

The primary prophylactic indications for filters are situations with a temporary risk, and filters may appear appropriate in

that they are removable. This requires they are indeed removed once the VTE risk period is over. The iatrogenic effects of the retrieval procedures are not well established, and the rate of successful retrieval is <100%, and all the more so given that retrieval is more difficult and takes longer than insertion.[31] Retrieval more than 3 months after insertion of the filter seems to be associated with a 50% failure rate. The procedure also requires that the person who performs the procedure has a good level of experience.[32] Unfortunately, about 50% of these filters that were inserted precisely because they are retrievable are never removed.[33] This nonretrieval may be due to filter thrombosis, failure to remove, patients lost to follow-up, or apprehension concerning the retrieval procedure.[32] It would thus appear essential to establish guidelines and routines at each center that uses filters in order to optimize the rate of retrieval and limit the long-term risk of complications of these filters, notably IVC thrombosis and postthrombotic syndromes.[32]

Considerations Regarding the Different Types of Retrievable IVC Filters

There is only one randomized study comparing two types of filters: Greenfield (Boston Scientific, Natick, MA, USA) and TrapEase (Cordis, Bridgewater, NJ, USA).[7] This study showed that the TrapEase filter appears to be associated with a higher risk of thrombosis than the Greenfield filter.

Observational series also suggest that certain types of filters may be associated with a higher risk of fracture (FIGURE 114.3) and embolization, for example, the first- and second-generation Bard Recovery filters (Bard Peripheral Vascular, Tempe, AZ, USA).[34]

Apart from these observations, there are not sufficient data to recommend one type of filter rather than another.

FIGURE 114.3. Complications of vena cava filters. Rupture of one leg of a filter.

Conclusion

Permanent vena cava filters, as well as retrievable filters, may be considered valuable aids to the management of patients at very high risk of VTE recurrence and/or patients with a contraindication to anticoagulant treatment. Fortunately, the majority of patients seem to benefit from less invasive methods of VTE prophylaxis or treatment. The use of vena cava filters is increasing, probably due to the availability of more easy-to-insert implants, but more trials are needed to confirm their benefit and accurately assess their safety and the feasibility of removal in clinical practice. While awaiting these data, it seems justified to recommend against the routine use of these devices when conventional prophylactic and therapeutic anticoagulation is not contraindicated.

STENTS AND ACUTE VENOUS THROMBOEMBOLISM

Until recently, the gold standard for the treatment of superior vena cava syndrome (SVCS) was surgical repair or surgical bypass. However, surgery for SVCS is fraught with high morbidity and mortality. Previously, malignant causes of SVCS were dominating, accounting for up to 90% of cases. Nowadays, an increasing proportion of SVCS (up to 40%) are of nonmalignant origin, due to more widespread use of central venous catheters and pacemaker/defibrillator leads in clinical practice. In this context, a percutaneous approach with endovascular stent implantation has recently been advocated as a viable alternative to surgery to treat SVCS in both malignant and nonmalignant causes. A number of small, nonrandomized studies have reported excellent feasibility, with technical success rates of up to 95%, and immediate- and long-term (1 year) patency rates exceeding 80%.[35,36–38] Symptom relief is immediate, with accompanying functional improvement. The complication rates reported with percutaneous stenting for this indication are extremely low, at a maximum of 4% to 5%, and no deaths.[36] The potential benefit of additional thrombectomy prior to stenting is currently being explored.[39]

SURGICAL AND PERCUTANEOUS EMBOLECTOMY

Current guidelines suggest that the prognosis of PE should be analyzed as an individual estimate of the risk of early PE-related death rather than the anatomical distribution of intrapulmonary emboli.[40] Patients are now classified as high risk versus intermediate or low risk, replacing the former terminology of acute massive, submassive, or nonmassive PE. High-risk PE accounts for 5% of all cases of acute PE, and constitutes a life-threatening emergency, since most deaths occur during the first few hours after admission. We will review here the current state of the art on surgical and catheter embolectomy in the management of acute PE.

Embolectomy

High-risk PE is associated with acute right-ventricular (RV) failure, which results in shock and severe arterial hypotension. In this setting, potentially life-saving therapies include rapid initiation of thrombolysis, surgical embolectomy, or catheter

thrombectomy, in addition to conventional anticoagulant therapy. Surgical embolectomy and catheter thrombectomy are alternative treatments to thrombolysis, particularly in the presence of an increased risk of bleeding. Indeed, approximately one-third of all high-risk PE patients are not eligible for thrombolysis because of major contraindications, including trauma, prior surgery, stroke, or concomitant active bleeding.[41]

Surgical Pulmonary Embolectomy

Up until the past few years, pulmonary embolectomy was restricted to clinically desperate circumstances in moribund patients who required cardiopulmonary resuscitation. However, the use of expanded indications for pulmonary embolectomy has been associated with a reduced operative risk. A case series with 47 patients with high- and intermediate-risk PE subjected to surgical embolectomy showed interesting results with 92% early survival.[42] Almost half the study population had a contraindication to thrombolytic therapy, and 10% of the patients had not responded to previous thrombolysis. Thus, widening the indications for surgical embolectomy in patients with intermediate-risk PE is associated with a prognosis similar to that observed after conventional treatment.

Unless intracardiac thrombi or a patent foramen ovale are present, surgical embolectomy should be performed avoiding aortic cross-clamping and cardioplegic cardiac arrest.[42,43] After median sternotomy and pericardiotomy, patients are heparinized and cannulated for cardiopulmonary bypass. The arterial cannula is placed in the ascending aorta with either a bicaval or a single-venous cannula placed through the right atrium. The procedure is performed under normothermia without cardiac arrest and with vacuum-assisted venous drainage. The clot is extracted through a longitudinal arteriotomy in the main pulmonary artery, under direct inspection using forceps.

The indications for surgical embolectomy are given in Table 114.2. Surgical embolectomy with cardiopulmonary bypass is recommended for the management of patients with high- or intermediate-risk PE in whom contraindications preclude thrombolysis. Other indications include patients who require surgical extraction of intracardiac thrombi or closure of a patent foramen ovale, as well as rescue in patients who do not respond adequately to thrombolysis. Indeed, rescue surgical embolectomy leads to a better in-hospital course when compared with repeat thrombolysis in the setting of unsuccessful previous thrombolysis. Registry data on 488 patients with PE and failed thrombolysis at a single center demonstrated that uneventful in-hospital evolution was significantly more common in the surgical group, due to a lower in-hospital mortality rate, less frequent episodes of major bleeding, and fewer recurrent PE.[44] Consequently, the transfer of patients who have not responded to thrombolysis to tertiary cardiac surgery centers could be considered as an option in this context. Prolonged periods of postoperative cardiopulmonary bypass and weaning may be necessary until recovery of RV function.[40] This surgical approach is of course associated with potentially severe complications. Particularly, extraction of old thrombi that have been in place for several days and become adherent to the pulmonary artery can lead to possible pulmonary hemorrhage.

Catheter Embolectomy

Percutaneous catheter embolectomy is the only alternative to thrombolysis or surgical embolectomy to reverse PE-related right heart failure and cardiogenic shock. Catheter embolectomy can be particularly useful when contraindications to thrombolytic therapy exist, or when surgical embolectomy is either unsuitable or unavailable. Unfortunately, no randomized controlled trial has ever compared catheter embolectomy with surgical embolectomy or thrombolytic therapy in this setting. Available data are limited to small cohort studies or case series.[45] In many cases, these various devices are used in association with local thrombolytic therapy. This combined approach makes it difficult to analyze the efficacy of the percutaneous catheter devices in isolation. The rate of clinical success observed with this approach, and defined as immediate hemodynamic improvement, appears to be over 80% and is associated with mortality rates from 0% to 25%.[46]

Various catheter-directed interventions are currently available, including clot fragmentation, suction thrombectomy, and rheolytic thrombectomy (Table 114.3).[47] The Greenfield Embolectomy (Boston Scientific/Meditech; Watertown, MA, USA) device is a 10F steerable catheter that was specifically designed for the treatment of massive PE.[48] The Amplatz thrombectomy device (Bard-Microvena, White Bear Lake, MN, USA) is a 7F catheter device with a distal impeller mounted on a drive shaft that rotates at high speed (150,000 revolutions per minute). The rotation creates a vortex of circulating blood that attracts the clots toward the rotating impeller, pulverizing and recirculating fresh thrombus.[49] Hydrodynamic or rheolytic catheter

Table 114.2

Current indications for surgical and catheter embolectomy in high-risk PE

Surgical Embolectomy
Valuable therapeutic option in patients with high-risk PE in whom thrombolysis is absolutely contraindicated or has failed, as well as in compromised patients with insufficient time for systemic thrombolysis to be effective
Catheter Embolectomy
Consider as an alternative to surgical embolectomy (either unsuitable or unavailable) in high-risk PE patients when thrombolysis is absolutely contraindicated or has failed, as well as in compromised patients with insufficient time for systemic thrombolysis to be effective.

Table 114.3

Catheter embolectomy devices for high-risk PE

Device	Manufacturer	Size, F	Thrombus Fragmentation	Clinical Success (%)
Greenfield suction catheter	Boston Scientific, US	10	Thrombus aspiration	81
Pigtail rotational catheter	Cook Europe, the Netherlands	6	Thrombus fragmentation	67
Amplatz thrombectomy device	BARD-Microvena, US	7	Thrombus pulverization and recirculation	88
Angiojet Xpeedior	Possis Medical, US	6	Thrombus fragmentation and aspiration	75
Hydrolyser	Cordis Europe, the Netherlands	6	Thrombus fragmentation and aspiration	92

Clinical success was defined as immediate hemodynamic improvement.
Adapted from Kucher N. Catheter embolectomy for acute pulmonary embolism. *Chest* 2007;132(2):657–663.

devices also create a vortex that causes fragmentation and aspiration of the clots (Hydrolyzer device, Cordis, Warren, NJ, USA; Oasis catheter, Boston Scientific/Meditech; AngioJet Xpeedior, Possis, Minneapolis, MN, USA).[50–52] The 11F Aspirex catheter thrombectomy device (Straub Medical, Wangs, Switzerland) is a high-speed rotational coil (40,000 revolutions per minute) that creates negative pressure at the catheter tip, macerates aspirated thrombus, and removes thrombus fragments.[53]

Percutaneous catheter device interventions are limited by a number of potential drawbacks that can cause serious complications. Indeed, it must be underlined that these procedures necessitate a vascular approach with selective catheterization of the pulmonary arteries and injection of contrast medium. The most serious complication that can arise is perforation of the myocardium or of a branch of the pulmonary artery. This can rapidly lead to tamponade or massive intrapulmonary hemorrhage, precipitating death in a large majority of cases. The risk of perforation is increased when the diameter of the pulmonary artery is below 6 mm. To minimize the risk of perforation and dissection, embolectomy should only be carried out in the main and lobar pulmonary arteries, and not in the segmental pulmonary arteries. Similarly, the procedure should be stopped as soon as there is an improvement in hemodynamic conditions, regardless of the angiographic result.[53] Some procedures can be complicated by distal embolization of proximal thrombi, which can exacerbate the patient's hemodynamic instability. Certain devices can also lead to substantial blood loss in case of prolonged aspiration, or even mechanical hemolysis. Finally, other complications can arise related to the procedure itself, including anaphylactic reaction to iodine contrast medium, contrast-induced nephropathy, ventricular arrhythmia, or vascular access complications.[46]

Catheter-directed interventions are therefore only appropriate when thrombolysis is contraindicated or has failed to improve the patient's clinical condition. A catheter-based approach might be particularly suitable in patients who are too frail for surgery, or in any patient with severe underlying pulmonary disease that makes successful cardiopulmonary bypass unlikely. Evidently, operators need to be very experienced, in view of the severity of the potential complications of these approaches. The current indications for catheter embolectomy are provided in Table 114.2. Overall, the use of percutaneous catheter devices should only be envisaged in high-risk PE, in the presence of at least one absolute contraindication to thrombolysis, in addition to the presence of subtotal or total filling defect in the left and/or right main pulmonary artery determined by CT scan or by conventional pulmonary angiography.[54]

Conclusion

Management of acute high-risk PE encompasses several therapeutic options, which must be selected on a case-by-case basis according to the patient's clinical profile. Systematic evaluation of the expected risk–benefit ratio is mandatory. Thrombolytic treatment should be first-line therapy in patients with high-risk PE presenting with cardiogenic shock and/or persistent arterial hypotension, with very few absolute contraindications. Both surgical and catheter pulmonary embolectomy are valuable therapeutic options in patients in whom thrombolysis is absolutely contraindicated or has failed.

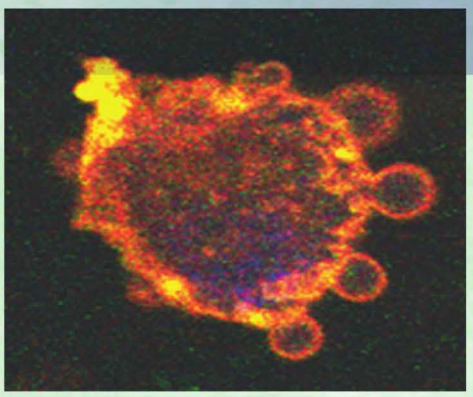
PART V



Hemostatic and Thrombotic Disorders Associated with Systemic Conditions

CHAPTER

115 Overview of Special Clinical Groups

VICTOR J. MARDER AND JOEL S. BENNETT

The majority of this textbook is devoted to basic aspects of hemostasis and thrombosis and specific hemostatic and thrombotic diseases. But more common in clinical practice are disorders in which hemostasis and thrombosis are complicating features of another pathologic process. In latter disorders, the homeostatic balance that maintains the fluidity of the blood, while at the same time leaving it poised to prevent hemorrhage after trauma, is perturbed by systemic processes to cause bleeding, thrombosis, or both. This section of the textbook considers the potential for hemorrhagic or thrombotic manifestations in select patient groups, from conception to old age. The goal of these chapters is to provide a conceptual framework for understanding pathogenesis. Details of treatment are provided in chapters devoted to individual therapeutic agents or to specific thrombotic and hemorrhagic events.

PREGNANCY AND THE POSTPARTUM STATE

Issues related to pregnancy, the postpartum period, and the use of oral contraceptive agents are discussed in Chapters 116, 117, and 118. The hormonal changes that accompany pregnancy and the use of oral contraceptive agents represent a particular challenge to the hemostatic balance since they favor thrombosis. While this may be advantageous for the integrity of the fetal–placental circulation and for the prevention of postpartum hemorrhage, it otherwise puts women at risk for venous thromboembolism, especially during the postpartum period; for placental thrombosis associated with fetal growth retardation, spontaneous abortion, and eclampsia; for the exacerbation of concurrent hemostatic disorders such as immune thrombocytopenia; and for diseases that commonly complicate pregnancy such as thrombotic thrombocytopenic purpura and disseminated intravascular coagulation.

HEMOSTASIS DURING INFANCY AND CHILDHOOD

As discussed in Chapter 119, the components of the hemostatic system undergo significant changes during the neonatal period and infancy, reaching levels found in adults at variable intervals, generally but not exclusively by 1 year of age. Nonetheless, the presence of normal concentrations of clotting factors and platelets belies the unique clinical presentations of bleeding and thrombosis in children, features of which are often unknown or unappreciated by "adult" hematologists. Similarly, therapy of children often requires appreciation of issues other than simply dosing modification due to the small size of children, issues that are discussed in detail in Chapters 120 and 121.

HEMOSTATIC AND THROMBOTIC DISORDERS ASSOCIATED WITH SYSTEMIC ILLNESS

The contribution of perturbed hemostasis to the morbidity of systemic illness becomes immediately apparent to the consulting hematologist who is "barraged" with questions regarding the basis for, and management of, the almost "ambient" thrombocytopenia in hospitalized patients; the preoperative management of the hemostatic disorders of patients with severe renal and liver disease; the treatment of sepsis; the management of stroke and acute chest syndrome in patients with sickle cell disease; the treatment of the ever-present venous thrombosis in patients with malignancy; and the hemostatic complications associated with iatrogenic vascular trauma (surgery) and the use of cardiopulmonary bypass devices. Moreover, with the appearance of facilities devoted to the treatment of traumatic injury, hematologists are now required to understand the hemostatic derangements that accompany trauma and issues regarding their management. Chapters 122 to 129 provide detailed discussion of each of these topics.

HEMOSTASIS AND THROMBOSIS IN THE ELDERLY

With the aging of the population, it has become apparent that both hemostasis and thrombosis are deranged in elderly patients. For example, not only are the elderly more prone to thrombosis, but they present challenges for the safe and effective administration of antithrombotic therapy when thrombosis does occur. Issues regarding the diagnosis and management of hemostatic and thrombotic disorders in elderly patients are considered in Chapter 130.

CHAPTER

116

Venous Thromboembolism during Pregnancy and with Hormonal Contraceptives

SASKIA MIDDELDORP, MATHILDE NIJKEUTER, AND MICHIEL COPPENS

PART I: PREGNANCY-RELATED VENOUS THROMBOEMBOLISM

Epidemiology

Venous thromboembolism (VTE) complicates 1 to 2 per 1,000 pregnancies.[1,2–4] Furthermore, VTE is the leading cause of maternal death in Western countries, accounting for 1 to 2 deaths per 100,000 pregnancies and 20% to 30% of all maternal deaths.[5,6,7] Compared to age-matched nonpregnant women, this implies a 4- to 16-fold risk increase during pregnancy.[1] In the postpartum period, the relative risk of VTE has been found to be as high as 60.[8]

Deep vein thrombosis (DVT) accounts for 85% of pregnancy-related symptomatic VTE, and the majority, that is 65%, occur during pregnancy.[9] Contrary to this, the majority (85%) of episodes of pulmonary embolism (PE) occur in the postpartum period.[1] Approximately 22% of episodes of VTE during pregnancy occur in the first, 34% in the second, and 48% in the third trimester.[10] Given the much longer duration of the antepartum period than the postpartum period, the daily absolute risk of VTE is highest postpartum.

Inherited thrombophilias also increase the risk, and absolute risk estimates are summarized in Table 116.1. The presence of a positive family history for VTE modifies the risk of a first pregnancy-related VTE and in this setting ranges between 1.7% and 14.0%, depending on the type of hereditary thrombophilia.[11,12] No data are available for the risk of a first pregnancy-related VTE in women with antiphospholipid syndrome. Outside of pregnancy, the persistent presence of lupus anticoagulants including anticardiolipin or β2-glycoprotein antibodies is associated with a 2- to 10-fold risk increase for a first VTE.[13,14] If all pregnancy-related VTE is considered, the presence of antiphospholipid syndrome is associated with a 15.8 (95% CI 10.9 to 22.8) times higher risk.[6] It should be noted that in this study, antiphospholipid syndrome was classified by hospital admission code and that this risk increase, at least in part, is likely due to the coexistent history of VTE, which in itself was the strongest risk factor for pregnancy-related VTE (odds ratio [OR] 24.8, 95% CI 17.1 to 36.0).[6] It is unclear what the risk of VTE is in women with antiphospholipid syndrome diagnosed on reproductive clinical criteria such as recurrent miscarriage. In a small study in women with recurrent miscarriage and antiphospholipid syndrome, the risk of subsequent thrombotic events was not increased compared to women with unexplained recurrent miscarriage.[15] The risk of pregnancy-related VTE also increases with age, mode of delivery, and presence of comorbid conditions.[1,6,16]

Despite these strong risk increases, a strong evidence base for the management of pregnancy-related VTE is missing. It is striking that, contrary to nonpregnant patients, diagnostic strategies, therapeutic options, and preventive measures for VTE in pregnant and postpartum women have not been addressed adequately in well-sized observational or intervention studies. Therefore, management is not standardized between physicians, centers, and countries.

Pathophysiology

The elements of Virchow's triad, that is, venous stasis, hypercoagulability, and vascular damage, are all more or less present during pregnancy and the postpartum period. This predisposition to develop VTE has probably evolved to protect women from hemorrhage during childbirth. Venous stasis already begins in the first trimester and is assumed to be caused by progesterone-induced venodilation.[17] Compression of the pelvic veins by the gravid uterus becomes more important in the second and third trimester of pregnancy. A third component leading to increased venous stasis is the crossing of the right iliac artery over the left iliac vein that may lead to pulsatile compression of the iliac vein (FIGURE 116.1). Pregnancy is a hypercoagulable state caused by decreased anticoagulant activity, increased procoagulant activity, and decreased fibrinolysis. The decrease in anticoagulant activity is due to a decrease in protein S concentration and an increase in activated protein C (APC) resistance. The increase in procoagulant activity is a result of an increase in factor V, VII, VIII, IX, X, and fibrinogen concentrations.[18] Fibrinolytic activity is decreased because of an increase in plasminogen activator inhibitor 1 and 2 activity and a decrease in tissue plasminogen activator (tPA). The third element of Virchow's triad, that is, vascular damage, is induced by delivery. Forceps, vacuum extraction, and surgical delivery can aggravate this vascular injury.

Clinical Presentation of VTE in Pregnancy

DVT in pregnant patients has a different distribution along the venous system as compared to nonpregnant patients. The predisposition for DVT to occur in the left leg, that is, almost 90% in pregnant patients, is much stronger than in nonpregnant patients (~60%).[10,19–21] Isolated iliac vein thrombosis occurs in 17% of all DVT in pregnant women, whereas this is very uncommon in nonpregnant patients.[20] Furthermore, in contrast to nonpregnant patients, more than 60% of DVT is restricted to the iliac and/or femoral vein, without calf vein involvement.[20]

Table 116.1

Risk of pregnancy-related VTE in thrombophilic women stratified by family history for VTE

Thrombophilic Defect	Prevalence in Population, %[145–149]	Estimated RR OR (95% CI)	Absolute Risk of VTE[a], % of Pregnancies (95% CI)	
			Family Studies	Nonfamily Studies
Factor V Leiden, heterozygous	2.0–7.0	8.3 (5.4–12.7)[150]	3.1 (2.1–4.6)[114,115]	1.2 (0.8–1.8)
Factor V Leiden, homozygous	0.2–0.5	34.4 (9.9–120)[150]	14.0 (6.3–25.8)[11,151]	4.8 (1.4–16.8)
Prothrombin, heterozygous	2.0	6.8 (2.5–18.8)[150]	2.6 (0.9–5.6)[112,152]	1.0 (0.3–2.6)
Prothrombin, homozygous	Very rare	26.4 (1.2–559)[150]	—	3.7 (0.2–78.3)
Antithrombin deficiency	<0.1–0.6	4.7 (1.3–17.0)[150]	3.0 (0.08–15.8)[153]	0.7 (0.2–2.4)
Protein C deficiency	0.2–0.3	4.8 (2.2–10.6)[150]	1.7 (0.4–8.9)[153]	0.7 (0.3–1.5)
Protein S deficiency	<0.1–0.1	3.2 (1.5–6.9)[150]	6.6 (2.2–14.7)[153]	0.5 (0.2–1.0)
Lupus anticoagulants (persistent)[b]	No consistent data	2 to 10 (wide confidence intervals)[13,14]	—	0.3 to 1.4 (95% CI uncertain)

[a]Observed in family studies, estimated from multiplying the baseline risk of 1.40 per 1,000 by the RR in nonfamily studies.[12]
[b]Risk increase is stronger for lupus anticoagulant than for anticardiolipin or β2-glycoprotein antibodies. Data are very limited; hence, the estimated absolute risk should be interpreted with caution.

Diagnosis of VTE in Pregnant Women

Clinical Decision Rules and D-Dimer Testing

Studies on the diagnostic management strategies of DVT and PE have excluded pregnant women. Currently, no single study has adequately demonstrated the safety of ruling out VTE by clinical probability assessment combined with the use of D-dimers. In pregnancy, as in nonpregnant patients, D-dimer tests should not be used as a stand-alone test because of the small but important risk of a false-negative result. Objective imaging remains therefore the cornerstone of diagnosis and is crucial to avoid treating women who do not have VTE.[22]

Safety of Diagnostic Imaging in the Pregnant Patient

Imaging techniques to diagnose or exclude VTE in pregnancy should take into account the radiation exposure of the fetus (Table 116.2). These are much lower than the threshold dose for induction of malignancies (100 mSv) in the fetus and clearly justify the use of diagnostic testing involving radiation in pregnancy for the exclusion of potentially fatal VTE.[23]

Concerns have been raised that breast tissue of pregnant women, which receives particularly high doses of radiation, is supposedly especially susceptible to its carcinogenic effects, but evidence supporting this concern is not available.[24]

The iodinated contrast agents used in CT scanning and venography cross the placenta. Fetal exposure to iodinated contrast media is thought to be relatively short-lived. Although no effect on fetal thyroid function has ever been reported with clinical doses of iodinated contrast media, it is standard care that neonates of all mothers exposed to iodinated contrast media during pregnancy are screened for hypothyroidism.[25,26] Gadolinium contrast agents are used during MRI and do cross the placenta, but no neonatal adverse effects have been described and tests postpartum are not necessary.[25] Only tiny amounts of iodinated or gadolinium contrast media are excreted in breast milk and only a minute proportion entering the baby's gut is absorbed. This is considered insufficient to warrant stopping breast-feeding for 24 hours following either iodinated or gadolinium contrast agents.[25]

Diagnosing Deep Vein Thrombosis in Pregnancy

Compression ultrasonography (CUS) should be performed as a first test in a pregnant patient with a clinical suspicion of DVT (FIGURE 116.2). CUS has a sensitivity of 97% to 100% and a specificity of 98% to 99% outside of pregnancy, is noninvasive, and carries no radiation exposure.[27,28] Serial CUS testing after an initial normal test is of less value in pregnant patients, since DVT in pregnancy usually occurs in proximal veins without involvement of the calf veins. If doubt about the presence of DVT persists, limited venography with abdominal shielding should be considered. If iliac or pelvic vein thrombosis is suspected because of abdominal, groin, or back pain combined with swelling of the entire leg, CUS needs to be followed by duplex Doppler ultrasound or, alternatively, full venography can be performed. An absent waveform on modulation of respiration strongly suggests iliac vein thrombosis, but due to slow flow and external compression by the gravid uterus, false-positive ultrasound results may occur as well as false-negatives due to nonocclusive thrombi or collaterals. In centers with the availability of, and experience with, MRI, MR venography is a reasonable alternative test to venography in demonstrating iliac or pelvic vein thrombosis. However, the safety of excluding DVT when MR venography is normal has not been prospectively studied.

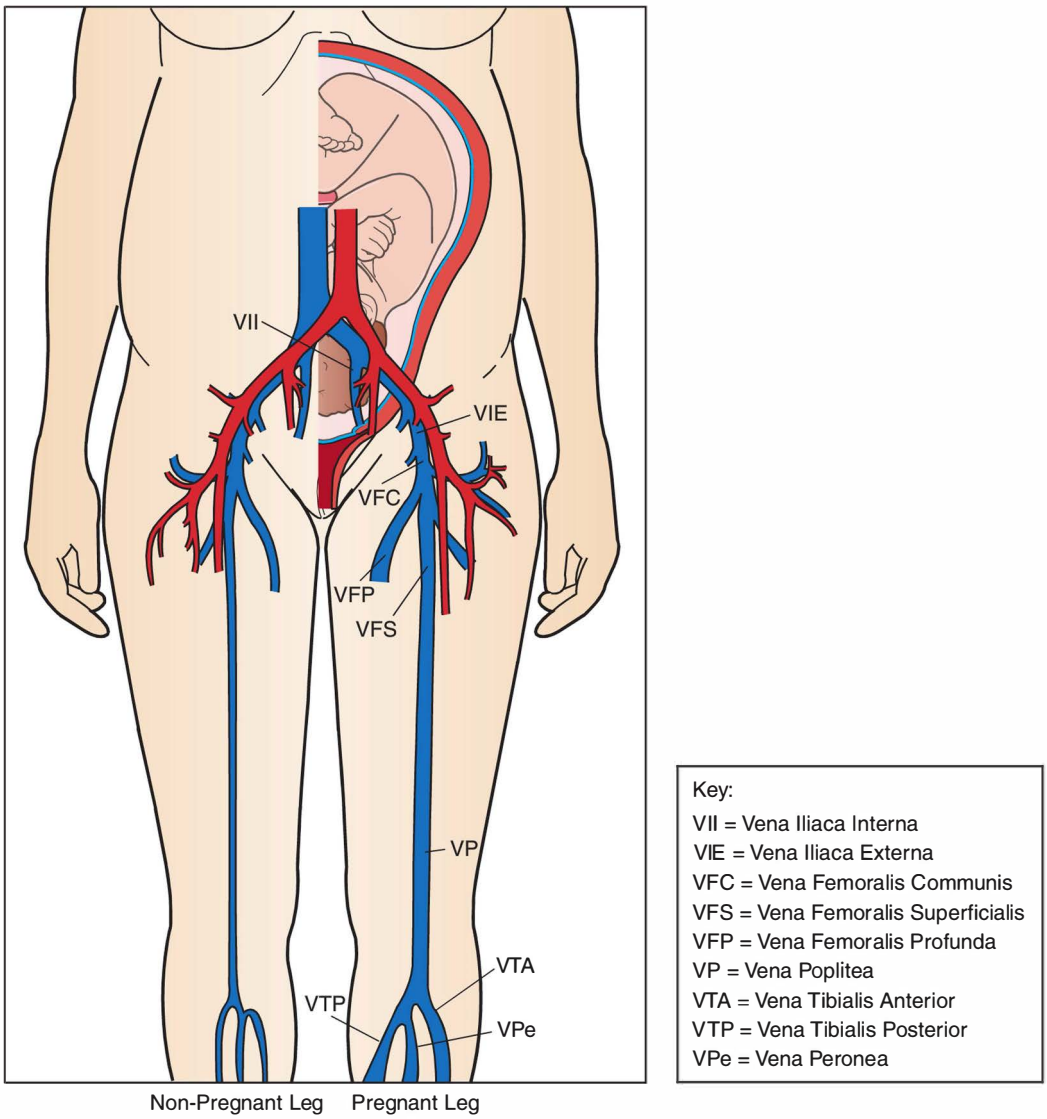


FIGURE 116.1 Venous stasis during pregnancy. The left leg represents the pregnant leg, while the right leg represents the nonpregnant leg. Venous stasis in pregnancy is caused by progesterone-induced venodilation and compression of the pelvic veins by the gravid uterus (here depicted posterior of the vessels for clarity, but in reality anterior of the blood vessels). These components of increased venous stasis during pregnancy add to the anatomic crossing of the right iliac artery over the left iliac vein that may lead to pulsatile compression of the iliac vein. VII, vena iliaca interna; VIE, vena iliaca externa; VFC, vena femoralis communis; VFS, vena femoralis superficialis; VFP, vena femoralis profunda; VP, vena poplitea; VTA, vena tibialis anterior; VTP, vena tibialis posterior; VPe, vena peronea.

Diagnosing Pulmonary Embolism

FIGURE 116.3 depicts several algorithms that can be used in pregnant patients with a suspicion of PE, depending on local availability and expertise.[22,29] Although the diagnostic yield of CUS (algorithm a) of the legs is low in asymptomatic women, it is a reasonable approach to avoid radiation in women suspected of PE. When CUS demonstrates DVT, further testing is not necessary and the patient can be considered to have a VTE. In a recent study, CUS showed proximal DVT in 39 of 139 (31%) nonpregnant patients suspected of PE but without symptoms of DVT.[30] In pregnant women, this percentage is probably much lower since the overall prevalence of VTE in suspected patients is lower, but there are no data available. Obviously, ultrasound testing should not lead to diagnostic delay and if negative must prompt objective diagnostic testing of the lungs. Furthermore, the possibility of a false-positive result should be taken into account, especially if the patient has had an ipsilateral DVT in the past.

Advantages of the algorithm starting with a CT scan (FIGURE 116.3, algorithm b) are the feasibility to reach a diagnostic conclusion and the possibility to detect an alternative diagnosis, combined with a low fetal radiation exposure. An ongoing prospective diagnostic management study in which CT as the single test was used to exclude PE during pregnancy in 85 women showed no symptomatic VTE during follow-up of 3 months (95% CI 0% to 3.5%; Nijkeuter et al., 2012). CT scan

Table 116.2

Radiation dose to the fetus by radiologic examination

	Radiation (mSv)
Unilateral venography without shielding	3.14
Unilateral venography with shielding	<0.5
Pulmonary angiography via femoral route	2.21–3.74
Pulmonary angiography via brachial route	<0.5
Perfusion scintigraphy (^{99m}Tc MAA, 200 MBq)	0.2–0.6
Perfusion scintigraphy (^{99m}Tc MAA, 40 MBq)	0.11–0.20
Ventilation scintigraphy (^{99m}Tc aerosol)	0.1–0.3
Ventilation scintigraphy (81 mKr, 600 MBq)	0.0001
Single-detector row helical CT	0.026
Multidetector row helical CT	0.013
Chest x-ray	0.001

Estimates of radiation exposure are derived from McMaster University and University Medical Centre Leiden.[154,155]
To convert mSv to rads: 1 mSv ~ 0.1 rad.

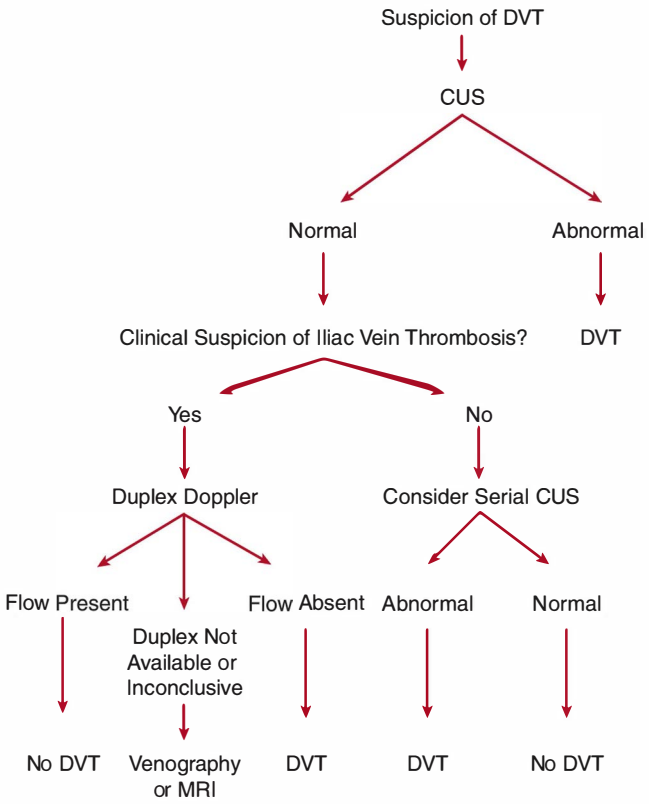

FIGURE 116.2 Algorithm of a clinical suspicion of DVT in pregnancy. CUS, compression ultrasonography; DVT, deep vein thrombosis; LMWH, low molecular weight heparin; MRI, magnetic resonance imaging.

results were inconclusive in 4 of 94 patients, that is, 4.2%. This percentage is much lower than the 19% and 35% reported in two retrospective studies but higher than in the nonpregnant population (0.9%).[31–33]

The algorithm containing perfusion scintigraphy (FIGURE 116.3, algorithm c) should bear in mind that a chest x-ray is advised to rule out other diagnoses and to increase the chance of a conclusive perfusion scan. Four studies evaluated the performance of lung scintigraphy in pregnancy; diagnostic scan results ranged from 75% to 94%.[32,34–36] Selection of patients by normal chest x-ray and no history of asthma or chronic obstructive pulmonary disease resulted in the higher percentage of diagnostic tests.[32,36] However, these were all retrospective studies that were subject to bias since no uniform diagnostic protocol was used. Hence, in up to a quarter of pregnant patients with suspected PE, perfusion scintigraphy needs to be followed by additional testing. This strategy obviously is associated with a higher amount of fetal radiation exposure.

Risks of Anticoagulant Drugs in Pregnant and Postpartum Women

In the next paragraphs, we discuss specific fetal and maternal safety issues for anticoagulant agents. Furthermore, as in the nonpregnant population, the most obvious maternal safety issue of any anticoagulant is the risk of bleeding, both antepartum as well as around delivery and in the postpartum period. These risks are described in the paragraphs of the specific agents if data are available in pregnant women.

Vitamin K Antagonists

Vitamin K antagonists (VKAs) cross the placenta and the induced vitamin K deficiency in the fetus may cause fetal wastage, bleeding, and coumadin embryopathy, a disorder that is characterized by nasal hypoplasia and stippled epiphyses.[37] This teratogenic effect is only present when VKAs are taken in the 6th to 12th weeks of gestation (defined as weeks after the 1st day of the last menstrual cycle). When VKAs are used throughout pregnancy, as is sometimes done in women with mechanical heart valves, the risk of congenital abnormalities is estimated between 3.7% and 6.4%.[37–39] Although exposure during the second trimester of pregnancy does not lead to overt handicaps, careful examination of school-aged children who had been exposed to VKA in utero showed that 18 out of 274 exposed children (7%) had an increased risk for a "multiple adverse outcome," that is, growth impairment, minor neurologic dysfunction, IQ < 80, and behavioral problems, in comparison to 2 children out of 231 nonexposed controls (risk difference 5.7%, RR 7.6, 95% CI 1.8 to 32.4).[40,41] The adverse outcomes were mainly found in boys, and of the affected children, 94% had been exposed during the second and third trimester only. From approximately 36 weeks gestation, the bleeding risk for the fetus during delivery is a reason to avoid VKA during this time.

Women can breast-feed during the use of VKAs; particularly nonlipophilic types such as acenocoumarol and warfarin.[42,43] Of the lipophilic phenprocoumon, only minute amounts are

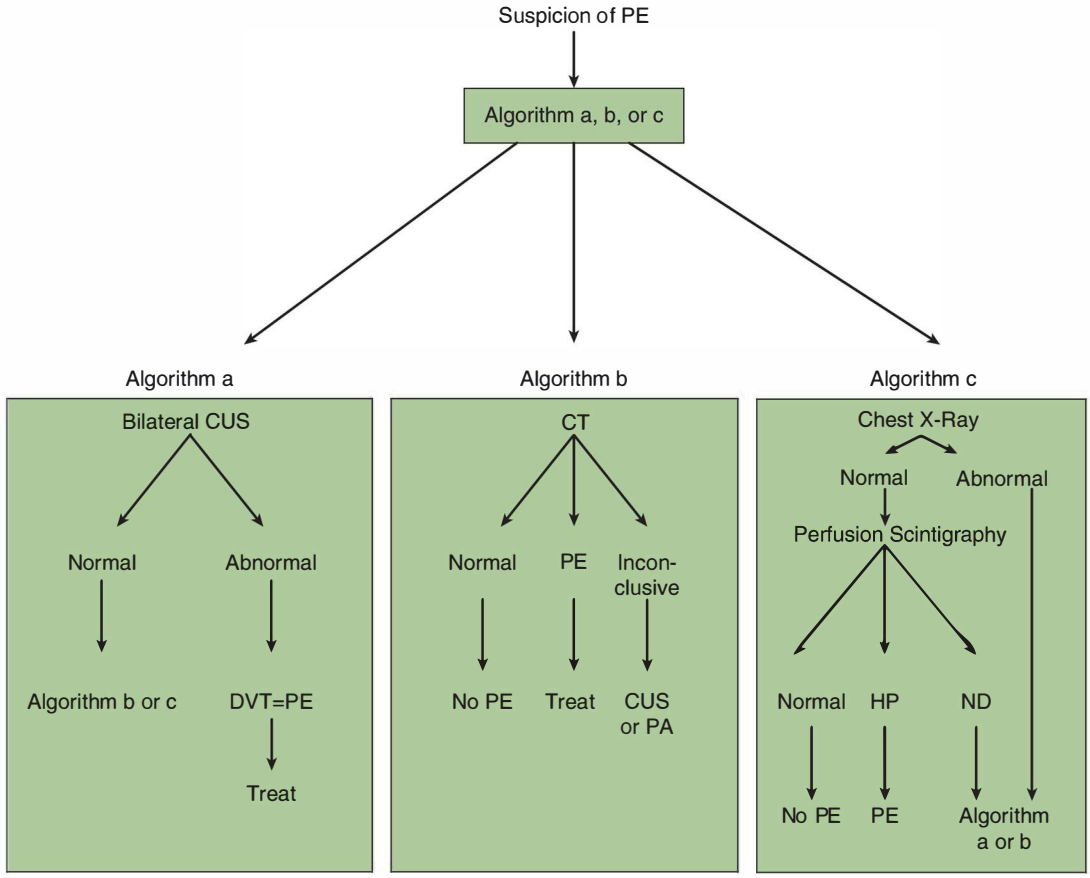

FIGURE 116.3 Algorithms of a clinical suspicion of PE in pregnancy. CT, computed tomography; CUS, compression ultrasonography; HP, high probability; ND, nondiagnostic; PE, pulmonary embolism; PA, pulmonary angiography.

excreted in the breast milk that are insufficient to prolong the prothrombin time in infants.[44]

In a systematic review of VKA use in pregnant women with mechanical heart valves, major bleeding events occurred in 2.5% (95% CI 1.7% to 3.5%) of all pregnancies, most at the time of delivery.[38]

Low Molecular Weight Heparin

There is ample experience with low molecular weight heparin (LMWH) in pregnant women. These agents do not cross the placenta and are considered safe to use in pregnancy, based on numerous observational studies.[12,45] The need for, usually once daily, injections is a nuisance of LMWH, and the long-term use in pregnant women frequently leads to skin reactions, which are mainly type IV delayed hypersensitivity reactions at the injection site.[46–48] Switching to another LMWH preparation is reported to be indicated in 25% of patients, and of these, about one-third also developed complaints with the use of another LMWH.[46] The incidence of heparin-induced thrombocytopenia (HIT) in pregnant patients who are only treated with LMWH is considered very low (<0.1%),[45] and therefore, the weak, grade 2C recommendation in the most recent American College of Chest Physicians (ACCP) guideline is to not routinely monitor platelet counts. The risk of HIT is assumed to be somewhat higher, between 0.1% and 1%, in women who have been exposed to unfractionated heparin prior to LMWH treatment and monitoring of platelet counts is advised.[49] Small studies of bone density in pregnant women receiving prophylactic doses of LMWH suggest that the use of this medication does not induce more bone loss as compared to pregnant women who did not receive LMWH.[50,51]

Although small amounts of LMWH are excreted into breast milk, LMWH is not absorbed after oral intake and this is unlikely to have any relevant effect in breast-fed infants.[12,52]

The risk of significant bleeding with the use of LMWH in pregnant women is generally reported to be around 2% and as being mostly related to obstetric causes.[45] These data are based on observational studies including a wide range of doses of LMWH with the majority of prophylactic and intermediate doses. Furthermore, these reports may be biased by selective publication of successful patient histories and underreporting of complications.[53–55] When therapeutic doses are employed, the incidence of major bleeding was estimated to be 1.7% (95% CI 0.4% to 5.0%) in a systematic review of 15 studies (including 6 case reports) reporting 174 women who had been treated for acute VTE.[45] In a prospective evaluation of 126 pregnant women with acute VTE, the risks for bleeding during pregnancy was 6%, with none of the episodes considered by the authors as major bleeding, although these included episodes of rectal bleeding from endometriosis and haemoptysis.[56] The risk of postpartum hemorrhage (>500 mL of blood loss) was 5% in the first 24 hours after delivery, and secondary major postpartum

hemorrhage occurred in 2% of the women in the days thereafter. In our own study of 83 women who had been treated with therapeutic doses of LMWH, the incidence of postpartum hemorrhage was around 10%, which was not statistically different from a cohort of women who delivered in the same hospital and who were not treated with anticoagulants.[57]

Unfractionated Heparin

Unfractionated heparin can be administered subcutaneously and dose adjustments can be made based on activated partial thromboplastin times (APTTs), but the short half-life leads to the need for a twice daily dosing regimen. Furthermore, unfractionated heparin is more frequently associated with osteoporosis, HIT, and type I allergic reactions than LMWH.[12] Long-term unfractionated heparin use is known to cause symptomatic osteoporosis in up to 2% of patients.[58] Thus, unfractionated heparin should be reserved for women with a contraindication to LMWH (mostly chronic renal failure with a creatinine clearance below 30 mL/min) or when LMWH is not available.[12]

Unfractionated heparin has a high molecular weight and a strong negative charge and does not pass into breast milk.

In a retrospective cohort study of 100 pregnancies in 77 women, the rate of major antepartum bleeding in pregnant women treated with unfractionated heparin was 1% (95% CI 0.2% to 5.4%), which is consistent with reported rates of bleeding associated with heparin therapy in nonpregnant patients.[59]

Other Heparin-Like Anticoagulants

Danaparoid and fondaparinux have been and are increasingly being used in pregnancy, although the experience in human pregnancies is limited.[12,60] Furthermore, minor anticoagulant activity could be detected in fetal cord blood in five neonates of mothers who were treated with fondaparinux, indicating some placental transfer of the pentasaccharide.[61] Thus, in the absence of extensive safety data, danaparoid and fondaparinux should be reserved for women who do not tolerate heparin, most often when all registered heparins lead to type I allergy, skin problems, or HIT.[62]

Very little is known about the passage of fondaparinux or danaparoid into human breast milk. Since both agents are not absorbed after oral intake, it is unlikely to have any anticoagulant effect in breast-fed infants.[63]

Thrombin and Factor Xa Inhibitors

A few case reports have described the use of parenteral thrombin inhibitors in pregnancy, but these data are insufficient to conclude on their safety in pregnant women.[12] There is no place for new oral anticoagulants, since the human reproductive risks of these medications, that is, dabigatran, rivaroxaban, and apixaban, are unknown. The summaries of product characteristics for dabigatran and rivaroxaban describe animal reproductive toxicity.

It is recommended by the manufacturers that breast-feeding women do not use these medications.[12]

Thrombolytics

Although thrombolysis is contraindicated in pregnancy, a recent literature review identified 13 case reports that described its use in pregnant patients with massive PE.[64,65] Recombinant tPA and streptokinase are large molecules that do not cross the placenta, whereas urokinase does.[64] In these severely ill women, fetal death occurred in 15% and preterm delivery in approximately 30% of cases.

The risk of maternal major bleeding complications was 30.8%; 95% CI (9.1 to 61.4).[64]

Treatment of Acute VTE in Pregnant Women

Pregnant women have been excluded from all clinical trials investigating various treatment regimens in acute VTE. In pregnancy, the volume of distribution of LMWH changes and glomerular filtration rate increases in the second trimester. Dosing therapeutic LMWH in pregnant women is associated with uncertainties about whether a prepregnancy weight or actual body weight needs to be used to determine the appropriate dose, whether dose adjustments are required as the pregnancy progresses, and whether a twice daily regimen should be preferred over a once daily regimen. Data from pharmacokinetic studies of various LMWHs in pregnant women have shown conflicting results with regard to the need for dose escalation to maintain levels within the therapeutic range.[66–71] The ACCP guidelines do not provide specific advice about anti-Xa level monitoring, in the absence of large studies using clinical endpoints demonstrating that there is an optimal therapeutic anti-Xa LMWH range or that dose adjustments increase the safety or efficacy of therapy.[12] Nevertheless, in our practice, we prescribe therapeutic doses of LMWH throughout pregnancy and monitor anti-Xa levels to achieve a 4-hour postinjection peak level of 0.8 to 1.6 U/mL with a once daily regimen of LMWH (0.6 to 1.0 if a twice daily regimen is used).[72] Prospective observational studies have not demonstrated an increase in the risk of recurrence with the once daily regimen over the twice daily regimen,[56,73] and a once daily regimen likely enhances adherence. Women should be treated at least until 6 weeks postpartum, since the daily risk in any woman to develop VTE is highest during this period.[8] Extrapolating the optimal duration of anticoagulation of nonpregnant patients with a VTE provoked by a major temporary risk factor, the minimum duration should be 3 months, so this postpartum treatment may be longer if VTE occurred in late pregnancy.[74]

For women in whom the need for rapid counteraction of the anticoagulant effect is anticipated, intravenous unfractionated heparin to achieve a therapeutic APTT is a reasonable short-term option. Unfractionated heparin has a short half-life (3 hours) and can be completely counteracted by protamine sulfate, although there are no solid safety data of the latter agent in pregnancy. In our experience, these presumed benefits are often counterbalanced by difficulty in achieving APTTs in the desired range, with the obvious risk of extending thrombosis as a result of undertreatment in a woman with acute VTE and overanticoagulation in a woman in whom this option is chosen because of an increased risk of bleeding.

In case of life-threatening PE, that is, pregnant women with an established diagnosis who are hemodynamically unstable, systemic thrombolysis with either recombinant tPA or streptokinase (whatever protocol is in place) is justified.[64]

Prevention of VTE

We identify three categories of women in whom pharmacologic prophylaxis of pregnancy-related VTE should be considered: (a) women with a history of VTE; (b) asymptomatic women with

an increased baseline risk of VTE, that is, known thrombophilia and/or a positive family history of VTE; and (c) women who have undergone a cesarean section.

LMWH is the agent of choice to prevent pregnancy-related VTE. The optimal dose of LMWH, however, is controversial, since no evidence from adequate randomized controlled trials are available.[12] Most centers use a prophylactic dose of LMWH in women who have an indication for thrombosis prophylaxis in pregnancy and the postpartum period. However, numerous treatment failures have been reported,[53,75,76] with an estimated risk of recurrent VTE despite the use of low-dose LMWH as high as 5% to 6%.[76–78] Potential benefits of the intermediate dose of LMWH consist of superior efficacy as compared to the low dose of LMWH. Harms consist of an increased risk of bleeding, mostly associated with delivery and neuraxial anesthesia. However, we observed no VTE recurrences in a retrospective study of 95 women who used therapeutic dose LMWH, whereas the risk of serious bleeding was not increased compared to 524 women who had delivered in the same hospital without LMWH use.[57] In the absence of evidence, the ACCP guidelines suggest either a prophylactic or an intermediate dose of LMWH to prevent recurrent VTE in pregnancy and the postpartum period, but it is clear that a randomized controlled trial between different doses of LMWH is needed.[12]

Prevention of Recurrent VTE

Women with a history of VTE have a three- to fourfold higher risk of VTE during subsequent pregnancies than outside of pregnancy.[79] The absolute risk of recurrent VTE during pregnancy, in the absence of pharmacologic prophylaxis, is estimated to be between 2.4% and 10%.[76,80,81] Data regarding prognostic factors for recurrent VTE during pregnancy, including the presence of provoking risk factors during the first event and hereditary thrombophilia, are inconsistent. In two retrospective studies, women who had their first episode of VTE provoked by use of oral contraceptives or related to pregnancy or the postpartum period had a nonsignificant higher risk of recurrent VTE in a subsequent pregnancy than women whose first VTE was unprovoked or associated with a nonhormonal transient risk factor.[76,81] Likewise, in a large population-based cohort study, women who had their first VTE associated with pregnancy or the postpartum period had a higher risk of recurrence during a subsequent pregnancy than women with an unprovoked first VTE, that is, 4.5% versus 2.7% (RR 1.71, 95% CI 1.0 to 2.8).[82]

According to the ACCP guidelines, patients can be categorized into groups at low risk (major transient risk factor for VTE), intermediate (hormone- or pregnancy-related or unprovoked VTE), or high risk (multiple prior unprovoked VTE or persistent risk factors such as paralysis) during pregnancy. All women with a history of VTE should receive prophylaxis with LMWH for 6 weeks postpartum. For antepartum prophylaxis, the ACCP guidelines suggest to withhold this in women with a low risk of pregnancy-related recurrence (major nonhormonal transient risk factor for VTE).[12] In women at moderate-to-high risk of recurrence who are not on long-term anticoagulant therapy, prophylaxis with LMWH is recommended during the entire pregnancy. The recommendations are summarized in Table 116.3.

Finally, in women who are on long-term anticoagulant therapy switching to full adjusted dose LMWH as soon as a urine pregnancy test is positive (i.e., before 6 weeks gestational age) and supplying vitamin K 5 mg orally for 3 days is a feasible regimen (for more details about the full-dose LMWH regimen, see the above section on treatment of acute VTE). Postpartum, women can switch back to their usual anticoagulant therapy with bridging of LMWH until the target international normalized ratio (INR) is reached.

Prevention of VTE in Asymptomatic Women with Thrombophilia

In women with a positive family history and/or hereditary thrombophilia who do not have a personal history of VTE, the decision to use pharmacologic prophylaxis is based on the absolute risk estimate of having VTE during pregnancy or in the postpartum period. The increase in risk begins early in pregnancy and when antepartum prophylaxis is utilized, it should be commenced as early as possible in the first trimester. The threshold to use antepartum prophylaxis is higher given the burden of self-injecting with LMWH over several months as opposed to 6 weeks in the postpartum period.

Table 116.3

Summary of recommendations to prevent a first or recurrent pregnancy-related VTE[a]

Antepartum and Postpartum Prophylaxis	Postpartum Prophylaxis During 6 Weeks[b]	No Pharmacologic Prophylaxis[b]
Women with a single unprovoked episode of VTE, or provoked by the use of oral contraceptives, pregnancy, or postpartum	Women with a history of a single episode of VTE related to a major nonhormonal transient risk factor	General population
Women with a history of recurrent VTE	Women with hereditary thrombophilia and a positive family history[c] of VTE	Women with a positive family history[c] of VTE
Women who are homozygous for factor V Leiden or prothrombin mutation who have a positive family history[c] of VTE	Women who are homozygous for factor V Leiden or prothrombin mutation who do *not* have a positive family history[c] of VTE	Women who are heterozygous for factor V Leiden or prothrombin mutation who do *not* have a positive family history[c] of VTE

[a]Recommendations are weak, based on a low level of evidence leaving room to individualize prophylactic strategies based on the patient's preferences.[12]
[b]Unless women can be categorized into one of the more aggressive prophylactic strategies in this table.
[c]A positive family history is defined as having a first-degree relative with VTE.

Based on the risk estimates in Table 116.1, the ACCP guidelines suggest both antepartum and postpartum prophylaxis only in homozygous carriers of the factor V Leiden or prothrombin gene mutations who have a positive family history of VTE.[12] In women with the other inherited thrombophilias who have a family history of VTE, or in homozygous carriers of the factor V Leiden or prothrombin gene mutations without a positive family history of VTE, clinical vigilance antepartum and postpartum prophylaxis with LMWH is suggested.[12] For postpartum prophylaxis, VKA is an alternative option in women without protein C or S deficiency (who are at risk of developing warfarin-induced skin necrosis) but is impractical because of the time needed to reach the target INR. The recommendations are summarized in Table 116.3.

Prevention of VTE After Cesarean Section

The absolute risk estimate of VTE after cesarean section ranges from 1 to 18 per 1,000.[12] The ACCP guidelines extrapolate from general surgery patients that the balance of desirable and undesirable consequences of thrombosis prophylaxis would suggest prophylaxis for women with an absolute VTE risk of 30 per 1,000 or higher.[12] With a baseline risk of 5/1,000 VTE postcesarean delivery, the presence or absence of risk factors will determine the absolute benefit of thrombosis prophylaxis. Table 116.4 provides an overview of major and minor risk factors to identify women with a high risk of VTE after cesarean section (30/1,000).[12] In women with no other risk factors for VTE except cesarean section, no prophylaxis is recommended apart from early ambulation. For women at increased risk of VTE after cesarean section because of the presence of one major or at least two minor risk factors, the ACCP guidelines suggest a prophylactic dose of LMWH (or mechanical prophylaxis in those with contraindications to anticoagulants) for as long as their hospital stay.[12] The optimal duration of prophylaxis after cesarean section is not established. A commonly used strategy is to continue prophylaxis until discharge from hospital and extend prophylaxis until 6 weeks postpartum in women with significant ongoing risk factors.

Management of Delivery and Postpartum Period

A well-described plan, made by a multidisciplinary team, should be available and depends on indication for and dose of LMWH, as well as local preferences and experience, rather than evidence. Several options are possible, including spontaneous labor and delivery, induction of labor, and elective cesarean section. If there is no obstetric indication for an induced delivery, women can be instructed to not inject LMWH as soon as labor starts with either contractions or rupture of the membranes. With this approach, most women will deliver within 24 hours, and with the peak anti-Xa level at 4 hours after the last injection, most women remain somewhat, but not fully, anticoagulated while in labor. Active management of the third stage of labor, that is, the delivery of the placenta, is necessary to minimize the risks of obstetric hemorrhage. In women who are expected to deliver fast or have a history of peripartum bleeding, switching to a twice daily regimen can be considered in the last weeks prior to expected delivery (e.g., from the gestational age of 37 weeks), although there is no pharmacokinetic rationale in pregnant women to support this approach.

A planned delivery should be considered in women at very high risk for extension or recurrent VTE (arbitrarily those in whom acute VTE was diagnosed within a month prior to expected delivery), so that the duration of time without anticoagulation can be minimized. These women can be switched to therapeutic intravenous unfractionated heparin, which is then discontinued 4 hours prior to the expected time of delivery or the use of neuraxial anesthesia (see also the above section on Treatment of VTE during pregnancy). In exceptional cases, for instance, in women who also have a contraindication to anticoagulation transiently (need for a cesarean section), the use of a temporary inferior vena cava filter may be considered. Still, experience with these devices during pregnancy is limited and filter migration and inferior caval vein perforation have been described in pregnant patients.[83,84]

Besides the potential increased risk for bleeding from obstetric causes, it is important to note that the use of LMWH precludes the use of neuraxial anesthesia, because of the (very low) risk of neuraxial hematoma. In prophylactic doses, LMWH should be discontinued at least 12 hours prior to neuraxial anesthesia and should not be restarted until 8 hours after catheter removal.[85] In therapeutic doses, LMWH should be discontinued at least 24 hours prior to neuraxial anesthesia and should not be restarted until 24 hours after catheter removal.[85] Discontinuation of anticoagulation for 48 hours or longer is not attractive in the setting of the treatment of acute VTE (arbitrarily defined as within 1 month).

Postpartum Management

Anticoagulation should be restarted after delivery, as soon as possible, but depending on the amount of estimated vaginal blood loss and the type of delivery. Generally, restarting anticoagulation 6 to 12 hours after delivery is feasible, but this period should be longer if hemostasis is not adequate. For women in whom resumption of VKA is planned, we restart LMWH at first, while the first dose of VKA is initiated at least 1 day later.

PART II: HORMONAL CONTRACEPTION AND VENOUS THROMBOEMBOLISM

Introduction

Combined oral contraceptives contain both an estrogen and a progestagen. They were first approved in the United States in 1960 and it is estimated that over 100 million women worldwide currently use an oral contraceptive pill.[86] Almost immediately after their introduction, it became clear that the use of these female hormones increased the risk of VTE and it is currently considered an important acquired risk factor for this disease.[87] Combined oral contraceptive pills are the most widely used contraceptives, but progestagen-only pills and nonoral hormone contraceptives, such as hormone releasing intrauterine devices (IUDs), injectables, subcutaneous implants, or skin patches, are also available. Apart from contraceptive purposes, female hormones can also be used for treatment of menstrual disorders and in lower doses as hormone replacement therapy

Table 116.4

Risk factors for VTE after cesarean section

Major Risk Factors (ORs >6): Presence of at Least One Risk Factor Suggests a Risk of Postpartum VTE of >3%
• Immobility (strict bed rest for a week or more in the antepartum period)
• Postpartum hemorrhage ≥1,000 mL with surgery
• Previous VTE
• Preeclampsia with fetal growth restriction
• Thrombophilia
- Antithrombin deficiency[a]
- Factor V Leiden (homozygous or heterozygous)
- Prothrombin G20210A (homozygous or heterozygous)
• Medical conditions
- Systemic Lupus Erythematodes (SLE)
- Heart disease
- Sickle cell disease
• Blood transfusion
• Postpartum infection
Minor Risk Factors (ORs >6 when combined): Presence of at Least Two Risk Factors or One Risk Factor in the Setting of Emergency Cesarean Section Suggests a Risk of Postpartum VTE of >3%
• BMI > 30 kg/m^2
• Multiple pregnancy
• Postpartum hemorrhage >1 L
• Smoking >10 cigarettes per day
• Fetal growth restriction (gestational age + sex adjusted birth weight <2.5th percentile)
• Thrombophilia
- Protein C deficiency
- Protein S deficiency
• Preeclampsia

[a]Although the OR in a systematic review was 4.69, confidence intervals were wide and numbers small.[150] Further, other retrospective studies have calculated ORs of 282 (95% CI 31–2,532) for type I antithrombin deficiency and 28 (95% CI 5.5–142) for type II deficiency.[159] Thus, antithrombin deficiency has been left as a major risk factor. Table from Bates SM, Greer IA, Middeldorp S, et al. Venous thromboembolism, thrombophilia, antithrombotic therapy and pregnancy: ACCP evidence-based clinical practice guidelines (ninth edition). *Chest* 2012;141:e691S–e736S. Used with permission. Original data from other studies.[6,16,73,150,156–158]

(HRT) to improve quality of life in women with perimenopausal complaints. The next section discusses the effects of female hormones on blood coagulation and the risk of VTE in women using them.

Hormonal Contraceptives

Risk of First VTE

The majority of risks estimates of VTE associated with hormonal contraceptives are derived from case–control or cohort studies that provide relative risk increases for users as compared to nonusers. In the interpretation of these relative risks, one first needs to know the absolute baseline risk of VTE. If no valid observations on the absolute risk associated with hormone use are available, one can estimate the absolute risk of VTE by multiplying this baseline risk with the relative risks of VTE associated with hormone use. This indirect estimation of the absolute risk is valuable for clinical practice but likely leads to a modest overestimation of the risk, because the age- and sex-specific baseline risks are derived from cohorts in which a proportion of the women used oral contraceptives.

The absolute risk of a first VTE increases sharply with age, in particular after the age of 45.[88–90] The absolute incidence of first VTE in women aged 20 to 44 was 0.39 per 1,000 person-years, increasing to 1.00 per 1,000 person-years in women aged 45 to 54 in a large Norwegian cohort.[89] Hence, the excess risk caused by hormonal contraceptive use is very modest for most women on the individual level and needs to be balanced against the beneficial effects of these hormones, such as avoidance of an unintended pregnancy. However, even a small increase of VTE risk is relevant due to the large numbers of women using oral contraceptives worldwide, leading to a significant population-attributable risk. Importantly, the relative risk of VTE is highest

in the first 3 months of use and gradually decreases during the 1st year. This was elegantly illustrated in a large case–control study of patients with a first VTE that showed an OR of 13 (95% CI 7 to 22) during the first 3 months of oral contraceptive use, decreasing to an OR of 5 (95% CI 4 to 6) after the 1st year.[91] Of note, despite this "starter effect," the increased risk of VTE associated with oral contraceptive use remains, even after long-term exposure (i.e., more than 5 years).[91] Furthermore, with increasing length of oral contraceptive use, the baseline risk of VTE increases with age, so that in absolute terms, the starter effect may have less absolute impact than the persisting relative risk.

Oral Contraceptives

Most currently available oral contraceptives are combined preparations containing both an estrogen (i.e., ethinylestradiol) and a progestagen. Numerous types of oral contraceptives are available containing different doses of estrogen and different types of progestagens. The first available preparations contained a high dose of estrogen of more than 50 μg. However, after the reported increased thrombotic risk associated with combined oral contraceptive use was attributed to the amount of estrogen in the contraceptive pill, the dose of estrogen was stepwise reduced. The initial lowering of the estrogen dose to 30 μg indeed decreased the risk of venous thrombosis by 30% to 50%.[91,92,93] Further reduction of the estrogen dose to 20 μg was shown to reduce the risk of VTE by another 20%.[91,94]

The progestagens in combined oral contraceptives modulate the prothrombotic effect of the estrogens. This leads to different thrombotic risks between contraceptives with different progestagens.[95] Numerous different types of progestagens with different chemical compositions are available. The oldest types of progestagens are lynestrenol and norethisterone. These so-called first-generation progestagens are not used very often nowadays. Combined oral contraceptives that contain the progestagens levonorgestrel or norgestrel are currently most widely used worldwide. The use of these second-generation oral contraceptives is associated with a three- to fourfold increased risk of VTE.[91,96] Newer types of oral contraceptives contain the progestagens gestodene, desogestrel, or norgestimate and these are often referred to as third-generation oral contraceptives. The use of these newer oral contraceptives is associated with a higher risk of VTE (OR 5 to 8 compared to nonusers) than levonorgestrel-containing oral contraceptives (OR 3 to 4 compared to nonusers).[91,96,97] Preparations containing cyproterone acetate are used for treatment of acne vulgaris, seborrhea, or mild hirsutism and have antiovulatory action similar to that of a progestagen. Preparations containing drospirenone, which is an antimineralocorticoid, also inhibit ovulation. These were heavily marketed arguing that these pills reduce side effects of older contraceptives including bloating and mood swings. However, the risk of VTE with these oral contraceptives is increased six- to sevenfold, that is, similar to the risk of the third-generation contraceptives.[91,96]

Progestagen-only preparations used for therapeutic reasons (mainly menstrual disorders), containing different progestagens or higher doses of progestagens than used in combined oral contraceptives, are associated with an approximately fivefold increased risk of VTE.[98,99] Contrary to this, progestagen-only pills used for contraception, so-called minipills, do not seem to increase the risk of VTE.[94,98,100] Table 116.5 shows the estimated relative and absolute risks of different types of oral contraceptives.

Nonoral Contraceptives

The levonorgestrel-releasing IUD is a T-shaped plastic contraceptive that, after insertion into the uterine cavity, releases 10 to 20 μg levonorgestrel per day, which leads to plasma levels of 150 to 200 pg/mL in the peripheral blood, as compared to a maximum level of 800 pg/mL during the use of a 30-μg levonorgestrel-only pill.[101] The use of this IUD was not associated with an increased risk of VTE in two studies.[96,102]

Depot medroxyprogesterone (DMPA) is an injectable contraceptive that is used once per 12 weeks. Although its effect on VTE has not been widely studied, its use seems to be associated with a mild-to-moderate increased risk of VTE.[100,102]

The etonogestrel-containing implant is a progestagen-only contraceptive that is implanted under the skin. Etonogestrel is an active metabolite of the third-generation progestagen desogestrel. The delivery dose varies over time from 60 to 70 μg/day in the 1st weeks of use to 25 to 30 μg/day after 3 years. Very little is known about the thrombotic risks associated with the use of this implant. Studies on coagulation markers in patients with implants do not show prothrombotic changes, providing some indirect evidence that there may not be an increased risk of VTE.[103,104]

Patches deliver hormones through the skin and are thereby uninfluenced by the first-pass metabolism in the gut wall and liver. The patch designed for contraception delivers 15 to 20 μg/day of ethinylestradiol combined with norelgestromin. The risk of VTE in women with the patch has not been compared to nonusers. However, two case–control studies compared the risk of this patch to the risk of a levonorgestrel-containing combined oral contraceptives showing a similar to twofold increased risk.[105–107]

Finally, the hormone-releasing vaginal ring delivers 15 μg/day of ethinylestradiol combined with etonogestrel. No studies on the risks of VTE in women who use this vaginal ring are available. Scarce studies on coagulation markers in women with a vaginal ring show conflicting results.[101,108,109] Table 116.5 shows the estimated relative and absolute risks of these nonoral contraceptives.

Risk of VTE in Women with an Increased Baseline Risk

The presence of hereditary thrombophilia increases the risk of a first VTE in carriers. The relative risk of VTE associated with the use of hormonal contraceptives is similar in women with or without thrombophilia, but due to the higher baseline risk in the former, the absolute risk increase is larger in women with thrombophilia. The baseline risk of VTE in women with thrombophilia depends on the setting in which they were tested. Women with thrombophilia, selected from families with a tendency for VTE, have a higher absolute risk than women with the same defect identified by population testing.[110] Furthermore, individuals with a first-degree relative with VTE have a twofold increased risk of VTE and women with more than one first-degree relative with VTE have a fourfold increased risk of VTE, regardless of the presence of thrombophilia.[111] For women with inherited thrombophilia and a positive family history of VTE, family cohort studies provide useful estimates of the absolute risk of VTE during oral contraceptive use.[112–116] However, due to the relatively small number of women using oral contraceptives in these family studies, no distinction between the risks of different types of oral contraceptives can be made. Table 116.6 shows the observed absolute incidences per year of

Table 116.5

Estimates of relative and absolute risks in women without previous VTE for different forms of hormonal contraceptives and HRT

	Odds Ratio (95% CI)	Absolute Risk (/ 1,000 Person-Years)[a]
Hormonal Contraceptives		
Strong Risk Increase (OR 5–8)		
• Ethinylestradiol[b]/desogestrel	7.3 (5.3–10.0)[91]	2.8 (2.1–3.9)
• Ethinylestradiol[b]/cyproterone	6.8 (4.7–10.0)[91]	2.7 (1.8–3.9)
• Ethinylestradiol[b]/drosperidone	6.3 (2.9–13.7)[91]	2.5 (1.1–5.3)
• Ethinylestradiol[b]/norgestimate	5.9 (1.7–21.0)[91]	2.3 (0.7–8.2)
• Ethinylestradiol[b]/gestodene	5.6 (3.7–8.4)[91]	2.2 (1.4–3.3)
• Ethinylestradiol[b]/lynestrenol	5.6 (3.0–10.2)[91]	2.2 (1.2–4.0)
• Oral progestagen only, high dose (5–30 mg)	5.3 (1.5–18.7)[98]	2.1 (0.6–7.3)
Moderate Risk Increase (OR 2–5)		
• Ethinylestradiol[b]/noresthisterone	3.9 (1.4–10.6)[91]	1.5 (0.5–4.1)
• Ethinylestradiol[b]/levonorgestrel	3.6 (2.9–4.6)[91]	1.4 (1.1–1.8)
• Injectable DMPA	3.6 (1.8–7.1)[102]	1.4 (0.7–2.8)
• Transdermal ethinylestradiol/norelgestromin[c]	1.0 (0.7–1.5)[107]	1.5 (0.5–4.1)
No Risk Increase		
• Levonorgestrel-releasing IUD	0.3 (0.1–1.1)[102]	0.1 (0.0–0.4)
• Progestagen only, low dose		
• Norethisteron 350 μg or levonorgestrel 30 μg	0.6 (0.3–1.0)[94]	0.2 (0.1–0.4)
• Desogestrel 75 μg	0.6 (0.2–1.9)[96]	0.2 (0.1–0.7)
Unknown[d]		
• Etonogestrel subcutaneous implant	n/a	n/a
• Vaginal ring (ethinylestradiol/etonogestrel)	n/a	n/a
Hormone Replacement Therapy		
Modest Risk Increase (OR 1.5–3.0)		
Oral combined estrogen/progestagen pills	2.6 (2.0–3.2)[130]	2.6 (2.0–3.2)
Oral estrogen only	2.2 (1.6–3.0)[130]	2.2 (1.6–3.0)
No Risk Increase		
Transdermal (combined estrogen/progestagen and estrogen only)	1.2 (0.9–1.7)[130]	1.2 (0.9–1.7)
Tibolone	0.9 (0.8–1.1)[133]	0.9 (0.8–1.1)

[a]Estimates of the absolute risk were obtained by multiplying the OR with the baseline incidence of VTE of 0.39/1,000 person-years for women aged 20–44 for hormonal contraceptives and of 1.00/1,000 person-years for women aged 45–54 for HRT.[89]
[b]Ethinylestradiol in the most commonly used dose of 30–40 μg daily.
[c]OR for VTE as compared to OCP: EE2/norethisterone. Therefore, the OR of EE2/norethisterone was used to estimate the absolute risk.
[d]No studies with clinical outcome available; studies assessing coagulation markers only were disregarded in this table.
95% CI, 95% confidence interval; OR, odds ratio.

oral contraceptive use derived from those family studies. With these absolute incidences, rough estimates can be calculated of the number of women with thrombophilia that need to refrain from oral contraceptive use in order to prevent one VTE. For deficiencies of antithrombin, protein C, or protein S, this number is around 50 and for the factor V Leiden and prothrombin 20210A mutations, this number is around 200 to 400. Finally, approximately 2,500 women with a family history of VTE need to refrain from oral contraceptive use in order to prevent one VTE, while this number is approximately 5,000 in women from the general population.[117]

As mentioned before, increasing age is another important factor that increases the baseline risk of VTE.[89] This implies that the excess risk increase induced by hormonal contraceptives, in absolute terms, is larger for older women than for younger women.

tahir99-VRG & vip.persianss.ir

Table 116.6

Absolute risk of VTE per year of oral contraceptive use in asymptomatic women with a positive family history for VTE, according to the type of thrombophilia

	Oral Contraceptive Use (% per Year of Use, 95% CI)[a]
Hereditary deficiencies of antithrombin, protein C, or protein S	4.3 (1.4–9.7)[115]
Factor V Leiden	0.5 (0.1–1.4)[114]
Prothrombin 20210A	0.2 (0.0–0.9)[112]
Elevated factor VIII	0.6 (0.2–1.5)[113]
Mild hyperhomocysteinemia	0.1 (0.0–0.7)[116]
Positive family history of VTE (≥1 first-degree relative)	0.1 (0.1–0.1)[b]

[a]Due to relatively small numbers of women using oral contraceptives in these studies, no risk differentiation of different oral contraceptives could be calculated.
[b]Estimated absolute risk by multiplication of the OR of 2.2 (95% CI 1.9–2.6) of a positive family history[111] with the baseline incidence of 0.039% per year.[89]
Observed in retrospective family studies that investigated first-degree family members of patients with VTE and a thrombophilia.
CI, confidence interval.

Risk of Recurrent VTE

Observational data indicate that women who resume oral contraceptive use after VTE have an increased risk of recurrence. In a relatively small follow-up study, women who used an oral contraceptive after VTE had a nonsignificant two- to threefold increased risk of recurrence, regardless of whether their first VTE was unprovoked or provoked by oral contraceptives.[118] Although oral contraceptive use is a clear and removable risk factor for developing VTE, there is some debate whether oral contraceptive use during a (first) VTE, either recently started or after long-term exposure, should be classified as a provoked VTE that would have a lower recurrence rate than an unprovoked VTE. As compared to women with an unprovoked VTE, the relative risk of recurrence in women with a first VTE associated with an oral contraceptive ranges from 0.3 to 1.2.[30,118–121]

Hormone Replacement Therapy

Initially, HRT was prescribed to improve cardiovascular risk factors and to protect women against the postmenopausal rise in the incidence of arterial cardiovascular disease.[122,123] This radically changed after large randomized controlled trials demonstrated that HRT does not prevent arterial cardiovascular disease and even has a detrimental effect in the first year of use.[124–126]

With regard to the risk of VTE, it is important to reemphasize that, due to increasing age, the population baseline risk of VTE is higher for women using HRT than for women using hormonal contraception.[89] Hence, a risk factor with an OR of 2.5 has a much larger impact on the absolute risk in older women.

Similar to hormonal contraceptives, HRT is available in various forms and generally provides a low dose of estrogen (either conjugated equine estrogens or esterified, synthetic estrogens), combined with a progestagen or progestin. HRT can be taken orally, or delivered via patches, creams, gels, or injection. Both observational studies and randomized controlled trials have consistently shown an approximately two- to threefold increased risk of VTE in women using oral HRT.[127–129,130] Although only a limited number of observational studies, with inconsistent results, have assessed the risk of VTE associated with transdermal HRT, the pooled risk estimate for first VTE was 1.2 (95% CI 0.9 to 1.7) in a metaanalysis of these studies.[130] Tibolone, which is used as an oral HRT, is a synthetic steroid whose metabolites have estrogenic, progestagenic, and androgenic activities. Its use does not seem to be associated with an increased risk of VTE.[131–133] However, there are concerns of other harmful effects, that is, an increased risk of stroke or recurrent breast cancer.[131,132] Table 116.5 shows the estimated relative and absolute risks of VTE for women using HRT.

HRT also increases the risk of recurrent VTE. A randomized controlled trial of HRT in women with prior VTE was terminated early because of a markedly increased risk of recurrence in women who were given HRT.[134]

Effects of Female Hormones on the Coagulation System

Hormonal contraceptive use is associated with changes in the coagulation system at different levels. Coagulation studies have demonstrated an increase in clotting factors II, VII, VIII, and X in women using oral contraceptives,[135] a decrease of the levels of the natural anticoagulant protein S,[136] and a decrease of fibrinolytic activity, mainly through an increase of thrombin-activatable fibrinolysis inhibitor.[137] The use of oral contraceptives leads to increased resistance to the natural anticoagulant activity of APC resistance, which is partly explained by decreases of free protein S and free tissue factor pathway inhibitor.[138,139]

Although it is clear that the use of oral contraceptives is associated with a prothrombotic state as measured by coagulation and fibrinolysis assays, one may question if these intermediate endpoints indicate a true increased risk of VTE associated with hormone use. For example, combined oral contraceptives that contain progestagens such as desogestrel or gestodene induce a more pronounced APC resistance than combined oral contraceptives containing levonorgestrel.[140,141] In line with this difference in APC resistance, there is convincing evidence that users of combined oral contraceptives with desogestrel or

tahir99-VRG & vip.persianss.ir

gestodene have an increased risk of VTE as compared to users of contraceptives with levonorgestrel.[97] All studies using these intermediate endpoints point in the same direction and are in line with observed risks of VTE, indicating that these coagulation markers may be valid as surrogate endpoints when studies with clinical endpoints are not yet available.

Implications for Use of Hormonal Contraception and Hormone Replacement Therapy

Hormonal Contraception

If an oral contraceptive is considered, a combined oral contraceptive containing levonorgestrel or norethisterone should be preferred over other combined oral contraceptives, because of the lower risk of VTE. Alternatively, a levonorgestrel-releasing IUD, low-dose progestagen-only pills, the contraceptive patch, or the DMPA injectable can be considered. However, costs, adverse effects, and patient preference should also be taken into account in the choice of the contraceptive method.

A common question is whether women with an increased baseline risk of VTE, especially hereditary thrombophilia, are allowed to use hormonal contraception. Although, in absolute terms, the risk increase caused by hormonal contraceptives is larger for women with a higher baseline risk, one should also take into account the risk of VTE caused by an unintended pregnancy. For example, condom use has a much higher failure rate than the use of combined oral contraceptives (12 vs. 0.2 per 100 women-years).[142] A recent study demonstrated that the risk of first VTE in women with hereditary thrombophilia is the same for women who use a condom for contraception as compared to women who use a combined oral contraceptive, due to the additional risk of VTE conferred by unintended pregnancies.[142] Therefore, although a contraceptive method with a low risk of VTE should be preferred, we strongly feel that women should be counseled about the best contraceptive method for their specific situation, taking into account patient preferences. This implies that there should not be an absolute contraindication for hormonal contraceptives.

After an episode of VTE, we strongly advise to refrain from further or future use of hormonal contraceptives. It is noteworthy that there is no immediate need to stop oral contraceptives in women at the time of diagnosis of VTE, as anticoagulant therapy effectively prevents extension and recurrence of VTE[143] and adequate contraception is crucial in women treated with VKA in order to prevent warfarin embryopathy.[12] Thus, oral contraceptives may be continued until shortly before discontinuation of anticoagulant therapy.

Hormone-releasing IUDs are a rational choice for women with previous VTE. Data suggest that this indeed is a safe contraceptive method with regard to VTE risk, although these studies were limited to first thrombotic events and the safety has not been tested in women with a history of VTE.[96,102]

Hormone Replacement Therapy

In the Women's Health Initiative, the harms of HRT (modest increase in breast cancer, arterial cardiovascular disease, and VTE) outweighed the benefits of HRT (improvement of perimenopausal symptoms and a small decrease in osteoporotic hip fractures and colorectal cancer).[124] The most common remaining indication for postmenopausal HRT is improvement of perimenopausal symptoms, especially hot flushes.[144] This benefit needs to be balanced against the increased risks of adverse events, of which VTE is the most important in terms of absolute risk. The shortest possible duration should therefore be preferred. Women with an increased baseline risk of VTE (i.e., hereditary thrombophilia or a positive family history of VTE) are generally advised to refrain from HRT, although risk estimates for these women are less precise.[130] Furthermore, women with a personal history of VTE should not use HRT, as this increases the risk of recurrence.[134] In women with an increased risk of VTE who wish to use HRT despite having been counseled about its risks, transdermal use is preferred over oral use.

Overall Conclusions

Pregnancy and the postpartum period, as well as the use of hormonal contraceptives and HRT, all impact on a woman's lifetime risk of VTE. Identifying women at risk based on a personal or family history of VTE facilitates prevention of pregnancy-related VTE and prudent prescribing of hormones, taking into account patient preferences. Particularly in the area of pregnancy and VTE, there is an urgent need to establish a strong evidence base to guide clinical practice.

CHAPTER

117 Gestational Vascular Complications

BENJAMIN BRENNER, ANAT AHARON, AND JEAN-CHRISTOPHE GRIS

PLACENTAL HEMOSTASIS IN NORMAL PREGNANCY AND GESTATIONAL VASCULAR COMPLICATIONS

The placenta is a highly vascularized organ receiving blood supply from fetal and maternal circulations. Maternal blood flows in the intervillous spaces, while fetal blood is confined in the intravillous blood vessels. This may result in potential hemostatic problems, mainly the risk of hemorrhage or placental vascular complications[1] (FIGURE 117.1).

The placental villus is lined with trophoblast cells, specialized epithelial cells, that invade through the maternal endometrial stroma, migrate down the lumen of spiral arteries, replace the vascular endothelial lining, and become embedded in the arterial walls.[2,3,4] The trophoblasts are involved in local hemostatic mechanisms as well as in maternal and placental crosstalk (FIGURE 117.1).

TISSUE FACTOR

During pregnancy, placenta and deciduas are putative sources of tissue factor (TF), which is localized on the cell membranes, can bind to factor VII, and initiate the coagulation cascade.[5,6] TF is also essential for embryogenesis, angiogenesis, invasion, and implantation.[7–9] Normally, TF is not presented on cells that are in contact with blood circulation; however, the placenta is a unique organ—its surface is in direct contact with maternal circulation and trophoblast cells constitutively express high levels of TF antigen and activity.[3,10] In addition, cytotrophoblast (CTB) differentiation and fusion to multinucleated cells—syncytiotrophoblasts (STB)—require initiation of apoptosis and exposure of negatively charged phospholipids on their membrane surface.[11] Membrane "flip-flop" and exposure of negatively charged phospholipids are known to promote coagulation. Blockade of TF with a monoclonal antibody prevents activation of the coagulation pathway, restores placental blood flow, precludes placental oxidative stress, inhibits release of soluble vascular endothelial growth factor (VEGF) receptor 1 (sFlt-1), and consequently rescues pregnancy.[12] The procoagulant nature of placental trophoblast and decidual cells may reflect the physiologic need for immediate inhibition of hemorrhage in the placental intervillous spaces, protecting against placental abruption (PA) and meeting the hemostatic demands of labor and delivery.

PHYSIOLOGIC ANTICOAGULANTS

Despite the above-mentioned observations, coagulation does not normally occur across the entire villous surface.[3] The high levels of TF are tightly regulated by a variety of physiologic anticoagulants—tissue factor pathway inhibitor (TFPI), endothelial protein C receptor (EPCR), thrombomodulin (TM), and annexin V—which act by a variety of mechanisms.

TFPI is highly expressed in placental tissues from the 10 weeks of pregnancy up to term.[13,14] TFPI is produced and pooled (50% to 80%) in the microvascular endothelial cells[15] and in trophoblast cells.[10,13] In normal pregnancy, free TFPI antigen in plasma increased between first trimester and delivery but remained lower in nonpregnant controls.[16]

TFPI-2, (placental protein 5—PP5) is prominently expressed in human placenta[17] and in isolated villous CTB cells,[18] but its physiologic role in the placenta is currently unclear. Inactivation of the murine TF or TFPI genes results in embryonic lethality, indicating that both of these genes are required for embryonic development. Remarkably, the expression of low levels of TF in transgenic mice (1% of human TF) rescues TF-null embryos. However, low-TF mice (mTF(−/−)/hTF+) develop hemostatic defects in the uterus, placenta, heart, and lungs.[19]

TF–TFPI balance in human placenta may be disturbed, resulting in gestational vascular complications (GVCs). It has been found that placental trophoblasts obtained from GVC pregnancies have a disturbed balance between TF and TFPI. While some studies have demonstrated an increase in TF, others have revealed a decrease in TFPI, with underlying mechanisms remaining unclear.[14,20] Inflammatory cytokines, whose levels are occasionally elevated in GVC, contribute to this imbalance.[10] Low molecular weight heparins (LMWHs) stimulate expression, synthesis, and release of TFPI in endothelial cells and may exert their effect in pregnant women at risk for GVC, by modulating local hemostasis at the placental STB surface.[14]

TM is a cell-surface receptor for thrombin that converts thrombin from procoagulant activity into the protein C (PC) anticoagulant pathway. Studies in mice demonstrated that abortion of TM-deficient embryos is caused by TF-initiated activation of the blood coagulation cascade at the fetomaternal interface. Activated coagulation factors induce cell death and growth inhibition of placental trophoblasts.[21] The TM amount observed on vascular endothelium and STB rose significantly with growing gestational age, and the higher levels found at term microvilli were associated with an increase in TM ability to activate PC.[22] TM-mRNA expression increased in villous vessels of intrauterine growth restriction (IUGR) placentas[23] and reduced in placentas of recurrent miscarriages compared to those of healthy pregnancies.[24]

Endothelial PC receptor enables PC activation by the thrombin–TM complex. In mice, EPCR is detected in the giant trophoblast cells at the fetomaternal boundary from E7.5. Disruption of the EPCR gene in mice causes placental thrombosis and early embryonic lethality.[25] $EPCR^{-/-}$ embryos that had been removed

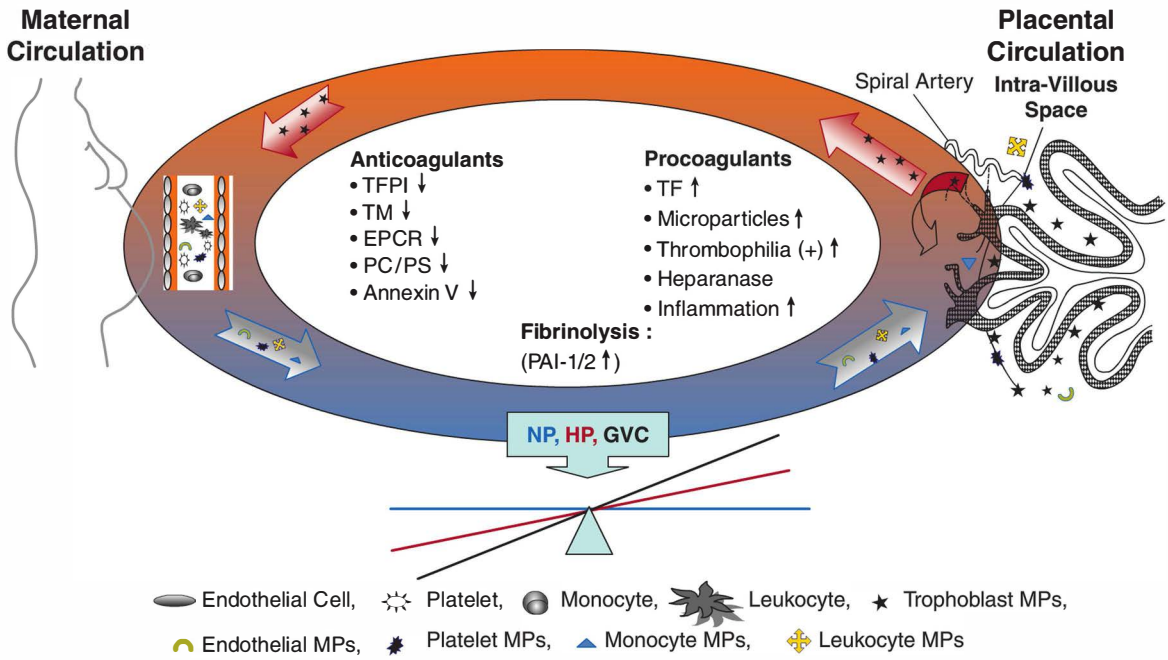

FIGURE 117.1 Placental–maternal crosstalk and hemostatic balance model. In pregnancy, the high levels of tissue factor (TF) on trophoblast cells and microparticles (MPs) are tightly regulated by a variety of physiologic anticoagulants: tissue factor pathway inhibitor (TFPI), endothelial protein C receptor (EPCR), thrombomodulin (TM), and annexin V, which act by a variety of mechanisms. In gestation vascular complications (GVCs), there are further increases in procoagulant properties, including maternal and placental MP levels, and further decreases in anticoagulant proteins, which perturb placental and maternal hemostatic balance. NP - non-pregnant HP - healthy pregnancy

from extraembryonic membranes and tissues at day E7.5 and cultured *in vitro* developed beyond E10.5, suggesting a role of EPCR in the normal function of the placenta and/or at the maternal–embryonic interface.[25]

The common variations in EPCR *gene* (c.323–20T>C, c.717+16G>C, c.323–9_336 duplication, c.655A>G) are rare and are not a major cause of recurrent miscarriage. However, the EPCR A6936G polymorphism was found to be associated with the risk of unexplained fetal loss in Mediterranean European couples and paternal EPCR 219Gly variant was found to be a mild and limited risk factor for deep vein thrombosis during pregnancy.[26–28]

Annexin V, an anticoagulant protein, is highly expressed on the apical surfaces of placental STBs. Binding of annexin V to the trophoblast procoagulant surfaces is crucial for the maintenance of blood flow through the placenta and consequently for fetal viability.[3,29] Reduced annexin V expression has been demonstrated in some placentas from women with preeclampsia (PE)[30] and fetal growth restriction.[31] Anti–annexin V antibodies are associated with higher incidence of intrauterine fetal loss, PE, as well as arterial and venous thrombosis. *In vivo* study demonstrated that anti–annexin V antibody induced trophoblast apoptosis and significantly reduced trophoblast gonadotropin secretion.[32]

Heparanase. Heparan sulphate proteoglycans are abundant in the extracellular matrix (ECM) of placenta and deciduas. Heparanase cleaves heparan sulfate at specific sites, leading to a release of growth factors that may be involved in placentation and trophoblast invasion decidualization and remodeling of the maternal vasculature in humans and mice. Heparanase is expressed in normal and abnormal placenta, in small fetal vessels, and in a variety of trophoblast subpopulations with different invasive potentials.[33,34] A high level of heparanase was observed in isolated first-trimester trophoblasts; however, failure of blocking antibody to inhibit trophoblast invasion suggests another role for heparanase during pregnancy.[35] Heparanase upregulates TF expression and interacts with TFPI on endothelial cells, resulting in increased cell-surface coagulation activity.[36] The regulatory effect of heparanase on TFPI and TFPI-2 in trophoblasts suggests a potential involvement of heparanase in early miscarriages.[37]

Fibrinolysis. Fibrin accumulation, characterizing term placenta, can cause occlusion and infarcts in placental blood vessels and intravillous spaces and may result in placental insufficiency and pregnancy loss (PL). Fibrinolysis is a process of clot degradation by plasmin that is converted from plasminogen by a tissue-type activator (tPA) or a urokinase-type plasminogen activator (uPA). Fibrinolysis is regulated by plasminogen activator inhibitor-1 and -2 (PAI-1, PAI-2) and by thrombin-activatable fibrinolysis inhibitor.[38] Both decidual and extravillous trophoblast cells of human placentas are capable of producing tPA, uPA, PAI-1, and PAI-2 to a different extent. Variations in the distribution of tPA and PAI-1 may be related to fibrinolytic activity at early stages of placentation and to separation of placenta at term, while differences in the distribution of uPA and PAI-2 may be promoted by degradation of trophoblast cell-associated ECM at early stages of placentation.[39] mRNA and protein levels of PAI-1 and PAI-2 were found to be higher in placental

tahir99-VRG & vip.persianss.ir

tissue of preeclamptic women compared to healthy pregnancies. Exposure of trophoblast cell culture to tumor necrosis factor-α results in an increased expression and secretion of PAI-1, with no significant alteration in tPA.[40,41] The change in PAI-1and PAI-2 could explain the imbalance of local fibrinolysis at the placental trophoblast level in gestational complications.

MICROPARTICLES IN NORMAL PREGNANCY AND GESTATIONAL VASCULAR COMPLICATIONS

Microparticles (MPs), membrane vesicles, are found in blood circulation under normal physiologic conditions, and their levels increase in a variety of disease states. MPs are shed from cell membranes upon activation or apoptosis (FIGURE 117.2) and vary in size (0.1 to 1 μm) as well as in phospholipid and protein composition, reflecting those of their cell origin. MPs can induce cell signaling that may lead to invasion, angiogenesis, or apoptosis[42–45] and are involved in thrombosis, inflammation, and vascular dysfunction.[46,47] Therefore, MPs may have a potential significant role in the maternal placental crosstalk.

An overview of the studies measuring circulating levels of MP and their cell origin in normal and complicated pregnancy demonstrates high variation.[48] Some of the trials showed an increase in MP subpopulations in women with PE compared to healthy pregnant females, including increase in the total number of MPs[49] or in total negatively charged phospholipid-bearing MPs,[50] elevation in platelet MPs[50] and activated platelet MPs,[51,52] as well as increase in endothelial MPs[53,54] and white blood cell MPs.[50,55,56] Other studies revealed no differences in the total number of MPs or negatively charged phospholipid-bearing MPs and platelet MPs between normal pregnant and preeclamptic women[53,55,57] or decrease in the total negatively charged phospholipid-bearing MPs and platelet MPs[51,58] and activated platelet MPs[59] in preeclamptic women compared to those with healthy pregnancies. The broad variation in the origin of cell MPs observed in healthy pregnancy and PE may be related to the differences in the characteristics of GVC as well as to the diversity in study methods used for MP characterization.[60]

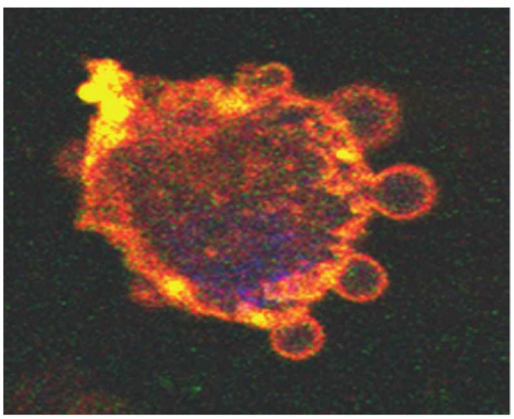

FIGURE 117.2 MP blebs from the membrane surface of umbilical vein endothelial cells (HUVECs) labeled with fluorescent-tagged antibody against CD31 and previously stimulated with monocyte MPs for 2 hours. This photograph was by confocal microscopy (60×).

MICROPARTICLE THROMBOGENICITY

MPs play a dominant role in coagulation initiation and thrombus formation.[47] MPs bearing TF and other coagulation factors may reflect the delicate hemostatic balance between maternal and placental cells (FIGURE 117.1).

MPs obtained from healthy pregnant women demonstrate high procoagulant activity compared to nonpregnant females. The procoagulant activity further increases in MPs of women with GVC without a change in the TF expression, but with reduction in TFPI.[61] On the other hand, other trials demonstrated that MP-associated thrombin generation was similar in normal and preeclamptic pregnancies,[62] the procoagulant activity generated by the total annexin V MPs was unchanged in pathologic pregnancies,[58] and prothrombin fragments 1 + 2 and subsequent thrombin generation were nearly similar in women with recurrent spontaneous abortion and controls.[63] The variance between the studies may be related, not only to the differences in the GVC characteristics and MP study methods, but also to the difference in coagulation assay sensitivity and diversity in the externalization patterns of negatively charged phospholipids and TF on MPs.[64]

TROPHOBLAST-DERIVED MICROPARTICLES

STB MPs are shed into the maternal circulation (FIGURE 117.1) and can be detected in normal pregnancies by the second trimester, while their numbers increase during the third trimester.[65,66] Excessive shedding of STB-derived MPs is a feature of preeclamptic women,[65] mainly in early-onset PE, but not of normotensive IUGR.[67] While normal pregnancy, labor, and placental separation have no effect on the shedding of STB MPs, PE is associated with an increase in STB MP shedding at full dilatation, compared to prelabor levels.[68]

Trophoblast differentiation is assumed to yield massive shedding of TF-bearing MPs that can be detected in the circulation of healthy pregnant women, and the percentage of total TF-bearing MPs significantly decreases in GVC. This represents an increase in the maternal source of TF-bearing MPs that potentially reflects the systemic nature of such pathologies.[61]

PE is characterized by a rise in inflammation markers. Higher amounts of circulating STB MPs in maternal blood might lead to endothelial dysfunction monocyte stimulation and excessive maternal inflammatory reaction.[65,66,69,70] Additionally, preeclamptic MPs have been shown to induce nuclear factor-κB activation and nitric oxide (NO) synthase expression and to enhance oxidative stress.[71]

In summary, the balance between the procoagulant TF and the physiologic anticoagulants is crucial for pregnancy and influences the placenta, embryo, and maternal crosstalk. The placental hemostatic balance has a major role in normal pregnancy, and the balance disruption may result in pregnancy complications. MPs affect physiologic processes (cell migration, invasion, and angiogenesis) and can promote pathologic states including thrombus formation, inflammation, and endothelial dysfunction. MPs participate in the placental and maternal crosstalk in normal pregnancies as well as in GVCs (FIGURE 117.1).

tahir99-VRG & vip.persianss.ir

HEMOSTATIC CHANGES IN NORMAL PREGNANCY

Normal pregnancy is characterized by a marked increase in the procoagulant activity, manifested by an elevation of coagulation factors VII, X, and VIII; fibrinogen; and von Willebrand factor[72] and an elevation in prothrombin fragments 1 + 2, and thrombin–antithrombin (AT) complexes,[73] which is maximal around term. There is a profound decrease in physiologic anticoagulants, manifesting by a significant reduction in protein S (PS) activity[74] and by acquired activated protein C resistance.[75] The overall fibrinolytic activity is impaired during pregnancy but returns rapidly to normal following delivery,[76] largely due to placenta-derived PAI type 2, which is present in substantial quantities during pregnancy.[77] Levels of D-dimer, a specific marker of fibrinolysis resulting from breakdown of cross-linked fibrin polymer by plasmin, increase as pregnancy progresses.[78]

IMPLANTATION AND HEMOSTASIS

Pregnancy requires successful implantation of competent embryo into a receptive endometrium. Monthly fecundity rates in humans compared to other mammalian species are relatively low at approximately 20%.[79] Of note, clinical pregnancy rates per embryo transfer for the year 2006 in Europe were around one-third.[80] Current data suggest that thrombophilia can be associated with repeated implantation failure. One study reported significantly higher prevalence of thrombophilias in women with four or more failed IVF cycles when compared with spontaneous conceptions (OR 3.6, 95% CI 1.25 to 10.6) or women who conceived after their first cycle (OR 2.9, 95% CI 1.02 to 8.4).[81] The mechanisms underlying these associations are less clear, partly due to the limited knowledge regarding the earliest stages of human implantation.

HEMOSTATIC CHANGES IN PREECLAMPSIA

Thrombocytopenia is a consistent finding in severe cases of PE closely correlating with activation of coagulation. A fall in platelet count in women with gestational hypertension may herald the onset of PE.[82] The platelet membrane shows an abnormal lipid composition with a raised cholesterol to phospholipid ratio in PE.[83] Assessment of platelet hyperactivity in whole blood may reveal elevated aggregation. Release of inflammatory mediators from activated platelets may trigger inflammatory reactions in endothelial cells. In theory, platelets are a potential regulator of trophoblast infiltration into maternal spiral arteries, thereby contributing to vascular remodeling.[84] While at present the role of activated platelets in the pathophysiology of PE remains to be established, evidence of platelet activation preceding the onset of PE is emerging.[85]

Alterations in the hemostatic system leading to excessive uteroplacental thrombosis are thought to be an important feature at the first stage in the pathogenesis of PE, involving reduced placental perfusion due to failed vascular remodeling in early pregnancy within the placental bed.[86] Coagulation factor levels including TF, factor VIII, fibrinogen, and von Willebrand factor are significantly higher in the peripheral circulation in PE compared with normal pregnancy. TF and free TFPI concentrations are significantly higher in maternal plasma of PE women compared with normal pregnancy.[87,88] The TFPI to TF ratio is significantly lower in patients with PE than in normal pregnancy, and there is a higher maternal plasma concentration of PAI-1 in PE compared to a normal pregnancy. Of interest, increased PAI-1 levels are detected in patients who show early evidence of placental dysfunction on uterine artery Doppler studies, while the low PAI-2 levels in PE may reflect placental dysfunction.

EPIDEMIOLOGY AND PATHOGENESIS OF PREGNANCY COMPLICATIONS

Unexplained PL and GVC, including PA, PE, and small-for-gestational age (SGA) pregnancies, are heterogeneous gestational pathologies associated with devastating maternal and fetal complications, variably affecting 5% to 15% of all pregnancies.

Up to 9% to 13% of women experience one clinically recognized PL, 5% two or more PLs, and 1% to 2% three or more losses.[89–93] Up to 50% of recurrent PLs remain unexplained, with unclear initial categorization[94] (Table 117.1). Early measurements of the fetus crown-rump length (CRL) and detection of fetal heart beats led to the definition of gestational age based on ultrasound (US)[95] assessment ("fetus" meaning fetal heart activity and/or a CRL > 10 mm), with four PL categories being recognized[95] (Table 117.2). Women with idiopathic PL tend to have recurrences at the same gestational age period,[96] with a likelihood of PL causes to be gestational age specific. Placental bed biopsies from karyotyped, late[97] and early[98] sporadic miscarriages suggest that only late miscarriages are associated with impaired trophoblast invasion and inadequate transformation of spiral arteries, similar to PE. Most recurrent PLs are nonfetal cases resulting from random repetition of aneuploidic pregnancies; normal embryonic karyotypes increase with the number of previous PLs ($n = 2$: <50%; >6: 75%)[99] and predict a subsequent PL.[100] First-trimester idiopathic recurrent PL occurs in 22%, 2%, and 0.6% before 6, 8, and 10 gestational weeks, respectively with only 3% following the detection of fetal heart activity.[101] Recurrent PL means at least three losses, usually of unknown cytogenetics: two euploid PLs identify couples at higher recurrence risk, likely to bear a causal noncytogenetic factor.[102]

PE complicates 4% to 10% of nulliparous pregnancies and is twofold more frequent in primigravidas.[103] The recurrence risk is around 15% after one previous PE, increasing to 30% after two consecutive PEs.[104] A severe recurrent early-onset type, with delivery before 34 weeks, affected by chronic genetic/environmental factors, opposes a milder sporadic form affected by transient factors (two-third of cases).[104] Severe PE subtypes are associated with various recurrence risks. Eclampsia generates a

Table 117.2

Contemporary definitions of PL types based on US measurements

Type of PL	Typical Gestation, Weeks (Range)	US Findings	Fetal Heart Activity	βHCG Levels and Kinetics
Biochemical loss	6 (0–6)	Pregnancy is not located	Never detected	Low then fall
Early PL, embryonic PL	Between 6 and 8 (4–10)	Empty sac or large sac with minimal structures	Not detected	Rise then fall
Late PL, fetal PL	From week 12 (10–20)	CRL > 10 mm	Detected then lost	Rise then are static or fall
Stillbirth	>20 (viable)	Crown-heel length > 25 cm Estimated weight > 500 g	Detected, confirmed then lost	—

mean 22% PE recurrence risk and a 2% eclampsia risk. In primigravidas, early-onset PE before 34 weeks generates a mean 25% PE risk and a 5% early-onset PE risk during the second pregnancy. Moreover, a second-trimester PE generates a 66% PE risk on the next pregnancy. Likewise, HELLP syndrome (hemolysis, elevated liver enzymes and low platelet counts) generates a mean 43% PE and a 27% HELLP syndrome recurrence risk. While smoking during pregnancy is associated with spontaneous abortion, stillbirth, preterm labor, fetal growth restriction, and PA, the incidence of PE is reduced in smokers.[105] Abnormal placentation and an imbalance in angiogenic factors are essential for the development of the PE syndrome,[106] with high levels of trophoblast-derived circulating antiangiogenic factors mediating maternal endothelial dysfunction, soluble fms-like tyrosine kinase-1, and soluble endoglin.

In PE, the loss of endothelial NO synthase activity promotes endothelial dysfunction due to production of superoxide instead of NO.[107] PE may arise due to loss of VEGF activity and from the possible elevation of soluble Flt-1 (sFlt-1).[108] In support of this, adenoviral overexpression of sFlt-1 in pregnant rats resembled manifestations of the disease[109] and serum levels of sFlt-1 and placenta growth factor were found to be associated with the clinical presentation of PE.[110–112] Finally, reducing circulating levels of free sFlt-1 below a certain threshold in women with PE could alleviate the clinical signs of the syndrome.[113]

PA, defined as premature separation of a normally inserted placenta prior to delivery of the fetus, complicates 1% of pregnancies. The maternal effect depends on PA severity, whereas the fetal PA effect is determined both by its severity and by its gestational age onset. PA involving more than 50% of the placenta leads to fetal death. Conditions associated with acute inflammation (premature rupture of membranes and intrauterine infection) are more prevalent in preterm PA than in-term gestation abruptions, whereas chronic processes inducing vascular dysfunction or chronic inflammation are present throughout gestation.[114]

PE, SGA pregnancies (<10th percentile adjusted on gestational age; severe if <3rd percentile), and PA are closely related heterogeneous diseases, with reduced trophoblast invasion, uteroplacental underperfusion, chronic hypoxia, and placental ischemia as the principal mechanism involved in their cause. Reasons for preterm births include first of all PE, then SGA, fetal distress, and PA (around 50% of cases).[115] A retrospective cohort study showed women with PE, SGA, and PA in their first pregnancy having an increased risk of recurrence of any of the GVCs,[116] suggesting some similarity of causative mechanisms.

THROMBOPHILIA AND FETAL LOSS

Acquired thrombophilia is associated with fetal loss, mainly first-trimester PL, and its rate is increased in women with essential thrombocythemia (ET).[117–119] The *JAK2*V617F mutational status was inconsistently found to be related to a higher incidence of ET pregnancy-associated complications. The incidence of the *JAK2* V617F mutation was increased in PL cases in a large cohort of women in first pregnancy,[120] with small series showing discrepant results.[121]

Antiphospholipid antibodies (aPL-Abs) and the primary antiphospholipid antibody syndrome (APS) are emblematic models.[122,123] Fetal loss at or beyond week 10 and recurrent consecutive embryonic losses before week 10 are classical features entering the obstetrical APS definition. A meta-analysis assessed the strength of association of lupus anticoagulant (LA), anticardiolipin antibodies (aCL-Abs), and anti-β_2 glycoprotein-1 antibodies (aβ_2GP1-Abs) with non-SLE–related recurrent miscarriages. LA was strongly associated with late PL (<24 weeks) with no evidence of association with early PL (<13 weeks); similar results were obtained for aβ_2GP1-Abs.[124] In contrast, aCL-Abs were associated with both early and late recurrent PLs. Retrospective studies have shown a stronger association with recurrent fetal loss >10 weeks in women positive for all the three tests.[125,126] Positivity for aβ_2GP1-Abs is found to correlate

tahir99-VRG & vip.persianss.ir

with a positive LA in women with PL.[127] Association of LA and aβ_2GP1-Abs with late PL is thus probably more reasonable.[128,129] The role and significance of other autoantibodies is currently under investigation. An observational study in a cohort of women with a first embryonic PL suggested that aPL-Abs–positive women have a higher risk of various GVCs during their second pregnancy.[130]

Anticoagulants, such as hirudin or fondaparinux, did not prevent PL in a mouse model of APS, suggesting that thrombosis is not the cause of fetal death in this model.[131] TF on maternal neutrophils is critical for the pathogenesis of aPL-induced fetal loss, with a suggested functional linkage between complement component C5a, TF, and neutrophil activation. Activated neutrophils release reactive oxygen species and proteolytic enzymes, leading to decidual damage and fetal wastage.[132] TF inhibition decreased sFlt-1 release, restored placental blood flow, prevented placental oxidative damage, and rescued pregnancies, suggesting that TF may be an interesting target for therapy in this model.

Constitutional thrombophilias. Scattered data suggest that pregnancy outcome in maternal homocystinuria is usually normal.[133,134] Mild hyperhomocystinemia, resulting from common polymorphism (homozygosity for the *MTHFR* C677T) and nutritional conditions (folate, vitamin B_6 and B_{12} deficiency), is associated with a noncausal enhanced risk of embryonic and fetal PL,[129,135] with vitamin supplementation attempts being unsatisfactory.[136]

Dysfibrinogenemia cases were associated with a high PL rate and, to a lesser extent, with stillbirths,[137] with prophylactic use of fibrinogen concentrates suggested to be of value. Fibrinogen supports the development of fetal–maternal interface and stabilizes embryo implantation in animal models.

The first systematic analysis of a possible association between PL and AT, PC, PS deficiency, or factor V Leiden (FVL) variant focused on cohorts of women from thrombotic families with a documented thrombophilia.[138,139] The EPCOT study has demonstrated the risk of PL to be increased in thrombophilic women, with a stillbirth risk being higher than other PL risk types. Additionally, combined defects were associated with a higher risk for PL. While AT and PS deficiencies reached significance for stillbirth, PC deficiency appeared to be significant for miscarriage.[139] The follow-up of females participating in the EPCOT trial[140] showed a slightly increased risk of fetal loss in untreated women with thrombophilia without a previous history of PL. The relative risk varied minimally from 1.4 for FVL to 1.6 for AT deficiency.

Case–control studies thereafter focused on women with various PL types[141–152] and generally found positive associations. However, in some of the studies, these associations were limited to the fetal-type PL,[146–152] while other reports failed to show significance.[26,153–155]

A crucial new function of the PC system in controlling the growth and survival of trophoblast cells had emerged from mouse models.[24] In human couples, presence of maternal and paternal *PROCR* polymorphism in the EPCR gene, a cell-surface trophoblastic receptor, could predict a first fetal loss.[156]

Several reviews and meta-analyses attempted to clarify the observed discrepancies regarding the prevalence of thrombophilic risk factors and GVCs[157,158,159] (Table 117.3). Conclusions of the TREATS study[159] pointed toward a significant, albeit modest, increase in the relative risk. The major findings included a higher risk for a late PL in the third trimester, stronger associations with recurrent PL, and a higher risk of second-trimester loss than of recurrent first-trimester loss for FVL and *F2* 20210A heterozygotes; finally, late PL was most strongly associated with PS deficiency. However, potential confounders and biases in design and conduction of available studies may have an impact on the results, thereby limiting the strength of conclusions.[94] A meta-analysis of prospective cohort studies, claimed to provide a superior methodologic design, showed the probability of PL in FVL women to be 52% higher, corresponding to a small absolute increase in risk of nonembryonic PL (3.2% to 4.2%), but lacked power to detect increased risks in women with *F2* 20210A polymorphism.

Evidence linking constitutional thrombophilias to PLs is still insufficiently characterized, lacking the systematic integration of categorization and cofactors. Routine screening of pregnant women cannot be recommended. Screening of previously symptomatic women depends on the assessment of beneficial therapeutics in women harboring thrombophilia. Even if thrombophilias are not strongly causative, they may contribute to miscarriage potential. In this regard, regulating hemostasis may have potential clinical advantage.[94]

tahir99-VRG & vip.persianss.ir

THROMBOPHILIA AND GESTATIONAL VASCULAR COMPLICATIONS

Acquired thrombophilias. Clinical criteria for the diagnosis of APS include one or more premature births of a morphologically normal neonate before the 34th week of gestation as a result of (a) eclampsia or severe PE, or (b) recognized features of placental insufficiency.[122] Definitive prospective studies examining the contribution of aPL-Abs to preterm births associated with placental insufficiency or severe PE are currently not available. The TREATS study found aCL-Abs, but not LA, to be associated with PE.

Constitutional thrombophilias. Genetic thrombophilias were first reported to be associated with various GVCs in late 1990s.[160] Further studies analyzed specific GVC subtypes. The TREATS study[159] (Table 117.4) showed the global risk of PE to be associated with heterozygous FVL or *F2* 20210A polymorphisms and homozygous *MTHFR* 677T polymorphism. The paucity of data related to AT, PC, and PS deficiencies is mainly due to the low prevalence of these risk factors. Evidence of heterogeneity was demonstrated in the analysis of heterozygous FVL, which was found to be related to severe PE only (OR 2.04 [1.23 to 3.36]), but not to mild PE.[158] Of note, the Ottawa review on prospective cohort studies[161] found a trend but no significant association of GVC and thrombophilia (Table 117.4).

While the global risk of PA was found to be significant for a heterozygous FVL or a heterozygous *F2* 20210A polymorphism,[159] it was not reported in prospective studies[161] (Table 117.4). A recent analysis[162] performed on 22 articles showed the random-effect OR for FVL to be 3.4 (1.4 to 8.3) and the fixed-effect OR for the *F2* 20210A polymorphism to be 6.7 (3.2 to 13).

Finally, the global risk for SGA pregnancies was nonsignificant for a heterozygous FVL or *F2* 20210A and for a homozygous *MTHFR* 677T polymorphism[159,161] (Table 117.4).

A large population-based nested case–control study performed in Finland showed FVL but not *F2* 20210A polymorphism to be a risk factor for late preterm birth at or after 32 weeks—OR 2.9 (1.5 to 5.6), with history of venous thrombosis increasing the risk.[163]

The evidence linking constitutional thrombophilias to GVCs is heterogeneous, lacks systematic integration of severity and cofactors, shows modest OR, and is mainly sustained in PA. Routine screening of pregnant women for thrombophilia cannot be recommended. Screening of previously symptomatic women will depend on conclusive therapeutic developments in women harboring thrombophilia.

ANTITHROMBOTIC THERAPY DURING PREGNANCY

Anticoagulant therapy is indicated during pregnancy for the prevention and treatment of venous thromboembolism (VTE), systemic embolism in patients with mechanical heart valves and, in combination with aspirin, in women with aPL-Abs and recurrent PL.[164] Currently available antithrombotics include unfractionated heparin (UFH), LMWH, and antiplatelet agents. In the past, UFH was the drug of choice for the prevention and treatment of VTE during pregnancy. However, because of its significant adverse effects, such as osteoporosis and heparin-induced thrombocytopenia (HIT), as well as the need for laboratory monitoring, UFH is being replaced by LMWH in gestational settings.[165] Both UFH and LMWH do not cross the placenta and are not secreted in breast milk; however, LMWHs exhibit a number of clinical advantages over UFH, including superior bioavailability, longer plasma half-life allowing once-daily dosing, and an improved safety profile.[166] The anticoagulant effect of heparin is mediated largely through its interaction with AT; this produces a conformational change in AT and so markedly enhances its ability to inactivate the coagulation enzymes thrombin, factor Xa, and factor IXa.[167] In addition, LMWH increases production and secretion of TFPI from endothelial cells.[168,169]

SAFETY OF LMWH DURING PREGNANCY

Although women with prior VTE have an increased risk of disease recurrence during gestation, no large clinical trials assessing the role of prophylaxis in pregnant women with previous VTE

are available.[164] A recent review of close to 2,800-treated pregnancies evaluated safety and efficacy of LMWH in pregnancy.[170] The main indications were prophylaxis of VTE and prevention of PL. The rate of bleeding complications was low and thrombocytopenia was rare, with no cases of HIT. Likewise, clinically significant osteoporosis was extremely rare. Live birth rates were 85% to 96%, depending on the indication for treatment.[171] A good safety profile in the use of enoxaparin during 624 pregnancies was also documented in a retrospective French study.[171]

ANTIPHOSPHOLIPID SYNDROME

In women with recurrent miscarriage associated with the antiphospholipid syndrome, the use of a combination of low-dose UFH and low-dose aspirin, compared to aspirin alone, showed an absolute increase of live birth rate from 41% to 72% in a randomized controlled trial (RCT),[172] with two other trials also reporting a benefit of this combination compared to aspirin alone.[173,174] Two RCTs where LMWH was added to aspirin did not demonstrate benefit of this combination therapy in this setting.[175,176] Notably, there are hardly any placebo-controlled trials to assess the efficacy of aspirin alone in women with antiphospholipid syndrome.[177] Currently, the grade 1B level of recommendation by the American College of Chest Physicians guidelines is not shared by other guidelines.[178]

PREGNANCY LOSS IN THROMBOPHILIC WOMEN

In an earlier study, 50 women who had thrombophilia and were presented with recurrent fetal loss were treated with the LMWH enoxaparin throughout gestation and 4 to 6 weeks in the postpartum period.[179] Of the 61 pregnancies, 46 (75%) resulted in a live birth, compared with a success rate of only 20% in these women in previous gestations without antithrombotic therapy.[180]

A study by Gris et al.[181] demonstrated that in women who had thrombophilia and previous one PL after a 10-weeks gestation, enoxaparin at a dose of 40 mg daily resulted in a significantly better live birth rate compared with low-dose aspirin (86% vs. 29%, respectively). The differences were found in women who had FVL and *F2* 20210A as well as in those who had PS deficiency.

LIVE-ENOX is a multicenter, prospective, randomized study comparing two doses of enoxaparin, 40 mg/day and 40 mg/every 12 hours, in women with thrombophilia and a history of PL.[182,183] Of the 180 women enrolled, live birth rate before the study was only 28%, but during the study, live birth rates were 84% for the 40 mg/day group and 78% for the 80 mg/day group. Late gestational complications decreased after enoxaparin treatment. Both doses of enoxaparin appeared to be safe and well tolerated, with low incidence of postpartum bleeding and enoxaparin-related allergic local skin reactions.

While these studies are encouraging, large prospective RCTs have not been preformed.

UNEXPLAINED PREGNANCY LOSS

An earlier study comparing enoxaparin 40 mg/day to low-dose aspirin reported similar live birth rate in women with unexplained PL in whom thrombophilia was excluded.[184] Three recent prospective multicenter randomized trials, ALIFE, SPIN, and HABENOX, reported that antithrombotic prophylaxis did not improve pregnancy outcome in women with at least two unexplained PLs.[185,186] Thrombophilia cases were a small minority in these trials. Indeed, the majority of cases of unexplained PL could be attributed to other causes, including aneuploidy.

ANTITHROMBOTIC PROPHYLAXIS FOR GESTATIONAL VASCULAR COMPLICATIONS

A pilot randomized trial compared dalteparin 5,000 U/day versus no prophylaxis in 110 women without identifiable thrombophilia who had prior placenta-mediated complications.[187]

Dalteparin was associated with a lower rate of the composite primary outcome (severe PE, birth weight < 5th percentile, major PA), which occurred in 5.5% of those in the dalteparin arm compared to 23.6% in the no prophylaxis arm (OR 0.15, 95% CI 0.03 to 0.70, NNT 5.5, $P = 0.016$).

In another study, 160 women with prior objectively confirmed PA were randomized to enoxaparin 4,000 IU/day until 36 weeks or to no drug intervention.[188] The primary composite outcome consisted of any of the following: PE, SGA PA, or IUFD. The primary outcome was significantly reduced from 31.3% (25/80) in the no intervention group to 12.5% (10/80) in the enoxaparin group. In a subsequent study, 224 women with prior objectively confirmed severe PE were randomized to enoxaparin 4,000 IU/day plus low-dose aspirin or to low-dose aspirin.[189] The primary outcome was the composite one described above. This primary outcome was significantly reduced from 25% (28/112) in the no intervention group to 8.9% (10/112) in the enoxaparin group. While promising, subsequent studies will be required to solidify these findings.

A small placebo controlled RCT demonstrated that enoxaparin 40 mg/day at the time of embryo transfer was associated with a significant improvement in live birth compared with placebo (23.8% vs. 2.8%, respectively; $P < 0.05$).[190] RCTs are needed in the setting of recurrent implantation failure to asses this clinical relevant question.

MONITORING OF LMWH THERAPY DURING PREGNANCY

Since LMWH preparations inhibit preferentially FXa and only to a low extent thrombin and activated partial thromboplastin time, anti-Xa assays have been developed and validated to determine their anticoagulant effect.[191] For the vast majority of patients, LMWH have proved to be effective and safe without the need for anticoagulant monitoring.[192] However, the need to adapt the LMWH dosage to the weight of the pregnant woman or to monitor LMWH treatment during pregnancy remains controversial.[193,194] Plasma levels of anti-Xa activity and TFPI may help to predict the outcome in LMWH-treated pregnancies.[168] Risk assessment of clinical history and thrombophilic risk factors as well as careful monitoring of LMWH therapy can be potentially beneficial for women with high-risk pregnancies.[195]

CHAPTER

118 Maternal Hemostatic Disorders and Obstetric Hemorrhage

PHILIPPE DE MOERLOOSE, FRANÇOISE BOEHLEN, AND JEAN-CHRISTOPHE GRIS

This chapter reviews conditions associated with disorders of the hemostatic system, which can affect the mother and lead to obstetric hemorrhage, excluding mechanical causes of antepartum hemorrhage (e.g., abnormal placentation, uterine rupture, vasa previa, infections, polyps, or trauma) or postpartum hemorrhage (PPH) (retained placenta, uterine atony, or cervical or vaginal lacerations).[1,2] In the latter situations, coagulation disorders are usually a consequence and not a cause of obstetric hemorrhage.

PLATELET DISORDERS

Thrombocytopenia is the most common hemostatic disorder encountered in pregnancy, and can be considered as isolated and mainly asymptomatic or part of a complex clinical context.

Isolated Platelet Disorders

The differential diagnosis of thrombocytopenia discovered during pregnancy is wide and varies with gestational age and is similar to that of nonpregnant women, but some are unique to pregnancy (FIGURE 118.1),[3,4,5,6] notably the "physiologic" decrease of platelet count.[7–9] Thrombocytopenia, defined as platelet count <150 G/L, is a very common and most often an incidental finding during pregnancy, occurring in 5% to 12% of pregnant women,[7,9–11] but a platelet count <100 G/L is present in only about 1% of pregnant women.[10,12]

Incidental Thrombocytopenia

Gestational thrombocytopenia of pregnancy is responsible for 75% to 80% of all pregnancy-associated thrombocytopenias,[4,10,11,13] occurring mainly in late pregnancy, in distinction to immune thrombocytopenia (ITP), which is the most common diagnosis during the first trimester of pregnancy. It is important to distinguish incidental thrombocytopenia from ITP, the implication for the pregnancy and the newborn being very different, but it often is not possible to distinguish between these two entities. Incidental thrombocytopenia is a diagnosis of exclusion,[14] requiring the following five criteria[15,16]:

- Asymptomatic, mild thrombocytopenia: typically >70 G/L (most often between 130 and 150 G/L)
- Occurrence typically in third trimester
- No prior history of thrombocytopenia (except possibly during a previous pregnancy)
- No fetal thrombocytopenia
- Spontaneous resolution after delivery

According to these criteria, the diagnosis can be confirmed only after birth. Incidental thrombocytopenia being by definition a mild thrombocytopenia, there is no risk for the mother. Indeed a platelet count of more than 70 G/L is usually considered as safe for a locoregional anesthesia and is not associated with an increased hemorrhagic risk during pregnancy and the postpartum period.[17,18] There is no risk for the newborn too since by definition this diagnosis implies that the newborn will have no thrombocytopenia.[10,16,19,20]

The mechanism of this thrombocytopenia is still uncertain. It could be a physiologic condition due to dilution and/or an increased platelet turnover.[21]

Immune Thrombocytopenia

ITP is an acquired immune-mediated disorder characterized by isolated thrombocytopenia,[22] a platelet count of <100 G/L now considered as the threshold for diagnosis.[23] ITP occurs in approximately 1 per 1,000 pregnant women, accounts for 3% to 5% of pregnancy-associated thrombocytopenias,[4,10,11,13,24] and is the most common cause of isolated thrombocytopenia in the first trimester.[4,13] According to the retrospective analysis of Webert et al.,[25] most women with ITP have only a mild to moderate decrease of platelet count; 30% to 50% of women with ITP are first diagnosed during pregnancy.[25,26] The diagnosis of ITP is essentially one of exclusion,[6,15,16,27,28] the most difficult distinction being from incidental thrombocytopenia of pregnancy. Search for antiplatelet antibodies has failed to differentiate these two pathologies.[12] The two most important points are the monitoring of maternal platelet count during pregnancy and after delivery and control of the newborn's platelet count at birth and during the 1st days of life. In general, as detailed in the next paragraphs, (a) the evolution of the platelet count during pregnancy is usually unpredictable;[28] (b) the risk of maternal hemorrhage depends upon the severity of thrombocytopenia;[25] (c) the risk of severe neonatal thrombocytopenia is relatively low;[10] (d) there is no way to predict the severity of fetal/neonatal thrombocytopenia;[10] and (e) maternal treatment does not influence the newborn's platelet count.[29]

Bleeding risk during pregnancy. Women have no bleeding symptoms (65.6%) or only mild or moderate symptoms (respectively 12.9% and 18.1%), and only 3% to 4% of pregnant women have severe symptoms (3.4%).[25] The "safe" platelet number allowing spinal or epidural anesthesia (without risk of epidural hematoma) remains controversial, and there are no data to support a minimum required platelet count.[30] However, as proposed in international consensus, a platelet count ≥70 to 80 G/L is usually considered as safe.[17,18,28]

Management

Treatment is recommended in case of bleeding symptoms or when the platelet count is below 20 to 30 G/L.[15,31] When the delivery date approaches, it is usually recommended to introduce

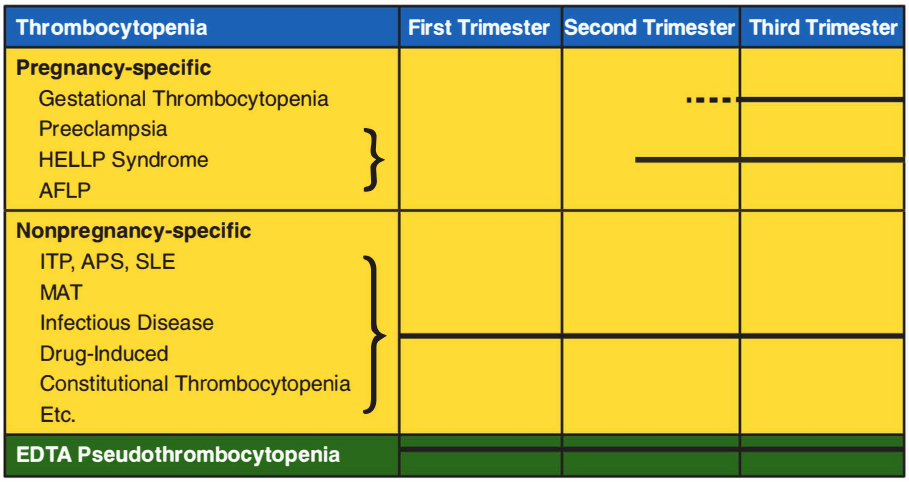

FIGURE 118.1 Differential diagnosis of thrombocytopenia discovered during pregnancy as function of gestational age. AFLP, acute fatty liver of pregnancy; APS, antiphospholipid syndrome; HELLP, hemolysis, elevated liver enzymes, low platelets; ITP, immune thrombocytopenia; MAT, microangiopathic thrombosis; SLE; systemic lupus erythematosus.

treatment to attain a platelet count of >50 G/L to allow good hemostasis during vaginal delivery or cesarean section and to avoid PPH. It is possible that a lower platelet count is acceptable for vaginal delivery without locoregional anesthesia.[6,13,15,31,32] Indeed, in a report of 92 women with ITP (119 pregnancies), the median platelet count at delivery was 85 G/L. In this report, 15% of these women had a platelet count <50 G/L and 6% had a platelet count <20 G/L. Hemorrhagic complications were reported in only four women (nonrequiring red cell transfusions) and were not related to the severity of thrombocytopenia.[25]

Treatment options for the management of ITP in pregnancy are usually similar to those proposed in the general population.[13] First line therapy is usually based on corticosteroids and/or intravenous immunoglobulins.[6,27,28,31] Classically, oral prednisone is initially administered at the dosage of 1 mg/kg/d based on the pregestational weight. This treatment can be associated with side effects for the mother during the gestational period (pregnancy-induced hypertension, gestational diabetes, weight gain, psychosis, etc.) and rarely for the fetus (suppression of the fetal adrenal glands).[31] To limit these side effects, prednisone could be started at a lower dose (e.g., 10 to 20 mg/d), and the dose can be progressively increased to obtain a safe platelet count according to the gestational age.[27] High doses of immunoglobulins (2 g/kg) may be safer than a high dose of prednisone with a similar efficacy but they need to be administered every 3 to 6 weeks.[13,31,33] In case of refractoriness, high dose of methylprednisolone could be used.[28,31,34–36] Azathioprine may be administered safely during pregnancy, but there are no available studies in the case of ITP.[31,37,38,39] Anti-RhD immunoglobulins have been proposed as second line therapy[28,40] but they have to be used with precaution, particularly with a careful monitoring of the neonate although complications are uncommon (neonatal jaundice, anemia, positive direct antiglobulin test after delivery).[28,40] Danazol has been used but only for short-term treatment.[41] Other immunosuppressive agents (such as cyclosporine or cyclophosphamide) cannot be used during pregnancy.[39] Experience with rituximab during pregnancy is limited and its safety for the fetus is uncertain (category C drug for FDA). It is therefore recommended to avoid rituximab during pregnancy unless the mother's health is critically dependent upon use of this medication.[39,42–44] There are no available data on the use of thrombopoietin receptor agonists in pregnancy. Splenectomy can be safely performed during the second trimester.[45,46]

If severe thrombocytopenia is diagnosed near delivery, acute treatment with intravenous immunoglobulin 1 g/kg/d for 2 to 3 days combined with methylprednisolone 1 g/d for 3 days will usually result in an increased platelet count within 24 to 48 hours.[22,32] In case of acute obstetric hemorrhage, for example, in a laboring woman, the treatment will differ. Intravenous immunoglobulin and methylprednisolone have to be considered and in addition platelet transfusion should be given.[47]

Due to the decreased survival of the transfused platelets in the case of ITP, the increase in platelet count will be low. In case of unresponsiveness to this therapy and persistence of hemorrhage, recombinant factor VIIa (rFVIIa) should be considered.[48]

Risk of Neonatal Thrombocytopenia

Maternal antiplatelet antibodies can cross the placenta and cause fetal/neonatal thrombocytopenia. There is no relation between maternal and fetal/neonatal platelet count, a severe neonatal thrombocytopenia can be observed in the newborn of a mother with a mild thrombocytopenia and newborn from a mother with a severe thrombocytopenia can have a normal platelet count at birth.[11,25,49–51] Data about the relation between neonatal thrombocytopenia and the presence or absence of detectable maternal antibodies are controversial.[49,51,52] So the detection of maternal antibodies has not been proven useful for making predictions about the fetal/neonatal platelet count.[12,16,53,54] Corticosteroids given to the mother have no effect on the neonatal platelet count.[29,49,55] Some data have shown that there is an increased risk of neonatal thrombocytopenia in women with a past history of splenectomy, particularly those who are refractory to splenectomy.[55,56,57] The best predictor of neonatal thrombocytopenia is a history of thrombocytopenia in a prior sibling.[25,55,57] Fetal blood sampling by cordocentesis or scalp blood sampling in early labor is not recommended due to the risk of erroneous result and also the risk of fetal distress associated with an invasive procedure.[15,49]

Mode of delivery of women with ITP is controversial. Historically, cesarean section was recommended based on a perinatal mortality of 12% to 21% resulting from birth trauma and intracranial hemorrhage (ICH).[28,58] More recent studies suggested that the neonatal mortality is much lower, around <1%.[25,49] Large prospective studies have then confirmed that the incidence of severe neonatal thrombocytopenia (defined as a platelet count <50 G/L) varied from 5% to 20%, and ICH occurring in 0% to 3% of newborn.[10,25,51–53,56,59,60] There is no evidence that cesarean section is safer for the thrombocytopenic fetus compared with uncomplicated vaginal delivery (which is usually also safer for the mother).[28,53] Cesarean delivery should be determined essentially by obstetric indications.[15,31,56]

Neonatal platelet count should be determined in cord blood immediately after delivery and followed during the 1st week after birth (nadir being often between day 2 and 5 leading to hemorrhagic complication not directly related to the delivery).[6,25,28,31,49] Indeed, it is important to underline that platelet counts of infants born to mothers with ITP may decrease deeply several days after birth.[56,59] It is therefore crucial to alert the pediatricians.[25,31]

Nonisolated Platelet Disorders

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura—Hemolytic Uremic Syndrome

The term thrombotic microangiopathies (TMAs) encompasses a spectrum of clinical syndromes in which common pathologic feature is the widespread formation of hyaline thrombi in the nonvenous microcirculation, the arterioles, and capillaries. They share thrombocytopenia and Coomb's negative, microangiopathic hemolytic anemia (MAHA) with the presence of schistocytes on the peripheral blood smear. The emblematic thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are extremely rare, afflicting 1 in 100,000 pregnancies,[61,62,63] are not placenta related, are often unexpected and initially confused with obstetric diagnosis: pregnancy can be continued without impairing the rate of therapeutic response,[64] and hemorrhagic complications are unusual. Nevertheless, a delay in diagnosis of TTP/HUS may result in life-threatening maternal and fetal consequences.

TTP–HUS is more common in women, being commonly associated with pregnancy and postpartum.[61,63,65] Patients bearing the autosomal recessive TTP, that is, Upshaw-Shulman syndrome, caused by mutations of the *ADAMTS13* gene, can remain asymptomatic until early adulthood (50%) and may present with TMA during pregnancy. Acquired TTP cases are characterized by severely depressed, autoantibody mediated, ADAMTS13 activities (<5%).[66] ADAMTS13 levels may decrease during pregnancy (however, values remaining >40%), but more decreased levels (however, remaining >10%) are associated with other diseases, including severe preeclampsia (PE) and hemolysis–elevated liver enzymes–low platelet (HELLP) syndrome. In contrast to pregnancy-associated TTP, the pathogenesis and presentation of pregnancy-associated diarrhea-negative, atypical HUS still remain ill-defined. A highly prevalent rate of alternative pathway C3 convertase dysregulation has, however, been confirmed.[67] This disease of complement overactivation may display mutations in gene encoding both complement regulators-complement factor H, complement factor I, complement factor H related proteins, membrane cofactor protein (MCP: CD46), the anticoagulant glycoprotein thrombomodulin that plays a role in the inactivation of C3a and C5a−, as well as complement activators—complement factor B, C3—or autoantibodies inactivating factor H.[68,69]

TTP and HUS manifest similar clinical and laboratory findings, with more profound neurologic symptoms in TTP and exaggerated renal abnormalities in HUS. As such, TTP and HUS have been considered by some to be a clinical continuum of diseases summarized by the acronym TTP/HUS, the challenge being their diagnosis in order to initiate plasma exchange. The classic diagnosis of TTP includes the pentad of Coomb's negative MAHA, thrombocytopenia, neurologic changes, renal symptoms, and fever. This pentad is only present in 40% of the time; 75% of patients present with a triad of MAHA, neurologic symptoms and thrombocytopenic purpura. This has changed to merely a dyad[70,71]: onlythrombocytopenia plus MAHA without an alternative apparent etiology is required to consider TTP/HUS, decreased stringency of diagnostic criteria resulting in an increase in the number of patients treated for TTP/HUS.[70] The clinical signs are in most cases subtle and nonspecific, including nausea, vomiting, abdominal pain, weakness, bleeding, easily bruisability, and flu-like symptoms.[62,72,73] TTP/HUS is most often diagnosed in the third trimester or peripartum, when severe PE/HELLP syndrome occur, which are more common diagnosed (0.5% of all pregnancies), both conditions sharing thrombocytopenia and hemolysis, neurologic symptoms with or without hypertension, and latency to treatment impairing maternal–fetal outcomes. Liver enzymes are elevated proportionally to thrombocytopenia in HELLP syndrome but are usually normal or mildly elevated in TTP/HUS in which MAHA associates with elevated lactate dehydrogenase (LDH) levels but minimal elevation of aspartate aminotransferase (AST) (LDH to AST ratio: 29:1)[74]: TTP/HUS coexisting with PE exhibits two to four times higher AST levels (LDH to AST ratio: 13:1)[75] than TTP/HUS alone. TTP/HUS should be suspected if women are normotensive or nonproteinuric during the third trimester or postpartum period, and if hypertension, proteinuria and abnormal laboratory tests are evidenced at <24 weeks gestation when HELLP syndrome is rare. Women diagnosed severe as PE/HELLP syndrome who do not normalize laboratory values within 2 to 3 days postdelivery, with normal coagulation parameters or resolving disseminated intravascular coagulation (DIC), should also be suspected.[71] Severe anemia, severe thrombocytopenia, and elevated LDH levels with minimal elevation of ALT (alanine aminotransferase) levels are sufficient to consider the diagnosis of TTP/HUS[74]: a peripheral blood smear confirms MAHA, the percentage of schistocytes being higher (2% to 5%) than in HELLP (≤1%). ADAMTS13 should be obtained where available and plasmapheresis initiated as soon as possible. The Oklahoma TPP-HUS registry[75] showed only 2 out of 10 pregnant women with ADAMTS13 activity <5% but 8 (7 with acute renal failure) >25%, which may rather indicate HUS than TTP. The risk of recurrent TTP/HUS in subsequent pregnancies is described but unknown. A subsequent pregnancy[75] accounts for 18% of recurrence cases (Table 118.1).

Early consideration of plasma exchanges/plasmapheresis best allows for optimal outcome. A review before the plasma exchange era described a 44% maternal mortality and 80% fetal loss rate.[76] Treatment is indicated for all patients with TTP/HUS whatever the level of ADAMTS13 activity is.[75] A reduced ADAMTS13 activity and anti-ADAMTS13 IgG-antibody in the neonate blood have been described in an autoimmune TTP[77] but without any clinically relevant fetal or neonatal thrombocytopenia.

Table 118.1

TTP—HUS versus severe PE/HELLP syndrome in a woman with thrombocytopenia, hemolysis, neurologic symptoms (shared symptoms)

	TTP/HUS	HELLP Syndrome
Incidence	1:100,000 pregnancies	1:200 pregnancies
Normotensive, nonproteinuric during the third trimester or postpartum period	Likely	Unlikely
Onset before 24 wk of gestation	Likely	Unlikely
Onset before 20 wk of gestation	Likely	No
PE/HELLP without normalization of laboratory values within 2–3 d post delivery	Likely	Unlikely
Normal or mildly elevated AST levels	Likely	Unlikely
LDH to AST ratio >22	Likely	Unlikely
Elevation of liver enzymes proportionally to thrombocytopenia	Unlikely	Likely
Peripheral blood smears: schistocytes 2%–5%	Likely	Unlikely
Peripheral blood smears: schistocytes ≤1%	Unlikely	Likely

Clinical features of pregnant/postpartum women, which must indicate consideration for the diagnosis and intervention with plasma exchange treatment, include mental status abnormalities, focal neurologic abnormalities, seizures, or oliguric acute renal failure.[70] The earlier plasmapheresis is performed in the gestation, the higher the likelihood of a successful maternal–fetal outcome.[71] Larger volumes of plasma exchange are usually required in pregnancy, by virtue of the 45% increase in maternal blood volume. In patients with chronic, relapsing TMAs who may develop recurrent episodes during pregnancy, some anecdotal evidence suggests that prophylaxis with antiplatelet agents or corticosteroids may reduce the frequency or severity of these relapses,[64] other patients being managed with regular transfusion of plasma or plasma-derived fractions[78] and even with monthly prophylactic plasma exchanges.[79] Plasma exchange is the essential therapy, dramatically improves survival, the current available evidence for other treatments being limited.

Some other disorders can mimic TMAs, including HELLP syndromes (see below), microangiopathic antiphospholipid syndromes, and catastrophic antiphospholipid syndromes.[80,81]

Hemolysis–Elevated Liver Enzymes–Low Platelet Syndrome

Although the term "HELLP syndrome" was not coined until 1982 by Weinstein,[82] its pathologic feature had been recognized for at least 100 years. This variant of severe PE is frequent (around 0.8% of pregnancies and one quarter of all severe PE cases) and is associated with increased maternal and perinatal morbidity and mortality rates to imprecise levels, due to the scarcity of registries and to the presence of numerous biases: reported maternal death rates range between 1% and 25%, maternal cerebral hemorrhage between 1.5% and 40%, perinatal death between 7.4% and 34%, intrauterine growth restriction between 38% and 61%, and premature delivery accounts for 70% of cases (15% before 28 gestational weeks). Rats expressing trophoblast-derived circulating antiangiogenic factors, soluble fms-like tyrosine kinase-1 (sFlt1), and soluble endoglin (sEng), alone or in combination, developed, only in the sFlt1 + sEng group, nephrotic-range proteinuria, severe hypertension, and biochemical evidence of complete HELLP syndrome. These experimental data definitely link HELLP syndrome to the two placental mediators, acting in concert to induce severe PE[83] and the related severe endothelial dysfunction. Liver biopsy, which is risky and nonnecessary for diagnosis, shows pronounced changes with extensive fibrinous thrombi along hepatic sinusoids and hemorrhages into the Disse space. HELLP syndrome is thus placenta-mediated and cured by delivery.

Patients manifesting the HELLP syndrome are usually seen in the late third trimester, before term (<36 weeks of gestation, frequently ≥34 weeks). But early-onset HELLP cases are seen before 34 weeks, with some rare cases being described as early as the second trimester, as well as after delivery. Most patients, but not all, will have concomitant signs and symptoms of PE (hypertension, proteinuria, and edema). Bleeding due to thrombocytopenia is a very uncommon mode of presentation. The complaints are often nonspecific,[84] such as malaise (90%), nausea and vomiting (50%), and sometimes flu-like symptoms. Jaundice is a presenting feature in fewer than 5% of cases. Epigastric or right upper quadrant pain (90%) may be severe, radiations to the neck or shoulder evoking complications such as the development of hepatic hematoma or hepatic rupture.

Three standardized diagnostic laboratory criteria have been proposed by Sibai[84]: MAHA with characteristic peripheral blood smear and serum lactate dehydrogenase LDH levels ≥600 IU/L; serum aspartate aminotransferase (ASAT) levels ≥70 IU/L, and platelet count <100 G/L. Partial HELLP syndromes are defined by one or two but not all the three features. The incidences of complete and partial HELLP syndromes were described similar among severe PE patients (21% vs. 22%, respectively, among 178 severe PE women).[85] Comparison of complete HELLP

syndrome versus partial syndrome versus severe PE showed more frequent gastrointestinal symptoms (nausea, vomiting, epigastric or right upper quadrant pain), lower gestational age at delivery, higher incidence of C-section and DIC, and need for transfusion in women with complete HELLP syndrome.[85] Strictly defined HELLP syndrome is usually considered as an indication for delivery in ≤48 hours whereas conservative management is frequently used in PE women. The platelet nadir impacts on the rapidity of postpartum disease recovery.[86] In women with platelet nadir bellow 50 G/L (class 1 HELLP syndrome of the Mississippi classification[86]), as long as 11 days are generally necessary to achieve 100 G/L. In women with platelet nadir between 50 and 100 G/L (class 2 HELLP syndrome), recovery is generally reached by the 6th postpartum day.

Differential diagnoses are acute viral hepatitis, gastroenteritis, appendicitis, cholecystitis, ITP, lupus, antiphospholipid syndrome, TTP/HUS, and acute fatty liver of pregnancy (AFLP). AFLP may be confused with HELLP syndrome, both occurring in late pregnancy and having similar presentations. Liver dysfunction is usually more severe in AFLP, more often associated with liver failure-induced coagulopathy, hypoglycemia, and renal failure whereas coagulopathy in HELLP syndrome develops as a part of DIC syndrome. Thrombocytopenia in TTP/HUS is usually not associated with DIC syndrome, reduced antithrombin levels suggesting HELLP syndrome.[87] Hepatic ultrasound, computed tomography and MRI can routinely confirm the diagnosis, most frequently finding significant intra-abdominal hemorrhage or subcapsular hepatic hematoma. The main maternal complications of HELLP syndrome are DIC (30%), abruptio placentae (16%), and acute renal failure (8%). Cerebral hemorrhage (1.2%), retinal detachment (0.9%), and subcapsular hepatic hematoma/hepatic rupture (0.9%), which often requires surgical management, occur less frequently. Hepatic rupture usually presents with hypovolemic shock, vaginal bleeding, abdominal signs, and pain.

Initial management is stabilization then rapid delivery, which is indicated in case of severe maternal complications, signs of fetal distress, or gestation term >34 weeks. Before 34 weeks, the mother–fetus couple being stable, intravenous steroids are given for fetal lung maturity acceleration. Retrospective and small randomized studies suggested that the use of high-dose dexamethasone (10 mg every 12 hours) reduced maternal morbidity and induced more rapid improvement of the platelet counts.[88] A systematic review, however, shows no clear evidence of any effect of corticosteroids on substantive clinical outcomes.[89] This review shows that steroids improve platelet counts, with a greater efficiency of dexamethasone than of betamethasone: they may be justified in some clinical situations in which increased rate of recovery in platelet count is considered clinically worthwhile.[89]

Acute Fatty Liver of Pregnancy

This is a rare and potentially fatal condition, the reported incidence varying between 1 in 7,270 and 1 in 13,000 of deliveries, with no ethnic or regional variability.[90] It is more common in primiparous women and may reoccur. AFLP onset occurs more commonly between 30 and 38 weeks of gestation, but cases as early as 26 weeks have been reported. Maternal mortality ranges between 3% and 12.5%, and perinatal mortality is 66%. The relationship between AFLP and PE is not clearly defined, but case reports suggest that most women with AFLP have some degree of PE, with significant overlap of clinical and laboratory features with the HELLP syndrome, both conditions presenting in the later terms of pregnancy in patients with background PE.[90] Histopathology is, however, different in these two processes. Extensive hepatocellular necrosis is virtually nonexistent in AFLP, but is a common feature of HELLP syndrome. HELLP syndrome is characterized by periportal hemorrhages and fibrin deposits, whereas AFLP is characterized by microvesicular fatty infiltration. A mixed histologic picture can however be observed in 5% of the cases. Deficiencies in the enzymes of mitochondrial β-oxidation of fatty acids (FAO) may play a role in the development of this condition, but the precise mechanism is unknown. The hypothesis is that a heterozygous mother carrying a homozygous fetus for the FAO enzyme deficiency develops AFLP as a result of an impaired maternal ability to handle an increased load of fatty acids due to pregnancy-associated increase in lipolysis.[90]

AFLP has been associated with laboratory evidence of persisting DIC and profoundly depressed antithrombin plasma levels,[91,92] interpreted as the consequence of secondary consumption coagulopathy and liver function worsening.

Women usually present in the late term with nonspecific signs (malaise, nausea, vomiting), jaundice, upper quadrant pain, and epigastric pain being common. Some patients may present with frank liver failure and acute bleeding due to liver failure–induced coagulopathy, these symptoms being more commonly seen 1 to 2 weeks later. Concomitant PE is seen in 50% of the patients. A DIC coagulation pattern is frequent, from 55% to 75% of the cases according to some studies.[93] Thrombocytopenia is common when DIC is present: otherwise it is unusual. A moderate elevation of transaminase is usually found, although widely variable values have been described, the degree of transaminase elevation being unrelated to the severity of liver function worsening. Emerging acute renal failure is reflected by creatinine levels. Hypoglycemia and elevated ammonia develop when liver function worsens. Liver biopsy is helpful early in the disease, or in mid cases. Hypoglycemia and prolonged prothrombin time are suggestive of AFLP; frank hepatic failure is rare in HELLP. Imaging is of little value in diagnosis of ALFP but is useful to exclude other processes (e.g., hepatic hematoma/rupture or Budd-Chiari syndrome). Patients with severe PE associated liver disease and HELLP have more profound hematologic abnormalities, associating severe thrombocytopenia and MAHA, hemolytic syndrome being negative in AFLP.

Timely delivery after initial stabilization is a cure, together with supportive treatment in ICU or hepatic failure units. Maternal stabilization includes airway management, treatment of hypertension, and correction of hypoglycemia, electrolyte, and coagulation abnormalities. Due to potential bleeding complications around delivery, stabilization of the coagulation system is most important. This usually leads to an early and aggressive substitution of fibrinogen and platelets in addition to red packed cells and fresh frozen plasma (FFP).[93–97] In the absence of specific evaluations in AFLP, the substitution of antithrombin remains questionable since there is no general benefit on mortality in critically ill patients, but an increase in bleeding risk.[98] In case of uncontrollable bleeding, the use of recombinant activated factor VIIa has been described in AFLP.[99] Careful management of intravenous fluids and blood products, as well as frequent maternal signs assessment, and evaluation of changes in mental status are all crucial. Therefore, collaboration among different specialties such as intensive care, gastroenterology, perinatology, and hematology are essential.

Depending on the presence of the complications, complete recovery from AFLP may take anywhere from days to weeks, prothrombin time improvement being the first sign of recovery of hepatic function. In general, there are no hepatic sequelae postpartum after AFLP, and liver transplantation is rarely needed. Neonatal testing for enzymatic defects of β-oxidation of fatty acids is warranted; neonatal 3-hydroxyacyl-CoA dehydrogenase deficiency presents with Reye-like syndrome and is potentially lethal by 6 months of age if left untreated, dietary intervention being lifesaving.

Inherited Disorders Affecting Platelet Function and Platelet Production

Congenital disorders associated with platelet dysfunction, without/with impaired platelet production, are rare entities, the estimated incidence of the most severe subtypes being lower than 1 in 1 million although this is likely to be an underestimate due to misdiagnosis and underreporting, some subtypes striking <1,000 people worldwide. They induce bleeding syndromes of varying intensity.[100] Spontaneous bleeding is mostly mucocutaneous in nature, and a feature of milder forms is excessive trauma-related bleeding. Invasive procedures and delivery are thus critical events in pregnant women carrying such defects, the clinical risk being variable according to the type of disorder.

Women with severe disorders will need platelet transfusion during childbirth and sometimes during a week postpartum, early hospital discharge being therefore rarely possible. High forceps and ventouse extraction are contraindicated. Fetal scalp electrode monitoring and fetal blood sampling should be avoided. Epidural anesthetics are contraindicated in women with severe bleeding disorders and this must be discussed with the woman during antenatal assessments.[101]

Platelet transfusion can generate multiple risks, including alloimmunization to human leukocyte antigens (HLAs) or missing surface glycoproteins in Bernard-Soulier syndrome (BSS) or Glanzmann thrombasthenia (GT) as well as transmitted infection and allergic reactions. Single donor apheresis platelet collections reduce receiver exposure. Delivery in BSS and in GT can be complicated by maternal peripartum or late PPH, which may occasionally occur 2 to 4 weeks after delivery. The risk of antiglycoprotein alloantibodies-mediated platelet transfusion refractoriness is higher in GT than in BSS.[102] Reported treatment strategies in pregnant women with GT complicated by anti-GpIIbIIIa alloantibodies include plasmapheresis[103] and steroids.[104] Despite the introduction of leukocyte depleted blood components, which limits the incidence of HLA alloimmunization, a review by the United Kingdom Haemophilia Doctor's Organization recommend to transfuse HLA-matched platelets in those patients.[105] Antifibrinolytics are generally used as a useful adjunct in preventing and controlling bleeding, despite the absence of available documented medical evidence in the management of delivery in thrombocytopathic women, in conjunction with platelet transfusion. The dose of tranexamic acid is 15 to 25 mg/kg three times daily orally and, in case of intravenous route, 10 to 15 mg/kg three times daily, up to four times daily in selected cases. Desmopressin (DDAVP) is of limited or no value in platelet receptor deficiencies,[101] but patients with storage pool deficiency may respond.[106] Activated recombinant factor VII (rFVIIa) is licensed for use in GT patients with anti-GpIIbIIIa and/or HLA antibodies, which demonstrated refractoriness to platelet transfusion: the recommended dose is 90 μg/kg intravenously every 2 hours if required for three doses or until bleeding stops,[107] and was successfully used in PPH.[108,109] The PFA100 device is sensitive in detecting major platelet function defects such as BSS and GT but is frequently falsely negative for milder platelet defects such as storage pool disease and Hermansky-Pudlak syndrome; there is no evidence in its ability to reflect the hemorrhagic risk during pregnancy and around delivery in BSS and GT, and no evidence that it can reflect the clinical response to treatments.

Transplacental passage of anti-GpIbIX alloantibodies in BSS women and of anti-GpIIbIIIa alloantibodies in GT women has been described in some neonates, with fetal/neonatal thrombocytopenia and sometimes antenatal ICH.[110–112] Despite the rarity of pregnancy in type 1 GT, although successful outcomes have been reported in neonates born to GT women with GpIIbIIIa antibodies, fetal/neonatal thrombocytopenia and, specifically, intracranial hemorrhage are clearly a concern. The presence of GpIbIX antibodies resulting in neonatal thrombocytopenia was seen in five neonates from GT mothers, one of whom developed antenatal ICH.

COAGULATION DISORDERS

Most coagulation factors increase during pregnancy so pregnant women with mild to moderate deficiencies tend to have no bleeding.[113] However, even in case of mild deficiencies, the peripartum and postpartum periods may represent a difficult time and bleeding may occur. The situation is different when severe deficiencies are present, bleeding may occur not only during the peri- and postpartum but also during pregnancy. Moreover, for severe fibrinogen and FXIII deficiencies, spontaneous abortions are the rule without factor substitution.

von Willebrand Diseases and Platelet-Type von Willebrand

von Willebrand Diseases

There is an increase of von Willebrand factor (vWF) level during pregnancy; consequently many women with type 1 deficiency (partial deficiency of both functional and protein vWF as well as FVIII) reach normal levels at term. This explains the low incidence of bleeding before delivery. An improvement will not occur in women with type 3 (severe defect in vWF) and with type 2 (mainly qualitative defects) since even if vWF increases in type 2, the functional defect remains. Depending on their bleeding history women with types 2 and 3 may require substitution during pregnancy.[32,114,115]

The main problem for all types of von Willebrand disease (vWD) is the peripartum management. For type 1, if vWF and FVIII are below 50 IU/dL, DDAVP can be administered. DDAVP does not cross the placenta. It is advised to maintain vWF > 50 IU/dL during labor, delivery, and up to 5 days postpartum. For type 3, vWF concentrates will be given with the same aim, a vWF and FVIII > 50 IU/dL during labor, delivery and, up to 5 days postpartum with a continued close follow-up next since PPH may occur more than the first 5 days after delivery. In type 2, concentrates are usually required.[116]

Platelet transfusions around delivery are usually not indicated, being reserved to rare uncontrolled hemorrhages after adequate substitution. Women should receive a purified vWF

concentrate for procedures or bleeding in the antenatal period. They usually require peripartum factor prophylaxis for up to 7 days after cesarean section and 4 to 5 days after vaginal delivery.

Type 2B vWD presents a special challenge. Indeed, it may present as thrombocytopenia during pregnancy.[117,118] Platelet counts progressively decrease, to levels that can reach 20 G/L, with reversal to normal or minimally reduced platelet counts in the early post gestational period. Moreover, conditions such as infections or inflammation associated with enhanced vWF secretion favor thrombocytopenia, which is due to *in vivo* platelet aggregation induced by the gain-of-function of vWF variants and in some rare mutation cases due to abnormal megakaryopoiesis with circulating macrothrombocytopenia.[119] The risk of bleeding is higher in patients with thrombocytopenia with an adjusted hazard ratio of 4.57 (95% confidence interval 1.17 to 17.90) as shown in a cohort study of 67 patients with vWD type 2B.[120] The UK Haemophilia Centre Doctor's of obstetric management of women with type 2B vWD does not provide any specific recommendations for a target platelet count, which should be maintained.[121] In a recent small case series, successful management without bleeding complications was obtained by maintaining platelet counts of at least 50 G/L.[122]

Platelet-Type vWD

Platelet-type vWD can be revealed by severe bleeding during pregnancy associated with apparently acquired severe thrombocytopenia.[123] Platelets are hypersensitive when interacting with vWF, due to gain of function mutations in GPIBA gene coding for platelet GpIbα leading to spontaneous binding of circulating native normal vWF. vWF multimers are cleared from the blood to various degrees, some patients having a sustained secondary vWF:RCo reduction to levels reaching 15% of control values despite vWF:Ag concentrations around 100%.[123] While not giant as typically seen in blood smears from BSS or in some families with type 2B Willebrand disease, platelet size may be increased and associated with a moderate chronic thrombocytopenia, which can worsen in situations associated with enhanced vWF secretion. Diagnosis is based on enhanced ristocetin-induced platelet agglutination in platelet-rich plasma, which is no more evidenced in platelet-poor plasma mixed with control platelets.

vWF concentrates were used to control bleeding during C-section–mediated second delivery (platelets: 58 G/L) but bleeding reoccurred several days after[123]; first C-section (platelets 30 G/L) had been complicated by bleeding persisting over several days despite platelet transfusions. In platelet-type vWD women, substitution with vWF concentrates induces an accelerated platelet clearance, which maintains bleeding tendency. Substitution with normal platelets, from donors without the gain of function receptor, is necessary to break this vicious circle, thus allowing hemostasis. Increasing thrombocytopenia has been reported with the use of vWF/FVIII concentrates.[124] Similarly, desmopressin is contraindicated because the release of large vWF multimers from endothelial cells could induce *in vivo* agglutination of platelets and worsen thrombocytopenia. Patients with platelet-type vWD usually require platelet transfusions to treat hemorrhage.[125]

Hemophilia A and B Carriers

Carriers of hemophilia usually do not require factor replacement.[32] However, factor VIII or IX levels need to be monitored during the third trimester and at the time of delivery because for some women with particularly low factor levels, the risk of bleeding exists. Hemophilia B carriers are more prone to PPH than hemophilia A carriers because factor IX levels do not rise during pregnancy. Factor concentrates are useful in case of acute bleeding whereas DDAVP, more useful as a preventive measure, can only be used in case of hemophilia A. The effects of DDAVP are likely explained by a direct action on certain endothelial cells, via activation of endothelial vasopressin V2R receptor and cAMP-mediated signaling: this leads to exocytosis from Weibel Palade bodies where vWF is stored, with a secondary FVIII release. Factor IX is synthesized in hepatocytes: its secretion cannot be induced by DDAVP.

Fibrinogen Deficiency

Diseases affecting fibrinogen may be both acquired or inherited.[126] Fibrinogen disorders affect either the quantity (hypofibrinogenemia, characterized by fibrinogen levels lower than 1.5 G/L and afibrinogenemia, characterized by the complete deficiency of fibrinogen) or the quality of the circulating fibrinogen (dysfibrinogenemia) or both (hypodysfibrinogenemia).

Women with congenital afibrinogenemia are able to conceive and embryonic implantation is normal, but the pregnancy usually results in spontaneous abortion at 5 to 8 weeks of gestation unless factor replacement is given.[114,127] The importance of fibrinogen in pregnancy is demonstrated in studies with fibrinogen knock-out mice where gestation cannot be maintained to term.[128,129] Women with afibrinogenemia may also have placenta abruption as well as antepartum and PPH (they are at particularly high risk of PPH).

Hypofibrinogenemic women are usually asymptomatic with fibrinogen levels around 1.0 G/L, levels that are in theory high enough to protect against bleeding and maintaining pregnancy. However, some hypofibrinogenemic women may also have problems with pregnancy, those with the lower fibrinogen levels having the higher risk of miscarriage and therefore a need for fibrinogen substitution.[130,131]

Like hypofibrinogenemic women who have fibrinogen levels high enough for hemostasis (including normal platelet function), women with inherited dysfibrinogenemia are frequently asymptomatic; however, some patients suffer from bleeding, thromboembolic complications, or both. Patients with dysfibrinogenemia associated with hemorrhage bleed most often after trauma, surgery, or in the postpartum. Thrombosis may also occur in the postpartum. Problems of pregnancy vary depending on the type of dysfibrinogenemia, therefore individualized treatment is the rule.[127] Women with dysfibrinogenemia and a history of recurrent poor pregnancy outcome should be treated with fibrinogen concentrate replacement as soon as pregnancy is confirmed, using a target trough fibrinogen level of 1 G/L.[132]

During pregnancy Kobayashi et al.[133] recommend keeping the fibrinogen level >0.6 G/L and if possible >1.0 G/L. Lower fibrinogen concentrations (<0.4 G/L) have proven adequate to maintain pregnancy but not to avoid hemorrhagic complications. Fibrinogen clearance increases as the pregnancy progresses and thus the amount of fibrinogen required increases with advancing gestation. Continuous infusion of fibrinogen concentrates during labor to maintain fibrinogen higher than 1.5 G/L or ideally >2.0 G/L is recommended. However, recommendations for high-level replacement during pregnancy should be moderated

by the fact that thromboembolic events can occur,[132] particularly with the use of cryoprecipitates that contain appreciable quantities of FVIII and vWF in addition to fibrinogen.

Factor XIII Deficiency

Like in case of afibrinogenemia, women with severe factor XIII (FXIII) deficiency are able to conceive and embryonic implantation is normal, but the pregnancy usually results in spontaneous abortion unless factor replacement is given.[113,134,135,136] Therefore, FXIII should also be given as early as possible and during the whole pregnancy to avoid miscarriage and bleeding. Regular therapy should be commenced as early as possible in pregnancy to prevent bleeding and pregnancy loss. A level >10% during pregnancy should be considered.[137] The treatment should also be continued during labor and delivery to minimize the risk of bleeding complications. Indeed, PPH is a frequent complication if insufficient FXIII levels are reached. FXIII concentrates are the treatment of choice.

Other Factor Deficiencies

In addition to fibrinogen and FXIII deficiencies, other rare bleeding disorders (RBDs) include the inherited deficiencies of FII, FV, FV+, VIII, FVII, FX, and FXI and combined deficiency of vitamin K–dependent factors.[113,136] Recent issues of *Haemophilia* (November 2008) and *Seminars of Thrombosis and Hemostasis* (June 2009) have covered the main available treatments for RBDs. Concentrates are the treatment of choice because they are safer than FFP or cryoprecipitate (decreased risk of bloodborne pathogen transmission), there is no fluid overload and more precise dosing can be accomplished. In case of pregnancy and severe RBD, the UK guidelines on therapeutic products for coagulation disorders and a recent review by Kadir et al. provide some recommendations about the best treatment options.[113,114]

Pregnancy in women with severe hypothrombinemia may be complicated by bleeding and miscarriages.[138] Although probable, it is not really demonstrated whether prophylactic therapy is required during pregnancy. These women are also potentially at risk of PPH, so a prothrombin level >25 IU/dL during labor and delivery has been suggested.[113,114]

Women with low FV levels usually do not suffer from miscarriages[139] but from PPH. Therefore, careful monitoring of labor and immediate postpartum period is necessary. Substitution therapy with FFP (no FV concentrates are available) to maintain FV levels around 20 IU/dL is recommended.

As for many factor deficiencies (particularly true for FXI) there is a relatively poor correlation between absolute FVII level and bleeding tendency. Therefore, a decision for a substitution should be individualized, based particularly on the personal bleeding history.[113,114] Available data do not seem to indicate an increased risk of miscarriage during pregnancy.[140] Women with severe FVII deficiency are at risk of PPH; therefore, prophylactic treatment is proposed at term and in the postpartum. Current therapeutic options include rFVIIa, plasma-derived FVII, prothrombin-complex concentrates, and FFP. Although there is a poor correlation between factor levels and bleeding complications, a level above 20% should be reached in women with severe factor deficiency and a significant bleeding history.[113]

Successful term pregnancies as well as failures have been described in women with severe FX deficiencies, so prophylactic administration of FX (with prothrombin complex concentrates or FFP) is controversial. Women with a history of adverse pregnancy outcomes should receive FX replacement and should also receive replacement therapy to cover labor and delivery.[113]

Contrary to most coagulation factors, FXI level does not increase during pregnancy. FXI deficiency has not been reported to be associated with an increased risk of miscarriage, but in case of miscarriage or termination of pregnancy, excessive bleeding may occur. Clear prophylactic measures are difficult to state since it is well known that the bleeding tendency is only partially related to factor levels.[141] When there is a bleeding history, tranexamic acid,[142] FXI concentrates (careful with thrombotic complications and inhibitor formation), or FFP (if FXI concentrates are not available) should be discussed and adapted to FXI level and mode of delivery. Recombinant FVIIa is an alternative option in case of inhibitor. To prevent PPH, tranexamic acid should be considered for most women up to 2 weeks post delivery, especially for those with a bleeding history.

There is very little literature on combined FV and FVIII deficiency or inherited deficiency vitamin K–dependent clotting factors and pregnancy.[113] Concerning FV and FVIII deficiency, since FV does not increase during pregnancy any bleeding is likely to be dependent on the FV level and not on FVIII, which increases during pregnancy. Vitamin K is the treatment of choice in case of inherited deficiency vitamin K–dependent clotting factors, and replacement therapy with vitamin K clotting factors could be considered in case of severe deficiency to cover delivery.[143]

Factor VIII Inhibitors

When a woman bleeds without obvious explanation in the postpartum period, the diagnosis of acquired hemophilia should be suspected. This condition may occur already during the puerperium but is observed also several months postpartum. Finding of a prolonged activated partial thromboplastin time, not corrected by incubating patient's plasma with a normal plasma, should lead to measure FVIII. The diagnosis of an inhibitor can be confirmed with the Nijmegen assay.[144] Management of women with acquired hemophilia depends on bleeding manifestations and on the titer of the inhibitor.[145] When bleeding is not severe, DDAVP and/or FVIII concentrates can be used. In case of acute bleeding, rFVIIa or activated prothrombin complex concentrates are more effective. Spontaneous remission is common when a FVIII inhibitor occurs after pregnancy, which is not the case in the aging population where immunosuppressive agents are often required.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a characteristic complication of obstetric dramas, including amniotic fluid embolism, severe PE/eclampsia/HELLP syndrome, placental abruption, *placenta praevia*, intrauterine fetal demise, septic abortion and intrauterine infection, PPH, and AFLP.[146]

Placenta is a key actor of most of the obstetrics-related DIC features, explaining obstetrical DIC management and an overall favorable clinical prognosis despite impressive acute coagulopathies. The vascular bed of the placenta contains fetal trophoblast cells, which can regulate hemostasis in the intervillous space. It

expresses high tissue factor and low TFPI levels[147] thus activating coagulation. It also produces PAI-2 and gradually increasing PAI-1 amounts, whereas t-PA levels are unchanged, thus impairing the fibrinolytic system. The spillover of localized coagulation activation from the placenta into the systemic circulation can disseminate thrombin generation, induce consumption coagulopathy, and precipitate organ damage. Acute placenta and vasculoplacental disorders/dramas, with their characteristic sudden onset, are thus prone to orientate the hemostatic system toward an enhanced activation state, which can become uncontrolled after inhibitors exhaustion. This generally leads to frank DIC features, in which the consumption coagulopathy predominates, with hemorrhagic symptoms and marked laboratory abnormalities. Accurate obstetrical intervention usually prevents DIC, even in its more severe forms, a particularity of most of the obstetrics-related DICs.

The clinical association between intrauterine fetal death and DIC has to be discussed. The incidence of undiagnosed intrauterine fetal demise is likely to be rare in a well-resourced obstetric environment: spontaneous delivery would usually ensue within the first 2 weeks whilst marked coagulation disturbances only tend to occur after a month of fetal demise.[148] The fetus being retained longer, up to 25% of cases develop a coagulopathy, which is mediated by the release of tissue factor from dead products of conception. This can be a slow process, which may correct spontaneously before evacuation. Even when pregnancies are complicated by death of one fetus and survival of another, marked coagulation disturbances are rare.[149]

It is necessary to recognize DIC early to facilitate timely intervention. Diagnosis of obstetrics-related overt DIC is possible through a scoring system as proposed by the International Society on Thrombosis and Haemostasis[150] (see Chapter 98). After checking for clinical conditions that may be associated with overt DIC, obstetric calamities being one of them, useful tests are platelet count, fibrinogen, prothrombin time, and a fibrin generation-related maker, practically D-dimers or soluble fibrin monomers, serial testing being recommended to increase diagnostic precision. Management involves delivery of the placenta and supportive treatment, including blood product substitution.

One peculiar feature is DIC complicating severe PPH. PPH is generally not due to an underlying intrinsic coagulation disorder, being mainly secondary to uterine atony, lower genital tract lacerations, and retained placental. PPH coagulopathy can be a complex disorder mixing consumption, dilution due to resuscitation, and effects of substitution. Fibrinogen levels assayed in PPH patients requiring uterotonic prostaglandin E2 infusion can anticipate the risk of severe bleeding if ≤2 G/L.[151] Normal but low fibrinogen, FXI, or vWF levels assayed in nonpregnant women are retrospectively not associated with the risk PPH, but to the risk of severe PPH, thus acting as risk factor for a poor outcome.[152]

CHAPTER

119 Developmental Hemostasis

PAUL MONAGLE, VERA IGNJATOVIC, AND LESLIE ROY BERRY

Hemostasis is a complex homeostatic system that is critical to maintaining healthy life. Disturbances of the hemostatic system account for a large proportion of the noninfectious morbidity and mortality in westernized societies and are integral to many disease processes including cardiovascular disease, stroke, venous thrombosis, and even cancer. In some respects, nothing has changed since the mid-1800s when the German doctor, Rudolf Virchow, described the critical components of hemostasis as being the blood vessel wall, blood composition, and blood flow (Virchow triad). In considering the nonflow aspects of this equation, hemostasis can be considered as an interaction between the blood vessel wall, coagulation proteins within the plasma, and blood cellular components, predominantly platelets. Clearly over recent years, however, there has been an explosion in our understanding of the interactions within this system, and in particular, of the roles of individual plasma proteins. The hemostatic system interacts with other physiologic systems such as wound repair, inflammation, and angiogenesis in a complex and as yet incompletely understood manner.

Hemostasis is a dynamic, evolving process that is age dependent and begins *in utero*. The evolution of the hemostatic system continues throughout life, as evidenced by studies of the coagulation system in centenarians.[1] However, the changes are most marked during childhood and hence are of most clinical relevance during this time. Although evolving, the hemostatic system in healthy fetuses, infants, and children must be considered physiologic. The term "Developmental Hemostasis" was coined in the late 1980s by Dr. Maureen Andrew to describe this phenomenon. Dr. Andrew demonstrated in a single large cohort study of Canadian children that the concentrations of the majority of coagulation proteins, as measured by functional assays, changed significantly with age. The landmark papers, published in *Blood* in 1987, 1988, and 1992, not only changed the approach to research related to the coagulation system in children, but also the clinical interpretation of coagulation assays used by many hemostasis laboratories around the world since that time.[2–4]

This chapter outlines our current understanding of developmental hemostasis, focusing on the plasma proteins. While there is evidence of age-related developmental changes in platelets[5,6,7,8–10] and the blood vessel wall,[6,7,8–11] these changes are beyond the scope of this chapter. The implications of developmental hemostasis are discussed, in particular the clinical implications, the evidence that the age-related changes in the coagulation system influence the age-related epidemiology of thromboembolic disease, and the potential implications of developmental hemostasis for integrated physiologic systems. The impact of development hemostasis on the pharmacology and effectiveness of anticoagulant drugs are discussed in Chapter 121. There remain many gaps in our knowledge, and much work is required in this area. An understanding of developmental hemostasis in the broadest sense optimizes the prevention, diagnosis, and treatment of hemostatic problems during childhood and undoubtedly provides new insights into the pathophysiology of hemorrhagic and thrombotic complications for all ages.

THE HEMOSTATIC SYSTEM

The fundamental principle underlying developmental hemostasis is that the functional levels of coagulation proteins change in a predictable way with age.[12] While the absolute values of these changes are reagent and analyzer dependent, the trends in changes observed are consistent across a number of studies.[13] These changes in functional protein levels are reflected in the results of global tests of coagulation such as the activated partial thromboplastin time (APTT). Other global measures of hemostasis may be more or less sensitive to age-related changes in hemostatic proteins. For example, there is little difference in normal thromboelastography (TEG) with age.[14] Studies in this field have predominantly involved functional assays of the coagulation proteins due to the fact that these assays are commonly used in clinical practice. In fact, differences in immunologic levels of the coagulation proteins have not been reported to date. Table 119.1 lists major studies that have described age-related changes in coagulation proteins and routine coagulation assays. Tables 119.2–119.8 list values for these parameters as reported in a more recent publication.

Early evidence suggests that these age-related changes in protein concentration are not isolated to the coagulation system, but are in fact evident across multiple protein systems within the plasma proteome. Variation in the human plasma proteome with age has been examined using plasma samples collected from healthy neonates (day 1 and day 3), children (<1 year, 1 to 5, 6 to 10, and 11 to 16 years), and adults. The study reported significant changes in number and abundance of up to 100 proteins across various age groups tested.[26] FIGURE 119.1 shows a two-dimensional (2-D) DIGE gel image demonstrating differences in plasma protein abundance between a day 1 neonate and an adult. Table 119.9 lists the plasma proteins that were shown in this initial study to significantly change in abundance with age. Further work is required to identify the many more proteins that likely change consistently with age. The implications of these age-related changes are yet to be understood.

The possibilities for how plasma levels of coagulation proteins are different in children compared to adults include regulation at the gene level, posttranslational modifications (PTMs) that affect protein function, delivery or release of proteins, as well as differences in protein clearance. A recent study

Table 119.1

Studies reporting age-related differences in coagulation assays or proteins during childhood

Author	Year	Assays/Proteins Reported	Age Groups	N
Perlman[15]	1975	PT, TT, APTT, fibrinogen, FDP, platelet count, hematocrit, FV, FVIII, plasminogen, hemoglobin	Healthy infants Small-for-dates infants Postmature infants	*N* = 35 *N* = 26 *N* = 30
Beverley et al.[16]	1984	APTT, FII-VII-X, fibrinogen, α_2-antiplasmin, platelet count, MPV, megathrombocyte index, plasminogen	Cord blood Newborns (48 h)	*N* = 80
Andrew et al.[3]	1987	PT, APTT, TCT, fibrinogen, FII, FV, FVII, FVIII, vWF, FIX, FX, FXI, FXII, PK, HMW-K, FXIIIa, FXIIIb, plasminogen, AT, α_2-M, α_2-AP, C_1E-INH, α_1-AT, HCII, protein C, protein S	Day 1 newborn Day 5 newborn Day 30 newborn Day 90 newborn Day 180 newborn Adult	28–75 samples per age group

demonstrated that even with a transplanted adult liver *in situ*, children maintain plasma levels of certain coagulation proteins at their expected age-specific levels.[27] Thus the liver, despite being the site of production for most of the coagulation proteins, is not the regulator of plasma levels. The authors hypothesized hormonal control, vascular endothelial control via an as yet unidentified mechanism, or control via variable clearance. However, whatever the mechanism, the vascular endothelium seems the most likely candidate as the primary regulator.[28] The endothelium is intimately involved with the function of the coagulation proteins.[29] Vascular endothelial dysfunction, as observed in disseminated intravascular coagulation, is usually measured by the degree of disturbance in coagulation proteins, even though it is not a primary disorder of coagulation.[30]

To date, efforts to understand developmental differences in the hemostatic system have mostly focused on *quantitative differences* in coagulation proteins based on functional assays.[3,4,12] However, coagulation proteins have complex tertiary structures, which in general bestow multiple functions.[31,32] PTMs affecting the structure of hemostatic proteins are known to occur and likely have significant impact on the function of these proteins.[31,32] As an example, fibrinogen has previously been demonstrated to exist in a "fetal" form, in cord blood of term infants.[32] This "fetal" form of fibrinogen has increased sialic acid content compared to adult fibrinogen, a direct result of PTM. The phosphorus content of fetal fibrinogen is increased up to fourfold compared to the adult form of this protein.[33,34] In addition, thrombin clotting times are prolonged in newborns, suggesting differences in polymerization of fibrin from "fetal" fibrinogen,[35] an observation that has led to claims that fibrinogen in infants is "dysfunctional."[36] The importance of differences in sialic acid content of fibrinogen is in the fact that sialic residues of fibrinogen directly bind Ca^{2+},[37] leading to a decrease in the intermolecular repulsion between fibrinogen chains and thereby facilitating fibrin polymerization.[37]

A recent study investigating differences in fibrinogen purified from neonates and children to that from adults determined that the molecular weight of the Aα fibrinogen chain

Table 119.2

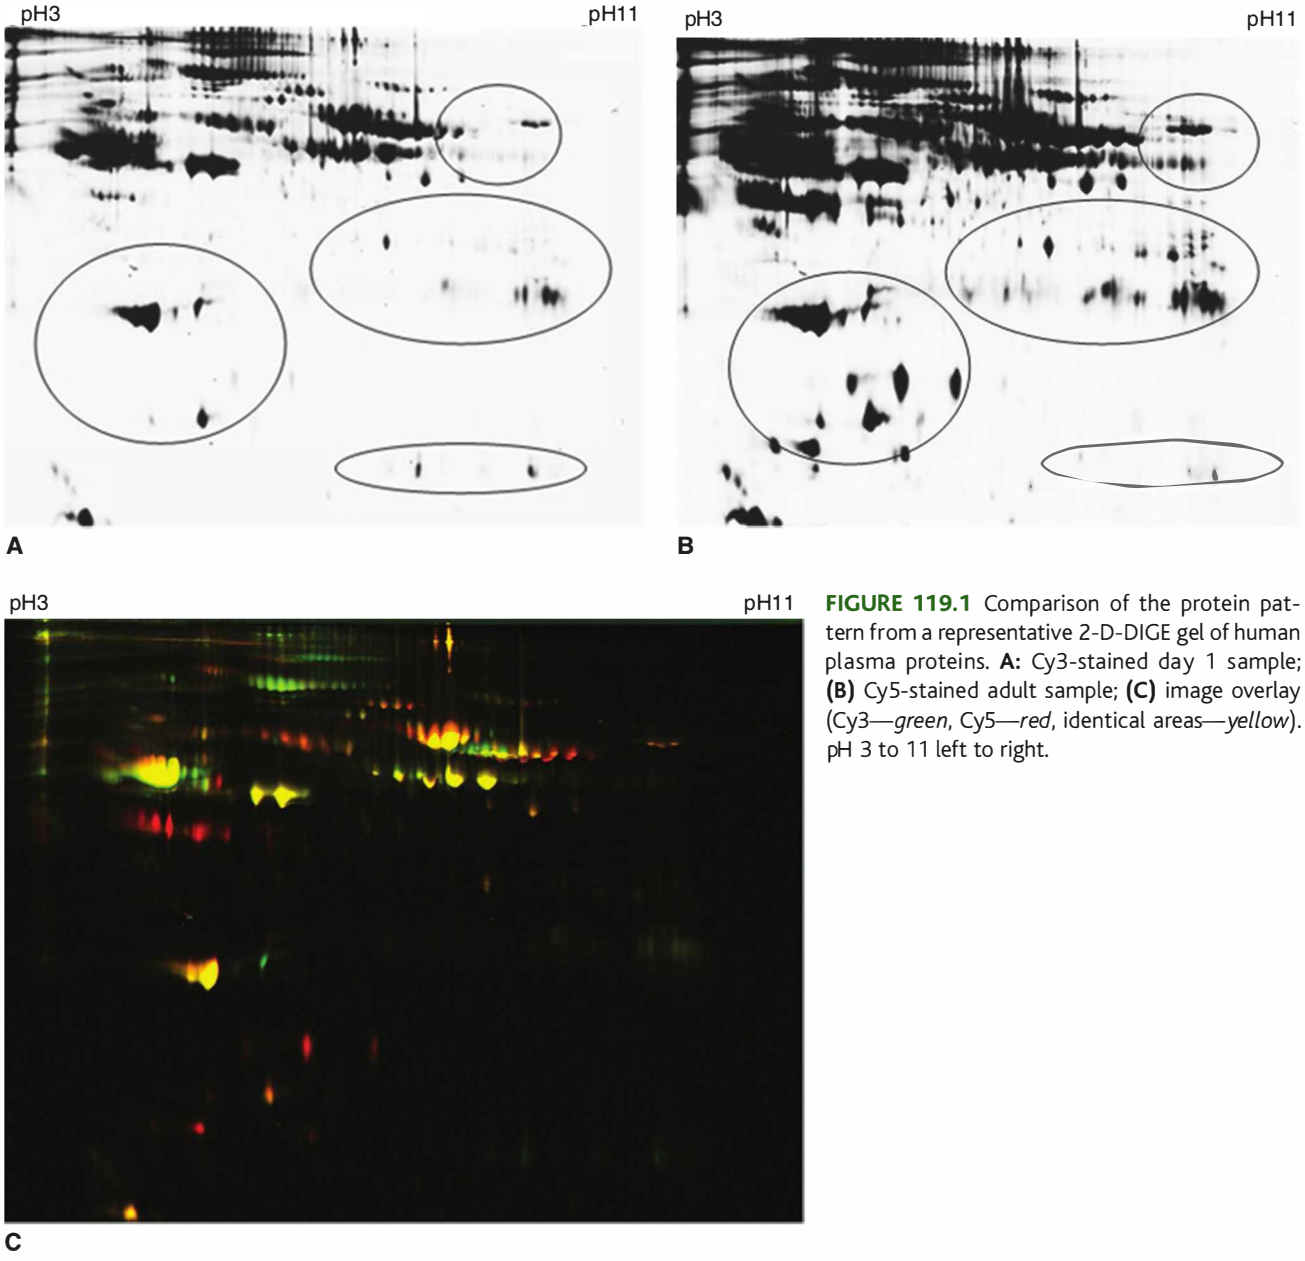

FIGURE 119.1 Comparison of the protein pattern from a representative 2-D-DIGE gel of human plasma proteins. **A:** Cy3-stained day 1 sample; **(B)** Cy5-stained adult sample; **(C)** image overlay (Cy3—*green*, Cy5—*red*, identical areas—*yellow*). pH 3 to 11 left to right.

was consistently higher by up to 1,500 Da in neonates and children compared to adults.[38] This trend toward a higher molecular weight of fibrinogen chains in younger age groups was also consistent for the Bβ and γ chains with differences of up to 400 and 500 Da, respectively. These differences in fibrinogen chains could represent multiple additional sialic acid or residues associated with increased glycan branching[39] in the neonatal and pediatric fibrinogen compared to the adult form of this protein. The same study also demonstrated significant differences in the chromatogram profile (area under the peak and peak height) in neonates and children compared to adults, suggesting differences in the interaction of the fibrinogen molecule from each age group with the chromatography column used, which also implies structural differences for fibrinogen in these age groups.[38]

There has been very little research examining whether age-related PTMs are relevant in other coagulation proteins, and none in humans. In addition to fibrinogen, a "neonatal" form of protein C has been detected in the ovine fetus.[40] Compared to the adult two-chain molecule, the "neonatal" protein C has an increased proportion of single-chain molecules. Preliminary reports have also indicated that forms of protein C with increased glycosylation are more prevalent in newborns than in adults. Differences have also been demonstrated in mRNA levels of antithrombin (AT) in fetal compared to adult sheep, suggesting age-specific differential translation for this protein.[41]

Despite changes in the concentration of individual coagulation proteins as well as in global tests of coagulation, the hemostatic system in neonates and children does not seem to be "disadvantaged" compared to the "normal" coagulation system

Table 119.9

Examples of plasma proteins known to change in abundance with age

Proteins that Increase in Abundance with Age	Proteins that Decrease in Abundance with Age
Clusterin	A2M
Haptoglobin	Complement C3
Alpha-1-antitrypsin	Complement factor B
Hemopexin precursor	Fibrinogen
Kininogen 1 variant	Vitamin D–binding protein
Chain A, human factor H	Fibronectin 1 variant
	Heparin cofactor II
	Alpha-1-antichymotrypsin
	Bikunin

Modified from Ignjatovic V, Lai C, Summerhayes R, et al. Age-related differences in plasma proteins: how plasma proteins change from neonates to adults. *PLoS One* 2011;6(2):e17213.

of adults. There is no data to support either an increased bleeding or thrombotic risk during infancy and childhood for any given stimulus, and on the contrary, one could argue that the hemostatic system in neonates and children protects against bleeding and thrombotic complications compared to adults. This is despite the fact that when considering individual proteins, many proteins exist at levels during stages of infancy that would be associated with disease in adults. For example, AT levels during the first 3 months of life are decreased compared to those observed in many adults with heterozygous AT deficiency and recurrent thrombosis.[32] Similarly, levels of factor IX in children may be below 30% of adult levels in early life and yet those children have no evidence of a bleeding phenotype. Prolongation of global tests of coagulation, such as the APTT, are also not associated with an increase in bleeding, despite the APTT being considerably prolonged compared to that in many adults with clinically relevant von Willebrand disease.[32] The absolute levels of hemostatic proteins as measured by the currently available functional assays are clearly not the key factor in determining clinical phenotype, and there remains much research to be performed to better understand the relationships between the concentration of hemostatic proteins and functional outcomes of the hemostatic system.

IMPLICATIONS OF DEVELOPMENTAL HEMOSTASIS

Clinical Implications

Defining Reference Ranges

As previously stated, a number of studies have confirmed that age-related reference ranges for coagulation assays in the healthy population are analyzer and reagent dependent.[13] Despite this, very few clinical laboratories have adequately determined age-related reference ranges specific to their analyzer–reagent combination, mostly for cost and ethical difficulties. Collecting blood from otherwise healthy children to enable reference range determination is not easy. However, the commonly used alternatives of either using adult reference ranges or published pediatric reference ranges are unsatisfactory in terms of the highest standard of clinical care of the patients.

A typical example would be a 4-year-old child who has an APTT performed using the PTT-A reagent (Diagnostica Stago, France) on an STA-compact analyzer (Diagnostica Stago, France). The 95% confidence interval for APTT results in this age group is 33 to 44 seconds (rounded to whole seconds).[13] On the other hand, if the reagent being used for the APTT assay is CK-PREST (Diagnostica Stago, France), even using the same analyzer, the reference range encompassing 95% of the population is reported to be 30 to 35 seconds.[32] Therefore, if one used the published reference range based on a CK-PREST analysis, but the actual laboratory used the PTT-A reagent, then over 30% of children (assuming normal distribution) in this age group would be labeled as having prolonged APTT when in fact they were perfectly healthy. The majority of APTT reagents currently in clinical use have no published age-specific references ranges, so one can only assume that such errors are likely to be frequent. As each new reagent is developed for clinical use, unless the appropriate normative data are available, then children will continue to be classified as either normal or abnormal erroneously.

Consider the other alternative strategy of using an adult-based reference range. For example, the adult reference range for an APTT using the PTT-A reagent (Diagnostica Stago, France) and an STA-Compact analyzer is 27 to 38 seconds (95% confidence intervals rounded to whole seconds). Once again approximately 30% of children aged 1 to 5 years would be classified as abnormal if they were compared to this adult-specific reference range, even if their samples were analyzed using the same reagent and analyzer combination.

The clinical implications of this type of error are significant. Considering the most common clinical indications for performing an APTT assay in nonhospitalized children, then the true cost of this misclassification is startling. Children commonly have coagulation studies ordered because they are preoperative and the surgeon is concerned about the past history ("my child bruises easily, or has blood noses"), or because of a positive family history. Erroneous interpretation of an APTT as prolonged, due to the use of an inappropriate reference range, leads to cancellation of surgery, multiple investigations, referral to specialist hematologists, and often overtreatment of the child during the procedure. Similarly, children often have coagulation studies because of a positive family history of a bleeding disorder. Misclassification of the child due to nonspecific reference ranges can lead to a child being mislabeled as having a bleeding or thrombotic disorder when in reality they do not. This can have significant lifestyle and other implications for the child and their family which can be problematic for many years to come. Reversing an already made "diagnosis" is never easy. Finally, children thought to be at risk from physical or mental abuse will often have coagulation studies as part of their workup if they present with unusual bruising or injuries. Forensic medicine requires exact and explainable answers if justice is going to be achieved and "at-risk" children protected.

All laboratories that report coagulation studies in neonates and children must ensure that they are using appropriate age-related reference ranges that are specific for their analyzer/reagent combination.

Diagnosing Disease

Understanding the true age-related 95th centiles of a hemostatic parameter is of scientific value. However, this does not necessarily help us in defining disease. For example, if the lower limit of the reference range for factor VIII in a child is 59% based on a population study, and a patient of appropriate age presents who, when using the same analyzer and reagent, has a factor VIII of 50%, then it is unlikely that the patient has even mild hemophilia. This is because by definition, we define hemophilia by arbitrary plasma levels (<30% for mild hemophilia), or at least plasma levels that are thought to be associated with increased risk of bleeding. In the absence of genetic studies, definition of heterozygote states remains difficult. The dilemma is that for the laboratory tests to be clinically useful, we need to understand the level at which results define clinically relevant disease probably more so than the levels at which the results are outside the 95% confidence limits of the healthy population. To date, there have been no specific studies in children which address this issue. Correlation of phenotype and genotype, as well as longitudinal studies mapping the hemostatic protein changes in a cohort of patients in conjunction with their clinical outcomes, would be most helpful. The issue of results being outside the reference range versus being indicative of clinical disease is most problematic when considering the procoagulant proteins. One must always remember that a positive diagnosis of a hemostatic disorder should include the presence of a family history, a positive clinical phenotype, and reproducible abnormal laboratory results. The problem is that the clinical phenotype is much more difficult to define given the infrequency of thrombotic events; the family history is often equivocal in terms of the role of clinical precipitants of thrombosis, and yet the labeling of children as having a thrombophilic condition can have significant impact. Frequently, clinicians are asked to advise on the need for thromboprophylaxis related to clinical interventions, oral contraceptive pill use, or prolonged travel in children in whom the presence or absence of a true thrombophilic condition seems almost impossible to determine.

The Risk of Thromboembolic Disease in Infants and Children

The epidemiology of thromboembolism in pediatric patients is vastly different from that observed in adults.[42,43–54] The evidence that infants and children are protected from thrombosis comes from a number of different perspectives. Patients with congenital deficiencies of AT, protein C, or protein S or with activated protein C resistance (APCR)[55–59] usually do not present with thrombosis until the late teenage years or even later. Similarly, thrombosis secondary to acquired risk factors occurs considerably less frequently in children compared to adults. For example, thrombosis in children with nephrotic syndrome occurs in only 2% of children compared with approximately 20% of adults.[60–65] Children routinely undergo major abdominal and lower limb orthopedic surgery and do not require anticoagulant prophylaxis because secondary thrombosis is so rare. In contrast, adults undergoing similar procedures have a high risk of thrombosis and benefit from prophylactic anticoagulant therapy.[66]

Thus for the same risk factor, whether inherited or acquired, the thrombosis risk is substantially reduced in children compared to adults, which suggests there are protective mechanisms in play. This may be secondary to age-related differences in hemostatic proteins, platelets, blood vessel wall, or a combination of all three.

Developmental Hemostasis and Integrated Physiologic Systems

The fundamental question remains as to why the plasma levels of coagulation proteins differ with age. Potentially, this has nothing to do with coagulation. Coagulation proteins are examples of broad-acting proteins such as serpins, and many have been shown to also have actions in multiple key biologic processes such as inflammation, wound repair, and angiogenesis.[30,67] Changing requirements of those systems could equally provide the rationale for developmental changes in the hemostatic system, which are therefore seen as necessary compensations allowing normal hemostatic function. Whether it is the requirements of one, two, or a mixture of these basic systems involved in multicellular organism survival that drive the plasma levels of these multifunctional proteins remains to be determined but is a most enticing theory. Evidence for this theory is mounting, and two important examples to consider are antithrombin and alpha-2 macroglobulin (A2M).

AT is a major plasma serine proteinase inhibitor (serpin) which inhibits thrombin and activated factor X generated upon activation of the hemostatic system.[68] The 3-D structure of AT was determined more than 15 years ago by two independent research groups.[69,70] AT inhibits thrombin and in the presence of unfractionated heparin (UFH), this ability to inhibit thrombin is increased by 1,000-fold.[71] AT is described as occurring in two distinct isoforms, native AT (NAT) or latent AT (LAT). Recent studies have demonstrated that LAT is associated with severe and sudden onset of thrombosis, has potent antiangiogenic properties, specifically downregulates several proangiogenic genes, and upregulates a number of antiangiogenic genes.[72]

Preliminary experiments demonstrate the concentration of the LAT isoform in the healthy population increases significantly with age, such that day 1 to 3 neonates, <1-year-old children, and 1- to 5-year-olds have 30%, 50%, and 80% LAT compared to adult levels, respectively (Unpublished data Vera Ignjatovic). In addition to NAT and LAT, AT isolated from adults has been shown to circulate as two glycoforms[73]; α-AT has four identical sialylated complex oligosaccharides attached to asparagines, which account for 15% of the 58 kDa total mass, while β-AT is only glycosylated on three of the potential four asparagine sites.[74] In adults, α-AT constitutes 90% to 95% of circulating AT, compared to only 5% to 10% β-AT, yet β-AT has higher affinity for UFH, endothelial surfaces and is a more effective thrombin inhibitor.[74–76] This suggests physiologically and clinically specialized functions for the AT glycoforms, where β-AT may be vital for controlling thrombogenic events arising from vessel wall injury, while α-AT may be largely responsible for inhibition of fluid-phase thrombin. The location of the carbohydrate side chain at Asn-135 in α-AT (absent in β-AT) interferes with the binding of UFH due to its proximity to the heparin-binding site.[77] This demonstrates that glycosylation or deglycosylation of a single amino acid, particularly in close proximity to the heparin-binding site of AT, has significant functional implications for the function of the AT molecule. Despite the clinical significance of the ratio of α-AT to β-AT in terms of their interaction

with UFH, whether this ratio changes with age or health state has not been investigated previously.

Recently, AT has been shown to have potent antiangiogenic properties as well as being an important anticoagulant.[72] AT has been shown to downregulate several proangiogenic genes and upregulate a number of antiangiogenic genes. The antiangiogenic forms of AT are known to include heparin-binding sites, and heparin is shown to potentiate this effect.[72] This is one of the postulated mechanisms in the positive effect of heparinoids on cancer survival which is independent of the antithrombotic effect.[78–80] AT levels are naturally reduced in newborns to <50% of the levels observed in adults and then increase to approach adult levels by approximately 6 months of age.[13] Early evidence suggests that there is a difference in the balance of isoforms of AT in newborns compared to adults. One postulated reason for the decreased levels of AT (and the altered balance of isoforms) observed in neonates is related to the role of this protein in angiogenesis.[41] Fetal and early neonatal life is a time of prolific angiogenesis, much more so than any later stage of life, and given the known antiangiogenic properties of AT, the low levels of this protein are likely beneficial for healthy development. Hence, AT replacement therapy during neonatal life may well be deleterious by altering the normal balance of angiogenesis. In the only published randomized trial of AT replacement therapy in newborn infants (as a treatment for lung disease of prematurity), there were seven (11.5%) deaths in the AT-treated group and three (4.9%) deaths in the placebo (no treatment) group.[81] A similar trial (reported only in abstract format) also reported a similar trend in the setting of a clinical trial; however, the mechanism for this finding was not established.[81]

Thus in summary, preliminary evidence indicates that age-related changes in the quantity, structure, and function of AT are important in normal physiologic development, with implications much broader than the coagulation system alone.

Another coagulation protein that is important in this context is A2M, a major natural inhibitor of thrombin that is present in two- to threefold higher concentrations during childhood compared to adults and remains elevated until adulthood.[3] As a major plasma protease inhibitor, A2M represents 2% to 4% of the total protein content in adult plasma[82,83] and plays a role in multiple processes including hemostasis, innate immunity, and inflammation. To date, there has been no evidence for a case of a total deficiency or homozygosity of A2M, which could be evidence of an absolute requirement of A2M for fetal survival *in utero*. In the hemostatic system, A2M exhibits anticoagulant, procoagulant, and antifibrinolytic activity. A2M has also been linked to the development of Alzheimer disease.[84] In addition, A2M has a function in the immune system, as a major inhibitor of metalloproteinases, assisting in their clearance from tissue fluids.[85] Recently, A2M has been demonstrated to also function as a molecular chaperone, where native A2M binds to plasma proteins that are partially unfolded or inactivated by heat or oxidative stress. Specifically, the A2M–protein complex is still able to interact with and inhibit proteases and subsequently the A2M–protein–protease complex is able to be rapidly cleared via endocytosis from the circulation.[86]

A2M levels are increased in healthy infants and children and only approach adult levels in late teenage years as confirmed in a number of studies.[2–4,82] A2M has been shown to be influential in the regulation of the hemostatic system in neonates, where A2M functions as a major inhibitor of coagulation.[87,88] Up to 64% of thrombin in neonates is bound and inhibited by A2M, while the corresponding inhibition of thrombin in adults accounts for 7% of thrombin.[89] In fact, in neonates and children, A2M plays a more important role in thrombin inhibition compared to AT, which is the predominant inhibitor in adults.[7] In AT-deficient children, thrombin inhibition by A2M was demonstrated to be as effective as in plasma from children and adults without the AT deficiency.[87] Hence, A2M has a compensatory role for thrombin inhibition in children with an AT deficiency.

Interestingly, decreased A2M levels have been reported in neonates with chronic heart disease compared to otherwise healthy neonates.[90] In contrast, asymptomatic dyslipidemia in children has been associated with increased levels of A2M (as well as plasminogen and fibrinogen) compared to control subjects.[91]

In summary, it seems highly likely that A2M may in fact have potential functions in the regulation of multiple growth processes. However, the biologic basis for the significantly elevated plasma levels of A2M in infancy and childhood has not been clearly defined to date, and much further research is clearly required.

The two examples discussed previously represent the two proteins for which there is the most available data at this time. Once the focus on research in this area increases, the list of coagulation proteins for which there are multifunctional reasons for age-related changes will also undoubtedly increase. A better understanding of the roles of each of the coagulation proteins in normal growth and development, and a better understanding of how these complex physiologic systems integrate and function in unison, is clearly important. Such knowledge would help in terms of understanding the effect of treating children with plasma products or anticoagulants, which directly impact on the plasma levels of such proteins, and likely change the balance of isoforms in circulation. Further, such knowledge may provide critical clues to the processes that underlie so much of the disease burden within Western society which is clearly associated with aging.

CONCLUSION

The fact that the hemostatic system changes with age is indisputable. However, fundamental questions remain as to why these changes occur, what the relative influence is of quantitative versus qualitative protein changes, and how in fact these changes are mediated. The implications of altering the time course or progress of these age-related changes are unknown, but may potentially be either advantageous or deleterious to long-term survival. There remain many unanswered questions about the hemostatic system in adults, and its role in health and disease, further complicating our ability to answer the unknown questions related to developmental hemostasis. Of specific and immediate interest is what these changes mean for anticoagulation and other hemostatic therapies in children. Given it is only 20 years since the pioneering work of Andrew et al. initiated the concept of developmental hemostasis, our lack of current knowledge is not surprising. However, we require a concerted research effort to ensure that 20 years from now we have a much greater understanding of developmental hemostasis.

CHAPTER

120 Bleeding in Neonates and Children

ANTHONY K. C. CHAN, ELIZABETH A. CHALMERS, SAM SCHULMAN, AND ALAN D. MICHELSON

Neonates and children may be born with a congenital bleeding disorder or they may acquire a bleeding disorder as a consequence of a disease process. Correct diagnosis is crucial to management of the disease and to reduce morbidity and mortality associated with any bleeding diathesis. The natural history of diseases in children can differ substantially from that observed in adult patients due to developmental differences in their hemostatic system amongst other causes. Thus, treatment and management of children with bleeding disorders is often age specific and cannot simply be extrapolated from adult data. The following chapter highlights some common bleeding disorders in neonates and children and where available, treatment recommendations are summarized.

NEONATAL THROMBOCYTOPENIA

Platelet production begins in fetal life and progressively increases to adult levels by the end of the first trimester (≥22 weeks gestational age). The normal range for adult platelet count of 150 to 450 × 10^9/L is reached in the healthy fetus by 22 weeks of gestation. Therefore, neonates with platelet counts <150 × 10^9/L are considered to have neonatal thrombocytopenia. Otherwise, healthy neonates commonly have platelet counts in the range of 100 to 150 × 10^9/L, but these are mostly transient thrombocytopenias and need no further investigation unless the clinical condition worsens.[1] Developmental differences in the size of the megakaryocytes between neonates and adults, such as smaller megakaryocytes, might predispose neonates to thrombocytopenia.[2]

The overall incidence of neonatal thrombocytopenia has been estimated to be 0.7% to 0.9%. However, the incidence is considerably higher in neonates admitted into the neonatal intensive care unit (NICU), where it is estimated to be 22% to 35%.[1] Neonatal thrombocytopenia can be caused by increased platelet consumption, decreased platelet production, hypersplenism, or a combination of any of these. Underlying causes include immune deficiency, infections, placental insufficiency, disseminated intravascular coagulation (DIC), genetic disorders, and medication-induced thrombocytopenia (Table 120.1).

In general, the underlying cause may be determined by the timing of the onset of thrombocytopenia as different conditions lead to either early-onset (within 72 hours of life) or late-onset (>72 hours) thrombocytopenia.[1] Although there can be significant overlap between pathologies underlying neonatal thrombocytopenia, specific diseases associated with early-onset type include alloimmune disease, parasitic infections, placental insufficiency, chromosomal defects (notably trisomies 13, 18, and 21), and familial thrombocytopenias.[1] Late-onset thrombocytopenias are usually associated with fungal infections, medication use (some antibiotics, heparin, anticonvulsants), and necrotizing enterocolitis (NEC).[1]

As stated, approximately three-quarters of all neonates with thrombocytopenia are transient or mild in nature and do not usually require further intervention. However, the remaining cases (20% to 25% or 2% to 9% of NICU admissions) require platelet transfusions in order to treat or decrease the risk of bleeding.[1] Although neonates with active major bleeds (intracranial, pulmonary, gastrointestinal [GI], hepatic or renal) with platelet counts <100 × 10^9/L receive platelet transfusions, the majority of platelet transfusions are given to thrombocytopenic neonates without bleeding events and with platelet counts <50 × 10^9/L.[2–4] There is only one randomized controlled study[5] investigating the effectiveness of platelet transfusions on reducing the incidence/severity of intracranial hemorrhage (ICH) in sick preterm infants with thrombocytopenia. The authors found no significant difference in the frequency or severity of ICH in the treatment group (platelet transfusions for platelet count <150 × 10^9/L) compared to the control group (platelet transfusions only for clinical indications or for a platelet count of <50 × 10^9/L). Although, platelet transfusion increased platelet counts and shortened bleeding times, it did not have an effect on the incidence or severity of ICH.[5]

There is a lack of solid evidence for guiding platelet transfusions in neonates, but several guidelines have been published,[1,3,6–10] providing a starting point of treatment options for thrombocytopenic neonates. Although there is a range of transfusion practices, since the early 1990s, there is a trend toward accepting a lower threshold of platelet count before starting platelet transfusions in nonbleeding sick and stable preterm infants (from platelet count <100 × 10^9/L to <30 × 10^9/L before initiating platelet transfusion).[1]

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) occurs when there is an incompatibility of fetomaternal human platelet antigens (HPAs). The incidence of NAIT has been estimated to be 1 in 5,000, but the incidence was higher (1 in 1,000) in screening studies using only HPA-1a incompatibility criteria.[11–13] Severe NAIT can occur even in the first pregnancy (~50% of the cases). In the most severe cases, there is massive ICH, but the presentation can in other cases be mild bleeding that is easily managed. The diagnosis is established by verification of incompatibility between the platelets of the mother and the baby. It is important to provide effective treatment quickly as NAIT is associated with 11% to 21% risk of ICH.[14] Screening studies have indicated that

Table 120.1

Neonatal thrombocytopenias and their typical time of presentation

Etiology	Examples	Onset
Alloimmune	Maternal antibodies against HPA-1a or -5b	Fetal—neonatal <72 h
Congenital infections	Cytomegalovirus, rubella, toxoplasma, HIV	Fetal—late neonatal
Aneuploidy	Trisomy 18/13/21; triploidy	Fetal
Autoimmune	ITP, systemic lupus	Fetal—neonatal <72 h
Severe Rhesus disease		Fetal
Congenital–inherited	*With abnormal platelet function* Wiskott-Aldrich, Bernard-Soulier, X-linked thrombocytopenia, or Chediak-Higashi syndrome, Quebec platelet disorder, giant platelet syndromes *Without abnormal platelet function* TAR, CAMT, Fanconi anemia, May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, Epstein syndrome, autosomal dominant thrombocytopenia	Fetal—late neonatal
Placental insufficiency	Intrauterine growth retardation, preeclampsia, diabetes	Neonatal <72 h
Perinatal asphyxia		Neonatal <72 h
Perinatal infection	*Escherichia coli*, group B *Streptococcus*, *Haemophilus influenza*	Neonatal <72 h
DIC		Neonatal <72 h
Thrombosis	Arterial or venous	Neonatal <72 h
Congenital leukemia		Neonatal <72 h
Kasabach-Merritt syndrome		Early–late neonatal
Metabolic disease	Propionic acidemia, methylmalonic acidemia	Early–late neonatal
Late-onset sepsis	NEC	Neonatal >72 h

CAMT, congenital amegakaryocytic thrombocytopenia; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; NEC, necrotizing enterocolitis; TAR, thrombocytopenia absent radius syndrome.

neonatal platelet count $<50 \times 10^9$/L identified 90% of patients with NAIT.[15–17]

Recommended platelet transfusion thresholds include neonates with severe thrombocytopenia (platelet count $<30 \times 10^9$/L), neonates with minor bleeding events and a platelet count of $<50 \times 10^9$/L or those with a sibling who previously had ICH, or neonates with severe bleeding with a platelet count of $<100 \times 10^9$/L.[1] The standard platelet dose is 10 mL/kg. However, dosing can be increased or repeated if response is insufficient.[18] The majority of antibodies are against HPA-1a and HPA-5b platelet antigens (79% and 9%, respectively).[19] Thus, platelet transfusion from HPA-1a/HPA-5b negative donors should be effective in increasing platelet counts in most cases of suspected or proven NAIT.[19,20] When compatible platelets are unavailable, high-dose intravenous immunoglobulin (IVIG) and/or a trial with random donor platelets may be a viable alternative. The recommended dose for IVIG is 1 to 2 g/kg administered as 0.4 g/kg daily for 3 to 5 days or 1 g/kg daily for 1 or 2 days.[21] Neonates with NAIT will respond to incompatible platelet transfusions;[22,23] thus random platelet transfusions can be used as first-line therapy, with close monitoring, for neonates with severe thrombocytopenia regardless of etiology.[18] Head sonography should be performed on thrombocytopenic neonates in order to determine the presence of ICH and to set appropriate platelet threshold for the treatment of the neonate. NAIT often resolves within 2 to 4 weeks, but platelet count should be followed until normal levels are attained off treatment to exclude inherited or other forms of thrombocytopenia.[18]

The recurrence of thrombocytopenia is very high and usually results in increased severity in subsequent pregnancies. Most of the current information is mainly derived from retrospective data. The highest risk of NAIT-related complications in subsequent pregnancies is among infants whose sibling had antenatal ICH.[24] Current management of subsequent pregnancies of women with a history of a child diagnosed with NAIT is focused on the prevention of ICH in the fetus during pregnancy and

delivery.[25] Antenatal diagnosis can be made with genotyping on chorionic villi or on amniotic cells. The titer of the maternal anti-HPA-1a antibody seems to be correlated with severe events to the fetus. The fetal development is followed with ultrasonography to detect ICH, preferably at tertiary care centers. The therapeutic options are weekly maternal injections with high-dose immunoglobulin, possibly with the addition of corticosteroids or, if that fails, weekly intrauterine transfusions with antigen negative platelets. A severely affected fetus should be delivered by cesarean section.

Neonatal purpura or hematoma as well as more serious bleeding complications is investigated with complete blood count and coagulation screening. The thrombocytopenia is severe in case of HPA-1a or -3a immunization, whereas the mother has a normal platelet count. The platelet phenotype and genotype of both parents and antibodies should be analyzed to verify the diagnosis. However, already with a strong suspicion of NAIT and a platelet count below 30×10^9/L, the baby should be transfused with washed and irradiated maternal platelets or with HPA-1b/1b platelets. Babies with higher platelet count should be followed closely and transfused in case of a sudden drop in platelet count. This monitoring is necessary for 1 to 2 weeks until the platelet count normalizes. ICH should be excluded with ultrasonography or magnetic resonance imaging. However, optimal management of high-risk pregnancies is still under debate. High-risk obstetric and adult hematologist with appropriate experience should be consulted.

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) is the result of platelet destruction by platelet autoantibody production coupled with impaired platelet production. Previously, it was thought that only macrophages in the reticuloendothelial system were involved in this process,[26,27] but emerging evidence now supports the involvement of both the cellular immune (T-cell abnormalities) and humoral immune (antibody secretion) systems.[28–30] ITP is one of the most common acquired bleeding disorders in children with complete resolution of thrombocytopenia in the majority of affected individuals within weeks or months of onset, regardless of whether therapy was instituted. It is estimated that 20% to 30% of these children will go on to have persistent thrombocytopenia (more than 6 months duration since diagnosis) but over 25% of these with persistent thrombocytopenia will have disease resolution by 12 months.[31]

Clinical Characteristics of ITP

ITP presentation can be at any age in childhood, with approximately 70% presenting between 1 and 10 years of age, peaking at age 5 to 6 years.[32] The majority of children do not have any documented infection prior to ITP presentation. However, in some children, it is preceded by a presumed viral illness or live-virus vaccination such as the measles, mumps, and rubella vaccine.[33,34]

Before ITP diagnosis, other causes of thrombocytopenia should be excluded by careful consideration of history, physical examination, and peripheral blood smear assessment.[35] Presentation symptoms in children include mucocutaneous bleeding, bruising, petechiae, purpura, epistaxis, hematuria, and menorrhagia (teenage girls). Physical findings and complete blood count are otherwise normal except for thrombocytopenia with large platelets. ITP with atypical clinical or laboratory findings warrant further investigations.[36] Even with severe thrombocytopenia (platelet count $<20 \times 10^9$/L) at the onset of ITP, the incidence of severe or life-threatening bleed is minimal.[32,37,38] The long-term outcome for children with ITP is favorable.[39–41]

Treatment of ITP

Many children with mild-to-moderate thrombocytopenia and minimal bleeding events require only close observation, although some with severe thrombocytopenia with overt bleeding will require therapy. The aim is to increase platelet counts to prevent hemorrhage while minimizing therapy side effects. Currently, there is no standard of care for children with symptomatic, acute, or chronic ITP. Thus, each case should be considered on an individual basis with benefits and risks of each treatment assessed when creating a management plan. Table 120.2 outlines some of the available therapies used for children with ITP.[36] These treatments do not cure or alter the disease course but are only helpful in the management of symptomatic ITP.

An alternative therapy for children with chronic ITP is splenectomy, but this should be reserved for children with severe thrombocytopenia in which conservative management is unsuccessful. There are many publications to support the effectiveness of splenectomy in children with ITP, citing successful response rates up to 85%.[35,51–55] However, long-term follow-up studies of children with splenectomy to assess failure/infection rates are lacking, and sepsis remains a significant risk. The recommendation from the American Society of Hematology group regarding consideration of splenectomy for children with chronic ITP include the following criteria: chronic thrombocytopenia >12 months duration, bleeding symptoms with severe thrombocytopenia, or thrombocytopenia that is unresponsive to "standard" therapy of corticosteroids, IVIG, and anti-D immune globulin.[35] Laparoscopic surgery is recommended for elective splenectomy with the patient immunized against *Neisseria meningitides*, *Streptococcus pneumoniae*, and *Haemophilus influenza* type B prior to surgery. Children must undergo lifelong monitoring to prevent infection and should receive daily prophylaxis against pneumococcal infection with antibiotics up to the age of 16 and in case of continued high risk also thereafter.[36]

Bleeding ITP patients who are refractory to steroids, IVIG, and anti-D immune globulin may be candidates for immunomodulatory therapy or thrombopoietin mimetics. Another second-line therapy in refractory patients with significant hemorrhagic problems may include rituximab. Standard doses of rituximab induce B-cell depletion for 3 to 6 months and is well tolerated in children, although the long-term effects of using this drug in children with immature immune systems is not known.[56] There are no randomized controlled studies of rituximab in children with ITP, but a review of cohort studies and case reports indicate that rituximab treatment results in a complete response (defined as platelet count $>50 \times 10^9$/L) in approximately 50% of the children with few adverse effects.[57] Prognostic indicators of response could not be identified.

INHERITED PLATELET DISORDERS

Hereditary disorders of platelet function are likely to be detected only when clinically relevant bleeding occurs. Many patients will have more than one hemostatic defect and will most likely already be undergoing evaluation for bleeding disorder so platelet dysfunction should be included as part of the investigative

Table 120.2

"Standard" therapies for children with chronic ITP

Type of Therapy	Dose	Side Effects
Corticosteroids	Various dose and regimens Short-course, high-dose corticosteroids without a taper[42,43] Suggested high-dose corticosteroid of ~4 mg/kg/d of prednisone or equivalent, orally or parenterally (for acute ITP) until cessation of bleeding or platelet count >20 × 10^9/L[42] Low-dose prednisone at 0.1–0.2 mg/kg/d orally[44]	High dose not recommended for long-term therapy due to adverse side effects (immunosuppression, hirsutism, weight gain, growth delay, osteoporosis, and cataracts)
IVIG	0.8–1.0 g/kg IVIG × 1–2 doses, slow infusion[42,45] Repeated doses can be given every 2–6 wk for symptomatic thrombocytopenia[44]	Higher doses are not recommended as it is associated with headaches[46] Infusion-related side effects include flushing, fever, headaches, allergic reactions, aseptic meningitis Minimal risk of pathogen transmission due to IVIG derived from pooled donor plasma
Anti-D immune globulin	75 μg/kg anti-D (used in children with ITP who are Rhesus+ with intact spleen)[47,48] Given as a short infusion, though s.c. route is well tolerated and effective[49]	Infusion-related headaches, chills, fatigue Mild anemia (Hb fall of 0.8–1.4 g/dL)[47] Severe hemolytic anemia with DIC and acute renal failure is rare (1 in 20,000–30,000 infusions)[50] Minimal risk of pathogen transmission due to anti-D derived from pooled donor plasma

DIC, disseminated intravascular coagulation; Hb, hemoglobin; ITP, immune thrombocytopenia purpura; IVIG, intravenous immunoglobulin; s.c., subcutaneous.

process. Typical bleeding manifestations indicative of platelet function defects can include inexplicable or extensive bruising, prolonged epistaxis (>30 minutes, causing anemia or hospital admission), menorrhagia, oral cavity bleeding, or bleeding after dental extraction or invasive procedures.[58] Severe platelet function disorder can lead to ICH and subdural hemorrhage or excessive bleeding in the umbilical stump in the neonatal period. Milder forms of platelet function disorders are more likely to present later in life. The lack of well-defined testing system for platelet function disorder makes diagnosis more complicated for the clinician.[59,60] There are guidelines and recommendations published by International Society on Thrombosis and Haemostasis (ISTH) subcommittees, Permanent Paediatric Group of the German Thrombosis and Haemostasis Research Society, and other scientific panels for the diagnosis of patients with inherited platelet disorders.[59,61,62]

Disorders of Platelet Numbers

Inherited thrombocytopenias are a group of heterogeneous conditions that consequently present as early-onset thrombocytopenia. Although rare, the clinical symptoms, including bleeding, can be severe.

MYH-9 Disorders

MYH-9–related thrombocytopenias are rare autosomal dominant disorders defined by the presence of deleterious mutations within the *MYH*-9 gene, coding for the nonmuscle myosin heavy chain IIa, that influences a component of the contractile cytoskeleton in megakaryocytes, platelets, and other tissues.[63–65] Defective megakaryopoiesis is responsible for the thrombocytopenia. This disorder encompasses other previously defined disorders including May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome.[63,64] Bleeding severity is usually mild, and life-threatening bleeds are rare. Other phenotypic manifestations can include hearing loss, glomerulonephritis, and cataract.[66,67] These patients usually have platelet counts in the range of 20 to 130 × 10^9/L, with most showing elevated mean platelet volume and a noticeable population of very large platelets with variable platelet morphology.[61,63]

A specific diagnostic strategy has been suggested by the Working Group on Standardisation in Perinatal and Pediatric Hemostasis for the group of children and neonates with inherited thrombcytopenias.[68] Differential diagnosis should include inspections of peripheral blood smear and platelet ultrastructural features as symptoms are similar to ITP or other causes of thrombocytopenia such as Bernard-Soulier syndrome.[69–71] Treatment options for inherited platelet function disorders include antifibrinolytic agents such as tranexamic acid to treat mucous membrane bleeding, desmopressin (DDAVP) for storage pool disorders or for mild bleeding events where tranexamic acid alone was unsuccessful, platelet transfusion for severe disorders but there is a risk of alloantibodies to HLA antigens, and recombinant FVIIa (rFVIIa) that has only been approved for use in patients with Glanzmann thrombasthenia.[68] It is stressed that treatment strategies should be discussed on a case-by-case basis, taking into account personal and family history, to determine the risk–benefit ratio for each patient.

Congenital Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare, recessive disorder caused by mutations in the MPL gene affecting the cytokine thrombopoietin receptor c-mpl that regulates megakaryopoiesis and platelet production.[72,73] CAMT usually presents in the neonatal period with bleeding symptoms as a result of severe thrombocytopenia associated with absent or markedly decreased megakaryocyte numbers in the bone marrow. Disease progression leads to hematopoietic failure and the development of severe aplastic anemia.[74] Physical abnormalities were also noted including cardiac defects, growth anomalies, and retardation of psychomotor development.[75] Molecular analysis of *MPL* gene will give definitive confirmation of CAMT. Management of CAMT initially includes platelet transfusion, but patients will eventually require hematopoietic stem cell transplantation due to the progression of the disease to severe aplasia.[58] Є-aminocaproic acid (EACA) used for bleeding episodes in adolescent and adult patients with amegakaryocytic thrombocytopenia decreases the need for platelet transfusions.[76]

Amegakaryocytic Thrombocytopenia with Radioulnar Synostosis

Amegakaryocytic thrombocytopenia with radioulnar synostosis seems to be dominantly inherited with mutations in the *HOXA11* gene,[77] which is thought to be involved in the regulation of megakaryocytic differentiation.[78] Platelet morphology is normal, but megakaryocytes are markedly decreased or absent in the bone marrow. This disease is similar to CAMT presenting with severe thrombocytopenia and bleeding symptoms early in the neonatal period but is associated with radioulnar synostosis, and some may present with other skeletal abnormalities.[79] Amegakaryocytic thrombocytopenia with radioulnar synostosis will lead to haematopoietic failure. Management of this disease includes platelet support, and some may need haematopoietic stem cell transplantation.[58]

Thrombocytopenia Absent Radius Syndrome

Thrombocytopenia absent radius (TAR) syndrome is characterized by severe isolated thrombocytopenia at birth that spontaneously improves after the 1st year of life. Physical abnormalities include the bilateral absence of radii with the retention of normal thumbs and may be associated with other defects including GI, renal, cardiac, and facial development.[80,81] Genetic basis of the disorder and mode of inheritance remain unclear. TAR syndrome is associated with megakaryocyte deficiencies in number and maturation.[58] Although there is progressive improvement in the severity of thrombocytopenia, the majority of morbidity occurs before 14 months of age according to a review of 100 cases.[81] Causes of death have been attributed to bleeding events resulting from thrombocytopenia (intracranial, visceral, and pulmonary hemorrhage), sepsis, and congestive heart failure (in a patient with teratology of Fallot).[81] Management of TAR syndrome includes platelet transfusions to prevent significant hemorrhage until platelet counts improve after infancy.[58]

X-Linked Thrombocytopenia with Dyserythropoiesis

This is an X-linked disorder as result of the mutations in the *GATA1* gene, which encodes for megakaryocyte and erythroid transcription factor affecting platelet and erythrocyte morphology.[82,83] Clinical presentations include abnormal hematopoiesis including severe macrothrombocytopenia with and without β-thalassemia and dyserythropoiesis with or without anemia.[82] Bleeding diathesis can occur at birth and continue onward. Confirmation of the diagnosis is by genetic finding of a mutation in the *GATA1* gene.[58] Patients with this syndrome may be treated with platelet transfusions for thrombocytopenia or DDAVP for mild-to-moderate bleeding.[84] Other forms of treatment include erythrocyte transfusions for anemia, parenteral antibiotics for confirmed neutropenia, and bone marrow transplantation may be considered as a cure for severe cases but it is associated with significant risks and morbidities.[84]

Disorders of Platelet Function

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is a rare X-linked recessive disease with multiple symptoms including thrombocytopenia with small platelets, recurrent otitis media, eczema, infections, and malignancies[85] with an incidence estimated to be 4 per million live births.[58] The genetic defect is in the *WASP* gene affecting signal transduction and maintenance of the cytoskeleton.[86,87] In the neonatal period, clinical presentation often involves bruising and purpura, GI bleeds, and prolonged bleeding after circumcision, and there is an increased risk of ICH. Eczema, usually occurring in the 1st year of life, is varied in its severity. Infection, usually in the first 6 months of life, can be bacterial such as otitis media and respiratory tract infection. Also, autoimmune disorders become more prevalent with increasing age, with hemolytic anemia and vasculitis being the most prominent.[85] Management of WAS should involve a multidisciplinary team to address bleeding manifestation, recurrent infections, eczema, autoimmune disease, and risk of malignancy. Stem cell transplantation should be considered if an HLA identical donor is available.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia is a rare autosomal recessive disorder, which affects platelet aggregation resulting in a bleeding diathesis. The genes *ITGA2B* and *ITGB3*, encoding for platelet glycoproteins GPIIb and GPIIIa, respectively, are affected.[88,89] The most common presenting features include purpura, epistaxis, gingival bleeding, and menorrhagia, with the majority presenting before the age of 5 years.[90] Major bleeding, such as ICH, in the neonatal period is rare.[91] Bleeding severity is unpredictable, and spontaneous bleeding is uncommon as most episodes occur posttrauma or postsurgery.[90] Diagnostic criteria for Glanzmann thrombasthenia include prolonged bleeding time, normal platelet count, and morphology but absent or diminished clot retraction and platelet aggregation defects. Definitive diagnosis can be determined by the absence of GPIIb and GPIIIa on platelets using antibodies CD41 and CD61, respectively, using flow cytometry.[58] Glanzmann thrombasthenia can be managed by supportive care. Platelet transfusion can be used to treat bleeding episodes.[90] However, use of random donor platelets in Glanzmann thrombasthenia is associated with a very high incidence of platelet alloimmunization. This is a significant complication of treatment and makes it difficult to provide optimal platelet support for these patients. Use of EACA, tranexamic acid, and DDAVP[92] has also been reported to be successful in the management of bleeding in thrombasthenia

patients.[93] rFVIIa has been reported to be successful in preventing bleeds in patients with thrombasthenia undergoing invasive dental procedures.[94,95] Bone marrow transplants can cure patients with severe bleeding episodes,[96] but risk/benefit ratio should be considered for each patient.

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is an autosomal recessive bleeding disorder, with an absence or decreased expression of GPIb/IX/V complex on the platelet surface resulting in platelet adhesion defects.[97] It is characterized by thrombocytopenia, large platelets, and prolonged bleeding time. It is distinguished from other syndromes by the failure of platelets to aggregate with ristocetin and is not corrected by the addition of normal plasma.[58] Although symptoms may present in childhood, some may be misdiagnosed or confused with ITP or NAIT, leading to inappropriate treatment.[98,99] The incidence has been estimated to be <1 in a million with common clinical symptoms of frequent epistaxis, gingival and cutaneous bleeding, and hemorrhage after trauma.[100] rFVIIa has also been reported for use in the management of Bernard-Soulier syndrome patients with severe bleeding episodes.[101]

VITAMIN K DEFICIENCY BLEEDING IN EARLY INFANCY

Vitamin K (VK) is an important factor for normal function of several proteins in the coagulation system. Research on developmental hemostasis has shown that neonates have almost half the normal adult values of plasma concentrations of VK-dependent coagulation factors.[102] These values gradually rise and reach adult levels by 6 months of age.[102,103] VK-dependent procoagulant proteins include prothrombin (FII), FVII, FIX, and FX. Protein C and protein S are also VK-dependent proteins that play a role in the negative feedback control of the hemostatic system. Taken together, failure to produce these functional hemostatic proteins will eventually lead to bleeding diathesis known as vitamin K deficiency bleeding (VKDB; previously known as hemorrhagic disease of the newborn). Thus, it has been standard practice in developing countries to give VK prophylaxis to newborns, especially those that will be exclusively breast-fed, as breast milk is low in VK.

Vitamin K Assessment

The ISTH Pediatric/Perinatal Subcommittee's definition of VKDB is "bleeding due to inadequate activity of VK-dependent coagulation factors (II, VII, IX, and X), correctable by VK replacement."[104] Early recognition of the signs of predisposing conditions such as prolonged jaundice and failure to thrive can reduce the incidence of intracranial VKDB.[104] The diagnostic criteria of VKDB in a bleeding infant include prolonged prothrombin time (PT) International Normalized Ratio >3.5, coupled with a normal fibrinogen level and platelet count. Diagnosis is confirmed if VK administration corrects PT and/or bleeding is stopped.[104]

When there is a deficiency of VK, FII, FVII, FIX, and FX are undercarboxylated and circulate as proteins induced in vitamin K absence (PIVKA) form. The PIVKA-II assay that detects undercarboxylated prothrombin has been used to identify subclinical VK deficiency in infants,[105,106] or enzyme immunoassays utilizing antibodies to PIVKA-II can also be used.[107,108]

Classification of VKDB

VKDB can be of three types, based on the time of presentation: early (first 24 hours), classical (days 1 to 7), and late (≥day 8, peaking at 3 to 8 weeks) (Table 120.3).[104,116] This helps to differentiate between idiopathic and secondary VKDB, where the latter has late onset and is associated with an undiagnosed disease such as biliary atresia, α_1-antitrypsin deficiency, cystic fibrosis, or drug effects on the mother or fetus.[116]

Early VKDB

Early VKDB presents within the first 24 hours after birth, and although rare, it is often life threatening. Common bleeding sites include scalp, intracranial, intrathoracic, intra-abdominal, or GI tract.[116] Its etiology may be due to maternal use of prescribed drugs, which may interfere with VK activity or metabolism.[110] The drugs include anticonvulsants (carbamazepine, phenytoin, and barbiturates, but not valproic acid), antibiotics (cephalosporins), tuberculostatic agents (rifampicin and isoniazid), and VK antagonists (phenprocoumon and warfarin).[104]

Classical VKDB

Clinical symptoms of classical VKDB present between days 1 and 7 (i.e., excluding the first 24 hours) with common bleeding sites in GI, umbilical, skin, nose, and circumcision sites. It is mainly idiopathic, but poor milk intake during breast-feeding may be a factor.[110,117,118] Prolonged bleeding after circumcision can reveal VK deficiency,[109] and although rare, ICH can lead to significant morbidity and death.

Late VKDB

Late VKDB occurs between day 8 and 6 months of age, incidence peaking at 3 to 8 weeks[104] often with ICH as the first presenting sign. In a pooled analysis of 131 published cases from 14 countries (1969 to 1992), 63% presented with ICH with a mortality rate of 14%.[119] Another study of 14 infants with late VKDB, in which 10 did not receive VK prophylaxis, indicated that the predominant clinical manifestation was ICH (78%), with a mortality rate of 57% and another 36% had neurological sequelae.[120] Late VKDB is mostly confined to exclusively breast-fed babies[119,121] and is more prevalent in boys than girls.[122] An underlying disease such as cholestasis or malabsorption problems is usually associated with infants with late VKDB, to whom VK prophylaxis has been given. Clinical manifestations may emerge earlier with mild bruises, nose bleeds, or umbilical oozing that can be "warning bleeds" of VKDB and may escalate to ICH.[104]

Incidence of VKDB

The incidence of VKDB is difficult to estimate as there is very little data available in industrialized countries and even more difficult to assess in underdeveloped countries. The incidence rate is also affected by the type of study whereby hospital-based surveys may have missed infants with mild bleeding symptoms that were not referred to the hospital or did not make it altogether which would result in a lower incidence report (Table 120.3). With the adaptation of prophylaxis with VK, the incidence of VKDB has decreased dramatically.[110]

Table 120.3

Characteristics of VK-deficient bleeding

	VK-Deficient Bleeding		
	Early	**Classical**	**Late**
Time of Presentation	**First 24 h**	**Days 1–7 (Excluding the First 24 h)**	**≥Day 8 up to 6 mo (peaking at 3–8 wk)**
Common bleeding sites	Scalp subperiosteal or skin Intracranial Intrathoracic Intra-abdominal GI tract	GI tract Umbilical Skin Nose Circumcision sites	Intracranial Skin GI tract
Etiological factors	Maternal drugs	Mainly idiopathic: breast-feeding (low milk intake)	Idiopathic or secondary: breast-feeding, undiagnosed cholestasis. Secondary cases from VK malabsorption (liver or bowel disease)
Incidence (publication date)		Cincinnati, USA (1967): 1.7% among breast-fed infant with no VK prophylaxis[109] British Isles (1991): 5.4 per 100,000 births[111] Ethiopia (1993): 0.9% for early and classic VKDB (80% had classic syndrome)[113] Malaysia (1994): 25 per 100,000 births (hospital-based study)[115] Thailand (1998): 89 per 100,000 births and 54 per 100,000 births (two longitudinal field studies)[114]	British Isles, Sweden, Switzerland, Germany (1980s): 4–7 per 100,000[110] Thailand (1988): 35 per 100,000 births (hospital-based study)[112] Thailand (1998): 72 per 100,000 births (regional field study)[114] Malaysia (1994): 13 per 100,000 births (hospital-based study)[115]

GI, gastrointestinal; VK, vitamin K; VKDB, vitamin K deficiency bleeding.

Prophylaxis for Neonates at High Risk for VKDB

The ISTH Pediatric/Perinatal Subcommittee published recommendations on VK prophylaxis, suggesting that for early VKDB, cessation or replacement of maternal medication causing VK deficiency be implemented if possible, or to initiate VK prophylaxis to the mother during pregnancy.[104] Infants born to mothers taking VK-interfering medication or those who will be exclusively breast-fed should receive a single dose of 1 mg VK intramuscularly very shortly after birth.[123] Oral or intramuscular VK (one dose of 1 mg) is suggested for classical VKDB, but intramuscular administration may provide better protection against late VKDB compared to a single oral dose.[104] Oral administration of VK prophylaxis should be followed by either weekly administration of 1 mg till 12 weeks or repeating 2 mg at weeks 1 and 4.[123] Pichler and Pichler[103] have published a mini-review outlining regimens of VK prophylaxis in different countries. Small preterm and sick full-term babies should be given 0.3 mg/kg VK (maximum 1 mg) immediately after birth via intramuscular or intravenous injection. The daily VK supply should be 5 to 10 mg/kg, and all babies should be given 2 mg VK orally at 4 weeks (or at discharge from the hospital, if earlier).[103]

Treatment for VKDB

In infants with suspected VKDB, VK should be given via intravenous or subcutaneous administration, while awaiting test results since VKDB is associated with a high risk of ICH. Intramuscular injection should be avoided due to the risk of severe intramuscular bleeding.[104]

Infants with non–life-threatening bleeds should be treated with vitamin K_1 given subcutaneously or slowly by intravenous route. A single IV dose of 250 to 300 μg/kg body weight is recommended. For infants up to 6 months of age, the dose range of 1 to 2 mg is sufficient to correct VK deficiency.[110] For severe bleeding in infants, fresh-frozen plasma (FFP) may be given at a dose of 10 to 15 mL/kg body weight.[110] For life-threatening bleeds, prothrombin complex concentrate (PCC) containing all four VK-dependent factors may be a better option with the added benefit of decreased volume load. There are no published guidelines for the use of PCC in neonates with VKDB, but extrapolation from adult data suggests a dose of 50 units/kg may

be sufficient.[110] In two reports of infants presenting with severe ICH due to VKDB, treatment with rFVIIa allowed for surgical intervention with little blood loss, but this therapeutic strategy cannot be assessed for its full benefits or risks based on so few cases.[124,125]

INHERITED COAGULOPATHIES

Hemophilia

The most common severe, inherited coagulopathy is hemophilia, with an incidence ratio between hemophilia A (deficiency of factor VIII) and hemophilia B (deficiency of factor IX) of 5:1 and in the population of 1 in 10,000 individuals but almost exclusively affecting males due to the X-linked inheritance. *De novo* mutations are the basis for a substantial minority of the cases, resulting in unexpected bleeding in the child. The first manifestation can be as ICH after a complicated vaginal delivery, as a muscle hematoma after injection of VK, as hemarthrosis when the child starts walking—and falling—or, for milder forms of hemophilia, only after surgical procedures or major trauma. Chapter 51 is devoted to the description of hemophilia.

von Willebrand Disease

In the severe form (type 3), von Willebrand disease (vWD) results in not only a severe lack of von Willebrand factor (vWF) but also of factor VIII. The manifestations can therefore be identical to hemophilia, whereas in milder forms with mainly a reduced level without or with a qualitative defect of the vWF (type 1 and type 2, respectively) but with normal factor VIII, there is a preponderance of mucocutaneous bleeding. The inheritance is autosomal, thus affecting both sexes. Neonatal bleeding occurs mainly in children with vWD type 3, which has a prevalence of 0.1 to 3 per million, depending on the geographical region. The type 1 and type 2 vWD forms are much more common. Chapter 52 provides a thorough description of vWD.

RARE COAGULOPATHIES

Inherited deficiency of factors V, VII, X, XI, XIII, prothrombin, and fibrinogen can, when they occur in the severe form, cause neonatal bleeding. This can present as ICH, as prolonged bleeding from the umbilicus, or after circumcision in the neonatal period. With the development of the Rare Bleeding Disorder Registries,[126] a better understanding of these rare conditions should be facilitated. The deficiencies are extensively described in Chapter 53 (*Rare Inherited Bleeding Disorders*) and in Chapter 54 (*Inherited Fibrinogen Disorders*).

INHERITED DISORDERS OF FIBRINOGEN

Inherited disorders of fibrinogen, although rare, could manifest quantitatively in the form of afibrinogenemia and hypofibrinogenemia (defect in synthesis or processing) or qualitatively in the form of dysfibrinogenemia (abnormal polymerization, cross-linking, or assembly in the fibrinolytic system). Clinical symptoms vary from asymptomatic to life-threatening bleeding or thromboembolic events.

Afibrinogenemia

The prevalence of afibrinogenemia is approximately 1 in 1,000,000, but the incidence is higher in countries where consanguineous unions are more common.[127,128] Fibrinogen levels are <0.1 g/L in plasma, and laboratory testing will show that PT, activated partial thromboplastin time (aPTT), and thrombin time (TT) are indefinitely prolonged and both functional (Clauss), and antigenic assays are unable to detect fibrinogen.[127] Clinical manifestation can present in early infancy with umbilical bleeds[129,130] or ICH.[131] Prophylaxis with cryoprecipitate or with 1 g of fibrinogen concentrate every 3 days to maintain trough levels of 1 g/L seems effective against recurrent bleeding.[131] Although extremely rare, afibrinogenemia has been associated with thrombotic events considered to be caused by thrombin-induced platelet aggregation due to the absence of the thrombin-neutralizing property of fibrin.[130]

Hypofibrinogenemia

This is a quantitative deficiency of fibrinogen with milder bleeding patterns, mainly after surgical procedures or major trauma. Fibrinogen levels are 0.1 to 2 g/L, aPTT is normal, and TT is mildly prolonged.[127] The incidence is lower than that of afibrinogenemia.

Dysfibrinogenemia

Dysfibrinogenemia is a mutation that affects the functional properties of fibrinogen. It is commonly diagnosed in adulthood (see Chapter 54).[127,132,133]

FXIII Deficiency

Congenital FXIII deficiency has an estimated incidence of 1 case per 2 to 5 million,[134,135] and generally higher in countries where consanguineous marriages are common. It is an autosomal recessive disease[135] that can present with umbilical bleeding in the neonatal period, soft tissue bruising, mucosal bleeding, and ICH. It is estimated that up to 30% of patients with this disorder have spontaneous ICH.[136] The first report of FXIII deficiency was in 1960 from Duckert et al.[137] who described a case of a 7-year-old Swiss boy with a history of bleeding. Bleeding episodes were delayed occurring 24 to 36 hours after injury and impaired wound healing. It was reported that the patient and his siblings had a similar bleeding tendency and his parents had a consanguineous marriage.[137] An observational case series of 10 children with FXIII deficiency in Pakistan (from 1996 to 2006) indicated that 9/10 had a history of prolonged umbilical bleeding, bruises and prolonged bleeding after trauma, and a positive family history of bleeding, and consanguineous marriage was present in 80% of the families.[138]

Standard laboratory testing of PT, aPTT, fibrinogen level, platelet count, and bleeding time, are all within normal parameters in FXIII-deficient patients[139] due to FXIII being involved in the final stages of coagulation. Quantitative FXIII activity and antigen assays are recommended over clot solubility testing, where the latter gives semiquantitative FXIII determination.[136] Interpretation of very low FXIII activity values, as measured by quantitative assays, are difficult and could complicate the start of prophylactic treatment.

A retrospective study of seven FXIII-deficient patients given purified, pasteurized concentrate of FXIII called Fibrogammin P (CSL Behring GmbH, Marburg, Germany) as prophylaxis showed a decreased incidence of bleeding episodes from 2.5 events per year to 0.2 events per year, with no reports of severe bleeds on prophylaxis.[140] Due to the long half-life of FXIII concentrate (7 to 12 days), administration for prophylactic treatment is scheduled once every 3 to 4 weeks with 10 to 30 units/kg given to prevent bleeding episodes. Fibrogammin P is derived from pooled human plasma screened for common viruses and has undergone extensive viral inactivation to minimize the chance of viral disease transmission.[140]

Additional commercially available products for treatment of FXIII deficiency are FXIII-BLP (Bio-Product Laboratory, Elstree, United Kingdom) and rFXIII-A2 (Novo Nordisk, Bagsvaerd, Denmark).[141] Other prophylactic treatment options include FFP (10 mL/kg every 4 to 6 weeks) and cryoprecipitate (1 bag per 10 to 20 kg every 3 to 4 weeks).[139,141] The prognosis is excellent for FXIII-deficient patients, despite the lifelong risk of bleeding.

FIBRINOLYTIC DISORDERS

α_2-Antiplasmin Deficiency

The deficiency of α_2-antiplasmin (α_2-AP) can be due to alterations in protein synthesis (low or no production of protein) or the synthesis of an abnormal protein (nonfunctional protein). Clinical manifestations of congenital α_2-AP deficiency include umbilical bleeding, central nervous system hemorrhage, epistaxis, hemarthrosis, and excessive blood loss during surgery or delayed bleeding after minor trauma.

There have been several publications of α_2-AP deficiency in children.[142–146] Many of the affected patients had shortened whole-blood clot lysis time (3 to 4 hours; normal >24 hour) and shortened euglobulin lysis time (~1.5 hours; normal >2 hours), but routine coagulation screening was normal (bleeding time, platelet count, PT, aPTT, fibrinogen, and FXIII levels).

Treatment of bleeding symptoms is usually with antiplasminic/antifibrinolytic agents such as tranexamic acid or EACA, as described in several case reports of patients with hetero- or homozygous deficiency of α_2-AP. Intraoral bleeding was treated with oral administration of 25 to 50 mg/kg per day of tranexamic acid and for tooth extractions 7.5 to 10 mg/kg was given every 6 hours for up to 7 to 10 days without any postoperative bleeding.[142,144,146]

Plasminogen Activator Inhibitor-1 Deficiency

Reports in adults have linked lifelong history of severe bleeding after surgery or trauma with defective functioning of plasminogen activator inhibitor-1 (PAI-1)[147,148] or undetectable PAI-1 antigen and activity.[149] Hemostatic screening is normal, but euglobulin lysis time is shortened. Also, the currently available diagnostic assays make it difficult to assess PAI-1 deficiency since accuracy in the lowest range of PAI-1 activity assays is lacking.[150–152] It is suggested that PAI-1 antigen and activity levels be assessed as well as taking a history to identify the presence of delayed posttraumatic or postsurgical bleeding before considering a diagnosis of PAI-1 deficiency.

Only a few cases have been reported, and the true incidence of PAI-1 deficiency is unknown. There is usually a history of bleeding episodes in early childhood. Bleeding symptoms are usually mild to moderate including epistaxis, easy bruising, and hematomas. Symptoms can be more significant such as ICH or menorrhagia in young women. Genetic analysis identified 7 individuals from 2 families that were homozygous for PAI-1 deficiency; all had bleeding tendencies after trauma or surgery, whereas, 19 other heterozygous carriers had no abnormal bleeding even after trauma or surgery.[153] Fay et al.[154] described a 9-year-old female child with a molecular defect that resulted in a complete loss of PAI-1 expression in both plasma and platelets. After genetic analysis, it was determined that PAI-1 deficiency was a heritable, autosomal recessive bleeding disorder. All bleeding episodes occurred after major hemostatic challenges such as trauma or surgery. A follow-up of this patient after 6 years showed significant improvement in her condition after management with tranexamic acid, taken orally for 3 to 5 days after a bleeding episode or prior to planned surgical procedures.[153] Menorrhagia was managed with low doses of tranexamic acid (25 mg/kg) one to two times daily, increasing to three times daily for the first few days of menstruation.[153]

A report of the youngest documented person with PAI-1 deficiency was that of a 4-month-old child who is homozygous for the mutant allele. A minor head bump on a table led to persistent head swelling and a large epidural hematoma that needed surgical drainage. Prior to surgery, 10 mg/kg of EACA was administered and no significant postsurgical bleeding was observed.[153] Other case reports confirm the efficacy of tranexamic acid for various bleeding manifestations, including hemarthrosis.[155,156]

SUMMARY

Bleeding disorders in children are complicated due to their developing hemostatic system that sets them apart from adults. There are many disease processes that are associated with bleeding diathesis and can lead to devastating consequences. Diagnosis and management of these disorders are challenging in the pediatric population, but research is ongoing and more pediatric patients are being successfully managed.

CHAPTER

121 Venous and Arterial Thromboembolism in Children

PAUL MONAGLE, M. PATRICIA MASSICOTTE, AND ANTHONY K. CHAN

INTRODUCTION

Thromboembolic disease in infancy and childhood has been described as a new epidemic of tertiary pediatric care. Evidence supports the concept that the frequency of thromboembolism (TE), in all forms including venous, arterial, and intracardiac thromboembolic phenomenon, is increasing in neonates and children. The reasons for this are likely related to the increased survival of children with severe underlying medical and surgical conditions; the increased intensity and invasiveness of supportive care, in particular the increased use of vascular access devices; heightened awareness of this condition amongst pediatricians leading to more regular and appropriate investigations; and potentially the ever lowering age at which traditionally "adult" therapies such as, for example, the oral contraceptive pill are being used en masse. Similarly, the increased prevalence of previously "adult" risk factors such as obesity may also contribute to increased thrombotic risk in children.

The diagnosis of thrombosis in children is often difficult for practical and theoretical reasons. Invasive and even noninvasive imaging of children often requires general anesthesia which not only increases the risks involved, especially in sick children, but pragmatically often makes timely diagnosis difficult to organize. Further the algorithms for interpretation of diagnostic vascular imaging have not been validated in children.[1] There are multiple reasons including reduced vessel size, lower pulse pressures, and blood flow rates, and potential other causes of bias that raise questions about whether the same algorithms and strategies used in adults are valid in children.

The natural history of TE in neonates and children remains largely unknown. This is problematic when clinicians are trying to balance the risks of antithrombotic therapy versus the risks of untreated disease. This dilemma is most evident when considering asymptomatic TE, which is often diagnosed on routine imaging or postprocedural examination. The aim of pediatrics in general is not only to ensure long-term survival of children, but to do so in a manner that enables the child to lead a productive and full adult life. Therefore, any impact of antithrombotic therapy on normal development needs to be considered, especially in situations that long-term anticoagulation therapy is being considered. Currently, the ability of clinicians to give parents and children good information about their longer term health and support requirements subsequent to a thromboembolic episode is very limited.

The use of antithrombotic drugs in pediatric patients is different from adults for a variety of reasons.[2] First, the epidemiology of TE in pediatric patients is vastly different from that seen in adults.[3–14,15] Second, the hemostatic system is a dynamic evolving entity that not only likely affects the frequency and natural history of TEs in children, but also the response to therapeutic agents.[16–18] Third, the distribution, binding, and clearance of antithrombotic drugs are age dependent.[19–21] Fourth, the frequency and type of intercurrent illnesses and concurrent medications varies with age. Fifth, limited vascular access reduces the ability to effectively deliver some antithrombotic therapies and can influence the choice of antithrombotic agent. Often, the only vascular access available is used for drug delivery; consequently accurate monitoring of blood anticoagulant levels is difficult. Sixth, specific pediatric formulations of antithrombotic drugs are not available, making accurate, reproducible dosing difficult. This is especially the case for vitamin K antagonists (VKAs) (no suspension/liquid preparation) and low molecular weight heparin (LMWH) (available most readily in predosed syringes based on adult weights). Seventh, dietary differences make the use of oral VKAs particularly difficult. This is especially true in neonates, as breast milk and infant formulas have very different vitamin K levels. Finally, compliance issues are vastly different in, for example, small infants who cannot understand the need for therapy, in adolescents who intellectually comprehend but emotionally are unable to cooperate, and in children who suffer the effects of inadequate parenting. The social, ethical, and legal implications of these issues frequently interfere with the ability to provide the "best" treatment for individual neonates and children.

This chapter discusses the epidemiology of TE in neonates and children, and then focuses on issues of clinical presentation, diagnosis, and management that are specific for children compared to adults. There remain many unanswered questions, and much research is required to improve the current standards of care for children with thromboembolic disease.

EPIDEMIOLOGY OF THROMBOEMBOLISM IN NEONATES AND CHILDREN

Venous Thromboembolism and Pulmonary Embolism

There are a number of published national or international registries that have collected data on venous thromboembolism (VTE) and other thrombotic events in neonates and children (Table 121.1).[4,11–13,22] Two neonatal registries from Canada and Germany have prospectively collected data on neonatal thrombosis, while a third from the Netherlands includes data from both neonates and older children.[11–13] Two registries (from Canada and the United Kingdom) have collected data on older children.[4,22] Inclusion criteria have varied between registries, particularly with regard to the registration of arterial and central nervous system (CNS) events, and the inclusion or not of asymptomatic events.

Table 121.1

National and international large pediatric thrombosis registries

Registry	Dates of Case Collection	Age Criteria for Inclusion	Number of Children Reported	Types of Thrombosis Included	Inclusion of CNS Thrombosis	Incidence of Venous Thrombosis
Canadian & International-Neonatal[12]	1990–1993	1st mo	*N* = 97	VTE Arterial	No	2.4/1,000 NICU[b] admissions
German-Neonatal[11]	1992–1994	1st mo	*N* = 79	VTE Arterial	Yes	0.51/10,000 births
Canadian-Children[22]	1990–1992	1 mo to 16 y	*N* = 137	DVT/PE	No	0.07/10,000 children
DPSU[13]	1997–1999	Birth to 18 y	*N* = 115	VTE[a]	Yes	0.14/10,000 children
BPSU[4]	2001–2003	1 mo to 16 y	*N* = 200	VTE Arterial	No	0.07/10,000 children
United States[15]	2001–2007	Birth to 18 y	*N* = 11 337	VTE	No	34–58/10,000 pediatric hospital admissions

[a]Includes asymptomatic neonatal events.
[b]Neonatal intensive care unit.

The incidence of VTE is dramatically influenced by age in adults such that the estimated incidence of first time deep vein thrombosis (DVT) in those aged 25 to 30 years is around 30 cases per 100,000 persons, which increases exponentially to 300 to 500 cases per 100,000 persons in those aged 70 to 79 years.[14] The incidence of DVT and pulmonary embolism (PE) in children in Canada, using data collected from 15 tertiary care centers, was estimated to be 0.07 per 10,000 children and 5.3 per 10,000 hospital admissions.[22] However, more recently, Raffini et al.[15] reported that the annual incidence of VTE in children discharged from pediatric hospitals in the United States increased from 34 per 10,000 admissions in 2001 to 58 per 10,000 admissions in 2007, representing an increase of 70% in 7 years. The Dutch registry collected data via the Dutch Paediatric Surveillance Unit (DPSU) using a monthly mailing system sent to all pediatricians in primary and secondary care and to specific contact persons in tertiary centres.[13] The overall incidence of venous thrombosis was 0.14 per 10,000 children aged 0 to 18 years and 0.05 per 10,000 children after excluding neonates and nonextremity VTE.[13] The British Paediatric Surveillance unit (BPSU) used a similar methodology,[4] and the estimated incidence of all events was 0.07 per 10,000 children. The first registry of neonatal thrombosis was an international registry involving 64 centers in Canada, the United States, and Europe. Based on data reported from Canada, which was considered to be complete, the incidence of clinically apparent thrombosis was 2.4 per 1,000 admissions to the neonatal intensive care unit (ICU).[12] In contrast, the German neonatal registry reported the incidence of symptomatic events was 0.51 per 10,000 births.[11] The Dutch study reported the incidence of neonatal venous thrombosis as 0.07 per 10,000 children.[13]

Many other studies have examined the rates of VTE in specific high-risk groups such as children and neonates with central venous access.[23,24,25] Children with malignancy, with or without central venous access, are often highlighted as a particular high-risk group, with rates as high as 30% to 50%, although there are many causative factors involved, including insertion technique, site of central line placement type of cancer involved, treatment protocol, and the diagnostic techniques applied.[7,10,26–28] Children with short-term central venous access whilst in pediatric intensive care units have thrombosis in 18.3% to 26% of cases.[29,30] Children undergoing solid organ transplant have frequent thromboembolic complications,[31–35] but perhaps the highest risk group in children is in those receiving long-term home parenteral nutrition, with cross-sectional studies reporting thrombosis in up to 66%.[36,37,38] With respect to PE, there is limited data on epidemiology. General population retrospective autopsy studies report PE in children at 0.05% to 4%[39–42] (Table 121.2).

Arterial Thrombosis

There are few studies that report the incidence of arterial thrombosis in children. The majority of arterial thrombosis in children are iatrogenic, related to invasive vascular access,[43–59,60,61–63] less commonly associated with solid organ transplantation and Kawasaki disease. Spontaneous arterial thrombosis is rare in children.[64–76] One prospective registry conducted between 1999 and 2002 reported arterial thrombosis at 8.5 per 10,000 hospital admissions (102 thromboses in 119,487 admissions),[77] suggesting that arterial thrombosis is as common as venous thrombosis in tertiary institutions.

Intracardiac Thrombosis

Right atrial and intracardiac thrombosis are most commonly diagnosed in children who have central venous access devices extending into the right atrium.[78,79] Children also may develop intracardiac thrombosis following cardiac surgery, including

Table 121.2

Incidence of pulmonary embolus in children with selected underlying clinical conditions

Author	Year	Study Design	N	Clinical Condition	Diagnostic Method	Incidence (%)

after Glenn,[80–85] Fontan,[86,87] Norwood procedures,[88,89] and prosthetic valve replacement.[90–106]

These complex surgical procedures are common in children with congenital heart disease, and the underlying surgical procedures may have specific implications for the potential consequences of intracardiac thrombosis.[107] A few specific examples are described below.

Blalock-Taussig (B-T) shunts are commonly performed in the neonatal period to increase pulmonary blood flow. B-T shunts may be performed as a single palliative procedure with more definitive surgery planned later or as part of a more complex surgical intervention (e.g., Norwood procedure). B-T shunts are performed as either classic or modified B-T shunts. In classic B-T shunts, the subclavian artery is anastomosed directly to the ipsilateral pulmonary artery. The shunt is usually performed on the right side unless there is a right-sided aortic arch, in which case, the shunt is performed on the left. In contrast, modified B-T shunts involve a Gore-Tex tube graft being placed between the subclavian artery and the ipsilateral pulmonary artery. The Gore-Tex tube may be as small as 3 mm in diameter, depending on the size of the infant, but is usually 3.5 or 4 mm in diameter. Blockage of the B-T shunt will compromise pulmonary blood flow and is often a major clinical event requiring immediate surgery. Patients with B-T shunts may have reduced peripheral pulses in the ipsilateral arm and may have measurably reduced growth of the arm. This can be of significance when assessing for postthrombotic syndrome, which may occur in the upper limbs secondary to central venous thrombosis.

The Norwood procedure is the initial surgery performed in infants with hypoplastic left heart syndrome (HLHS). The surgery is performed early in the neonatal period. HLHS usually includes severe hypoplasia of the left ventricle, hypoplasia of the ascending aorta and aortic arch, and critical stenosis of aortic or mitral valves.

The first stage involves the following:

1. Division of the main pulmonary artery and closure of the distal stump with a patch.
2. Ligation and division of the patent ductus arteriosus.
3. Using an aortic or pulmonary artery allograft, the proximal pulmonary artery is anastomosed to the hypoplastic aortic arch, which itself is enlarged to create a large arterial trunk.

4. The atrial septum is excised to allow adequate interatrial mixing.
5. A modified B-T shunt (right-sided, Gore-Tex tube, usually 3.5 to 4 mm) from the right innominate to the right pulmonary artery. This will be the only source of pulmonary blood flow.

This procedure results in systemic venous and pulmonary venous return entering into a common atrium. Blood then enters a common ventricle and leaves the heart via a common outflow tract, providing systemic blood flow via the aortic arch and pulmonary blood flow via the B-T shunt.

The implications of this procedure with respect to thrombosis are as follows:

1. Venous flow has direct access to systemic arterial flow, so deep venous thrombosis, whether central venous line (CVL) related or otherwise, readily causes systemic emboli and potentially arterial ischemic stroke.
2. A clotted B-T shunt causes loss of entire pulmonary blood flow.
3. There are substantial intravascular suture lines as potential sources of thrombosis.
4. The patients will need a subsequent Glenn procedure and eventually completion to a full Fontan procedure. The development of central thrombosis with associated collateral branches can significantly hinder these subsequent surgical interventions. Therefore, increased aggressiveness of any antithrombotic therapy may be appropriate. Even in the absence of symptoms, thrombolysis or surgical thrombectomy may be considered if a central venous thrombosis was thought to be impairing the hemodynamics required for future surgery.

The bidirectional cavopulmonary shunt (BCPS) or bidirectional Glenn procedure is an end (superior vena cava [SVC]) to side (right pulmonary artery) venous shunt. This is a palliative procedure that increases oxygen saturation, but without increasing left ventricular work, and is usually performed in children with univentricular cardiac physiology as the first stage of the two-stage Fontan procedure. The inferior vena cava (IVC) is unchanged after a Glenn procedure.

The implications with respect to thrombosis are that, following a Glenn procedure, the SVC blood flows directly to the lungs without any assistance from the heart. Hence, any reduction in SVC flow, owing to thrombus occlusion, will dramatically reduce pulmonary blood flow. Pulmonary emboli are of specific concern in that if the pulmonary vascular resistance is increased, the patient may become unsuitable for a Fontan completion, which limits long-term survival significantly in the absence of cardiac transplantation. Blood flow from the IVC still bypasses the lungs, meaning that any thrombus in the lower venous system can give rise to paradoxical emboli. Collateral branches around central venous thrombosis may interfere with the ability to complete the Fontan surgery. The threat of being unable to complete the Fontan may be justification for more aggressive antithrombotic therapy (thrombolysis or surgery) than might otherwise be indicated.

There are numerous modifications of the final Fontan procedure, but the basic principles remain the same. Both the SVC (usually done in a first-stage BCPS) and the IVC are anastomosed to the pulmonary arteries. Hence, the pulmonary blood flow is totally passive, depending on venous flow mechanisms without any cardiac pump assistance. The univentricle is then able to function as a left ventricle, providing systemic blood flow. Postoperatively, many patients have deliberate, limited, right to left interatrial shunting via a "fenestration." The blood flow in such cases increases the risk of paradoxical emboli.

The implications with respect to thrombosis following Fontan surgery are significant. First, the presence of right to left communication continues the potential for paradoxical emboli. Second, any pulmonary emboli that increase pulmonary vascular resistance have an accentuated impact on pulmonary blood flow because the pulmonary pressure cannot be increased to overcome a pressure gradient. The Fontan circuit makes the diagnosis of pulmonary emboli particularly difficult. Depending on the attachment of the SVC and IVC to the pulmonary arteries, isotope may need to be injected into both an arm and a leg to achieve full lung perfusion scanning. As for patients with severe pulmonary hypertension having ventilation–perfusion scans, the transient obstruction of pulmonary capillaries by the macroaggregated isotope-labeled albumin may rarely precipitate a hypoxic episode. Finally, depending on the exact type of Fontan surgery, the risk of late (many years later) thrombosis associated with dysrhythmias may be increased.

CLINICAL PRESENTATION OF THROMBOSIS IN NEONATES AND CHILDREN

Venous Thrombosis

The clinical symptoms/complications of VTE can be classified as acute or long term and vary depending on site and severity. A high proportion of venous thrombosis in children occur in the upper venous system (defined as subclavian, brachiocephalic, internal jugular veins, and SVC), as distinct from the lower venous system (defined as the popliteal, femoral, iliac veins, and the IVC), which is more commonly affected in adults with VTE. These upper system VTEs are commonly associated with CVL placement. The acute clinical symptoms, besides loss of CVL patency, include swelling, pain, and limb discolouration,[22] swelling of the face and head with SVC syndrome,[108] and respiratory compromise with PE.[8] Renal vein thrombosis (RVT) classically presents with a flank mass, hematuria, proteinuria, thrombocytopenia, and nonfunction of the involved kidney. Any venous thrombosis may present with a paradoxical embolus causing a stroke, notably in neonates with a patent foramen ovale.

Children often do not present with acute symptoms (FIGURES 121.1 and 121.2). Long-term clinical symptoms and/or complications include prominent cutaneous collateral circulation, loss of CVL patency requiring local thrombolytic treatment, CVL replacement, loss of venous access, CVL-related sepsis, chylothorax,[109,110] chylopericardium,[111] recurrent VTE necessitating long-term anticoagulation, and postthrombotic syndrome (PTS).[112] Specific long-term sequelae of umbilical vein catheter (UVC)-related VTE include portal hypertension,[113] splenomegaly,[114] gastric and esophageal varices, variceal bleeding, and hypertension.[115]

Arterial Thrombosis

Arterial thrombosis is most frequently iatrogenic, and loss of vascular access is a common presenting symptom.[77] Acute symptoms will depend on the site of arterial thrombosis and whether there is adequate collateral flow to prevent tissue ischemia. Peripheral limb ischemia is characterized by diminished

FIGURE 121.1 This boy presented at 10 years of age with prominent abdominal collaterals. He had gastroschisis repaired during the neonatal period and had a lower system venous access device placed during this period. There were no acute symptoms of thrombosis documented; however on current scans he has chronic thrombosis with no flow to the IVC below the renal veins.

or absent pulses, a prolonged capillary refill time, and a cool, pale limb. Thrombotic occlusion of the radial artery produces more severe symptoms with accompanying ulnar artery occlusion. Chronic symptoms may develop even in the absence of acute symptoms and include limb hypoplasia and claudication (FIGURE 121.3). The clinical presentation of umbilical artery catheter (UAC)-related thromboembolic events varies, the majority of newborns being asymptomatic or only minimally affected, but a small proportion having major symptoms of severe leg ischemia and organ dysfunction, including necrotizing enterocolitis secondary to mesenteric artery occlusion, hypertension with or without renal failure secondary to renal artery thrombosis, and limb compromise secondary to embolic events.

DIAGNOSIS OF THROMBOEMBOLISM IN NEONATES AND CHILDREN

Venous Thromboembolism

There are no studies comparing the validity of the commonly used diagnostic tests for DVT in neonates, and little is known about the precision and accuracy of noninvasive imaging techniques. The low pulse pressure in premature newborns likely makes ultrasound (US) difficult to interpret, and the presence of a CVL makes compressibility difficult to assess, reducing sensitivity of the test. In neonates with UVCs, Doppler US is inferior to contrast venography for detecting asymptomatic thrombi.[116]

By contrast, US is the gold standard for diagnosing RVT, because of its sensitivity to an enlarged kidney, which is echogenic with prominent echo-poor medullary pyramids. Renal swelling subsequently decreases, with loss of corticomedullary differentiation, and ultimately, depending on the degree of recovery, US may demonstrate focal scarring or atrophy. Magnetic resonance imaging (MRI) and computed tomography (CT) have also been used to diagnose RVT, but have no apparent advantages over color Doppler, which may show absent renal venous flow in the early stages of RVT. In neonates with suspected VTE, venography is the gold standard, but clinicians must use clinical assessment and suboptimal imaging to make decisions, because the gold standard is practically unachievable.

In older children, US is poorly sensitive (20%) for upper system CVL-related thrombosis, compared to venography. In a comparison of venography versus US for the diagnosis of asymptomatic upper venous system CVL-related VTE, US had a sensitivity of only 20% for intrathoracic thrombosis, but detected jugular vein thrombi that were missed by venography.[24] Shankar et al studied 25 children with multiple CVL insertions, who were suspected of having major central venous thrombosis. The authors found: catheter contrast studies consistently underestimated the extend of thrombosis; US identified jugular thrombosis, but failed to identify more central thrombosis, in fact detecting only 7 of 18 thrombosis noted by magnetic resonance venography (MRV), and underestimated the extent of the thrombosis in 4 of the 7. (ref 116) Further, MRV identified a patent vein for reinsertion of CVL in 22 of 25 children, subsequently confirmed in 20 of 22 patients (91%).[116] Further, MRV identified a patent vein for reinsertion of CVL in 22 of 25 children, as confirmed in 20 of 22 patients (91%). There are no reported studies that determine the sensitivity and specificity of diagnostic testing for lower venous system CVL-related thrombosis in children.

In summary, for children with suspected upper system thrombosis, a combination of US (jugular veins) and bilateral upper limb venography (subclavians and central veins) is recommended, although MRV may be a viable alternative to formal venography depending upon local expertise. US is a reasonable alternative for DVT distal to the groin, based on adult experience, but for more proximal veins, venography or MRV should be considered.

Pulmonary Embolus

There are no published studies determining the sensitivity and specificity of diagnostic testing for PE in children. However, literature would support that PE is significantly underdiagnosed in children, especially in the ICU setting. There are difficulties with interpreting ventilation/perfusion (V/Q) scans in children in at-risk children, particularly following Fontan cardiac surgery, during which total pulmonary blood flow cannot be assessed by upper limb isotope injection. There are concerns as well regarding the safety of perfusion scanning in children with significant right to left cardiac shunts, as likely significant amounts of macroaggregated albumin may lodge in the cerebral circulation.[117] Ventilation perfusion scanning remains the recommended

A B

FIGURE 121.2 This girl presented during her teenage years with a rash on her legs that was demonstrated to be severe postthrombotic syndrome **(A)**. She developed venous ulceration 6 months later **(B)**. Imaging confirmed femoral vein occlusion with chronic collateral circulation. She had had a right femoral vein cardiac catheter when 3 years of age and had no immediate symptoms of her thrombosis.

FIGURE 121.3 This girl presented with right leg length shortening and atrophy. The femoral artery was occluded as a result of thrombosis following catheterization 10 years previously. There were no acute symptoms at the time of the catheter procedure.

investigation for PE in neonates and children, although pulmonary angiography is the gold standard, and clinicians may need to make a presumptive diagnosis based on clinical findings and the presence or absence of source thrombosis. CT pulmonary angiography may miss small peripheral pulmonary emboli, and repeat studies involve significant radiation exposure, notably to breast tissue in young female patients.[118] Clinical prediction rules, such as the Well clinical probability score, have been validated in adults presenting with symptoms of PE and provide a useful measure of pretest probability.[119]

The combination of a negative D-dimer and low clinical probability score can safely rule out PE, negating the need for diagnostic imaging.[120] However, no such clinical probability score has been validated in a pediatric cohort, and evidence suggests that the algorithms are not valid.[121] Further, a negative D-dimer test did not rule out PE in 4 of 30 children tested and was negative in 36% and 40% of children with PE in two other studies,[122] demonstrating a poor negative predictive value of this assay. Use of highly sensitive D-dimer tests would probably lead to more false-positive results. As symptoms and signs of DVT may be masked by the underlying diagnosis, the roles of clinical probability scores and D-dimer assays are currently unknown in children and should not be utilized.[121,123]

Arterial Thrombosis

There is little specific information related to diagnostic strategies in neonates or children,[77] although contrast angiography remains the "gold standard." Peripheral arterial thrombosis is usually diagnosed clinically, and US is the most commonly used diagnostic test.[72,124–126] Aortic thrombosis, either secondary to

UAC, or spontaneous, requires radiologic diagnosis. US cardiac echocardiography is of value if the obstruction is in the aortic arch.[68]

Contrast angiography is rarely feasible in critically ill newborns. In one comparative study, US failed to visualize aortic thrombosis in four patients, three of whom had complete aortic obstruction by contrast angiography. Thus, clinicians often use clinical findings and suboptimal imaging to make clinical decisions. In older children, arterial thrombosis is usually diagnosed on clinical grounds alone. False-negative US is reported in spontaneous femoral artery thrombosis in children, and false-positive MRA has been reported for chronic femoral artery obstruction, in comparison with angiography.[127] In suspected peripheral artery thrombosis, clinicians should consider the possibility of intramural or external hematoma causing arterial compression in the differential diagnosis, and for peripheral arteries, US may be sufficiently sensitive to exclude this phenomenon.[128] For hepatic artery thrombosis after liver transplant, serial testing with pulsed Doppler combined with real-time US of the liver parenchyma has a sensitivity of approximately 70%. As false-positive and -negative results occur, angiography is usually required to confirm the diagnosis, but CT may be useful in equivocal cases.[129] Spiral CT is sensitive and specific in adults, but the value of MRI is yet to be fully determined.

Intracardiac Thrombosis

Three studies have compared transthoracic echocardiography (TTE) to transesophageal echocardiography (TEE) in the diagnosis of intracardiac thrombosis following Fontan surgery.[130–132] Stumper et al. found three intracardiac thromboses in 18 patients using TEE, of which only one was detected by TTE, Fyfe et al. found six thrombi in four pediatric patients using TEE, of which only one was detected by TTE, and Balling et al. found 17 of 52 patients (33%) with intracardiac thrombosis after Fontan surgery by TEE, of which only one was identified on TTE. Thus, TTE is likely insufficient to exclude intracardiac thrombosis in children after Fontan surgery. Right atrial thrombosis, especially CVL-related thrombosis, is commonly diagnosed using TTE.[79]

ANTITHROMBOTIC THERAPY IN PEDIATRIC PATIENTS

The evidence supporting most recommendations for antithrombotic therapy in neonates and children remains weak.[133] Studies addressing appropriate drug target ranges and monitoring requirements are urgently required in addition to site- and clinical situation-specific thrombosis management strategies.[133] While there is some data to guide treatment decisions in neonates, almost none of the data reported separates premature from term infants, despite the obvious differences in risk/benefit considerations. Similarly adolescents are often managed according to data based on adults, but at what point an adolescent should transition from recommendations based on data in children to that in adults and whether age alone should be the determining factor for that transition is unknown.[133] The remainder of this chapter discusses the principles of antithrombotic therapy applicable to neonates and children. For specific treatment recommendations, the reader is referred to the most recent guidelines published by the American College of Chest Physicians.[133]

Heparin in Neonates and Children

Unfractionated heparin (UFH) remains a commonly used anticoagulant in pediatric patients. In tertiary pediatric hospitals, approximately 15% of inpatients are exposed to UFH each day.[134] There are a number of specific factors that may alter the effect of UFH in children. For example, UFH acts via antithrombin (AT)-mediated inhibition of thrombin and factor Xa, but children have reduced levels of AT and prothrombin,[17,135–137] reduced capacity to generate thrombin,[3,136,138] an age-related different ratio of anti-Xa: anti-IIa activity,[139–141] alterations in plasma binding of UFH,[19–21,139] and age-related differences in tissue factor pathway inhibitor release.[139] The clinical implications of these changes on dosing, monitoring, and the effectiveness/safety profile of UFH in children remain to be fully elucidated.

There have been no reported clinical outcome studies to determine the therapeutic range for UFH in neonates or children, so the therapeutic range for all indications is extrapolated from those used in adults. This equates to an activated partial thromboplastin time (APTT) that reflects a heparin level by protamine titration of 0.2 to 0.4 U/mL or an antifactor Xa level of 0.35 to 0.7 U/mL.[142] Extrapolating the APTT range from adults to pediatric patients may well be invalid. For example, baseline APTTs in pediatric patients, especially neonates, are often increased compared to adults, so a therapeutic range represents a reduced increment in APTT values in pediatric patients receiving adult-equivalent heparin therapy.[17,18] Schmidt reported that routine assays underestimate UFH concentration especially in neonates.[143] Recent *in vitro* and *in vivo* data also indicate that the APTT range that correlates to an antifactor Xa level of 0.35 to 0.7 U/mL varies significantly with age and heparin dose.[19,138–141,144] Further, protamine titration results vary with age[140] and different commercial anti-Xa kits produce substantial variations in results on the same samples.[138] These differences are magnified in infants whose endogenous AT levels are reduced.[145]

Bolus doses of 75 to 100 U/kg result in therapeutic APTT values in 90% of children at 4 to 6 hours postbolus. Maintenance UFH doses are age dependent, with infants (up to 2 months) having the highest requirements (average 28 U/kg/h) and children over 1 year of age having lower requirements (average 20 U/kg/h).[146] The doses of UFH required for older children are similar to the weight-adjusted requirements in adults (18 U/kg/h).[147] However, boluses of 75 to 100 U/kg in children receiving cardiac catheter prophylaxis result in excessive prolongation of APTT for over 100 minutes, implying that the recommendations may need to be reexamined.[140] Clearance of UFH is faster in newborns than in older children due to a larger volume of distribution.[148,149] Further, the pharmacokinetics of UFH in children fits a first-order model and is a function of weight rather than age.[140] Methodologically correct pharmacodynamic studies of UFH in children have not been performed.

Monitoring of UFH therapy is current standard practice, but there are difficulties with interpreting the monitoring assays, related to a lack of correlation between the anti-Xa, APTT, and thrombin clotting time,[138,140,148] as well as in making dosage adjustments.[147,150] There are no published studies in children that establish the ideal frequency of UFH monitoring.[151]

One cohort study reported bleeding in 1.5% (95% CI 0.0% to 8.3%) of children treated with UFH for DVT.[22] However, many children were treated with subtherapeutic doses of UFH in this study,[146] and a single-centre cohort study reported major bleeding in 24% of children in the pediatric ICU receiving UFH.[152] Further studies are required to accurately determine the frequency of UFH-induced bleeding in optimally treated children. Probably the most common cause of fatal bleeding secondary to UFH relates to accidental overdose, especially in neonates. While rarely reported in the medical literature, the number of cases reported in the popular press appears to be increasing.[18,153–158] In addition, anaphylaxis has been reported related to contamination of heparinoid drugs.[159–174] There are only three case reports of pediatric UFH-induced osteoporosis, two of whom received concurrent steroid therapy,[175,176] the third receiving high-dose IV UFH for a prolonged period.[176] Given the convincing relationship between UFH and osteoporosis in adults, clinicians should avoid long-term (weeks to months) use of UFH in children, especially considering the increased risk for heparin-induced osteoporosis in children compared to adults.[177,178]

Accurate diagnosis of heparin-induced thrombocytopenia (HIT) in children remains problematic. Overdiagnosis may occur in adults,[179] especially in the postcardiac surgical setting.[180] The frequency of HIT in children varies, likely related to criteria of patient inclusion and laboratory technique,[134,181–185] rates varying from almost nonexistent in unselected heparinized children[134] to 2.3% in children in the pediatric ICU.[183] Presumed HIT is a frequent reason for children to receive novel anticoagulant drugs,[186] including danaparoid, hirudin, and argatroban.[187–215]

Low Molecular Weight Heparin in Neonates and Children

LMWH has become the anticoagulant of choice in many pediatric patients, both for primary prophylaxis and for treatment of TE.[216] The potential advantages of LMWH for pediatric patients include reduced monitoring requirements compared to VKAs, lack of interference by other drugs or diet, reduced risk of HIT, and probable reduced risk of osteoporosis with long-term use. However, the predictability of the anticoagulant affect with weight-adjusted doses is less than in adults,[217] presumably due to differences in binding to plasma proteins.[21,218] Most clinical data of LMWH in pediatric patients utilized enoxaparin.[216,217,219–223,224,225–228] At 0.25 U LMWH/mL, thrombin generation is delayed and reduced by 50% in newborns compared to adults,[229] although no difference was observed in the anti-Xa activity of enoxaparin *in vitro* between plasma of children and adults.[230]

Therapeutic ranges for LMWH are extrapolated from results in adults and are based on anti-Xa levels, the guideline for subcutaneous administration twice daily being 0.50 to 1.0 U anti-Xa/mL at 2 to 6 hours following injection. Most studies in children have used this therapeutic range, although one study used a lower maximal level (0.8 U/mL) with good efficacy and safety outcomes.[228] For children dosed once daily, a target peak level of 0.5 to 0.8 U/mL or a trough level of 0.1 U/mL may be used.[224,228] Continuous infusion of intravenous LMWH has used the same target range of 0.5 to 1.0 U/mL.[231]

Table 121.3

Results of pharmacokinetic studies for LMWH in children

LMWH	Number of Patients	Maintenance Dose	Age or Weight
Enoxaparin[233]	19	1.6 mg/kg BD 1.0 mg/kg BD	<2 mo >2 mo
Enoxaparin[354]	12	1.0 mg/kg BD	>2 mo
Reviparin[355]	12	100 U/kg BD	>5 kg
Nadroparin[356]	154	146 U/kg BD	15 d to 8 y
Tinzaparin[357]	10	280 U/kg daily	0–2 mo
	8	245 U/kg daily	>2–12 mo
	6	240 U/kg daily	1 to >5 y
	4	200 U/kg daily	5 to >10 y
	7	177 U/kg daily	10 to >16 y

A two-compartment model describes enoxaparin kinetics in children, body weight being the most predictive covariate for clearance (15 mL/kg/h), central volume of distribution (169 mL/kg), intercompartmental clearance (58 mL/h), peripheral volume of distribution, and absorption rate. Interindividual variability is 54% for clearance and 42% for volume of distribution.[228] The subcutaneous doses of LMWH required in pediatric patients to achieve adult therapeutic peak anti-Xa levels have been assessed for enoxaparin, reviparin, dalteparin, tinzaparin, and nadroparin; however only enoxaparin, reviparin, tinzaparin, and nadroparin have been subjected to formal pharmacokinetic studies (Table 121.3).[224]

While initial doses most likely attain the therapeutic range, considerable interpatient dose differences exist, suggesting that routine monitoring of anti-Xa levels in children and neonates remains necessary.[232] Initial reports indicated that neonates required higher per kg doses than older children,[233,234] but recent studies of nadroparin[235] and enoxaparin[218] demonstrate a difference in dose requirements across age groups well outside of the newborn period. Whether clinical effectiveness will be altered by having multiple age-related initial and maintenance dose recommendations is unclear. Reviews of clinical reports of final dose requirements for neonates have suggested that an even higher initial dose schedule is more appropriate,[236] especially in preterm infants.[227,237,238]

A recent review of enoxaparin compiled data from multiple studies to describe a total of 240 neonates and reported that minor side effects were common and that major bleeding occurred in 12 (5%), although individual study results for major bleeding varied from 0% to 19%.[238] There were 10 premature neonates included in this review, with no major bleeds,[238] but the data are not sufficient to draw definitive conclusions. Risk factors for major bleeding are the use of subcutaneous catheters in newborns with little subcutaneous tissue and the presence of preexisting CNS abnormalities. For older children, a review of 308 children treated with therapeutic LMWH for VTE showed 9 children (1.2%) with major bleeding and 72 (23.4%) with minor bleeding.[224] This review included 133 children treated

with prophylactic doses of LMWH, of which 1 (0.8%) had major bleeding and 4 (3%) had minor bleeding. There are no data on the frequency of osteoporosis, HIT, or other hypersensitivity reactions in children exposed to LMWH; two cases of temporary hair loss are published.[239,240]

Vitamin K Antagonists in Neonates and Children

VKAs are problematic in newborns for several reasons. First, the plasma levels of the vitamin K–dependent coagulation factors are physiologically decreased in comparison with adult levels. Second, infant formula is supplemented with vitamin K to prevent hemorrhagic disease, which makes formula-fed infants resistant to VKAs. In contrast, breast milk has low concentrations of vitamin K, making breast-fed infants sensitive to VKAs,[241,242] a situation that can be compensated for by feeding 30 to 60 mL of formula each day. Third, VKAs are available only in tablet form in most countries, thus being unsuitable for newborns even if suspended in water. Fourth, VKA therapy requires monitoring, because of rapidly changing physiologic values of the vitamin K–dependent coagulation proteins, and changes in diet.[243] Finally, there is little efficacy or safety information specific to VKA use in neonates.

Warfarin is the most commonly used and studied VKA worldwide.[244–248] Acenocoumarol is administered with high frequency in some European and South American countries,[249,250] and phenprocoumon is the preferred VKA in some parts of Europe, although data about doses of phenprocoumon in pediatric patients have been reported. The current therapeutic international normalized ratio (INR) ranges for children are extrapolated from recommendations for adult patients, because there are no clinical trials that have assessed the optimal INR range for children. For most indications, the therapeutic target INR is 2.5 (range 2.0 to 3.0). The therapeutic range for prosthetic valves is also extrapolated from adult data and varies according to the type and position of the prosthetic valves.

The capacity of plasma from children receiving VKAs to generate thrombin is delayed and decreased by 25% compared to plasma from adults with a similar INR.[6] This raises the issue of whether the optimal INR therapeutic range for children should be lower than that for adults. This hypothesis is further supported by the observation that plasma concentrations of a marker of endogenous thrombin generation, prothrombin fragment 1.2, is significantly lower in children compared to adults at similar INR values.[6]

The published age-specific and weight-adjusted doses for children vary due to different study designs, patient populations, and varied results due to small sample size of the studied populations of children. The largest cohort study ($n = 319$) found that infants required an average of 0.33 mg/kg and teenagers 0.09 mg/kg warfarin to maintain an INR of 2.0 to 3.0.[248] For adults, weight-adjusted doses for VKA are not precisely known, but are in the range of 0.04 to 0.08 mg/kg to achieve an INR of 2.0 to 3.0.[251]

Monitoring oral anticoagulant therapy in children is difficult and requires close supervision with frequent dose adjustments.[244,248,252] Only 10% to 20% of children are safely monitored monthly.[244] Studies in children comparing point-of-care monitors to venepuncture INR, including comparison to WHO reference thromboplastins in the laboratory method, confirm their accuracy and reliability.[253,254] The major advantages of point-of-care devices include reduced trauma of venepunctures, minimal interruption of school and work, ease of operation, and portability.[254–260]

Bleeding is the main complication of VKA therapy, the risk for serious bleeding for treatment of mechanical prosthetic valves being <3.2% per patient year.[261] In one large cohort of 391 patient years, with variable target INR ranges, the bleeding rate was 0.5% per patient year.[255] In a randomized trial of 41 subjects, target INR range was 2.0 to 3.0 for 3 months and bleeding occurred in 12.2% (95% CI 4.1 to 26.2).[262] A single-center study with a nurse-coordinated anticoagulant service reported a bleeding rate of 0.05% per patient year.[263] Adequate patient and family education protocols are major factors in reducing bleeding events in children on warfarin therapy.[264,265] Nonhemorrhagic complications of VKA, such as tracheal calcification or hair loss, have been described on rare occasions in young children.[266,267] Two uncontrolled cohort studies described reduced bone density in children on warfarin for >1 year.[268,269]

Alternative Thrombin Inhibitors

Reports have documented pediatric use of argatroban,[195,197,200,202,270,271] bivalirudin,[194,272] lepirudin,[198,199,203,205,209,273–275] dabigatran,[276,277] danaparoid,[191,193,208,212,278–285] and fondaparinux,[271,286–290] most often used in children diagnosed with HIT. Two recent reviews have summarized the clinical indications, doses used, monitoring schedules, and clinical outcomes.[186,291] There is a wide range of dosing regimens reported, and most are empirical with relatively few formal dose-finding studies published. The clinical outcomes in children receiving these agents are often poor, and their use is difficult to recommend except in exceptional circumstances.[186]

Thrombolysis in Neonates and Children

At birth, plasma concentrations of plasminogen are approximately 50% of adult values (21 mg/100 mL),[292–294] slowing plasmin generation[295] and reducing the potential thrombolytic effect of streptokinase (SK), urokinase (UK), and tissue plasminogen activator (tPA) in *in vitro* fibrin clot systems.[137] Supplementation of plasma with plasminogen increases the thrombolytic effect of the agents.[137,296]

No study has compared the efficacy, safety, or cost of different thrombolytic agents in children. However, tPA has become the agent of choice in pediatric patients,[137,296,297,298–300] this preference being the result of a Federal Drug Administration (USA) warning regarding UK, improved clot lysis *in vitro* compared to UK and SK, fibrin specificity, and low immunogenicity.[301,302] However, tPA is considerably more expensive than SK or UK, and the increased *in vitro* clot lysis by tPA has not been demonstrated in clinical trials in children. There is minimal experience with other thrombolytic agents in children.[297,299,303] A recent survey has shown no consensus in indications for thrombolysis, dose, mode of delivery, or duration of therapy,[300] reflecting the lack of good quality studies available to guide clinicians in this area.

Success rates for thrombolysis in pediatric patients vary. Albisetti[297] reviewed the pediatric literature and described complete resolution of target thrombosis in 64% of 413 reported children receiving SK, UK, and tPA (53%, 43%, and 69%, respectively), but 21% had no response. Nowak Gottl reviewed

thrombolysis in neonates and calculated an overall thrombolytic patency rate of 39% for children with aortic thrombosis to 86.5% with intracardiac thrombosis. The collected data suggested no difference in efficacy between SK, UK, and tPA.[298] Differences in success rates have also been reported for thrombolysis in venous versus arterial thrombosis in children.[304] Most studies that have reported success or failure of thrombolysis have used thrombus resolution as an outcome measure, with methods of detection ranging from clinical assessment to radiologic assessment. One series of nine patients with DVT reported the postthrombotic syndrome as an outcome measure.[305] Despite a number of case series that have reported using thrombolysis for treatment of a wide range of venous and arterial thrombosis in children,[58,302,304,306–310] the likelihood of reporting bias, and the lack of control groups, who did not receive thrombolytics, and the use of inconsistent outcome measures makes the interpretation of data difficult.[299]

Manco-Johnson et al.[311] described specific contraindications for children, including prematurity (<32 weeks gestation). However, thrombolytics have been successfully given to premature babies,[307,312–316] including one with preexisting intraventricular haemorrhage,[317] but the number of studied patients was small.

At this time, there is no evidence to suggest that there is an advantage of local over systemic thrombolytic therapy in children with thrombotic complications.[297,322–324] There are more recent small case series reporting catheter-directed thrombolysis in children.[305,318,319]

Thrombolytics may not inhibit clot propagation; hence thrombin inhibition is required as adjunctive therapy. Concurrent low-dose heparin followed by therapeutic heparinization has since been described in single-centre studies.[304,305,307,310] While concurrent LMWH has also been reported,[310] easily reversible anticoagulation seems more appropriate.

Thrombolytic therapy has significant bleeding complications in children, requiring packed red blood cell transfusion in approximately 20% of patients.[296] A large single institution study reported bleeding in 68% of patients, requiring transfusion in 39%.[302] Multiple other studies have reported varying results.[58,304,306,316] Albisetti[297] calculated hemorrhage with the use of tPA as 26% minor and 17% major events.

In summary, there remains considerable variation in the risk of bleeding associated with thrombolysis use in children. The lack of uniform treatment regimen and lack of controlled data make the true adverse bleeding event rates difficult to estimate. However, it does appear that the bleeding risk from thrombolysis in children is at least an order of magnitude higher than the bleeding risk of anticoagulation alone. This risk needs to be weighed against the potential benefits of therapy in any child considered for thrombolysis.

Vena Caval Interruption

In addition to pharmacologic therapy, IVC are used for specific clinical indications in adults, primarily to reduce the risk of PE in patients with proven thrombosis in whom anticoagulation is contraindicated or who have failed anticoagulation therapy. There are reports on the use of IVC filters in children as young as 6 years of age.[320–325] Increasingly, temporary filters are used so they can be retrieved once the risk of pulmonary embolus is reduced, or the contraindication to anticoagulation has resolved. Temporary filters have been left *in situ* for over 140 days.[326] Raffini et al.[327] reported an institutional program that resulted in 5% of children presenting with DVT having IVC filters inserted, with minimal adverse outcomes. Chaudry et al.[328] reported the use of filters in the internal jugular veins as well as in the IVC. There are no specific guidelines for the use of filters in children and the risk/benefit ratio needs to be considered individually in each case. We strongly support, when required, the exclusive use of temporary filters in children.

Surgical Therapy

Surgical thrombectomy is rarely used in children and is restricted to situations such as IVC thrombosis in association with intravascular extension of Wilms' tumor, acute thrombosis of B-T shunts, life-threatening intracardiac thrombosis after complex cardiac surgery, prosthetic valve thrombosis, septic thrombosis, and peripheral arterial thrombosis secondary to vascular access.[79,128,329–339] There are no controlled data to compare the value of conservative therapy, and it is unlikely such data will become available. In most cases, concurrent or subsequent anticoagulation therapy is used.

CONCLUSION

Venous and arterial thrombosis in children are common clinical problems, especially in tertiary care facilities. There are significant differences to many key aspects of the epidemiology, pathogenesis, and coexisting conditions of thrombosis in children when compared to adults. There remains little information about the natural history of TE, and the potential for long-term consequences is significant. When considering treating thromboembolic events in children, clinicians must be aware of important differences in pharmacokinetics and pharmacodynamics of anticoagulant drugs from values in adults, as well as significant difficulties in performing and interpreting monitoring tests. The use of anticoagulants in children of all ages requires urgent research to improve the safety and efficacy of these drugs. Recent reviews and specific consensus guidelines are helpful for clinicians in this rapidly changing field.[151,186,340–342]

CHAPTER

122 Thrombotic Complications of Sickle Cell Disease

KENNETH I. ATAGA AND ELLIOTT P. VICHINSKY

In addition to its well described vaso-occlusive and hemolytic complications, patients with sickle cell disease (SCD) are at risk for a variety of thrombotic complications. Patients with SCD have an increased risk of stroke, pulmonary hypertension, avascular necrosis of large joints, pregnancy-related complications, and leg ulcers, all of which may be due, at least in part, to thrombotic vascular occlusion.[1] A retrospective study based on reported discharge diagnoses showed that SCD patients were more likely to be diagnosed with pulmonary embolism compared with race-matched controls without SCD (0.44% vs. 0.12%), although interestingly, the prevalence of deep vein thrombosis was similar between the two groups.[2] SCD also appears to be a significant risk factor for pregnancy-related venous thromboembolism, with an odds ratio of 6.7 (95% confidence interval [CI]: 4.4 to 10.1).[3,4] Finally, although distinct from SCD in its clinical manifestations, individuals with the sickle cell trait appear to be at increased risk of venous thromboembolism compared to race-matched controls, with an odds ratio of about two.[5,6] Sickle cell trait appears to be associated with pulmonary embolism, rather than deep vein thrombosis,[5] analogous to the situation in patients with SCD.[2]

THE RED BLOOD CELL AND HEMOGLOBIN S POLYMERIZATION

Sickle hemoglobin (HbS) occurs when the normal β^6 glutamic acid residue is replaced by valine (GAG to GTG mutation at codon β^6). The polymerization of HbS ($\alpha_2\beta_2^S$) following its deoxygenation is the primary event in the pathophysiology of SCD and results in damage to red blood cells (RBCs), tissues, and organs.[7] The rate and extent of HbS polymer formation depend on the degree of deoxygenation of HbS, the intraerythrocytic HbS concentration, and the intracellular concentration of fetal hemoglobin (HbF).[7] The lag period required for the formation of HbS polymer is referred to as the delay time. As the range of transit times in the microcirculation is short relative to the range of delay times of sickle RBCs, polymers do not form in most of the cells.[8] HbF inhibits the polymerization of HbS, primarily owing to the glutamine residue at codon γ87, which prevents a critical lateral contact in the double strand of the sickle fiber.[7]

Patients with SCD exhibit an unusually broad density distribution of sickle RBCs due mainly to the high number of reticulocytes, with a relatively low intracellular hemoglobin concentration, and the presence of a high number of very dense cells. Dense cells occur due to enhanced cellular dehydration following polymerization-induced damage to the cell membrane.[7] As HbS polymerization is strongly dependent on the intracellular hemoglobin concentration,[9] dense sickle RBCs are more likely to polymerize and contribute to the hemolytic and vaso-occlusive complications of SCD than less dehydrated cells.

LEUKOCYTES

Leukocytes play an important role in the pathogenesis of SCD. Increased white blood cell count is a risk for early death,[10] acute chest syndrome,[11] and hemorrhagic stroke[12] in patients with sickle cell anemia. In addition, severe episodes of vaso-occlusive crisis and acute chest syndrome have occurred following the administration of granulocyte-colony stimulating factor (G-CSF) to patients with SCD in their steady state.[13,14] Leukocytes interact with sickle RBC and vascular endothelium and are stimulated to release injurious cytokines.[15,16] In addition to the adhesion to vascular endothelium, leukocytes interact with erythrocytes and platelets to form cell aggregates, stabilized via CD36-TSP, CD31-CD31, and CD62L-CD162 bonds.[17,18] Using intravital microscopy in mice expressing human HbS, sickle RBCs were observed to bind to adherent leukocytes in inflamed venules, producing vaso-occlusion of cremasteric venules.[17] However, both the adhesion of leukocytes to endothelium and the interaction of leukocytes with sickle RBCs were substantially reduced in sickle mice that were deficient in P- and E-selectins, suggesting that adhesion to endothelial selectins may enhance the ability of adherent leukocytes to bind circulating sickle RBCs.

Monocytes are activated in sickle cell anemia and can enhance vaso-occlusion through an endothelial inflammatory response promoted by the nuclear factor-κB (NFκB)-mediated upregulation of adhesion molecules and tissue factor (TF).[19] The activation of endothelial cells by sickle monocytes appears to be mediated by tumor necrosis factor-α and interleukin-1β, both markers of monocyte activation. The activated endothelial cells increase their expression of ligands for adhesion molecules on leukocytes and RBCs, thereby promoting vaso-occlusion.

ENDOTHELIUM

As the potential for sickle RBCs to initiate a vaso-occlusive event is dependent on whether the rate of polymer formation is within the range of the capillary transit time,[20] any factor that slows the transit of these cells through the microcirculation could be expected to have an effect on the pathogenesis of vaso-occlusion. Multiple studies demonstrate that sickle RBCs attach more readily to cultured endothelial cells than do normal RBCs.[21–24] Indeed, the degree of adherence of sickle RBCs to vascular endothelium strongly correlates with disease severity.[21]

In addition to WBC adhesion to endothelium, adhesion reactions are mediated by interactions between receptors on sickle RBCs and endothelial cells or subendothelial matrix proteins. The plasma ligand, thrombospondin (TSP) provides a bridge between the RBC receptor CD36 and several constitutively expressed endothelial receptors,[25,26] including the vitronectin receptor ($\alpha_v\beta_3$), the transmembrane glycoprotein CD36, and endothelial cell surface heparan sulfate proteoglycans. Sickle RBCs also interact with immobilized TSP via the integrin-associated protein, CD47.[27] Interactions occur between the integrin complex, $\alpha_4\beta_1$ (VLA-4), expressed on reticulocytes, and both endothelial vascular-cell adhesion molecule 1 (VCAM-1)[28–31] (typically expressed on the surface of endothelial cells following activation by inflammatory cytokines and hypoxia) and fibronectin.[32] High molecular weight multimers of von Willebrand factor (vWF)[33,34] promote RBC adhesion to endothelial vitronectin receptor, $\alpha_v\beta_3$ and the GPIb-IX-V complex. Interactions also occur between sickle RBC and subendothelial immobilized matrix proteins, including laminin via the erythrocyte basal cell adhesion molecule-Lutheran protein receptor, the protein that carries Lutheran blood-group antigens,[35] as well as TSP, vWF, and fibronectin, proteins that are also present in plasma in a soluble form.[36] Nonreceptor-mediated adhesive mechanisms include a role for RBC sulfated glycolipids and phosphatidylserine (PS).[37–39]

INFLAMMATION

SCD is often referred to as a chronic inflammatory state due to the presence of a chronic elevation in leukocyte counts, abnormal activation of cellular elements including neutrophils and monocytes,[40,41] circulating endothelial cells,[42] and platelets[43,44] as well as activation of the coagulation system.[1] In addition, patients exhibit elevated levels of inflammatory mediators (such as interleukin-6, tumor necrosis factor α, interleukin-1, placenta growth factor [PlGF]), acute phase reactants (such as C-reactive protein, secretory phospholipase A2, and G-CSF), and markers of endothelial cell injury (such as soluble VCAM)[40,45,46] even in the non-crisis, "steady state." The inflammatory biology in SCD patients may result from infection, as well as iron replete (or overloaded) states, sickle RBC adhesion to endothelium, and the reperfusion-injury physiology observed in these patients.[40]

COAGULATION ACTIVATION

As nearly every component of hemostasis, including platelet function, and the procoagulant, anticoagulant, and fibrinolytic systems, is altered in the direction of a procoagulant phenotype, SCD is frequently referred to as a "hypercoagulable state[1] (FIGURE 122.1)." Patients exhibit a loss of normal membrane phospholipid asymmetry in a subpopulation of RBCs, occurring in mature cells, RNA-containing reticulocytes, and transferrin receptor–positive "stress" erythrocytes.[47,48] PS is normally found in the inner monolayer of the plasma cell membrane, whereas choline-containing phospholipids such as phosphatidylcholine and sphingomyelin are located in the outer monolayer.[49] RBC membrane phospholipid asymmetry is usually maintained by the action of an ATP-dependent aminophospholipid translocase (or flipase), that transports PS and phosphatidylethanolamine from the outer to the inner membrane surface.[49] In addition, movement of all phospholipids in both directions is produced by scramblase, following activation by an influx of extracellular calcium, resulting in rapid PS exposure.[50] The abnormal PS exposure in sickle RBCs may occur due to repeated cycles of sickling and unsickling linked to polymerization and depolymerization of HbS, which results in the production of terminal spicules or microvesicles with exposed PS.[51] The abnormal exposure of PS may also result from reduced flipase activity in RBCs due to oxidative stress and sulfhydryl modification.[49,52,53] Abnormal PS exposure functions as a recognition signal for cell removal during apoptosis of nucleated cells,[54] as well as a docking site for enzymatic complexes involved in coagulation and anticoagulation pathways.[50] The external exposure of PS alters the adhesive properties of sickle RBCs[55] and has been reported to be involved in the hemostatic changes observed in SCD.[56,57] Several data show evidence for a relationship between RBC PS exposure and the coagulation activation in SCD. Plasma levels of prothrombin fragment 1.2 (F1.2) are associated with the number of circulating PS-positive RBCs.[57] However, although the number of PS-positive sickle RBCs is significantly correlated with plasma F1.2, D-dimer, and plasmin–antiplasmin (PAP) complexes, no correlation is found between PS-positive platelets and any of these markers of coagulation activation,[56] suggesting that sickle RBCs, and not platelets, are responsible for the coagulation activation observed in SCD. Finally, sickle RBCs containing high amounts of HbF are less likely to result in microparticle (MP) formation, PS exposure, and thrombin generation,[57] suggesting a protective effect of HbF on membrane bilayer flip-flop and PS exposure.

Measures of hemolysis are associated with plasma markers of coagulation activation such as thrombin–antithrombin complexes (TAT), F1.2, and D-dimers in patients with SCD.[45,58] Heme, an inflammatory mediator and a product of intravascular hemolysis, has been reported to induce TF expression on the surface of both macrovascular and microvascular endothelial cells in a concentration-dependent manner.[59] In addition, heme resulted in an upregulation of the expression of TF mRNA, TF protein, and TF procoagulant activity in endothelial cells in a time-dependent manner, effects that may be mediated, at least in part, by the transcription factor, NFκB. Heme-induced endothelial TF expression may provide a pathophysiologic link between hemolysis and the coagulation activation observed in patients with SCD.

The inflammatory state in SCD may also contribute to coagulation activation. Studies in transgenic SCD mice demonstrate that exposure of the mild sickle cell phenotype, NY1DD mice, to a hypoxic environment for 3 hours followed by a return to ambient air for 18 hours resulted in increased TF expression in the pulmonary veins. Thus, ischemia-reperfusion injury in patients with SCD may play a pathophysiologic role in the activation of coagulation.[60] The endothelial TF expression in the NY1DD mouse appears to be highly dependent on NFκB (p50) in peripheral blood mononuclear cells but not in the vessel wall.[61] Furthermore, a study of NY1DD animals bred to overexpress endothelial nitric oxide synthase (eNOS) or to have an eNOS knockout state demonstrated that eNOS modulates endothelial TF expression *in vivo* by downregulating it, suggesting that the biodeficiency of NO, characteristic of SCD patients, may increase the risk of coagulation activation.[62]

Finally, increased levels of soluble CD40 ligand, a tumor necrosis factor family member, may contribute to coagulation activation in SCD. Plasma from patients with sickle cell anemia

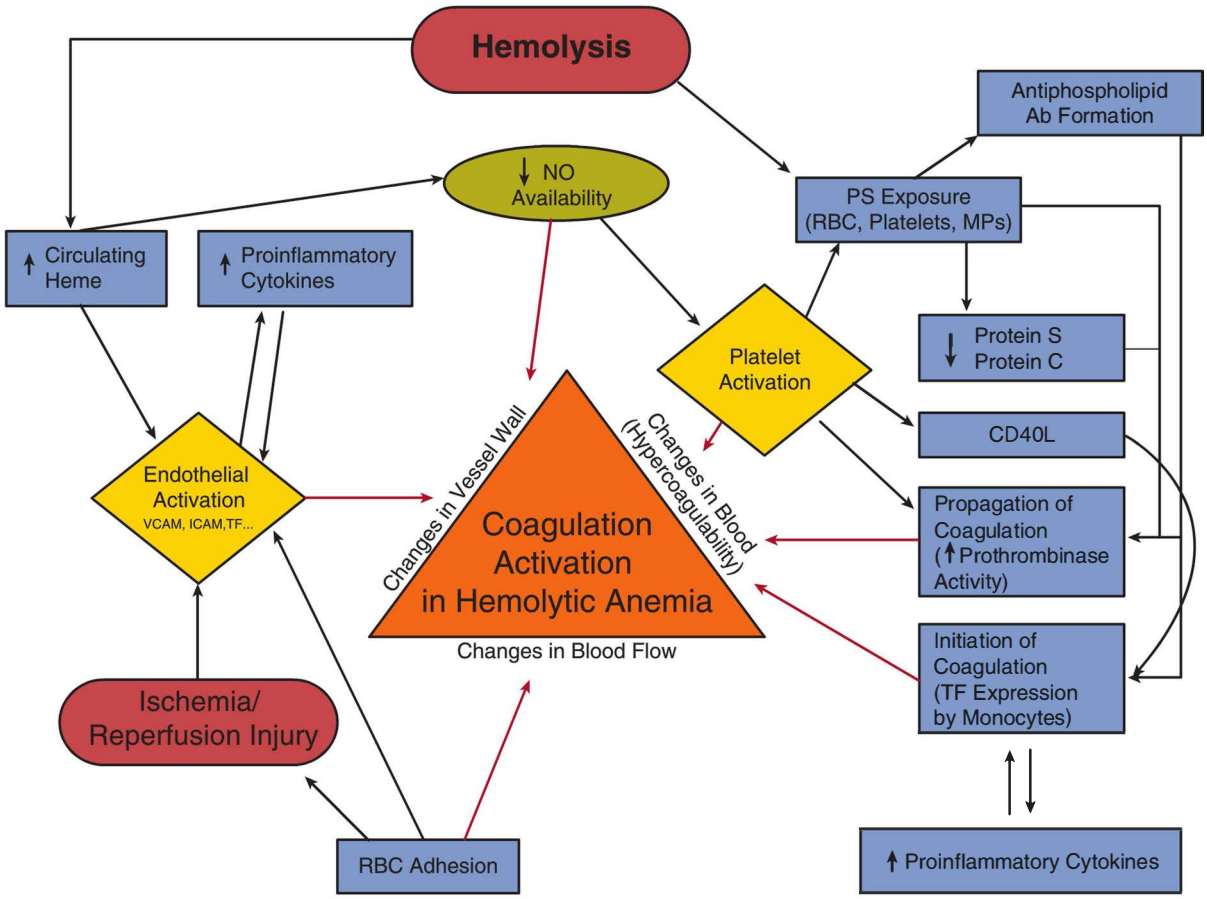

FIGURE 122.1 Schematic representation of pathophysiologic mechanisms (described or postulated) leading to activation of coagulation in SCD. Based on Virchow triad, the illustrated pathways contribute to activation of coagulation (and possibly eventual thrombosis) by one of three broad mechanisms, that is, (1) changes in the vessel wall; (2) changes in blood flow; and/or (3) changes in the composition of blood components ("hypercoagulability"). NO, nitric oxide; PS, phosphatidylserine; RBC, red blood cell; MPs, microparticles; TF, tissue factor; SCD, sickle cell disease. (Modified from Ataga KI, Key NS. Hypercoagulability in sickle cell disease: new approaches to an old problem. *Hematology Am Soc Hematol Educ Program* 2007:91–96.)

induced a significant increase in TF production in monocytic THP-1 cells relative to plasma from HbAA individuals or media alone.[44] Furthermore, preincubation of the THP-1 cells with a function blocking anti-CD40 antibody prevented increased TF expression in five of eight individual cases, suggesting that the CD40:CD40L interaction is only partly responsible for the elevation in TF production.

INCREASED TISSUE FACTOR EXPRESSION

The TF-FVIIa complex is the physiologic initiator of hemostasis.[63] Patients with SCD exhibit abnormal expression of TF on circulating endothelial cells, and this TF expression is increased further during acute pain episodes.[64] In addition, both TF antigen and TF procoagulant activity are elevated in the circulation of SCD patients when compared with normal controls,[44,65,66] although no difference in whole blood TF procoagulant activity was observed in patients in the non-crisis, "steady state" compared to those with pain crises.[65]

While numerous plasma factors that could increase TF expression in hematopoietic and/or endothelial cells such as thrombin, tumor necrosis factor, interleukin-1, and endotoxin are elevated in SCD patients, multiple potential mechanisms for the increased TF expression in these patients have recently been described. As already described, these include hemolysis with increased levels of heme,[59] ischemia-reperfusion injury,[60] as well as increased plasma levels of soluble CD40 ligand.[44]

CHANGES IN MARKERS OF THROMBIN GENERATION AND ANTICOAGULANT PROTEINS

Patients with SCD have increased plasma levels of markers of thrombin generation in the non-crisis, "steady state," although there are conflicting data on the effect of acute pain episodes on the levels of these markers.[67,68] Plasma levels of F1.2 and TAT complexes, both markers of thrombin generation, are elevated in SCD patients in the noncrisis, steady state.[67,68] Plasma levels of D-dimers,[66,67,68] PAP complexes,[67] and fibrinopeptide A[68] are also observed to be elevated in SCD patients in the non-crisis, "steady state." The frequency of pain episodes correlates with the extent of fibrinolytic activity (assessed by D-dimer levels) in

the non-crisis, "steady state," suggesting that D-dimer levels may predict the frequency of pain crises.[67]

The levels of natural anticoagulant proteins, protein C and protein S, are also decreased[68,69] in the non-crisis, "steady state" and perhaps even more so during acute pain episodes.[68,70] The reduced levels of these regulatory proteins may be a consequence of (a) chronic consumption due to increased thrombin generation resulting from intravascular TF expression and RBC prothrombinase activity; (b) increased binding of protein S by sickle RBCs due to red cell membrane PS exposure[71]; and/or (c) inhibition of the binding of protein S to β_2-glycoprotein 1 by antiphospholipid antibodies,[72] resulting in inactivation of protein S by circulating C4b-binding protein. Significantly decreased levels of proteins C and S have been reported in SCD patients who developed thrombotic strokes compared to neurologically normal SCD children.[73] Plasma levels of the serine protease inhibitor (SERPIN), heparin cofactor II, are also reported to be decreased in SCD patients.[74]

Antiphospholipid antibodies are frequently detected in SCD patients.[68] In addition, levels of certain subtypes of antiphospholipid autoantibodies, particularly those directed against PS, are markedly elevated in patients with sickle cell anemia, whereas they are normal in patients with HbSC disease.[68] In sickle cell anemia patients, a strong correlation exists between antibodies against PS and plasma D-dimers, suggesting a significant role for anti-PS antibodies in coagulation activation in SCD.[68]

PLATELETS, ENDOTHELIAL CELLS AND MICROPARTICLES

There is ample evidence suggesting that circulating platelets are chronically activated in patients with SCD, a phenomenon that may contribute to the observed coagulation activation in SCD.[44] Although there are conflicting reports of platelet survival,[75,76] platelet aggregation responses do appear to be increased in adult patients in the non-crisis, "steady state."[77] This may be explained by an increased number of circulating young, metabolically active platelets, or increased plasma levels of platelet agonists such as thrombin, epinephrine, and adenosine diphosphate. There is increased expression of both CD62P (P-selectin) and CD40L in platelets of SCD patients.[67,78] In addition to elevated plasma levels of the α-granule constituents, TSP, platelet factor 4, and β-thromboglobulin,[67] platelet-derived plasma soluble CD40 ligand is elevated in the non-crisis, "steady state," compared to normal controls.[44] The pathogenesis of platelet activation in SCD appears to be due, at least in part, to hemolysis with subsequent decreased bioavailability of NO.[79]

Circulating platelet aggregates (including both platelet–erythrocyte and platelet–monocyte aggregates) are increased in SCD patients during the non-crisis, "steady state"[77,80,81] and appear to increase further during acute pain episodes.[82] Platelets have also been detected in the heterotypic interaction between the monocyte and reticulocyte in a P-selectin/P-selectin glycoprotein ligand-1–dependent interaction.[83] Decreases in platelet lifespan and platelet counts have been reported during acute pain episodes.[75,76] In addition, acute pain episodes appear to be associated with increased platelet activation compared to the non-crisis, "steady state".[44,68] These findings suggest that decreased platelet survival and increased consumption occur during acute pain episodes.

Increased numbers of circulating endothelial cells have been reported in SCD patients in the non-crisis, "steady state," with a further increase during acute pain episodes.[42] In addition to expressing adhesion markers, these circulating cells abnormally express TF antigen in the "steady state", and to a greater extent during acute pain episodes.[64] Furthermore, these endothelial cells are positive for TF mRNA, with excellent correlation between TF antigen and mRNA expression.[64]Circulating MPs, small membrane-derived vesicles released by cells following activation or apoptosis, may be derived from RBCs, platelets, endothelial cells, and monocytes.[41] Both the total number of MPs as well as the number of TF-positive MPs are increased in SCD patients, with further increases during acute pain episodes. These TF-positive MPs are derived from endothelial cells and monocytes, but not from RBCs and platelets.[84] Plasma markers of coagulation activation, such as D-dimer, TAT, and F1.2, appear to correlate with total MPs, total TF-positive MPs, monocyte-derived TF-positive MPs, and with RBC-derived MPs,[84] suggesting a role for MPs in the hypercoagulable state observed in patients with SCD. In a more recent study, the majority of MPs in SCD patients were reported to originate from platelets and erythrocytes, and the numbers of these MPs did not differ significantly between crisis and steady state.[85] No MPs originating from monocytes or endothelial cells were detectable and no MPs expressing TF were identified.[85] However, erythrocyte-derived MPs correlated strongly with plasma levels of hemolytic markers, as well as with vWF, D-dimer, and F1.2 levels.

THERAPEUTIC IMPLICATIONS

Despite the abundant laboratory evidence of both platelet and coagulation activation in SCD patients, the vast majority of studies using anticoagulants and antiplatelet agents have not provided any convincing benefit in the prevention or treatment of vaso-occlusive complications. As most of these studies have been small and/or poorly controlled, it still remains uncertain whether the observed platelet and coagulation activation observed in these patients contribute to the vascular occlusive episodes that characterize SCD.

Multiple studies of anticoagulants[86,87,88,89,90] (Table 122.1) and antiplatelet agents[91–96] (Table 122.2) have been conducted in SCD patients with varying results. Unfractionated heparin decreases the adhesion of sickle RBCs to endothelium under static conditions, as well as P-selectin–mediated flow adherence of sickle cells to thrombin-treated human vascular endothelial cells.[97] A randomized, double-blind, placebo-controlled study of SCD patients during acute pain episodes showed that treatment with the low molecular weight heparin, tinzaparin, resulted in a significant reduction in the overall duration of painful crisis, number of days with the most severe pain scores, and duration of hospitalization compared with placebo.[90] The glycoprotein IIb/IIIa inhibitor, eptifibatide, was reported to be safe in a pilot study of sickle cell anemia patients.[96] By inhibiting platelet aggregation and decreasing the levels of the inflammatory mediator, soluble CD40 ligand, eptifibatide may be beneficial in the treatment of certain SCD-related complications.[96] Table 122.3 shows the rationale for the use of anticoagulants or antiplatelet agents in selected SCD-related complications.

Hydroxyurea is the only drug approved by the U.S. Food and Drugs Administration specifically for treating SCD. It has been shown to reduce the frequency of hospitalizations, acute painful

Table 122.1

Published studies of anticoagulants in patients with SCD

Study	Genotype	Number of Subjects	Treatment	Randomized	Duration	Efficacy Outcome
Salvaggio (1963)	HbSS	12	Warfarin	No	12–34 mo	Modest ↓ frequency of VOE
Chaplin (1989)	HbSS	4	Heparin	No	2–6 y	↓ Frequency of VOE
Wolters (1995)	HbSS HbSC	6 1	Acenocoumarol	No	2 mo	↓ F1+2
Schnog (2001)	HbSS HbSC	14 8	Acenocoumarol vs. placebo	Yes	14 wk	↓ Markers of coagulation markers, no ↓ in VOE with active treatment
Qari (2007)	HbSS	253	Tinzaparin vs. placebo	Yes	Maximum (7 d)	↓ in days with most severe pain score, duration of overall pain crisis and hospitalization duration with active treatment

VOE, Vaso-occlusive episodes

Table 122.2

Published studies of antiplatelet agents in patients with SCD

Study	Genotype	Number of Subjects	Therapy	Randomized	Duration	Efficacy Outcome Measure and Results
Chaplin et al. (1980)	HbSS	3	Aspirin/ Dipyridamole	No	104 wk	Modest decrease in frequency of pain episodes, platelet count, and fibrinogen level
Osamo[a] (1981)	HbSS	100	Aspirin	Yes	6 wk	Increase in oxygen affinity, hemoglobin, and RBC life span
Greenberg (1983)	HbSS HbSC HbS-O Arab	40 8 1	Aspirin vs. placebo	Yes	21 mo	No decrease in frequency of pain episodes
Semple (1984)	HbSS HbS-β thalassemia	8 1	Ticlopidine vs. placebo	Yes	4 wk	No improvement in frequency of pain episodes or platelet survival, but decrease in platelet release products
Cabannes[b] (1984)	HbSS	140	Ticlopidine vs. placebo	Yes	6 mo	Reduction of frequency and duration of pain episodes
Zago (1984)	HbSS HbS-β thalassemia	25 4	Aspirin vs. placebo	Yes	5 mo	No differences in frequency of pain episodes, hemoglobin, reticulocyte count, irreversibly sickled cells and HbF level
Lee (2007)	HbSS	4	Eptifibatide	No	1 wk	Decrease in platelet aggregation, decrease in plasma level of soluble CD40 ligand, and decrease in MIP-1α, TNFα, and myoglobin

[a]Increase from baseline in hemoglobin (7.5 ± 0.35 to 10 ± 0.39 g/dL, $P < 0.01$), O_2 saturation (80 ± 3.6% to 94 ± 3.7%, $P < 0.01$), pO_2 (52 ± 2.7 to 68 ± 2.9 mm Hg, $P < 0.01$), and decrease in 2,3-diphosphoglycerate levels (7.2 ± 0.24 to 4.6 ± 0.20 μmol/mL, $P < 0.01$) in patients on aspirin after 6 wk of treatment. No data provided for patients on placebo.
[b]Decrease in number of crises (−81% vs. −47%, $P = 0.0001$) and duration of crises (2.862 ± 1.75 d vs. 3.952 ± 2.2 d, $P = 0.001$) in patients on ticlopidine vs. placebo.

Table 122.3

Rationale for use of anticoagulants and/or antiplatelet agents in SCD

Complication	Anticoagulant/ Antiplatelet Agent	Caveat
Retinopathy	No	This is no evidence to support the use of anticoagulants or antiplatelet agents in this setting. Furthermore, these agents may increase the risk of bleeding in patients with neovascular malformations.
Thrombotic stroke	? Antiplatelet agent	Chronic RBC transfusion remains the standard of care in the management of thrombotic stroke in children with SCD. Although thrombotic stroke occurs less commonly in adult patients, chronic transfusion is also the accepted treatment. With the finding of superimposed thrombosis in large cerebral vessels in these patients, antiplatelet agents may be useful, particularly in those patients in whom RBC transfusion is not feasible. However, controlled clinical studies are required. There is concern about the use of anticoagulants in this setting because of the risk of intracranial bleeding, particularly in those patients with Moyamoya.
Pulmonary hypertension	? Anticoagulant	Anticoagulants are reported to prolong survival in patients with pulmonary arterial hypertension. With the similar pathologic findings of *in situ* thrombosis in SCD patients with pulmonary hypertension, anticoagulants may be similarly beneficial. Controlled studies of anticoagulants in SCD-associated pulmonary hypertension are required to confirm their benefit in this setting.
Acute pain episodes	? Anticoagulant/ antiplatelet agent	Although not standard of care, full dose anticoagulation with the low molecular weight heparin, tinzaparin, has been shown to shorten the duration of acute pain episodes. In addition, as platelets exhibit increased activation during acute pain episodes compared to the "steady state," antiplatelet agents may also be useful in this setting.
Acute chest syndrome	No	While pulmonary fat embolism is a known cause of acute chest syndrome, there is no evidence that thrombotic embolism is associated with acute chest syndrome. As a result, therapeutic anticoagulation is not recommended. However, as for most SCD-related hospitalizations, prophylactic anticoagulation to decrease the risk of deep venous thrombosis is required, unless there is a contraindication.
Priapism	No	This is no evidence to support the use of anticoagulants or antiplatelet agents in this setting.
Deep venous thrombosis/ pulmonary embolism	Yes	Anticoagulation is indicated. Although SCD is referred to a hypercoagulable state, the duration of anticoagulation is uncertain as the risk of recurrence is not defined. Most patients are treated based on recommendations for patients without SCD.
Leg ulcers	No	This is no evidence to support the use of anticoagulants or antiplatelet agents in this setting.

episodes, acute chest syndrome, and blood transfusions in severe sickle cell anemia.[98] Furthermore, treatment with hydroxyurea is reported to reduce mortality in adults with severe SCD.[99,100,101] Treatment modalities frequently employed in SCD appear to affect the hemostatic system in these patients. Hydroxyurea and the hypomethylating agent, decitabine (that also increases levels of HbF), have been reported to decrease plasma levels of markers of thrombin generation.[102,103] Prophylactic RBC transfusion significantly reduces the risk of strokes in children with sickle cell anemia. It has been proposed that the beneficial effect may in part be related to normalization of the levels of F1.2,[104] although another study found no significant reduction

in thrombin generation when children with SCD undergoing chronic transfusion were compared with normal controls.[105]

STROKE

The Cooperative Study of Sickle Cell Disease (CSSCD) defined stroke as "an acute neurologic syndrome due to vascular occlusion or hemorrhage in which neurologic symptoms lasted more than 24 hours."[12] In addition, imaging studies may show infarction of the brain in the absence of a history of neurologic symptoms, a condition referred to as "silent infarction." Neurologic symptoms lasting <24 hours are considered to be the result of a transient ischemic attack (TIA). However, if the results of neuroimaging studies show the presence of infarcts or hemorrhage, the patients are usually classified as having had a stroke.[106]

Based on data from the CSSCD, a natural history study that followed approximately 4,000 patients for up to 10 years, the overall prevalence of stroke in SCD was 4%, with a prevalence of 5% in patients with sickle cell anemia.[12] The annual incidence of first stroke was approximately 0.6 per 100 patient-years in sickle cell anemia, with the highest incidence occurring in the first decade of life with rates of 1.02 per 100 patient-years in sickle cell anemia patients 2 to 5 years of age and 0.8 in those 6 to 9 years of age. The cumulative risk of first stroke in patients with sickle cell anemia was 11% by age 20 years, 15% by 30 years, and 24% by 45 years.[12] Infarctive strokes are relatively more common in children than in adults, and hemorrhagic strokes are more common in adults. In the CSSCD report, the risk of hemorrhagic stroke (0.44 per 100 patient-years) was highest in the 20 to 29 year age group.

Prior TIA, low steady-state hemoglobin level, systolic blood pressure, acute chest syndrome within 2 weeks of the stroke event, and the rate per year of acute chest syndrome were found to be significant risk factors for infarctive stroke in the CSSCD.[12] Low steady-state hemoglobin levels and high white blood cell counts were significant risk factors for hemorrhagic stroke. In addition, the protective effect of alpha thalassemia on the incidence of stroke in sickle cell anemia was due largely to the improvement in steady-state hemoglobin level. There was no association between the frequency of pain episodes and stroke. Furthermore, the level of HbF was not associated with the risk of stroke.[12] Nocturnal hypoxemia is also recognized as a risk factor for acute neurologic events (stroke, TIA, or seizures).[107] However, the best predictor of stroke risk at the present time is an elevated transcranial Doppler (TCD) velocity.[108]

Genetic factors may increase the risk for stroke in SCD patients. In a clinical epidemiology study, 42 sibships of patients with sickle cell anemia in which one sibling had a stroke showed a greater than expected number of families having two or more children with a stroke.[109] HLA Class I and II typing of sickle cell anemia patients showed differences in Class I HLA-B, Class II HLA-DRB1, and DQB1 between 22 patients with cerebral infarction detected by magnetic resonance imaging (MRI) and 31 with normal MRI examination.[110] Although there are conflicting reports on the association between stroke and β-globin haplotypes,[109,111,112] coinheritance of alpha thalassemia genes may be associated with diminished stroke risk.[12,113,114] Single nucleotide polymorphisms (SNPs) within the vascular cell adhesion molecule-1 gene may influence the risk of stroke, although no increased risk was noted with genes regulating immune function and inflammation.[115,116] Distinct allelic associations were found with stroke in children enrolled in the CSSCD. In this population, the TNF(-308)A, IL4R 503P, and ADRB2 27E polymorphisms were associated with the large vessel subtype of stroke,[115] a finding that has been replicated in an independent population of children with sickle cell anemia.[117] A Bayesian network, a multivariate dependency model that accounts for simultaneous associations and interactions among multiple genes and their interplay with clinical and physiologic factors, was used to analyze 108 SNPs in 39 candidate genes involved in vasoregulation, inflammation, cell adhesion, coagulation, hemostasis, cell proliferation, oxidative biology, and other functions using data and samples from 1,398 patients in the CSSCD.[118] Eleven genes whose variants had a direct effect modulated by levels of hemoglobin F and nine genes whose variants were indirectly associated with stroke were determined in 92 patients with overt stroke and the results were validated in a population of 114 individuals not included in the original study. The model predicted the correct outcome for all individuals with stroke and for 105/107 individuals without stroke, yielding an overall predictive accuracy of 98%. Finally, using blood outgrowth endothelial cells from patients shown to be either at risk or not at risk for ischemic stroke, gene expression profiling identified no significant single gene differences between the two groups, although an analysis of Biological Systems Scores, using gene sets that were predetermined to survey each of nine biologic systems, suggested that the pathobiology of circle of Willis disease in sickle cell anemia predominantly involves inflammation biology.[119]

The pathogenesis of cerebral infarction in children with SCD is not simply sickling of RBCs in the microcirculation. Large vessel arterial obstruction with superimposed thrombosis is commonly observed in SCD patients with ischemic stroke.[120] In response to chronic anemia and hypoxemia, cerebral blood flow is markedly increased in SCD.[121] When acute or chronic conditions lead to diminished availability of oxygen, the increased hypoxic stress combined with the inability of the cerebral vasculature to undergo further dilatation leads to ischemia.[110]

Endothelial injury is likely a major contributor to the pathophysiology of stroke in SCD. Chronic intravascular hemolysis is associated with a state of endothelial dysfunction characterized by reduced NO bioavailability and pro-oxidant and pro-inflammatory stress, resulting in a proliferative vasculopathy.[122] It has been proposed that pulmonary hypertension, priapism, leg ulceration, and stroke may be linked to the intensity of hemolysis.[122] A case series reported the association of obliterative central nervous system vasculopathy with pulmonary hypertension and a high rate of hemolysis in six patients with SCD.[123] Compared with 164 patients of similar age, those with newly diagnosed or clinically active cerebrovascular disease had significantly lower hemoglobin and higher lactate dehydrogenase levels.[123] Levels of plasma-free hemoglobin, lactate dehydrogenase, and bilirubin were found to be lower in patients receiving chronic transfusion as treatment for the secondary prevention of stroke.[124] A study of 74 adult SCD patients, 11 with a history of stroke, showed lower hemoglobin levels and higher levels of lactate dehydrogenase, soluble VCAM, and PlGF in patients with a history of stroke, although the difference in PlGF did not achieve statistical significance.[125]

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) addressed the use of prophylactic RBC transfusion in sickle cell anemia patients aged between 2 and 16 years, at high risk for an initial stroke based on TCD ultrasonography.[126] The incidence

of stroke in patients randomized to receive prophylactic transfusions to reduce the hemoglobin S level below 30% (1 of 63) was significantly decreased compared to those patients who received standard care (11 of 67). The optimum duration of chronic transfusion necessary to provide protection from a cerebrovascular event remains uncertain. In the Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP 2) trial, involving 79 patients with abnormal TCD before transfusion and who had received at least 30 months of RBC transfusion, the patients were randomized to stop or continue transfusions.[127] Of the 41 patients who were randomized to discontinue RBC transfusion, 16 reached the primary end-point events (14 patients reverted to high-risk TCD and 2 patients had ischemic strokes) compared to neither of these events in the 38 patients on continued RBC transfusions. Based on these results, discontinuation of chronic transfusion after 30 months cannot be recommended. There are, to date, no primary prevention trials of cerebrovascular events in older patients with SCD.

The recurrence rate of stroke in children with ischemic events not receiving subsequent treatment was found to be 66%.[128] Two case series demonstrated that long-term blood transfusion substantially reduced the risk of recurrence.[129,130] The current clinical practice is to begin a chronic transfusion program to maintain the HbS level below 30%. After 3 to 4 years a decrease in frequency of transfusion to allow the target value to rise to 50% may be considered.[131] Randomized clinical trials addressing the duration of transfusion for secondary stroke prevention have not been conducted. Children stopping transfusion after 5 to 12 years experienced a 50% recurrence rate.[132] The current standard of care is to continue a chronic transfusion program indefinitely. Recurrent events are observed for patients continuing on a chronic transfusion program. A retrospective multicenter study of 137 children with stroke maintained on chronic transfusion for at least 5 years reported a recurrence rate of 2.2 per 100 patient-years.[133]

Hydroxyurea therapy combined with phlebotomy has been evaluated in children as an alternative to chronic transfusion.[134] The stroke recurrence rate was 5.7 events per 100 patient-years with a mean duration of 3.5 years of follow-up. The protocol was modified to overlap hydroxyurea rather than abruptly discontinuing transfusions and resulted in a reduced recurrence rate of 3.6 events per 100 patient-years. A recent multicenter randomized controlled trial examining hydroxyurea and phlebotomy as an alternative to chronic RBC transfusion and iron chelation for the prevention of secondary stroke and reduction of transfusional iron overload was discontinued due to an increased rate of stroke in the hydroxyurea and phlebotomy arm and no differences in the level of iron overload.[135]

PULMONARY HYPERTENSION

Pulmonary hypertension is defined as a mean pulmonary artery pressure that exceeds 25 mm Hg at rest on right heart catheterization.[136] Multiple studies, based on echocardiographic assessment, suggest a high prevalence of pulmonary hypertension in adult patients with SCD, with prospective screening studies reporting a prevalence of approximately 30%.[137,138] More recently, a multicenter study found no evidence of pulmonary hypertension following right heart catheterization in 72 of 96 patients with elevated tricuspid regurgitant jet velocities on echocardiography, suggesting that Doppler echocardiography may overestimate the prevalence of this condition.[139] Although several studies report that children have a varying prevalence of elevated tricuspid regurgitant jet velocity on echocardiography,[140–143] the significance of this elevation remains uncertain.

Right heart catheterization of SCD patients with pulmonary hypertension shows evidence of a hyperdynamic state.[137,144] The mean pulmonary artery pressure in SCD patients with pulmonary hypertension is approximately 40 mm Hg, and pulmonary vascular resistance is approximately 250 dyn·sec·cm^{-5}.[145] The relatively low pulmonary vascular resistance is thought to be due to the high cardiac output that is characteristic of anemia. Up to 40% of patients have left ventricular end-diastolic pressures that are >15 mm Hg, indicating a component of left ventricular diastolic dysfunction.[146] Despite the relatively low pulmonary vascular resistance in SCD-associated pulmonary hypertension, these patients have an increased risk of death.[137,145,147,148] Follow-up from a prospective study of pulmonary hypertension in SCD[137] showed that patients with a tricuspid regurgitant jet velocity of 2.5 to 2.9 m/s had a rate ratio for death of 4.4 (95% CI, 1.6 to 12.2; $P < 0.001$) compared with those with a velocity of <2.5 m/s. Patients with a velocity of 3.0 m/s or more had a rate ratio of 10.6 (95% CI, 3.3 to 33.6; $P < 0.001$).[145] Furthermore, patients with both elevated tricuspid regurgitant jet velocity and echocardiographic evidence of diastolic dysfunction are at particularly high risk for death (relative risk ratio, 12.0; 95% CI, 3.8 to 38.1; $P < 0.001$).[149] It remains uncertain whether pulmonary hypertension, particularly at lower tricuspid regurgitant jet velocities, is causative of death or is simply a marker of a severe vasculopathy that predicts an increased risk of death.

The pathophysiology of pulmonary hypertension in SCD is likely multifactorial. The destruction of nitric oxide (NO) by cell-free plasma hemoglobin and reactive oxygen species may play a central role.[150–152] NO is normally produced by the endothelium and regulates basal vasodilator tone,[153,154] inhibits platelet and hemostatic activation,[155–157] inhibits transcriptional expression of NFκB–dependent adhesion molecules such as VCAM-1, intercellular adhesion molecule-1, and the selectins, and reduces superoxide levels through radical scavenging.[158] Furthermore, arginase, which converts L-arginine (the substrate for NO synthesis) to ornithine, is released following hemolysis,[159] and elevated arginase activity, with the resultant decrease in the arginine/ornithine ratio, is associated with pulmonary hypertension in SCD.[137,160] Recently, doubts have been raised about the role of NO depletion in the pathophysiology of pulmonary hypertension in SCD.[161] These authors argue that SCD-associated pulmonary hypertension is more likely due to pulmonary embolization or *in situ* thrombosis than by NO scavenging by elevated plasma hemoglobin. However, several mouse models of hemolysis, including the Berkeley sickle cell mouse[162] and the spherocytosis mouse,[163] have been shown to develop spontaneous pulmonary hypertension and right heart failure. In addition, pathologic evaluation in these models found no chronic thrombosis in the pulmonary vasculature, but rather a functional impairment in NO signaling driven by NO scavenging by plasma hemoglobin.[164] Increased levels of erythropoietin,[165] PlGF,[166–168] soluble fms-like tyrosine kinase-1,[169] platelet-derived growth factor-BB,[170] as well as interleukin-6 and possibly other cytokines[45,170] are associated with elevated tricuspid regurgitant jet velocity, while high vascular endothelial growth factor concentration has been reported to be associated with decreased odds of elevated tricuspid regurgitant velocity in SCD patients.[170]

Although pulmonary emboli and in situ thrombosis are often identified clinically or at autopsy in SCD patients with lung disease (171,172), large to medium sized pulmonary artery obstruction has been reported to be uncommon following ventilation-perfusion scintigraphy of SCD patients with elevated tricuspid regurgitant jet velocity.[173] Following three dimensional, contrast-enhanced, magnetic resonance angiography in six adult sickle cell anemia patients with an elevated tricuspid regurgitant jet velocity, five had no thrombi in their pulmonary arteries, with filling defects observed in only one patient with multiple hospitalizations for pain and acute chest syndrome.[174] Platelet activation marked by activated fibrinogen receptor is correlated with the tricuspid regurgitant jet velocity and may contribute to thrombosis and pulmonary hypertension in SCD.[79] Although several studies have shown correlations between the measures of hemolysis and the plasma markers of thrombin generation in SCD,[45,173,175] no significant differences in these markers have been identified in SCD patients with pulmonary hypertension diagnosed based on Doppler echocardiography compared with patients without this complication.[45,173] However, it is possible that plasma-based studies may not be sensitive enough to detect differences in hypercoagulability in these patients. Indeed, a recent study in patients with β thalassemia, a condition characterized by hypercoagulability,[176] much like SCD, showed evidence of hypercoagulability upon evaluation using whole blood thromboelastometry, while thrombin generation determined in platelet-poor plasma was not significantly different from that in healthy individuals.[177] There are, to date, no published studies evaluating hypercoagulability in SCD-associated pulmonary hypertension using thromboelastometry of whole blood. Multiple studies in SCD have shown an association between nephropathy and pulmonary hypertension diagnosed using Doppler echocardiography,[137,147,148] suggesting that both complications may share a similar pathophysiology. Soluble fms-like tyrosine kinase-1, a vascular endothelial growth factor receptor family member, by inducing endothelial dysfunction, may be a link between nephropathy and pulmonary hypertension in SCD.[178] Finally, although it is widely held that repeated episodes of the acute chest syndrome, with resulting chronic lung disease, causes pulmonary hypertension,[179] multiple studies show no association between pulmonary hypertension and history of acute chest syndrome.[137,147,148,180]

The symptoms of pulmonary hypertension in patients with SCD are nonspecific in the early stages.[181] With the association of pulmonary hypertension with increased mortality, many experts in the field recommend screening using Doppler echocardiography.[137,147] However, as Doppler echocardiography may overestimate the presence of pulmonary hypertension, a right heart catheterization is required to confirm the diagnosis and obtain additional hemodynamic measurements. The 6-minute walk test has been validated in SCD and correlates inversely with the tricuspid regurgitant jet velocity as well as the estimated pulmonary artery systolic pressure.[182] Evaluation and management of these patients should be performed by a hematologist and pulmonologist or cardiologist with expertise in pulmonary hypertension.

There is no consensus on the management of SCD-associated pulmonary hypertension. As hypoxia results in pulmonary vasoconstriction,[183] supplemental oxygen would be expected to be beneficial in hypoxic patients. Patients with breathing disorders during sleep should also be evaluated for nocturnal hypoxia. Although there are conflicting reports on the effect of hydroxyurea in this setting[137,147,165] and the role of blood transfusion remains uncertain, it is generally accepted that SCD treatment should be maximized. There are no studies of anticoagulation as treatment for pulmonary hypertension. However, as SCD is characterized by hypercoagulability, patients with pulmonary thromboembolic disease associated with pulmonary hypertension will likely benefit from anticoagulation. Chronic thromboembolic pulmonary hypertension in SCD has been treated surgically with success.[184] A short course of oral arginine given to 10 SCD patients with PHT produced a significant decline in the estimated pulmonary artery systolic pressures.[185] However, adequately powered, controlled studies are required to confirm the efficacy of arginine in these patients. Two randomized, double-blind, placebo-controlled studies of bosentan, a dual endothelin-1 receptor antagonist, in SCD patients with pulmonary arterial hypertension and pulmonary venous hypertension were discontinued for slow accrual.[186] More recently, a randomized, placebo-controlled, multicenter trial of sildenafil, a phosphodiesterase-5 inhibitor, as treatment for SCD-associated pulmonary hypertension was terminated prematurely due to an increased frequency of pain crises in the active treatment group compared with placebo.[187]

CHAPTER

123 Thrombohemorrhagic Complications of Sepsis

MARCEL LEVI

Sepsis is a clinical syndrome that is caused by an infection, often associated with bacteremia and characterized by the presence of systemic signs and symptoms of inflammation.[1] When sepsis leads to organ failure, the term severe sepsis is used. The incidence of sepsis is estimated to be about 2.5 per 1,000 in the Western world and shows a rapid 8.7% annual increase over the last 20 years.[2] Total inhospital mortality of sepsis is around 20%, whereas severe sepsis is associated with mortality rates of 40% to 50%.[3] Treatment of sepsis is focused on adequate antibiotic therapy, source control, and appropriate supportive care and organ function replacement, if required.

Virtually all patients with sepsis have coagulation abnormalities. These abnormalities range from subtle activation of coagulation that can only be detected by sensitive markers for coagulation factor activation to somewhat stronger coagulation activation that may be detectable by a small decrease in platelet count and prolongation of global clotting times to fulminant disseminated intravascular coagulation (DIC), characterized by simultaneous widespread microvascular thrombosis and profuse bleeding.[4,5] Septic patients with severe DIC may present with manifest thromboembolic disease or clinically less apparent microvascular fibrin deposition and multiple organ dysfunction.[6,7,8] Alternatively, severe bleeding may be the leading symptom,[9] but quite often a patient with DIC has simultaneous thrombosis and bleeding. Bleeding is caused by consumption and subsequent exhaustion of coagulation proteins and platelets, due to the ongoing activation of the coagulation system.[10] In its most severe form, this combination may present as the Waterhouse-Friderichsen syndrome as seen during fulminant septicemia.[11]

INCIDENCE OF COAGULATION ABNORMALITIES IN SEPSIS

Clinically relevant coagulation abnormalities may occur in 50% to 70% of patients with sepsis, whereas about 35% of patients will meet the criteria for DIC.[1,12] In general, the incidence of thrombocytopenia (platelet count $<150 \times 10^9$/L) in critically ill medical patients is 35% to 50%.[13–15] Typically, the platelet count correlates with sepsis severity, decreasing during the first 4 days of illness.[16,17] The factors that contribute to thrombocytopenia are impaired platelet production and increased consumption, destruction, or sequestration. Although the high levels of platelet production-stimulating proinflammatory cytokines and thrombopoietin circulate,[18] marked hemophagocytosis by monocytes and macrophages[19] and thrombin-induced platelet activation and destruction at the endothelial cell surface explain the thrombocytopenia.[20] A prolonged global coagulation time (prothrombin time [PT] or activated partial thromboplastin time [aPTT]) occurs in 14% to 28% of patients.[21,22] Other coagulation abnormalities include high fibrin split products in virtually all patients with sepsis[23,24,25] and decreased levels of coagulation inhibitors, such as antithrombin-3 (AT3) and protein C in 90% of sepsis patients.[25,26]

RELEVANCE OF COAGULATION ABNORMALITIES IN PATIENTS WITH SEPSIS

There is strong evidence that activation of coagulation in concert with inflammatory activation can result in microvascular thrombosis, which contributes to multiple organ failure in patients with severe sepsis.[27] Autopsy findings include diffuse bleeding and microthrombi in small blood vessels and thrombi in midsize and larger arteries and veins, in association with ischemia and necrosis.[28–30] Further, experimental bacteremia or endotoxemia causes intra- and extravascular fibrin deposition in kidneys, lungs, liver, and brain, and interventions in these experimental models improve organ failure and, in some cases, mortality.[31–33,34,35] Last, clinical studies support the notion of coagulation as an important denominator of clinical outcome, DIC being an independent predictor of organ failure and mortality in patients with sepsis,[6,36] associated with mortality in 43%, as compared with 27% in patients without DIC.[37]

Thrombocytopenia in patients with sepsis is related to an increased risk of bleeding, those with a platelet count of $<50 \times 10^9$/L having a four- to fivefold higher risk than patients with a higher platelet count.[13,15] The overall risk of intracerebral bleeding in ICU patients with sepsis is relatively low (0.3% to 0.5%). However 88% of patients with intracranial bleeding have platelet counts $<100 \times 10^9$/L.[38] Regardless of the cause, thrombocytopenia is an independent predictor of ICU mortality in multivariate analyses, with a relative risk of 1.9 to 4.2.[13,15,39] In particular, a sustained thrombocytopenia for more than 4 days after ICU admission or a drop in platelet count of >50% during ICU stay is related to a four- to sixfold increase in mortality.[13,16] The platelet count is a stronger predictor for ICU mortality than composite scoring systems, such as the Acute Physiology and Chronic Health Evaluation (APACHE) II score or the Multiple Organ Dysfunction Score. Prolonged global coagulation tests to >1.5 times control also predict excessive bleeding and increased mortality.[21,22]

PATHOGENETIC PATHWAYS IN THE COAGULOPATHY OF SEPSIS

Various mechanisms at different sites in the hemostatic balance act simultaneously toward a procoagulant state (FIGURE 123.1), the most important mediators of which are cytokines.[40] There

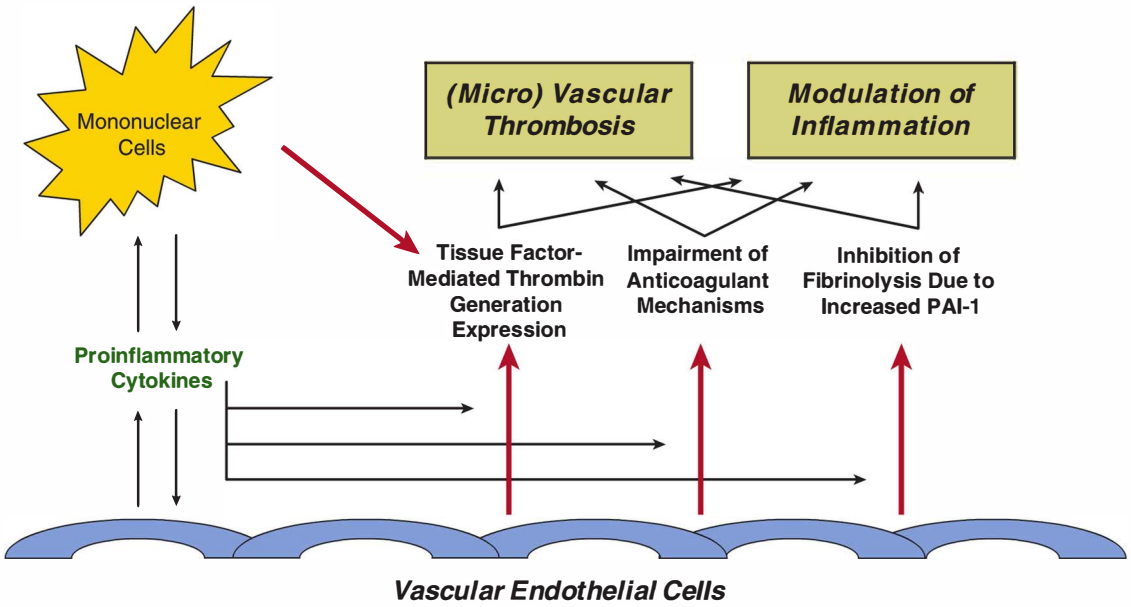

FIGURE 123.1 Schematic representation of pathogenetic pathways involved in the activation of coagulation in sepsis. During sepsis, both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that mediate coagulation activation. Activation of coagulation is initiated by TF expression on activated mononuclear cells and endothelial cells. In addition, downregulation of physiologic anticoagulant mechanisms and inhibition of fibrinolysis by endothelial cells will further promote intravascular fibrin deposition. PAI-1; plasminogen activator inhibitor type 1.

is extensive cross-talk between inflammation and coagulation,[41] and interestingly, systemic activation of coagulation and inflammation in sepsis can have some organ-specific manifestations.[42]

Initiation of Coagulation Activation

Systemic activation of coagulation in patients with sepsis has been considered to be a result of direct activation of the contact system by microorganisms or endotoxin.[43] However, it has become apparent that the principal initiator of thrombin generation in sepsis is tissue factor (TF), without significant change in markers reflecting activation of the contact system.[44,45] Furthermore, abrogation of the TF/factor VII(a) pathway by monoclonal antibodies completely inhibits thrombin generation in endotoxin-challenged chimpanzees and prevents DIC and mortality in baboons that are infused with *Escherichia coli*[33,46,47]

TF is a transmembrane 45 kDa protein, that is constitutively expressed on a number of cells throughout the body.[48] The majority of these cells are in tissues not in direct contact with blood, such as the adventitial layer of large blood vessels. However, TF gets into contact with blood upon disruption of the vascular integrity, or if cells present in the circulation are altered to express TF. In sepsis, circulating mononuclear cells, stimulated by proinflammatory cytokines, express TF, but other than in severe meningococcemia,[49] it is difficult to demonstrate *ex vivo* TF expression on monocytes of septic patients or experimental animals. However, low dose endotoxemia in healthy subjects results in a 125-fold increase in monocyte TF mRNA levels.[50] Another source of TF may be on polymorphonuclear cells,[51] although it is unlikely that these cells actually synthesize TF in substantial quantities.[52] Based on the transfer of TF from leukocytes to activated platelets in an *ex vivo* perfusion system, it is hypothesized that this "blood borne" TF is transferred between cells through microparticles derived from activated mononuclear cells.[53]

Platelets play a pivotal role in the pathogenesis of coagulation abnormalities in sepsis. Platelets can be activated directly by proinflammatory mediators, such as platelet activating factor.[54] Once thrombin forms, additional platelets are activated, which then accelerates further fibrin formation. The expression of P-selectin on the platelet membrane not only mediates the adherence of platelets to leukocytes and endothelial cells but also enhances the expression of TF on monocytes by nuclear factor kappa-B (NFκB) activation.[55] P-selectin is shed from the platelet membrane and soluble P-selectin levels are increased during systemic inflammation.[55]

Impairment of the Antithrombin, Protein C, and TFPI Anticoagulant Pathways in Sepsis

Activation of coagulation is regulated by three major anticoagulant pathways, namely, AT3, the protein C system, and TF pathway inhibitor (TFPI). During sepsis-induced activation of coagulation, the function of all three pathways can be impaired (FIGURE 123.2).

AT3 is a serine protease inhibitor and the main inhibitor of thrombin and factor Xa. During severe inflammatory responses, AT3 levels are markedly decreased due to consumption (as a result of ongoing thrombin generation), impaired synthesis (as a result of a negative acute phase response), and degradation by elastase from activated neutrophils.[56,57] A reduction in

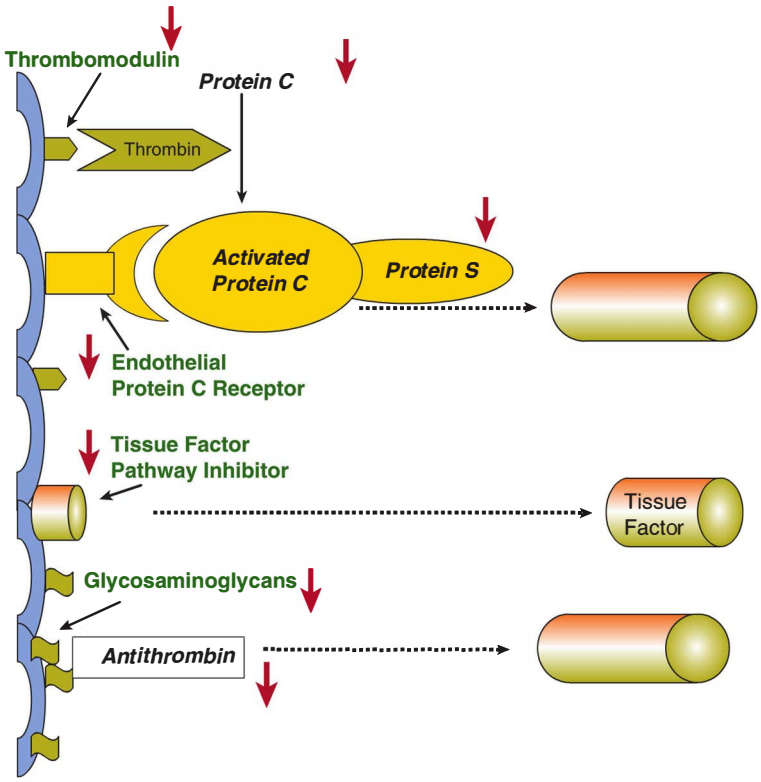

FIGURE 123.2 Schematic representation of the three important physiologic anticoagulant mechanisms and their point of impact in the coagulation system. In sepsis, these mechanisms are impaired by various mechanisms (*red arrows*). The protein C system is dysfunctional due to low levels of zymogen protein C, downregulation of TM and the EPCR, and low levels of free protein S due to acute phase-induced high levels of its binding protein, that is, C4b-binding protein. There is a relative insufficiency of the endothelial cell-associated TFPI. The antithrombin system is defective due to low levels of antithrombin and impaired glycosaminoglycan expression on perturbed endothelial cells.

glycosaminoglycan availability at the endothelial surface (due to the influence of proinflammatory cytokines on endothelial synthesis) also contributes to reduced AT3 function, since glycosaminoglycans act as physiologic heparin-like cofactors of AT3. Binding of glycosaminoglycans to AT3 induces a conformational change at the reactive center of the molecule, thereby rendering this protease inhibitor from a slow to a very efficient inhibitor.[58] Prospective clinical studies in patients at high risk for sepsis show that a marked decrease in levels of AT3 precedes the clinical manifestation of the infection, which may indicate that AT3 is involved in the early stages of coagulation activation during sepsis.[59]

Endothelial dysfunction is even more important in the impairment of the protein C system during inflammation. Under physiologic conditions, protein C is activated by thrombin bound to the endothelial cell membrane–associated thrombomodulin (TM). TM is a membrane protein with several domains, including a lectin-like domain, six epidermal growth factor (EGF)-like repeats, a transmembrane domain and a short cytoplasmatic tail.[60] The binding of thrombin to TM occurs at the site of the EGF-repeats.[61] This binding not only results in a 100-fold increase in the activation of protein C, but also blocks thrombin-mediated conversion of fibrinogen to fibrin and inhibits thrombin binding to other receptors on platelets and inflammatory cells. TM accelerates the activation of the plasma carboxypeptidase thrombin-activatable fibrinolysis inhibitor (TAFI), an important inhibitor of fibrinolysis.[62] Activated protein C (APC) regulates coagulation activation by proteolytic cleavage of the essential cofactors Va and VIIIa. Binding of protein C to the endothelial protein C receptor (EPCR) results in a fivefold augmentation of protein C activation by the TM–thrombin complex.[63] However, during sepsis, in addition to low levels of protein C due to impaired synthesis[56] and degradation by neutrophil elastase,[64] the protein C system is defective due to downregulation of TM at the endothelial surface, mediated by the proinflammatory cytokines tumor necrosis factor-alpha (TNF-α) and IL-1β.[65]

Observations in patients with severe Gram-negative septicemia confirm the downregulation of TM in vessels with and without thrombosis and impaired activation of protein C *in vivo*.[66] Low levels of free protein S (the cofactor of APC) may further compromise function of the protein C system. In plasma, 60% of protein S is complexed to a complement regulatory protein, C4b binding protein (C4bBP). Increased plasma levels of C4bBP as a consequence of the acute phase reaction in inflammatory diseases may result in a relative free protein S deficiency. Although the β-chain of C4bBP (which mainly governs the binding to protein S) is not much affected during the acute phase response,[67] C4bBP infusion increases organ dysfunction and mortality in septic baboons.[68] Animal experiments of severe inflammation-induced coagulation activation convincingly show that compromising the protein C system results in increased morbidity and mortality, whereas restoring an adequate function of APC improves survival and organ failure.[69] Interestingly, experiments in mice with a one-allele targeted deletion of the protein C gene (resulting in heterozygous protein C deficiency) have more severe DIC and organ dysfunction and a higher mortality than wild type littermates.[70]

A third inhibitory mechanism of thrombin generation involves TFPI, the main inhibitor of the TF–factor VIIa complex. TFPI is a complex multidomain Kunitz-type protease

inhibitor that binds to the TF–factor VIIa complex and factor Xa.[71] The TFPI–factor Xa complex binds to negatively charged membrane surfaces, which may increase the local concentration of TFPI at cellular sites and facilitate inhibition of membrane-bound TF–factor VIIa complex. The role of TFPI in the regulation of inflammation-induced coagulation activation is not completely clear. Administration of recombinant TFPI (r-TFPI) (and thereby achieving higher than physiologic plasma concentrations of TFPI) blocks inflammation-induced thrombin generation in humans, and pharmacologic doses of TFPI prevent mortality during systemic infection and inflammation.[31,72] However, the endogenous concentration of TFPI is presumably insufficient to regulate coagulation activation and downstream consequences during systemic inflammation, as confirmed in patients with sepsis.[73,74]

Inhibition of Endogenous Fibrinolysis in Sepsis

Experimental models indicate that at the time of maximal activation of coagulation in sepsis, the fibrinolytic system is largely shut off. The acute fibrinolytic response to inflammation is the release of plasminogen activators, in particular tissue-type plasminogen activator and urokinase-type plasminogen activator, from storage sites in vascular endothelial cells. However, this increase in plasminogen activation and subsequent plasmin generation is counteracted by a delayed but sustained increase in plasminogen activator inhibitor type 1 (PAI-1).[75,76] The resulting effect on fibrinolysis is complete inhibition and, as a consequence, inadequate fibrin removal, thereby contributing to microvascular thrombosis. Experiments in mice with targeted disruptions of genes encoding components of the plasminogen–plasmin system confirm that fibrinolysis plays a major role in inflammation-induced coagulation. Mice with a deficiency of plasminogen activators have more extensive fibrin deposition in organs when challenged with endotoxin, whereas PAI-1 knockout mice, in contrast to wild-type controls, have no microvascular thrombosis upon endotoxin.[77,78] A functional mutation in the PAI-1 gene, the 4G/5G polymorphism, not only influences the plasma levels of PAI-1, but also is linked to significantly higher plasma PAI-1 concentrations and an increased risk of death.[79] The PAI-1 polymorphism does not influence the risk of contracting meningitis, but probably increases the likelihood of developing septic shock from meningococcal infection.[80]

Regulatory Role of Cytokines in the Coagulopathy of Sepsis

Most proinflammatory cytokines activate coagulation *in vitro*. In patients with sepsis high levels of cytokines are detectable in the circulation, and experimental bacteremia or endotoxemia results in the transient enhancement of serum cytokine levels.[81] TNF is detectable first, followed by an increase in levels of interleukin-6 (IL-6) and IL-1 (Table 123.1). The hypothesis that TNF plays an important role in coagulation activation *in vivo* is strengthened by studies in which cancer patients or healthy human volunteers injected with purified recombinant TNF showed coagulation activation that is virtually identical to endotoxin-induced effects on coagulation.[45,82] However, blocking TNF activity completely abolished endotoxin-induced increase in TNF but coagulation activation was unaffected.[83,84]

Table 123.1

Most important cytokines governing the interaction between inflammation and coagulation

Proinflammatory Cytokines	
TNF-α	First cytokine to appear after endotoxin challenge, major regulator of impairment of physiologic anticoagulant pathways (e.g., downregulation of TM) and antifibrinolytic effect (upregulation of PAI-1)
IL-6	Most important driver of TF expression on mononuclear cells and endothelial cells
IL-1	Important effect on coagulation propagation and downregulation of coagulation inhibitors and fibrinolysis
Anti-Inflammatory Cytokines	
Soluble TNF receptors 1 and 2	Physiologic inhibitors of TNF-α and downstream effects
IL-10	Main anti-inflammatory cytokine, blocker of TNF-α and IL-6 effects

Also, in baboons infused with a lethal dose of *E. coli*, treatment with an anti-TNF antibody had little or no effect on fibrinogen consumption.[85] Moreover, clinical studies in septic patients with an anti-TNF monoclonal antibody did not show a beneficial effect of this treatment.[86]

These observations forced a reconsideration of the role of TNF as principal mediator of endotoxin-induced activation of coagulation. Subsequent studies of IL-6 showed that infusion of a monoclonal anti–IL-6 antibody resulted in the complete abrogation of endotoxin-induced activation of coagulation in chimpanzees.[87] In addition, studies in cancer patients receiving recombinant IL-6 indicated that thrombin is generated following the injection of this cytokine.[88] These data suggest that IL-6 rather than TNF is the relevant mediator for the procoagulant response in DIC.

While IL-1 is a potent agonist of TF expression *in vitro*, its role has not been clarified *in vivo*. Administration of an IL-1 receptor antagonist partly blocks the procoagulant response in a baboon sepsis model and treatment of patients with an IL-1 receptor inhibitor reduces thrombin generation.[89–91] However, most of the procoagulant changes after an endotoxin challenge occur well before IL-1 becomes detectable in the circulation, leaving a potential direct role of IL-1 in coagulation activation in sepsis an unresolved issue. Anti-inflammatory cytokines, such as IL-10, may modulate coagulation activation. Infusion of recombinant human IL-10 completely blocks the endotoxin-induced changes in coagulation and fibrinolysis in human volunteers,[92] but its relevance in the pathogenesis of the sepsis-associated coagulopathy remains to be established.

Cross-Talk Between Coagulation and Inflammation in Sepsis

Coagulation proteases and protease inhibitors not only interact with coagulation protein zymogens, but also with specific cell receptors to induce signaling pathways. In particular, protease interactions that affect inflammatory processes may be important in sepsis. Coagulation of whole blood *in vitro* results in a detectable expression of IL-1β mRNA in blood cells,[93] and thrombin markedly enhances endotoxin-induced IL-1 activity in culture supernatants of guinea pig macrophages.[94] Similarly, clotting blood produces IL-8 *in vitro*.[95] Factor Xa, thrombin, and fibrin can also activate endothelial cells, eliciting the synthesis of IL-6 and/or IL-8.[96,97] The most important mechanisms by which coagulation proteases influence inflammation is by binding to the so-called protease-activated receptors (PARs), of which four types (PAR 1 to 4) have been identified, all belonging to the family of transmembrane domain, G-protein–coupled receptors.[98] A peculiar feature of PARs (in contrast to most other receptors of the superfamily) is that they serve as their own ligand. Proteolytic cleavage by an activated coagulation factor leads to exposure of a neoamino-terminus that activates the same receptor, initiating transmembrane signaling. PARs 1, 3, and 4 are thrombin receptors whereas PAR-2 (and PAR-1) can be activated by the TF–factor VIIa complex and factor Xa. PARs are localized in the vasculature on endothelial cells, mononuclear cells, platelets, fibroblasts, and smooth muscle cells.[98] Binding of thrombin and TF–factor VIIa to its receptor in macrophages affects neutrophil infiltration and proinflammatory cytokine (TNF-α, IL-1β) expression.[99,100] Administration of recombinant factor VIIa to healthy human subjects causes a three- to fourfold rise in plasma levels of IL-6 and IL-8.[101]

Fibrinogen and fibrin can directly stimulate expression of proinflammatory cytokines (such as TNF-α and IL-1β) on mononuclear cells and induce production of chemokines (including IL-8 and MCP-1) by endothelial cells and fibroblasts.[102] The effects of fibrin(ogen) on mononuclear cells are at least in part mediated by Toll-like receptor-4, which is also the receptor of endotoxin.[103] Fibrinogen-deficient mice indeed show inhibition of macrophage adhesion and less thrombin-mediated cytokine production *in vivo*.[102]

There is also considerable cross-talk between physiologic anticoagulant pathways and inflammatory mediators. AT3 can act as a mediator of inflammation by direct binding to neutrophils, thereby attenuating cytokine and chemokine receptor expression.[104] The protein C system has an important function in modulating inflammation.[60,105] APC inhibits endotoxin-induced production of TNF-α, IL-1β, IL-6, and IL-8 by cultured monocytes/macrophages,[106,107] abrogates endotoxin-induced cytokine release and leukocyte activation in rats *in vivo*,[108] and blocking the protein C pathway by monoclonal antibody in septic baboons exacerbates the inflammatory response, as evidenced by increased levels of proinflammatory cytokines.[109,110] Conversely, administration of APC ameliorates inflammatory activation, for example, APC improves organ function and survival in an experimental *E. coli* sepsis model in baboons, and improves organ function in endotoxin-induced shock and lung and kidney injury in rats.[69,105] Mice with a one-allele targeted disruption of the protein C gene (resulting in heterozygous protein C deficiency) not only have a more severe coagulation response to endotoxin but also demonstrate higher levels of circulating proinflammatory cytokines.[70] Binding of APC to the EPCR affects gene expression profiles of cells by inhibiting endotoxin-induced calcium fluxes, by blocking NFκB nuclear translocation, which is a prerequisite for increases in proinflammatory cytokines and adhesion molecules,[111,112] and by activation of PAR-1.[113] Like APC, EPCR itself may have anti-inflammatory properties. Soluble EPCR, the extracellular domain of the cell-associated EPCR shed from the cell surface by the action of an inducible metalloproteinase,[114] in complex with proteinase 3, binds to the adhesion integrin macrophage 1 antigen[115]; its inhibition with a monoclonal antibody aggravates both the coagulation and the inflammatory responses to *E. coli* infusion.[110] Lastly, binding of APC to the EPCR inhibits endothelial cell apoptosis.[116,117]

TM also exerts significant anti-inflammatory activity via TAFI activation.[62] TAFI is a primary enzyme responsible for inactivation of complement factor C5a[118] a process that likely protects against complement-mediated injury in the microvasculature. The lectin-like domain of TM has a function in inhibiting leucocyte adhesion to activated endothelium.[119]

DIAGNOSTIC APPROACH TO COAGULATION ABNORMALITIES IN SEPSIS

Apart from DIC there are several other reasons for coagulation abnormalities in patients with sepsis (Table 123.2). Although thrombocytopenia is common in patients with severe sepsis, this may also be caused by other (sometimes simultaneously occurring) diseases, such as immune thrombocytopenia, medication-induced bone marrow depression, heparin-induced thrombocytopenia, or thrombotic microangiopathies.[14,120] Laboratory tests can be helpful in differentiating the coagulopathy in sepsis from other hemostatic disorders, but since such conditions may occur simultaneously, this differentiation is not always simple.[121,122]

Tests for Intravascular Fibrin Formation and Fibrin Degradation Products

According to the current understanding of sepsis-associated coagulation abnormalities the determination of soluble fibrin in plasma appears to be crucial.[123–126] Indeed, initial clinical studies indicate that if the concentration of soluble fibrin has increased above a defined threshold, a diagnosis of DIC can be made.[23,123,125,127] Most of the clinical studies show a sensitivity of 90% to 100% for the diagnosis of DIC but a rather low specificity,[128] and there is a wide discordance among various assays for soluble fibrin.[129] Since soluble fibrin in plasma can only be generated intravascularly, this test will not be influenced by extravascular fibrin formation.

Fibrin degradation products (FDPs) may be detected by specific ELISA or by latex agglutination assays, allowing rapid and bedside determination in emergency cases.[130] None of the available assays for FDPs discriminates between degradation products of cross-linked fibrin and fibrinogen degradation, which may cause spuriously high results.[131,132] The specificity of high levels of FDPs is therefore limited and many other conditions, such as trauma, recent surgery, inflammation, or venous thromboembolism, are associated with elevated FDPs. Tests that detect

Table 123.2

Routine laboratory value abnormalities in patients with sepsis, due to DIC or other causes

Test	Abnormality	Causes Other than DIC Contributing to Test Result
Platelet count	Decreased	Sepsis, impaired production, major blood loss, hypersplenism hemophagocytosis, immune thrombocytopenia, microangiopathy, heparin-induced thrombocytopenia
PT	Prolonged	Vitamin K deficiency, liver failure, major blood loss
aPTT	Prolonged	Liver failure, heparin treatment, major blood loss
Coagulation factors II, X, IX	Decreased	Liver failure, vitamin K deficiency
Fibrinogen	Decreased or false	Acute phase response may positively affect normal levels and may mask ongoing consumption
FDPs	Elevated	Surgery, trauma, infection, hematoma
Antithrombin	Decreased	Liver failure, capillary leakage
Proteins C and S	Decreased	Liver failure, vitamin K deficiency
Plasminogen activators	Increased	May also be due to plasminogen activators complexed to PAI-1
PAI-1	Increased	Liver failure

DIC, disseminated intravascular coagulation; aPTT, activated partial thromboplastin time; PAI-1, plasminogen activator inhibitor type 1.

an epitope related to plasmin-degraded cross-linked γ-chain, resulting in fragment D-dimer, better differentiate degradation of cross-linked fibrin from fibrinogen or fibrinogen degradation products.[133] D-dimer levels are high in patients with DIC, but also poorly distinguish patients with DIC from patients with venous thromboembolism, recent surgery, or inflammatory conditions.[130,134]

Markers for Thrombin Generation and Coagulation Activation

Activation peptides that are released upon the conversion of a coagulation factor zymogen to an active protease are sensitive markers for coagulation activation. Examples of such markers are prothrombin activation fragment F1 + 2 (F1 + 2), and the activation peptides of factors IX and X.[135–137] Elevated plasma concentrations of thrombin–antithrombin complexes reflect the increased generation of thrombin, and thrombin-mediated conversion of fibrinogen to fibrin can be monitored by increased levels of fibrinopeptide-A.[138,139] All these markers are increased in most patients with sepsis and their high sensitivity may be helpful in detecting even low-grade activation of coagulation. The specificity of coagulation factor activation is limited, since many conditions may result in elevated plasma levels. The most important disadvantage of these tests may be that their use is limited to specialized coagulation laboratories, so their practical use in clinical medicine is limited.

Platelet Count and Coagulation Factors in Patients with Sepsis

The platelet count in sepsis is inversely correlated with markers of thrombin generation, since thrombin-induced platelet aggregation is for a large part responsible for platelet consumption.[120] A progressive drop in platelet count, determined at intervals of about 4 hours, may indicate the generation of thrombin causing intravascular platelet aggregation. Low levels of coagulation factors in patients with sepsis result from consumption, impaired synthesis, and loss via massive bleeding.[140] Although the accuracy of one-stage clotting assays in DIC may be influenced by activated coagulation factors in plasma, the level of coagulation factors correlates with DIC severity.[140] Plasma levels of factor VIII may be paradoxically increased in patients with DIC, due to massive release of von Willebrand factors from the endothelium in combination with an acute phase increase of factor VIII.[141] Measurement of fibrinogen has been widely advocated as a useful tool for the diagnosis of DIC but it is not useful for the diagnosis of DIC.[10,142] Fibrinogen is an acute-phase reactant and despite ongoing consumption, plasma levels can remain within the normal range. In a consecutive series of patients the sensitivity of a low fibrinogen level for the diagnosis of DIC was only 28%, and hypofibrinogenemia was detected in very severe cases of DIC only. Sequential measurements of fibrinogen might be more useful.

AT3 is the principal inhibitor of thrombin and may be exhausted during continuous thrombin generation; plasma levels of AT3 are strong predictors for survival in patients with sepsis and DIC.[59] In patients with meningococcal septicemia, very low plasma levels of protein C may play a pivotal role in the occurrence of purpura fulminans,[143,144] and the plasma level may be a strong predictor for outcome in DIC patients.[145]

Point of Care Tests

Thrombelastography (TEG) is a method that has been developed decades ago and provides an overall picture of *ex vivo* coagulation. Modern techniques, such as rotational thrombelastography, enable bedside performance of this test and is popular

in acute care settings.[146] The theoretical advantage of TEG over conventional coagulation assays is that it provides an idea of platelet function as well as fibrinolytic activity. Hyper- and hypocoagulability as demonstrated with TEG correlates with clinically relevant morbidity and mortality,[147,148] although its superiority over conventional tests has not unequivocally been established.[149] There are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of DIC.

A new method that has proved sensitive and specific for hypercoagulability in critically ill patients is the partial thromboplastin test biphasic waveform analysis.[150,151] This test, which requires specific instrumentation, detects precipitates of very-low-density lipoprotein and C-reactive protein complexes that appear very early in DIC. When such complexes first appear in the plasma of individuals with diseases known to predispose to hypercoagulability, they confer a >90% sensitivity and specificity for subsequent development of DIC and fatal outcome.[150]

Composite Scoring Systems

A simple scoring system has been developed for the diagnosis of DIC (see Chapter 98), calculated with routinely-available laboratory tests.[152] Tentatively, a score of 5 or more is compatible with DIC, whereas a score of <5 may be indicative but is *not* affirmative for nonovert DIC. Prospective studies show that the sensitivity of the DIC score is 93%, and the specificity is 98%.[153,154] The severity of DIC according to this and other scoring systems is related to the mortality in patients with sepsis (FIGURE 123.3).[37,155] Linking prognostic determinants from critical care measurement scores such as APACHE-II to DIC scores is an important means to assess prognosis in critically ill patients. In a prospective study in 840 patients, continuation of coagulopathy during the first calendar day correlated with development of new organ failure and 28-day mortality in patients with severe sepsis.[156]

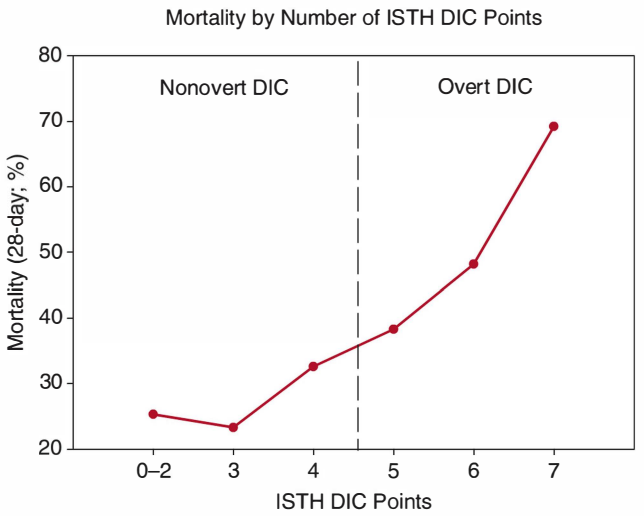

FIGURE 123.3 Number of points on the ISTH DIC score and 28-day mortality in patients with severe sepsis. Data were derived from the placebo group (n = 840) in the Prowess trial on the efficacy of APC in sepsis.

SUPPORTIVE TREATMENT OF COAGULATION ABNORMALITIES IN SEPSIS

The keystone of the treatment of hemostatic abnormalities in patients with sepsis is appropriate antibiotics to control the infectious source. However, in many cases, additional treatment aimed at circulatory and respiratory support and replacement of organ function is required, and coagulation abnormalities may proceed even after proper treatment has been initiated.

Plasma and Platelet Substitution Therapy

Plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or who are at risk for bleeding complications.[157] The suggestion that administration of blood components might "add fuel to the fire" has in fact never been proven in clinical or experimental studies. The presumed efficacy of treatment with plasma, fibrinogen, cryoprecipitate, or platelets is not based on randomized controlled trials but appears to be rational therapy in patients with active bleeding and who have significant depletion of hemostatic factors.[158]

It may be necessary to use large volumes of plasma to correct the coagulation defect. Coagulation factor concentrates, such as prothrombin complex concentrate, may overcome this obstacle, but these compounds may lack essential factors, such as factor V. Moreover, in older literature caution is advocated with the use of prothrombin complex concentrates in DIC, since it may worsen the coagulopathy due to small traces of activated factors in the concentrate. It is, however, not clear whether this is still relevant for the concentrates that are currently in use. Specific deficiencies in coagulation factors, such as fibrinogen, may be corrected by administration of purified coagulation factor concentrates.

Anticoagulants

Experimental studies have shown that heparin can at least partly inhibit the activation of coagulation in sepsis.[159] Uncontrolled case series in patients with sepsis and DIC have claimed to be successful. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials,[160] and the safety of heparin is debatable in DIC patients who are prone to bleeding. Therapeutic doses of heparin are indicated in patients with clinically overt thromboembolism or extensive fibrin deposition, like purpura fulminans or acral ischemia. Patients with sepsis may benefit from prophylaxis to prevent venous thromboembolism, which may not be achieved with standard low-dose subcutaneous heparin.[161] Theoretically, the most logical anticoagulant agent to use in DIC is directed against TF activity. Potential agents include r-TFPI, inactivated factor VIIa, and recombinant NAPc2, a potent and specific inhibitor of the ternary complex between TF/factor VIIa and factor Xa.[162] Phase II trials of r-TFPI in patients with sepsis showed promising results[163] but a recently completed phase III trial did not show an overall survival benefit in patients that were treated with r-TFPI.[164]

Restoration of Anticoagulant Pathways

In view of the deficient state of physiologic anticoagulant pathways in patients with sepsis, restoration of these inhibitors may be a rational approach.[165] Since AT3 is one of the most important

physiologic inhibitors of coagulation, AT3 concentrates have been studied intensively in patients with DIC. All trials show some beneficial effect in laboratory parameters, shortening of the duration of DIC, or even improvement in organ function,[10] and small trials show a modest (nonstatistically significant) reduction in mortality in AT3-treated patients.[166–168] A large-scale, multicenter, randomized controlled trial to directly address this issue showed no significant reduction in mortality of patients with sepsis who were treated with AT3 concentrate,[169] although *post hoc* subgroup analyses indicated some benefit in patients who did not receive concomitant heparin and in those patients with the most severe coagulopathy.[170]

Based on the notion that depression of the protein C system may contribute to the pathophysiology of DIC, supplementation of APC might be beneficial.[171] A beneficial effect of recombinant human APC was demonstrated in two randomized, controlled trials. In a dose-ranging clinical trial, 131 patients with sepsis[172] received APC by continuous infusion at doses of 12 to 30 μg/kg/h. Based on D-dimer plasma levels the optimal dose of recombinant human APC was 24 μg/kg/h, and there was a trend (not statistically significant) toward a 40% lower mortality in patients receiving higher doses of APC. A subsequent phase III trial of APC concentrate in patients with sepsis was prematurely stopped because of efficacy in reducing mortality.[25] All-cause mortality at 28 days was 24.7% in the APC group versus 30.8% in the control group (19.4% relative risk reduction). APC caused an amelioration of coagulation abnormalities and APC-treated patients had less organ failure.[173] Interestingly, a recent analysis demonstrated that patients who classify for having overt DIC (see Table 123.2) had a relatively greater benefit of APC treatment than patients who did not have overt DIC[37] (relative risk reduction in mortality 38% versus 18% in patients with sepsis who did not have DIC). Recombinant human-APC has been licensed for treatment of patients with severe sepsis and two or more organ failures. The most frequently encountered adverse effect of APC is bleeding, the incidence of major bleeding during the infusion period being 2.4% as compared with 1.0% in the control group ($p = 0.02$), and 3.5% in the APC group and 2.0% in the placebo group during the 28-day study period ($p = 0.06$).[25] Most bleeding episodes were procedure-related or occurred in patients with a severely deranged coagulation system (aPTT > 120 seconds or PT [INR] > 3.0), and spontaneous bleeding was rare. Of note, severe thrombocytopenia (i.e., platelet count $<50 \times 10^9$/L) was an exclusion criterion for the trial, but patients with lower platelet counts had relatively more benefit of APC than patients with higher platelet counts.

In an extensive analysis recombinant APC was beneficial in virtually all subgroups defined, including age, type, and site of infection.[174] Efficacy was most prominent in patients with a relatively high disease severity. To prospectively analyze this issue, the ADDRESS trial was performed in 2,640 patients with sepsis and a relatively low disease severity (defined as a single sepsis-associated organ failure or an APACHE II score below 25).[175] The initial sample size of this trial was 11,400 patients; however, the trial was prematurely stopped after a second interim analysis according to the predefined futility rules. The 28-day mortality rates were 18.5% in the APC group and 17.0% in the placebo group ($p = 0.34$). Disappointingly, in patients with two or more organ failures, the 28-day mortality rate was not lower in patients treated with APC as compared with those that received placebo (20.7% vs. 21.9%, not significant), although a direct comparison with PROWESS is not possible due to many differences in the patient population between the two studies.[176] Treatment with APC seems not to be indicated in patients with sepsis and a relatively low disease severity.

Patients treated with the combination of APC and heparin appeared to have a higher mortality, but as the decision to administer heparin was not random, this result may have been biased. The XPRESS trial enrolled 1,994 patients with severe sepsis (and two or more organ failures), who received APC and were subsequently randomized to unfractionated heparin, low molecular weight heparin, or placebo.[177] The results of the trial did not meet the noninferiority assumption, but showed a small survival advantage in the group of patients treated with APC and heparin (28.3% vs. 31.9% in the group treated with APC and placebo, $p = 0.08$). Interestingly, a subgroup analysis demonstrated that the difference between the two groups was mainly driven by the subset of patients that were already receiving heparin before entering the trial. The mechanism underlying this result is not entirely clear, however, it has been suggested that cessation of heparin is associated with a rebound hypercoagulability.[178] The conclusion from this trial was that adding prophylactic heparin to treatment with APC is not harmful, but that interruption of heparin in patients with severe sepsis should be done with caution or prevented.

There is debate on the role of recombinant APC in the treatment of sepsis. Clearly, the pivotal phase III clinical trial (PROWESS) showed a reduction in 28-day mortality and this study formed the basis for the approval of this therapy by regulatory agencies. Consequently, the use of APC in patients with severe sepsis and multiple organ failure, and in the absence of major risk factors for bleeding, has been advocated in guidelines for the treatment of sepsis.[179] However, meta-analyses of published literature conclude that the basis for treatment with APC, even in patients with a high disease severity, is not very strong or even insufficient.[180,181] The series of negative trials in specific populations of patients with severe sepsis has added to the skepticism regarding the use of APC. In view of these equivocal results many clinicians believe that one placebo-controlled trial is not enough to support the use of this agent in patients with severe sepsis, whereas—in contrast—others believe it is ethically not justified to withhold APC in patients with severe sepsis and multiple organ failure and to expose these patients to placebo. On top of that, there is uncertainty regarding the bleeding risk of APC in patients with severe sepsis. The bleeding rate in the clinical trials seems to be acceptable,[182] but it may be that in the "real world" the risk of bleeding, including intracranial bleeding, is higher.[183,184] Taken together, there is quite some uncertainty and doubt surrounding the exact place of APC in patients with severe sepsis and this equipoise has convinced the manufacturer of this agent to start a new placebo-controlled trial in patients with severe sepsis and septic shock.[185] Certainly, the result of this trial will be helpful to more precisely assess the effectiveness and safety of APC in the treatment of patients with severe sepsis.

Hemorrhagic Fevers: Epidemiology, Pathophysiology, and Clinical Features

L. GAYANI TILLEKERATNE, JENNIFER COHN, AND HILLARY DUNLEVY

HEMORRHAGIC FEVERS

Background

Hemorrhagic fevers (HF) refer to illnesses largely caused by several distinct classes of viruses. The syndrome is characterized by fevers, multisystem illness, vascular permeability, and coagulopathy, which results in hemorrhage that ranges from mild to life-threatening in severity.[1]

Four classes of viruses have been implicated in most cases of HF: the Arenaviruses, Filoviruses, Bunyaviruses, and Flaviviruses. These are all RNA viruses with a lipid envelope and are transmitted to humans either directly through animal hosts or through arthropod vectors.[1] The epidemiology of disease in humans is thus largely determined by the geographical areas of the animal reservoir and vectors (FIGURES 124.1 and 124.2).[2] Rodents and domesticated animals are the main reservoirs for viruses causing viral HF. Rarely, nonviral pathogens such as scrub typhus, caused by *Rickettsia tsutsugamushi*, can result in HF.[1]

Human cases of HF occur when vector arthropods bite humans or when humans come into contact with urine, blood, or other body excretions from infected vertebrates.[1] Ebola, Marburg, Lassa, and Crimean–Congo hemorrhagic fever viruses can be transmitted between humans.[2]

Burden of Disease and Emerging Infections

Although there are accounts of HF-like syndromes since at least 1,545, the epidemiology of many HF is changing and new viruses are emerging.[3] In 2009, heightened surveillance of acute febrile illness in China led to the identification of a novel Bunyavirus.[4] The incidence of several HF has recently increased dramatically and spread to novel areas due to changes in global climate, the increased incidence of global travel, and the rise of urbanization.[2] The past 50 years have seen a 30-fold increase in cases of dengue virus, and there has been a sharp increase in both the incidence of dengue fever and dengue hemorrhagic fever/dengue shock syndrome since 2000. This is largely attributed to the geographic expansion of the vector, *Aedes aegypti* mosquitoes, leading to increased co-circulation of all four serotypes of dengue.[5] Expansion of the vector and increasing urbanization with crowded housing and poor sanitation have also increased the risk for yellow fever (YF) outbreaks.[6]

Scope of Clinical Illness

The symptoms of HF vary by type of pathogen and the immune system of the host. General initial symptoms include fever, headache, myalgia, and malaise. Patients with HF may exhibit signs of mild hemorrhage including petechiae and gingival bleeding or more severe hemorrhage including gastrointestinal bleeding. Considering the differential diagnosis in the initial presentation of HF is important, as it includes treatable illnesses, including malaria, typhoid, rickettsial, and other bacterial infections.

In general, the viral HF has a high case fatality rate. However, even with severe hemorrhage, patients do not usually die from blood loss. Death is often related to shock from a capillary leak syndrome and nervous system malfunction including coma and seizures.[1] Laboratory findings often show thrombocytopenia, transaminitis, a coagulopathy, and/or evidence of disseminated intravascular coagulation (DIC).

Travel history and incubation period of particular HF must be considered when evaluating a patient in the United States with a febrile multisystem illness and a bleeding diathesis. An infectious disease consultant and hospital infection control team should be immediately notified of any suspected case of HF.

Diagnosis and Treatment

Given that many of these diseases occur in resource poor settings, diagnosis is often clinical. General lab tests may reveal leukopenia with predominant lymphopenia, thrombocytopenia, and elevated transaminase. During the early viremic period of the illness, PCR may be useful in detecting the virus.[7] Paired acute and convalescent serology is also used.[8,9] Treatment is generally supportive, and those with hemorrhagic complication deserve ICU level care.[10] For those without clinically significant bleeding, replacement of blood products (particularly platelets) and clotting factors is not indicated but should be pursued in those with significant bleeding complications. Ribavirin has been shown to have benefit in human or animal models, the Arenaviridae and Bunyaviridae.[11] Treatment with hyperimmune plasma has been shown to have some benefit in Argentinean and Bolivian HF in case studies but needs further study.[12]

Pathogenesis

The exact pathogenesis is incompletely understood. Initial local replication of virus in dendritic cells and macrophages progresses to viremia and widespread viral replication, which causes an intense cytokine response.[13,14] Cells, particularly macrophages, infected early in the course of disease produce an inflammatory response that is characterized by a variety of cytokines including IL-6, IL-8, reactive oxygen species, and nitrogen oxide. These cytokines may trigger immunosuppression by inducing lymphopenia through promotion of apoptosis as well as hypotension through increased vascular permeability and vasodilation.[15,16] In addition to vascular permeability and vasodilation, infection of and damage to the adrenal glands promote relative adrenal insufficiency and shock. Although

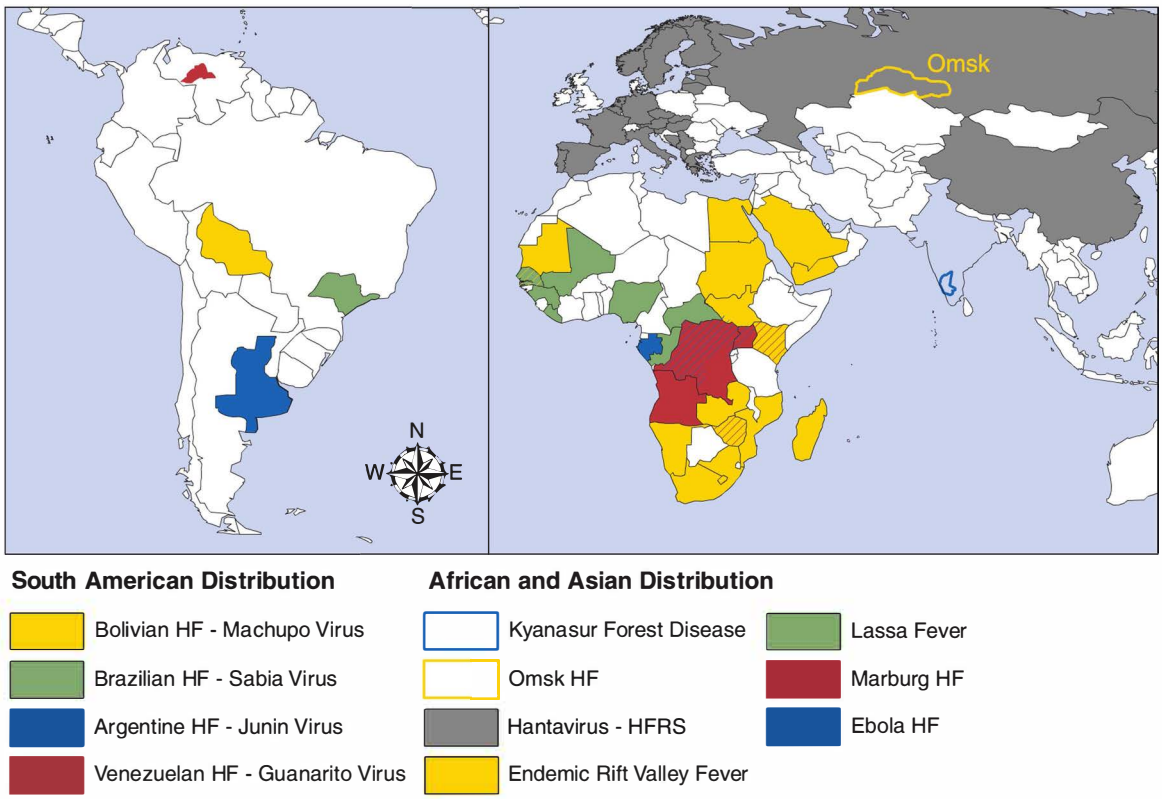

FIGURE 124.2 Distribution of other important hemorrhagic fevers (HF). (Courtesy of Colleen Kiley.)

cytokines may trigger widespread tissue damage, particularly of the liver, infection and direct injury to endothelial cells seem to be a late event in the disease.[17]

Several different mechanisms lead to hemorrhage including coagulopathy, vascular injury, vasodilation, and permeability of blood vessels.[18,19] Bleeding is frequently mucosal and includes gastrointestinal bleeding. Cytokines, in particular IL-6, are associated with coagulopathy that may be partially driven by increased expression of tissue factor.[12] Rapid decrease in protein C has also been noted in Argentine hemorrhagic fever. Additionally, most HF can cause liver damage through direct viral mechanisms or through cytokine-induced injury, with resulting alteration in coagulation factors. Thrombocytopenia and deranged platelet function may be related to maturation arrest of megakaryocytes.[12] DIC is most commonly noted in Rift Valley fever (RVF) and the Filoviruses but may be seen in late stages of any of the HF and represents a poor prognostic factor.[20]

Important Hemorrhagic Fever Viruses

Flaviviridae

The genus Flavivirus contains two of the most prevalent HF: YF and dengue. Omsk hemorrhagic fever virus and Kyasanur Forest virus can also cause severe disease in their endemic regions (Table 124.1).

Yellow Fever Virus

YF occurs in tropical and subtropical areas of Central and South America as well as sub-Saharan Africa, with the vast majority of cases occurring in Africa (see FIGURE 124.1).[21] YF is characterized by sporadic outbreaks, and annual incidence may vary from a few thousand to hundreds of thousands of cases each year. Mosquitoes transmit the virus either from an infected monkey or another human.

After an infective mosquito bite, the incubation period lasts 3 to 6 days, with viral replication at the site of inoculation spreading to the lymphatics, liver, and spleen.[22] The patient subsequently becomes viremic and infective for several days. Approximately 50% of patients are asymptomatic. For those who develop symptoms, viremia brings on a flu-like illness that may be associated with conjunctival injection, flushed skin, and relative bradycardia while febrile.

While most YF illness does not progress to the hemorrhagic form, in those that do, there is a 20% to 60% mortality.[23] After the initial flu-like illness, individuals may experience an afebrile period lasting 1 to 2 days after which the fever returns accompanied by myalgias, abdominal pain, vomiting, and somnolence followed by jaundice and bleeding diathesis leading to gastrointestinal bleeding and the coffee-ground emesis that typically accompanies hemorrhagic YF. The liver may undergo extensive noncoagulative necrosis leading to the loss of synthetic function. Lab tests proteinuria, transaminitis (AST greater than ALT), anemia, and leukopenia.

Isolation from mosquitoes is important to prevent vector transmission, especially during the viremic period. Although no specific treatment exists, several potential antiviral agents and YF-specific hyperimmune γ-globulin deserve further study.[24] Immunity is conferred either through natural infection or through the 17D live attenuated vaccine. YF vaccine is effective and leads to long-lasting (at least 10 years) immunity in over 95% of recipients.[25]

Dengue Virus

Dengue occurs throughout the world in tropical and subtropical regions (see FIGURE 124.1). The World Health Organization states that 2.5 billion people are now at risk for the disease and estimates the annual incidence to be 50 million people.[26] There are four virus species of dengue (dengue-1 to dengue-4) that have incomplete cross-immunity and an individual who has

Table 124.1

Other hemorrhagic fever viruses of importance

Disease	Virus	Principal Vectors	Geographic Area
Arenaviruses			
Argentine hemorrhagic fever	Junin virus	Drylands vesper mouse	Argentina

Hanta fever	Hantaan, Dobrava, Puumala, and Seoul viruses	Rodents	Asia, Europe, North and South America
Flaviviruses			
Alkhurma hemorrhagic fever	Alkhurma virus	Possibly ticks	Saudi Arabia
Kyasanur Forest disease	Kyasanur Forest virus	Ticks	South Asia, China
Omsk hemorrhagic fever	Omsk hemorrhagic fever virus	Ticks	Forest-steppe regions of northern Russia

been infected with one species is at risk for subsequent dengue infections with other species.

After an infective bite from an *A. aegypti* mosquito, a 3 to 7 day incubation is usually followed by a self-limited, flu-like illness with prominent myalgias (hence the name breakbone fever), fatigue, diffuse and blanching rash, vomiting, and retro-orbital headache. Minor bleeding and few scattered petechiae may occur even with uncomplicated dengue. Mild-to-moderate hepatitis and cytopenias are common.[22]

Severe dengue is also referred to as dengue hemorrhagic fever–dengue shock syndrome (DHF–DSS). This severe form of dengue occurs almost exclusively in those who have had a previous dengue infection and acquire a secondary dengue infection. DHF–DSS is an example of antibody-dependent enhancement where nonneutralizing antibodies actually increase viral entry into cells, leading to increased infectivity and worse clinical outcomes. Returning US travelers who have not previously spent time in an endemic area are at low risk for severe dengue.[27]

The WHO defines DHS–DSS as a patient with a febrile illness suspected to be dengue who also has a bleeding diathesis, severe thrombocytopenia, a plasma leak syndrome leading to hemoconcentration, and, in more severe cases, hypovolemic shock. DHF–DSS is often accompanied by hepatosplenomegaly, anasarca, and petechiae. Mortality from DHF–DSS ranges from 1% to 50% depending on one's access to experienced health care.[22]

Filoviridae

The family *Filoviridae* members, Ebola and Marburg, cause a severe febrile illness in humans and primates that often results in death.[28] Transmission of the Filoviruses occurs during close contact with infected persons through bodily fluids, including sweat, and infection of health care providers has occurred. Airborne transmission in humans has not been documented but has been observed with nonhuman primates in a laboratory setting.[20] Though the reservoir has not been definitively identified, the fruit bat is suspected.[29–31]

Marburg virus has been seen in a few sporadic cases and was first discovered in 1967 when lab workers in Germany and Yugoslavia handled tissues from green monkeys and subsequently developed HF. The fatality rate for Marburg HF ranges from 25% to 90%.[32]

Ebola virus was first detected in 1976 with two almost simultaneous outbreaks in the Democratic Republic of Congo (DRC) and Southern Sudan with two different species of virus. Ebola became known as one of the most deadly viruses with fatality rates in the DRC of 90% and in Sudan 50%. Large outbreaks have occurred in 1995 in the DRC and in 2000 in Uganda.[33,34]

The Filoviridae target dendritic cells and macrophages and replicate to infect parenchymal cells of organs and endothelial cells. Suppression of innate cell response, lack of T-cell activation, apoptosis, and release of cytokines such as TNF-α, interferon-γ, and nitric oxide lead to vascular permeability and multiorgan failure. Specific organ effects include liver necrosis, interstitial pneumonitis, and cerebral infarcts. Cases resulting in death usually do not have an adequate antibody response.[14,20,30] In convalescent patients, the virus has been identified in semen weeks after recovery.[20]

Incubation of Marburg virus is 3 to 9 days and Ebola virus is 2 to 21 days with symptoms initially very similar to other viral HF, including fever, chills, myalgia, chest pain, and sore throat followed by a maculopapular rash, conjunctivitis, gastrointestinal symptoms, and hepatitis.[34,35] This leads to a more severe clinical picture of hemorrhage and shock.[30] No specific treatment is currently available for these viruses, but some success has been seen in animal studies with treatment with factor VIIa/tissue factor and with activated protein C.[36]

Arenaviridae

The Arenaviridae family of viruses includes Old World and New World. Lassa fever and Lujo virus are examples of the Old World viruses, while New World viruses include Junin, Machupo, Guanarito, Sabia, and Chapare viruses. Lassa fever virus is described in more detail below.[37]

Lassa Fever Virus

Lassa fever is found throughout West Africa, with approximately 300,000 cases each year and 5,000 deaths. The animal host is the multimammate rat, a common household pest.[28,38] After direct contact or inhalation of mouse excrement, incubation lasts 6 to 21 days. Lassa fever is mild in 80% of those infected with the virus with bleeding in only 15% to 30%. For those who are symptomatic, the clinical presentation is similar to other viral HF with fever, myalgia, cough, vomiting and diarrhea, and coagulopathy.[14] It differs in that it leads to hearing loss (up to 33% of patients), anasarca, and neurologic manifestations such as tremors.[38] Women in their third trimester are more susceptible to severe disease, death, and spontaneous abortion. Poor prognostic indicators are high levels of viremia, bleeding, AST >150 IU/L, encephalitis, edema, and being in the third trimester of pregnancy.[36,39,40]

Bunyaviridae

The family Bunyaviridae contains several genera, members of which include the Hanta virus group, Crimean–Congo hemorrhagic fever (CCHF) virus, and RVF virus. CCHF and RVF virus are described in further detail below.

Rift Valley Fever

RVF is transmitted by *Aedes* mosquitoes or through contact with fresh carcasses or blood of the animal reservoir, generally cattle and sheep. The primary range of RVF is sub-Saharan Africa.

RVF has an incubation period of 3 to 6 days and then presents as a febrile illness with mild hepatitis. Complications of the illness include a retinitis in about 10% of patients occurring 1 to 3 weeks after the initial illness, potentially leading to blindness. Approximately 1% of patients may also experience meningoencephalitis 1 to 4 weeks after initial symptoms. Less than 1% of patients go on to develop hemorrhagic complications. For these patients, after 3 to 6 days of fever, hepatitis and jaundice accompany spontaneous bleeding, myalgia, headaches, and joint pain. The overall case fatality rate for all manifestations of RVF is around 1% but is 20% to 50% in those with the hemorrhagic form.[41]

Crimean–Congo Hemorrhagic Fever Virus

CCHF may be acquired from the bite of an infected *Hyalomma* tick or through contact with blood from infected herd animals. The disease primarily occurs in the former Soviet Union states, Middle East, and Africa, especially during spring and fall, times of high tick activity.[9]

After an incubation period of 2 to 6 days, patients experience the sudden onset of fevers, headaches, photophobia, myalgias,

and abdominal pain. Several days into the illness, the patient may have episodes of somnolence and agitation. In the second week of the illness, liver failure, bleeding complications, and DIC become apparent and may progress to hepatorenal syndrome, multisystem organ failure, and death. Case fatality approaches 30%.[41]

PREVENTION AND CONTROL

Since vaccines have only been developed for a handful of HF viruses including YF and Argentine HF, and pharmacologic treatment options are minimal, preventive efforts are of great importance.[1] For mosquito-borne infections, vector control including insecticide fogging of affected areas and source control of larvae have been implemented by public health officials.[42] For tick-borne infections, personal preventative efforts including performance of frequent tick checks are useful. For HF viruses such as Ebola and Marburg, which can be transmitted from person to person, avoiding close contact with infected patients and their body fluids is of great importance.[43] These viruses can be destroyed with heat, cleaning detergents, and acidity but can persist for weeks at room temperature.

NEW RESEARCH AND FINDINGS

Given the rapidly rising number of dengue cases worldwide, the search for a dengue vaccine has become especially important. The development of an effective vaccine has been hampered by the need for providing complete protection against all four serotypes of dengue, as infection with one serotype provides immunity against that type but often enhances disease severity to infections with other serotypes. A live, attenuated, chimeric vaccine that uses the 17D YF virus vaccine as its backbone has recently been shown to induce 100% seroconversion against all four serotypes of virus, when given in 3 doses over 15 months.[5] Phase III efficacy trials are ongoing in several dengue-endemic countries, and licensure of a successful vaccines is expected as early as 2014.[44] Vaccines for several other HF are currently in development, and other novel control techniques, including the engineering of mosquitoes that have a short life span or that cannot transmit viruses, are under exploration.[45] Finally, researchers are exploring immunomodulation and therapies directed at interrupting signals that cause derangements of the clotting cascade.[12]

CHAPTER

125 Cancer-Related Thrombosis

ANNA FALANGA, AGNES Y. Y. LEE, AND FREDERICK R. RICKLES

The close association between malignant disease and thrombosis is well known and was first described more than a century ago by Trousseau, a French doctor who first observed that unexplained episodes of migratory thrombophlebitis in patients with gastrointestinal symptoms might indicate an underlying, undiagnosed tumor. Subsequent postmortem studies showed an increased incidence of thromboembolic disease in cancer, particularly in patients who died of mucinous cancer of the pancreas, lung, and gastrointestinal tract. On the other hand, we know today that venous thromboembolism (VTE) may be indeed the first manifestation of an occult malignancy in an otherwise healthy individual, anticipating the clinical detection of tumor by months or even years. Unlike thrombosis in other settings, venous thrombosis in cancer can be migratory, may involve superficial as well as deep veins, may affect unusual sites such as the arms and chest, and may be relatively unresponsive to standard anticoagulant therapy. However, thromboembolism is not the only form of abnormal hemostasis found in patients with cancer. Also of importance is the bleeding diathesis that results from consumption of platelets and clotting factors as occurs in disseminated intravascular coagulation (DIC). Cancer patients commonly present with abnormalities in laboratory coagulation tests, indicating an ongoing subclinical hypercoagulable condition. The results of laboratory tests demonstrate that a process of fibrin formation and removal parallels the development of malignancy, which is of particular interest since fibrin and other clotting products are of importance for both thrombogenesis and tumor progression. Many factors can increase the thrombotic risk in cancer patients, including classical risk factors such as immobility, old age, surgery, and cancer-specific factors such as advanced disease stage, and cancer therapies. In addition, tumor cell–specific prothrombotic properties and the subsequent host cell inflammatory response dramatically enhance the risk for thrombosis in these patients. Cancer cells produce and release procoagulant and fibrinolytic proteins, as well as inflammatory cytokines. In addition, they are capable of directly adhering to host cells (i.e., endothelial cells [ECs], monocytes, platelets, and neutrophils), thereby stimulating additional prothrombotic properties of the host effector cells. Notably, most of these mechanisms, in addition to generating thrombosis, can also promote tumor growth and metastasis.

EPIDEMIOLOGY

VTE, including deep vein thrombosis (DVT) and pulmonary embolism (PE), is the most extensively studied thrombotic complication associated with malignant disease. However, arterial thromboembolism, migratory thrombophlebitis, thrombotic nonbacterial endocarditis, and DIC add to the spectrum of complications. The incidence of VTE in cancer populations has been estimated at approximately 1 out of 200 patients,[1] and active malignant disease is an independent risk factor for VTE.[2,3] Overall, 18% to 29% of all VTE events in the population are associated with cancer.[4–6] In a registry of 5,451 patients hospitalized with objectively confirmed DVT, cancer was reported in 39% of patients; of these 62% had ongoing cancer and 38% a history of cancer.[7] Several large retrospective analyses of hospital discharge data reported a 28% to 36% increase in VTE events over the period 1995 to 2003.[8,9] Hospitalization, anticancer surgery, and active treatment regimens, particularly chemotherapy, further increase the risk of thrombosis in cancer patients.[2,8,10]

The Risk of VTE Associated with Cancer

Large, population-based studies have shown that the risk of VTE is increased between four- and sevenfold in patients with malignancy,[2,11] and studies based on hospital discharge have reported an overall VTE incidence of 0.6% to 7.8% in patients with cancer, more than double that in patients without cancer.[8,9,12–14] Recently, a retrospective cohort study of nearly 2 million patient hospitalizations in the United States reported an overall VTE rate of 4.1% among 1,015,598 cancer patients.[8] Nevertheless, the incidence of VTE in patients with cancer is probably underestimated by retrospective, population-based studies that report only symptomatic or objectively confirmed VTE events. Routine-staging CT scans in cancer patients have reported a high prevalence of unsuspected PE,[15–17] for example, in 4% of inpatients and 0.9% of 589 outpatients.[15]

The increased risk of VTE associated with cancer portends an increased likelihood of VTE recurrence. For example, in a retrospective analysis of 1,303 patients with symptomatic VTE receiving oral anticoagulant therapy, patients with cancer ($n = 264$) experienced greater VTE recurrence compared with patients without malignancy (27.1 vs. 9 events per 100 patient-years, $P = 0.003$).[18] Likewise, a prospective follow-up study of 842 patients with confirmed DVT, with 181 patients with cancer and 661 without cancer, reported an annual VTE recurrence rate of 20.7% in cancer patients compared with 6.8% in patients without malignancy.[19] These studies also found that cancer patients are more likely to suffer bleeding complications during VTE treatment,[18,19] both bleeding and recurrence being correlated with the extent of cancer.[19]

Among cancer patients, those experiencing a VTE event have a worse survival outcome compared to thrombosis-free subjects.[8,9,20,21] A report from the Danish Cancer Registry highlighted a mortality ratio of 2.2 in cancer patients with symptomatic

VTE compared with matched cancer patients without VTE.[21] A retrospective analysis of 68,142 patients reported that VTE was a significant predictor of mortality within 1 year of colorectal cancer diagnosis among patients with local (hazard ratio [HR] 1.8, 95% confidence interval [CI] 1.4 to 2.3) and regional malignancies (HR 1.5, 95% CI 1.3 to 1.8),[22] and a necropsy review revealed that 21.8% of fatal PE events occurred in hospitalized medical cancer patients.[23]

These studies are strengthened by findings from the RIETE registry of 14,391 patients with symptomatic, acute VTE, in which the 2,945 patients with cancer had significantly higher rates of fatal PE (2.6% vs. 1.4%) and fatal bleeding (1.0% vs. 0.3%) than those without cancer.[24] Among 512 patients who presented with upper-arm DVT,[25] those with cancer had a higher rate of recurrent VTE (6.1% vs. 2.8%, odds ratio [OR] 2.2), major bleeding (4.1% vs. 0.9%, OR 4.4), and mortality (22% vs. 3.5%, OR 7.8) than did patients without cancer. The risk of VTE steadily accumulates with each additional patient-related thrombotic risk factor in cancer patients, for example, advanced age, prolonged immobility, prior history of VTE, and comorbid conditions of infection and cardiopulmonary disease.[2,9,19,26]

The Incidence of VTE According to Tumor Type and Stage

Cancer with the highest rates of VTE include those involving the pancreas, stomach, and kidney,[27] and studies based on hospital discharge data confirm autopsy data that link VTE with tumors of the brain, pancreas, ovary, lung, and uterus and leukemia[9,28] (FIGURE 125.1). Among the hematologic malignancies, lymphoma and myeloma have the highest rates of VTE.[8] A retrospective cohort study of 66,106 adult neutropenic cancer patients reported an overall rate of symptomatic VTE of 8%: among these, patients with lymphoma and leukemia represented a third of all cases of VTE and almost half of the arterial thrombotic events.[9] Advanced metastatic cancer is associated with an increased risk of VTE compared with localized tumors.[27] Data from the California Cancer Registry (1993 to 1995) highlighted metastatic disease as the strongest predictor of VTE complications.[20] Similarly, Blom et al.[28] reported that cancer patients with distant metastases had almost a twofold increased risk of VTE compared with those without metastases.

The Effect of Anticancer Treatments on VTE Incidence

Many anticancer treatments increase the risk of VTE, including surgical procedures, nonsurgical treatments, and use of a central venous catheter (CVC).[29]

Surgery

In 1975, V.V. Kakkar et al. analyzed 4,031 patients undergoing major abdominal surgery; half of these received low-dose unfractionated heparin (UFH) to prevent thromboembolism. Overall, 170 (4.2%) of patients died postoperatively. The autopsies, performed in about 70% of patients who died after surgery, demonstrated the great benefit of heparin prophylaxis. In particular, among the 23% of patients operated for malignant disease, the frequency of fatal PE was 1.6% in the control group and 0.4% in the heparin group.[30] Patients with cancer are at increased risk (i.e., three- to fivefold) for postoperative thrombosis compared to noncancer patients.[31] Without prophylaxis, the postoperative incidence of symptomatic or asymptomatic DVT in cancer patients is 40% to 80% and that of proximal DVT 10% to 20%.[30] Data from the @RISTOS registry identified VTE as the most common cause of death 30 days after surgery in cancer patients (46%); 40% of VTE events occurred >21 days after surgery.[10]

Nonsurgical Cancer Treatments

Nonsurgical cancer treatments are associated with a high incidence of VTE, including the use of chemotherapy, adjuvant chemotherapy, hormones, and antiangiogenic agents. In a population-based study of VTE risk factors among 625 patients, malignant disease increased the risk of VTE 4.1-fold, but with chemotherapy it increased by 6.5-fold.[2] By contrast, radiotherapy has not been proven to increase the risk of VTE.[28,32]

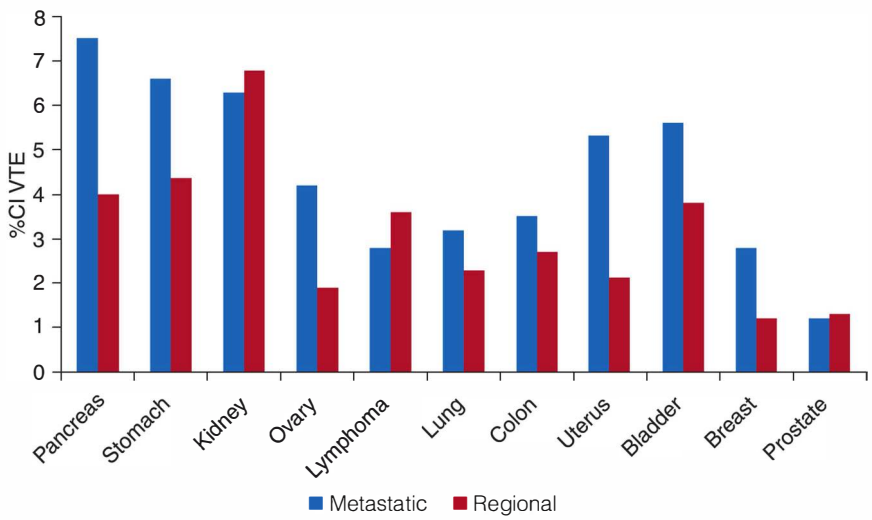

FIGURE 125.1 VTE according to type and stage of cancer. Cancer types associated with the highest incidence of VTE are pancreas, stomach, kidney, uterus, and bladder, whereas lymphoma, prostate, and breast have a much lower incidence. For the majority of cancers, VTE risk is further increased when the tumor is metastatic. CI, cumulative incidence. (Adapted from Wun T, White RH. Epidemiology of cancer-related venous thromboembolism. *Best Pract Res Clin Haematol* 2009;22(1):9–23.)

Chemotherapy and Hormonal Therapy

A prospective study of nearly 4,500 patients receiving outpatient chemotherapy reported a 2.7-fold increase in arterial thrombosis, and a 47-fold increase in the mortality rate from VTE compared with the general population.[33] At present, it is not known if specific chemotherapeutic agents carry a higher risk of thrombosis. An elevated prechemotherapy platelet count is associated with an increased risk of VTE.[32] There is a cause-and-effect relationship between L-asparaginase use and thrombosis,[34] and high-dose corticosteroids are associated with a 3.5-fold increased risk of VTE.[35] Women who receive the selective estrogen receptor modulator tamoxifen have a 1.5- to 7.1-fold increase in the risk of developing symptomatic VTE, compared with placebo or no treatment.[36]

Adjuvant Chemotherapy

The incidence of VTE in women with early-stage, node-negative, or node-positive breast cancer receiving chemotherapy treatment is 0.9% to 9.6%,[37] with the greatest risk seen in older postmenopausal women.[38] In 1988, Levine et al.[39] published the results of a randomized multicenter trial comparing chemotherapy with chemohormonal therapy in 205 women with stage II breast cancer. There were 14 objectively confirmed symptomatic VTE events distributed in both groups, and all occurred during active treatment. Anastrozole, a third-generation aromatase inhibitor used as an alternative agent for adjuvant treatment in women with early breast cancer and a low risk of recurrent tumors,[37] may be associated with a lower risk of VTE complications than tamoxifen.[40]

Antiangiogenic Agents

Targeted antiangiogenic agents, such as bevacizumab, the monoclonal antibody to vascular endothelial growth factor (VEGF), have shown efficacy in improving survival rates among patients with advanced malignant disease.[41–43] However, the addition of bevacizumab to chemotherapy regimens is associated with a high incidence of thrombotic events. A recent meta-analysis from 15 randomized controlled trials of 7,956 patients with advanced solid tumor indicated that bevacizumab was associated with an increased risk of VTE, with a relative risk of 1.33.[44] Similarly, treatment regimens involving thalidomide or lenalidomide are associated with an increased risk of VTE when used concomitantly with chemotherapy or corticosteroids in patients with multiple myeloma.[45,46]

Supportive Therapy

The use of recombinant human erythropoietin (EPO) and other hematopoietic growth factors as supportive therapy in cancer patients appears to increase the risk of VTE. A study in 147 patients with nonmetastatic cervical or vaginal cancer showed that EPO increases the risk of thrombosis by 15-fold.[47] The use of EPO and granulocyte growth factors is independently associated with VTE risk among patients on chemotherapy.[32] Red blood cell transfusion may increase the risk of VTE, one study reporting that 7.2% of patients receiving transfusions developed VTE compared with 3.7% of patients who did not receive transfusions; transfusions were also associated with an increased risk of in-hospital mortality.[48]

Central Venous Catheters

CVCs promote thrombosis through a number of mechanisms such as trauma to vessel wall, and by local high drug concentrations delivered by the CVC.[49] Retrospective studies indicate a risk of CVC-related thrombosis in malignancy of 12% to 66%, depending on the type of cancer and its treatment, and the type, position, and duration of catheter use.[50] However, recent randomized controlled trials in cancer patients report lower rates of CVC-related thrombosis, 3.1% to 4.0% symptomatic and 18.1% asymptomatic. The use of warfarin, dalteparin, or enoxaparin did not reduce the incidence of catheter-related DVT.[51–53] The RIETE registry revealed that among patients diagnosed with an objectively confirmed symptomatic DVT, upper-extremity DVT was more frequent in patients with cancer than in those without.[25] Upper-extremity DVT typically presents as symptomatic PE less often than lower-extremity DVT (9% vs. 29%), but is associated with a higher rate of recurrent VTE (6.1% vs. 2.8%) and overall mortality (22% vs. 3.5%).[25]

PATHOPHYSIOLOGY AND RISK ASSESSMENT

Patients with cancer display many types of hemostatic disorders,[39] including overt hemorrhage, thrombosis, and DIC, or only a finding of hemostatic abnormality recognized as the result of laboratory testing that reflects an *in vivo* hypercoagulable state.

The Hypercoagulable State

The underlying principle in patients with cancer is that the clotting system is systemically activated, coagulation factors are consumed, and fibrinolysis is activated. Approximately half of all patients with cancer, and as many as 90% of those with metastases, exhibit abnormalities in one or more routine coagulation parameters.[54–57] The development of novel laboratory tests with increased sensitivity has enabled the detection of subtle alterations in the hemostatic system. Levels of plasma markers of activation of coagulation, such as the thrombin–antithrombin (TAT) complex, prothrombin fragment 1+2 (F1+2), fibrinopeptide A (FPA), and D-dimer, tend to be universally elevated in patients with cancer,[58,59] indicating the presence of *in vivo* thrombin generation and fibrin formation and fibrinolysis. These abnormalities can worsen with the start of antitumor therapies.[60] For example, Falanga et al.[61] demonstrated that the plasma levels of F1+2 and plasminogen activator inhibitor type 1 (PAI-1) in patients with non-Hodgkin lymphoma and multiple myeloma were elevated at baseline and significantly increased after receiving high-dose cyclophosphamide, followed by granulocyte colony-stimulating factor (G-CSF) for hematopoietic stem cell mobilization (FIGURE 125.2).

Hemostatic Markers and Risk of VTE

Few prospective studies have evaluated the utility of serial measurements of hemostatic markers for predicting the occurrence of VTE (as confirmed by objective test) in cancer patients. One such study of patients undergoing surgery for abdominal cancer found that presurgical TAT complex levels were significant predictors of postoperative DVT.[62] Khorana et al. showed that a prechemotherapy platelet count >350,000/μL is predictive of subsequent thrombosis during chemotherapy,[32] and data from the Vienna Cancer and Thrombosis Study (CATS) show that a P-selectin level above the 75th percentile is predictive of thrombosis in cancer patients[63] and increased levels of both D-dimer and F1+2 characterize the highest risk of VTE in patients with cancer.[64]

Improvements of laboratory techniques allow the measure of plasma microparticles (MPs), the small vesicles shed by platelets,

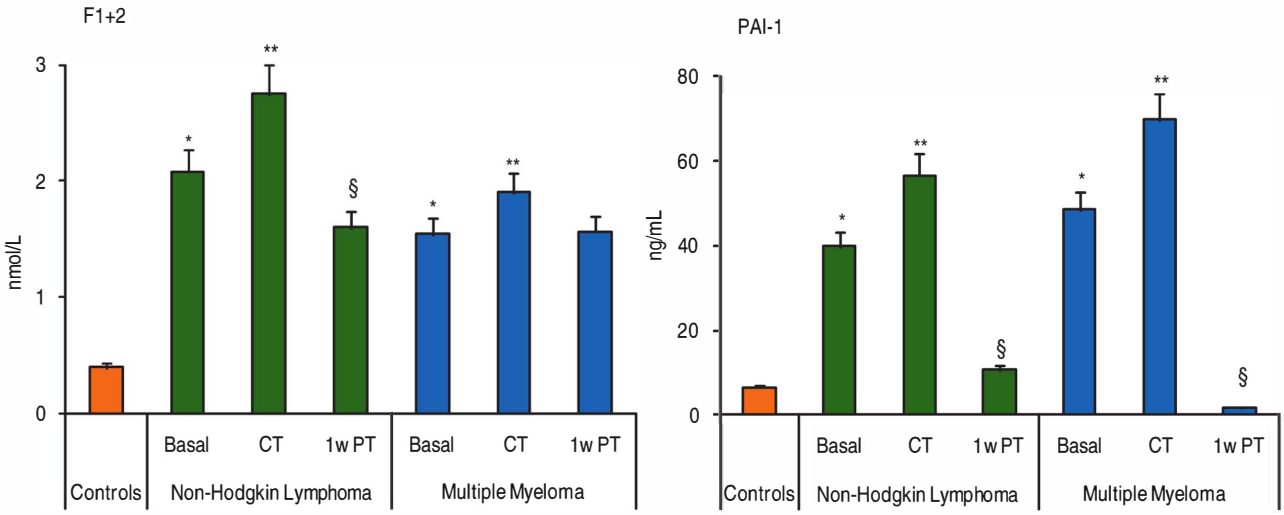

FIGURE 125.2 Hypercoagulation (F1+2) and endothelial activation (PAI-1) markers in patients with non-Hodgkin lymphoma or multiple myeloma. Patients received high-dose cyclophosphamide for autologous hematopoietic stem cell transplantation. Hemostatic markers were evaluated at different time points: basal, before chemotherapy; CT, after high-dose chemotherapy (before starting G-CSF); 1w PT, 1 week posttransplantation. F1+2 and PAI-1 levels increased under chemotherapy and returned toward normal after transplantation. Data are expressed as mean ± SE. $^{*}P < 0.05$ versus controls, $^{**}P < 0.05$ versus basal, §$P < 0.05$ versus CT. (Modified from Falanga A, Vignoli A, Marchetti M. Coagulation in hematological malignancies. *Cancer Invest* 2009;27(Suppl 1):17–27.)

leukocytes, and endothelium in response to cell activation. The MPs are characterized by a diameter of <1 μm, the presence on their surface of antigens of the parental cell, and by procoagulant properties. The procoagulant capacity is related to the presence of higher amount of the anionic plasma membrane phospholipid phosphatidylserine and of tissue factor (TF). Toth et al.[65] showed that levels of MP derived from platelets are elevated in patients with breast cancer, compared to patients with benign breast lesions, and Trappenburg et al.[66] showed that the levels of circulating platelet and EC MPs in patients with essential thrombocythemia increased with the number of risk factors for thrombosis. TF-bearing MPs are elevated in 60% of cancer patients with VTE and in 27% of those without VTE, thus predicting a significantly increased risk of VTE.[67,68] A large prospective study is currently assessing the predictive value of determining TF-rich MP levels, along with other factors, in patient populations with cancer at high risk for developing VTE (Clinicaltrials.gov NCT00876915). The MicroTEC study (Microparticles and Thromboprophylaxis with Enoxaparin in Cancer Study, Clinicaltrials.gov NCT00908960) is evaluating the benefit of primary thromboprophylaxis in patients with advanced colon, lung, or pancreatic cancer, administered on the basis of their level of TF-bearing MPs.[69]

Risk Stratification

The interaction and relative effects of the risk factors associated with VTE in cancer patients is highly complex, making the pretreatment assessment of VTE difficult. Several demographic, cancer-associated and treatment-related factors increase the risk of thrombosis in patients with cancer (FIGURE 125.3). A VTE risk assessment model for use in patients undergoing chemotherapy patients described in 2008 by Khorana et al. is based on five predictive variables, namely, cancer site, platelet count, hemoglobin level (or the use of erythropoiesis-stimulating agents), leukocyte count, and body mass index,[70] and is under evaluation in a prospective cohort of cancer patients initiating outpatient chemotherapy but not receiving thromboprophylaxis.[71] Preliminary results show that 27% of cancer outpatients deemed at high risk with this prediction rule developed VTE. Recently, Pabinger et al. expanded the Khorana model[70] by adding P-selectin and D-dimer quantification, allowing an even better stratification of thrombotic risk. In particular, the HR of patients with the highest score compared with those with the lowest score was 25.9.[72]

THE PATHOGENESIS OF THE HYPERCOAGULABLE STATE

The pathogenesis of the prothrombotic state of cancer patients is due at least in part to the ability of cancer cells to activate the coagulation system and interactions that may favor tumor progression (FIGURE 125.4).

The Activation of the Hemostatic System by Tumor Cells

Several complex and not fully recognized interactions between malignant cells and coagulation shift the hemostatic balance toward a procoagulant state in multiple ways.[73]

Tumoral Production of Hemostatic Factors

Procoagulant Proteins

TF is a transmembrane glycoprotein that is the primary initiator of hemostasis. TF forms a complex with activated factor VII (TF/FVIIa) to trigger coagulation by proteolytically activating

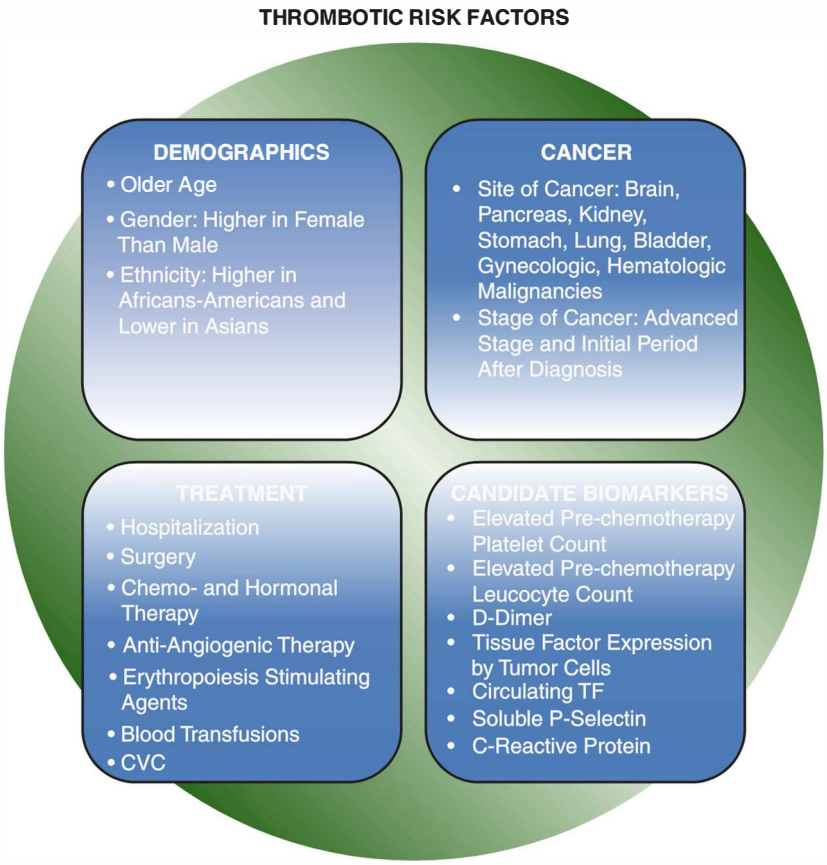

FIGURE 125.3 Prothrombotic risk factors in cancer patients. Several factors can contribute to thrombotic risk in cancer patients; these include their demographic characteristics, site and stage of cancer, anticancer therapies (including surgery), and hospitalization. CVC, central venous catheters; TF, tissue factor.

FIX and FX. ECs and monocyte–macrophages do not normally express TF, unless they are stimulated.[74] Differently, constitutive TF expression characterizes numerous malignant tumor tissues. In addition, TF expression can be induced on tumor-associated macrophages and EC either by inflammatory endogenous agonists, that is, tumor necrosis factor-alpha (TNF-α) and interleukin-1 beta (IL-1β), or by exogenous agonists, that is, bacterial endotoxin or tumor-specific antigens. In breast cancer, the expression of TF in tumor stroma correlates with progression to invasive cancer. Similarly, the expression of TF by

The scheme summarizes the ways by which tumor cells activate the coagulation cascade and hemostatic cellular components, ultimately leading to thrombin generation and fibrin formation.

glioma cell lines and glioma surgical specimens correlates with the histologic grade of malignancy.

Cancer procoagulant (CP) is a cysteine protease that directly activates FX in the absence of FVIIa. CP is synthesized by malignant cells, and its activity has been found in extracts of different tumors.[75–77] The presence of CP antigen as well as of CP procoagulant activity (PCA) have been identified in cancer patients' sera. Although CP is found almost exclusively in malignant cells, its role as a tumor marker or as a factor predictive of clinical thrombosis has not been demonstrated. CP expression in acute promyelocytic leukemia blasts parallels the degree of malignant transformation and is lost upon cellular differentiation after therapy with all-transretinoic acid (ATRA). In contrast, cells resistant to ATRA maintain their malignant phenotype, including CP expression.[78] Similar observations have been reported for breast cancer.[79]

MPs released by tumor cells have been associated with the hypercoagulable state of cancer. The first demonstration that tumor-shed vesicles possess PCA was made by Dvorak et al.[80] in 1981, who showed that a mouse breast carcinoma cell line and a guinea pig hepatocarcinoma cell line released PCA in culture and *in vivo*, in association with small vesicles shed by the tumor cell surface. Circulating MPs have been described in the plasma of patients with various tumors, such as pancreas and breast adenocarcinoma, giant-cell lung carcinoma, colorectal cancer, and acute leukemia.[81–83] MPs contribute to intravascular thrombin generation by exposure of phosphatidylserine and procoagulant proteins such as TF[84] and may explain the increased TF level in the blood of cancer patients. Patients with colorectal cancer have twofold higher TF-positive MPs compared to healthy controls, and levels of MP correlate positively with the levels of D-dimer as a marker of clotting activation.[85] Elevated MP-associated TF activity significantly relates to the development of VTE in patients with disseminated mucinous carcinoma.[81]

Fibrinolytic Proteins

Tumor cells possess both the urokinase-type and the tissue-type plasminogen activators and can also produce PAI-1 and PAI-2. There are specific receptors on tumor cells that support the assembly of the fibrinolytic components, thus facilitating the activation of the fibrinolytic cascade.[86] In patients with leukemia, the expression of these activities by blast cells may play a role in bleeding symptoms. On the other hand, a defect in the generation of normal plasma fibrinolytic activity, for example, by increased production of PAI-1, has been found in patients with solid tumors and may represent another mechanism for these patients to develop VTE.[59]

Inflammatory Cytokines

Tumor cells synthesize and release a variety of cytokines including proinflammatory (TNF-α, IL-1β) and proangiogenic factors (VEGF, basic fibroblast growth factor [bFGF]). Cytokine overproduction also derives from inflammatory tissues as a part of the host-reactive process in response to the tumor. Most of these cytokines induce the expression of a procoagulant phenotype by monocytes and ECs. Monocyte activation occurs in malignant tissue both *in vitro* and *in vivo*, expressed, for example, as significantly more TF than in control cells.[59] Cytokines stimulate ECs to increase the production of PAI-1 and upregulate EC surface TF expression and downregulate expression of thrombomodulin,[87,88] a potent anticoagulant that forms a complex with thrombin to activate the natural anticoagulant protein C.[88]

Adhesion Molecules

The expression of tumor cell-surface adhesion molecules and/or their receptors allows the direct interaction of these cells with host cells, including EC, platelets, and leukocytes. The attachment of tumor cells to vascular ECs is relevant to promote localized clotting activation to the vessel wall and to start thrombus formation. The adhesion can occur directly or via the cooperation of granulocytes. The interaction between tumor cells and ECs is mediated by different pathways of adhesion molecules expressed by different tumor types.[89] In flow conditions, the interaction involves rolling and firm adhesion, depending on the respective adhesive properties of both ECs and tumor cells. Some tumor cell types roll and adhere using E-selectin, while others adhere without rolling using vascular cell-adhesion molecule-1.[90] Thus, a variety of molecules expressed on EC surface, including selectins, integrins, and immunoglobulins, are necessary for the adhesion of cancer cells and their migration to distant sites to form metastases. P-selectin (CD62P) is an important cell-adhesion molecule expressed by stimulated ECs and activated platelets, which mediates heterotypic aggregation of activated platelets to cancer cells and the adhesion of cancer cells to stimulated ECs. In addition, P-selectin mediates the homotypic aggregation of activated platelets and the transfer of procoagulant MPs between cells, which further contribute to fibrin deposition and microthrombus formation.[91]

Oncogene-Driven Activation of the Hemostatic System

In 2000, Rak and Klement[92] first postulated that "the procoagulant conversion of tumor cells is related to their oncogene status." In 2005, three seminal papers were published that provided support for this hypothesis,[93,94,95] the evidence for which has only grown stronger over the ensuing years.[96] In particular, Boccaccio et al.[94] developed a model for human liver carcinoma by targeting activated human MET oncogene to mouse liver with a lentiviral vector and liver-specific promoter. Genome-wide expression profiling of mouse hepatocytes expressing the MET oncogene demonstrated significant upregulation of the genes for PAI-1 and cyclooxygenase-2, along with two- to threefold increases in circulating levels of the proteins. Rong et al.[95] initially linked inactivation of the tumor suppressor gene PTEN in human astrocytoma cell lines with induction of TF gene expression, and Magnus et al.[97] provided further support for the importance of both PTEN loss and the expression of the oncogenic epidermal growth factor receptor and its mutant (EGFRvIII) in the aggressive cell behavior of glioblastoma multiforme. These models show that direct oncogene activation and/or tumor suppressor gene inactivation may result in the upregulation of blood clotting *in vivo*. Furthermore, these data imply that targeting clotting proteins might prove to be complementary to traditional chemotherapy, perhaps by reducing the risk for thrombosis, as well as by impairing tumor growth.[96]

The Role of the Coagulation System in Tumor Progression

TF induces angiogenesis via clotting-dependent mechanisms by downstream generation of thrombin and fibrin and by thrombin-induced platelet activation. In addition, the formed fibrin induces upregulation of TF on tumor cells and EC and

the secretion of the proangiogenic factor, interleukin-8, thus generating a vicious cycle of clot formation and tumor growth.[98] The function of TF in tumor angiogenesis can also be mediated through mechanisms independent of thrombin generation and fibrin deposition. These mechanisms are induced via the phosphorylation of the TF cytoplasmic tail and subsequent signal transduction cascades. In a protease-receptor pathway, the TF/FVIIa complex activates one or more protease-activated receptors (PARs), which, coupled to G proteins, impact multiple signaling pathways and support angiogenesis *in vivo*.[99] TF can also promote an increased expression of the angiogenic factor VEGF and decreased expression of the antiangiogenic peptide thrombospondin. Moreover, TF promotes tumor invasion and metastasis by (a) the capacity of TF–VIIa–Xa complex to promote local thrombin generation with subsequent proteolytic activation of platelet and endothelial PARs and fibrin deposition; (b) the capacity of the tumor-associated TF–VIIa–Xa to directly activate PAR-1 and PAR-2 signaling pathways; (c) the capacity of TF/FVIIa complex to cooperate with TF pathway inhibitor expressed by tumor vessels in inducing cell adhesion and migration by a thrombin-independent circle (FIGURE 125.5).[73]

Thrombin is an effective activator of angiogenesis via clotting-dependent mechanisms involving platelet activation and fibrin deposition. Furthermore, thrombin induces angiogenesis through clotting-independent mechanisms mediated by PAR activation and resulting signal transduction cascades. Thrombin activation of PARs leads to upregulation of many angiogenesis-related genes, including VEGF, VEGF receptors (VEGFR), TF, bFGF, and metalloproteinase (MMP)-2. In addition, thrombin stimulates the release of VEGF and angiopoietin from platelets, which induce tube formation by EC. Thrombin contributes significantly to a more malignant phenotype by inducing (a) platelet-tumor aggregation, (b) tumor adhesion to EC and extracellular matrix (ECM), and (c) tumor cell proliferation and metastasis. Important in this setting is the capacity of thrombin to trigger the release of growth factors, chemokines, and extracellular proteins that promote the proliferation and migration of tumor cells. The prometastatic activity of thrombin is demonstrated by experimental pulmonary metastasis models, in which lung metastases are increased by thrombin-treated tumor cells compared to untreated tumor cells.[100,101,102] The role of thrombin-activated platelets is shown by murine models, in which the elimination of circulating platelets results in a significant reduction in tumor metastasis formation. Indeed activated platelets facilitate tumor cell adhesion to EC and favor their migration through the vessel wall by the release of heparinase activity. Additionally, tumor cell–associated platelets may support metastasis formation by preventing interactions between tumor cells and innate immune cells, as shown by immunodepletion studies *in vivo*.[103] Finally, activated platelets support the angiogenic process by releasing VEGF and platelet-derived growth factor.[104]

Fibrin plays important roles in thrombogenesis as well as in tumor progression, and its deposition within the vascular endothelium of new tumor vessels, or attached around inflammatory cells or tumor cells, suggests that angiogenesis is facilitated. Local deposits of fibrin can stabilize the adhesion of tumor cells or tumor cell–associated emboli to the endothelium, particularly in a high-shear stress environment. In addition, fibrin matrix provides an excellent scaffold for the formation of new vessels.[105] Last, the fibrin matrix protects from proteolytic degradation the proangiogenic growth factors bFGF, VEGF, and insulin-like growth factor-1.[106]

Leucocytes, particularly polymorphonuclear (PMN) leukocytes, promote tumor growth and metastasis,[107–110] as the interaction of tumor cells with PMN or EC represents a crucial step in the early phase of extravasation and formation of new metastatic lesions.[111] In fact, PMN may adhere to tumor cells facilitating their migration across the endothelial barrier. In addition, PMNs release numerous MMP that hydrolyze ECM components and favor cancer cell dissemination. Furthermore, the selectins, including L-, E-, and P-selectin, mediate the initial interactions between circulating PMNs, activated ECs, and tumor cells. During hematogenous metastasis, tumor cells carrying selectin ligands enter the circulation and may encounter vascular selectins, thus

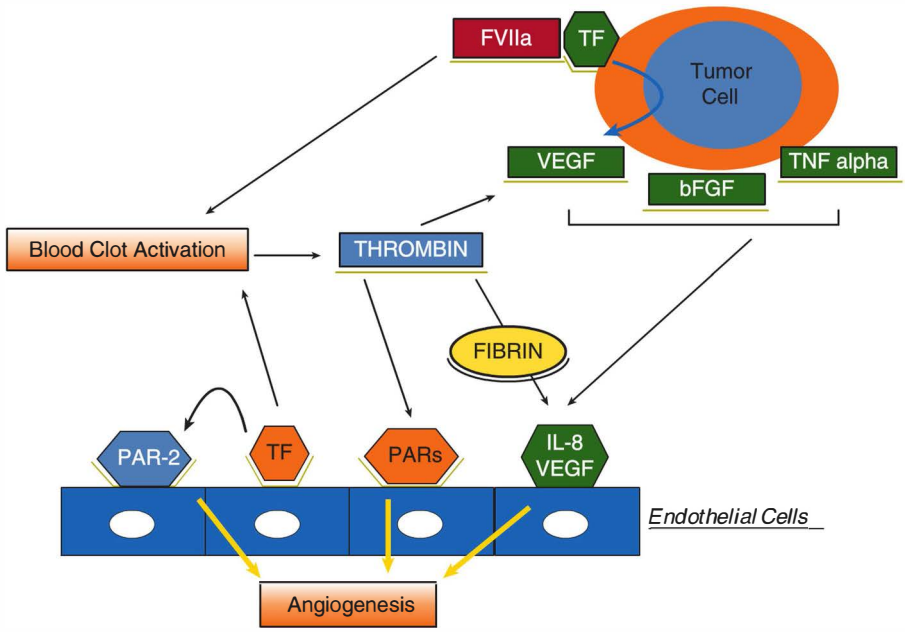

FIGURE 125.5 Role of coagulation system in tumor progression. In addition to their primary role in hemostasis and blood coagulation, hemostatic proteins play several roles in tumor angiogenesis, via clotting-dependent or -independent mechanisms. TF, tissue factor; IL-8, interleukin-8; PAR, protease-activated receptor; FVIIa, activated coagulation factor VII.

supporting cancer progression, as shown by different studies using mouse models and carcinoma cell lines.[111]

THROMBOPROPHYLAXIS IN CANCER PATIENTS

The prevention and treatment of VTE in cancer patients pose difficulties, in light of increased recurrence rates and bleeding complications.[18,19] Cancer patients undergoing surgery benefit from effective pharmacologic and mechanical prophylaxis,[112] as reflected in current guidelines that patients undergoing major cancer surgery should receive heparin-based prophylaxis for a minimum of 7 to 10 days, with supportive mechanical prophylaxis in patients at highest risk.[113,114]

Surgical Patients

Clinical trials have demonstrated the efficacy of subcutaneous UFH in preventing DVT and PE in patients undergoing major surgery, with or without a diagnosis of cancer.[115,116] In a meta-analysis of eight trials that included patients undergoing surgery for cancer, no differences in asymptomatic DVT, clinical PE, death, and major bleeding were detected between low molecular weight heparin (LMWH) and UFH.[117] In a subgroup analysis of over 6,000 patients with malignant disease receiving perioperative UFH or LMWH, compared to 17,000 patients without malignancy, fatal PE was three times as common in patients with cancer than in surgical patients who did not have cancer, regardless of the use of thromboprophylaxis.[118] In a study of over 2,000 patients undergoing laparotomy for cancer, increasing the dose of the LMWH dalteparin from 2,500 to 5,000 IU once daily was associated with a reduction in the frequency of postoperative DVT from 14.9% to 8.5%,[119] with no significant increase in bleeding complications. Although there was a reduction in the frequency of postoperative DVT with the higher dose of LMWH in patients without malignant disease, the increased dose was associated with an increase in perioperative bleeding complications.[119] A number of trials have shown that venographically documented DVT can be reduced with extended out-of-hospital prophylaxis with LMWH in patients undergoing major hip or knee replacement surgery.[120] In the ENOXACAN II study, patients undergoing surgery for abdominal malignancy received 1 week of enoxaparin and were randomized to enoxaparin or placebo for another 21 days.[113] Bilateral venography performed at the end of treatment showed a statistically significant reduction in DVT from 12% with placebo to 4.8% with extended prophylaxis; these results have been confirmed by a trial of patients undergoing general surgery who received routine postoperative or extended prophylaxis with LMWH dalteparin.[121] No benefit of extended prophylaxis has so far been demonstrated on symptomatic VTE.

Medical Cancer Patients

Hospitalized Cancer Patients

Patients with cancer who are bedridden, for example, in relation to pain crisis, infection, or hypercalcemia, are at risk for thrombosis. Clinical trials have demonstrated clear-cut benefit of VTE prophylaxis in hospitalized medical patients, including those with cancer. The first important study was the MEDENOX study,[122] in which a *post hoc* analysis demonstrated a 50% risk reduction of objectively confirmed VTE in cancer patients receiving LMWH enoxaparin compared with placebo.[123]

These results were substantially confirmed by the subsequent PREVENT trial, in which the incidence of VTE in acutely ill medical patients was reduced from 5.0% (73 of 1,473) in the placebo group to 2.8% (42 of 1,518) in the group treated with LMWH dalteparin.[124] A *post hoc* analysis revealed that in cancer patients, the VTE rate fell from 8.3% with placebo to 3% with LMWH, with a 63% risk reduction.[125]

Ambulatory Cancer Patients

Few data on the primary prevention of thrombosis in ambulatory patients with cancer are available. In a double-blind randomized trial, 311 patients with metastatic breast cancer were given either very low-dose warfarin (1 mg/day for 6 weeks followed by an adjusted dose to a target PT INR of 1.3 to 1.9) or placebo while receiving chemotherapy.[126] There was an 85% risk reduction in the rate of thromboembolism, which was statistically significant, without an increase in bleeding, but despite this study, oncologists do not routinely use prophylaxis in this situation. The CONKO-004 trial found a 87% risk reduction of VTE using LMWH enoxaparin at 1 mg/kg once daily for 3 months compared with no prophylaxis (9.9% vs. 1.3%, $P < 0.01$),[127,128] while the FRAGEM study reported a 61% risk reduction using the CLOT study therapeutic regimen of LMWH dalteparin (31% vs. 12%, $P = 0.02$).[129] However, results from CONKO-004 and FRAGEM trials are in contrast with other studies evaluating LMWH. In particular, the TOPIC-1 and TOPIC-2 trials in patients with advanced breast or non–small cell lung cancer did not show statistically significant improvement of VTE rate with the use of LMWH compared to placebo.[130] Similarly, in the PRODIGE study, the VTE rate was lower in patients with malignant glioma who received LMWH dalteparin (9%) compared to placebo (14.9%), but this difference did not reach statistical significance.[131]

This contrasting evidence suggests that standard prophylaxis doses of LMWH may be insufficient in patients with cancer to prevent thrombosis. However, another interpretation is that prophylaxis is beneficial in only certain tumor types. Recently, the PROTECHT study randomly assigned 1,150 patients with lung, gastrointestinal, pancreatic, breast, ovarian, or head and neck cancer to receive subcutaneous injections of LMWH nadroparin (3,850 anti-Xa UI/day) or placebo for the duration of chemotherapy or to a maximum of 4 months.[132] The results showed that 15/769 (2%) patients treated with nadroparin had a thromboembolic event versus 15/381 (3.9%) patients treated with placebo ($P = 0.02$). More recently, an ultra-LMWH, semuloparin 20 mg daily, was compared with placebo in patients with metastatic or locally advanced solid tumors starting on chemotherapy for a mean of 3.5 months.[133] There was a significant reduction of symptomatic or fatal VTE with semuloparin (1.2% vs. 3.4%, HR 0.36, 95% CI 0.21 to 0.60) without any increase in major bleeding.[134]

Overall, there is sound evidence that LMWH is effective in reducing clinically important VTE in selected outpatients receiving chemotherapy, but the optimal dose, duration, and specific patient populations have to be further defined.

Recommendations

Experts' guidelines and consensus statements have been published on the use of VTE prophylaxis for cancer patients, most notably by the American College of Chest Physicians,[134] the

International Union of Angiology,[135] the National Comprehensive Cancer Network (NCCN),[136] the Italian Association of Medical Oncology (AIOM),[137] French National Federation of the League of Centers Against Cancer (FNCLCC),[138] European Society of Medical Oncology (ESMO),[139] and the most recent guidelines from the American Society of Clinical Oncology (ASCO)[140] (Table 125.1). There is broad agreement among the scientific panels on the importance of thromboprophylaxis in hospitalized patients with cancer. Prophylaxis is not yet recommended for ambulatory patients with cancer (with exceptions) or for CVCs. All of the panels agree that LMWH is preferred for the long-term treatment of VTE in cancer.

Surgical Cancer

The AIOM, NCCN, ESMO, and ASCO guidelines recommend prophylactic anticoagulation in the surgical oncology setting. In particular, the ASCO guidelines recommend that patients undergoing laparotomy, laparoscopy, or thoracotomy lasting more than 30 minutes should receive pharmacologic thromboprophylaxis with either low-dose UFH or LMWH unless contraindicated because of a high risk for or active bleeding. Mechanical methods may be added to pharmacologic methods, but should not be used as monotherapy for VTE prevention unless pharmacologic methods are contraindicated. A combined regimen of pharmacologic and mechanical prophylaxis may improve efficacy, especially in the highest-risk patients. These recommendations are echoed by the NCCN and AIOM guidelines.

Since cancer surgery patients remain at elevated risk for VTE for an extended period of time following hospital discharge, the ASCO panel recommends that prolonged prophylaxis for up to 4 weeks be considered in patients undergoing major abdominal or pelvic cancer surgery with high-risk features, such as residual malignant disease postresection, obesity, or a previous history of VTE. The NCCN guidelines also recommend that all cancer patients with high risk (age ≥ 60 years, advanced cancer, operative times more than 2 hours, previous VTE, and >3 days of bed rest) undergoing major surgery should be considered for extended VTE prophylaxis. The AIOM and ESMO guidelines take an even stronger stance by recommending that prolonged prophylaxis be considered the standard of care for patients undergoing elective cancer surgery.

Hospitalized Medical Cancer Patient

ASCO guidelines recommend that hospitalized patients with cancer should be considered for thromboprophylaxis. NCCN guidelines recognize that multiple intrinsic and extrinsic factors play a role in the risk of VTE during hospitalization and ask that clinicians take into account these risk factors. The NCCN panel therefore recommends that all patients with cancer or suspected to have cancer should receive risk-stratified VTE prophylaxis on hospital admission. The AIOM and ESMO guidelines focus on immobility as a major risk factor and recommend prophylaxis only in immobilized hospitalized patients with cancer with an acute medical illness. These guidelines all recommend either low-dose UFH, LMWH, or fondaparinux as anticoagulants for thromboprophylaxis without expressing a preference for a particular agent or class of agents.

Ambulatory Patients

The guideline panels largely agree on not recommending routine thromboprophylaxis in this setting. Outpatient VTE prophylaxis is recommended by the AIOM, NCCN, ASCO, and ESMO panels only for multiple myeloma receiving highly thrombogenic thalidomide- or lenalidomide-based combination chemotherapy regimens. Recommendations in this setting may change in the near future with the availability of a validated thrombosis risk assessment tool.

Central Venous Catheters

Anticoagulant prophylaxis has yet to be proven effective in reducing the incidence of CVC-related DVT. Therefore, until effective regimens are identified, AIOM, NCCN, FNCLCC, and ESMO do not recommend routine prophylaxis for this purpose. However, AIOM and ESMO guidelines suggest tailoring prophylaxis based on individual risk profiles without specifying a method of risk assessment in this setting, while FNCLCC guidelines emphasize the importance of positioning the catheter tip at the superior vena cava–right atrial junction.

DIAGNOSIS AND TREATMENT OF CANCER-RELATED THROMBOSIS

Diagnosis of VTE

Deep Vein Thrombosis

Diagnosis of DVT in patients with cancer relies on the same principles and imaging criteria as in patients without cancer (see Chapter 83). Because cancer patients without DVT can have symptoms consistent with DVT, objective testing is of utmost importance to accurately confirm or exclude the

Table 125.1

Primary prophylaxis in the cancer patient: recommendations

Patients undergoing surgery	Prophylaxis with low-dose UFH or LMWH for at least 7–10 d Extended prophylaxis up to 4 wk after discharge in patients with high-risk features	If patient has contraindication to anticoagulation: consider mechanical methods alone
Hospitalized patients	VTE prophylaxis with anticoagulants	If patient has contraindication to anticoagulation
Ambulatory patients receiving chemotherapy	Only patients with multiple myeloma receiving thalidomide or lenalidomide prophylaxis with LMWH or adjusted-dose warfarin	Otherwise, no routine prophylaxis

presence of DVT. Compression ultrasonography is considered the first test of choice for the diagnosis of DVT, but it is sometimes not available and serial testing to detect extension of a distal DVT may be problematic. To reduce the need for ultrasonography, clinical prediction rules and D-dimer testing have been introduced and validated as reliable tools in excluding DVT.[141] Standardized management algorithms using a combination of these tests are used to maximize diagnostic accuracy and efficiency. However, it is important to note that these diagnostic tests and algorithms have not been evaluated rigorously in patients with cancer. Although many diagnostic studies included oncology patients, the results of this subgroup are often not reported separately. Definition of cancer may also vary from study to study, leaving some uncertainty as to whether the results are comparable across studies or generalizable to different cancer populations. Consequently, clinicians should be cautious in applying clinical prediction rules and D-dimer testing for excluding thrombosis in oncology patients and understand the limitations of these tools in this high-risk population.[142,143]

Clinical predictions rules, in general, have not included cancer-specific risk factors. Tumor type, stage of cancer, and timing of the cancer diagnosis are important determinants of the risk of thrombosis and should be considered when estimating a cancer patient's pretest clinical probability. For example, tumors of the pancreas and brain, advanced or metastatic disease, and the initial few months after a diagnosis of cancer are all associated with the highest risks of thrombosis.[11,22,28] In addition, alternative diagnoses that give rise to symptoms that mimic DVT may in fact increase the risk of thrombosis, rather than diminish it. For example, pelvic adenopathy can cause extrinsic venous compression, giving rise to leg swelling that mimic DVT, but it can also produce sufficient venous stasis to trigger thrombus formation. This alternative diagnosis creates a dilemma in deciding whether to reduce or increase the prediction rule score when estimating the pretest probability of thrombosis.

The use of D-dimer testing in cancer patients is also questionable. In patients without cancer, normal D-dimer levels have a high negative predictive value and, in combination with a low clinical probability or a normal leg ultrasound, can reliably exclude DVT.[141] In oncology patients, D-dimer levels are often elevated in the absence of thrombosis. This lowers the specificity of the test and limits its usefulness or efficiency in ruling out DVT (Table 125.2).[142–147] Also, the high prevalence of thrombosis can reduce the negative predictive value and increase the false-negative rate of moderately sensitive assays in this high-risk population.

A number of retrospective analyses have been done to critically evaluate the accuracy and usefulness of combining a clinical prediction rule and D-dimer testing in cancer patients. Using data from prospective cohort studies that applied the Wells rule and performed D-dimer testing at baseline using the SimpliRED whole-blood agglutination test, one study found that the prevalence of DVT in cancer patients was 9.7%, 27.1%, and 61.6% in the low, moderate, and high probability categories, respectively.[148] These are approximately twice as high as the corresponding values in patients without cancer. Similarly, the prevalence of DVT in the negative D-dimer group was 7.8% among cancer patients, versus 3.5% in patients without cancer. Overall, only 6% of cancer patients presenting with suspected DVT had a combination of a low clinical probability and a negative D-dimer result. Consequently, 94% of patients with cancer would require further investigations such as ultrasonography despite applying the prediction rule and performing D-dimer testing. This raises the question whether these tools are useful in oncology patients. Last, although the negative predictive value of the combination of low probability and negative D-dimer result was 100% (95% CI 69.8% to 100%) in this study, the lower bound of the CI suggests that up to 30% of patients with low probability and a negative D-dimer result may have a DVT. Similar findings were reported in a study using data derived also from prospective cohort studies.[149] In this study,

Table 125.2

Performance of D-dimer assays in patients with cancer

D-Dimer Assay	Cancer Patients (N)	VTE Incidence (%)	Sensitivity (%)	Specificity (%)	NPV (%) (95% CI)
SimpliRED[142]	121	49	86	48	7 (63%–90%)
SimpliRED[143]	217	40	98	48	97 (89–100)
MDA[144]	66	44	97	46	94 (73%–100%)
MDA[145]	50	34	100	45	100 (78%–100%)
Minutex[145]	47	62	100	22	100 (71%–100%)
Tinaquant[147]	72	26	100	21	100 (72%–100%)

NPV, negative predictive value.

the prevalence of thrombosis in cancer patients was 41%. The negative predictive value of a low clinical probability and negative D-dimer was also 100% (95% CI 85% to 100%), but only 9% of the cancer patients had this combination.

In summary, given the limited evidence available, it is uncertain if clinical prediction rules and D-dimer testing add much value to ultrasonography in diagnosing DVT in cancer patients. Further objective testing in those with a low clinical probability score and negative D-dimer result might be warranted, particularly if the physician's clinical suspicion is high or if a moderately sensitive D-dimer test was used.

Pulmonary Embolism

The diagnosis of PE has advanced in the past decade largely due to more sensitive and readily available imaging studies.[150] Computerized tomography pulmonary angiography (CTPA), or spiral CT, has become the first test of choice for most clinicians. This imaging technique enables physicians to accurately confirm or refute a diagnosis of PE in the majority of suspected cases. In contrast, ventilation–perfusion lung scanning has become less popular because of the lack of accessibility and perhaps lower sensitivity.[151] In patients with cancer, CTPA can also provide staging information and reveal an alternative diagnosis in many cases. Clinical prediction rules and D-dimer testing have been evaluated for diagnosis of PE.[152–155] Unfortunately, as in DVT, there is a paucity of evidence in support of these tools in cancer patients. Similar to clinical prediction rules used for diagnosing DVT, rules for PE also do not consider cancer-specific risk factors that are strong predictors of thrombosis. Many conditions give rise to the same symptoms as PE, making it difficult to decide on the significance of an alternative diagnosis. Studies have reported sensitivities and negative predictive values of 100% for D-dimer testing using enzyme-linked immunoassay methods[147,156] and that combining clinical probability and D-dimer testing appears to safely rule out PE.[157] But the numbers of patients with cancer in these studies were small, and so there is less confidence in applying these tools in oncology patients. The low prevalence of patients with a low clinical probability and negative D-dimer result at presentation also limits the usefulness of these tools, as fewer than 10% of patients would not require further testing.[157]

Incidental Thrombosis

Although advances in CT imaging have improved the accuracy in the diagnosis of PE, they have also led to the identification of an increasing number of incidental or unsuspected PE during routine cancer staging and treatment response assessment. The prevalence of incidental PE varies among different studies, ranging from 1.2% to 11%.[17,158,159] Up to 75% of these cases have proximal and multiple emboli. Furthermore, a retrospective study found that 75% of patients with unsuspected thrombosis in fact had symptoms of PE at the timing of scanning. This suggests that physicians often overlook these symptoms or attributed them to the underlying cancer or other conditions, such as anemia.

Staging CT scans of the abdomen and pelvis can also detect unsuspected DVT of the inferior vena cava (IVC) and iliofemoral veins. In a retrospective analysis of 435 consecutive staging CT scans performed at a single institution, an overall prevalence of DVT or PE observed was 6.3%.[159] The prevalence of unsuspected iliofemoral thrombosis was 6.8%, unsuspected common iliac thrombosis 1.2%, unsuspected IVC thrombosis 0.3%, and unsuspected PE in 3.3%. Thrombosis was more common in inpatients and in those with advanced disease. This finding is consistent with other reports.[160,161]

The clinical importance of these unsuspected thrombotic complications and whether treatment with anticoagulant therapy is necessary are uncertain. One report suggests that proximal PE (segmental level or higher) is associated with increased mortality while subsegmental PE does not have an impact on survival.[162] Because the majority of cases with unsuspected thrombosis were treated in studies, the "natural" history or outcome of these patients without treatment is unknown. Few studies have reported favorable outcomes in some patients who did not receive anticoagulation, but the numbers are small.[163] Given the bleeding risk and logistic burden associated with anticoagulant therapy is not insignificant, it should not be prescribed without careful discussion with each patient. On the other hand, proximal thrombosis and embolism are potentially life threatening, particularly in hypercoagulable cancer patients, and likely warrants standard treatment.

Treatment of VTE

LMWH is the preferred agent for monotherapy of cancer-associated thrombosis.[164,165] This replaces the traditional regimens for the treatment of acute VTE using initial therapy with UFH, LMWH, or fondaparinux followed by long-term therapy with a vitamin K antagonist (VKA). Novel oral anticoagulants that achieve rapid inhibition of activated factor X or thrombin may offer an easier solution than LMWH, but studies focusing on treatment of cancer-associated thrombosis with these agents are lacking. To date, some of these new agents have shown comparable efficacy and safety compared with traditional anticoagulants in randomized trials that included primarily patients without cancer.[166,167]

Initial Treatment

Multiple randomized trials and meta-analyses of these trials have confirmed that for initial therapy LMWH is at least as efficacious as UFH in reducing recurrent thrombosis and is associated with a lower risk of major bleeding.[168] Data for the cancer patient subgroup are much more limited but suggest a reduction in the 3-month mortality with LMWH use.[168,169] Fondaparinux also has similar efficacy and safety as the heparins for the initial treatment of VTE in the general population.[170,171] However, a recently published *post hoc*, subgroup analysis of the 477 cancer patients in the MATISSE DVT and PE trials suggests that fondaparinux may be less effective than LMWH but more effective than UFH.[172] Bleeding associated with these parenteral agents for initial therapy in cancer patients has not been reported.[173] Unfortunately, formal clinical trials comparing UFH, LMWH, and fondaparinux are unlikely to be conducted to define their relative risks and benefits in the oncology population.

Long-Term Treatment

In contrast, formal randomized trials have compared the effects of LMWHs with warfarin and other VKAs for long-term therapy in patients with cancer (Table 125.3).[174,175,176,177]

Table 125.3

Randomized studies comparing LMWH with VKA therapy for long-term treatment of cancer-associated thrombosis

Study	Patients (N)	Long-Term Treatment	Recurrent VTE (%)	Major Bleed (%)	Death (%)	P-Value
Meyer et al. 2002[174]	71	Warfarin	21.1		22.7	NS
	67	Enoxaparin 1.5 mg/kg	10.5		11.3	NS
Lee et al. 2003[175]	336	Warfarin	17	4	41	0.002
	336	Dalteparin 200/150 IU/kg	9	6	39	0.002
Deitcher et al. 2006[176]	30	Warfarin	10	2.9	8.8	NS
	29	Enoxaparin 1.0 mg/kg	6.9	6.5	6.5	NS
	32	Enoxaparin 1.5 mg/kg	6.3	11.1	19.4	NS
Hull et al. 2006[177]	100	Warfarin	10	7	19	NS
	100	Tinzaparin 175 IU/kg	6	7	20	NS

VTE, venous thromboembolism; NS, not significant.

Of these, the largest trial is the CLOT study.[175] In this trial, 676 cancer patients with proximal DVT, PE, or both were randomized to receive usual treatment with dalteparin followed by VKA therapy or dalteparin alone for 6 months. Patients in the dalteparin group received full therapeutic doses at 200 IU/kg once daily for the 1st month and then 75% to 80% of the full dose for the next 5 months. The cumulative risk of recurrent VTE at 6 months was reduced from 17% in the VKA group to 9% in the dalteparin group, resulting in a statistically significant risk reduction of 52% (log-rank $P = 0.002$). Overall, there were no differences in bleeding and mortality between the groups. The other trials differ in design from the CLOT study mainly in the duration of treatment (3 months) and the type and dose of LMWH used. Although none of these other trials demonstrated statistically significant differences between the LMWH and warfarin, there were strong trends favoring LMWH in all the studies. Based on published evidence, the use of LMWH alone for the treatment of DVT in patients with cancer is endorsed by international guidelines.[164,165] The dalteparin regimen used in the CLOT study is currently the only LMWH with regulatory approval for extended use in preventing recurrent VTE in cancer patients.

Novel Anticoagulants

Novel anticoagulants, including dabigatran, rivaroxaban, and apixaban, have limited data in patients with cancer. These are effective anticoagulants with no requirement for laboratory monitoring and have minimal drug interactions. They are administered orally once or twice a day, making them very attractive options for long-term use. The treatment trials to date vary in design, with one trial maintaining the two-phase approach starting with a 1-week course of heparin followed by either warfarin or dabigatran (RE-COVER),[166] while other studies initiated rivaroxaban (EINSTEIN DVT)[167] or apixaban (AMPLIFY) in the initial treatment phase. In the dabigatran trial, the risk of recurrent thrombosis and major bleeding were comparable between dabigatran and warfarin.[166] However, only 120 patients with cancer (5% of the total study sample) were included, and their results were not reported separately. In the EINSTEIN DVT trial, there was similarly a small number of oncology patients without separately reported results.[167]

One small phase II randomized feasibility trial has studied the use of apixaban in patients with advanced or metastatic cancer.[178] Patients were randomized to one of three doses of apixaban or placebo during the first 12 weeks of first- or second-line chemotherapy. With approximately 30 patients per group, the study found a very low bleeding rate in those treated with apixaban and a time and dose effect on F1+2 and other markers of coagulation.

Given the higher risk of recurrent thrombosis and bleeding in patients with cancer, it is important that further research is done to understand the antithrombotic impact of these new agents in cancer patients before accepting it for treatment of cancer-associated thrombosis.

Treatment of Recurrent Thrombosis

Up to 9% of patients with cancer-associated thrombosis treated with LMWH or 20% treated with warfarin can develop recurrent VTE. Studies have suggested that presence of metastasis, younger age, or a short interval between VTE and cancer diagnosis (>3 months) are predictors of recurrent thrombosis despite anticoagulation.[179,180] Whether the risk factors that increased the risk of a first episode of thrombosis also contribute to a higher risk of recurrent thrombosis is unknown.

Although randomized controlled trial data are lacking to guide optimal management in oncology patients with recurrent thrombosis, observational data and increasing clinical experience support the use of LMWH in this setting. In patients who developed a recurrence while on warfarin therapy, the recommended practice is to switch these patients to LMWH because it is more efficacious than warfarin. Raising the intensity of warfarin therapy is not recommended because of the potential for increasing bleeding without a benefit in reducing recurrent VTE. Patients with cancer have a high risk of bleeding as well as a high

risk of recurrent thrombosis despite achieving therapeutic and even higher INRs.[18,181]

For patients who developed a recurrence while on LMWH, dose escalation of LMWH is often effective. In a small cohort study of oncology patients with recurrent thrombosis while on LMWH or warfarin, escalating the dose of LMWH by 20% to 25% or switching to LMWH, respectively, was effective in preventing further thrombotic episodes.[181] During 3 months of follow-up, 6 of 70 (8.6%) of patients developed another recurrence while 1 patient had a major bleeding event and 2 had minor bleeding. The success of escalated doses of LMWH suggests that the standard weight-adjusted dose regimens are insufficient in some patients with cancer. This is not surprising given the heightened prothrombotic state of these patients. Anecdotal experience has found that doses twice that of the standard recommended LMWH dosing might be required to achieve therapeutic anti-Xa levels and are well tolerated in some oncology patients.

Inferior Vena Cava Filter

Insertion of a vena cava filter has been recommended for oncology patients with recurrent VTE despite adequate long-term LMWH therapy. However, adequate studies have not been done to evaluate or document the outcomes. Retrospective series have reported that up to 32% of oncology patients with filters inserted for thrombosis develop recurrent VTE.[182] The high recurrence rate is not surprising since filters do not treat the underlying hypercoagulable state in patients with cancer. The single randomized trial studying the efficacy of filters in patients who were also treated with anticoagulation showed a reduction in symptomatic PE but higher rates of recurrent DVT in the filter group.[183] Overall, the total VTE rates were the same and a difference in overall survival was not observed. Considering the cost and invasiveness of filters and the lack of proven efficacy, they should be used only in situations where anticoagulant therapy is contraindicated because of serious, active bleeding.

CONCLUSIONS

Patients with cancer are at high risk of developing VTE, and the risk of VTE varies according to the type of malignancy and its disease stage. The pathogenesis of cancer-associated VTE is multifactorial and includes demographic, cancer-associated, and treatment-related risk factors. Hospitalization, surgical, and nonsurgical cancer treatments (i.e., chemotherapy, hormonal, or immunosuppressive agents in conjunction with chemotherapy), or the presence of a CVC, increase the risk of VTE patients. Effective VTE prophylaxis for cancer patients at significant risk of thrombosis reduces the burden of VTE and improves outcomes. The current development of VTE predictive models, using the increasing knowledge of the clinical and biological markers of thrombosis in cancer, is important for identifying high-risk patients and reducing associated morbidity and mortality.

CHAPTER

126 Hemostatic Challenges in Liver Disease

CHARLES S. EBY AND STEPHEN H. CALDWELL

The liver is the predominant site for synthesis and clearance of proteins involved in formation and lysis of fibrin, as well as its regulation, and the predominant source of thrombopoietin (TPO). Therefore, acute and chronic liver diseases cause major changes in multiple components of the hemostasis system. In the past, these changes have been viewed as shifting the balance toward bleeding based on traditional screening hemostasis tests and common bleeding problems in cirrhosis. However, the view is changing based on *in vitro* studies supporting suppression of both prothrombotic and regulatory pathways to produce a fragile, but rebalanced hemostasis state. The inability of traditional screening hemostasis tests to predict bleeding complications is perhaps most apparent in successful liver transplantation with minimal blood product replacement and minimal blood loss.[1] Multiple observations have also identified evidence of a hypercoagulable predisposition in chronic liver disease patients who are at risk for thrombotic consequences. General application of this new paradigm to patients with severe liver disease awaits development and validation of novel laboratory methods and therapies in order to evaluate alternative strategies for assessment and management of hemostatic dysfunctions in patients with advanced liver diseases.

At this time, it is not possible to provide detailed, evidence-based guidelines for management of important clinical situations including prophylaxis and treatment of bleeding complications. Recognition of these knowledge gaps continues to stimulate clinical and laboratory research of hemostasis challenges in liver disease, and it is likely that in the coming years there will be more definitive management recommendations.

ACUTE LIVER FAILURE

Acute liver failure (ALF), defined as new-onset encephalopathy and coagulopathy following the development of jaundice in patients without preexisting liver disease,[2] has an estimated incidence of approximately 2,000 cases/year[3] and a mortality rate of approximately 33% in the United States, primarily due to cerebral edema, sepsis, and bleeding.[2] The leading causes of ALF in the underdeveloped world are viral hepatitis A, B, and E, while in Europe and the United States, acetaminophen toxicity, idiosyncratic drug reactions, and indeterminate causes are the main etiologies.[4]

At presentation, most ALF patients have diminished procoagulant factors evident by international normalized ratio (INR) 1.5 to 5.0 in 81.1%, INR > 10 in 4.8%, platelet count <120,000/μL in 86.1%, and <30,000/μL in 2.6%, based on data from the Acute Liver Failure Study Group (ALFSG) prospective cohort study of 1,074 patients.[5] Decreased hepatic synthesis of procoagulant, anticoagulant, and fibrinolytic proteins and accelerated consumption of hemostasis factors and platelets are consistent features of ALF regardless of underlying cause.[6–9] Plasminogen activator inhibitor-1 (PAI-1), von Willebrand factor (vWF), and factor VIII are elevated, likely reflecting the endothelial response to inflammatory cytokines.[6–7,10] Despite considerable hemostatic derangements, spontaneous bleeding complications are uncommon (<10%) in ALF patients,[5] and prophylactic plasma and platelet transfusions are inappropriate since they increase vascular volume and may exacerbate cerebral hypertension.[11]

Assessment of coagulopathy plays a role in determining if ALF patients should be listed for liver transplantation. The King's College criteria for transplantation include INR > 6.5, while the Clichy-Villejuif criteria include factor V activity <20%,[4] and initial factor VII activity <20% is associated with increased mortality.[12] A high model of end-stage liver disease (MELD) score (in part dependent on INR, Table 126.1) appears to be a sensitive predictor of death without transplant, but requires validation.[13] Indications for liver biopsy (rarely done) and intracranial pressure monitoring, and blood component transfusions prior to these invasive procedures, are controversial.[11,14] "Safe" INR and platelet count targets are not evidence based, and aggressive transfusion practices may worsen intracranial pressure.[5,14] Based on favorable anecdotal reports, the ALFSG recommends that cautious treatment with fresh frozen plasma (FFP) or cryoprecipitate (avoiding potentially detrimental volume overload) followed by recombinant activated factor VIIa (rFVIIa) be limited to highly invasive procedures such as insertion of intracranial pressure monitors.[11] Notably, one recent study showed that ALF patients often maintain normal thromboelastography (TEG) in spite of prolonged INR consistent with the concept of a rebalanced system in liver disease.[15]

In bleeding patients who are also at high risk for thrombotic complications, plasma exchange could be an alternative therapy to improve hemostasis. A European randomized trial compared three daily plasma exchanges to routine management in 182 ALF patients. Fifty-nine percent of plasmapheresed patients survived to leave the hospital compared to 48% in the control group.[16] However, confirmation of these preliminary findings is necessary before considering plasma exchange to be a standard strategy in ALF.

CHRONIC LIVER DISEASE

Causes of chronic liver injury include hepatitis B and C; alcohol; nonalcoholic steatohepatitis; autoimmune, inherited disorders; and cryptogenic disease. Chronic liver disease has long been associated with disturbances in hemostasis, and

Table 126.1

Prognostic scoring systems in cirrhosis

Model of End-Stage Liver Disease (MELD) Score

9.57 × ln (creatinine mg/dL) + 3.78 × 3.78 × ln (bilirubin mg/dL) + 11.2 × ln (INR) + 6.43

Child-Pugh-Turcotte Score

Parameter	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	<2.0	2.0–3.0	>3.0
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
PT prolong (s)	<4.0	4.0–6.0	>6.0
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Grades 1–2	Grades 3–4

Child A: 5–6 Points—well compensated
Child B: 7–9 Points—significant functional compromise
Child C: 10–15 Points—decompensated

both pro- and antithrombotic effects are recognized.[17] As liver disease progresses, conventional indices of the clotting cascade worsen and have been incorporated into liver disease prognostic scores including the classical Child-Pugh and the MELD scores (Table 126.1). The latter is now used to guide organ allocation in liver transplant candidates.[18] The relationship between abnormal coagulation indices and progressive liver fibrosis and cirrhosis is robust across various forms of chronic liver disease.

REBALANCED COAGULATION PATHWAYS IN STABLE CIRRHOSIS

The concept of a rebalanced but fragile hemostatic system in chronic liver disease has become established over the past few years (FIGURE 126.1).[1,19,20,21] In stable cirrhosis, the relative deficiency of hepatocyte-derived protein C and S, and antithrombin (AT), and increased factor VIII activity counterbalance the deficit in procoagulant factors. This concept is supported by *in vitro* methods that measure cumulative thrombin generation. Using small amounts of tissue factor and phospholipid to activate the extrinsic pathway, thrombin formation is monitored by measuring hydrolysis of a fluorescent-labeled peptide substrate to determine total thrombin generation or endogenous thrombin potential (ETP). Thrombin generation decreases as the severity of cirrhosis worsens.[20] However when endogenous protein C activation (aPC) is incorporated into the thrombin generation test, the ratio of (ETP + aPC)/(ETP unmodified) was significantly higher in the cirrhotic groups compared to healthy controls.[20,22,23] A higher ratio suggests a prothrombotic imbalance. Overall, the data suggest that protein C anticoagulant dysfunction is greater than the acquired coagulopathy in stable cirrhotic patients, producing a procoagulant state similar to congenital protein C deficiency or factor V Leiden (FVL) heterozygosity[24] despite prolonged prothrombin time (PT)/INR. Importantly, *in vitro* thrombin generation results have not yet been correlated with clinical outcomes so clinical recommendations cannot yet be formalized, although this work provides strong evidence for questioning long-standing practices such as INR cutoffs as indications for plasma transfusion.

Therefore, conventional coagulation tests such as PT/INR and activated partial thromboplastin time (aPTT) do not accurately reflect the bleeding risk in compensated cirrhosis patients. Reduced hepatic synthesis of AT accompanies progressive liver disease and may also contribute to a prothrombotic imbalance. However, while AT infusion prior to liver transplantation corrects the deficiency, it does not reduce thrombin generation.[25] Presently, there is no evidence to support a clinical benefit from AT replacement under any circumstance in patients with end-stage liver disease.

REBALANCED PRIMARY HEMOSTASIS IN STABLE CIRRHOSIS

Platelets serve as the phospholipid scaffold for the clotting cascade and undergo complex quantitative and qualitative changes in cirrhosis.[26] Prevalence estimates of thrombocytopenia in patients with chronic liver disease vary widely from 6% to 64%.[27] Severe thrombocytopenia requiring prophylactic platelet transfusions or corrective intervention is uncommon[27,28] and typically occurs in patients with decompensated liver disease (the term "decompensated" is a common way to describe cirrhotic patients requiring more aggressive care and often hospitalization for a variety of complications related to chronic liver failure and portal hypertension—*see also Decompensated Cirrhosis section*).

The major causes of thrombocytopenia in cirrhosis include splenic sequestration, decreased survival, and decreased production. However it can be challenging to identify and prioritize the likely causes for individual patients. Using radiolabeled platelets, investigators determined that thrombocytopenic, cirrhotic patients sequestered 50% to 90% of platelets in their spleen in an exchangeable pool while maintaining near-normal total body platelet mass and mild-to-moderate shortened platelet lifespans.[29,30] Splenic sequestration is a complex process, not simply dependent upon portal hypertension, as evidenced by

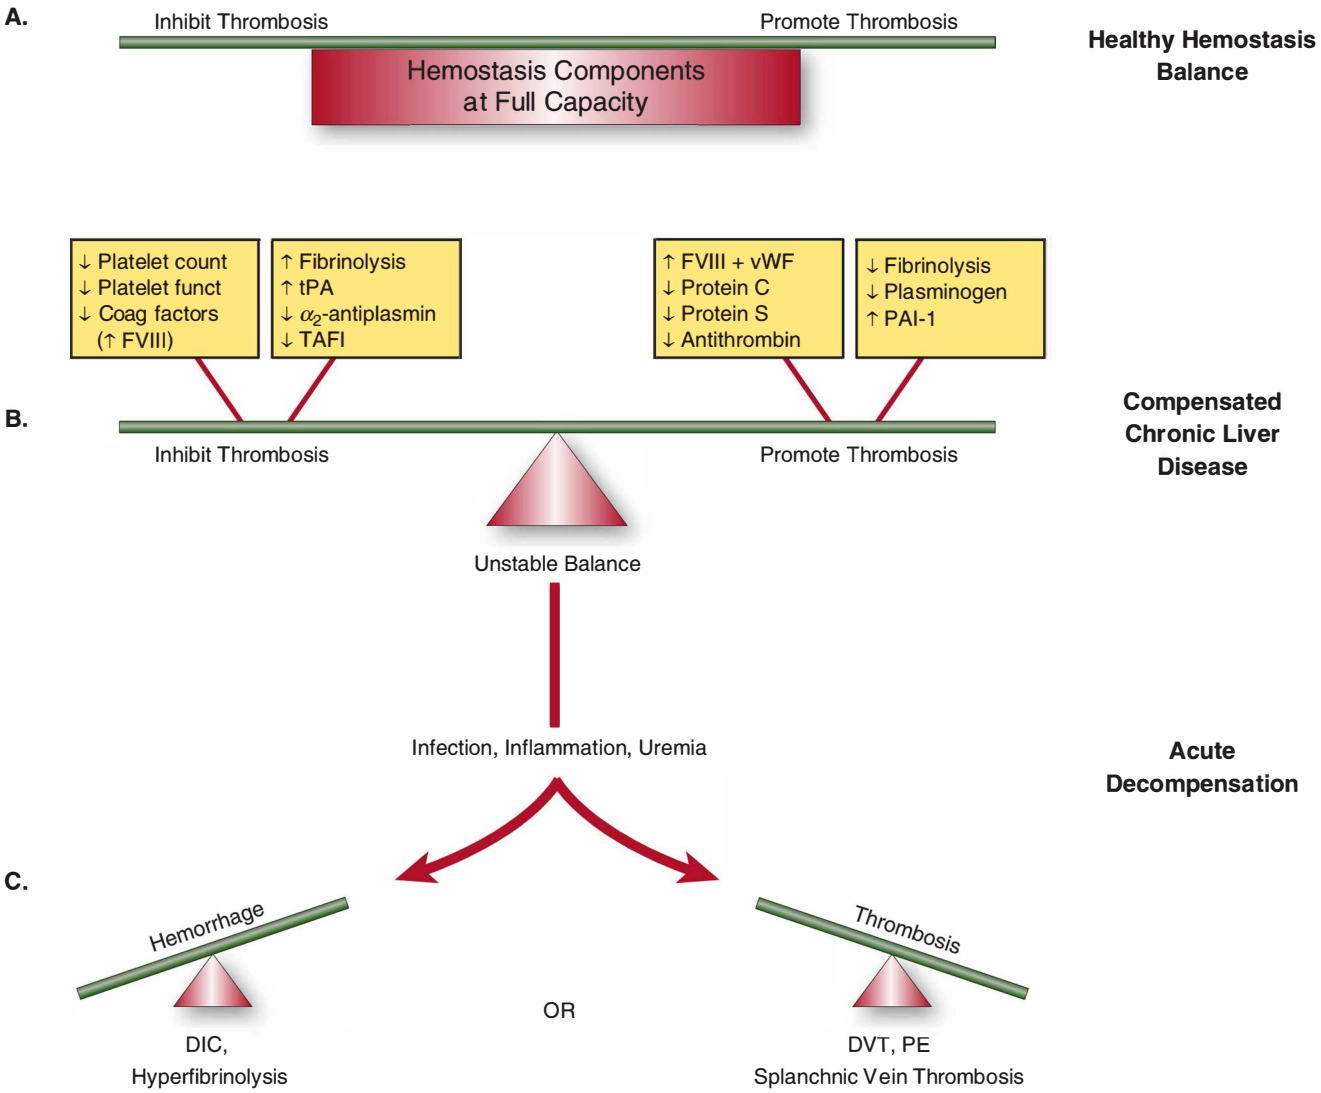

FIGURE 126.1 Changes in hemostasis balance with progressive liver disease. In healthy individuals **(1A)**, cellular and protein components of prohemostasis and antihemostasis pathways have adequate capacities to adapt to acute physiologic stresses. In patients with compensated liver disease **(1B)**, reductions in most coagulation/fibrinolysis factors and platelet number/function are offset by reductions in anticoagulant/antifibrinolysis factors and increased FVIII and vWF, resulting in a tenuous rebalancing of hemostasis. In patients with decompensated liver disease **(1C)**, comorbidities further deplete most pro- and antihemostasis functions producing a fragile and imbalanced state and increased risk of hemorrhage and thrombosis.

inconsistent improvement in platelet counts after transjugular intrahepatic portosystemic shunting or surgical decompression procedures.[31] Reduction of splenic tissue, by splenectomy[32] or partial splenic embolization,[33] results in higher platelet counts, albeit with potential morbidity. Shortened platelet survival due to immune-mediated platelet destruction may be a factor in patients with severe thrombocytopenia out of proportion to the stage of hepatic dysfunction, and in some cases, there have been responses to steroids or other immunosuppression therapies.[34,35] However, there is no value in routinely measuring platelet-associated immunoglobin G in thrombocytopenic patients with chronic liver disease due to a lack of specificity of the assay. Causes for decreased platelet production include suppression of megakaryopoiesis due to decreased hepatic production of TPO, or viral illness (HCV, HIV), alcohol, or medication (alpha interferon) toxicity.[36] Observations of platelet kinetics following orthotopic liver transplantation (OLT) indicate that TPO biology is disrupted in thrombocytopenic patients with advanced liver disease. A day after OLT, TPO concentrations increase followed by increased reticulated platelets and

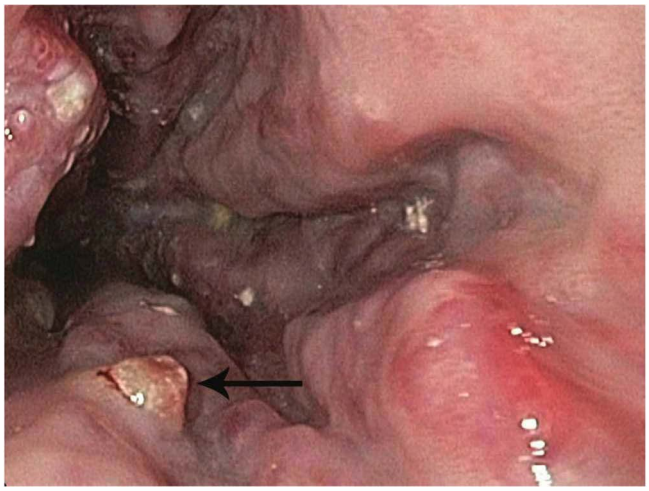

FIGURE 126.2 Gastric varices with platelet plug ("nipple") sign indicated by arrow. A scant amount of blood can be seen to be oozing from the base of the plug. (Image courtesy of Dr. Andrew Wang.)

resolution of thrombocytopenia.[37] In addition, pharmacologic interventions with recombinant TPO, TPO mimetics, and IL-11 increase platelet production.[28] However, TPO concentration in patients with chronic liver disease correlates poorly with platelet count,[28] partly explained by analytical problems for measuring TPO.[38] Therefore, it is of little value to measure TPO concentrations in thrombocytopenic patients with liver disease.

In vitro evidence supports thrombocytopenia as a contributor to defective hemostasis in patients with liver disease. Tripodi et al.[39] compared thrombin generation between healthy controls and patients with cirrhosis in the presence of soluble thrombomodulin and platelets. When platelet counts were normalized to 100,000/μL, ETP was similar in both groups. However, when platelet-rich plasmas were adjusted to patient and control whole-blood platelet counts, respectively, there was a positive correlation between platelet count and ETP.

Platelet dysfunction is especially important in mucosal and wound bleeding and possibly even in early stages of pressure-driven variceal bleeding, based on the well-known significance to endoscopists of the platelet plug sign (FIGURE 126.2).[40] There is ample experimental evidence of acquired platelet adhesion, activation, and aggregation defects in liver disease patients.[1,41,42] However *in vitro* model systems designed to assess platelet adhesion and aggregation in whole blood from liver disease patients under physiologic flow conditions suggest that primary hemostasis is not demonstrably defective, perhaps due to compensation from increased vWF activity.[26,43] Patients with advanced cholestatic liver diseases (primary biliary cirrhosis and primary sclerosing cholangitis) appear to have fewer bleeding complications and higher rates of portal vein thrombosis (PVT) compared to patients with hepatocellular injury.[42] Preliminary *in vitro* studies suggest enhanced platelet activity may be involved.[44,45]

FIBRINOLYSIS IN STABLE CIRRHOSIS

Multiple alterations to components of the fibrinolytic system occur with advanced liver disease[46,47] (Table 126.2). A lack of clinically validated functional tests to assess both fibrinolysis and its regulation hampers patient assessment.[48] Consequently, there is debate as to whether the dominant process is excess plasmin generation, due to increased tissue plasminogen activator (tPA) activity, decreased thrombin activatable fibrinolysis inhibitor (TAFI)[46,47] or diminished a_2-antiplasmin causing hyperfibrinolysis and elevated D-dimer, or decreased hepatic synthesis and clearance of fibrinolytic proteins and fibrin degradation products.[49] It is reasonable to propose that compensated cirrhotic patients have a fragile, poorly regulated fibrinolysis system, which can be tipped over into overt hyperfibrinolysis by increased thrombin generation due to activators from ascites, infection, malignancy, or hemorrhage.[21,47]

Clinically important secondary hyperfibrinolysis is estimated to occur in 5% to 10% of cirrhosis patients, typically during unstable, decompensated periods.[50,51,52–54] In one series of 86 consecutive admissions to an inpatient liver unit, 36% of cirrhotic patients had a shortened euglobulin lysis time (<120 minutes) and 22% had signs of mucocutaneous bleeding.[55] The condition should be suspected with spontaneous or delayed postprocedure bleeding and is accompanied by acute decreases in fibrinogen and platelet count, increased D-dimer, and prolonged PT and aPTT, or detected by TEG in the absence of significantly abnormal INR (personal observation). The clinical presentation and associated changes in hemostasis parameters are compatible with disseminated intravascular coagulopathy, although end-organ thrombotic injury is uncommon. Patients can present with spontaneous mucosal bleeding or multiple large hematomas due to primary hyperfibrinolysis and without evidence of an underlying precipitating event or multiorgan compromise. Typical laboratory results include acute hypofibrinogenemia and markedly shortened euglobulin lysis time, worsening anemia, but stable platelet count, PT, and aPTT.[56] Recognition of this clinical entity is important as more specific therapy is available (see Specific Agents section).

DECOMPENSATED CIRRHOSIS

A number of complications that influence the hemostatic system balance can occur in stable cirrhosis patients. "Decompensation" in this situation refers to the development of overt problems associated with worsening portal hypertension and liver failure such as ascites and encephalopathy, often in the setting of jaundice, which commonly necessitate hospitalization—a process more recently referred to as "acute on chronic liver failure."[57] Bleeding is common and sometimes precipitates the decompensation. In this situation, bewildering arrays of complex processes are evident, but three principle conditions affect hemostatic balance and bleeding risk: *infection, renal failure, and vasomotor dysfunction*.[58–60]

Bacterial infection, for example, subacute bacterial peritonitis, urinary tract infection, or cellulitis, is a common cause of decompensation in cirrhosis, and more subtle bacterial effects such as changes in intestinal permeability and endotoxemia impact the hemostatic system.[61] One mechanism is release of endogenous heparinoids that inhibit factor Xa.[62,63] Renal failure, a common problem in decompensated cirrhosis (hepatorenal syndrome), contributes to platelet dysfunction.[64] In this setting, hemodialysis can be viewed as a hemostatic intervention by reversing uremic platelet dysfunction and reducing volume overload.[64,65] Cirrhotic endothelial dysfunction is most evident by the occurrence of "hyperdynamic circulatory dysfunction," an arteriolar vasodilated state characterized by stable but low mean arterial blood pressure and increased cardiac output that can progress to the hepatorenal syndrome.[66] Experimentally, the condition is associated with impaired vascular smooth muscle contractility and impaired vasoconstriction in cirrhosis.[67] Increased nitric oxide (NO) synthesis by activated or injured endothelial cells may have a role in cirrhosis-related altered vasodilatation since NO and vWF increase with progressive liver disease and elevations of both are associated with endotoxemia.[68,69] Other indirect signs of endothelial stimulation or damage in cirrhosis include progressive elevation of soluble thrombomodulin and tissue factor.[70]

LABORATORY ASSESSMENT OF BLEEDING RISK

Assessment of hemostatic status in patients with advanced liver disease is crucial for management decisions, including priority for liver transplantation, bleeding risk assessment, and monitoring response to treatment. However, most routine hemostasis tests are seriously flawed for lack of convincing evidence for prediction of bleeding tendency, incomplete interrogation of complex, regulated pathways, methods based on nonphysiologic conditions, and interlaboratory imprecision. This leaves clinicians in the difficult position of either using arbitrarily determined hemostasis test "cutoffs"[71] or relying on clinical assessment of bleeding risk when deciding whether or not to use potentially harmful hemostatic therapies.

The hemostasis system in most patients with compensated, advanced liver disease appears to be functionally, but precariously, rebalanced (see FIGURE 126.1). Much of the data correlating hemostasis test results with bleeding complications are derived from percutaneous liver biopsy (PLBx) experience in relatively stable patients. Major bleeding complications after PLBx have been consistently low,[72] with rates of 0.5% to 0.6% in large contemporary series.[73,74] Platelet count, occasionally a platelet function screening test, and INR thresholds are typically used to assess bleeding risk, and when exceeded, mandate alternative biopsy techniques or blood component transfusions. However, the supporting evidence for hemostasis parameter limits is insufficient.[72,75]

Retrospective case series have shown higher bleeding complication rates after PLBx with platelet counts <50,000/μL,[73,76,77] leading to widespread acceptance of a minimal platelet count.[73,74] Platelet function tests are limited in their utility to assess bleeding risk in patients with liver disease. Bleeding time (BT) may be prolonged in 40% of cirrhotic patients,[78] but a prolonged BT is a poor predictor of post PLBx bleeding, with the possible exceptions of bone marrow transplants.[78,79]

While a prolonged INR is an indicator of decreased hepatic synthetic capacity, it is a poor predictor of bleeding risk in patients with liver disease.[73,75,76,80] Therefore, an INR cutoff to determine bleeding risk prior to liver biopsies has limited value because the INR reflects the reduction in procoagulant factors, but not the decline in the protein C regulatory pathway. The thrombin generation test is an alternative method to assess changes in both procoagulant and regulatory functions in cirrhotic plasma, but it is neither standardized nor routinely available.

The INR is also limited because differences in reagents and instruments make it inappropriate to adopt specific INR thresholds derived from a single institution for general use, and conversion of a PT ratio to an INR is also problematic (FIGURE 126.3). INRs performed on plasma specimens from patients with liver disease demonstrate markedly poor interlaboratory agreement when using an ISI (International Sensitivity Index) exponent calculated from patients on oral vitamin K antagonists.[81,82] In addition to making uniform INR cutoffs for invasive procedures

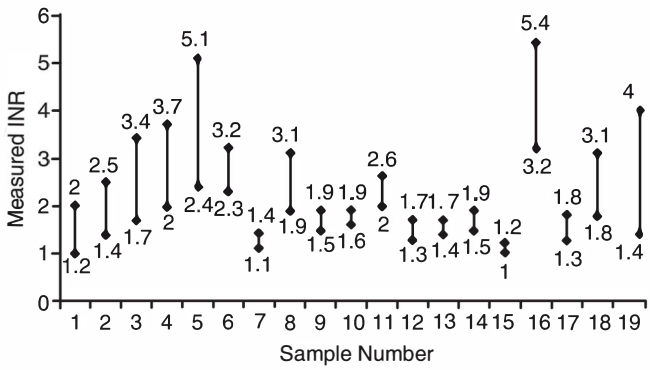

FIGURE 126.3 Interlaboratory variation of INRs performed on plasmas from patients with cirrhosis. For each sample (1 to 19 on *X*-axis), the table shows the high and low INR values (*Y*-axis) obtained from laboratories using different coagulation reagents and instruments. There is marked interlaboratory imprecision when reporting INRs on patients with cirrhosis using thromboplastins whose ISIs are derived from patients anticoagulated with vitamin K antagonists. (Reprinted from; Caldwell S, Northup PG. Bleeding complication with liver biopsy: is it predictable? *Clin Gastroenterol Hepatol* 2010;8:826–829, with permission from Elsevier.)

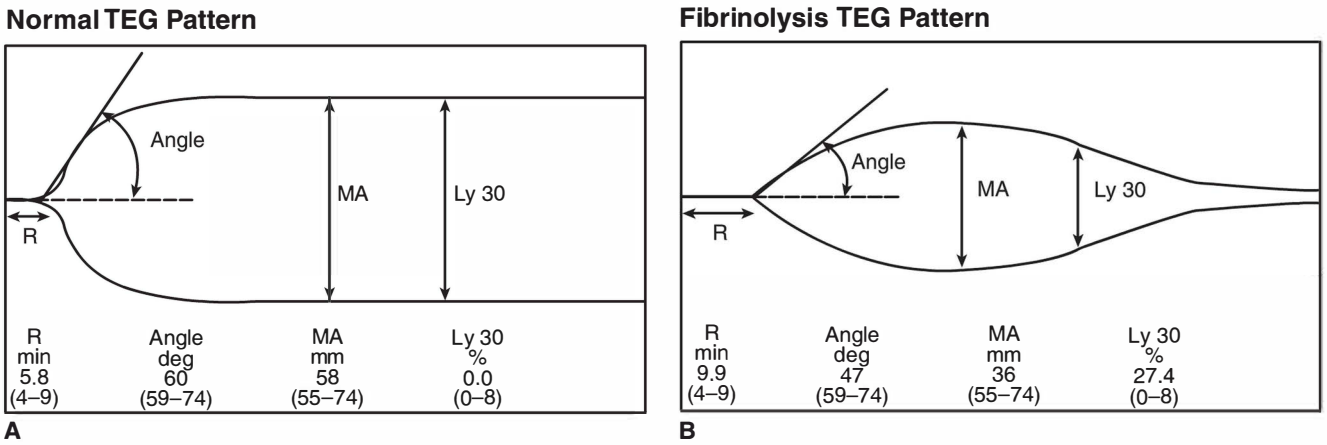

FIGURE 126.4 Thromboelastogram (TEG) patterns. Kaolin and calcium are added to a cup containing citrated blood. A pin attached to a torsion wire immersed in the cup records changes in whole-blood "shear elasticity" due to platelet aggregation and fibrin formation and lysis as the specimen cup rotates approximately 5 degrees clockwise and counterclockwise (*Y*-axis, mm) over time (*X*-axis, minutes). Measured parameters include: R-time to initial fibrin formation, α angle rate of increasing clot strength, MA (maximal amplitude)–clot strength, and Lys 30% change in clot strength due to fibrinolysis. **A**: TEG tracing from a healthy control. **B**: TEG tracing during OLT: Onset (R) and rate (α angle) of clot formation are delayed, and maximum clot strength (MA) is reduced, consistent with coagulation factor, fibrinogen, and platelet depletion. There is also evidence of hyperfibrinolysis indicated by 27.4% reduction of clot strength after 30 minutes (Lys 30). (TEG 5000, Haemonetics Corp. Braintree, MA, USA.)

untenable, INR variability affects the MELD score. If thromboplastin ISIs are calibrated with plasmas from patients with a prolonged PT due to liver disease (ISI_{liver}), INR and MELD score agreements are markedly improved,[81,82] but logistical challenges have prevented integration of the INR_{liver} into the MELD formula.[83]

TEG is a global hemostasis test sometimes used by anesthesiologists and surgeons to guide blood product utilization during OLT. A TEG test records changes in viscosity of whole blood over time as clot formation and fibrinolysis occur (FIGURE 126.4). Parameters are derived from the tracing, which correlate with routine hemostasis tests: PT and aPTT with TEG (R), and fibrinogen, factor VIII, and platelet count with TEG alpha (α) angle and maximum amplitude (MA).[84] TEG parameters are also sensitive indicators of hemostasis changes occurring when decompensated liver disease patients are infected,[61] but the utility of TEG to assess bleeding or clotting risks in patients with liver disease has not been adequately investigated.[85] In addition, TEG does not assess the protein C pathway. Nonetheless, clinical studies are underway to assess the clinical utility of various forms of TEG on the liver disease wards.

MANAGEMENT APPROACHES TO HEMOSTASIS IN LIVER DISEASE PATIENTS

Bleeding is common among liver disease patients and includes spontaneous hematomas, oozing from oropharyngeal mucosa, gastrointestinal (GI) hemorrhage, bleeding after dental extractions, skin puncture and biopsy sites, and rarely, intracranial bleeding. Approximately 50% of cirrhotic patients develop gastroesophageal varices, and one-third will experience variceal hemorrhage. With an in-hospital mortality rate of approximately 15% for each episode of acute bleeding,[86] variceal bleeding is the cause of death for approximately 6% of patients with cirrhosis.[87] Predictors of the first upper GI hemorrhage in cirrhotic patients include the presence[88] and endoscopic appearance of varices,[89] elevated variceal pressures,[90] and laboratory evidence of decreased hepatic synthesis, coagulopathy, and thrombocytopenia.[88] Scoring systems based on these parameters identify patients at high risk of GI bleeding.[88,91] Once bleeding has occurred, an elevated MELD score (≥17[92] or ≥18[93]), which includes INR, is the best predictor of early rebleeding and early mortality.

Prophylaxis versus Rescue Interventions

In general, the approach to bleeding in liver disease patients can be divided into prophylactic interventions, for example, prior to an invasive procedure, and rescue therapy for active bleeding.[94] Effective prophylaxis implies a valid means of risk stratification. However, recognition of the complex hemostatic changes in cirrhosis has eroded support for plasma administration to achieve empiric INR targets, resulting in a reevaluation of the risk/benefit of this practice. Although some societal guidelines continue to recommend INR targets to guide prophylactic FFP infusions,[95] others have recognized the limitations of this approach.[72] In contrast, a greater consensus exists for platelet administration in thrombocytopenic cirrhosis patients (threshold 50,000/μL) prior to moderate- or high-risk procedures.[39]

The rescue approach uses directed interventions for a bleeding complication and acknowledges the availability of emerging but nonestablished therapeutics.

General Supportive Measures

Several general measures should be considered to improve hemostasis in decompensated cirrhosis, including control of infection, therapy of renal failure, and avoidance of volume expansion to avoid effects on portal pressure and the collateral vascular bed including varices.[60] The recognition that volume expansion increases portal pressure and exacerbates bleeding in cirrhotic patients has led to the development of the "low-volume" approach to patients undergoing liver transplantation and to conservative recommendations for target hematocrit levels in variceal bleeding.[96,97] Treating the hyperdynamic state with octreotide (and/or terlipressin) to improve vascular tone may also diminish bleeding in collateral vessels other than varices for which these agents are commonly used.[98] For example, based on anecdotal experience, one of the authors (SC) recommends such agents prior to sphincterotomy in portal hypertensive patients to diminish mucosal vascular congestion.

Specific Agents

Vitamin K

Although replacement therapy is generally advised, in most decompensated cirrhosis patients, vitamin K replacement therapy for prolonged INR is ineffective. Vitamin K deficiency (causing impaired gamma-carboxylation of factors II, VII, IX, X, and proteins C and S)[99] is uncommon, unless there is coexisting cholestasis, antibiotic therapy, or recent malnutrition. If utilized, vitamin K should be administered parenterally, as oral absorption may be impaired in patients with liver failure. Intravenous vitamin K therapy carries a rare risk of anaphylaxis,[100] and absorption after subcutaneous administration may be reduced in patients with edema.

Plasma, Cryoprecipitate, Red Blood Cells, and Platelets

Plasma at common dosing (2 to 4 units or 10 mL/kg) has minimal effect on coagulopathy,[101] and only 10% of cirrhosis patients reach target reductions of INR.[102] INR imprecision in cirrhosis, the adverse effects on intravascular volume, and the risk of transfusion-associated acute lung injury (TRALI) have combined to temper enthusiasm for this approach.[103] Cryoprecipitate has the advantage of replacing fibrinogen if deficient without substantial volume expansion. In this regard, measurement of fibrinogen levels has been anecdotally recommended preprocedure with a target level of 120 to 150 mg/dL (using cryoprecipitate) to facilitate activity of rescue agents such as rFVIIa. However, there are no conclusive data to support a specific fibrinogen level to trigger replacement. Packed red blood cell replacement should also be tempered due to the effects on portal pressure.[97] Current recommendations indicate a target hemoglobin of 7 to 8 g/dL in variceal bleeding.[97] Platelet transfusion to target levels of 50,000/μL is reasonable based on *in vitro* studies discussed above but lacks a foundation in clinical outcomes research.

Desmopressin, 1-Deamino-8-Arginine Vasopressin

Intravenous or subcutaneous desmopressin, 1-deamino-8-arginine vasopressin (DDAVP) 0.3 to 0.5 μg/kg decreases BT possibly due to acute release of vWF from endothelial cells.[104,105] Intranasal DDAVP was as effective as FFP or platelet transfusions in cirrhosis patients with elevated INRs and/or platelet counts <50,000/μL undergoing dental extractions.[106] However, no benefit was seen in a study of variceal bleeding which compared terlipressin plus DDAVP to terlipressin alone.[107] Another randomized trial comparing DDAVP and placebo prior to partial hepatectomy in patients with hepatocellular cancer and cirrhosis showed no difference in blood loss or transfusion requirements.[108] The necessity of DDAVP prior to liver biopsies in patients with end-stage kidney disease was not supported by a review of 78 liver biopsies without DDAVP in hepatitis C patients on chronic dialysis that identified one minor bleeding complication.[109] While side effects from DDAVP appear low, and this agent is commonly used preprocedurally, clinical efficacy has not been established for most applications.

Antifibrinolytics

Antifibrinolytics may be useful when cirrhosis-related hyperfibrinolysis is strongly suspected or proven. The two agents are ε-aminocaproic acid (EACA) and tranexamic acid (TA), both of which inhibit binding of plasminogen or plasmin to fibrin, thus inhibiting fibrinolysis. EACA can be used topically (e.g., post-dental extraction), and both medications are available for oral or intravenous administration in the United States. Other than a handful of case reports, there is no convincing evidence associating thromboembolic complications with EACA and TA.[110] A reduction in red cell transfusions during OLT was confirmed in a meta-analysis of randomized control trial (RCT) comparing TA to placebo.[111] The efficacy of EACA during OLT is unproven due to only one underpowered RCT.[111] Results from single-institution case series indicate EACA is effective for controlling mucosal and subcutaneous bleeding in patients with shortened euglobulin clot lysis times[112] and TA reduces mortality in cirrhotic patients with GI bleeding,[113] but these observations have not been confirmed. There is a risk of ureteral occlusion with hematuria due to resistant clot lysis, and GI side effects, but overall the antifibrinolytic agents appear to be safe and well tolerated in decompensated cirrhotic patients.[55,112]

Recombinant Activated Factor VII

The development of rFVIIa to control hemorrhage in hemophilia A and B males with inhibitors led to application to cirrhosis-related hemostasis disorders. However, no controlled trial has demonstrated efficacy for prevention or control of hemorrhage compared to placebo[114–119] (Table 126.3). Arterial and venous thromboembolic (VTE) complication rates were low in cirrhotic patients exposed to rFVIIa and similar to rates in placebo groups.[120] However efficacy studies were not designed to detect thrombotic adverse events, and both safety and cost remain valid concerns.[119,121] Based on recent insights into cirrhotic hemostasis, it would be possible to determine if there is a subset of hypocoagulable cirrhotic patients, using thrombin generation or TEG testing, who would potentially benefit from rFVIIa.

Prothrombin Complex Concentrate

Prothrombin complex concentrate (PCC) contain clotting factors II, IX, X, and variable amounts of factor VII, protein C, and protein S, offering the possible advantage of restoring vitamin K–dependent coagulation factors with minimal volume and no risk of TRALI. PCCs are labeled with factor IX content, indicating the original indication to treat hemophilia B patients. PCCs are divided into two groups: four-factor PCCs (similar amounts

Table 126.3

rFVIIa clinical trials in chronic liver disease patients

Indication (Reference)	Design	rFVIIa Dosing	Frequency	Endpoint(s)	Outcome
Dental surgery (113)	RCT DB	Placebo 20 μg/kg 80 μg/kg	× 1	Hemostasis ≤15 min	No difference
Partial hepatectomy (114)	RCT DB	Placebo 50 μg/kg 100 μg/kg	Q 2 h to end of surgery	RBC treatment	No difference
OLT (115)	RCT DB	Placebo 20, 40, 80 μg/kg	×1 preop	RBC treatment	No difference
OLT (116)	RCT DB	Placebo 60 or 120 μg/kg	Repeat doses?	RBC treatment	No difference
UGI bleeding (117)	RCT DB	Placebo 100 μg/kg	8 doses/30 h	No bleeding ≤24 h Rebleed d 1–5 Death ≤d 5	No difference
UGI bleeding (118)	RCT DB	Placebo 300 μg/kg 600 μg/kg	5 doses/20 h	No bleeding ≤ 24 h Rebleed d 1–5 Death ≤d 5	No difference

OLT, orthotopic liver transplantation; RBC, red blood cell; RCT DB, randomized control trial, double blind; UGI, upper gastrointestinal bleeding.

of factors IX, X, VII, and II) or three-factor PCCs (contain minimal factor VII). In most countries, other than the United States, four-factor PCCs are available. PCCs are frequently used for "off-label" reversal of vitamin K antagonist therapy, but there is a paucity of clinical information regarding the efficacy and safety of PCC in liver disease patients. Twenty-two patients with advanced liver disease requiring immediate therapy for bleeding or invasive procedures received 26 IU FIX/kg of a four-factor PCC. Clinical response was very good in 76%, and there were no overt thrombotic complications, but FVIIa, F1.2, and thrombin–AT complex levels increased.[122] Infusing an activated PCC (factor VIII inhibitor bypass activity [FEIBA]) or a combination of a PCC or FEIBA with rFVIIa to control or prevent bleeding in hemophiliacs with inhibitors has generated a consumptive coagulopathy and thrombosis[123] and would be unsafe in patients with advanced or decompensated liver disease. Studies are underway in Europe to investigate appropriate PCC dosing, efficacy, and safety in cirrhosis patients.

Thrombopoietin Mimetics

Using TPO receptor agonists is an attractive approach to manage thrombocytopenia in patients with advanced liver disease. In a phase II trial of thrombocytopenic hepatitis C patients, most subjects (n = 53) randomized to daily oral eltrombopag (30, 50, or 75 mg/day) for 4 weeks reached target platelet counts of >100,000/μL, started peginterferon and ribavirin, and completed 12 weeks of antiviral therapy, while no subjects (n = 18) in the placebo arm reached a platelet count of 100,000/μL, and only 6% completed 12 weeks of antiviral therapy.[124] Side effects were mild, and there were no thrombotic complications. Another trial compared eltrombopag, 75 mg/day, to placebo for 14 days prior to an invasive procedure in 292 chronic liver disease patients with platelet counts <50,000/μL.[125] Average platelet counts on day 14 were 103,000/μL for the eltrombopag group and 39,000/μL for the placebo group. Avoidance of platelet transfusions occurred in 72% and 19% of eltrombopag and placebo patients respectively. However, the study was terminated early due to increased thrombotic events, primarily in the portal vein system, in the eltrombopag arm compared to the placebo arm. While awaiting results from additional ongoing clinical trials, off-label use of TPO receptor agonists is not recommended.

THROMBOTIC RISKS AND MANAGEMENT APPROACHES IN CHRONIC LIVER DISEASE

Epidemiologic, imaging, and histologic data support the conclusion that acquired coagulopathies and thrombocytopenia do not protect patients with chronic liver diseases from peripheral or visceral VTE complications. In a population-based case–control study of VTE in Danish citizens from 1985 to 2005, patients admitted with noncirrhotic liver disease or cirrhosis had increased relative risks of 1.74 (95% CI 1.54 to 1.95) and 1.87 (95% CI 1.73 to 2.03) for VTE compared to patients without liver disease.[126] Estimates of VTE frequency in hospitalized chronic liver disease patients, based on chart reviews or analysis of hospital discharge databases, range from 0.8% to 6.8%, reflecting differences in study design and patient populations.[127–134] Comparisons of VTE rates between hospitalized patients with and without liver disease either support an increased risk with cirrhosis,[132,134] or report a lower risk.[129] Variables associated with increased VTE risk in chronic liver disease patients include decreased albumin,[132,133] elevated aPTT,[132] and age <45.[134] Variables that did not correlate with VTE risk include MELD score,[133] INR quartile,[130] etiology,[132]

or decompensated cirrhosis.[129,132] Despite heterogeneous methods and results, these studies disprove the dogma that hospitalized patients with chronic liver disease and cirrhosis are "autoanticoagulated" and not at risk for VTEs. However, the risks and benefits of prophylactic anticoagulation of chronic liver disease patients during periods of additional acquired VTE risks have not been adequately investigated. Emerging literature suggests current prophylactic and therapeutic dosing guidelines for low molecular weight heparin (LMWH) may be subtherapeutic in patients with advanced cirrhosis due to decreased AT and larger volumes of distribution.[135]

Patients with chronic liver disease are also at increased risk for *visceral* venous thrombosis, particularly in the portal vein (PVT) and its tributaries. Risk factors for PVT include regional events (venous stasis, inflammatory, infectious, and malignant conditions), and possibly systemic acquired and inherited thrombophilias. As patients' cirrhosis progresses from stable to decompensated stage due to worsening portal hypertension, the prevalence of PVT increases, ranging from 6% to 17% and is as high as 44% in patients diagnosed with hepatocellular cancer.[136] Comparisons of the prevalence of inherited and acquired thrombophilias in cirrhotics with and without PVT do not consistently support an association of antiphospholipid antibodies,[137,138] or FVL and prothrombin gene 20,210 mutations,[137,139–142] with PVT. Assessment of inherited protein C, protein S, and AT deficiencies and PVT risk are complicated by acquired deficiencies of these natural inhibitors due to hepatic disease. In one prospective cohort study of serial ultrasound screening for PVT in 100 cirrhotic patients, the only independent variable was decreased portal vein blood velocity.[143] Published experience with anticoagulant therapy to prophylaxis against PVT is limited. A prospective trial randomized 51 patients with advanced cirrhosis without PVT to enoxaparin 40 mg/day or placebo for 12 months with periodic imaging. No patient in the treatment arm developed PVT or a bleeding complication, compared to 5 (20%) PVTs in the placebo group.[144]

While PVT can be an asymptomatic, incidental finding, complications include extension into the superior mesenteric vein causing small intestinal ischemia and portal hypertension leading to ascites, varices, and GI bleeding. In noncirrhotic patients with acute and chronic PVT, expert opinion supports searching for precipitating risk factors, and starting anticoagulant therapy, or occasionally thrombolytic therapy or thrombectomy in critical situations.[145] However, high-quality evidence on which to base recommendations is limited. Several small series employing LMWH or a vitamin K antagonist in cirrhotic patients with asymptomatic or symptomatic PVT report complete or partial recanalization rates of 29% to 59% and bleeding complications <3%.[146,147] Many issues require further investigation, including the long-term consequences of asymptomatic PVT, effects of anticoagulation therapy on portal hypertension, and variceal bleeding, in order to provide clinicians with practice guidelines for anticoagulation treatment of cirrhotic patients with PVT.

Clinical, histologic, and experimental evidence suggest that systemic and localized prothrombotic conditions may promote hepatic microvascular occlusions, tissue injury, and fibrosis in patients with chronic liver disease. The rate of hepatic fibrosis progression is faster in FVL-positive compared to FVL-negative hepatitis C patients.[148] In addition, investigators have observed hepatic and portal microvascular venous thrombi in human cirrhotic liver tissue.[149] Several mechanisms for intrahepatic venule thrombosis have been proposed. Liver inflammation may cause portal venule thrombosis, localized ischemia, hepatocyte death, and fibrosis, that is, parenchymal extinction.[149,150] Excess thrombin generation may also activate PAR-1 receptors on hepatic stellate cells with subsequent stimulation of fibrosis.[151] Platelets appear to play a role in experimental liver injury, and sequestration of activated platelets within the liver may contribute to parenchymal extinction as well.[152,153]

ADAMTS-13 activity decreases and vWF antigen concentration increases with progressive cirrhosis,[154] and some cirrhotic patients have circulating unusually large plasma vWF multimers,[155] suggesting a possible link between acquired ADAMTS-13 deficiency, thrombocytopenia, platelet sequestration within the hepatic microvascular, and ischemic liver damage.

CONCLUSION

Recent laboratory investigations are providing new insights into the hemostatic changes associated with acute and chronic liver disease. A reduction in both prothrombotic and antithrombotic components produces a fragile rebalancing that can be tipped in favor of either bleeding or clotting complications by additional acquired events including infection, renal failure, immobilization, inflammation, and trauma. While it is clear that screening coagulation tests such as PT/INR are imprecise and potentially misleading in the setting of advanced liver disease, alternative *in vitro* tests such as thrombin generation and TEG have not been sufficiently validated to be recommended as replacements. On the other hand, prophylactic use of plasma based on INR cutoffs is a questionable practice, and there are risks associated with its use. Avoidance of overvolume expansion, and its attendant effects on portal pressure and the collateral vascular beds, is supported by reports from liver transplant surgery. Both prophylactic and rescue management of bleeding complications remains empiric at this time, rests on experience, and must be individualized. Attention to treating infection, renal failure, and volume overload are supported by existing data. Antifibrinolytics also appear to have a role in liver disease patients with hyperfibrinolysis, but off-label use of hemostatic products such as rFVIIa, TPO receptor agonists, and PCCs is expensive and has potential thrombotic risks. While the future may bring better evidence, their use is not supported by sufficient clinical evidence at this time to make formal recommendations. Patients with advanced liver disease do develop VTEs. However, the risk/benefits of anticoagulant prophylaxis and treatment are unclear at this time. Clearly, there is a great need for clinical research to address these knowledge gaps.

CHAPTER

127 Hemostatic Abnormalities in Renal Disease

MIRIAM GALBUSERA, GIUSEPPE REMUZZI, AND PATRIZIA ONDEI

Patients with renal disease suffer from complex hemostatic abnormalities leading to two opposite complications: bleeding tendency and thrombotic risk. Bleeding may be a serious complication of acute and chronic renal failure.[1] The clinical manifestations vary from ecchymoses, epistaxis, bleeding from gums, venipuncture sites, and sites of fistula access to overt gastrointestinal bleeding. Although the frequency of severe hemorrhage has been reduced by the advent of dialysis and the use of erythropoietin to correct anemia, a bleeding diathesis still represents a problem for uremic patients, particularly during surgery or invasive procedures such as biopsies.

Nonetheless, abnormalities of blood coagulation and fibrinolysis in chronic renal failure render uremic patients highly susceptible to the development of cardiovascular and thrombotic complications. In addition, contemporary patient populations are older and have a high prevalence of hypertension and atherosclerotic vascular disease.[2] The presence of these comorbidities renders uremic patients more likely to receive drugs such as antiplatelet agents and anticoagulants that may increase the risk of bleeding.

PATHOGENESIS OF UREMIC BLEEDING

In patients with kidney diseases, platelet defects and platelet–vessel wall abnormalities are the main determinants of hemorrhagic tendency, but other contributing factors including the abnormal production of nitric oxide (NO), uremic toxins, and anemia account for a multifactorial pathogenesis of bleeding (Table 127.1).

Platelet Abnormalities

Severe thrombocytopenia is very rare and is limited to renal failure associated with disseminated intravascular coagulation, hemolytic uremic syndrome (HUS)/thrombotic thrombocytopenic purpura (TTP), eclampsia, and renal allograft rejection. Thrombocytopenia may also be caused during hemodialysis by the anticoagulant heparin.[3]

The majority of studies on uremic platelet were reported during the 1980s and 1990s and identified numerous biochemical abnormalities (reviewed in ref.[4,5]) including a decreased capacity to synthesize thromboxane A_2 by the prostaglandin-forming enzyme cyclooxygenase,[6,7] a reduction in platelet granule ADP and serotonin content,[8] an increase in cyclic AMP (cAMP),[9] dysregulation of adenylate cyclase,[10] and impairment of Ca^{2+}-dependent platelet function.[11,12] A storage pool defect is supported by finding subnormal dense granule content,[8,13] impaired release of α-granule proteins and β-thromboglobulin,[14] and reduced release of platelet ATP in response to thrombin.[13] Moreover, platelet cytoskeletal dysfunction due to either a reduction in cytoskeletal proteins or a decrease in actin incorporation after thrombin stimulation has been reported.[15] All the above abnormalities and the defective platelet aggregation in response to various stimuli contribute to impaired platelet adhesion and aggregation in injured vessels.

Platelet adherence to foreign surfaces is significantly impaired in patients with end-stage renal disease.[16–18] Defective function of the platelet glycoprotein (GP)IIb–IIIa complex receptor may account for the decreased binding of von Willebrand factor (vWF) and fibrinogen to stimulated uremic platelets[19] and the reduced vWF-dependent adhesion and thrombus formation.[16–18] Dialysis improved the binding capacity of GPIIb–IIIa complex, suggesting a role of uremic toxins or receptor occupancy by fibrinogen fragments present in uremic blood.[19,20]

Although quantitative and qualitative vWF abnormalities have not been consistently reported in uremic patients,[17,21,22] a functional defect in the vWF-platelet interaction cannot be excluded based on evidence that cryoprecipitate (a plasma derivative rich in vWF) and desmopressin (a synthetic derivative of antidiuretic hormone that releases autologous vWF from storage sites) significantly shorten the bleeding time in these patients.[23,24] Increased levels of the platelet inhibitors prostacyclin (PGI_2) and NO have also been reported in uremia.[25,26] The beneficial effect of conjugated estrogens on the bleeding times of uremic patients might be mediated by changes in the NO synthesis pathway since the NO precursor L-arginine reversed the effect of estrogens on bleeding.[27] Dialysis partially correct platelet dysfunction, suggesting that uremic toxins such as the guanidinosuccinic acid involved in NO generation[26] may play a role in platelet abnormalities.

Role of Anemia

Anemia is a constant feature of acute and chronic renal failure and is the main determinant of the prolonged bleeding time in uremic patients. There is evidence that the bleeding time is inversely related to the hematocrit in uremia[28,29] as well as in other types of anemia. The cloning of the human erythropoietin gene and the production of recombinant human erythropoietin (rhEPO) has provided clinicians with a powerful tool to correct the anemia associated with renal failure, thereby eliminating dependency upon transfusion.

Dialysis

Dialysis improves platelet functional abnormalities and reduces, but does not eliminate, the risk of hemorrhage. Hemodialysis, because of the interaction between blood and artificial surfaces, may induce chronic platelet activation that

Table 127.1

Factors involved in uremic bleeding

- Abnormal Platelet Function
- Decreased capacity to form thromboxane A_2; reduction in serotonin and ADP content; increased intracellular cAMP; impaired Ca^{2+}-dependent functions; reduction in dense granule content; impaired release of the platelet α-granule protein and β-thromboglobulin; abnormalities in *ex vivo* platelet aggregation; impaired platelet adhesion and aggregation to injured vessel
- Enhanced Production of NO
- Uremic Toxins
- Anemia
- Altered blood rheology; defective platelet diffusivity; decreased release of ADP by erythrocytes; erythropoietin deficiency
- Medication Effects
- Anticoagulants; antiplatelet agents; NSAIDs; β-lactam antibiotics; third-generation cephalosporins

can lead to platelet exhaustion and dysfunction. It has been found that plasma levels of the potent NO inducers TNF-α and IL-1β increase during dialysis.[30,31] These cytokines are generated *in vivo* by monocytes during hemodialysis with complement-activating membranes. Thus, while dialysis removes uremic toxins, it also affects platelet activation and NO synthesis. Heparin, used to prevent filter clotting, can occasionally induce platelet activation and thrombocytopenia.[3]

Role of Medications

Antiplatelet agents such as aspirin, as well as anticoagulants, increase the frequency of major bleeding in individuals with chronic renal insufficiency. Aspirin, at a dose of 100 mg/day, has been shown to significantly prolong the bleeding time in uremic patients when compared to controls[32] and anticoagulant therapy increases rates of bleeding in patients with end-stage renal disease as compared to the general population.[33,34,35] A recent study[36] showed that the risk for major bleeding episodes per year of exposure was 0.8%, 3.1%, 4.4%, and 6.3% in patients undergoing hemodialysis while taking neither warfarin nor aspirin, taking warfarin alone, taking aspirin alone, or taking the combination of warfarin and aspirin, respectively.

Given this bleeding risk, randomized, controlled trials are necessary to evaluate the efficacy and the safety of these agents in the secondary prevention of cardiovascular events in this high-risk population. Other medications that may increase the risk of bleeding in uremia include β-lactam antibiotics that accumulate in uremic patients[37] and act by perturbing platelet membrane function and interfering with ADP receptors.[38] The prolonged bleeding time and the abnormal platelet aggregation are related to the dose and duration of treatment and are promptly reversible after drug discontinuation. Third-generation cephalosporins may also inhibit platelet function and lead to marked disturbance of blood coagulation.[39] Nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin, ibuprofen, naproxen, phenylbutazone, and sulfinpyrazone also inhibit platelet cyclooxygenase and disturb platelet function, but, in contrast to aspirin, the inhibitory effect of these compounds is readily reversed as the blood concentration of the drugs falls upon cessation of administration.[40]

Clinical Manifestation

The clinical presentation of uremic bleeding ranges from mild and clinically unimportant bleeding (petechiae, purpura, and epistaxis) to severe hemorrhage (gastrointestinal bleeding, intracranial bleeding, and hemorrhagic pericarditis). Gastrointestinal bleeding occurs with the greatest frequency and has been observed in up to one-third of uremic patients. Low-grade gastrointestinal bleeding may be even common. Upper gastrointestinal bleeding accounts for 3% to 7% of all deaths in patients with end-stage renal disease.[41] A prospective study[42] found that acute gastrointestinal hemorrhage in patients with impaired renal function was associated with an increase in mortality and a 37% increase in length of hospital stay as compared to nonrenal patients.[42] The causes of bleeding are usually peptic ulcers, hemorrhagic esophagitis, gastritis, duodenitis, gastric telangiectasias, and diverticular disease.[43,44] Other bleeding complications reported in chronic uremia are subdural hematoma, spontaneous retroperitoneal bleeding, spontaneous subcapsular hematoma of the liver, intraocular hemorrhage, and although now rare, hemorrhagic pericarditis with cardiac tamponade.[1]

LABORATORY ASSESSMENT

To identify patients at risk for hemorrhagic complications several tests have been used to establish which abnormal laboratory findings in uremia correlate best with an increased likelihood of clinically significant bleeding. Coagulation screening tests such as activated partial thromboplastin time, prothrombin time, and thrombin time are generally normal in uremia,[45] and there is no good correlation between blood urea nitrogen or creatinine and clinical bleeding.[45] Diagnosis of uremic bleeding still relies on clinical symptoms, and the cutaneous bleeding time (normal values: 1 to 7 minutes)[45] remains the most useful test for bleeding caused by uremia.[46,47] The bleeding time is an index of the primary phase of hemostasis, that is, the interaction of the platelet with the blood vessel wall, and the formation of the platelet plug.

THERAPEUTIC STRATEGIES FOR UREMIC BLEEDING

The approach to uremic bleeding must be considered in two contexts: the treatment of patients with active bleeding and the prevention of bleeding in patients at high risk because of

invasive procedures or surgery. The strategy depends on the urgency of the situation, the severity of uremia, and the previous therapy employed (Table 127.2).

Dialysis

Bleeding in uremia has been easier to control since the introduction of dialysis.[28,48] Studies indicate that dialysis ameliorates clinical bleeding,[49] improves platelet aggregation[49,50] and prothrombin consumption index.[49] Dialysis removes uremic toxins, including urea, creatinine, phenol, phenolic acids, or guanidinosuccinic acid, and improves platelet functional abnormalities.[51–53] However, platelet activation induced by interaction of blood with the artificial surface and the use of systemic anticoagulation may contribute to bleeding tendency. The risk of bleeding may be minimized by using peritoneal dialysis or alternatives to routine heparinization to prevent clotting in the extracorporeal circulation during hemodialysis.

Peritoneal dialysis is more effective in correcting platelet abnormalities than hemodialysis.[54] The reasons for the superiority of peritoneal dialysis in ameliorating platelet function abnormalities are not completely understood, but are likely due in part to the avoidance of heparin and better clearance of the middle molecular weight molecules.

To minimize the risk of bleeding in hemodialysis and continuous renal replacement therapies several strategies (reviewed in ref.[55]) such as low-dose heparin, heparin-free dialysis, and regional anticoagulation with citrate can be used.

In patients with moderate risk of bleeding, the use of minimum dose of heparin reduces bleeding complications when compared with other methods such regional heparinization. The protocol usually involves a bolus of 500 U of heparin every 30 minutes or a continuous infusion of heparin to keep the activated clotting time >150 but <200 seconds. This technique has the advantage that no additional equipment is needed in the dialysis circuit, but some minimal degree of anticoagulation still occurs.[55]

Heparin-free dialysis is the method of choice in patients with active bleeding or at high risk of bleeding. To avoid clotting of dialyzer, extracorporeal blood flow is rapidly increased to 250 to 350 mL/min and maintained throughout the treatment and 250 to 300 mL saline flushes are administered every 15 to 30 minutes into the arterial limb (predialyzer) to reduce hemoconcentration and to wash fibrin strands. The volume of saline is removed during the dialysis session. Because of its simplicity and safety, heparin-free dialysis can be used in approximately 90% of intensive care patients.[55]

Low molecular weight heparin (LMWH) has been proposed to cause less bleeding and less thrombocytopenia than heparin, but is not different from heparin in terms of dialysis-related bleeding or other complications, and once a patient develops heparin-induced thrombocytopenia (HIT) LMWH cannot be used as a safe substitute due to the extensive cross-reactivity with heparin.

Regional citrate anticoagulation[56] is an alternative to heparin-free dialysis. Citrate binds to free plasma calcium; the fall in the plasma concentration of this ion (i.e., required for coagulation process) is responsible for the anticoagulant activity. Regional citrate anticoagulation involves the continuous infusion of isosmotic trisodium citrate solution into the arterial side of the dialyzer; the rate of infusion is adjusted to keep the activated clotting time above 200 seconds in the arterial limb. To prevent the return of blood with a very low ionized calcium concentration to the patient, the process is reversed by the infusion of 5% $CaCl_2$ into the venous return line. The rate of infusion is constantly adjusted according to frequent measurements of plasma calcium concentration to prevent hypo- or hypercalcemia. The advantages of regional citrate anticoagulation over heparin-free dialysis are blood flow rate not high and rare clotting. The major problems are hypocalcemia or hypercalcemia, hypernatremia, and metabolic alkalosis, but, if closely monitored, the complication rate is relatively low.[56]

Correction of Anemia

Platelet adhesion and aggregation in flowing systems[57,58] are greatly potentiated by red blood cells. Erythrocytes enhance platelet function by releasing ADP,[59] by inactivating PGI_2,[60] and by

Table 127.2

Guidelines for the prevention and treatment of bleeding in patients with uremia

In all patients with hemorrhagic complications or who are undergoing major surgery, the adequacy of dialysis should be reviewed
- The dialysis schedule—using alternatives to routine heparinization—should be changed for 1 or 2 months in patients who have experienced severe hemorrhage or who have undergone recent cardiovascular surgery
Patients with acute bleeding episodes may be treated with desmopressin at a dose of 0.3 μg/kg, administered intravenously (added to 50 mL of saline over 30 min) or subcutaneously
- Intranasal administration of this drug at a dose of 3 μg/kg is also effective and well tolerated
- The effect of desmopressin lasts only a few hours, and it tends to lose efficacy when repeatedly administered
In patients with persistent chronic bleeding, the treatment of choice should lead to a long-lasting hemostatic competence
- Bleeding in patients with renal failure and hematocrit <30% must be treated with erythropoietin
- Blood or red blood cell transfusions to improve hematocrit values should be administered to severely anemic patients. Hemostatic effect of red blood cell transfusion is achieved when the hematocrit rises above 30%
- Conjugated estrogens given by intravenous infusion in a cumulative dose of 3 mg/kg as daily divided doses (i.e., 0.6 mg/kg for 5 consecutive days) is the most appropriate treatment

increasing platelet–vessel wall contact by displacing platelets away from the axial flow and toward the vessel wall.[57] Since hemoglobin is a scavenger of NO,[61] the decrease of available hemoglobin in anemia may contribute to platelet dysfunction. These erythrocyte activities explain the successful managing of hemorrhagic tendency in uremia by raising the hematocrit value to above 30%.[29]

Treatment with rhEPO induces a progressive increase in hematocrit and is accompanied by a significant decrease in the bleeding time.[62,63] The hematocrit during rhEPO treatment should be controlled carefully because complete correction of anemia carries the risk of hypertension, encephalopathy, thrombosis, and hyperkalemia. A threshold of hematocrit between 27% and 32% has to be reached for the bleeding time to become normal, or nearly normal, indicating that a partial correction of renal anemia is sufficient for this purpose.[63] In patients treated with rhEPO and with hematocrit values of 36% to 39%, there is significant improvement of the quality of life, cardiac function, physical work capacity, cognitive function, and sexual function.[64] However, the benefits and the risk of complete correction of anemia (hematocrit, 38% to 42%) and the optimal target hematocrit have not yet been established. The safety of the long-term maintenance of a normal hematocrit has been questioned as a consequence, in part, of the early termination of the Normal Hematocrit Cardiac Trial, in which the patients randomly assigned to the normal hematocrit group had a higher mortality and a higher incidence of nonfatal myocardial infarction.[65]

Cryoprecipitate and Desmopressin

Cryoprecipitate is a plasma derivative, obtained when plasma is frozen and slowly thawed. Cryoprecipitate is rich in vWF, fibrinogen, and fibronectin and has traditionally been used in the treatment of hemophilia A, von Willebrand disease, hypofibrinogenemia, and dysfibrinogenemia. In the original report, the six uremic patients treated with cryoprecipitate had normalization or significant shortening of the bleeding time.[66] The maximal effects on the bleeding time are obtained 4 to 12 hours (average: 8 hours) after the infusion, and effects are no longer detected by 24 to 36 hours. *Further studies confirmed the original findings but also indicated that shortening of the bleeding time and the control of clinical bleeding may be quite variable in uremic patients* since as many as 50% of patients fail to respond to cryoprecipitate.[67–69] This therapy, which may also carry the risk of transmitting blood-borne diseases, has been largely replaced by other approaches. A therapeutic alternative to cryoprecipitate is desmopressin acetate (1-deamino-8-D-arginine vasopressin, DDAVP), a synthetic derivative of antidiuretic hormone. DDAVP induces the release of autologous vWF from storage sites into plasma and avoids the risk of transmitting serum hepatitis or other blood-borne diseases through the administration of blood products. DDAVP shortens the bleeding time in 1 hour and its effect can last for 4 to 8 hours.[23] The bleeding time returns to baseline values within 24 hours. Desmopressin loses its efficacy when repeatedly administered,[70] probably due to a progressive depletion of vWF stores in endothelial cells, but the response to DDAVP is usually restored when the drug is withheld for 3 to 4 days.[71] However, tachyphylaxis does not prevent the clinical use of DDAVP since most prophylaxis for minor surgical procedure and most bleeding episodes generally require only one or a few doses of drug.[71] The guidelines for DDAVP treatment are summarized in Table 127.2.

Although remarkably free of serious side effects, DDAVP is reported to cause a mild to moderate decrease in platelet count, facial flushing, mild transient headache, nausea, abdominal cramps, and mild tachycardia, water retention, and hyponatremia. Rarely, thrombotic events followed DDAVP administration, particularly in patients with underlying advanced cardiovascular disease. Nonetheless, desmopressin is useful in the treatment of bleeding, and it is used prophylactically in the prevention of bleeding during surgery or invasive procedures.[72]

Conjugated Estrogens

The anecdotal observation of diminished gastrointestinal bleeding in uremic patients treated with conjugated estrogens and the improved hemostasis in von Willebrand disease during pregnancy led to investigations of the effect of estrogens on the bleeding tendency in uremia.[22,73] One oral 25 mg dose of conjugated estrogens normalizes the bleeding time for 3 to 10 days with no apparent ill effects.[74] A controlled study showed that conjugated estrogens, given intravenously at the cumulative dose of 3 mg/kg divided over 5 consecutive days, produced a long-lasting reduction in the bleeding time in uremics. At least 0.6 mg/kg estrogen was needed to reduce bleeding time,[74] and four or five infusions spaced 24 hours apart were needed to reduce the bleeding time by at least 50%. The guidelines for estrogen treatment are summarized in Table 127.2. Low-dose transdermal estrogen (estradiol 50 to 100 μg/24 h) applied as a patch twice weekly was found to reduce recurrent gastrointestinal bleeding with parallel improvement of bleeding time and no side effects.[75] Estrogens are safe and well tolerated. Thus, estrogens may be a reasonable alternative to cryoprecipitate or desmopressin in the treatment of uremic bleeding, especially when a long-lasting effect is required.

PREVENTION OF UREMIC BLEEDING

It is safer to prevent uremic bleeding than to treat it, so patients with uremia who are to undergo elective surgery should be advised to avoid acetylsalicylic acid (ASA) and other NSAID for at least 1 week prior to the operation; patients receiving dialysis should have an adequate session before surgery, preferably without heparin, because patients who do not receive adequate dialysis tend to bleed more. It has been demonstrated increased intraoperative complications in uremic patients with preoperative hematocrits levels ranging from 20% to 26%.[76] Before surgery, a threshold hematocrit between 27% and 32% should be reached and iron stores should be checked and replaced if needed because patients who are receiving erythropoietin treatment and are maintaining relatively normal hematocrit levels usually do not have bleeding problems during the perioperative period.

ABNORMALITIES OF COAGULATION AND FIBRINOLYSIS

Despite a hemorrhagic tendency, activation of coagulation has been demonstrated in uremic patients. This finding is more prominent in patients treated by hemodialysis. Abnormalities of the coagulation cascade proteins such as increased plasma fibrinogen, FVIII:C and vWF, and decreased protein C anticoagulant activity and protein S have been found in uremic patients.[4,77] Thrombin is continuously formed, as demonstrated

by the increased levels of thrombin–antithrombin III levels,[78,79] D-dimers, and fibrinopeptide A,[79] and enhanced platelet aggregability has been reported. Increased expression of active tissue factor may be triggered by the anaphylatoxin C5a produced through complement activation induced by hemodialysis membranes.[80]

Contrasting results have been obtained regarding the fibrinolytic system.[81] First, a decrease of fibrinolytic activity has been found in uremia, either absolutely or relative to the extent of activation of the coagulation. This has been used as an explanation for the hypercoagulable state. On the other hand, later reports found activation of fibrinolysis in uremia, with an increase in plasmin–antiplasmin complexes,[78] and fibrinogen and fibrin degradation products,[78,79] together with a decrease of plasminogen activator inhibitor activity[78] after a hemodialysis session. Dialysis partially corrects the abnormalities of coagulation and fibrinolysis found in uremia.

THROMBOTIC COMPLICATIONS

The hemostatic abnormalities in chronic kidney disease may account for an increased risk of both atherothrombotic events and bleeding. The early stages of chronic kidney disease are dominated by derangements likely to result in an increased risk of cardiovascular events, while in advanced chronic kidney disease platelet dysfunction gives rise to an increased risk of hemorrhagic events. However, cardiovascular events related to thrombosis are a predominant cause of death and account for important morbidity in patients with end-stage renal disease who are either treated conservatively or when renal function is replaced by dialysis or transplantation. Cardiovascular disease accounts for about 40% of all deaths in patients undergoing dialysis.[82,83] Increased cardiovascular risk in uremic patients is also due to the higher prevalence of type 2 diabetes, obesity, hypertension, and older age.[84] Other potential factors affecting cardiovascular risk include malnutrition, endothelial dysfunction, arterial calcification, and vitamin D deficiency.[85] In addition, end-stage renal disease is associated with accelerated atherosclerosis due to oxidative stress, inflammation, and lipid disorders.[86]

Hemostatic abnormalities consistent with a hypercoagulable state have been widely described in patients with end-stage renal failure on hemodialysis. Risk factors, summarized in Table 127.3, include enhanced platelet aggregability, abnormalities of coagulation, impaired fibrinolytic activity, increased plasma lipoprotein(a), increased plasma concentrations of homocysteine, and the presence of lupus anticoagulants (reviewed in ref.[4]).

The association of the nephrotic syndrome with renal vein thrombosis has long been recognized.[87,88] In nephrotic syndrome, a hypercoagulable state caused by increased levels of coagulation factors, reduced levels of antithrombin, and an increased platelet response to various stimuli plays an important role in the development of renal vein thrombosis and other venous and arterial thromboembolic complications.[4,89]

Activity of the vWF-cleaving protease ADAMTS13 is reduced in uremia.[90] Complete loss of ADAMTS13 activity due to congenital or immune-mediated deficiency is the main cause of thrombotic occlusion of arterioles and capillaries in the majority of patients with TTP.[91] Undetectable ADAMTS13 activity has also been found in a subgroup of patients with an atypical form of hemolytic uremic syndrome.[91] Replacement of deficient ADAMTS13 activity with plasma is the treatment of choice for congenital cases of TTP, and clearance of the autoantibodies by plasma exchange, or inhibition of their production by immunosuppressive agents, is the key component of treatment in the immune-mediated form of the disease.

Table 127.3

Factors involved in thrombotic risk in patients with kidney disease

- Abnormalities of Coagulation
- Increased levels of fibrinogen, FVIII:C, and vWF
- Decreased protein C anticoagulant activity and protein S
- Decreased Fibrinolytic Activity
- Enhanced Platelet Aggregability
- Increased Levels of Homocysteine
- Accelerated Atherosclerosis
- Oxidative stress inflammation
- Lipid disorders
- Arterial Calcification
- High Prevalence in Patients With Chronic Kidney Disease of Type 2 Diabetes, Obesity, Hypertension, and Older age

PREVENTION AND TREATMENT OF THROMBOTIC COMPLICATIONS

Because platelet aggregation plays a major role in thrombus formation, antiplatelet agents have been used, with encouraging results. Aspirin, dipyridamole, ticlopidine, and sulfinpyrazone have proved useful in several studies. To prevent thromboembolic complications, systemic anticoagulation may be achieved with warfarin or acenocoumarol. Despite a significantly higher variability of coagulation parameters in hemodialyzed patients, oral anticoagulation therapy should not be considered automatically contraindicated in this patient group. Fibrinolytic agents, such as streptokinase or urokinase, as well as recombinant tissue plasminogen activator, have produced contrasting results. Generally, they can be effective in declotting recently occluded vascular hemodialysis accesses, whereas they can be useless in case of marked venous stenosis or sclerosis.[92] No data are available for systemic treatment of uremic patients with fibrinolytic agents.

For anticoagulants and/or antiplatelets eliminated through the kidneys, the doses used for treatment of thromboembolic or arterial events carry a higher risk of drug accumulation and bleeding in respect to the prophylactic doses. This implies that patients with chronic kidney disease should be strictly monitored and that an appropriate adjustment of the dosage is necessary.[93,94]

The current treatment recommendations for patients with chronic kidney disease are based on clinical trials conducted in the general population; thus further research is required to better understand the procoagulant state in patients with chronic kidney disease and to identify potential therapeutic interventions that could translate into improved cardiovascular outcomes.

Since a precarious balance of hemostasis is present in chronic renal failure, resulting both in bleeding and in thrombosis, therapeutical intervention must be carefully evaluated as it can shift the hemostatic equilibrium toward hemorrhage or thrombosis.

Vascular Access Thrombosis

As a consequence of the need for vascular access for hemodialysis, uremic patients are exposed to additional thrombotic complications. Percutaneous cannulation, arteriovenous shunts, native vein or prosthetic arteriovenous fistulas, and fistulas made of the artificial polymers used for chronic hemodialysis are particularly prone to thrombotic occlusion, accounting for 20% to 25% of hospital admission of dialysis patients.[95]

Access failure is primarily due to arteriovenous fistula thromboses that, when uncorrectable, accounts for 80% to 85% of arteriovenous access loss. The main predisposing factor is anatomic venous stenosis. Pathogenesis and risk factors are summarized in Table 127.4.

Strategies to prevent thrombosis, other than treatment of stenoses by percutaneous transluminal angioplasty, endovascular stent, or surgical revision, include antiplatelet agents, such as dipyridamole and low-dose aspirin with or without sulfinpyrazone.[96,97] Nowadays, the role of antiplatelet agents in preventing fistula thrombosis in patients with previous thrombosis is uncertain because of the high recurrence rate of access failure. Few data are available for the effectiveness of systemic anticoagulation to improve access patency. Warfarin can be used in patients with recurrent thrombosis but without anatomic stenosis.[98]

To prevent vascular access thrombosis in hemodialyzed patients, the use of clopidogrel, homocysteine-lowering agents, beta-hydroxybetamethyglutaryl coenzyme-A reductase inhibitors, heparinoids, eicosapentaenoic acid, renin–angiotensin system antagonists, calcium channel blockers, and alpha adrenergic antagonists has been proposed.[99–101] However, no randomized trials studying the effects of these agents are available in hemodialyzed patients.

Table 127.4

Vascular access thrombosis

- Pathogenesis
- Procoagulant environment
- Endothelial damage
- Inflammation
- Extrinsic deficiency of antithrombotic factors
- Mechanical obstruction associated with intimal hyperplasia
- Prothrombotic Risk Factors
- Diabetes; age > 65
- Antibodies: antiheparin-platelet factor 4; anticardiolipin IgM; antiprotein C; antiprotein S
- Increased levels of PAI-1, FVIII, prothrombin fragments 1+2; C reactive protein
- Hyperhomocysteinemia
- Hb between 10 and 12 g/dL
- Genetic risk factors
- Homozygous mutation of factor V Leiden
- 4G/5G PAI-1 polymorphic variant

In patients with unexplained recurrent access thrombosis, it should be useful to screen for lupus anticoagulant activity and anticardiolipin antibodies.

Therapeutic options to treat fistula thromboses include the use of thrombolytic agents, surgical thrombectomy, and mechanical dissolution. Thrombolysis in origin gave disappointing results, but now dosing adjustment improved the success rate and reduced the incidence of bleeding in patients with no contraindications for thrombolytic therapy (i.e., severe hypertension, recent bleeding episodes, or bleeding disorders).[102,103] The use of thrombolytic treatment with mechanical clot disruption yields access patency in the majority of cases with minimal complications.[102]

Heparin-Induced Thrombocytopenia

The use of anticoagulant heparin may cause HIT, a syndrome characterized by decrease in platelet count to <100,000 μL and/or thrombosis.[104] HIT, which usually present 5 to 14 days after the start of heparin therapy, is an immune-mediated disease due to the presence of IgG antibodies raised against the complex of platelet factor 4-heparin.[105] These antibodies possess the ability to activate platelets.

Thrombocytopenia, thrombosis, skin necrosis at heparin injection sites, venous limb gangrene, and acute systemic reaction that rises shortly after intravenous bolus of unfractionated heparin are events associated with HIT.[104]

In patients undergoing hemodialysis, the complications of HIT (reviewed in ref.[104]) range from no clinical sequelae despite positivity for HIT antibodies to thrombocytopenia, frequent clotting of extracorporeal circuit, and increase in arteriovenous fistula failure. Major complications include pulmonary embolism, deep venous thrombosis, myocardial infarction, and limb ischemia. A mortality of 30% has been reported in patients with HIT and thrombosis.[106]

In patients with thrombocytopenia developing during or shortly after heparin administration HIT should be suspected. Diagnostic criteria for HIT include normal platelet count before heparin treatment, presence of acute thrombotic event, no other known causes of thrombocytopenia, resolution of thrombocytopenia after heparin discontinuation, and HIT-antibody seroconversion.

After cessation of heparin, thrombocytopenia usually resolves in 1 to 2 weeks. Treatment (reviewed in ref.[104]) should be on the basis of clinical finding and not be delayed until laboratory confirmation is reached. In patients with high risk of HIT, alternative nonheparin anticoagulation should be sought and heparin discontinued. Platelet transfusion should be avoided. Platelet count normalization should be awaited before warfarin starting.

Systemic anticoagulation should be maintained in active HIT until platelet count is low to reduce the risk of life-threatening thrombosis. In patients with HIT, regional citrate anticoagulation can be employed together with alternative anticoagulation such as the direct thrombin inhibitors lepirudin and argatroban, and the factor Xa inhibitor danaparoid.

CONCLUSION

The association between a bleeding tendency and uremia has been demonstrated repeatedly. Although modern dialysis techniques and the use of erythropoietin to correct anemia

have reduced its frequency, bleeding is still a potentially life-threatening complication in uremic patients and limits surgery and invasive procedures. The pathogenesis of uremic bleeding is multifactorial and is not completely understood. However, it has been attributed mainly to abnormalities of primary hemostasis, particularly platelet dysfunction and impaired platelet–vessel wall interaction. Despite this hemorrhagic tendency, abnormalities of coagulation and fibrinolysis, as well as the presence of thrombotic risk factors, also predispose uremic patients to a hypercoagulable state and to thrombotic complications.

CHAPTER

128 Multitrauma Derangements in Hemostasis and Thrombosis

DIANE A. SCHWARTZ, LUCY Z. KORNBLITH, JOHN B. HOLCOMB, AND MITCHELL JAY COHEN

Despite significant advances in prevention of traumatic incidents and focus on prehospital medicine, emergency medicine, and surgical and critical care, trauma remains the leading cause of death in adults until the age of 45.[1] Military trauma data and their application to the civilian population provide much of our recent knowledge regarding coagulopathy and hemostasis; these topics remain at the forefront of clinical research, the impact of which may affect the primary cause of death in the civilian pediatric and adult populations.

HISTORICAL PERSPECTIVE

Historically, trauma mortality has been defined by a trimodal temporal distribution.[2] The first phase comprises patients with nonsurvivable injury. These injuries result in uncontrollable and nearly instantaneous exsanguinations or catastrophic brain injury. The second phase on the spectrum encompasses the patients who succumb to early hospital death as a result of ongoing, uncorrected hemorrhagic shock or severe brain injury. The late phase of the model defines patients who have had reversible hemorrhage, either by surgical or interventional control, and manageable and correctable coagulopathy, but whose late course is complicated by inflammatory dysfunction and infection stemming from the initial traumatic insult.

The commonest contributor to immediate death after trauma, in both military and civilian settings, remains uncontrolled hemorrhage.[3] Seventy-five percent of early deaths, recognized above as phases one and two of the defined model, are due to uncontrolled hemorrhage, but late deaths tend to occur secondary to sepsis and related multiorgan failure to which early bleeding and coagulopathy contribute.[4,5,6]

Recent data have called the classic trimodal distribution into question because it seems that trauma deaths now fall largely within the first two phases.[7,8] The trimodal distribution is no longer valid because mortality rates are actually increased in the initial hours following the traumatic event, not evenly distributed among three phases. In reality what occurs is a large peak of early deaths, those seen in the first 6 to 12 hours, followed by a tail of later deaths.[4,9] Several centers even describe an earlier peak, one that occurs within the first 6 hours after injury. Large urban centers agree that few hemorrhagic deaths occur after 24 hours, and fewer patients die of multiorgan failure and sepsis than originally described in the trimodal model[10,11,12] (FIGURE 128.1).

Traditionally, bleeding after trauma was thought to be caused by surgical bleeding, which was then exacerbated by iatrogenic coagulopathy.[13] This mantra of iatrogenic coagulopathy has been altered and is no longer believed to be the singular cause of continued bleeding once surgical causes have been controlled.[14] Coagulopathy after trauma is now primarily caused by the injury and shock and can be compounded by the lethal combination of dilution, hypothermia, and acidosis and additional iatrogenic influences.[15,16]

In the past, trauma resuscitation included large volume crystalloid and cold blood product administration, which contributed to dilution and hypothermia. Surgery was expected to control hemorrhage but contributed further to the coagulopathy by worsening the hypothermia and perpetuating the acidosis. Considerable literature exists documenting the detrimental effects of hypothermia, acidosis, and dilution on coagulation and bleeding.[17] From this initial understanding, trauma and resuscitative efforts have evolved to combat these significant players of the downward spiral of coagulopathy and death.

Important to the evolution of the understanding of coagulopathy is the observation that trauma patients with life-threatening injuries who have not received large volume fluid resuscitation still arrive to the hospital coagulopathic. Several groups have explored these observations and coined the term, acute traumatic coagulopathy, or ATC.[14,18,19,20] ATC occurs in approximately 25% to 35% of trauma patients nearly immediately after severe trauma and shock, occurs prior to and independent of iatrogenic causes, and remains a primary determinant of poor outcome after severe injury.[18,19,21]

ACUTE TRAUMATIC COAGULOPATHY

While the traditional causes of the "lethal triad" of coagulopathy have been known and studied for some time, trauma practitioners have also described a coagulopathy that is independent of acidosis, dilution, and hypothermia. This coagulopathy, termed ATC, appears concurrently in works by Brohi et al.[19] and Macleod et al.[18] in 2003. Brohi et al. reported that one fourth of his study population demonstrated evidence of coagulopathy within 75 minutes of hospital arrival, without having received significant resuscitation volume or suffering acidosis or hypothermia. Patients afflicted with this newly described coagulopathy were four times more likely to die than those with a normal coagulation profile.[22] Macleod et al. also demonstrated the relationship of ATC to concurrent tissue injury and shock. ATC is clearly exacerbated and affected by hypothermia, acidosis, and dilutional causes, but it is equally clear that it is a separate entity.

In order to understand ATC, one must be well versed in the function of protein C, which is the main mediator of ATC.[22,23] Protein C is a serine protease. After minor tissue injury, it is

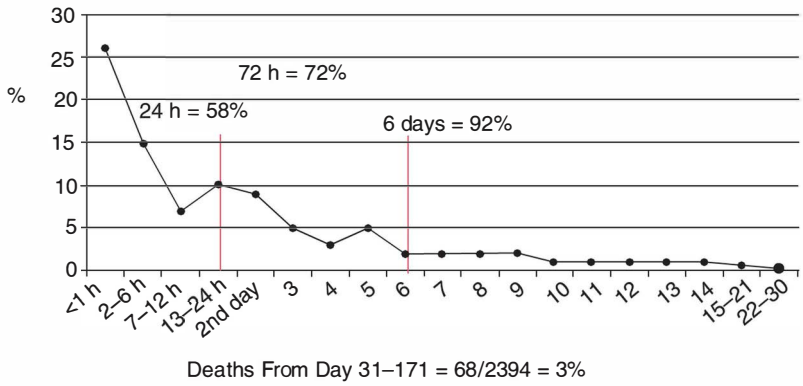

FIGURE 128.1 Trauma deaths experience at University of Texas Health Science Center-Houston (1999 to 2008). Of 26,028 trauma admissions, there were 2,394 deaths (6.6%), early deaths (at ≤24 hours) occurring in 1,398 (58%), and only 68 (3%) between days 31 and 171.

cleaved to its active form *via* the complexing of thrombin, thrombomodulin, and the endothelial protein C receptor (EPCR).[24–26] In patients without severe injury who are not coagulopathic, this pathway will downregulate itself from the inherent elevation in thrombin levels that occur after tissue injury. However, in patients with ATC, there is a pathologic response. Protein C is activated to the point of being acutely depleted. Thereafter, this event leads to global inactivation of factors V and VIII and yields an increase in tissue-type plasminogen activator and D-dimer.[22] Factors V and VIII are the main cofactors for thrombin and factor X activation, respectively. This derangement, stemming from the depletion of activated protein C (APC), which prohibits thrombin production, is the cornerstone of ATC.

ATC is characterized by prolonged prothrombin time (PT) and/or activated partial thromboplastin time, despite normal and appropriate thrombin production prior to injury.[27] As tissue injury progresses at the molecular level, there is a congruent reduction in thrombin in patients who have increasing levels of APC. In the face of tissue injury and hemorrhagic shock, the decrease in thrombin production and the subsequent resultant increase in fibrinolysis cause a proportional coagulopathy that defines ATC.[22,28] While thrombocytopenia and hypofibrinogenemia are clear contributors to hemorrhage and have been separately studied, ATC occurs even in patients with normal fibrinogen levels and platelet counts.[22]

It is not well understood why thrombin depletion is seen following severe traumatic injury and shock. It seems counterintuitive because mild tissue injury is known to cause an elevation in thrombin production, which is in contrast to the abrupt decrease seen in the severely injured patient.[29] It is believed that ATC is initiated with tissue injury, which exposes tissue factor, thereby inducing the coagulation cascade.[14] In patients who are not in shock, exposure of tissue factor leads to production of thrombin, fibrin deposition, and clot formation. However, in the severely injured patient, hypoperfusion secondary to hemorrhagic shock causes increased expression of thrombomodulin and EPCR on the endothelium while simultaneously activating and then depleting protein C.[30] Further augmentation of the coagulopathy of severe injury is the result of decreased activation of the thrombin-activatable fibrinolysis inhibitor, which depletes plasminogen activator inhibitor-1.[22,31] Thrombomodulin complexes with thrombin, diverting the normal cleavage of fibrinogen toward the APC and the consequent inhibitory effect on thrombin formation as described above.[32]

One protective mechanism to injury is the elaboration of thrombus formation at the site of injury. For reasons still being elucidated, patients in severe shock from trauma develop an exaggerated response of protein C, which prevents local thrombus formation. These complicated mechanistic relationships between injury, shock, and ATC are important avenues of research.

EFFECTS OF PROTEIN C DEPLETION IN ACUTE TRAUMATIC COAGULOPATHY

While there are numerous proteins involved in the generation of the traumatic response, protein C is one that is responsible for mediating the late cytoprotective response to injury.[33–35] Protein C activation is a primary instigator of ATC. Poorly regulated protein C activation, which occurs during the acute traumatic injury or hemorrhagic shock, will eventually deplete the natural baseline levels of protein C that the body otherwise, in physiologic normalcy, depends upon to fight infection and thrombotic complication. This is because, in addition to its anticoagulant effects, protein C has been shown to be cytoprotective and anti-inflammatory.[36,37] This mechanism is derived *via* its signaling through protease-activated receptor-1 and EPCR.[38] Cytoprotective effects of APC can be appreciated when observing their role in the pulmonary system. In patients with persistently low levels of protein C, such as those seen in the trauma population, there is a decrease in capillary endothelial barrier function. This decrease in barrier function, which is thought to be modulated in part by protein C, leads to higher rates of ventilator-associated pneumonia.[30,39,40] There is evidence that similar cytoprotective and anti-inflammatory effects of APC also exist in acute kidney injury.[41]

It seems that the phenomenon of early protein C activation, perpetuation of ATC, and eventual depletion of usable protein C may in fact represent one link of hemorrhagic shock to later inflammatory complications seen in the trauma population. The initial APC has an overall detrimental effect of contributing to coagulopathy. Additionally, while inflammatory modulation is helpful in combating the initial stress of injury and shock, the depletion of protein C is further detrimental because it occurs at a time when the patient requires an ongoing stress response and is at risk for thrombotic, inflammatory, and infectious sequelae.

This conundrum may drive investigation to further characterize and modulate these mechanisms in severely injured patients.[42]

ADDITIONAL CONTRIBUTORS TO ATC AND COAGULOPATHY

Additional factors that contribute to the ATC are reductions in natural anticoagulants, such as antithrombin and protein S.[43–46] Pharmaceutical hemostatic agents include recombinant factor VIIa (rFVIIa), prothrombin complex concentrate (PCC), and several antifibrinolytics. These hemostatic pharmaceutical adjuncts are used, at times off label, in patients with traumatic coagulopathy.

rFVIIa (NovoSeven; Novo Nordisk A/S: Bagsvaerd, Denmark) can be used for rapid correction of coagulopathy induced by Coumadin and may also have a role in the correction of ATC secondary to the association of exposed tissue factor.[47] There have been two randomized controlled trials using rFVIIa in traumatic hemorrhage, demonstrating a moderate reduction in total units transfused, but no mortality benefit.[48,49] In addition to reduction in packed red blood cells (pRBCs) and plasma requirements, these studies demonstrated a decreased incidence of multiorgan failure and acute respiratory distress syndrome, which may be attributed to the molecular control of ATC, protein C, and other unknown contributors. While thromboembolic events are thought to be a consequence of factor VII use, these events occurred with similar frequency in the trauma groups receiving rFVIIa and the control group.[49,50–52] Interestingly, a subset of patients will see no correction of their PT despite receiving rFVIIa. These patients have a significantly higher 24-hour and 30-day mortality and are considered nonresponders to this agent.[53,54]

It has also been demonstrated that rFVIIa is impaired by acidosis; "nonresponders" in some studies demonstrate a lower mean pH than those patients who achieved hemostasis with rFVIIa.[55,56] It is widely understood that the role of rFVIIa in trauma patients has decreased for two reasons: The randomized studies showed no survival benefit, and the iatrogenic resuscitation injury of excessive crystalloid and unbalanced plasma and RBC transfusion is less frequent than in previous years.

PCC was originally developed for hemorrhagic complications of hemophilia B and is rich in factors II, VII, IX, X, and there are several different formulations in use.[57] It also has a significant role in warfarin reversal because of its composition of vitamin K–dependent clotting factors.[58] There may be increased thromboembolic risk associated with its use, but this has not been well substantiated.[59,60] Fries et al. in 2006 corrected coagulopathy in the porcine model with the use of PCC. This model showed that clot formation was enhanced, blood loss decreased, and mortality improved with administration of PCC in uncontrolled hemorrhage.[61] While the indications for use after injury in humans have not been completely delineated, the porcine model and observational study through clinical application are provocative.[61–63]

ATC has a well-definable antifibrinolytic component, so it is reasonable to use antifibrinolytic agents as adjuncts in the correction of traumatic hemorrhage. Tranexamic acid (TXA) is an antifibrinolytic that targets the lysine binding pocket of plasminogen and has been shown to significantly improve survival after trauma.[64,65,66,67] Fibrinolysis is well documented in the trauma patient by the thromboelastogram, indicating a swifter than expected breakdown in clot formation.

In 2010, Shakur et al. published the CRASH-2 study, which randomized trauma patients to receive TXA versus placebo. All-cause mortality was decreased from 16% in placebo to 14.5% in the treatment group, with the risk of death from bleeding significantly reduced and no reported safety issues.[67] Approximately, 50% of the patients randomized in the study were not transfused any blood products. Unfortunately, when TXA was given more than 3 hours after injury, death rates were increased.[65,66,67] These data influenced others to carefully examine the use of TXA in the trauma population.

It is now known that a prolonged Ly30 on thromboelastography in a patient in hemorrhagic shock corresponds to a severe state of fibrinolysis and increased mortality.[64] Higher doses of TXA may lower seizure threshold, and this requires further investigation in trauma patients.[67,68] Aminocaproic acid, which has not been extensively evaluated in traumatic hemorrhage, is a similar lysine-based plasminogen binding inhibitor. This agent has been shown to decrease hemorrhage during elective surgery.[65] Its application to the acutely hemorrhaging trauma patient is an interesting avenue of research.

Apoprotinin is a nonspecific protease inhibitor originally used for coronary bypass–associated coagulopathy. It has been studied in traumatic coagulopathy, where it demonstrated reduction in total transfusion requirements, but no other outcome differences.[69,70] It therefore cannot be yet extrapolated for use in trauma.

While many of these agents potentially show promise for application to the trauma population, none other than TXA has been shown in this population to make a difference in outcome. More studies are anticipated before universal use can be recommended.

IATROGENIC COAGULOPATHY

As discussed above, traumatic coagulopathy was traditionally attributed to the "lethal triad" of hemodilution, hypothermia, and acidosis, leading to an imbalance and consumption of clotting factors.[13,71,72] Dilutional iatrogenic coagulopathy occurs in part by massive crystalloid resuscitation.[13,73] Large crystalloid volume followed by multiple units of transfused pRBCs further augments the coagulopathy because pRBC units are equally devoid of coagulation factors.[74] Traditionally, there was no defined limitation to crystalloid resuscitation, and the guidelines for massive transfusions encouraged coagulopathy-inducing ratios of fresh frozen plasma:platelet:RBC. Crystalloid volumes in the range of 20 to 30 L over 24 hours were not uncommon. Resultant dilution of all aspects of the complex coagulation system including the procoagulant, anticoagulant, and fibrinolytic systems created a complex coagulopathy, prompting investigation of targeted protocols for transfusion and resuscitation.

It has been shown that thrombin activity is decreased with traditional large volume crystalloid-based resuscitations, although it may be that thrombin dysfunction is partially counteracted by inhibitory actions of antithrombin.[75,76] In addition, reduced fibrinogen levels as well as impaired fibrinogen bioavailability have been reported as a result of trauma and subsequent resuscitation-based dilution.[77,78] Fibrinogen levels are decreased earlier and more significantly, compared with other coagulation factors, in massive transfusions and situations in which large volume of crystalloid is administered.[78] The functionality of fibrinogen is depleted at 150% of blood volume loss, whereas

critical levels of coagulation factors and platelet count do not occur until 200% blood volume loss.[77,78] It should be noted that fibrinogen level of 100 mg/dL, which is defined by most massive transfusion protocols as being the level at which function is altered, is an arbitrary definition with few data to support it. The polymerization of fibrinogen is the final common pathway for hemostasis, clot formation, and thrombin activation.[79] Functional fibrinogen deficiency can be caused by dilution with crystalloid and colloid infusion leading to abnormal fibrin polymerization.[34] Additional studies, both *in vivo* and *in vitro*, have demonstrated that increasing fibrinogen concentrations incompletely reverses dilutional impairment of clot formation.[79,80] Dilutional effects on coagulopathy may even occur at small resuscitation volumes of <500 mL as discussed in the Acute Traumatic Coagulopathy section.[81]

The second contributor to iatrogenic coagulopathy is hypothermia. Hypothermia, defined as core body temperature <35°C, remains a significant problem in trauma patients.[82,83] Acute blood loss results in decreased heat production. In addition, patients are often brought in from the field suffering from evaporative heat loss due to environmental factors. These same patients are then exposed in the trauma bay for evaluation, causing further heat loss by convection and radiation. Many patients are then taken to the operating room; open body cavities result in additional evaporative losses. Exacerbating heat loss is the administration of room temperature or colder resuscitative fluid.[84] Compounding all these factors is the loss of endogenous heat generation, secondary to shock. At 33°C, even if clotting factors are at normal levels, the clotting process is functionally equivalent to a factor IX deficiency, meaning that the functionality of these factors is only around 30%.[85,86] In addition, it has been shown that thrombin production decreases by 10% for each hypothermic degree.[87] There is a known synergism of hypothermia, dilution, and acidosis leading to impaired coagulation and poor outcomes.[88] Hypothermia is additionally an independent predictor of mortality in trauma, as shown by Gentilello and Jurkovich et al. in several studies involving hypothermia and active rewarming.[84,89] Additionally, there may be an inhibitory effect of hypothermia on platelet aggregation and the clotting cascade.[89,90]

Trauma patients suffer from significant metabolic acidosis. Acidosis in traumatic injury is multifactorial but is known to be caused by shock. Acidosis contributes to impaired thrombin production and disrupted coagulation.[71] Crystalloid exacerbates acidosis, which is why initial hemorrhage should not be treated with any volume of crystalloid replacement.[13,71,72] Clotting dysfunction becomes apparent at a pH below 7.2, which is not uncommon in hemorrhagic shock or severely injured patients, and its effects are persistent. However, correcting pH does not completely reverse the effects of the acid-induced coagulopathy.[56,82,91]

Taken together, metabolic perturbations and ATC, which cause coagulopathy after trauma, represent a significant contribution to bleeding and worsened outcome after injury. Considerable focus has been directed toward modification of resuscitation and surgical intervention of hemorrhage with the intent to mitigate the coagulopathic state.

DIFFUSE INTRAVASCULAR COAGULATION

"Consumptive coagulopathy," otherwise known as diffuse intravascular coagulation, describes impaired clot formation with simultaneous fibrinolysis. It is one probable cause of traumatic coagulopathy, although its specific role early in the trauma patient's clinical course continues to evolve.[71] The consumptive mechanism seen in traumatic coagulopathy appears similar to that seen in disseminated intravascular coagulation (DIC) on multiple laboratory tests.[92] It is possible, though not proven, that the tissue injury, which induces ATC, also predisposes patients to DIC. Following injury, tissue factor is exposed, which activates the extrinsic coagulation cascade, and increases thrombin production. "Thromboplastins" may also be released at the time of severe injury; these are defined as lipids from bone marrow, amniotic fluid, and brain phospholipids, all of which may contribute to DIC.[93]

In contrast to this multifactorial causation of DIC, ATC is usually only seen when tissue injury and systemic hypoperfusion occur simultaneously.[32] ATC is independent of thrombin production or consumption. Consumption is also not likely to be the sole or primary cause of ATC because ATC is known to occur sporadically in patients with varied degrees of both tissue damage and thrombin production. Additionally, fibrinogen levels are not generally decreased on initial presentation after injury in patients with ATC. In fact, platelet counts and fibrinogen levels have been shown to be normal after initial injury in studies of ATC.[22,94,95] It is possible that ATC may be an early player on the spectrum of DIC, but DIC, by definition, requires thrombocytopenia or hypofibrinogenemia, which may not occur in ATC.[96–98]

DIC and ATC are likely overlapping entities but are mechanistically different, and the strict criteria needed for DIC does not account for the dynamic changes seen in ATC.[99,100] DIC is a diagnosis made based on laboratory criteria including low platelets and fibrinogen, prolonged PT, and elevated fibrin/fibrinogen split products.[97] Conversely, in patients presenting with ATC, fibrinogen levels are rarely decreased, and platelet counts are generally normal. D-dimer levels are frequently elevated in DIC, which may indicate fibrinolysis, but fibrinolysis is unusual immediately after traumatic injury.[94,95]

THROMBOEMBOLIC COMPLICATIONS IN TRAUMA: THE PROCOAGULANT STORY

DVT/PE

Deep vein thrombosis (DVT) and pulmonary embolism (PE) are two complications of trauma that are more common than historically appreciated.[101–103] Lower extremity DVT has been reported in an average of 1% of those with multisystem trauma, rising to 15% in severely injured patients; pulmonary embolus with hemodynamic compromise is seen in about 1% of patients with multitraumatic injuries.[104]

There are several potential reasons for why trauma patients are susceptible to the development of DVT and PE. There are known hypercoagulable abnormalities seen as early as the first admission labs.[105,106] Thromboelastography is currently being used at the University of Texas at Houston Health Science Center. Maximum amplitude (MA) is the point in time at which an aliquot of the patient's blood reaches its full thrombotic strength. MA higher than 65 with more than 2 non–weight-bearing extremities puts patients at an increased risk of DVT and subsequent PE and may be an indication for early inferior vena cava filter.[107] Extremity fractures, rib fractures, and pulmonary contusions also likely cause microvascular damage to the venous structures, predisposing patients with these injuries to thrombus

formation.[108–111] The immobility associated with traumatic injury is also a risk factor for DVT and PE.[112,113] Up to 62% of spinal cord injured patients and 80% of patients with femoral fractures developed DVTs in a study of 716 trauma patients.[108] The risk of DVT and PE exists throughout the patient's entire hospitalization and even in the final phases of his recovery. Severely injured patients who survive the initial hypocoagulation or coagulopathy associated with shock and transfusion are at high risk of late thromboembolic events as well.[43,114–116]

TREATMENT OF BLEEDING AFTER TRAUMA

Hemorrhagic shock was classically treated with crystalloid bolus, followed by RBCs, and then at a later time, plasma, platelets, and cryoprecipitate. This resulted in a disorganized administration of blood product. The initial coagulopathy of trauma was worsened by this approach, and it became clear that new transfusion protocols were needed. Previously recommended ratios of plasma:pRBC of 1:4 or 1:10 and sporadic platelet transfusions were replaced.[117,118] As the understanding of ATC has progressed, so have the resuscitation protocols developed from the ongoing military experience focused on "hemostatic resuscitation" or "damage control resuscitation."[119]

Based on results from the military, new algorithms and transfusion protocols have emerged over the last 9 years, changing the way many trauma centers transfuse blood products.[120] Surgical bleeding must be addressed and corrected. Strategies of permissive hypotension, limitation of crystalloid infusion, and maintenance of balanced transfusions of plasma, platelets, and RBCs in a balanced infusion scheme to avoid unbalanced resuscitation patterns are now employed.[121,122]

There are many studies demonstrating civilian and military utilization of 1:1:1 plasma:platelet:RBC ratios in massive transfusion protocols; however, it should be stressed that there is still considerable debate in the literature regarding the best ratio combination.[117,123,124] Holcomb et al. reported the largest and broadest of these civilian studies in support of a 1:1:1 ratio in 2008. They are currently completing an observational study at 10 trauma centers.[125] The original 2008 study of 466 massively transfused patients at 16 major US level I trauma centers showed decreased mortality in higher transfusion ratios. Patients with ≥1:1 plasma:pRBC had 2% and 25.5% 6-hour and in-hospital mortality, compared to 15.2% and 41.1% in those transfused with 1:4 to 1:1, and 37.3% and 54.9% in patients transfused with ratios <1:4. In addition, higher plasma:pRBC transfusion ratios were associated with lower overall units transfused (18 vs. 13 within the first 24 hours).[126] Multiple other civilian and military studies have corroborated these findings showing association with improved early and late survival.[121,122,127]

Debate exists in the literature regarding the most appropriate ratio to use for massive resuscitation. Borgman et al. demonstrated improved survival in 246 massively transfused military patients who received 1:1.4 plasma to pRBC transfusion ratio versus a more standard 1:3 ratio.[128] Additionally, some groups demonstrate no survival advantage to ratios that approximate 1:1.[129,130] Snyder et al.[131] suggested that the beneficial findings of high ratio resuscitation might be due to a survival bias of patients who receive plasma in their initial resuscitation. Kashuk et al.[129] reported a survival benefit as the ratio approached 1:2 but increased mortality at 1:1, in a small single center study. Finally, Riskin et al.[118] suggested that the benefit might derive from early aggressive therapy rather than the ratio itself. Ho and colleagues have recently reviewed most of the trauma transfusion data and concluded that survival bias threatens most of these studies. Because of the time-sensitive nature of rapid bleeding and highly variable ordering and supply of blood products from blood banks, randomized studies are required to answer the important questions raised by the retrospective transfusion studies.

There still exists considerable debate on the best transfusion method, but most clinicians agree on an early, balanced, aggressive plasma, platelet, and RBC-based resuscitation with limitation of crystalloid. Although there is a significant literature detailing the known risk of transfusion-related lung injury, acute respiratory distress syndrome, and cardiac volume overload associated with transfusion of plasma and platelets, the majority of this work was conducted at a time when crystalloid administration was not as limited in hemorrhagic shock as it is now.[132–137] Many centers are reporting decreases in crystalloid use during the initial phases of resuscitation, and these same patients are demonstrating corresponding decreases in organ failure and improved survival.[138,139,140]

FUTURE DIRECTIONS

Trauma-related coagulopathy and definitive hemostasis are complex and diverse subjects. Not only are the mechanisms of each not completely understood, but there are diverse and widespread molecular interplays that contribute to ongoing coagulopathy. Its consequences can be deadly or lead to extensive morbidity, and its treatment is incompletely elucidated. There is opportunity for continued research in all aspects of its mechanism, treatment, and complications. Algorithms for massive transfusions have dramatically changed over the last 5 years. The entities of ATC and of iatrogenic coagulopathy have been defined, and hemostatic resuscitation guidelines have been developed. Integrated basic and clinical research efforts are needed to deliver rapid, accurate, and predictive laboratory data, understand early hypocoagulopathy, decrease the number of hemorrhage-related deaths, prevent late venous thromboemboli, and optimize how we use blood products.

CHAPTER

129 Blood Management in the Cardiovascular Surgical Patient

LAWRENCE TIM GOODNOUGH AND L. HENRY EDMUNDS, JR.

Bleeding is a potential complication of any surgery and a major concern of all surgeons. All surgeons are trained to control visibly bleeding vessels, but additional skills and information are necessary for successful management of complex operations, trauma victims, and patients who require mechanical circulatory assistance. Surgical hemostasis now requires knowledge of perioperative coagulation disorders, blood conservation techniques, and the risks and benefits of blood component replacement and transfusion therapy. This chapter outlines a practical approach to the principles of blood management related to all surgery, but particularly cardiac surgery.

Blood management is defined as the appropriate use of blood and blood products, with the goal of minimizing their use.[1] The conservation of blood is historically based on principles related to blood risks, blood inventory, and blood costs. Cardiothoracic surgery programs led the development of intraoperative and postoperative salvage techniques because of concerns regarding blood availalbity.[2] Subsequently, recognition of blood-transmitted hepatitis and HIV infections fueled further efforts to limit blood transfusions[3,4] (Table 129.1). Accurate accounting of blood costs has identified that alternatives to allogeneic blood (e.g., autologous blood salvage and reinfusion) may be cost equivalent.[5] Blood risks and known and unknown emerging pathogens will continue to drive blood conservation and blood transfusion practices.[6,7]

Considerable variation in transfusion practices has been identified in several studies over the last 20 years,[8,9,10] despite guidelines emphasizing more prudent transfusion practices, with suggested transfusion triggers of 6 to 8 g/dL in the perioperative setting.[11–13] A randomized trial in patients undergoing cardiac surgery demonstrated that a restrictive transfusion strategy (Hgb ≤ 8 g/dL) resulted in equivalent patient outcomes, compared to patients treated with a liberal (Hgb ≤ 10 g/dL) transfusion strategy.[14] This trial supported a previous randomized trial in critical care patients that demonstrated similar clinical outcomes in patients transfused for Hgb ≤ 7 g/dL compared to Hgb levels <10 g/dL.[15] Point-of-care testing (FIGURE 129.1) linked with a transfusion algorithm for plasma and platelet transfusions has improved patient care and reduced transfusions of blood and blood components[16] along with substantial cost savings.[17]

PREOPERATIVE ASSESSMENT

Preoperative planning is essential to reducing or avoiding perioperative allogeneic transfusion.[1,18] Preadmission testing should take place as far in advance as possible (e.g., 30 days) of elective surgery to allow time for adequate identification, evaluation, and management of anemia,[19] as illustrated in FIGURE 129.2. The estimated equivalent to number of units "saved" by various blood conservation strategies available in blood management of the surgical patient in the preoperative, intraoperative, and postoperative intervals is listed in Table 129.2.[20]

The preoperative evaluation of a patient who requires surgery varies with the type and urgency of the operation. For all patients, a thorough history is the best method to discover clinically significant bleeding disorders. A good history reveals bleeding related to previous surgical and dental procedures; epistaxis; menorrhagia; excessive bleeding with major trauma; and easy bruising or joint or muscle swelling after minor trauma. Positive answers raise the possibility of hereditary or acquired coagulation deficiencies, antibodies to specific coagulation proteins, von Willebrand disease (vWD), or platelet disorders. The patient's medication profile may reveal ingestion of inhibitory drugs, such as aspirin or aspirin-containing compounds, nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin, chronic steroid use, platelet inhibitors, or injections of standard or low molecular weight heparin. The history may also reveal acquired hemorrhagic conditions associated with parenchymal liver disease, renal failure, or myeloproliferative syndromes.

The physical examination includes assessment of a possible bleeding tendency. One may find purpura, which is particularly important if not associated with a known history of trauma. Other findings include petechiae, splenomegaly, hepatomegaly, lymphadenopathy, joint deformities, lack of mobility, palpable collections of blood arising as deep hematomas, and evidence of gastrointestinal (GI) bleeding on digital rectal examination. Discovery of blood in stool is the most effective way to detect occult sources of GI bleeding from esophageal varices, duodenal ulcer, gastritis, diverticulitis, polyps, cancer, ingestion of NSAIDs, and other disorders. Comorbid diseases, such as uremia, cirrhosis, aortic stenosis, polycythemia vera, or continuous flow ventricular assist devices, may enhance bleeding from local lesions in the GI tract.

The results of the history and physical examination and the proposed operation determine the selection of preoperative laboratory tests for coagulation disorders and the need for special preoperative or intraoperative therapy.

Blood must be typed, and a sample sent to the blood bank for antibody screening (type and screen/crossmatch) for all patients prior to scheduled surgery. A complete blood count is obtained in all patients, and traditionally both a prothrombin time (PT) and activated partial thromboplastin time (aPTT) are measured. A prolonged PT detects deficiencies of the extrinsic coagulation pathway, which may be due to vitamin K deficiency or liver disease; a prolonged aPTT detects deficiencies of proteins in the intrinsic coagulation pathway. Results of these measurements

Table 129.1

Risks of major infectious and noninfectious complications of transfusion in the United States

Complications	Risk
Transfusion-transmitted Disease Agents	
Human immunodeficiency virus	1:1,800,000
Hepatitis C virus	1:1,600,000
Hepatitis B virus	1:220,000
Bacteria (platelets, apheresis)	1:75,000
Noninfectious Complications	
Acute hemolytic reaction	1:25,000
Mistransfusion[a]	1:19,000
Transfusion-related acute lung injury	1:5,000
Transfusion-associated circulatory overload[a]	1:400
Fever/allergy	1:100

[a]Can occur in association with transfusion of autologous blood as well as allogeneic blood.
Modified from Uhl L. Patient blood management: a 68 year old woman contemplating autologous blood donation before elective surgery. *JAMA* 2011;306:1902–1910.

are generally laboratory specific, and the predictive value for bleeding is low, but values exceeding the normal range should be investigated. For example, familial factor XI deficiency may not be detected by a bleeding history, but does prolong the aPTT. A history of bleeding episodes or physical signs of bleeding mandate a full bleeding workup and consultation with a hematologist to assess platelet numbers and function and the presence of inherited or acquired coagulation factor deficiences.[21]

The role of erythropoiesis-stimulating agents (ESAs) in management of preoperative anemia patients undergoing cardiovascular surgery and its safety in this setting are unresolved issues. In a European trial,[22] the authors found no differences in mortality, thrombotic events, or serious adverse events among their 76 patients, whether treated with ESA or placebo. A US study also concluded that no differences in adverse events between ESA- and placebo-treated patients were observed and that ESA therapy was well tolerated.[23] The safety of ESA in surgical settings has been under re-review since the completion of the SPINE study, in which patients scheduled for elective spine surgery had higher rates of thrombovascular events with an ESA versus placebo in subjects who did not receive prophylactic ESA therapy during spinal surgery.[24] Nevertheless, there was an uneven distribution of adverse events between the two treatment groups. Use of ESA remains a valuable tool for patients with special requirements, such as Jehovah's Witness patients for whom blood transfusion is not an option.[18] Until additional

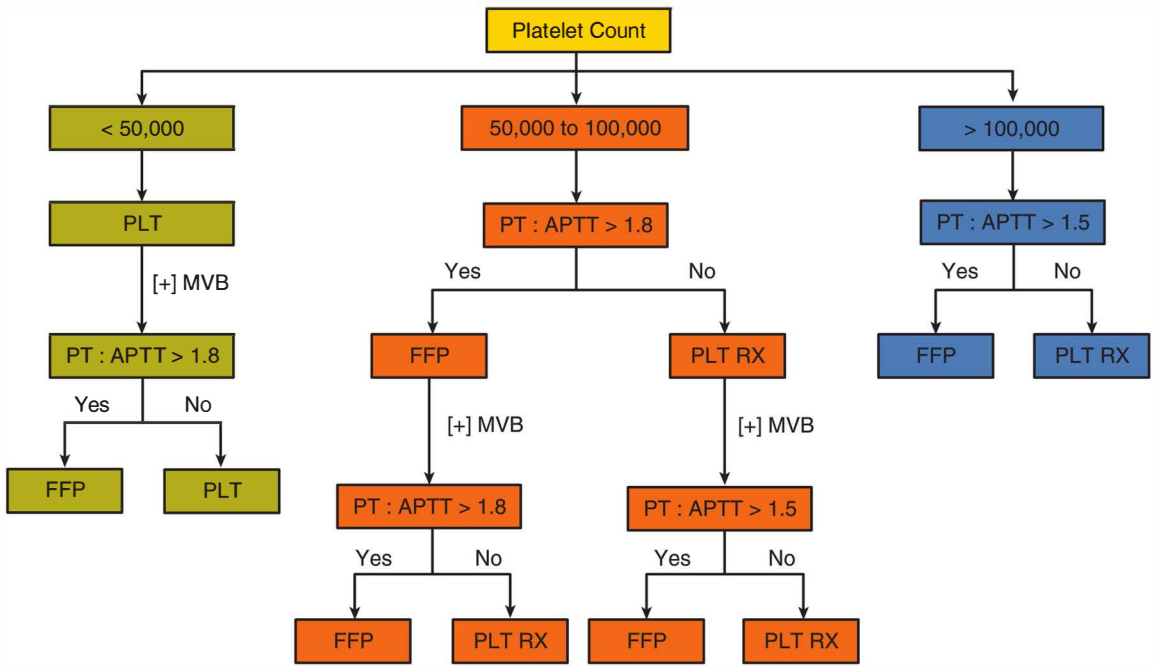

FIGURE 129.1 Transfusion algorithm based on preoperative platelet count. An initial platelet count of <50,000 (*left arm*: severe platelet deficiency) warrants platelet transfusion. If the initial platelet count is >50,000 (*middle* and *right arms*), the PT:aPTT ratio (patient vs. normal reference) would delineate whether platelet therapy or plasma was to be administered. *Platelets*, Platelet transfusion (6 random donor units); PLT RX, platelet therapy (6 random donor units or 0.3 mg/kg DDAVP at physician's discretion); FFP, 2 units of thawed plasma; [+] MVB, persistent microvascular bleeding. Detection, evaluation, and management of preoperative anaemia in the elective orthopaedic surgical patient: NATA guidelines. *Br J Anaesth* 2011:106:13–22.)

safety data are forthcoming, however, the off-label use of ESA in patients undergoing cardiac or vascular surgery in the United States cannot be recommended.[25]

CONDITIONS THAT INCREASE PERIOPERATIVE BLEEDING

Genetic and Acquired Clotting Abnormalities

Hereditary coagulation deficiencies are usually identified by history or screening test and are confirmed by specific laboratory evaluation. The most common inherited coagulation protein deficiencies are hemophilia A and B and vWD. Patients with hemophilia A or B may develop IgG antibodies to the deficient coagulation proteins, FVIII or FIX, from chronic replacement therapy. Deficiencies in coagulation proteins are usually treated by replacement therapy, and many of these are now available as recombinant human proteins. Inherited deficiencies in fibrinolytic inhibitors, α_2-antiplasmin or plasminogen activator inhibitor-1, may also cause substantial bleeding due to excessive fibrinolysis, and these are effectively treated by lysine analogs, epsilon aminocaproic acid, or tranexamic acid.[26] A variety of genetic defects may affect platelets and disturb platelet numbers and function.[27] Some may respond to desmopressin or require platelet transfusions, but consultation from an expert hematologist is needed, particularly since patients may develop antibodies against the diminished receptors from prior transfusions. Osler-Weber-Rendu and Ehlers-Danlos syndromes may cause troublesome bleeding problems during surgery even though circulating coagulation factors and platelets are normal. Marfan syndrome is not associated with increased risk of bleeding.[27]

Acquired bleeding disorders of coagulation proteins, fibrinolysis, and platelets occur more often than hereditary bleeding diseases. Drug-induced antibodies (quinidine, quinine, some antibiotics) against specific coagulation proteins are uncommon. Surgeons, however, may encounter patients with antibodies to factor V due to prior use of topical bovine fibrin glue for local hemostasis.[28,29] Advanced liver disease may diminish nearly all

Table 129.2

Approximate contributions of selected modalities to blood management in the surgical patient

Options	Number of Blood Units
Tolerance of anemia (reduce transfusion trigger)	1–2
Increase preoperative red blood cell mass	2
Preoperative autologous donation	1–2
Intraoperative options	
Meticulous hemostasis and operative technique	1 or more
Acute normovolemic hemodilution	1–2
Blood salvage	1 or more
Postoperative options	
Restricted phlebotomy	1
Blood salvage	1

coagulation and regulatory proteins of the coagulation system to levels that affect hemostasis and/or promote severe fibrinolysis.[30] However, drugs prescribed to inhibit platelet function cause the most common acquired bleeding disorders that concern surgeons.

Surgeons must also be aware of a large menu of genetic procoagulant clotting disorders that increase the likelihood of thrombotic and embolic complications. Factor V_{Leiden} mutation, which impairs activation of the natural anticoagulant protein C, is prevalent (2% to 5%) in Northern European whites and their descendants and the prothrombin 20,210 mutation is prevalent (1% to 3%) in Southern Europeans.[31] Both mutations increase the risk of venous thrombosis.[31] Lupus anticoagulant and anticardiolipin antibodies may produce thrombotic complications during and after major surgery.[32]

Platelets. Thrombocytopenia or platelet dysfunction that are not drug related occur in patients with myeloproliferative diseases, uremia, acquired vWD, antiplatelet antibodies (e.g., immune thrombocytopenia), posttransfusion purpura, and cirrhosis.[33] Aspirin and some NSAIDs irreversibly inactivate platelet cyclooxygenase for the life of the platelet (~10 days). Cyclooxygenase blockade partially inhibits platelet function by preventing endoperoxide and thromboxane A2 synthesis.[34] Aspirin prolongs the bleeding time[35] and blocks platelet aggregation,[36] but may increase the bleeding time to a greater extent if other, mild hemostatic deficiencies (e.g., vWD) are present. Aspirin resistance caused by genetic or acquired mechanisms occurs in approximately 10% of patients with acute coronary syndromes.[37]

Major surgery, including cardiac surgery, in patients with aspirin-inhibited platelets may increase perioperative bleeding.[36,38,39,40] Nearly all patients presenting with acute coronary syndromes receive aspirin as part of their initial therapy, but usually the impact on surgical hemostasis is minor.[38] Aspirin-related bleeding is treated by platelet transfusions, since aspirin is cleared from blood in <90 minutes.[41]

Clopidogrel and more recently prasugrel are thienopyridines that are irreversible platelet inhibitors that prevent adenosine diphosphate binding to platelet $P2Y_{12}$ receptors. Both drugs have rapid platelet inhibition, but the kinetics of prasugrel are faster and more consistent and the drug is preferred for management of acute coronary syndromes.[42,43] Median plasma half-life is 7 to 8 hours, but platelet inhibitory effects vary and last 3 to 10 days after the drug is discontinued.[33] Both drugs are routinely used in combination with aspirin to reduce adverse cardiac ischemic events.[44] Major bleeding complications from the combination of aspirin and prasugrel are slightly, but significantly higher (2.4%) than with aspirin and clopidogrel (1.8%).[42] For this reason, the Society of Thoracic Surgeons' guidelines recommend stopping thienopyridines at least 3 days and preferably 5 days before elective coronary arterial bypass surgery.[39] However, reversal of thienopyridines is highly variable between patients. A point-of-care device, which assesses platelet responsiveness to ATP, showed reduced platelet aggregation in some patients who had stopped thienopyridines within 7 days of operation.[45]

Platelet GPIIIa/IIb ($\alpha_{IIb}\beta_3$) receptor antagonists (abciximab, eptifibatide, and tirofiban) inhibit most platelet functions and prolong bleeding times considerably longer than aspirin.[46] Abciximab (Reopro) rapidly binds to the platelet receptors and remains bound for the life of the platelet.[47] Eptifibatide and tirofiban are reversible inhibitors and relatively short acting. Inhibitory effects of abciximab last approximately 48 hours, whereas that of eptifibatide lasts <1 hour.[47] Certain prostaglandins inhibit platelets by activating platelet adenylate cyclase or inhibiting cyclic nucleotide phosphodiesterases (e.g., prostacyclin and dipyridamole).[33] All of these platelet inhibitors increase the bleeding time.[33]

Warfarin. For minor or superficial operations, it is usually not necessary to reverse warfarin, but for major operations, warfarin should be stopped for 3 to 5 days before surgery, if the likelihood of a clotting event within that interval is low.[13] The PT should be checked before operation to be sure that most, if not all, of the warfarin effect has been reversed. In patients that cannot safely tolerate interruption of anticoagulation (e.g., mechanical heart valves), intravenous heparin may be used to maintain anticoagulation until 2 to 3 hours before incision.

Oral vitamin K (2 to 4 mg) administration usually corrects the PT to normal within 24 hours.[48] In an emergency, warfarin anticoagulation can be reversed by intravenous vitamin K (10 mg IV, infused slowly over 30 minutes) and plasma infusion (15 to 30 mL/kg, or 4 to 8 units in an adult) over 4 to 6 hours, with careful attention to volume status of the patient.[49,50]) Transfusions of prothrombin complex concentrates (PCCs), some of which contain high concentrations of vitamin K–dependent coagulation factors II, VII, IX, and X, have also been utilized. PCC acts rapidly but may have a risk of thrombosis.[51,52] If replacement therapy is not effective, administration of recombinant factor VIIa (rFVIIa) (2 mg IV, or 20 to 40 μg/kg for 100 to 50 kg patients) is another alternative in patients with emergency or life-threatening bleeding[39,53]; however, this agent also has defined risks of arterial thrombotic complications, particularly in the elderly or at higher doses.[54]

Dabigatran is a recently approved, oral inhibitor of thrombin that does not require blood monitoring.[55–57] The drug is taken twice daily and is effective prophylaxis in patients with paroxysmal or chronic atrial fibrillation (AF),[58] in treatment of acute venous thromboembolism,[57] and in acute coronary

syndromes.[59] Plasma half-life is 12 to 17 hours,[56] and the drug is cleared by the kidney.

Rivaroxaban is a new, oral factor Xa inhibitor that is rapidly absorbed and has a half-life of 9 to 12 hours and can be given as a fixed dose.[59,60]. Most of the drug is eliminated in urine and the remainder in feces. Rivaroxaban has been approved for preventing stroke in patients with AF (ROCKET-AF trial),[61] as it reduced the incidence of stroke and intracranial bleeding compared with warfarin treatment (0.49 vs. 0.74%). If emergency surgery is required before either dabigatran or rivaroxaban is eliminated, rFVIIa may be attempted to control bleeding, but its value is not certain as an antidote for anticoagulants.[62]

Fibrinolytic drugs. If operation occurs within 12 hours of the last dose of streptokinase or tissue-plasminogen activator (t-PA), the risk of surgical bleeding is increased.[63] If excessive bleeding occurs in such patients, plasma fibrinogen can be replaced with cryoprecipitate, fresh frozen plasma, or fibrinogen concentrate (available in Europe). Platelet transfusion may also be needed, especially if a long-acting platelet inhibitor such as a thienopyridine or abciximab is circulating. Antifibrinolytic drugs are not generally utilized, as the thrombolytic agent will have been cleared from the circulation in most cases. Fibrinolytic drugs are cautiously recommended for treating thrombotic strokes. Potential benefits appear to outweigh the risk of intracranial hemorrhage or surgical site bleeding.[64–66]

ANTICOAGULANTS USED DURING CARDIAC AND VASCULAR SURGERY

Standard, unfractionated heparin (UFH) is universally used to maintain the fluidity of blood during mechanical circulation outside the body.[67] Heparin greatly accelerates inhibition of thrombin and to a lesser extent activated coagulation factors IXa and Xa by the binding action of antithrombin, which is an abundant plasma protein. The drug does not inhibit thrombin bound in fibrin clots.[68] UFH acts rapidly, can be given intravenously, and is reversed by protamine sulfate (PS), but disadvantages include incomplete suppression of thrombin formation; heparin resistance (low antithrombin concentrations); interaction with platelets, complement, and various plasma proteins that variously affect clearance; and stimulation of IgG antiplatelet factor 4 antibodies in some patients. "Heparin resistance" occurs when plasma antithrombin concentrations are deficient from either malnutrition in cyanotic infants or cachectic patients or from sustained heparin administration just prior to operation.[69]

Low Molecular Weight Heparin

Low molecular weight heparins (LMWHs) catalyze antithrombin, but primarily inhibit factor Xa. Theoretically, these heparins should prevent thrombin formation, but they fail to do so during extracorporeal circulation, as monitored by protein fragment, F1.2, in recirculated human blood[70] or in baboons.[71] LMWHs can be given intravenously, act rapidly, are long acting (plasma half-life 4 to 8 hours), are monitored by anti–factor Xa activity, are not completely reversed by PS, may generate antiplatelet IgG antibodies (10% as frequently as with UFH), do not reliably prevent clot formation in the circuit, and are associated with excessive postoperative bleeding.[72,73] LMWH anticoagulants are not suitable for cardiopulmonary bypass (CPB).

Bivalirudin (Hirulog) is a synthetic, 20–amino acid, reversible, direct thrombin inhibitor,[74] which acts rapidly, has a half-life in plasma of 25 to 36 minutes,[75,76] is cleared by proteolysis and the kidneys,[77] but has no antidote.[76] Dosage is preferably monitored by ecarin clotting time,[78,79] but it has also been successfully monitored with the activated clotting time (ACT)[80,81] and aPTT. Bivalirudin is essentially nonantigenic and has no major side effects except bleeding. The drug has been evaluated in patients with acute coronary artery syndromes,[82] during off-pump coronary arterial surgery,[83] in cardiac surgery with CPB,[84,85] and during extracorporeal membrane oxygenation.[86] The pharmokinetics of the drug are attractive for use during CPB, but very careful and rigorously monitored protocols must be followed to prevent clotting within the perfusion circuit. Drug dosage remains under investigation: initial dosing schedules combine 1.5 mg/kg iv and 50 mg in the pump prime and a continuous infusion at 2.5 to 3.5 mg/kg/h.[84,87]

Lepirudin (recombinant hirudin) directly binds and inactivates thrombin, including thrombin within fibrin clots. The drug has a plasma half-life of approximately 80 minutes and is primarily excreted by the kidney.[88] The duration of anticoagulant activity of lepirudin is inversely proportional to creatinine clearance and is prolonged up to 3 to 5 hours by anesthesia.[88] Plasma concentrations are monitored by ecarin clotting time or by aPTT.[89] There is no antidote, the major side effect is bleeding, and allergic reactions are minimal. Lepirudin is approved by the US Food and Drug Administration for use during CPB in patients with heparin-induced thrombocytopenia (HIT) or heparin-induced thrombocytopenia with thrombosis (HITT) and is the most widely used alternative to standard heparin.[88,90]

Argatroban is a synthetic, low molecular weight, reversible, direct thrombin inhibitor that avidly binds thrombin even in fibrin clots.[91] Given intravenously, the drug acts rapidly, has a half-life in plasma of approximately 45 minutes,[92] and is metabolized by the liver. Anticoagulant activity is monitored by aPTT, but when high doses are used, ACTs are recommended.[91,92] There is no antidote, bleeding is the major side effect, and no toxic or allergic reactions are known. Argatroban has been used for CPB in patients for whom heparin was contraindicated,[93] but difficulties with excessive bleeding or clotting within the circuit are reported.[94,95]

EXCEPTIONAL SURGICAL BLEEDING PROBLEMS

Heparin-Induced Thrombocytopenia

An unexpected low platelet count in patients who received heparin 5 to 15 days earlier raises the possibility of HIT and the possibility of complicating thrombosis (HITT).[96] HIT is mediated by IgG antibodies to a complex of heparin and platelet factor 4 (PF4).[87,97] The disease affects approximately 2% of all cardiac surgical patients.[98–100] HIT is strongly suggested when the platelet count precipitously decreases by 30% to 50% or by 100,000/μL after exposure to heparin.[87] A serotonin release test or enzyme immunoassay to detect the presence of anti-heparin/PF4 IgG antibodies[101,102] is mandatory before more heparin is given. Thrombocytopenia and thrombosis due to massive platelet consumption may produce platelet counts below 30,000/μL, but platelet transfusions are not recommended.[103]

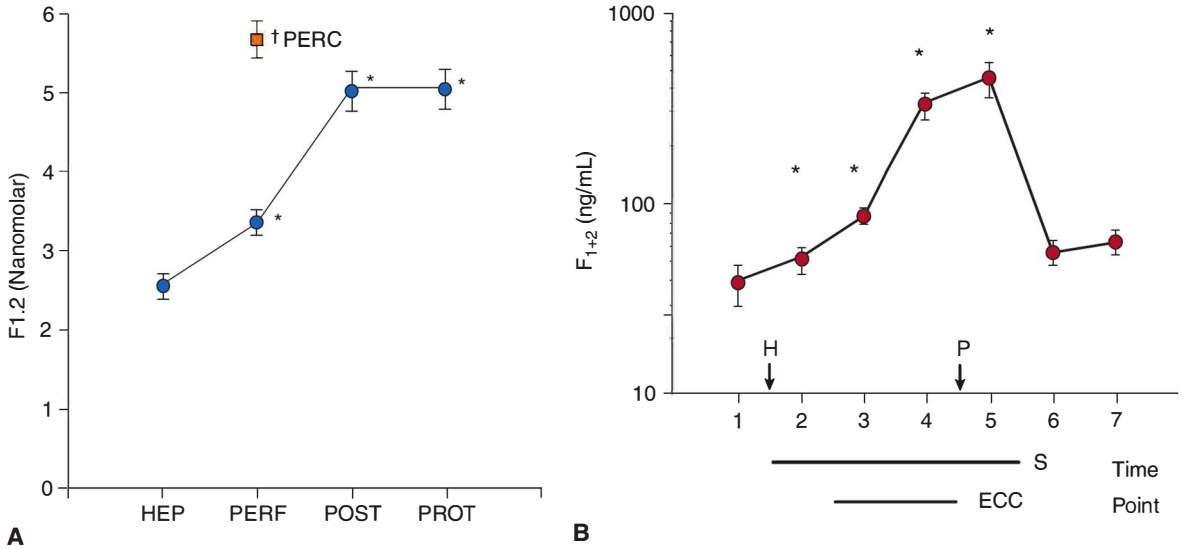

FIGURE 129.3 **A:** F1.2 concentrations taken from the perfusion circuit during cardiac surgery. Thirty to forty-five minutes after beginning CPB, simultaneous samples were drawn from the pericardial well surrounding the heart (PERC) and the circuit (PERF). Disseminated intravascular coagulation (DIC) is a consumptive coagulopathy that may complicate severe trauma, particularly if brain is injured, or complicate postoperative septicemia. The underlying disease (e.g., trauma or infection) initiates thrombin generation primarily by tissue factor exposed in injured tissues[105,106] and on monocytes and endothelial cells.[107–110,111,112] DIC may coexist with a fibrinolytic state.[105,113] Effective therapy requires control of the initiating cause of the coagulopathy. Except for life-saving transfusions, replacement of blood constituents is usually futile until the etiology of DIC is brought under control.[114] Preparation for surgery varies, but consumed procoagulants should be replaced, and if intravascular thrombosis is present, heparin or a direct thrombin inhibitor to control thrombin generation may be required. In a multi-institutional, prospective, randomized trial, tranexamic acid significantly reduced both bleeding and death in trauma victims, who had a defined, significant risk of major hemorrhage.[115] Emerging therapy includes the use of rFVIIa in patients with massive trauma and coagulopathy.[116–118]

CPB and cardiac surgery expose the blood to synthetic surfaces of the perfusion circuit and to the open wound, and coagulation of blood must be prevented by use of systemic patient anticoagulation. High doses of UFH are universally used, but do not completely prevent generation of thrombin.[119,120] Endothelial cells maintain the integrity of the vascular system and fluidity of blood by active metabolic processes, which are absent when circulated blood passes through the heart–lung machine or contacts the surgical wound.[67,121] The net result is continuous generation of thrombin; fibrinolysis;[122] and activation of platelets, complement, neutrophils, and monocytes.[67] Platelets adhere to surface-adsorbed fibrinogen and other adhesive proteins, become activated, release granule contents, and are partially destroyed by shear forces. At the end of CPB and open heart surgery, platelet counts are typically reduced by 40% to 60%, circulating platelets are dysfunctional, and template bleeding times are approximately twice normal.[98,99] During CPB and cardiac surgery, thrombin is generated in both the perfusion circuit and the surgical wound, but most of the thrombin is produced in the wound[111,123] (FIGURE 129.3A). Protein fragment F1.2, which is produced when prothrombinase cleaves prothrombin to α-thrombin, rises continuously during perfusion and peaks at the time PS is given after CPB[119,124] (FIGURE 129.3B).

Thrombin stimulates endothelial cells to produce t-PA, which cleaves plasminogen into the active enzyme, plasmin. D-Dimer, a marker of plasmin activity, and fibrin/fibrinogen degradation products appear in high concentrations in the surgical wound (FIGURE 129.4A),[125] as compared to the circulating perfusate (FIGURE 129.4B). Circulating D-dimer levels peak when PS is given,[126] as does F1.2, but fibrinolysis continues for hours after CPB ends. Thus cardiac surgery with CPB produces a consumptive coagulopathy that primarily occurs in the surgical wound, but also peaks in the perfusate when heparin is reversed by PS.

INTRAOPERATIVE MANAGEMENT OF BLEEDING

Wound Management

Meticulous surgical hemostasis is the cornerstone of any blood conservation program. During open heart surgery, careful

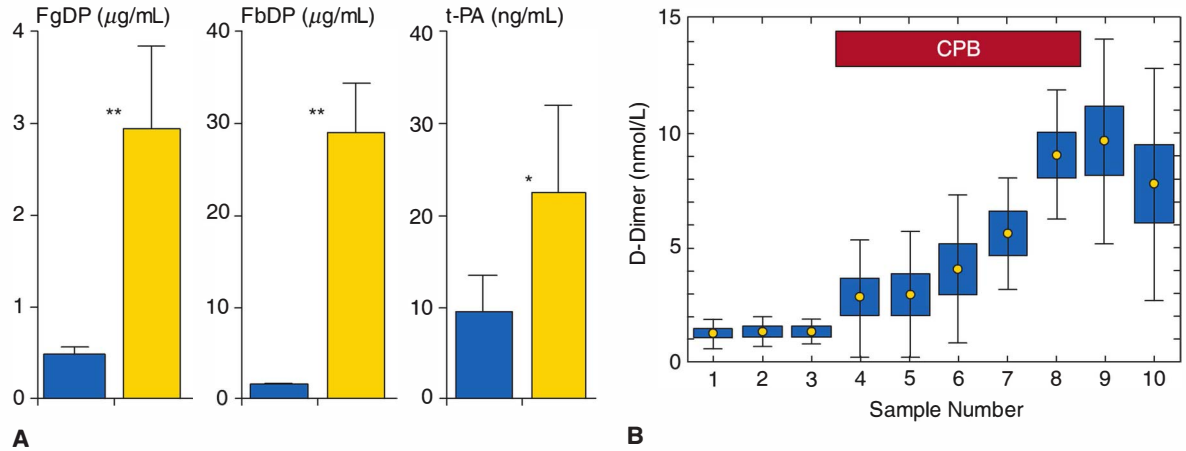

FIGURE 129.4 A: Simultaneous measurements of fibrinogen degradation products (FgDP), fibrin degradation products (FbDP), and tissue-type plasminogen activating factor (t-PA) drawn from the perfusion circuit (*blue bars*) and from the wound (*yellow bars*). Activation of fibrinolysis in the pericardial cavity during cardiopulmonary bypass. *J Thorac Cardiovasc Surg* 1993;106:828–833, with permission.) **B:** Ten serial measurements of D-dimer during cardiac surgery with CPB (*blue bar*). Protamine was given at sample 9; sample 10 was taken 2 hours later. (Reproduced from Chandler WL, Valen T. Plasmin generation and d-dimer formation during cardiopulmonary bypass. *Blood Coagul Fibrinolysis* 2004;15:583–591, with permission.)

hemostasis before heparin and CPB is important to minimize bleeding during the pump run, but general oozing from cut tissues is expected. The electrocautery or ultrasonic scapel and hemostatic clips speed the process of dissection and facilitate hemostasis.[127]

Reinfusion of Shed Wound Blood

Three methods are used to recover heparinized blood that accumulates in the surgical wound during surgery with CPB. Aspirated blood is either filtered in a reservoir and returned directly to the perfusate or is processed by centrifugation or ultrafiltration. Centrifugation recovers largely red cells (hematocrit ~65 to 70), whereas ultrafiltration saves proteins and red cells.[39] Comparison reinfusion studies of coronary revasculation operations[128] fail to show significant differences in postoperative blood loss, hematocrit, or platelet count between the three methods.[129] Direct comparison of centrifugation versus ultrafiltration also fails to show differences in postoperative blood losses or transfusion requirements.[39] No data are available regarding the superiority of the three methods of blood salvage in more complicated operations.[128]

Intraoperative Tests

For most noncardiac surgery procedures, intraoperative tests of the coagulation system are not necessary unless unexpected, substantial, or nonsurgical bleeding occurs. In cardiac patients managed with CPB, tests for platelet number, hemoglobin concentration, and coagulation tests (aPTT and PT) are obtained and replacement therapy prescribed as indicated. Platelet counts <100,000/μL prompt platelet transfusion if bleeding is a problem at the time. PS reversal of heparin anticoagulation is monitored by ACT measured in the operating room. New point-of-care devices are also available to monitor fibrinolysis, which may occur in some noncardiac patients, who have large surgical wounds or who develop a consumptive coagulopathy from massive trauma or sepsis.

Suppression of Bleeding in the Surgical Wound

During cardiac surgery with CPB, the wound is the major source of thrombin generation and fibrinolysis, which continues after CPB is stopped and PS is administered.[128] Studies demonstrate that topical treatment of the surgical wound after PS administration with an antifibrinolytic drug reduces postoperative blood loss.[125,130,131] Epsilon amino caproic acid (EACA) and tranexamic acid are lysine analogs that block lysine-binding sites on plasminogen and thereby interfere with plasminogen binding to fibrin.[104] Tranexamic acid has been associated with increased postoperative seizures,[132] but both are effective in appropriate doses. EACA is not associated with toxicity even in high doses.[128] Aprotinin is a serine protease inhibitor that binds plasmin with high affinity and kallikrein with approximately 100-fold less affinity,[129] but is no longer available for systemic use in the United States. Topical treatment of the surgical wound with an antifibrinolytic reduces blood loss.[125,130,131]

Systemic lysine analogs are also used during cardiac surgery with CPB to suppress circulating plasmin and are usually given as loading doses before incision, in the priming volume of the heart–lung machine and as a continuous infusion during and up to 3 hours after stopping CPB.[134,135] This practice of "frontloading" lysine analogs during CPB is designed to suppress fibrinolysis during CPB. However, D-dimer concentrations peak when protamine is given at the end of CPB and continue to be elevated for many hours after operation.[134] Since blood clotting is desired after protamine is given, logic suggests that a high concentration of a lysine analog is needed in the wound and also in the systemic circulation during the first several hours after CPB ends.[128]

A number of topical compounds[39] are used in open wounds to reduce nonsurgical bleeding and bleeding at sites of vessel or cardiac anastomoses. "Compression hemostatic agents" are designed to provide a scaffold upon which clotting is encouraged and include bovine or recombinant human thrombin, fibrinogen, serum, or albumin in various vehicles or are designed to activate platelets.[39] Other newer topical anastomotic sealants derived from plants or chitin have also been developed, but efficacy is not yet established.[39] These "tissue glues" are directly applied to oozing surfaces.

None of these topical agents directly address the mechanism of nonsurgical bleeding in the cardiac surgical wound, which is primarily due to reduced platelet numbers and function and fibrinolysis.[67,128] Nevertheless, these products are often effective for microvascular bleeding in cardiac operations,[136] debridement of skin burns and oozing vascular anastomoses, and as a sealant for dural suture lines and parenchymal lung leaks. Use of bone wax to reduce marrow bleeding from sternotomy edges is contraindicated because of adverse effects and embolization.[137,138]

Off-Label Use of Recombinant Factor VIIa

rFVIIa is an expensive, recombinant protein that is nearly identical with plasma factor VIIa. A bolus dose (90 μg/kg) immediately increases plasma factor VIIa from 1% to about 15%.[139] rFVIIa is approved at 90 μg/kg dosage for treatment of bleeding in patients with hereditary or acquired hemophilia who have inhibitors, and it has been used increasingly off-label in a variety of patients with trauma or surgical bleeding.[140]

Gill et al.[141] recently published a RCT of rFVIIa in adult patients undergoing cardiovascular surgery with CPB. In this 30-center trial, patients with ongoing bleeding following reversal of heparinization after CPB were randomized to receive placebo ($n = 68$) or rFVIIa at doses of 40 μg/kg ($n = 35$) or 80 μg/kg ($n = 69$). Treatment with the higher rFVIIa dose significantly decreased the need for reoperation ($P = 0.04$), and patients in both groups received significantly fewer allogeneic RBC transfusions ($P = 0.01$). Mortality was not significantly different between groups, but there was a trend toward a higher rate of serious adverse events, particularly stroke, in the patients receiving rFVIIa. The authors concluded that rFVIIa should not be used for cardiovascular surgery until larger controlled clinical trials have been performed.

The risk of thrombotic adverse events (TAEs) observed in clinical trials evaluating off-label uses of rFVIIa has raised concerns. Available data suggest that the risk of TAE is increased when rFVIIa is used in off-label settings, with particular concerns being raised about arterial thrombosis in the elderly and at higher doses.[54]

Delayed Wound Closure

Occasionally, after cardiac surgery, the chest cannot be closed safely because of compression of the heart, persistent microvascular bleeding, or hemodynamic instability.[142–144] In such circumstances, the wound is packed with sponges and left open. The open wound is covered with a rubber dam or silicone membrane, which is sutured or stapled to the skin edges.[142–144] Delayed closure is frequently necessary in patients who require mechanical circulatory assistance. In one series, 46 of 86 patients had delayed wound closure after implantation of a centrifugal flow left ventricular assist device.[145] In newborns and infants, the incidence of delayed closure is approximately 4% to 9%[143]; in adults the incidence is slightly <2%.[142] Closure of surviving patients is achieved at a mean of 3 to 4 days,[142–144] but may be delayed as long as 2 weeks.[146] Wound infections are surprisingly uncommon; a few patients have superficial infections[143,144]; deep infection and poor sternal healing are rare.[144,146] A survey of 37 congenital heart surgical programs found no difference in wound infections between patients with immediate or delayed wound closures.[147]

POSTOPERATIVE MANAGEMENT

Monitoring and Initial Tests

Bleeding after most operations is most often related to delayed bleeding from a vascular suture line; from a clipped, ligated, or cauterized vessel; or from continuous generalized ooze into a hidden body cavity. Management requires prompt restoration of the circulating blood volume, control of the bleeding source, and evacuation of space occupying hematomas. Two to four percent of patients who have open heart surgery are returned to the operating room for control of postoperative bleeding.[148–151] Reoperations, complex procedures, and many aortic operations are associated with increased postoperative bleeding and the need for replacement transfusions.[128] Approximately one-third of patients who require ongoing mechanical circulatory assistance require reexploration within a few days after operation.[145,152] After cardiac surgery, the pericardium is not closed and chest tubes are routinely left in the mediastinum and opened pleural cavities and are placed on gentle (10 to 20 cm H_2O) suction to monitor the rate of bleeding and to prevent cardiac tamponade. Bleeding patients with an elevated PT or fibrinogen concentrations below 100 mg/dL receive fresh frozen plasma. An elevated aPTT is treated with an additional dose of 25 to 50 mg of PS. Platelet counts below 100,000/μL are treated with platelet transfusions in patients who are actively bleeding. If ongoing fibrinolysis is suspected, D-dimer is measured and/or EACA or tranexamic acid is given empirically.

Indications for Wound Exploration

Bleeding at the rate of 10 mL/kg in the 1st hour after operation is an indication for prompt wound exploration. If postoperative bleeding during wound closure is anticipated, a platelet count, PT, and aPTT are sent from the operating room. Any deficiencies are corrected as soon as possible. After cardiac operations, persistent bleeding that equals or exceeds 5 mL/kg/h for each of the next 3 hours or bleeding that totals 20 mL/kg in the first 4 hours after operation are indications for mediastinal exploration. Bleeding over 5 mL/kg/h for the 1st postoperative hour should prompt repeating the platelet count, PT, and aPTT. Postoperative platelet counts below 100,000/μL in a bleeding patient are treated with one or two packs of pooled platelets. Elevated PTs (INR > 1.3) are usually treated with fresh frozen plasma. Elevated aPTT (>40 seconds) is an indication for additional PS, after which the aPTT test is repeated.

Truly massive bleeding or a sudden increase in the rate of bleeding with or without hemodynamic instability is justification for opening the wound in the intensive care unit to secure a major surgical bleeding point.[153] Stabilization often is achieved

in the intensive care, and sometimes the wound may be reclosed *in situ*.[154] Bleeding is the most common early postoperative complication following implantation of circulatory assist devices, occurs in a high percentage of patients, and is frequently substantial.[145,155,156] In a series of 86 patients, 17 (20%) returned to the operating room for control of bleeding.[145] During the 1st week after implantation, chest tube drainage averaged 5,880 ± 4,480 mL for the entire cohort and required an average of 15.6 ± 12.6 units of red cells, fresh frozen plasma, and platelet packs in addition to 11.6 ± 7.5 units during operation.[145] Many of these patients have a consumptive coagulopathy[155–157]; topical treatment of the surgical wound and systemic administration of EACA or tranexamic acid guided by serial measurements of systemic D-dimer offers a mechanistic based solution to the problem and likely is safer than empirical administration of PCCs or rFVIIa.[128,158–160]

PATIENT BLOOD MANAGEMENT

Blood management has been defined as "the appropriate use of blood and blood components, with a goal of minimizing their use[1]." This goal has been motivated historically by (a) known blood risks, (b) unknown blood risks, (c) preservation of the national blood inventory, (d) and constraints from escalating costs.[161] Known risks of blood include transmissible infectious disease, transfusion reactions, and potential effects of immunomodulation (e.g., postoperative infection or tumor progression). Unknown risks include emerging pathogens transmissible by blood (e.g., new variant Creutzfeldt-Jakob disease and West Nile virus).[162–164] Additionally, several studies have linked allogeneic blood transfusions with occurrence of unfavorable outcomes including increased risk of mortality and various morbidities.[165–167] For example, studies have indicated that the risk of postoperative infections such as sepsis is as much as two to four times higher in transfused patients compared with untransfused cohorts.[168,169] Taken together, these lines of evidence support the implementation of blood management as a means to improve the clinical outcomes of the patients. Blood management was cited recently as one of the ten key advances in transfusion medicine over the last 50 years.[170]

Patient blood management encompasses an evidence-based medical and surgical approach that is multidisciplinary (transfusion medicine specialists, surgeons, anesthesiologists, and critical care specialists) and multiprofessional (physicians, nurses, pump technologists, and pharmacists).[1,171] Preventative strategies are emphasized to identify, evaluate, and manage anemia[19,172,173] (e.g., pharmacologic therapy[174] and reduced iatrogenic blood losses from diagnostic testing)[175]; to optimize hemostasis (e.g., pharmacologic therapy[176] and point-of-care testing)[177]; and to establish decision thresholds (e.g., guidelines) for the appropriate administration of blood therapy.[165,178,179]

Anemia Management

Guidelines for detection, evaluation, and management of anemia in elective surgery patients have been published (FIGURE 129.2).[19] Predictors of blood transfusion for patients have long been identified, with the most important being the preoperative circulating red blood cell mass,[180] as estimated by the patient's hemoglobin concentration. In addition to being a risk factor for blood transfusions, preoperative anemia is also an independent predictor of morbidity and mortality in patients undergoing noncardiac surgery.[181–184] Evaluation of anemia should begin with an initial assessment of iron-restricted erythropoiesis, which can occur in either the presence or absence of inflammation. Iron-restricted erythropoiesis can cause anemia due to an absolute deficiency of storage iron, an iron-sequestration syndrome due to inflammation, or a functional iron deficiency due to erythropoietin-stimulated erythropoiesis.[185,186] The evaluation of unexpected anemia must additionally consider unexpected diagnoses including chronic kidney disease or occult malignancy. In order to facilitate this, screening and detection of anemia should occur as far as possible (up to 30 days) in advance of an electively scheduled surgery.[19] This requires close collaboration among the patients' primary care physicians, surgeons, anesthesiologists, and the medical directors of the institution's preadmission testing program.

Red Blood Cell Transfusion

When feasible, the patient's own (autologous) blood can serve to reduce or eliminate the need for allogeneic blood. In preoperative autologous donation, the patients donate their own blood over a period of a few weeks preceding the elective procedure.[187] In acute normovolemic hemodilution, the donation takes place in the operating room before the surgery and reinfusion occurs before the patient leaves the operating room. In cell salvage, the reinfusion occurs during or after the surgery as patients' blood is collected and reinfused.

Preoperative autologous donation has some limitations.[174] As with allogeneic blood units, autologous blood is susceptible to acquired storage lesions, such as depletion of 2,3-diphosphoglycerate and impaired ability for erythrocyte to unload oxygen to tissues. Many predonated blood units may be wasted rather than transfused. Additionally, preoperative autologous donation induces anemia, with an attendant increased subsequent likelihood of blood transfusion with the associated risks, including errors in blood administration. Thus, preoperative autologous donation is generally not cost-effective but may be of value in selected patient populations, such as in patients previously alloimmunized with erythrocyte antibodies.[174]

Acute normovolemic hemodilution causes blood losses during surgery to be diluted, thus reducing actual total blood losses. Acute normovolemic hemodilution offers several advantages compared with preoperative autologous donation, including avoidance of blood storage lesions, no risk of blood labeling or patient identification errors, and adaptability for patients undergoing nonelective procedures.[188] However, evidence on efficacy of acute normovolemic hemodilution is mixed.[189–191] Reasons for low acceptance include lack of standardized protocols, variations in the target hemoglobin, types of fluids used, heterogeneity in surgical blood losses by procedure, and patient selection criteria. Acute normovolemic hemodilution is most effective in procedures with large blood loss.[192]

Autologous blood cell salvage and reinfusion has been demonstrated to be safe and effective in reducing allogeneic blood transfusions in a variety of patient populations.[193,194] The procedure requires the collected shed blood to be washed resulting in loss of platelets and plasma, which could potentially cause dilutional coagulopathy or thrombocytopenia with large blood volumes processed. However, reinfusion of the yielded autologous blood is still preferred rather than allowing the shed blood to be completely wasted, or using allogeneic blood which is also devoid

of platelets and plasma and carries the same if not more risks at large volumes. The American Association of Blood Banks (AABB) has Standards for Perioperative Autologous Blood Collection and Administration[195] to provide guidance on quality management for facilities who seek accreditation for these activities.

Indications for Blood Transfusion

Guidelines for blood transfusion attest to the inadequacy of discrete hemoglobin levels as "triggers" for transfusion, and in addition to recommending transfusion of one blood unit each treatment event, they also acknowledge the necessity of considering other more physiologic criteria.[196] It is generally agreed that transfusion is not of benefit when hemoglobin levels are >10 g/dL and are beneficial when hemoglobin levels are <6 g/dL.[12,13] The variability in transfusion outcomes in patients undergoing cardiothoracic surgery continues to persist even after adjusting for patient- and institution-related factors.[197,198] Moreover, prospective randomized trials in patients undergoing cardiac[14] and noncardiac[15,199] surgery have each demonstrated that such patients can tolerate perioperative anemia without transfusion to hemoglobin levels between 7 and 8 g/dL and have equivalent clinical outcomes comparable with transfusions to hemoglobin levels >10 g/dL.

A Cochrane meta-analysis of prospective randomized trials[200] comparing "high" versus "low" hemoglobin thresholds on more than 3,700 patients found that "low" hemoglobin thresholds were well tolerated; RBC transfusions were reduced (~37%) significantly in patients randomized to the "low" hemoglobin cohorts; infections were reduced by 34% in patients in the "low" hemoglobin cohorts; and a hemoglobin of 7 g/dL was sufficient for the majority of patients. More recently, a randomized controlled trial of 2,016 elderly patients with history or risk factors of cardiovascular disease who underwent hip surgery demonstrated that mortality rates, inability to walk independently, and in-hospital morbidity rates were similar in liberal- versus restrictive-transfused patients, despite significant fewer transfusions in the restrictive group.[199]

Patient blood management strategies for patients undergoing cardiac surgery have been shown to be safe and effective in reducing transfusion while at the same time delivering high-quality outcomes. One institution[201] reported that only 11% of patients undergoing cardiac operations received blood transfusions, in which the program ranked first in their state for lowest risk-adjusted mortality. Current initiatives in research for blood transfusions are reflected in the growing literature on adverse effects of blood storage and their possible implications for oxygen delivery by blood transfusion.[202]

Plasma Transfusion

In an evidence-based review, the Transfusion Practices Committee of the AABB recommended plasma therapy for only a few clinical indications, based on the available evidence in the literature (which was assessed to be of "weak quality"): trauma patients with substantial hemorrhage, patients undergoing complex cardiovascular surgery, and patients with intracranial hemorrhage requiring emergency reversal of warfarin-associated coagulopathy.[203] Patients with mild prolongations of the INR (<1.7) are not at risk of bleeding and do not need plasma therapy for minor procedures,[204] so that for the majority of clinical settings there is ample evidence that plasma transfusions are inappropriate. However, logistical/technical barriers that prevent effective and timely plasma therapy (possibly resulting in plasma therapies that are "too little, too late") have probably contributed to the paucity of evidence demonstrating any benefit for plasma therapy.[176,205]

The paucity of evidence for benefit of plasma transfusion therapy has been accompanied by growing evidence that risks of plasma have been underrecognized; in a prospective study, 6% of transfused patients developed transfusion-associated cardiac overload,[206] which is much higher than previously reported rates in retrospective studies.[207,208] Transfusion-related acute lung injury[209] is a significant cause of morbidity/mortality from blood transfusions, whose incidence has declined subsequently with use of plasma from male donors or female donors who have no history of pregnancy.[210]

PLATELET TRANSFUSION

Guidelines for platelet therapy have been pushlished.[12,13,211] For therapeutic platelet transfusions, algorithms for platelet transfusions based on point-of-care testing (FIGURE 129.1) have demonstrated promise in patients who have platelet-derived bleeding such as in cardiothoracic surgery[177,212] and in trauma.[213] As for the evidence-based literature for plasma therapy, additional studies in platelet transfusion are also needed.[214]

Long-Term Consequences of Transfusion

Careful retrospective studies have revealed that transfusions during and after cardiac surgery are associated with reduced life expectancy in proportion to the number of allogenic red cell units transfused, and possibly also in association with storage duration of RBCs.[215,216] A multicenter trial randomizing patients undergoing cardiothoracic surgery to transfusions with "younger" versus "older" RBC is currently underway to address this issue.[217] Additional studies indicate that reoperation for bleeding and red cell transfusion independently increase morbidity after cardiac surgery.[148,218–221]

CHAPTER

130 Thrombohemorrhagic Events in the Elderly: Special Considerations

ISABELLE MAHE AND LUDOVIC DROUET

Our society is gradually aging, and in view of the increased incidence of thrombotic conditions associated with the elderly, knowledge of anticoagulation drugs and how to use them in older patients has become essential. The treatment of elderly patients is complex, since older patients are at increased risk for both thrombosis and bleeding.

AGE: A RISK FACTOR FOR THROMBOSIS

It has been widely demonstrated that the incidence of thromboembolic diseases increases sharply after the age of 65[1–4]: venous thromboembolism (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), but also atrial fibrillation (AF) and associated risk of cardioembolic stroke. Elderly patients are therefore the main target population for anticoagulation therapy. In the general population, VTE disease has an incidence of 1 to 2 per 1,000 individuals per year, but this incidence is almost 1% per annum in patients aged over 70[1,2] (FIGURE 130.1). Overall 70% of patients with VTE are over 60 years of age.[3] Age is also an independent risk factor for death in patients with PE.[4] The mortality due to PE during hospital stay is 21% in patients older than 65 years and may be as low as 2% in patients younger than 40 years.

DVT is a common age-related condition in medical inpatients: in a prospective study, the prevalence of asymptomatic DVT within 48 hours after admission was 17.8% in patients over 80 years and 0% in patients under 55 years.[5] While the reasons for this high incidence of VTE have not yet been fully elucidated,[6] it has been suggested that the causes are multiple, a combination of (a) malignancy (attributable risk of malignancy is close to 35% in this subset, compared to 20% in the general population with VTE), (b) acquired prothrombotic conditions that are much more common in the elderly (population attributable risk for comorbidities of 25%), and (c) the ageing vascular system with the prothrombotic/antithrombotic systems tilting toward the former in the elderly. The benefit-to-risk ratio of antithrombotic therapy may be difficult to assess in the elderly since they are at the highest risk of severe VTE but also of bleeding events while on anticoagulants. That was observed in the RIETE registry comparing patients older and those under 80 years treated for VTE events: 50% of all patients with fatal PE and 36% of those with fatal bleeding were >80 years old.[7] In those patients, the 3.7% incidence of fatal PE outweighed the 0.8% of fatal bleeding, supporting the favorable benefit-to-risk ratio of anticoagulants in elderly patients with VTE. Haspel et al.[8] tried to model the expected effect of vitamin K antagonist (VKA) treatment in patients older than 80 as compared with patients 60 years of age, taking into account age-appropriate thromboembolic recurrence rates after PE, major bleeding risks of warfarin use, and the contribution of falls to major bleeding episodes in anticoagulated elderly patients. Extended anticoagulant therapy for idiopathic PE is still favorable in elderly patients who tolerate the initial 6 to 12 months of therapy without bleeding complications, irrespective of fall risk.

AF affects 1% to 2% of the population. The prevalence rises dramatically with age, reaching 5% to 15% at the age of 80[9,10] (FIGURE 130.2). The lifetime risk of developing AF is 25% in patients who have reached the age of 40.[11] In addition, aging is an independent major risk factor for ischemic embolic stroke; patients aged 75 years or older have a significant thromboembolic and therefore stroke risk, even if they have no other embolic risk factors.[12,13,14] Patients over 75 years of age have an individual yearly risk of thromboembolism of 4%.[14] In the recent recommendations of the European Society of Cardiology, age was considered a major risk factor for embolic events, as was a history of cardioembolic events, accounting for 2 points in the calculation of the CHA_2DS_2-VASc score. In addition, age over 75 is associated with a worse prognosis for stroke and mortality than hypertension or diabetes.

With increasing age, the efficacy of VKA for the prevention of arterial embolic events in AF patients does not decrease whilst antiplatelet therapies lose their efficacy, becoming negligible by the age of 77.[15,16] In view of the higher incidence of cardioembolism in elderly patients, VKA treatment is at the present time, almost the only effective prophylactic agent in this population.[17,18] As the population ages, the number of elderly patients who require warfarin therapy is rising steadily, owing to an increase in the prevalence of AF and VTE, the main indications for anticoagulant therapy.

AGE: A RISK FACTOR FOR BLEEDING

Anticoagulants and Risk of Bleeding in Elderly Patients

A large number of studies performed with various anticoagulants (e.g., unfractionated heparin [UFH] and low molecular weight heparins [LMWHs], or VKA) have concluded that the risk of bleeding is higher in elderly patients.[19,20] Intracerebral bleeding is the most serious and feared complication of VKA treatment. Aging is a major independent risk factor for intracerebral hemorrhage, especially in patients aged over 85: the relative risk for intracranial bleeding in patients over 75 is 3.7 as compared to patients aged <75. The relative risk for major bleeding is 4.5 in patients over 80 versus those younger than 80.[21–25]

Aspirin is often intuitively preferred to warfarin in elderly patients because of the risk and the fear of bleeding. There are several arguments against this strategy: first, VKA is the only

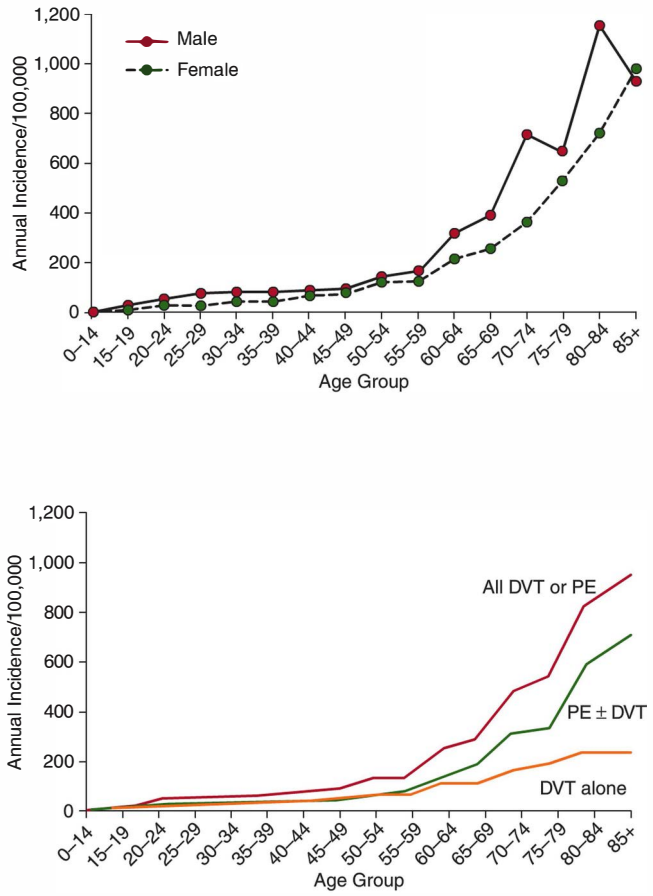

FIGURE 130.1 The increasing probability of developing VTE with age. (From Heit JA, Silverstein MD, Mohr DN, et al. The epidemiology of venous thromboembolism in the community. *Thromb Haemost* 2001;86:452–463.)

effective drug in elderly patients, and second, the risk of major bleeding with aspirin in elderly patients approaches the risk associated with warfarin, as shown in the Birmingham Atrial Fibrillation Treatment of the Aged study (2.0% per year in both groups).[25] One of the main advantages of therapeutic doses of LMWH over UFH is the lower risk of major bleeding events (1.2% vs. 2%; odds ratio [OR] 0.57; 95% confidence interval [CI] 0.39 to 0.83).[26] Elderly patients, however, are frequently renally impaired. A French Drug Agency survey showed that independent risk factors for hemorrhage in patients treated with LMWH are: age over 75, renal impairment, and prolonged duration of treatment.[27] Conversely, in the Innohep in Renal Insufficiency Study (IRIS)[28] comparing UFH and the LMWH, tinzaparin at therapeutic doses followed by VKA treatment in patients older than 70 years presenting with DVT (mean age 82.6 years), found no difference in the risk of clinically relevant bleeding at 3 months (11.9% in both arms, $P = 0.97$). In this trial, 25% of the population had severe renal impairment.[28]

The risk of major bleeding with new anticoagulants is also higher in elderly patients. Dabigatran is the first drug demonstrating a significant reduction of intracranial—including intracerebral—bleedings in the whole population with AF and also in elderly patients. However, this reduction in the risk of intracranial bleeding is counterbalanced by an increase in major gastrointestinal bleedings, the mechanism for which remains unknown.[29,30]

Risk Factors for Bleeding in Elderly Patients

The general risk factors for bleeding in association with anticoagulant therapy are described in Chapter 107. This chapter deals with the aspects specifically related to the elderly. The risk of bleeding depends on both patient- and treatment-related factors (Table 130.1). The incidence of major bleeding events also depends on the duration of anticoagulant treatment; it is

FIGURE 130.2 The increasing probability of developing AF with age. (From Go AS, Hylek EM, Phillips KA, et al. Prevalence of diagnosed AF in adults: national implications for rhythm management and stroke prevention: the AnTicoagulation and Risk Factors in Atrial Fibrillation (ATRIA) study. *JAMA* 2001;285:2370–2375.)

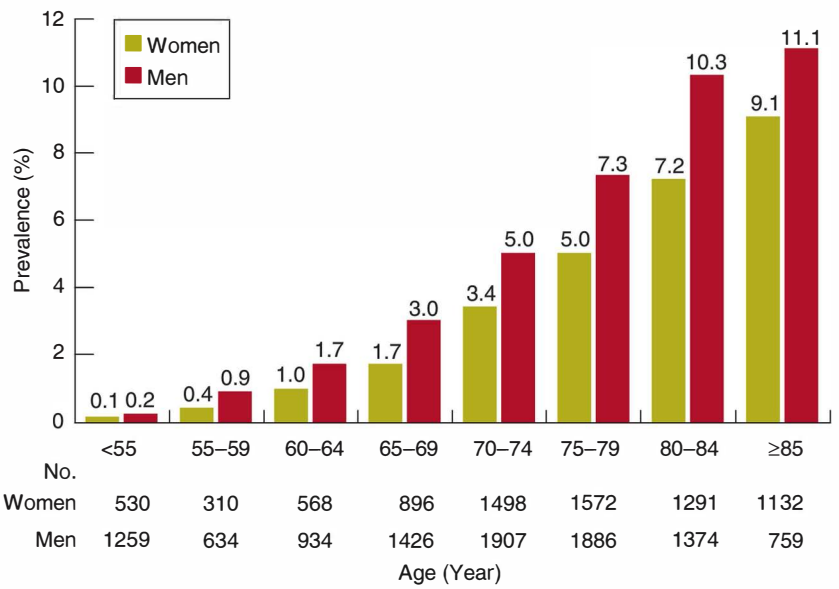

Table 130.1

Risk factors for bleeding in elderly patients receiving VKAs

Patient-Related Risk Factors	Treatment-Related Risk Factors
Age > 75 y	Intensity of anticoagulation (× 1,4 per INR-point)
Recent major bleeding	High INR fluctuation
Stroke	Duration of treatment
Uncontrolled high blood pressure	Beginning of treatment (+++ 3 first months)
Renal impairment	Concomitant treatments (antiplatelet agents)
Hepatic impairment	
Cancer	
Anemia	
Diabetes	

INR, international normalized ratio.

highest at the beginning of treatment, drops to 3% during the 1st month of anticoagulation, to 0.8% per month during the 1st year, and 0.3% per month thereafter.[24] In a recent inception cohort study, Hylek et al.[31] reported a reliable high risk (7.2%) of major bleeding during the 1st year following VKA initiation in patients ≥65 years of age with AF, with 4.7% for those <80 years, and 13.1% for those ≥80 years.

Factors Related to Treatment

VKA Treatment

The risk of major bleeding increases exponentially with international normalized ratio (INR) over 4 compared to an acceptably low incidence at INR between 2 and 3; it should be noted that the risk of intracranial bleeding is not significantly lower at treatment intensities <2.0.[22] Excessive dosing of VKA is common in geriatric patients: two observational studies reported an incidence of 25% among patients (aged over 80) with at least one INR result higher than five while it was <15% in patients <60 years, $P = 0.003$.[32,33]

INR Variability

Extreme INR values (both very low and very high) are more common in the elderly than in young patients, resulting in frequent measurements and dose adjustments.[32] The elderly are more prone to instability due to an increasing number of comorbidities as well as of drugs that interact with warfarin. There is a 21% fall over a 15-year period in the dose of VKA needed in the elderly to reach the same INR target.[34] This increase in sensitivity with age appears to be independent of other demographic factors.[35] Consequently, elderly patients are more sensitive to even very moderate dose adjustments. Low-dosage-VKA formulations (warfarin) are therefore recommended.[36]

Patient-related Factors

Comorbidities

Elderly patients have a higher risk of bleeding owing to an accumulation of comorbidities and polypharmacy. Acute as well as chronic comorbidities and acute concomitant diseases tend to have an impact on the sensitivity to VKA. Diseases that affect the sensitivity to VKA and that are common in elderly patients are listed in Table 130.1.[37,38] Hepatic function is also altered in the elderly and any fluctuation affects the synthesis of coagulation factors, VKA metabolism, and the anticoagulant effect. Another major point, often missed in elderly patients, is the nutritional status.[38–40] Dietary changes have long been recognized as a factor for instability of anticoagulation. In the elderly, dietary vitamin K intake is most often low, which contributes to their increased sensitivity to VKA.[39] In a 6-month randomized placebo-controlled study, a daily vitamin K supplementation in patients with unstable anticoagulation resulted in a significant improvement in anticoagulation control versus the previous 6-month period and to a greater extent than in the placebo group.[40]

Another crucial modulator is hypothyroidism, which is observed in approximately 15% of elderly individuals.[41] Fluctuations in thyroid function result in instability of anticoagulation. Increasing thyroid activity (hyperactivity of the thyroid gland or from exogenous thyroid hormones) is associated with a hypercoagulable state.[42,43] Hyperthyroidism may also increase the sensitivity to VKA, perhaps by boosting catabolism of vitamin K–dependent factors.[39] Patients with suspected thyroid dysfunction should be carefully monitored when receiving VKA and must be made aware that any change in their thyroid function may have a knock-on effect on their anticoagulant response.

Compliance with Treatment

In elderly patients, compliance with treatment is often difficult to obtain as a result of progressive cognitive impairment. Waterman demonstrated that age over 80 is predictive for out-of-range INR, resulting from insufficient compliance.[44] In practical terms, these patients should be given their pill by a caregiver.

Leukoaraiosis and Microbleeds

A recently recognized risk factor for intracerebral bleeding in elderly patients is leukoaraiosis,[45] which is defined as a diffuse, confluent white matter abnormality with low density on computed tomography (CT), and hyperintensity on T2-weighted or FLAIR magnetic resonance imaging. No consensus on the precise mechanisms linking the pathology of the vessel walls with tissue injury has been reached; ischemia, blood–brain barrier dysfunction, and endothelial dysfunction have all been suggested as causative mechanisms. The Stroke Prevention In Reversible Ischemia Trial, in which patients with cerebral ischemia were randomized to warfarin (INR 3 to 4.5) or aspirin,[46] was stopped before its scheduled end because of an excess risk of intracerebral bleeding. Leukoaraiosis was an independent risk factor for bleeding in this study (OR 9.2). Furthermore, in patients with a history of ischemic stroke, leukoaraiosis is a major and independent risk factor for subsequent warfarin-associated intracranial hemorrhage with an OR of 12.9 (95% CI, 2.8 to 59.8), as observed in a case–control study.[47] More recently, leukoaraiosis was reported to be associated with poor prognosis

after spontaneous hemorrhage.[48] In a review of the literature, O'Sullivan[45] found support for a link between gait disturbance, falls, and leukoaraiosis, which is associated with an increase in the risk of fractures and hospitalization.

In a recent systematic review on cerebral microbleeds and the risk of cerebral hemorrhage, users of antithrombotic drugs were compared to nonusers.[49] Patients with microbleeds at baseline and who were treated with antithrombotic agents had an increased risk of subsequent intracerebral hemorrhage (OR 12.1, 95% CI 3.4 to 42.5), suggesting that microbleeds may play a role in the risk of warfarin-related intracerebral bleeding.[49]

Drug Interactions

Elderly patients frequently take multiple concomitant medications. Polypharmacy is an independent risk factor for bleeding: Kagansky et al.[50] reported an OR of 6.14 (95% CI, 1.2 to 42.4) for major bleeding in elderly patients receiving more than seven medicines versus those receiving seven or less. Nonsteroid anti-inflammatory drugs (NSAIDs) and especially aspirin increase the risk of bleeding when associated with anticoagulant drugs. Many mechanisms are involved, including long duration of action, platelet function inhibition, gastric erosion and ulcerations causing gastrointestinal bleeds.[19]

Susceptibility to Falls

A susceptibility to falls is often the direct reason for not prescribing VKA to elderly patients. Falls are very common in this population, causing morbidity and mortality.[51] Dizziness and disequilibria occur frequently and are usually the cause of falls in the elderly.[52] The associated risk of bleeding is most often overstated.[53] The real risk of intracranial bleeding induced by falling is so low that a patient would have to fall 300 times per year before the risk associated with VKA outweighs the benefit of stroke prevention. This type of fall must be distinguished from syncope, which causes sudden falls without any prodromal symptoms, usually related to cardiac conduction disorders.

Renal Impairment

Renal function decreases gradually with age. A substantial proportion of elderly patients (>75 years) have moderate or severe renal impairment.[54] With age-related decline in renal function presents the issue of accumulation of renally eliminated antithrombotic drugs. Nevertheless, renal impairment on its own is a demonstrated risk factor for bleeding during anticoagulant treatment, affecting anyone of UFH, LMWH, and VKA[19,20,55,56] and even the new oral anticoagulants. It must, however, be kept in mind that this condition not only increases the risk of bleeding but also the risk for thromboembolic events and death.[57–59,60]

The optimal method of assessment of renal function in the elderly is a matter of debate. In routine setting, it is only possible to explore renal function and glomerular filtration rate (GFR). Serum creatinine is not a good indicator since total creatinine decreases with age as the muscle mass decreases. Two different methods are used to calculate GFR as a function of patient characteristics (age, sex, and serum creatinine): the Cockcroft-Gault (CG) formula and the modification of diet in renal disease (MDRD) equation. MDRD offers advantages over CG (no need for weight measurements) but the MDRD equation has never been validated in patients older than 70.[61] In addition, MDRD may underestimate creatinine clearance in elderly patients,[62,63] and clinical trials therefore use the CG equation.

Table 130.2

HAS-BLED bleeding risk score

Letter	Clinical Characteristic	Points Awarded
H	Hypertension	1
A	Abnormal renal and liver function (1 point each)	1–2
S	Stroke	1
B	Bleeding	1
L	Labile INRs	1
E	Elderly age (e.g., age > 65 y)	1
D	Drugs or alcohol (1 point each)	1 or 2

INR, international normalized ratio.
From European Society of Cardiology, www.escardio.org.

Bleeding Risk Scores

Many bleeding risk scores have been established that stratify risk by age at 60 or 65 years, but none has been fully validated in the elderly since mean age of AF patients is 75 years.[64,65] The European Society of Cardiology recently proposed the HAS-BLED bleeding risk score (Table 130.2).[14] This was developed subsequent to the Euro Hart Survey, which included 3,978 European patients with AF[66] (see also Chapter 107).

ANTICOAGULANTS IN ELDERLY PATIENTS: EFFECTIVE BUT POORLY DOCUMENTED

VKA Underuse

Despite evidence that warfarin is highly effective in preventing thromboembolism in patients with AF, it remains underused in elderly patients.[67–69] In the FALSTAF observational study performed in France from August to December 2002 in 5,893 patients with AF (FIGURE 130.3), there was a sharp drop in prescription of VKA with age from 83.9% in patients <60 years to 63.5% in patients >80 years.[67]

As a pharmacologic class, VKAs are associated with one of the highest rates of adverse events in the elderly.[70] This contributes to the fear of bleeding events and to the underuse of VKA in this population and denies elderly patients access to effective stroke prophylaxis.[71] In a survey of 142 doctors practicing internal medicine, the individual assessment of the risk of cerebral hemorrhage was 10-fold the risk observed in clinical trials for the corresponding patient.[71] In addition, the thromboembolic risk is not systematically assessed, which influences the choice of antithrombotic drug. In most studies on patients "suitable" for anticoagulant treatment or "unsuitable" for that and therefore given antiplatelet agents, for example, the ACTIVE W and ACTIVE A trials,[72,73] the $CHADS_2$ score for thromboembolic risk is the same in both groups depending on the decision of the clinician favoring anticoagulant or antiplatelet therapy. Even in the most recent AVERROES trial (apixaban vs. placebo), the $CHADS_2$ score of patients who were considered to be

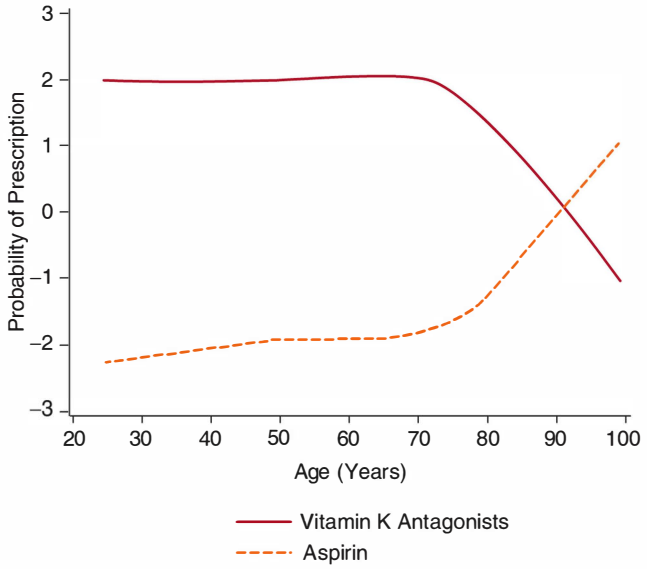

FIGURE 130.3 FALSTAF study: probability of VKA and aspirin use in patients with AF.

"unsuitable candidates" for anticoagulant therapy was similar to that of parallel studies with anticoagulant agents.[74]

Overall, there are several reasons for this under use of anticoagulant agents: first, there is the fear of bleeding based on an overestimation of the risk of bleeding. Second, thromboembolic risk is not systematically assessed in elderly patients. Third, there is some skepticism as to whether the results from clinical trials (high efficacy and acceptable risk of bleeding in elderly patients) can be extrapolated to a routine clinical setting.[71] Fourth, no single but combined geriatric characteristics contribute to the underuse of VKA in older patients with AF.[75] In addition, there is the doctor's belief that aspirin is a safe alternative to warfarin for stroke prevention in elderly frail patients.[76] The recent AVERROES study has clearly demonstrated that the hemorrhagic risk can be similar in aspirin-treated and anticoagulated elderly patients.[73] Current European guidelines plainly state that VKA is the only effective treatment for stroke prevention in the majority of AF patients, with the benefit outweighing the risk of bleeding.[14] Furthermore, aspirin is a far from safe alternative in elderly frail patients.

Clinical Trials and Real Life—a Gap in Knowledge Translation

To date, patients with high risk of bleeding have often been excluded from participation in specific clinical trials assessing anticoagulant drugs.[28,37,38,77] Hansen observed in a registry study that the risk of fatal and nonfatal bleeds was higher (3.9% per patient-year) than the usual rate reported in clinical trials.[78] Many explanations can be put forward: first, patients are included in clinical trials after a rigorous selection process minimizing the risk for bleeding in the evaluation of new anticoagulants; second, many of those patients were previously on warfarin (selection by attrition).

Observational studies like the RIETE Registry provide more realistic data on patients with VTE in terms of risk and management.[7] Of the 13,000 patients, 22% were 80 years or older. In this subset compared to the younger patients, both the incidence of major bleeding (3.4% vs. 2.1%, OR 1.7, 95% CI 1.3 to 2.1) and the risk of fatal PE (3.7% vs. 1.1%, OR 3.6, 95% CI 2.7 to 4.7) were higher. Nonetheless, the benefit-to-risk favored anticoagulant treatment in these patients. Vasco more specifically studied nonagenarians in the RIETE Registry, in which 2.8% of 21,873 patients fulfilled this criterion.[79] The most frequent thromboembolic risk factor was recent immobilization (for 4 days or more) (39%). However, only 22% of these patients had previously received thromboprophylaxis, which is an indicator of its underuse in the elderly.

PRESCRIBING ANTICOAGULANT TREATMENTS IN ELDERLY PATIENTS

Low Molecular Weight Heparin

Each specific LMWH[80,81] has its unique spectrum of anti-IIa and anti-Xa activity. This variability is due to the differences in glycosaminoglycan chains (length, composition radicals, etc.), which influences both the anti-Xa/anti-IIa ratios and the differences in the mode of elimination. These chains change place with chains in the endothelial glycocalix. The higher molecular weight fractions are exchanged with the endothelial glycanic cell coat and are cleared by the reticuloendothelial system whereas the lower molecular weight chains are mostly cleared renally.[80–82] This explains kinetic differences between LMWHs such as tinzaparin (mean MW 6.5 kDa) and enoxaparin (mean MW 4.5 kDa), but also explains that LMWHs cannot have true bioequivalent counterparts. Plasma–anti-Xa activity is the usual method for assessing LMWH activity; it is sampled when at its peak concentration (~4 hours postinjection—based on studies in younger adults) but only explores the circulation of glycanic chains containing the pentasaccharide sequence that is merely one of the characteristics and modes of action of LMWHs. Although anti-Xa levels do not correlate with bleeding risk in clinical trials, very high anti-Xa–plasma levels may indicate an increased risk of hemorrhage.[59,83] Furthermore, dose-finding studies with LMWHs at therapeutic doses have demonstrated that a further increase of the dose is associated with higher anti-Xa levels and an increased risk of major bleeding.[81] In studies demonstrating the efficacy of a thromboprophylactic drug to reduce the risk of VTE, subgroup analyses consistently reached the conclusion that the elderly patients constituted the subgroup, which gained the most benefit of prevention with enoxaparin, dalteparin, or fondaparinux without a significant increase of the risk of bleeding.[84–87] In order to determine whether prophylactic doses of LMWH accumulated in elderly patients, we measured anti-Xa at peak level (Cmax) in patients who were hospitalized in internal medicine wards. We observed that more than 50% of patients had an anti-Xa activity of more than 0.5 IU/mL, only 48 hours after the initial dose.[88] Subsequently, we recruited patients >75 years of age, and found that those at the highest risk of rising anti-Xa levels were patients with severe renal impairment and low body weight.[89] Finally, we prospectively compared the pharmacokinetic and pharmacodynamic properties of two different LMWHs in patients aged 75 years and more, by measuring anti-Xa levels at baseline and after 8 days of prophylactic doses. The primary endpoint was the accumulation factor (ratio of anti-Xa Cmax on day 8 to anti-Xa Cmax on day 1), which

increased in patients receiving enoxaparin (1.22; $P < 0.001$) while it tended to remain stable in patients receiving tinzaparin (1.05; $P = 0.29$).[90] This confirms that LMWHs are not identical and vary in how they are metabolized in elderly patients. Nevertheless, the risk of bleeding in patients with severe renal impairment who are given thromboprophylactic doses is low,[91] the clinical relevance of the different anti-Xa activities observed is unknown, and neither dose adjustment nor monitoring is required for thromboprophylactic dosing in elderly patients.[92]

Although laboratory monitoring of LMWH is not routinely required, experts and guidelines have recommended this for selected patients receiving LMWH at treatment doses.[81,93] Anti-Xa measurement is suggested as a means of detecting bioaccumulation after administration of multiple doses and to avoid overdosing in the patients at highest risk, that is the elderly, particularly those with low body weight. If such monitoring is warranted, the chromogenic anti-Xa activity assay is the only test recommended.[94] Anti-Xa activity has never been shown to correlate with efficacy. Use of anti-Xa activity monitoring has not been studied in large trials. Since LMWHs are mainly excreted renally, repeated administration of LMWHs to patients with a reduced creatinine clearance may result in accumulation of the drug with an increased risk of bleeding. A meta-analysis of 12 studies and 4,971 patients demonstrated that patients with creatinine clearance <30 mL/min receiving curative doses of LMWH had elevated anti-Xa levels and an increased risk of major bleeding compared to those with higher clearance (5.0% vs. 2.4%, OR for major bleeding 2.25, 95% CI 1.19 to 4.27).[56]

Differences exist among LMWHs used at therapeutic doses in elderly patients. Mismetti et al.[95] showed a significant correlation between anti-Xa and creatinine clearance in elderly patients receiving nadroparin (180 IU/kg/day) for 9 days. Three studies, two prospective observational and one randomized, in elderly patients receiving tinzaparin at therapeutic doses suggested that this LMWH is less prone to cause accumulation in the event of renal impairment. In the first of these, Siguret et al.[96] did not detect any change in mean anti-Xa levels over the period from day 2 to day 10 in 30 subjects (mean age 87 years) receiving tinzaparin once a day (175 IU/kg) for acute VTE. Pautas followed 200 patients with a mean age of 85 years receiving tinzaparin once daily for up to 30 days. In both studies, there was no correlation between anti-Xa levels and creatinine clearance or age.[33,36] The mean creatinine clearance (CG calculation) in these studies was 41 and 51 mL/min, respectively.[33] The prospective randomized study compared the safety of UFH versus tinzaparin both followed by VKA in elderly patients with VTE and renal impairment (IRIS study).[28] The study was prematurely stopped because of a difference in mortality favoring the UFH group (11.5% vs. 6.3%, $P = 0.034$) at the predefined interim analysis after 541 patients had been enrolled. The difference in mortality could not be explained by deaths due to bleeding or VTE. There was importantly no significant difference in the risk of major bleeding at day 10 between the treatment groups, reflecting the risk related to the heparin component of the treatment. The translation of these differences between LMWHs into clinical practice is difficult to assess since severe renal impairment is an exclusion criteria for clinical trials and the elderly patients are also often excluded.

There are four possible strategies/options for the treatment of elderly patients with severe renal impairment: (a) use of UFH, as recommended by American College of Chest Physicians but the risk of bleeding is not clearly lower than with LMWHs[81]; (b) half dose LMWH, which is an empirical reduction in the dose to minimize the risk of bleeding. Few studies performed evaluating this option have shown that it is effective and relatively safe (grade 2C).[81] This suggestion has a low grade of evidence. A dose reduction by 50% in patients with severe renal impairment may underdose enoxaparin and lead to loss of efficacy; (c) anti-Xa monitoring with adjusted dose of LMWH to target the peak anti-Xa levels 4 hours after SC injection at 0.6 to 1.0 IU/mL for twice-daily administration and 1.0 to 2.0 IU/mL for once-daily administration;[81] and (d) possibly selection of a LMWH that is less likely to accumulate in case of renal impairment. Although UFH is the recommended anticoagulant treatment for patients with severe renal failure, there is a rationale for the use of an adjusted treatment with LMWH.

These alternative strategies are open to criticism: there are no data in the literature supporting a dose reduction in elderly patients treated for VTE, with all existing data derived from studies on acute coronary syndrome (ACS) setting. The studies performed with enoxaparin in ACS[97] used the dose adjustments to maintain the peak anti-Xa activity between 0.5 and 1.0 IU/mL. The resulting lower dose was not associated with an increased rate of major bleeding compared to UFH but the rate of MI and death may be higher, particularly in case of anti-Xa activity <0.5 IU/mL.[98,99] No prospective clinical trial supports adjusting the LMWH dose on the basis of anti-Xa activity. In pivotal clinical trials, the dose is adjusted to body weight, without dependence on monitoring of anti-Xa activity. Current reference on anti-Xa activity for treatment with LMWH has been extrapolated from anti-Xa activities observed in patients enrolled in clinical trials using body weight–adjusted doses.

As a general rule, it is recommended that each LMWH should be administered at the dose and for the indication used during studies. In routine practice, the safety of LMWH can be improved by measuring body weight and calculating the creatinine clearance to assess the risk of bleeding and to avoid drugs that increase this risk.

Fondaparinux

Fondaparinux has specific anti-Xa activity without any inhibition of factor IIa. The clearance is exclusively renal. There is so far no study on monitoring of anti-Xa activity in patients receiving fondaparinux. To date, the absolute contraindication is severe renal impairment. There is a rationale for reducing the dose in renally impaired patients.[100] The PROPICE study was a prospective observational study designed to establish that the thromboembolic and bleeding risk in patients with creatinine clearance is 20 to 50 mL/min and they required thromboprophylaxis in routine clinical practice. The recommended dosage in those patients is 1.5 mg compared to the standard dose of 2.5 mg.[101] The study population consisted of elderly patients (mean age 81.4 ± 6.6, 86% were older than 75 years) with renal impairment (mean creatinine clearance 39 ± 8 mL/min, 16% <30, 33% between 30 and 40, 49% between 40 and 50 mL/min).

In this high-risk population, the 1.5 mg dosage reduced the risk of bleeding without increasing the risk of thromboembolism (distal DVT 0.5% at day 10 and 0.7% at 1 month). The risk of major bleeding was 4.5% at day 10 and 5.2% after 1 month.

Vitamin K Antagonist

Warfarin is the most widely prescribed oral anticoagulant for the primary and secondary prevention of venous or arterial thromboembolism. Elderly patients require lower anticoagulant doses to achieve the therapeutic range, although the mechanism of this heightened sensitivity to warfarin observed with aging is not well understood.[102,103] In addition, these patients respond more slowly to warfarin dose adjustments.[36,102,104] In a study performed in a geriatric setting (106 patients, mean age 85 years), the mean time required to reach the steady state rose to 9 ± 4.5 days.[36] This delay must be taken into account both when starting VKA treatment and also to avoid premature dose changes while the effect of the previous dose is not completely established. This contributes not only to poor INR control in elderly patients but also to an increased risk of bleeding.

Two studies have evaluated warfarin initiation algorithms adapted for elderly inpatients. In a randomized control trial Gedge et al.[105] compared the established "Fennerty regimen" with a new lower-dose regimen in 120 patients, aged 65 to 75 years. The first dose (if INR < 1.4) was 10 mg, followed by 1 mg (INR 1.8 to 2.0) or 5 mg (INR < 1.8) with further daily adjustments. Another strategy was applied by Siguret et al.[36] in 106 even older inpatients (mean age 85), initiating with 4 mg warfarin daily for 3 days without monitoring and then adjusting according to the INR (Table 130.3). Both algorithms provided results that were advantageous regarding surrogate outcomes such as more time in the therapeutic range and fewer high INR levels but none of them was powered to demonstrate a reduced risk for thromboembolic and bleeding events. Just as the time required to reach a steady state is longer in elderly patients starting VKA treatment (vs. younger patients), when vitamin K is used to reverse VKA, the delay to achieve the maximum effect is longer than the 6 hours expected in younger patients.[106]

Education and Anticoagulation Clinics for Elderly Patients

According to the WHO, anticoagulation training allows patients to achieve and keep capacities and competencies, which will help them live better with their disease. It has been demonstrated in an observational study that insufficient patient education is an independent, strong risk factor for major bleeding events in elderly patients.[50] The specific risks, potentially adjustable with education and supportive tools, of this population are numerous, including multiple intakes of the dose, missed doses, poor nutritional status, and automedication, for example, with salicylates or NSAIDs. In addition, both patient education on VKAs and anticoagulation training have been effective in improving anticoagulation control.[107] However, education should be adapted to this population to take into account limits

Table 130.3

Algorithm for initiation of warfarin in elderly patients (>70 years)

Day	INR Value	Warfarin Dosage
0	Do not measure	4 mg[a]
1	Do not measure	4 mg
2	Do not measure	4 mg
3	<1.30	5 mg
	1.30–1.49	4 mg
	1.50–1.69	3 mg
	1.70–1.89	2 mg
	190–2.49	1 mg
	≥2.50	Measure INR daily and omit doses until INR <2.50, then give 1 mg
6	<1.60	Increase by 1 mg/day
	1.61–2.50	Maintain dosage
	2.51–3.50	
	If warfarin dosage ≥2 mg	Reduce by 1 mg/day
	If warfarin dosage = 1 mg	Maintain dosage
	>3.50	Management of supratherapeutic INR[b]

INRs were determinated in the morning, and warfarin doses were given in the evening. The target INR was 2.50.
[a]This algorithm does not apply to patients who have a pretreatment INR > 1.30.
[b]Supratherapeutic INRs are managed according to expert recommendations.
INR, international normalized ratio.
From Siguret V, Gouin I, Debray M, et al. Initiation of warfarin therapy in elderly medical inpatients: a safe and accurate regimen. *Am J Med* 2005;118:137–142.

of learning (physical and cognitive limits, etc.), low comprehension, and low motivation. The "caregiver" plays a major role, and should be involved in the management of VKA treatment and take part in the patient education.

Specialized anticoagulation clinics have been shown to be effective in reducing the risk of thromboembolic and bleeding events in outpatients.[108] A recent study demonstrated that an anticoagulation clinic is also beneficial for elderly inpatients.[109]

Perspectives on New Oral Anticoagulants

New oral anticoagulants have clear advantages over classic anticoagulants: oral route of administration, no need for monitoring, and a wider therapeutic window. Until now they have not been assessed in patients with severe renal impairment, which was an exclusion criterion in studies with dabigatran and rivaroxaban. The approval by the Food and Drug Administration of dabigatran at a dose of 75 mg twice a day for stroke prophylaxis in AF for elderly patients with severe renal impairment (creatinine clearance 15 to 30 mL/min) raises concerns about the risk of overdosing in this population. Furthermore, this is a lower dosage than the lowest dose tested in the phase III trial.[29]

In conclusion, practitioners are faced with a dilemma: elderly patients are considered to be at high risk of bleeding events. Simultaneously they are at the highest risk of thromboembolic events. Most of the time, the benefit-to-risk ratio is in favor of anticoagulant treatment. Fear of bleeding should not be a limitation to the initiation of anticoagulant treatment and give rise to a situation where patients who could benefit from intervention, are withheld from it. This and the development of new anticoagulant drugs, which would increase the benefits of treatment without increasing the risk of bleeding in the elderly, are the challenges for the future.

initiation, *72,* 1269
pregnancy and lactation, 1279
purple toe syndrome, 1279
resistance, 1279–80
skin necrosis/limb gangrene, 1278–79
Web resources, genetics, 31t–33t
Weibel-Palade body
agonist stimulation, 203
vs. platelet alpha-granules, 202–03
vWF, 200

tahir99-VRG & vip.persianss.ir

Weibel-Palade body (*Continued*)
DDAVP therapy, 200
P-selectin, 202, 203
storage function, 201, 202
ultralarge VWF multimer, 204
Wells score, 957, 980, 982
White blood cell (WBC), 1249
White thrombus, 5
Whole-genome duplication (WGD), phylogenetic tree representation, *13*
Whole-genome sequencing, 37
Wiskott-Aldrich syndrome (WAS), 1428

X
Xenograft cardiac valves, 1132
Ximelagatran, 1104
X-linked thrombocytopenia, dyserythropoiesis, 1428
X-linked thrombophilia, 969–70

Y
Yellow fever virus, *1464*, 1465

Z
ZPI (protein Z–dependent protease inhibitor (ZPI), 144, *144*
Zymogens
proteinase formation, 41
serine protease zymogens, 168
